Phenolic phytochemicals are secondary metabolites synthesized by plants to protect themselves against biological and environmental stresses such as pathogen attack or high energy radiation exposure (1,2). These compounds involved in the plant defense response are one of the most abundant classes of phytochemicals and are also invariably important components of our diets (3,4,5). Commonly consumed fruits such as apples, bananas, grapes, and several types of berries and their beverages are examples of plant foods as sufficiently rich sources of phenolic phytochemicals. Similar phytochemicals in our diet are also obtained from diverse commonly consumed vegetables such as tomato, cabbage, and onions to grains such as cereals and millets as well as legumes such as soybean, common beans, mung beans, fava beans, and peas, depending on the specific regions of the world (4,5,6). In addition many different types of herbs and spices containing phenolic

phytochemicals are widely consumed through the diet. Therefore, there are many different types of phenolic phytochemicals from the diet that are mediators of different biological functions for health and wellbeing. The profile of phenolic phytochemicals is often a characteristic of that plant species and is a result of the evolutionary pressures experienced by that species (5,6,7). The most abundant phenolic compounds in fruits are flavonols and flavonoids. Flavonoids, isoflavonoids, phenolic acids, and tannins are important phenolic phytochemicals in many legumes (5,6,7). Biphenyls such as rosmarinic acid are common in many herbs (1).

Chemically phenolic phytochemicals refers to a wide range of chemical compounds containing at least one aromatic ring and a hydroxyl substituent. Metabolic processing in plants after their synthesis results in chemical variations in basic phenolic structure (8). More than 8000 different phenolic structures, categorized into 10 subclasses, have been identified and are a result of differences in substituent groups and linkages. Structurally different phenolic phytochemicals having distinct properties range from simple molecules (e.g., phenolic acids with a single ring structure) to biphenyls and flavanoids having two or three phenolic rings (9,10). Polyphenols that contain >10 phenolic groups are another abundant group of phenolic phytochemicals in fruits and vegetables. Proanthocyanidins, tannins, and their derivatives phlorotannins are often referred to as polyphenols (9,10).

Phenolic phytochemicals are synthesized in plants via a common biosynthetic pathway and derive precursors from the shikimate–phenylpropanoid and the acetate–malonate (polyketide) pathways (1,11). Cinnamic acid, coumaric acid, and caffeic acid, and their derivatives are widespread in fruits, vegetables, and herbs and are derived primarily from the shikimate/phenylpropanoid pathway (1). Oxidative modifications of side chains produce benzoic acid derivatives, which include protocatechuic acid and its positional isomer gentisic acid. Fruits and legumes are especially rich sources of another group of phenolic phytochemicals called flavonoids and iso-lavonoids, which constitute the most abundant group of phenolic phytochemicals derived from the phenylpropanoid–acetate–malonate pathway (2,11).

Flavonoids are subdivided into several families such as flavonols, flavones, flavanols, isoflavones, and antocyanidins, which are formed as a result of hydroxylation, methylation, isoprenylation, dimerization, and glycosylation of the substituents in the aromatic rings (2,11). Phenolic phytochemicals are often esterified with sugars and other chemicals such as quinic acid to increase their solubility and to prevent their enzymatic and chemical degradation. Esterification also helps to target the phenolics to specific parts of the plant (11). Phenolic phytochemicals esterified via their hydroxyl groups to sugars are called glycosides. The sugar most commonly involved in esterification is glucose. However, the glycosides of phenolics with galactose, sucrose, and rhamnose are also found in some plant species (11).

2.2 BIOLOGICAL FUNCTION OF PHENOLIC PHYTOCHEMICALS

Reactive oxygen species (ROS) are now associated with manifestation of several oxidation-linked diseases such as cancer, cardiovascular diseases (CVD) and diabetes; epidemiological studies indicate that diets rich in fruits and vegetables are associated with lower incidences of such oxidation linked diseases. These disease protective effects of fruits and vegetables are now linked to the presence of antioxidant vitamins and phenolic phytochemicals having antioxidant activity, which support the body's antioxidant defense system (12–15). This has led to an interest in the use of diet as a potential tool for the control of these oxidative diseases (5,16–18). This is further supported by recent *in vitro* and clinical

studies which have shown that lack of physical activity, exposure to environmental toxins, and consumption of diets rich in carbohydrate and fats induced oxidative stress, which was decreased by consuming fruits, vegetables, and their products (19–26).

Phenolic phytochemicals with antioxidant properties are now widely thought to be the principle components in fruits, vegetables, and herbs that have these beneficial effects. Most phenolic phytochemicals that have positive effect on health are believed to be functioning by countering the effects of reactive oxygen species (ROS) species generated during cellular metabolism. Consumption of natural dietary antioxidants from fruits, vegetables, and herbs has been shown to directly enhance scavenging of ROS, prevent the formation of ROS, and enhance the function of the antioxidant defense response mediated by Glutathione, Ascorbate, superoxide dismutase (SOD), catalase (CAT), and glutathione–s–transferase (GST) interface (15–20).

Specifically, oxidation of biological macromolecules as a result of free radical damage has now been strongly associated with development of many physiological conditions that can manifest into disease (27–31). The first and widely accepted mode of action of these phenolic phytochemicals in managing oxidation stress related diseases is due to the direct involvement of the phenolic phytochemicals in quenching the free radicals from biological systems. Phenolic phytochemicals, due to their phenolic ring and hydroxyl substituents, can function as effective antioxidants due to their ability to quench free electrons and chelate metal ions that are responsible for generating free radicals (32). Phenolic antioxidants can therefore scavenge the harmful free radicals and thus inhibit their oxidative reactions with vital biological molecules (32).

Emerging research into the biological functionality of phenolic phytochemicals also strongly suggests their ability to modulate cellular physiology both at the biochemical/physiological and at molecular level. Structural similarities of phenolic phytochemicals with several key biological effectors and signal molecules have been suggested to be involved in induction and repression of gene expression or activation and deactivation of proteins, enzymes, and transcription factors of key metabolic pathways (27,33–35). They are believed to be able to critically modulate cellular homeostasis as a result of their physiochemical properties such as size, molecular weight, partial hydrophobicity, and ability to modulate acidity at biological pH through enzyme (dehydrogenases) coupled reactions. As a consequence of many modes of action of phenolic phytochemicals they have been shown to have several different functions. Potential anticarcinogenic and antimutagenic properties of phenolic phytochemicals such as gallic acid, caffeic acid, ferulic acid, catechin, quercetin, and resveratrol have been described in several studies (36–38). It is believed that phenolic phytochemicals might interfere in several of the steps that lead to the development of malignant tumors, including, inactivating carcinogens, inhibiting the expression of mutant genes (39). Many studies have also shown that these phenolic phytochemicals can repress the activity of enzymes such as cytochrome P 450 (CYP) class of enzymes involved in the activation of procarcinogens. Their protective functions in liver against carbon tetrachloride toxicity (40) have shown that phenolic phytochemicals also decrease the carcinogenic potential of a mutagen and can activate enzymatic systems (Phase II) involved in the detoxification of xenobiotics (41). Antioxidant properties of the phenolic phytochemicals linked to their ability to quench free radicals has been shown to prevent oxidative damage to the DNA which has been shown to be important in the age related development of some cancers (42). Phenolic phytochemicals have been shown to inhibit the formation of skin tumors induced by 7, 12-dimethyl-benz(a) anthracene in mice (43). Skin tumors in mice, and development of preneoplastic lesions in rat mammary gland tissue in cultures in the presence of carcinogens, were inhibited by resveratrol which is an important biphenyl found in wine (44,45).

Ability of phenolic phytochemicals is preventing of cardiovascular diseases (CVD) has been well described by epidemiological studies. The "French paradox" describes a famous study linking the lower incidences of CVD in the population consuming wine as part of their regular diet (46). Recent research has revealed that these beneficial effects of wine are due to the presence of a biologically active phenolic phytochemical "resveratrol." Inhibiting of LDL oxidation (47) and preventing platelet aggregation (48) are now believed to be the mechanisms by which resveratrol and other phenolic antioxidants prevent development of CVD. Phenolic phytochemicals have also been able to reduce blood pressure and have antithrombotic and antiinflammatory effects (48,49). Phenolic phytochemicals have also been shown to inhibit the activity of alpha-amylase and alpha-glucosidase which are responsible for postprandial increase in blood glucose level, which has been implicated in the manifestation of type-II diabetes and associated cardiovascular diseases (50,51).

In addition to managing oxidation linked diseases, immune modulatory activities of phenolic phytochemicals such as antiallergic (52) properties as a result of suppressing the hypersensitive immune response have also been defined. Antiinflammatory responses mediated by suppression of the TNF-alpha mediated proinflammatory pathways were also shown to be mediated by phenolic phytochemicals (53). Several studies have shown phenolic phytochemicals to have antibacterial, antiulcer, antiviral, and antifungal properties (54–57) and therefore are being implicated in management of infectious diseases.

2.3 PHYTOCHEMICALS AND FUNCTIONAL FOOD

The use of foods and food components such as phenolic phytochemicals as medicine has had an extraordinarily long history in the East and is still practiced successfully in many countries in Asia with Ayurvedic Medicine in India being one of many examples. However, the origin of the modern concept of "functional foods" as a separate and government regulated category of foods is quite new and was first developed in Japan in the 1980s. Faced with inflationary health care costs, the Japanese government instituted a regulatory system to approve certain foods with documented health benefits in order to improve health. These foods have a special seal and are known as "Foods for Specified Health Use" (FOSHU) (1). According to a recent report, as of September 2001, 271 food products had FOSHU status in Japan (58).

Interestingly, with this exception, there is no international, nor in most cases national, agreement on how functional foods should be defined nor is there a legal or regulatory definition. Functional foods seem to be regarded simply as foods that have physiological and psychological effects beyond traditional nutritional effects (59). In spite of the lack of legal or regulatory status consumers are extremely interested in the potential "medicinal" effects of food because they are becoming more and more convinced that their health and quality of life is, in part, a controllable gift, and they want to be an active participant in the process of this control. Added to this desire is a health care system, or lack thereof, which is increasingly perceived as distant, cold, and uncaring along with an explosion in emerging science which points to nontraditional health benefits of foods, food components, and plants (botanicals). This does not imply that consumers wish to give up traditional food, medicine, or health care but means that other options are being offered to the consumer, that form a continuum of treatment. These options are attractive to the consumer but they are also extremely attractive to governments who are being overwhelmed by the cost of health care and to growers and the food industry as a source of new value added products, which fulfill consumer demand and have the potential to create a healthier and higher quality of life.

The concept of functional foods is thus a key component in the new paradigm for health care. This paradigm is unique in that it appeals to not only consumers but governments and industries as well. The paradigm is illustrated graphically in Table 2.1, Table 2.2, and Table 2.3, which have been modified from Clydesdale (60). Each table shows some of the disease states that may be linked to diet and an approximation of the percentage of the population at risk. For these disease states three traditional options are shown "Established Public Health Programs," "Emerging/Controversial Public Health Recommendations," and "Clinical Research." In Table 2.1 the scope of therapy to achieve these treatments is shown as a continuum from individualized treatment of the disease for critical care patients to reduction of risk of the disease for those responding to public health programs. In Table 2.2 the level of health professional involvement in order to

Table 2.1

achieve these therapies is also shown as a continuum from a high level for individual treatment to a low level for reduction of risk utilizing established public health programs. In the latter case there is an important educational component even though health professional involvement is low compared to the rest of the continuum. In Table 2.3 several other continua are overlapped on those in Table 2.2. With the advent of functional foods it can be seen that the scope of delivery options has been enlarged. The options continuum begins with drugs at the high cost, low consumer participation end, and then moves through medical foods, supplements, herbs, and finally functional foods and beverages at the low cost, high consumer participation preventative end of the spectrum. Functional foods and beverages are becoming, therefore, a part of established public health programs to reduce the risk of specific diseases.

The ultimate success of functional foods will depend on the ability to deliver bioactive healthful components from plants in a predictable and assured manner after they have been proven scientifically to be efficacious in reducing the risk of disease. In addition to the availability of bioactives such as phenolic phytochemicals, we will also need to insure that the foods we create with these components will provide a stable environment for them so they can deliver their physiological benefits as well as being sensorially pleasing, convenient, safe, and affordable.

It has been proposed that the effectiveness of a public health measure can be defined in the following equation:

$$\text{Effectiveness} = \text{Efficacy} \times \text{Compliance} \quad (2.1)$$

Therefore it is essential that functional foods do not compromise flavor or convenience to insure continued use (compliance) by consumers.

Functional foods are intended to be eaten as part of a healthy diet and in so doing reduce the risk of disease in the future along with the symptoms of disease which destroy our quality of life.

The other part of the equation, efficacy, requires sound science in order to validate a food's effectiveness. The question always arises as to the type of science and how much is necessary to validate effectiveness and thus make a claim of some sort for the food. The Keystone National Policy Dialogue on Food, Nutrition, and Health (61) noted that three types of evidence were considered by the FDA in assessing the validity of health claims:

Epidemiology: clinical data derived from observational epoidemiologic studies assessing associations between food substances and disease

Biologic mechanisms: data derived from chemical, cellular, or animal models investigating plausible mechanisms of action of food substances

Intervention trials: controlled assessment of clinical food substance interventions in the human population

The FDA felt that these combinations of data met their "significant scientific agreement" standard of proof. It should be mentioned that the "significant scientific agreement" standard has been called into question and FDA is facing legal challenges in the landmark "Pearson vs. Shalala" dietary supplement claims case. A Federal appeals court directed FDA, based on first amendment rulings, to allow certain health claims accompanied by FDA approved label disclaimers, even though they had failed to meet FDA's "significant scientific agreement" standard (62). This issue has not yet been fully resolved.

A slightly different approach to validate efficacy has been suggested in a consensus document for Europe (63): "The design and development of functional foods is a key issue, as well as a scientific challenge, which should rely on basic scientific knowledge relevant to target functions and their possible modulation by food components. Functional foods themselves are not universal, and a food based approach would have to be influenced by local considerations. In contrast, a science based approach to functional food is universal and, because of this, is very suitable for a panEuropean approach. The function driven approach has the science base as its foundation — in order to gain a broader understanding of the interactions between diet and health. Emphasis is then put on the importance of the effects of food components on well identified and well characterized target functions in the body that are relevant to health issues, rather than solely on reduction of disease risk."

In this case the European position suggests validation of the efficacy of functional foods on functions in the body rather than disease states as is the case with the FDA. In both cases the need for government accepted biomarkers (biological markers of disease) is implicit and unfortunately there is no standard procedure to follow to have biomarkers approved. Hopefully this situation will be rectified in the not to distance future.

One might argue that the three types of evidence suggested by the FDA would be valid for proving the efficacy of a food to reduce the risk of disease or to affect a function

in the body that is relevant to health. Thus, in the U.S. evidence from epidemiology, biological mechanisms and clinical trials could be used to validate both health claims and structure-function claims with the difference being the end point in question. In health claims the end point would be disease or an accepted biomarker of disease and in structure function claims the end point would be the specific structure or function in question.

It is probably fair to say that the majority of countries who have policies on functional foods would be within the parameters of evidence set by the U.S., Europe, and Japan (59). Functional foods, however, may be viewed more broadly than the preceding discussion indicates. For instance the American Dietetic Association (ADA) takes a very broad view in a position statement issued in 1999 (58). ADA stated that functional foods are "any potentially healthful food or food ingredient that may provide a health benefit beyond the traditional nutrients it contains." In addition they added that functional foods may be whole, fortified, enriched, or enhanced foods, to have a beneficial effect on health. A functional food would have to be consumed as part of a varied diet on a regular basis, at effective levels, and it is likely that all foods are functional at some physiological level.

Indeed, Milner (64) has asked "What is a functional food? I have never identified a nonfunctional food. I do not think anyone can truly describe one. All foods should be functional under the right circumstances." He goes on to use diet colas as an example of being functional for one who wishes to avoid calories, to increase palatability or to use the caffeine in it as a stimulant. All this simply means is that both consumers and those working on functional foods should have a definition in mind because most governments do not currently have one. In fact as noted by Clydesdale (59) it might be more productive to focus on what might ethically and scientifically be said about foods and what health claims might be made, rather than on the concept of functional foods themselves. If the discussion becomes involved with terminology, one can easily become lost in a morass of terms, such as functional foods, nutraceuticals, phytochemicals, natural remedies, bio-chemo-preventatives, medical foods, dietary supplements, and foods for special medical purposes that may or may not be regulated, depending on the country.

Further, we should be clear that our focus is on foods and not on drugs and that we make a clear difference between the two. In the U.S., the terms prevention and cure are generally ascribed, by statute, to drugs. Indeed, one of the U.S. statutory drug definitions relies on intended use whereby a drug is any article intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man (65). Therefore, potential health claims for foods or beverages that ascribe prevention, mitigation, or cure relationship between the compound and the disease would therefore, be drug claims. Thus food and beverage claims should be limited to a level that ascribes risk reduction or improved biological function (60). Foods, in general, will have a future benefit rather than an immediate benefit like drugs. Because of this they rarely have side effects as their level of bioactivity is lower and therefore long term rather than high and short term like drugs. Foods therefore have a presumption of safety for the entire population, at every age, gender, and ethnic group, which drugs do not. The benefit/risk of drugs is used as part of their regulatory approval in the U.S. whereas the regulation of foods cannot consider benefit/risk assessments.

If the bioactive component of a food botanical was found to be drug-like in its function then a functional food utilizing the bioactive would become a drug if a claim for prevention or cure of a disease was made. This would mean that there would not be a presumption of safety and testing under the drug statutes would have to be conducted.

As noted previously the European Commission has taken a different approach (63) in which they select and discuss key target functions in detail (66). Based on this they concluded that key target functions should (63):

play a major role in maintaining an improved state of health and wellbeing or reduction of risk of disease
appropriate markers should be available and feasible
potential opportunities should exist for modulation by candidate food components

Such reasoning would lend scientific credibility to structure function claims and this along with the scientific rigor required for health claims in the U.S. would provide for a meaningful measure of efficacy for use in the equation:

$$\text{Effectiveness} = \text{Efficacy} \times \text{Compliance} \tag{2.2}$$

Food is a wonderful vehicle for bioactive ingredients such as phenolic phytochemicals because the consumer finds little difficulty with compliance as long as the food is appealing; tastes, smells, and looks good; has good storage stability; is convenient; and is reasonably priced. However, one should not gloss over the importance of food as a vehicle because the technology to create an optimum vehicle for bioactive ingredients is as critical as the science and technology to create physiologically important bioactive compounds. Food, the vehicle which will carry these bioactive compounds must provide an environment which maintains their stability, bioactivity, and bioavailability during preparation and storage such that the bioactive ingredients are consumed at a known and efficacious level by the consumer.

It is important that consumers understand that claims for functional foods are based on sound science. This is at times made difficult by the different types of claims, differences in the laws which govern foods and supplements, and the wide diversity of terminology mentioned previously. However, as society becomes more accustomed to foods with specific biological properties these issues should and must be resolved. The science to provide proof of quality, safety, and efficacy is critical to the future success of functional foods. As Gruenwald (67) notes: the key market for herbal medicines is Germany, followed by France, because these countries have the highest sales but also the most rigid requirements regarding quality, safety, and efficacy.

Understanding the physiological benefits of foods and their ingredients has the potential to provide significant advances in public health, not only from the benefits provided by the bioactive ingredients but also from the impetus provided to consumers to take some responsibility for their own health. Certainly sales of supplements botanicals and functional foods have been growing with functional foods showing the largest rate of growth in the U.S. since 2000 (68). This, however, may be somewhat deceptive as the greatest growth has been in sports bars, beverages, and meal supplements, many of which are legally classified as supplements in the U.S. rather than functional foods. Nevertheless, the future has great potential and new foods will be developed as science allows us to uncover the bioactivity of the foods and plants that we eat.

2.4 RELEVANCE OF PHENOLIC ANTIOXIDANTS FOR FUNCTIONAL FOOD AND COMPARATIVE METABOLIC BIOLOGY CONSIDERATIONS

It is clear that food plants are excellent sources of phenolic phytochemicals, especially as bioactives with antioxidant property. As is evident, phenolic antioxidants from dietary

sources have a history of use in food preservation, however, many increasingly have therapeutic and disease prevention applications (69–72). Therefore, understanding the nutritional and the disease protective role of dietary phytochemicals and particularly phenolic antioxidants is an important scientific agenda well into the foreseeable future (73). This disease protective role pf phytochemicals is becoming more significant at a time when the importance of in the prevention of oxidation linked chronic diseases is gaining rapid recognition globally. Therefore, disease prevention and management through the diet can be considered an effective tool to improve health and reduce the increasing health care costs for these oxidation linked chronic diseases, especially in low income countries.

As discussed earlier, phenolic phytochemicals have been associated with antioxidative action in biological systems, acting as scavengers of singlet oxygen and free radicals (74–77). Recent studies have indicated a role for phenolics from food plants in human health and, in particular, cancer (76,78). Phenolic phytochemicals (i.e., phenylpropanoids) serve as effective antioxidants due to their ability to donate hydrogen from hydroxyl groups positioned along the aromatic ring to terminate free radical oxidation of lipids and other biomolecules (79). Phenolic antioxidants, therefore, short circuit destructive chain reactions that ultimately degrade cellular membranes. Examples of food based plant phenolics that are used as antioxidant and antiinflammatory compounds are curcumin from *Curcuma longa* (80–82), *Curcuma mangga* (83), and *Zingiber cassumunar* (84), and rosmarinic acid from *Rosmarinus officinalis* (72,85). Examples of phenolics with cancer chemopreventive potential are curcumin from *Curcuma longa* (80,86–89), isoflavonoids from *Glycine max* (90–92), and galanigin from *Origanum vulgare* (93). Other examples of plant phenolics with medicinal uses include lithospermic acid from *Lithospermum* sp. as antigonadotropic agent (94), salvianolic acid from *Salvia miltiorrhiza* as an antiulcer agent (95), proanthocyanidins from cranberry to combat urinary tract infections (96,97), thymol from *Thymus vulgaris* for anticaries (98), and anethole from *Pimpinella anisum* as an antifungal agent (99).

We have targeted enhanced production of oxidation disease relevant plant biphenyl metabolites such as rosmarinic acid, resveratrol, ellagic acid, and curcumin using novel tissue culture and bioprocessing approaches. Other phenolic phytochemicals also targeted are flavonoids, quercetin, myrcetin, scopoletin, and isoflavonoids. Among simple phenolics, there is major interest in the overexpression of L-tyrosine and L-DOPA from legumes in a high phenolic antioxidant background (100,101). Rosmarinic acid has been targeted from clonal herbs (1,69) for its antiinflammatory and antioxidant properties (85,102,103). Resveratrol has shown antioxidant and cancer chemopreventive properties (104,105) and its overproduction has been targeted from several fruits using solid-state bioprocessing (106,107). Ellagic acid has been targeted for antioxidant and cancer chemopreventive properties (108,109) and has been similarly targeted via solid-state bioprocessing from fruits and fruit processing byproducts (106). Extensive studies have shown cancer chemopreventive and antioxidant properties for *Curcuma longa* and its major active compound, curcumin, (81,86,110) and the developmental and elicitor stress mediated overexpression of curcumin is being investigated.

The emergence of dietary and medicinal applications for phenolic phytochemicals, harnessing their antioxidant and antimicrobial properties in human health and wellness has sound rationale. As stress damage on the cellular level appears similar among eukaryotes, it is logical to suspect that there may be similarities in the mechanism for cellular stress mediation between eukaryotic species. Plant adaptation to biotic and abiotic stress involves the stimulation of protective secondary metabolite pathways (111–113) that results in the biosynthesis of phenolic antioxidants. Studies indicate that plants exposed to ozone responded with increased transcript levels of enzymes in the phenylpropanoid and lignin pathways (114). Increase in plant heat tolerance is related to the accumulation of phenolic metabolites and heat shock proteins that act as chaperones during hyperthermia (115).

Phenolics and specific phenolic-like salicylic acid levels increase in response to infection, acting as defense compounds, or to serve as precursors for the synthesis of lignin, suberin, and other polyphenolic barriers (116). Antimicrobial phenolics called phytoalexins are synthesized around the site of infection during pathogen attack and, along with other simple phenolic metabolites, are believed to be part of a signaling process that results in systemic acquired resistance (111–113). Many phenylpropanoid compounds such as flavonoids, isoflavonoids, anthocyanins, and polyphenols are induced in response to wounding (117), nutritional stress (118), cold stress (119), and high visible light (120). UV irradiation induces light-absorbing flavonoids and sinapate esters in *Arabidopsis* to block radiation and protect DNA from dimerization or cleavage (121). In general, the initiation of the stress response arises from certain changes in the intracellular medium (122) that transmit the stress induced signal to cellular modulating systems and results in changes in cytosolic calcium levels, proton potential as a long distance signal (123), and low molecular weight proteins (124). Stress can also initiate free radical generating processes and shift the cellular equilibrium toward lipid peroxidation (125). It is believed that the shift in prooxidant–antioxidant equilibrium is a primary nonspecific event in the development of the general stress response (126). Therefore, protective phenolic antioxidants involved in such secondary metabolite linked stress responses in food plant species has potential as a source of therapeutic and disease-preventing functional ingredients for oxidation disease linked diet (high carbohydrate and high fat diets) and environment (physical, chemical, and biological) influenced chronic disease problems (69).

2.5 CLONAL SCREENING OF PHENOLIC SYNTHESIS IN HERB SHOOT CULTURE SYSTEMS

The hypothesis that the biosynthesis of plant phenolic metabolites is linked to the proline linked pentose–phosphate pathway (1,69; Figure 2.1) was developed based on the role of the proline linked pentose–phosphate pathway in regulation of purine metabolism in mammalian systems (127). Proline is synthesized by a series of reduction reactions from glutamate (69). In this sequence, P5C and proline known to be metabolic regulators function as a redox couple (127,128). During respiration, oxidation reactions produce hydride ions, which augment reduction of P5C to proline in the cytosol. Proline can then enter mitochondria through proline dehydrogenase (129) and support oxidative phosphorylation (alternative to NADH from Krebs/TCA cycle). This is important because shunting the TCA cycle toward proline synthesis likely deregulates normal NADH synthesis. The reduction of P5C in the cytosol provides $NADP^+$, which is the cofactor for glucose-6-phosphate dehydrogenase (G6PDH), an enzyme that catalyzes the rate-limiting step of the pentose–phosphate pathway. Proline synthesis is therefore hypothesized and has been partly shown to both regulate and stimulate pentose–phosphate pathway activity in erythrocytes (130) and cultured fibroblasts (131) when P5C is converted to proline. This was shown to stimulate purine metabolism via ribose-5-phosphate, which affects cellular physiology and therefore function (127,132).

Based on several studies, Shetty (1,69) proposed a model that the proline linked pentose–phosphate pathway (PLPPP) could be the critical control point (CCP) of shikimate and phenylpropanoid pathways and hypothesized that stress linked modulation of PLPPP could lead to the stimulation of phenolic phytochemicals (1,69; Figure 2.1). Using this model, proline, proline precursors, and proline analogs were effectively utilized to stimulate total phenolic content and a specific phenolic metabolite, rosmarinic acid (133,134). Further, it was shown that proline, proline precursors, and proline analogs

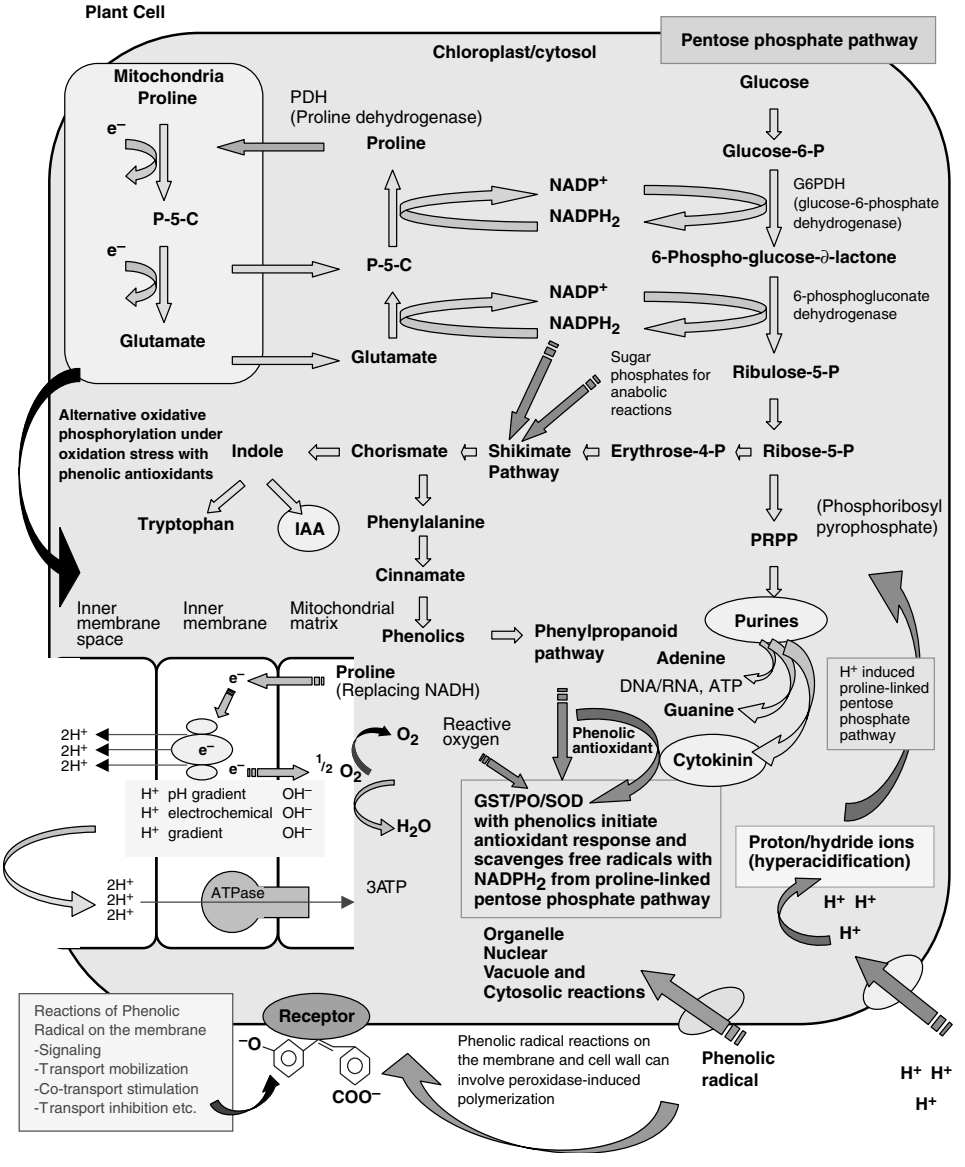

Figure 2.1 Model for the role of proline linked pentose–phosphate pathway in phenolic synthesis and its utilization for screening high phenolic clonal lines of single seed genetic origin.

stimulated somatic embryogenesis in anise, which correlated with increased phenolic content (135). It was also established that during *Pseudomonas* mediated stimulation of total phenolic and rosmarinic acid (RA), proline content was stimulated in oregano clonal shoot cultures (136). Therefore, it was proposed that $NADPH_2$ demand for proline synthesis during response to microbial interaction and proline analog treatment (1,69), may reduce the cytosolic $NADPH_2$/ $NADP^+$ ratio, which should activate G6PDH (137,138). Therefore, deregulation of the pentose–phosphate pathway by proline analog and microbial induced proline synthesis may provide the excess erythrose-4-phosphate (E4P) for shikimate and, therefore, the phenylpropanoid pathways (69). At the same time, proline and P5C could

serve as superior reducing equivalents (RE), alternative to NADH (from Krebs/TCA cycle) to support increased oxidative phosphorylation (ATP synthesis) in the mitochondria during the stress response (69,127,128).

The proline analog, azetidine-2-carboxylate (A2C), is an inhibitor of proline dehydrogenase (139). It is also known to inhibit differentiation in Leydig cells of rat fetal testis, which can be overcome by exogenous proline addition (140). Another analog, hydroxyproline, is a competitive inhibitor of proline for incorporation into proteins. According to the model of Shetty (1,69), either analog, at low levels, should deregulate proline synthesis from feedback inhibition and stimulate proline synthesis (1,69). This would then allow the proline linked pentose–phosphate pathway to be activated for $NADPH_2$ synthesis, and concomitantly drive metabolic flux toward E4P for biosynthesis of shikimate and phenylpropanoid metabolites, including RA. Proline could also serve as a RE for ATP synthesis via mitochondrial membrane associated proline dehydrogenase (129,69).

Using this rationale for the mode of action of proline analogs and links to the pentose–phosphate pathway, high RA-producing, shoot based clonal lines originating from a single heterozygous seed among a heterogeneous bulk seed population of lavender, spearmint, and thyme have been screened and isolated based on tolerance to the proline analog, A2C, and a novel *Pseudomonas* sp. isolated from oregano (Figure 2.2; 141–143). This strategy for screening and selection of high RA clonal lines is also based on the model that proline linked pentose phosphate pathway is critical for driving metabolic flux (i.e., E4P) toward shikimate and phenylpropanoid pathways (Figure 2.1). Any clonal line with a deregulated proline synthesis pathway should have an overexpressed pentose phosphate pathway which allows excess metabolic flux to drive shikimate and phenylpropanoid pathway toward total phenolic and RA synthesis (69). Similarly, such proline overexpressing clonal lines should be more tolerant to proline analog, A-2-C. If the metabolic flux to RA is overexpressed, it is likely to be stimulated in response to *Pseudomonas* sp (69). Therefore,

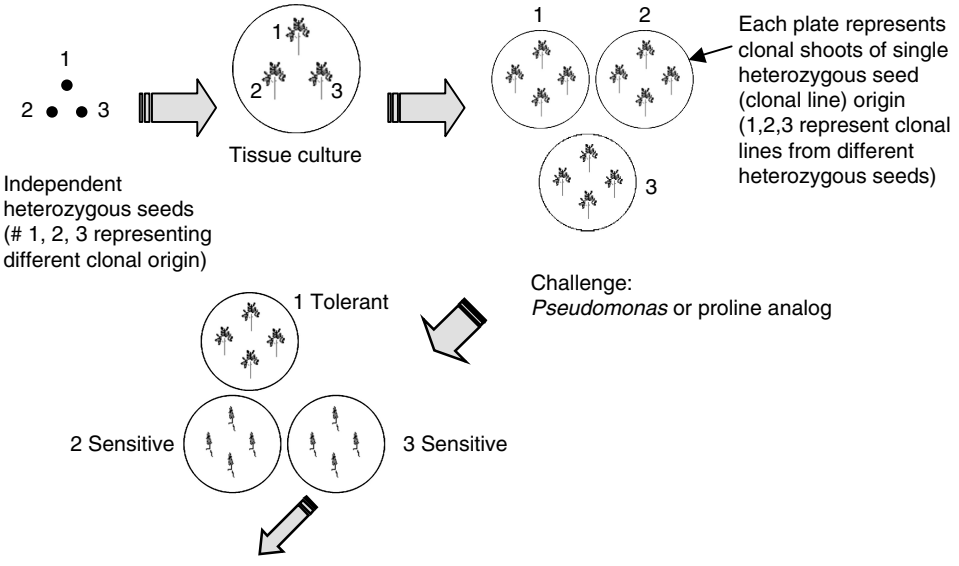

Figure 2.2 Isolation of clonal lines of single seed origin based bacterial or proline analog tolerance. Clonal lines can be used for investigations on Rosmarinic acid inducibility and endogenous antioxidant enzyme response in various clonal lines under various nutritional conditions. Further, high phenolic clonal lines can be used for development of ingredient profiles of single seed clonal origin.

such a clonal line is equally likely to be tolerant to *Pseudomonas* sp. Further, such a clonal line should also exhibit high proline oxidation and RA content in response to A2C and *Pseudomonas* sp. The rationale for this model is based on the role of the pentose–phosphate pathway in driving ribose-5-phosphate toward purine metabolism in cancer cells (127), differentiating animal tissues (140), and plant tissues (144). The hypothesis of this model is that the same metabolic flux from over expression of proline linked pentose–phosphate pathway regulates the interconversion of ribose-5-phosphate to E4P driving shikimate pathway (69). Shikimate pathway flux is critical for both auxin and phenylpropanoid biosynthesis, including RA (69). This hypothesis has been strengthened by preliminary results in which RA biosynthesis in several oregano clonal lines was significantly stimulated by exogenous addition of proline analog (e.g., A2C) and ornithine (133,134). The same clonal lines are also tolerant to *Pseudomonas* sp. and respond to the bacterium by increasing RA and proline biosynthesis (136,145). High RA-producing clonal lines selected by approaches based on this model (141–143,145–147) are being targeted for preliminary characterization of the key enzymes in phenolic synthesis and large scale production of such phenolics using tissue culture generated clonal lines in large scale field production systems. This strategy for investigation and stimulation of phenolic biosynthesis in clonal plant systems using PLPPP as the CCP can be the foundation for designing dietary phenolic phytochemicals from cross-pollinating, heterogeneous species for functional foods (1,69).

2.6 PHENOLIC SYNTHESIS IN SEED SPROUTS

Preliminary results (1,69,72,133,134,148) have provided empirical evidence for a link between proline biosynthesis and oxidation, as well as stimulation of G6PDH. In light mediated sprout studies in pea (*Pisum sativum)*, acetylsalicylic acid in combination with fish protein hydrolysates (a potential source of proline precursors) stimulated phenolic content and guaiacol peroxidase (GPX) activity during early germination with corresponding higher levels of proline and G6PDH activity (149). In parallel light mediated studies in pea, low pH and salicylic acid treatments stimulated increased phenolic content and tissue rigidity. Similarly, there was concomitant stimulation of G6PDH and proline (148). This work supported the hypothesis that pentose–phosphate pathway stimulation may be linked to proline biosynthesis and that modulation of a proton linked redox cycle may also be operating through proline linked pentose–phosphate pathway (148). In dark germinated studies in pea, high cytokinin-containing anise root extracts stimulated phenolic content and antioxidant activity, which correlated with increased proline content but inversely with G6PDH activity (150). In further dark germination studies in mung bean (*Vigna radiata*), dietary grade microbial polysaccharide treatments stimulated phenolic content and enzyme activity, G6PDH and GPX compared to controls (151), with concomitant stimulation of proline content. In addition, specific elicitors xanthan gum, yeast extract, and yeast glucan stimulated antioxidant activity. In additional studies, oregano phenolic extracts were used as elicitors to stimulate phenolic content during dark germination of mung bean. Again, increased phenolic content corresponded to an increase in activity of G6PDH and GPX and phenolic related antioxidant activity were also stimulated (152). In studies with dark germinated fava bean, support for the hypothesis that stimulation of proline linked pentose–phosphate pathway would stimulate phenolic metabolism under elicitor and stress response was probed (69). In polysaccharide elicitor studies, gellan gum stimulated fava bean total phenolic content ninefold in late stages of germination with a corresponding increase in proline content and GPX activity, although the effect on antioxidant and G6PDH activity was inconclusive (100). In the same fava bean system, UV mediated stimulation of phenolic content in dark germinated fava bean

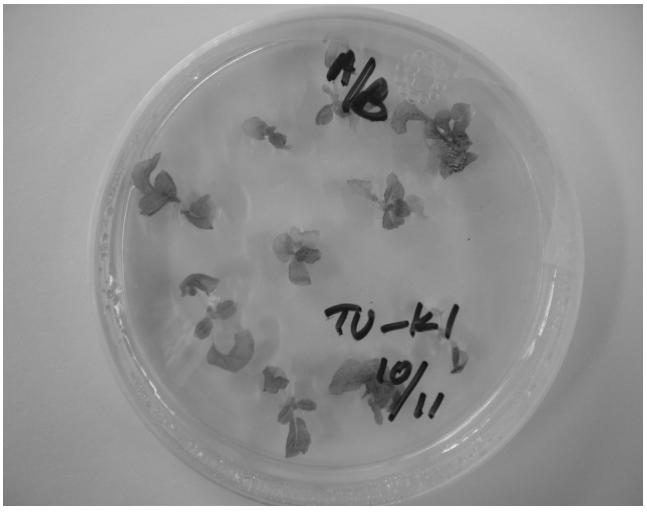

Figure 2.3 High phenolic clonal shoot culture of oregano (*Origanum vulgare*) with genetic origin from single heterozygous seed.

sprouts indicated a positive correlation to G6PDH and GPX activities with a concomitant increase in proline content (153). It was further confirmed that proline analog, A2C also stimulated phenolic content in fava bean with positive correlation to G6PDH and GPX activities as well as proline content (154). Similar to studies in clonal shoot cultures of thyme (133) and oregano (134), the proline analog mediated studies in fava bean confirmed that proline overexpression was not only possible, but involved stimulating G6PDH and therefore likely diverted the pentose–phosphate pathway toward phenylpropanoid biosynthesis. The late stage stimulation of phenolic content and GPX activity in response to microwave mediated thermal stress in dark germinated fava bean strongly correlated with stimulation of free radical scavenging activity of free phenolics as measured by the quenching of 1,1-diphenyl-2-picrylhydrazyl (DPPH) free radical assay and stimulation of superoxide dismutase (SOD) activity (155). Therefore, using elicitor and physical stress in early stages of seed sprouting could be effectively used to stimulate key phenolic phytochemicals for design of functional foods. In designing appropriate phenolic phytochemical extracts diverting carbohydrate and protein metabolic flux through the proposed CCP, proline linked pentose–phosphate pathway (PLPPP) has substantial potential. This CCP link to PLPPP could be the basis for a more effective Systems Biology approach for metabolic control of functional phenolic phytochemicals and appropriate design of phytochemicals from different seed sprout systems for different oxidation linked disease targets.

2.7 SUMMARY OF STRATEGIES AND IMPLICATIONS

In an age where diet and environmental related oxidation and infectious diseases are on the rise, the role of dietary phenolic phytochemicals in preventive management of diseases is becoming important. Strategies to improve functional phytochemicals that addresses the problem of consistency have to be developed. Within this framework we have developed strategies for isolating clonal dietary herbs of single seed genetic origin with a specific profile of phenolic phytochemicals and also stress elicitation based enhancement of phenolic phytochemicals during legume seed sprouting. The rationale for development of

these techniques for phenolic phytochemical enhancement for functional food design is based on harnessing the potential of proline linked pentose–phosphate pathway (PLPPP) as the critical control point (CCP) in clonal shoots of single seed genetic origin such as herbs from the family Lamiaceae and seed sprouts in self-pollinating species such as various legumes. This strategy can be extended to develop foods with better phenolic phytochemical profile and functionality. Further it can be extended to develop functional foods and supplements with consistent ingredient profiles targeted against a disease condition. This concept is now being extended to specifically isolate antioxidants for diverse disease conditions, antimicrobials against bacterial pathogens, phytochemicals for diabetes management, angiotensin converting enzyme inhibitors for hypertension management, L-DOPA for Parkinson's management, dietary cyclooxygenase (COX-2 inhibitors) for inflammatory diseases and isoflavones for women's health.

2.03

Genomic Basics for Food Improvement

Gabriela Olmedo, Socorro Parra, and Plinio Guzmán

CONTENTS

3.1 INTRODUCTION

One ultimate goal of many plant scientists is to gain in depth knowledge of the function of each gene in a given plant. Understanding how genes coordinate growth and development of a living being is of great importance in many areas of science and technology. In the last decade, sequencing projects turned out myriads of genes. Because traditional approaches involve studying genes one at a time, and given that there are at least 20,000 genes in any given plant species, understanding the functions of all these genes requires new strategies. In the last few years, several technological advances for deciphering and manipulating the genetic information revolutionized the field of genetics, giving birth to a new area in biological sciences: genomics. Genomics provides the strategies for the simultaneous study of hundreds or thousands of genes. Using microarrays, for instance, the expression of many genes can be studied in parallel. Furthermore, it is hoped that genomics can be complemented with proteomics to also assess the function of each gene's product.

Genomics deals with the molecular cloning and characterization of entire genomes. It studies the organization and function of the genetic information, and its goal in a given species is to determine the sequence of the complete genome and to establish the function of all genes contained in it. The basic understanding of how a microorganism, a worm, an insect, a plant, a fish, or a mammal functions provides invaluable information for biotechnological

developments. Drugs can be manufactured using new approaches, and early detection of a number of diseases can be envisioned. Crop and livestock productivity as well as food quality and safety can be expected to improve. Because genomics deciphers the structure of the genome it will also impact our knowledge of the evolution of species.

Two major areas of genomic research are considered here: the structural and the functional analysis of the genome. The structural analysis of the genome, known as structural genomics, establishes the composition and organization of the whole genome; and the functional analysis of the genome, known as functional genomics, studies the expression of the genetic elements and searches for the function of every gene product. Pioneer genomic projects have been accomplished in several of the research model systems and current projects are now being established in a wide range of organisms, including crops of nutritional importance. Structural and functional genomics have already generated information from some of the model systems, but most of the genomic projects are still at the structural analysis stage. In plant biotechnology the weed *Arabidopsis thaliana*, as the main model systems in dicots, is driving the genomic field. The sequence of its genome has been completed and tools for the functional analysis of its genes are now available. Likewise, the draft of the rice genome has been created, providing a first panoramic view of the genome of this very important food crop. This chapter reviews the existing knowledge of the approaches and tools used in the genomic analysis of plants.

3.2 WHOLE GENOME SEQUENCING OF PLANT GENOMES

Deciphering the basic composition of a genome is a crucial step in the understanding of its function as a whole. A central procedure in genomics is DNA sequencing; this has undergone several improvements since first described by Sanger in the 1970s (1). The automation of routine processes for template preparation (the DNA to be sequenced) and the development of sophisticated machines have speeded up DNA sequence procedures; now the determination of vast amounts of DNA sequence is possible in much less time and at much less cost than a decade ago.

The complete sequence of a genome is obtained by first determining the DNA sequence of small segments and then deducing the position of each one in a linear order. One approach begins with the cloning of fragments representing the entire genome into vectors with high cloning capabilities, usually greater than 150.000 base pairs long. These are the Yeast Artificial Chromosome vectors (YACs), manipulated in yeast, and the Bacterial Artificial Chromosomes (BACs) and P1 Artificial Chromosome vectors (PACs) maintained as *Escherichia coli* clones (2). Overlapping clones (clones containing segments of identical sequence) are then arranged into contigs, a series of contiguous clones, to generate a physical map of the organism. Next, 500–1000 base pair long fragments are obtained from each of the clones and subcloned into vectors for the subsequent determination of the DNA sequence. The subclones are sequenced randomly, and overlapping sequences are used to assemble the complete original clone *in silico*. Another approach is to start to sequence random clones from the beginning. In this approach, a library of small size clones (1000 base pair long inserts) is generated and sequenced randomly, and then the entire genome is assembled from overlapping sequences. The first output is the draft sequence that is used to assemble the original clone or genome. However, to ensure data accuracy, additional sequencing is performed, resulting in 5–8 sequences from each individual clone. This process clarifies uncertainties in the sequence and helps find most of the overlapping sequences between clones. There are regions of the genome of plants and mammals that cannot be cloned or that are very unstable. These regions are not sequenced

and are not present in the description of the complete sequence of a genome. These are the heterochromatic regions of the chromosome, including centromeres, telomeres, and regions rich in repeated sequences.

Whole genome sequencing projects have been completed in several organisms, ranging from small bacterial genomes to large mammalian and plant genomes. In eukaryotes, the genomes from three model organisms were the first to be completed: the yeast *Saccharomyces cerevisiae* (3), the worm *Caenorhabditis elegans* (4), and the insect *Drosophila melanogaster* (5). To date there are 261 genomes that have been sequenced: 21 archaeal, 207 bacterial, and 33 from eukaryotic organisms (see http://wit.integratedgenomics.com/GOLD/). The first plant genome to be sequenced was that of *Arabidopsis thaliana* (6), and more recently two draft sequences of the rice genome were reported (7,8). The completion of the sequence of a genome is only the beginning of new challenges in biological research. *Arabidopsis thaliana* is a weed of the Brassicaceae family that does not have any agriculturally important value. However, this weed provides the resources to understand basic phenomena in plant growth and development. One result of a complete genome is establishing the exact number of genes in an organisms and the map location of each. This permits the identification of single copy genes as well as the composition of gene families. The next challenge is to establish the role for all the genes encoded in the genome. The genome of *Arabidopsis* will be the reference book for other plant genomes; comparative analysis will help with gene identification and to establish gene function in crop species.

A landmark in plant genomics is the availability of the DNA sequences of the *Arabidopsis* and rice genomes. These two species possess the smallest known genomes among plants (see Table 3.1), and represent two important lineages in the plant kingdom: monocots and dicots. The availability of the complete sequences of the *Arabidopsis thaliana* and rice genomes permits researchers to inquire for the first time about the number of conserved genes between plant species (see Figure 3.1). There are 25,000 genes encoded in *Arabidopsis* and 32,000 to 55,000 in rice. Analysis of the presence of *Arabidopsis* genes in rice revealed that 85% of predicted genes are also present in rice, and about 12% of these with high homology, suggesting that they are important genes for cell functioning. For another 30% of the conserved genes there is no information in databases, indicating potential genes to be discovered. Plant specific genes can also be enlisted (see Figure 3.1); these genes are present in both *Arabidopsis* and rice genomes but absent in other eukaryotic genomes like *S. cerevisiae, D. melanogaster,* and *C. elegans*. Another group of genes that may reveal specific genes for dicot plants are those that do not have homologues in

Table 3.1
Genome Size of Some Plant Genomes

Organism	Genome Size (Mega Base Pairs)
Arabidopsis thaliana	125
Oriza sativa	430
Lotus japonicus	450
Medicago truncatula	500
Gossypium hirsutum L cv. Maxxa	2,118
Hordeum vulgare var. distichum	5,000
Zea mays	5,000
Avena sativa	16,000
Triticum aestivum	16,000

Data obtained from: http://wit.integratedgenomics.com/GOLD

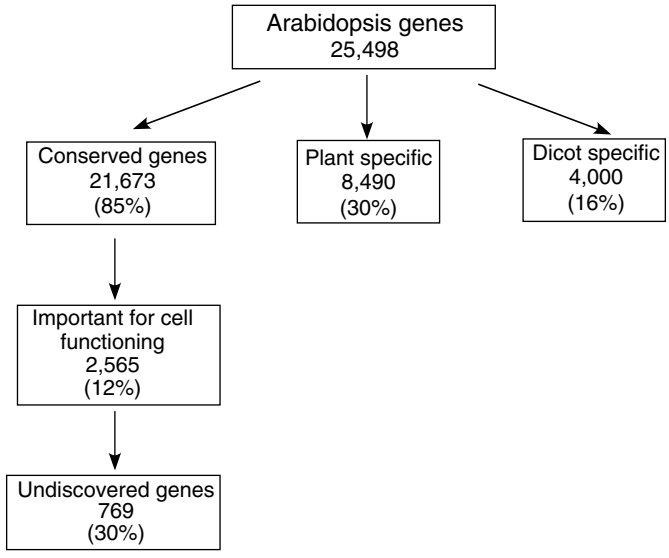

Figure 3.1 Conservation of genes between two plant species: *Arabidopsis* and rice. Conserved genes are those present in both plant species; genes important for cell functioning are those that show a high homology between them; undiscovered genes have no annotation in databases; plant specific genes are present in both species but absent in other sequenced genomes; dicot specific genes are those only present in *Arabidopsis*. Data adapted from (7).

rice or other eukaryotes (see Figure 3.1). Additionally, the availability of the rice sequence also permits confirmation of observations previously only inferred in *Arabidopsis*; there are genes that are neither encoded in *Arabidopsis* nor in rice. Examples of this are the genes encoding the nuclear steroid receptors, Notch/Lin12, p53, Hedgehog, and Wingless/Ent. Conversely, genes that are found in high numbers in *Arabidopsis* when compared to other eukaryotes are also found in high numbers in the rice genome. These are families of RING zinc fingers and F-box containing proteins. Interestingly, these two classes of genes are involved in the regulation of protein turnover in other organisms, suggesting that such large gene families have a function particular to plants, possibly participating in some stages of plant growth and development (7).

Comparative analysis between *Arabidopsis* and rice can also be applied to address specific questions. An example is the comparison of the number of transcription factors between both species. Transcriptional regulation of gene expression is intrinsic to most of the biological phenomena in all living organisms. Differential expression of sets of genes during development is controlled by transcription factors, and basic changes in transcription factors may give rise to diversity among species. The *Arabidopsis* and rice genomes encode for at least 1533 and 1306 predicted transcription factors, respectively, and show a similar number of members in each of the classes (7, 9); an example of these are displayed in Table 3.2. Almost 45% of these regulatory proteins constitute families specific to plants, such as the AP2/ERF/RAV and WRKY families. Others are found in higher numbers in plants than in nonplant eukaryotes, such as Myb and MADS factors. In general plant transcription factors show sequence conservation with other eukaryotes primarily in the DNA binding domains.

The next complete plant genomes to be sequenced may be those of two legume species, *Lotus japonicus* and *Medicago truncatula* (10). *Lotus japonicus* is a model for forage legumes with a genome size of 450 Mb. *Medicago truncatula* is a model system for studying crop species relative to alfalfa; its genome is similar to *L. japonicus* in size, 500 Mb. Pilot sequencing

Table 3.2
Transcription factors in Arabidopsis and Rice

Transcription Factor Family	Arabidopsis	Rice
Ap2/ERF/RAV	144	143
WRKY	72	83
MYB	190	156
MADS box	82	71
C2H 2zinc finger	105	125
Dof	36	21
BZip	81	75

Data adapted from (7, 9)

projects have been initiated for *M. truncatula* using shotgun cloning strategies, and the entire sequence of the chloroplast genome has been completed. Legumes have a key role in food production, with many of them having been the source of very nutritious seeds for many years. Another significant feature is that legumes benefit from symbioses with nitrogen-fixing rhizobia and mycorrhiza when growing in soils limited in nutrients. Legumes also have unique pathways for secondary metabolite biosynthesis.

Not all the plant genomes have the size and simplicity of *Arabidopsis* (Table 3.1). Genome sizes in most crops show immense variations; for instance, the genome size of oats and wheat are estimated to be in the 16,000 Mb range, 5 times larger than that of the human genome. In addition, wheat is hexaploid and oat is an allopolyploid of three genomes. The size difference does not correlate with the number of genes. Enormous sizes are caused by the invasion of the genome with transposable elements and repetitive sequences. These repeats impair sequence analysis, making it impossible to assemble overlapping clones. Nevertheless, there are at least 16 genome projects ongoing in plants. Genome sequencing is very revealing, because regulatory elements located outside transcribed regions are contained in the sequence. Likewise, genes transcribed at very low levels are obtained that would be difficult to obtain by other means. A futher problem is how to obtain sequence information from complex plant genomes. An original approach has been described in maize (11). It was shown that repeats are preferably modified by methylation. By selecting clones in methylation-restrictive *E. coli* hosts, or by using methylation-sensitive restriction enzymes to generate libraries, the clones containing methylated DNA can be circumvented. This approach enriches the number of nonmethylated sequences that are likely to correspond to genes.

3.3 LARGE SCALE EST SEQUENCING PROJECTS IN CROP SPECIES

As mentioned previously, genomes are complex and possess not only coding genes but repetitive and structural elements as well. The approach of some sequencing projects is to sequence coding genes exclusively. Coding genes give rise to mRNAs that can be separated and converted into cDNAs. ESTs (expressed sequence tags) are partial DNA sequences obtained from either the 5′ or 3′ ends of cDNAs. ESTs provide very helpful data on the nature of coding regions of genes and constitute a basic tool for the assembly of high density cDNA microarrays for global expression studies. A shortcoming of ESTs is that the cDNAs lack DNA sequence information encoded beyond the transcribed region of the gene; consequently knowledge about regulatory elements that are not encoded in the

transcript cannot be obtained. Likewise, genes that contain large untranslated regions make it difficult to discover genes, because sequence comparison is less feasible.

Considering the size and complexity of most crop genomes, large scale ESTs sequencing projects have been an effective alternative for getting insights into their genomes. A list of current EST projects, including those of plants important for human nutrition, is displayed in Table 3.3. The rising number of sequences in data bases is astonishing; more than 100,000 ESTs are available for some crops, such as oats, soybeans, and corn; and more than 400,000 ESTs are reported for wheat (Table 3.3). EST collections are usually obtained from cDNA libraries constructed from specific tissues or from tissues representing specific developmental stages, or from different treatments such as response to pathogens or to abiotic stresses. This diverse array of treatments provides invaluable information on the pattern and level of expression of genes in an organism. For example, 21 libraries are the sources of the current EST collection in maize (12). These libraries were prepared from various developmental stages: embryos collected at different days after pollination; immature apical meristem tissue; whole premeiotic anthers and pollen shed; from diverse organs: tassel, kernel, silk, husk, root, and leaf; and under diverse conditions: adult silk infected with the fungus *Fusarium* and salt-stressed seedlings and shoots.

Table 3.3
Number of ESTs and Database Entries for Plant Species

	ESTs	Nucleotide Entries	Protein Entries
Triticum aestivum (wheat)	415642	418106	2177
Hordeum vulgare (barley)	339034	35341	1239
Glycine max (soybean)	308564	320244	2168
Zea mays (corn)	198523	546188	4850
Medicago truncatula (barrel medic)	180939	185548	227
Lycopersicon esculentum (tomato)	148566	162415	2252
Solanum tuberosum (potato)	94423	95874	1661
Sorghum bicolor (sorghum)	84712	120337	517
Pinus taeda (loblolly pine)	60226	60721	184
Populus tremula × *Populus tremuloide*	56013	56190	61
Gossypium arboreum (tree cotton)	38894	38953	39
Lotus japonicus	33124	80015	381
Mesembryanthemum crystallinum (common ice plant)	25446	25689	355
Sorghum propinquum	21387	27470	1
Beta vulgaris (beet)	19617	14	17
Gossypium hirsutum (upland cotton)	10725	13867	733
Secale cereale (rye)	8930	9221	222
Lycopersicon pennellii	8346	8377	21
Lycopersicon hirsutum	2504	2535	20
Marchantia polymorpha (liverwort)	1415	1515	710
Medicago sativa (alfalfa)	805	1363	679
Avena sativa (oat)	501	730	190

Data obtained from: www.ncbi.nlm.nih.gov/PMGifs/Genomes/PlantList.html

Since the early days of DNA sequencing it was noted that the genomes of eukaryotes share conserved sequences. The comparative analysis of complete genomes, known as comparative genomics, confirmed that different genomes have a substantial quantity of conserved genes. Such genes are mostly involved in basic cellular processes. Comparison of ESTs in databases facilitates the detection of conserved sequences among diverse and unrelated organisms. This fact increases the possibility of accurate annotation of unknown cDNA clones; that is, to be able to classify a gene only by analyzing the information of its predicted coding product. Percentages of maize ESTs that correspond to protein homologues in other plants is shown in Table 3.4. As expected, the greatest number of matches is from *Arabidopsis* and rice, given that their complete genome sequence is known. Comparative genomics between *Arabidopsis* genes and wheat EST sequences shows that about 50% of *Arabidopsis* genes match 2 or more wheat ESTs (Figure 3.2) (13). About 75% of the matching genes are annotated with a description, many of them corresponding to genes with a possible function in general processes. This comparison is useful as an initial categorization to distinguish genes involved in species–specific processes. These

Table 3.4
Percentages of Maize EST Protein Homologs by Organism

Organism	Percentage
Arabidopsis thaliana	42.7
Oryza sativa	23.4
All remaining species	5.8
Triticum aestivum	1.2
Hordeum vulgare	1.1
Sorghum bicolor	0.2

genes may be those that do not have a match in both genomes. The rapid increase in the number of sequences in the databases will greatly improve the annotation process of genes from plants of nutritional importance.

3.4 GENOME WIDE ANALYSIS OF GENE EXPRESSION USING DNA MICROARRAYS

The analysis of the presence and the measurement of the level of different mRNAs during specific growth or developmental conditions is a method that provides useful information about the function of a gene. The availability of large collections of genes from several organisms and of complete genome sequences has prompted the development of technology to facilitate the analysis of the expression of thousands of genes at the same time. This technology is known as DNA microarrays, also referred to as DNA chips, and one of its uses is to monitor global expression patterns (14). DNA microarrays consist of DNA samples bound to a solid surface and arrayed in a defined order so that the identity of each is known. These arrayed samples are then hybridized to RNA that has been labeled with fluorescent dyes to allow the detection of the DNA sample represented in the array corresponding to the expressed RNA.

There are basically two different DNA microarray methods for monitoring gene expression. One depends on the use of cDNA clones and the other on the use of oligonucleotides. Amplification of cDNA clones in a size range of 200 to 2000 base pairs by PCR is the most common source of DNA. These cDNA clones are usually obtained form EST sequencing projects and primers from vector sequences can direct the amplification of the cDNA inserts. Amplification of genes using genomic DNA as a template is also a source of DNA to be tested. In this case the genomic sequence has to be known to be able to design gene specific primers. The second option makes use of synthetic oligonucleotides 60 to 80 nucleotides long. This alternative has the advantage that the oligonucleotides can be designed to be gene specific, which helps in the analysis of gene families, as it increases the possibility of getting a differential hybridization among its members. This approach obviously needs previous knowledge of the gene sequences to be able to design the specific oligonucleotides to be spotted.

The supports for spotting the DNA samples in the microarrays are either glass or nylon. When DNA samples are mechanically spotted at a high density on a glass slide using a robotic spotter, these are known as glass microarrays. Nylon is also used for spotting microarrays but it has some disadvantages that increase the experimental error. The nylon membrane can shrink, the degree of hybridization of each DNA sample adhered to the membrane is variable, and, as in glass, the amount of DNA that binds to the membrane is not always constant; nevertheless nylon is a good choice for analysis of gene expression on a small scale.

There is an alternative method to spotting, which is the direct synthesis of oligonucleotides on a modified glass surface by a photolithographic technique. In this technique, 25 nucleotid-long oligonucleotides with a long linker arm are directly synthesized on a surface (15). Two types of oligonucleotides are designed and placed on the same chip. One type perfectly matches the target sequence, and is called the perfect match (PM); the other is a corresponding oligonucleotide that displays a single nucleotide difference in the center of the sequence, called the mismatch (MM). For each one of the genes on the array, 10–20 PM oligonucleotides and their corresponding MM oligonucleotides are synthesized. These oligonucleotides include some that are designed from nonconserved regions of the genes, usually the 3′ untranslated region (UTR). This method has several advantages: the long linker arm allows each base to be equally accessible to hybridization, thus the hybridization kinetics is similar

to that in solution; and very high density and uniform microarrays can be manufactured, reducing the background fluorescence and producing high quality and reproducible data.

Glass microarray experiments from either spotted cDNA or synthetic oligonucleotides are simultaneously hybridized with two mRNA samples obtained from two conditions or sources that will be compared (see Figure 3.3). Each mRNA sample is labeled by reverse

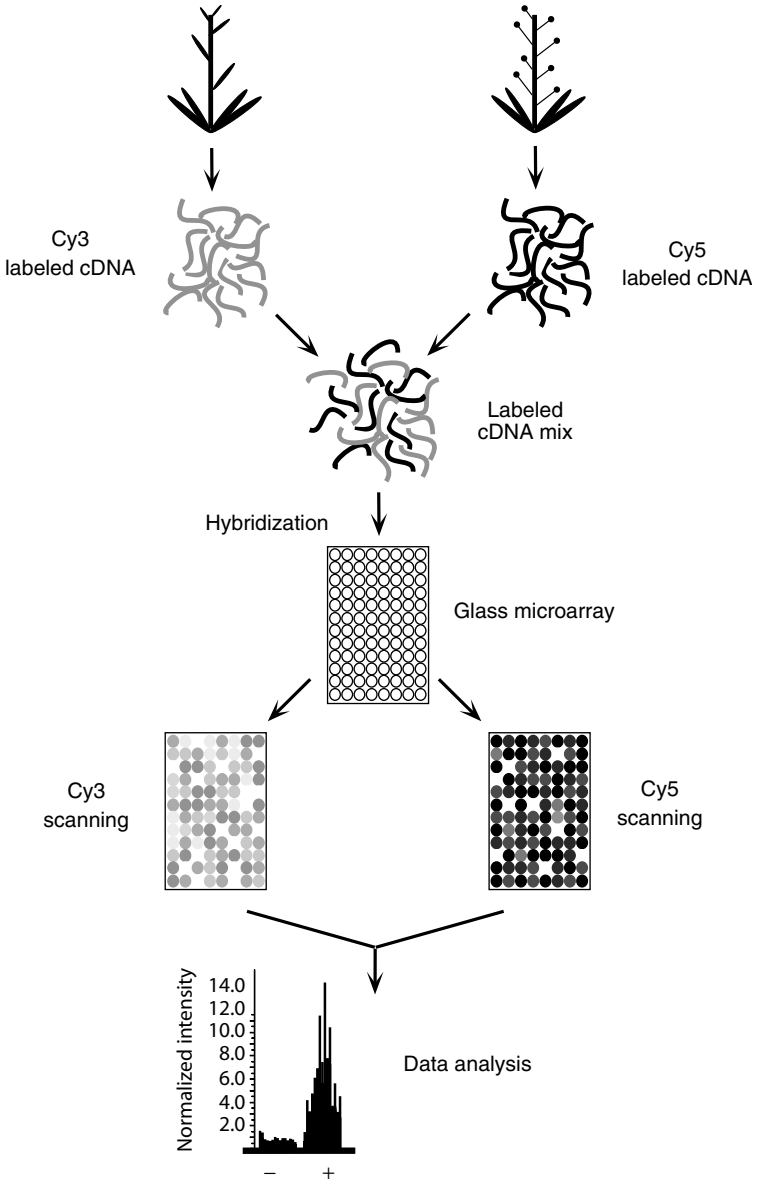

Figure 3.3 Glass microarrays. RNA is isolated from each sample (plant or tissue) and labeled by means of reverse transcription. One sample is labeled in the presence of Cy3, a green-fluorescent dye (depicted in gray and tones of light gray), and the other in the presence of Cy5, a red-fluorescent dye (depicted in black and dark gray). Samples are then mixed and used to hybridize a single microarray. After hybridization and washing, the fluorescent intensities for Cy3 and Cy5 are independently scanned and compared. The data is evaluated using software designed for microarray analysis.

transcription into cDNA, incorporating during the reaction a different fluorescent dye: cyanine 5 (Cy5), a red fluorescent dye, or cyanine 3 (Cy3), a green fluorescent dye. The fluorescence is determined separately for each fluorophore at each one of the spots using a scanner. The ratio of the measurements of intensity between these two fluorophores is used to compare transcript expression levels (16). For high density photolithographic oligonucleotide microarray experiments, however, a single labeled sample is used for each hybridization (see Figure 3.4). The method employs the synthesis of a biotinylated antisense copy of the mRNA (cRNA) followed by staining using streptavidin coupled to phycoerythrin; chips

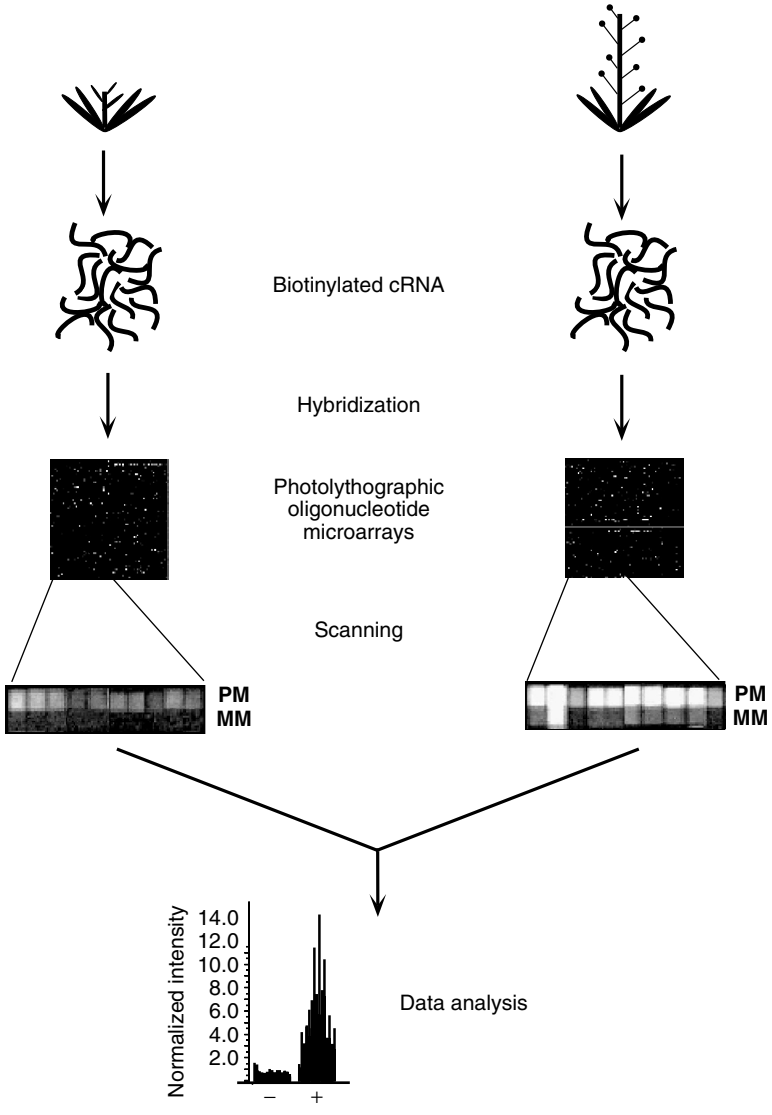

Figure 3.4 Photolithographic oligonucleotide microarrays. RNA is isolated from each sample and labeled in the presence of biotinylated ribonucleotides by means of T7-polymerase. The resulting cRNA is amplified and fragmented into small segments. The fragmented cRNA is used to hybridize a single microarray. After hybridization the microarray is stained with streptavidin coupled to phycoerythrin and then scanned. The data is evaluated using software designed for microarray analysis.

are then scanned and the measurements compared with the results of other chips from the experiment (15). In this case the hybridization occurs from RNA to DNA, whereas in spotted cDNA or oligonucleotide microarrays the hybridization occurs from DNA to DNA.

A very important aspect of microarrays is the design of a "good" experiment. When planning a microarray experiment it is necessary to program enough controls, and to include experimental and biological replicas, because hybridizations are very sensitive to experimental errors. Likewise, validation of the data by an independent method such as RT-PCR, Northern blot, or real time PCR is advisable. Because microarrays assess the expression of thousands of genes in a single experiment, statistical analysis is needed for the examination of the intensities of the spots; several software products are now available to perform such tasks (17).

The use of microarray technology for global gene expression studies is in its infancy in most of the crop species of nutritional importance. cDNA microarrays are preferred for most species because nonredundant clones obtained from EST projects can be readily employed to design the array. cDNA microarrays have been used in strawberries to study gene expression patterns during fruit ripening. Interestingly, an important gene involved in flavor biogenesis was identified after the analysis of the data (18). The global expression analysis unveiled novel processes connected to ripening such as the development of the vascular system, oxidative stress, and auxin-regulated gene expression (19). The strawberry is not a real fruit; it is the expansion of the receptacle carrying in the surface of the epidermis the achenes, the real fruit. In an attempt to establish specific gene expression profiles, DNA microarrays were also used to compare gene expression between receptacle and achene (20). Another example is cacao, where a genomic project that includes microarray analysis has been initiated. Microarrays of 997 cDNAs have been hybridized to samples isolated from leaves or beans from five different cacao genotypes. This project will contribute to the understanding of disease resistance, because pests cause major devastation of cocoa plants, and will seek new traits important for cocoa production (21). cDNA microarrays are also being developed for the model legumes. An array of 18,144 nonredundant ESTs has been used to analyze up regulated and down regulated genes during early stages of nodule formation in *Lotus*. Likewise, an array of 8,000 cDNAs from *M. truncatula* has been developed to analyze the gene expression under several conditions (10).

Significant advances in microarray technology have been achieved in model plant species. A variety of arrays have been generated for *Arabidopsis*, some of them including almost all the genes encoded in the genome. cDNA microarrays have been used to analyze expression profiles during seed development (22), light stress (23), defense response, drought, cold, and high salinity stress conditions (24), among others. Three types of microarrays for *Arabidopsis* are now commercially available. One is an oligonucleotide array of 14,800 genes represented by oligonucleotides 60 bases long (www.chem.agilent.com). Genes for the array were selected considering availability of the annotation and accuracy on gene prediction. A collection of 26,029 oligonucleotides 70 nucleotides long is also available (www.qiagen.com). The genes for this array were obtained from experimental data, ESTs, and predicted transcripts. To generate the array, the collection has to be spotted on glass slides using a robotic arrayer. Photolithographic oligonucleotide microarrays representing approximately 24,000 *Arabidopsis* genes were generated using eleven pairs of oligonucleotides for each transcript (www.affymetrix.com). A previous version of this microarray containing 8,256 genes was used to analyze gene expression profiles in several experiments, including responses to gravity (25), wounding, biotic and abiotic stresses, and response to hormones (26–29).

Large scale expression analysis in rice is also under way. cDNA microarrays from 10,243 cDNA sequences have been constructed from EST sequencing projects and about

30% of these genes have been annotated (www.jircas.affrc.go.jp). To assemble the array, each gene is represented by a full length cDNA insert and by a segment of its 3'UTR. The addition of the 3'UTR is useful in some cases to resolve gene specific expression between members of gene families. This microarray was used to obtain expression profiles for low temperature, high salt, nutrient deprivation, oxidative stress, and hormone response, among others. A custom whole genome photolithographic oligonucleotide microarray was made for rice and is under evaluation (www.tmri.org). It contains 50,119 rice genes selected by gene prediction; 43% of them with high evidence, 25% with some evidence and 32% with low evidence. In the design of this array, ten perfect match oligonucleotides for each gene were included and the mismatch oligonucleotides (MM, see Figure 3.4) were eliminated.

cDNA microarrays have been also used in maize to obtain gene expression profiles. An array of 5,376 unique genes was designed and the expression from thirteen samples from seven organs assessed (30). To discern hybridization occurring between closely related members of gene families, oligonucleotides of 45 nucleotides were simultaneously included in the microarray for members of some gene families. Almost all genes were expressed in all organs with little variation between samples; 7% of the genes displayed at least a fourfold difference in level of expression in one of the organs and 37% displayed differences between two and fourfold. Interestingly, from the analysis of the gene expression profiles novel patterns of expression and organ hierarchies were established. It was inferred that gene expression in silks, immature ears, and embryos is closely related, and that it is different from vegetative tissues. Photolithographic oligonucleotide microarrays representing approximately 1,400 maize selected genes have been also manufactured (31). These arrays were tried out to establish gene expression profiles of endosperm in wild-type maize and in the mutants altered in storage protein synthesis, opaque2 and floury2; these experiments are the basis of the understanding of the mutant phenotypes.

New technologies for microarray analysis have been recently tested in plants. Laser-capture microdissection (LCM), a high resolution technique for gene expression analysis, was used in maize (32). LCM has been widely used in mammals to isolate specific cell types and to obtain global profiles from such cells. LCM was recently successfully tested in maize to isolate epidermal cells and vascular tissues to obtain a gene expression profile for each of these cell types in a cDNA microarray. Another approach combines genome wide genetic analysis and global gene expression profiling strategies in the same experiment (see Figure 3.5). In this strategy, termed genetical genomics, DNA fingerprinting and microarray analysis are performed on each individual of a segregating population. This procedure has been tested with human, mouse, and maize samples. In maize both QTLs (quantitative trait loci) and a microarray of 24,473 60-nucleotide-long oligonucleotides were used. By these means it is possible to identify gene expression patterns associated with a specific genetic trait.

The correlation of the expression of a gene with a particular response is not sufficient to definitely assign a function to it. A powerful strategy to prove that a gene has a certain function is to actually mutate the gene and observe the effect caused by its disruption. Reverse genetic tools have been successfully established for *Arabidopsis*. Gene knockouts caused by insertional mutagenesis have been instrumental to establish gene function in plants. Transfer T-DNA of *Agrobacterium tumefaciens* and transposable elements have been adapted as insertional mutagens. In various cases a direct correlation of a knockout phenotype with gene function can be made. Large collections of insertion lines compiling more than 100,000 insertions exactly positioned within the genome are available for *Arabidopsis* (http://signal.salk.edu/tabout.html) (33). These lines were generated by T-DNA insertion; the position of a single insertion for each line was determined by sequencing the genomic region flanking the insertion. Lines harboring T-DNAs on genes of interest can be

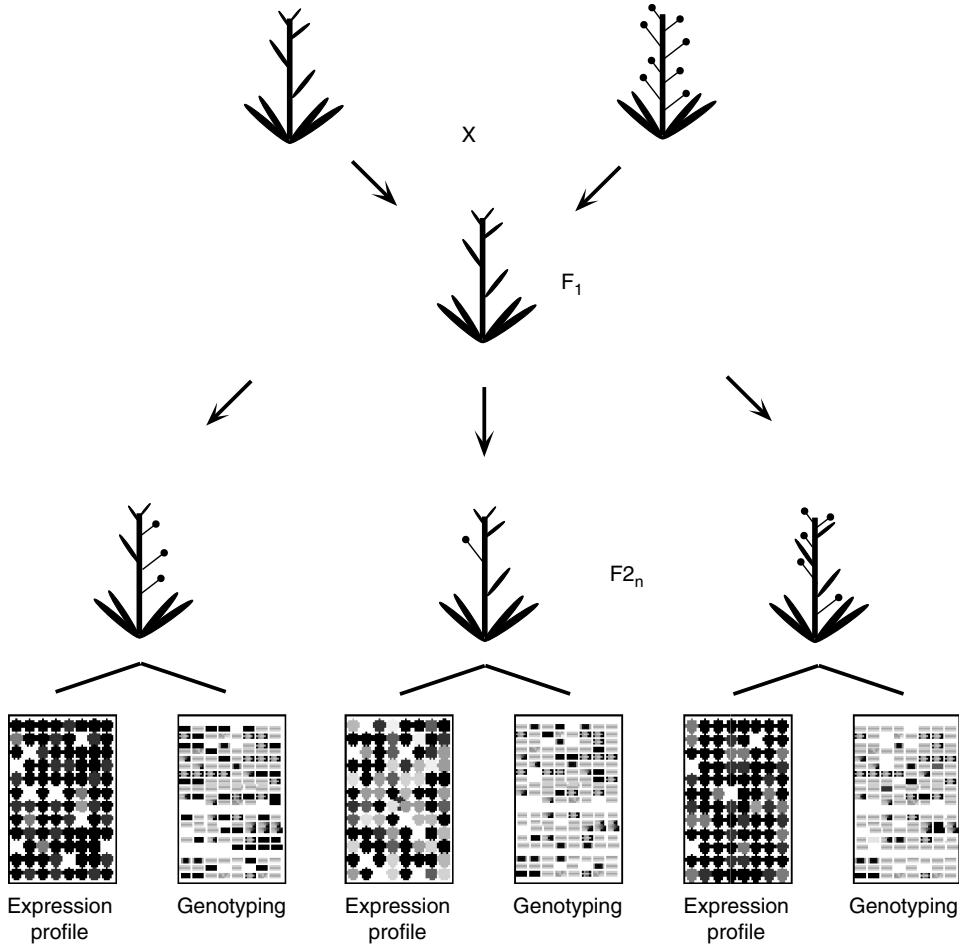

Figure 3.5 Genetical genomics approach. The F1 generation of the cross of two plant lines is generated, and subsequently, an F2 population (sufficiently large to carry out statistical analysis) is obtained. By correlating phenotypical variation with molecular genotyping, any trait that is subject to quantification can be tracked down to a chromosomal location. Likewise, variation in gene expression for each individual in the population can be monitored. Thus, specific chromosomal locations that correlate with altered gene expression are revealed. In each individual, the left panel represents expression profiles generated by microarray analysis and the right panel shows genotyping analysis.

readily identified in databases. Although these collections of lines are valuable tools for gene discover in plants, they have some limitations; members of gene families often do not display scorable phenotypes, hindering gene function prediction.

Because a T-DNA insertional library represents a random library, the estimated 25,000 genes in *Arabidopsis* (with a fourfold redundancy) require approximately 100,000 insertional mutants to cover most of the genome. In principle, the number of insertional mutants should be proportional to the genome size, not the number of genes. If the process of generating insertional mutants is random, and, if on average there is a gene every 5 kb in the plant genome, then one needs 24,000 mutants for *Arabidopsis*, which has a genome size of 1.2×10^8 bp. To allow a margin of safety, obtaining a tenfold redundancy means 240,000 mutants. Using the same calculations, one needs 800,000 mutants for rice (genome size 4×10^8 bp) and 4,800,000 for maize (genome size 2.4×10^9 bp).

3.5 PROTEOMICS: SYSTEMATIC AND HIGH THROUGHPUT CHARACTERIZATION OF GENE PRODUCTS

Analysis of mRNA transcripts on microarrays has provided information regarding which genes are expressed in cells under a given set of experimental conditions, yielding clues as to which proteins are involved in certain pathways. However, differences in the half-lives of RNA and proteins, as well as posttranslational modifications important to protein function (such as phosphorylation, glycosylation, or cleavage of an N- or C-terminal peptide) prevent mRNA profiles from being perfectly correlated to the actual protein profiles. In a given organism, the set of gene products encoded in the genome are called the proteome and "proteomics" would be the counterpart to genomics, aimed at the high throughput characterization of the proteome.

Protein analysis at a global scale is more technically demanding than genomics. For instance, mRNAs are chemically homogeneous molecules and thus a single method is useful for the identification of every mRNA. Protein separation, in contrast, is complex, given the different sizes and physical–chemical properties of proteins. The systematic analysis of expressed proteins requires three key technologies: the first is used for separating the proteins, and is most commonly two dimensional polyacrylamide electrophoresis; the second is a high throughput method of protein identification, which is afforded by mass spectrometry; and the third comprises the bioinformatics tools for the analysis and storage of data.

Proteomics is in a very early stage of advance in plant species and most of the work is now being carried out in *A. thaliana*. Many *A. thaliana* proteins have been characterized and localized by a two dimensional gel system. The usefulness of the analysis of differences in protein expression for distinguishing between closely related genotypes has been pointed out for many plant species (34,35). This approach was used to classify different developmental mutants of *Arabidopsis*, with the discrimination obtained being in agreement with phenotypical and physiological traits (36). *Oryza sativa* has also been studied at the proteome level. The rice genome has been used as a source for mapping proteins and linking genomic with proteomic data for function analysis (37–39). There is an increasing number of reports dealing with the use of proteomic techniques to identify proteins from specific tissues and developmental stages, such as rice anther young microspore (40), proteins related to abiotic stress (41), and proteins expressed during plant–microbe interactions in rice (42). Protein reference maps of subproteomes of different plant species obtained by two dimensional gel electrophoresis are expected to become a central tool for cataloguing and analyzing plant proteomes.

Most proteins do not function alone; rather they are components of protein complexes and networks. In many cases, knowing the proteins with which an unknown protein interacts helps to understand its function. Recently, three methods (the yeast two-hybrid system, protein microarrays, and mass spectrometry) have reached a proteomic scale to examine protein networks (43). Since its invention, the yeast two-hybrid system has been successfully used to identify protein–protein interactions of proteins from several organisms, including plants. This system is based on the reassembly of an active transcription factor in yeast by the interaction of two domains carried by two different recombinant proteins (each of which is therefore a hybrid protein). The hybrids are each coupled either to the DNA binding domain or to the activation domain of a yeast transcription factor. This reassembled transcription factor triggers the expression of a gene, usually a reporter gene that is easy to detect or to select for. Automation of the process and the generation of arrays of yeast strains expressing fusion proteins have permitted the analysis of thousands of interactions in a single experiment. A network of 2,358 interactions among 1,548 proteins has been established in the yeast *S. cerevisia*e. It was possible to predict the functional category

for 72% of the 1,393 known yeast proteins and to infer a possible function for 364 unknown proteins (44). Likewise, maps of protein–protein interaction networks during vulval development and DNA damage response in *C. elegans* have been obtained (45,46).

Mass spectrometry is a strategy that is also used to identify protein–protein interactions. A protein of interest is the affinity reagent used to purify a protein complex that binds to it. Compared with two-hybrid and chip-based approaches, this strategy has the advantage that the fully processed and modified protein is used for the binding, that the interactions take place in the native environment and cellular location, and that multicomponent complexes can be isolated and analyzed in a single operation (47). Mass spectrometry-based protein interaction experiments have three essential components: presentation of the protein used to trap the interacting proteins, affinity purification of the complex, and analysis of the bound proteins. Ideally, endogenous proteins can serve as trap or bait if an antibody or other reagent exists that allows specific isolation of the protein with its bound partners. A more generic strategy is to tag the proteins of interest with a sequence readily recognized by an antibody specific for the tag.

With the advent of high throughput molecular biology, it is now possible to prepare large, normalized collections of cloned genes. Recently, protein arrays are emerging as a new tool for the profiling and functional characterization of recombinant proteins encoded by globally or differentially expressed cDNA clones. This technology implies the cloning of large numbers of cDNA clones in appropriate expression vectors or the throughput subcloning of open reading frames (48). Protein arrays (or protein chips) are constructed by spotting many hundreds of capture molecules onto a solid surface, which can then be used to interrogate a particular sample for protein content. A critical first step in generating these arrays has been the development of general methods for arraying a genomic set of proteins on a solid surface without denaturing the proteins, and at high enough density for detection of activity. It was demonstrated that a single protein could be detected at high resolution on a single glass slide in the midst of 10,799 identical spots of another protein, showing the huge potential of protein microarrays for parallel biochemical analysis (49).

Peptides can also be analyzed using microarrays. Synthesis of peptide microarrays may become more practical with the development of methods for *in situ* synthesis of high density peptide microarrays, using photolithography. Carbohydrate and small molecule microarrays have also shown great potential for characterizing proteins to small molecule binding activities (43). Another type of microarray is the analytical microarray, in which a genomic set of protein-specific ligands such as antibodies, nucleic acid aptamers, or chemical probes are spotted on a microarray, and then the levels of different proteins in an extract are quantified in parallel by binding protein extracts to the microarray. Protein microarray analysis in plants is at an early stage of development. However, work is in progress to gain access to this revolutionary technology; for example, using the ORF approach for cloning different *Arabidopsis* genes into a specialized *E. coli* expression vector, for the synthesis of recombinant proteins to generate *Arabidopsis* protein chips for future applications (48).

3.6 IMPACT OF GENOMICS ON NUTRITION

Scientific innovation in biotechnology holds great promise for meeting the food needs of a growing world population and for protecting human health through novel strategies to improve the nutritional qualities of plant crops. In this century, there is urgent need to increase food production without expansion of cultivable lands. The increase in food supply is possible by reducing the losses caused by pests and diseases, changing environments

and postharvest losses. Genomic sciences can assist both "classical" and transgenic approaches to improve crops. These technologies will also impact areas such as food quality and safety.

The goal of genomic techniques is to identify the key biomolecules controlling a specific biological process; theoretically if all mRNAs (genomics), proteins (proteomics), or metabolites (metabolomics) that respond to environmental changes are identified; subsequently, differences and potential links between the data can be identified through bioinformatics. Thus, the major tasks for genomics research over at least the next 25–50 years will be to correlate data on the DNA sequence of each gene and its protein product with biological functions. One of the postgenome challenges will be interpreting the vast amount of new data. Scientific knowledge obtained on the biology of plant cells, tissues, and organization pathways is expected to increase tremendously, and thus novel strategies and new technologies are expected to arise.

The main impact that genomics techniques will have on classical breeding is to accelerate it and make it more accurate. Transgenic technology is not ready to handle the important quantitative traits, and genetic transformation of some crops is still challenging. Molecular techniques offer a more effective way to manipulate germ plasm via marker-assisted selection for elucidating genetic bases of traits with complex inheritances, identifying optimal germ plasm for specific breeding objectives and monitoring response to selection and breeding progress. The knowledge of the genome organization and the assignment of special functions will facilitate the identification of plant material with a desired combination of traits.

Genetic engineering involves taking genes from one species and inserting them into another in an attempt to transfer a desired trait or character. Scientists have introduced genes taken from bacteria, viruses, insects, animals, or even humans into plants. Crops resistant to pests or weeds, more tolerant to salt or drought, or that produce foods that are tastier or more nutritious have been genetically engineered. Plants have been also modified to produce specific compounds, such as industrial oils, plastics, enzymes, and even drugs and vaccines. There is abundant literature that refers to the techniques involved in producing transgenics (50). Transgenic technology will benefit by incorporating the desired gene(s) identified by genome analysis. Moreover, transgenic technology will itself develop into a more precise and controlled technology. EST and microarray technologies are being used to identify promoters that meet specific quantitative, temporal, tissue specific, or cell specific gene expression requirements for a particular trait. Synthetic promoters and novel transcription factors are being designed to increase gene expression levels. Efforts are also directed at stabilizing and enhancing gene expression and to reducing effects related to the insertion site of a transgene. Chemically regulated promoter systems have also been used to regulate gene expression (51). Additionally, because there is so much concern about possible unintended effects of transgenic plants, the use of genomics, proteomics, and metabolomics provides an ample, nonbiased screen to assess any possible changes associated with the recombinant plant.

Genomics has the potential to greatly enrich the availability and quality of food supplies. Thousands of different plant species are grown for food, and many more plants that are not even cultivated are known to produce secondary metabolites of medicinal, nutritive, or commercial interest. It is not feasible, however, to carry out the sequencing and expression profiling of every crop of interest. The challenge to agricultural plant scientists is to exploit the databases being generated for rice, maize, and *Arabidopsis* toward the genetic improvement of nonmodel crop species.

From a dietary standpoint, rice alone is the main staple food for half of the world population, while pearl millet, sorghum, maize, or wheat sustain an important portion of the food requirements of the remaining half. With the genomic sequence of rice already

available, the next logical step is to capitalize on this information using the rice plant as a model system to develop strategies and tools for quickly isolating genes in cereals, deciphering their function, and determining their potential role in improving food security and nutritional value. As genes become associated with specific functions or traits in rice, it will be feasible to search the database to identify orthologs governing the same trait in other cereals. To this end, a powerful and so far underutilized approach is offered by comparative genomics based on gene colinearity (52). The comparative analysis across cereals of mutants and QTLs influencing key traits will allow us to identify a number of genomic targets for the implementation of more detailed studies profiling the proteome and the metabolome (53). Collectively, these studies will lead to the identification and cloning of a number of genes controlling the traits of interest, many of which will target different types of abiotic and biotic stresses, growth, and composition of the grain.

Genomics is already having great impact in providing "fingerprinting" of plant materials that may be used to determine, from the species and cultivars of given plants, to the quality and authenticity of foods, whether a given plant product is or derives from a GMO. These will be easily and accurately determined with microarray techniques. Functional proteomics will aid the identification of marker proteins that can be used as a screening tool, such as indicators of plant conditions and ageing, indicators of genomic traits (e.g., disease resistance, bending of the stem of flowers, abiotic plant or root stress, plant growth), and quality indicators (e.g., for screening of raw materials or development of agrochemicals).

Microbial genomics is an area necessarily linked to food production. Novel molecular genetic methods are being applied to detect, identify, and classify mycotoxigenic fungi, plant pathogens, food-borne pathogenic bacteria, food spoilage microorganisms, fungi, and bacteria used for biological control of agricultural pests, and microorganisms used for conversion of raw agricultural materials into value added products. Whole genome information can be used to improve industrial and food-related microorganisms. In many instances analyzing the components of the growth media to make secondary metabolite production a more reproducible process can identify critical parameters. Also, in complex fermentations containing different microorganisms and complex substrates, quality of the proteome or metabolome of the starter culture can be used to predict the quality of the fermented end product. For example, as ripening is often a long process, enormous cost savings can be achieved if "bad" starter culture batches can be identified and eliminated beforehand.

In nutritional genomics a main focus is the identification and isolation of genes that are required for the synthesis and accumulation of a target compound desired in human diet. Research has mainly concentrated on vitamins (like folate and vitamins E, B6, and A) and minerals (like iron, calcium, selenium, and iodine). In the past, breeding programs largely overlooked the micronutrient composition and density of crops. For many plant secondary metabolites, including those of nutritional importance to humans, gene identification by classical biochemical approaches has given way to molecular genetic approaches. For example *Arabidopsis* mutants exhibiting altered production of carotenoids, flavanoids, tocopherols, and ascorbic acid have been used to establish the genetic basis for their synthesis. Research for health-promoting secondary metabolites, such as anticarcenogenic or infection-inhibiting compounds, has not reached the state of development of micronutrients because the best known plants produce those compounds in very small amounts or not at all (54).

Finally, for agribusiness companies, insect genomics are another point of interest. Insect genomics will be very useful for the development of new chemical pesticides or other biological control agents for insects. Just as *Arabidopsis* is the model system of plant genomics, *D. melanogaster* represents the model for insect genomics. The whole sequence of the genome is known (5) and tools to manipulate gene expression have been developed.

Molecular Design of Soybean Proteins for Enhanced Food Quality

Nobuyuki Maruyama, Evelyn Mae Tecson-Mendoza, Yukie Maruyama, Motoyasu Adachi, and Shigeru Utsumi

CONTENTS

4.1 INTRODUCTION

Generally, the protein contents of seeds are high; those of legume seeds and cereal seeds range from ~20% to 40% and from ~7% to 15%, respectively (1). Protein contents of soybean seeds are especially high, and those of some cultivars are more than 40%. Thus, they play an important role as a protein resource for human and domestic animals. In addition, soybean seeds are oil seeds, with oil content comprising ~20% of total weight. The annual production of soybean seeds in the world is ~180 million tons with more than 80% being used for oil expression. The amount of proteins in the residues after oil expression reaches around 58 million tons. The residues after oil expression have a history of safe use as food material for many years. Most of them are used as feed for domestic animals and as fertilizer. They are very cheap (U.S. $1.2/10kg). Even isolated soybean proteins extracted from the residues are cheap (700–850 yen/kg or U.S. $6–8/kg).

Fuji Oil in Japan and Dupont in U.S.A. have endeavored to develop new foods for which soybean proteins are utilized, but their applications have been limited due to inadequate physicochemical properties of soybean proteins. Food proteins should have specific nutritional quality, palatability, physicochemical functions, safety, economical efficiency, and physiological properties as food material (1). Nutritional quality is a property determined by the amino acids, especially the essential amino acids, of the protein. Soybean proteins are deficient in sulfur containing amino acids. Nutritional quality is also influenced by the digestibility of the protein. On the other hand, palatability is determined by taste and sensory quality (texture and hardness). Generally, animal proteins are superior to plant proteins in terms of palatability.

Physicochemical properties are properties such as gelation, emulsification, foaming, and water absorption properties and are determined by structural features of soybean proteins. Thus, the physicochemical properties unique to soybean make it possible to produce traditional foods such as tofu, koori-tofu, and ganmodoki from soybeans, and to use soybean proteins as a modifier for chilled food and sausage.

The physiological property of a protein can help maintain and enhance human health. It is well known that ingestion of 6 g of soybean proteins per day lowers serum cholesterol levels in humans (2). Recently, it has been reported that soybean proteins also lower serum triglyceride levels in humans (3). Soybean proteins, therefore, are capable of improving lipid metabolism. The soybean Bowman-Birk protease inhibitor has been reported to be capable of suppressing cancer of the colon (4), prostrate cancer (5,6), oral cancers, and cancer of the head and neck (7). A soybean peptide called *lunasin* has been isolated and shown to have antimitotic activity (8,9) and is a possible chemopreventive agent (10). While some soybean proteins may have excellent physiological or biological activities, in general, the nutritional quality and physicochemical functions of soybean proteins are inferior to those of animal proteins.

Recently, in Japan and in many developed countries, health problems related to obesity, such as hypertension and heart disease, have increased. Aging of the population has also progressed. In many developing countries, the problems of lack of food and protein malnutrition exist, and legumes like soybeans are the major source of proteins. Therefore, it is desirable to develop foods that will address these problems. It is estimated that world population will be about 8.4 billion around 2070, and food production at the present rate will be insufficient to feed the growing population. Therefore, this situation demands an increase of food production at a worldwide scale.

Soybeans could serve as a major source of proteins for the world's growing population. Soybean proteins have excellent physiological properties, are cheap, and can be produced in large quantities. Further, their physicochemical and functional properties can be improved. Protein engineering provides a means to improve the properties of soybean proteins by modifying their primary structures through gene manipulation. The ultimate objective, of course, is to develop crops in which soybean proteins with enhanced food quality accumulate. As a requisite, modification by protein engineering for enhanced quality must not disturb the folding ability of proteins. If the modified proteins cannot fold correctly, they may be degraded during the processes of biosynthesis, transportation and accumulation, and may therefore not accumulate in seeds (11,12). Thus, it is most important to understand the structures of soybean proteins.

This review will discuss the structures and improvement of nutritional quality, physicochemical functions, and physiological properties of soybean proteins, with emphasis on seed storage proteins, by protein engineering.

4.2 SOYBEAN PROTEINS

Most soybean proteins are seed storage proteins. Globulins, salt soluble proteins, are the primary storage proteins. The globulins of legume seeds are classified into two types according to their sedimentation coefficients; the 7S globulin and 11S globulin (13). Both account for approximately 80% of soybean proteins. The ratio of 11S and 7S globulins varies from 0.5 to 1.7 among soybean cultivars (14). This ratio determines the nutritional quality and physicochemical functions of soybean proteins. Aside from the 7S and 11S globulins, γ-conglycinin and basic 7S globulin also exist in soybean proteins.

4.2.1 β-Conglycinin

The 7S globulin of soybean is called β-conglycinin. β-conglycinin is a glycoprotein with a trimeric structure composed of three subunits and has a molecular mass of 150–200 kDa. The constituent subunits of β-conglycinin are α, α', and β. The α and α' subunits are composed of an extension region and a core region, while the β subunit consists of only the core region (15). The core regions of three subunits exhibit high absolute homologies (90.4%, 76.2%, and 75.5% between α and α', between α and β, and between α' and β, respectively). The extension regions of the α and α' subunits exhibit lower absolute homologies (57.3%) and a highly acidic property. The α and α' subunits are glycosylated at two sites (α, Asn199 and Asn455; α', Asn215 and Asn471), and the β subunit is glycosylated at one site (Asn328) (16). The N-glycosylation site of the β subunit corresponds to the latter site of the α and α' subunits. The α and α' subunits and the β subunit are synthesized on polysomes as preproform and preform, respectively. Their signal peptides are removed cotranslationaly in the endoplasmic reticulum, and the resultant subunits assemble into trimers. The trimers are targeted from the endoplasmic reticulum to protein storage vacuoles. Finally, the propeptides of the α and α' subunits are removed, resulting in the mature forms. Molecular heterogeneity of a subunit composition is present (17,18). In other words, ten molecular species having different subunit compositions with random combinations exist (homotrimers; $\alpha 3$, $\alpha' 3$, and $\beta 3$; heterotrimers; $\alpha 2\beta 1$, $\alpha 1\beta 2$, $\alpha' 2\beta 1$, $\alpha' 1\beta 2$, $\alpha 2\alpha' 1$, $\alpha 1\alpha' 2$, and $\alpha 1\beta 1\alpha' 1$).

4.2.2 Glycinin

The 11S globulin is called glycinin. Glycinin is a simple protein composed of six subunits, with a molecular mass of 300–400 kDa. Some of them have a potential glycosylation site, but none of them is glycosylated. The constituent subunits are A1aB1b, A1bB2, A2B1a,

A3B4, and A5A4B3. Five subunits are classified into two groups according to their amino acid sequences: group I (A1aB1b, A1bB2 and A2B1a) and group II (A3B4 and A5A4B3). The sequence identity in each group and between groups is about 80% and 45%, respectively. Each subunit is composed of an acidic polypeptide with acidic pI and a molecular mass of 30–40 kDa, and a basic polypeptide with basic pI and a molecular mass of 18–22 kDa. The acidic and basic polypeptides are linked together by a disulfide bond. It is considered that many molecular species having different subunit compositions with random combinations exist (19). The processes of synthesis, assembly, and accumulation of glycinin are shown in Figure 4.1. The constituent subunits are synthesized as a single polypeptide precursor, the preproglycinin. The signal peptide is removed cotranslationaly in the endoplasmic reticulum and the resultant proglycinin assembles into a trimer. Proglycinins are sorted into a protein storage vacuole and a specific posttranslational cleavage occurs. The cleavage results in a mature form of the glycinin. In contrast to β-conglycinin, none of the peptides is removed by this processing.

4.3 THREE DIMENSIONAL STRUCTURES OF SOYBEAN PROTEINS

4.3.1 Crystallization

X-ray crystallography is a suitable technique to elucidate three dimensional structures of proteins of high molecular masses. X-ray crystallography needs high quality crystals. However, it is difficult to obtain crystals of samples prepared from normal soybean seeds because of the molecular heterogeneity of both β-conglycinin and glycinin. Both proteins from soybean seeds had not been crystallized. To exclude the influence of molecular

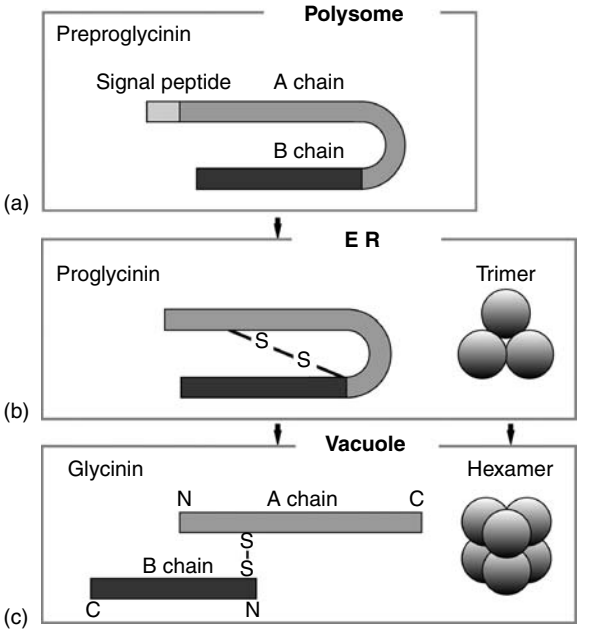

Figure 4.1 Schematic representation of processes of (a) biosynthesis, (b) assembly, and (c) transportation of soybean glycinin.

heterogeneity, we purified the storage proteins by constructing an *Escherichia coli* expression system and by using soybean seeds of mutant cultivars containing β-conglycinin or glycinin composed of a single or limited subunits.

Molecular species composed of a single subunit can be prepared easily by means of an *E. coli* expression system, because the cDNA of a single subunit is expressed in *E. coli*. Thus, we constructed an *E. coli* expression system for deletion mutants of the α and α' subunits lacking the extension regions (α_{core} and α'_{core}) in addition to individual normal subunits of β-conglycinin (α, α' and β) and A1aB1b and A3B4 subunits of glycinin. The pET-21d was used as an expression vector. *Escherichia coli* does not contain enzymes for the processing of the pro regions of the α and α' subunits and a specific posttranslational cleavage of the proglycinins. Therefore, we expressed the α and α' subunits without the pro regions. As a result, mature forms of the α and α' subunits and proglycinin A1aB1b and A3B4 were prepared by means of the *E. coli* expression system. Meanwhile, researchers of the Ministry of Agriculture, Forestry, and Fisheries of Japan have developed mutant soybean cultivars containing β-conglycinin lacking the α subunit, the α' subunit or both subunits (20,21). Further, mutant soybean cultivars containing glycinin composed of only the A3B4 subunit were developed (22,23). As a collaborative effort, we prepared native homotrimers of individual subunits of β-conglycinin (α3, α'3 and β3) and A3B4 homohexamer (glycinin A3B4) from seeds of these mutant cultivars.

Crystallization of the purified glycinin and β-conglycinin from the mutant cultivars was done by means of vapor diffusion, dialysis, and a batch method under various conditions such as pH, protein concentration, and temperature using polyethyleneglycol, 2-methyl-2,4-pentanediole and ammonium sulfate as a precipitant. The crystals of the recombinant and native β homotrimer (β3), the recombinant α'_{core} homotrimer (α'_{core}3), the recombinant A1aB1b homotrimer (proglycinin A1aB1b), the recombinant A3B4 homotrimer (proglycinin A3B4), and the native glycinin A3B4 were suitable for X-ray crystallography for analysis of their three dimensional structures.

4.3.2 X-ray Crystallography

When we started X-ray crystallography of soybean proteins, the crystal structures of the 11S globulin had not been reported; only those of French bean phaseolin and jack bean canavalin, 7S globulins, had been determined (24–26).

4.3.2.1 β-Conglycinin

We tried to determine the crystal structures of the native and recombinant β3 by the molecular replacement method using the protein structure models of phaseolin and canavalin as a search model. As a result, we determined the three dimensional structure of β3 by molecular replacement using canavalin as a search model (27) [Figure 4.2]. The β monomers consist of aminoterminal and carboxyterminal modules which are very similar to each other and are related by a pseudodiad axis. Each module of the β monomer is subdivided into a β-barrel and an α-helix domain. The superposition of the models of the native and recombinant β monomers shows a root mean square deviation (RMSD) of 0.43–0.51 Å for 343 common Cα atoms within 2.0 Å. This result indicates that the N-linked glycan does not influence the final structure of β3. Four regions including N- and C-termini were not included in the models of all the recombinant and native β monomers, because electron density maps in these regions were too thin to trace the correct sequence. These are likely to be disordered on the molecular surface [Figure 4.3(a)]. Comparison of sequences between 7S globulins by Wright (28) showed conserved regions (amino acid identity is high) and variable regions (amino acid identity is low), and it was noted that five variable

Kohno, Y. Takenaka, E. Okuda, S. Nakagawa, B. Mikami, S. Utsumi, *Eur. J. Biochem*. 268:3595–3604, 2001.)

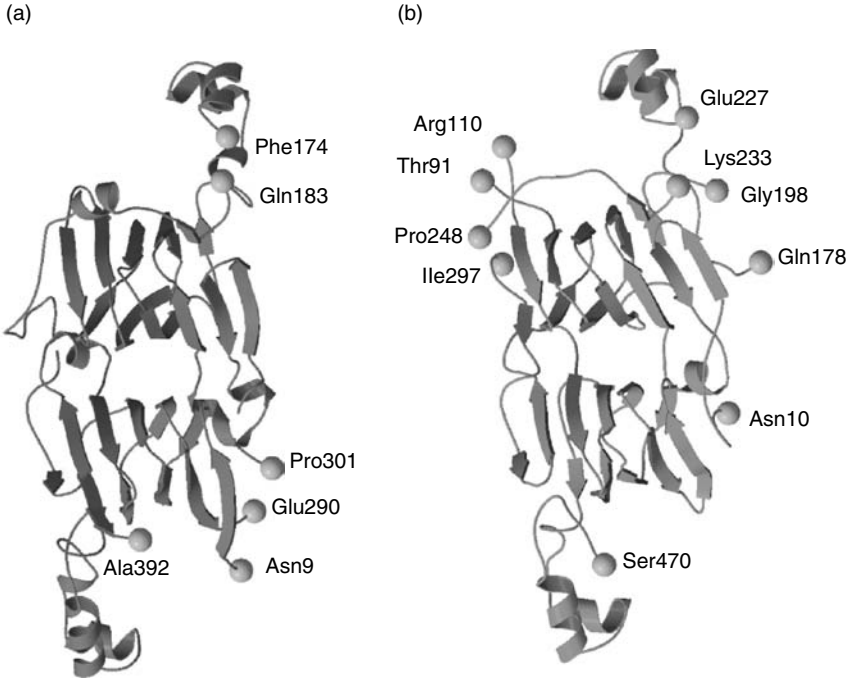

Figure 4.3 Disordered regions of soybean proteins. Disordered regions of β-conglycinin β (a) and of glycinin A1aB1b (b). The termini of the disordered regions are indicated by balls.

regions exist. In fact, there are only four variable regions, because one of them was identified by using an incorrect sequence of the α' subunit (15). Therefore, the disordered regions in the β subunit are consistent with the four variable regions. An amino acid replacement is liable to occur in variable regions, because they are disordered regions.

α3 and α'3 among the three homotrimers of β-conglycinin formed only small crystals, but α_{core}3 and α'_{core}3 with no extension region formed crystals suitable for X-ray crystallography. Therefore, the presence of the extension region probably perturbs the formation of crystals of good quality. We determined the three dimensional structure of α'_{core}3 by the

molecular replacement using the model of α3 (unpublished data). The scaffold of $\alpha'_{core}3$ was identical to that of β3. All α atoms of the α'_{core} monomer and homotrimer could be superimposed on corresponding atoms of the β monomer and homotrimer with a small RMSD of 0.6 and 0.7 Å, respectively. These values indicate that scaffolds of these two proteins are very similar to each other.

4.3.2.2 Glycinin

The amino acid identity between 7S and 11S globulins is only 15%, but they do exhibit partially significant identity. Therefore, it is considered that these two globulins are evolutionarily related. The 11S globulin has a hexameric structure, but proglycinin has a trimeric structure. In other words, there is a possibility that pro forms of 11S globulins have a structure analogous to the 7S globulin. Thus, we tried to determine the structure of proglycinin A1aB1b by molecular replacement using the model of β-conglycinin β3, canavalin, and phaseolin but failed. Finally, we successfully determined the structure of proglycinin A1aB1b by the multiple isomorphous replacement method using heavy atom derivatives (29). Our results showed that the structure of proglycinin A1aB1b is similar to that of β-conglycinin β (Figure 4.4). Superposition of the structure of proglycinin A1aB1b on that of β-conglycinin β exposes the high similarity between the proteins (Figure 4.5). A least squares fit of a protomer between them produced an RMSD of 1.35 Å, and that of β-barrel in a protomer between them was 1.2 Å. Further, RMSDs of the comparable Cα atoms of β-barrel domains in both N- and C-terminal modules between proglycinin A1aB1b and β-conglycinin β were approximately 0.9 Å, whereas those of α-helix domains in N- and C-terminal modules were 1.35 and 1.39 Å, respectively. This indicates that the scaffold of proglycinin A1aB1b is very similar to that of β-conglycinin β, but that the configurations between a β-barrel and an α-helix domain in protomers are slightly different.

All six disordered regions existing in proglycinin A1aB1b protomer are located on the molecular surface similarly to β-conglycinin [Figure 4.3(b)]. Amino acid sequences have been previously aligned among various 11S globulins from legumes and nonlegumes, and five variable regions have been proposed (14). Five of the six disordered regions correspond to the five variable regions. The only disordered region that does not correspond to the variable region is the shortest one. The second disordered region from the C-terminus is the

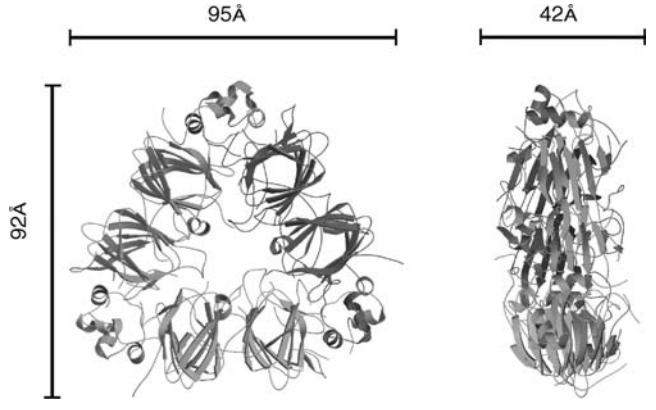

Figure 4.4 Ribbon diagram of the three dimensional structure of A1aB1b homotrimer. The view in the left diagram is depicted with the threefold symmetry axis running perpendicular to the paper, whereas the depiction on the right is related to the view on the left by a rotation of 90º. (From: Adachi, M., Y. Takenaka, A.B. Gidamis, B. Mikami, S. Utsumi., *J. Mol. Biol*. 305:291–305, 2001.)

longest, and the region of A1aB1b is composed of 48 residues. This region is called the hypervariable region, because both an amino acid sequence and a number of an amino acid in this region are the most variable among the five.

The three dimensional structure of the native glycinin A3B4 homohexamer is determined by the molecular replacement using the model of proglycinin A1aB1b (Figure 4.6) (30). As a result, a trimer of a proglycinin assembles into a hexamer by stacking of faces in which the processing site for a mature form exists.

Utsumi. *Proc. Natl. Acad. Sci. USA*, 100:7395–7400, 2003.

4.3.3 Cupin Superfamily

The 7S and 11S globulins are classified into the cupin superfamily (31,32).

Cupin comes from "cupa," the Latin term for a small barrel. The characteristic cupin domain comprises two conserved motifs, $G(x)_5HxH(x)_{3,4}E(x)_6G$ and $G(x)_5PxG(x)_3N$ (31,32). Based on structural features, cupin proteins are classified as either a monocupin having one cupin motif per one monomer, and a bicupin having two cupin motifs per one monomer. The 7S and 11S globulins are bicupins. Cupin proteins are also known to have diverse functions. For example, in addition to seed storage proteins, an oxalate oxidase and a sucrose binding protein belong to this group (33,34).

In the three dimensional structure of the cupin protein phaseolin, which was determined at the early stage of research of the cupin superfamily, the cupin motifs are located at the C and D strands and at the G and H strands of the β-barrel (Figure 4.7). The length between motifs varies largely among species of proteins. Later, the three dimensional structures of many cupin proteins were shown to have a jellyroll type β-barrel structure. Further, it was elucidated that in addition to a tertiary structure, a quaternary structure is common among cupin proteins. Three dimensional structures of many cupin proteins indicate that an arabinose binding domain of AraC transcription factor from *E. coli*, a dimeric dTDP-4-dehydrorhamnose 3,5-epimerase from *Salmonella enterica*, a hexameric germin from barley and an oxalate decarboxylase from *Bacillus subtilis* are very similar to the domain, protomer, and trimer of proglycinin and β-conglycinin, and the hexamer of glycinin, respectively (27,29,33,34) (Figure 4.7).

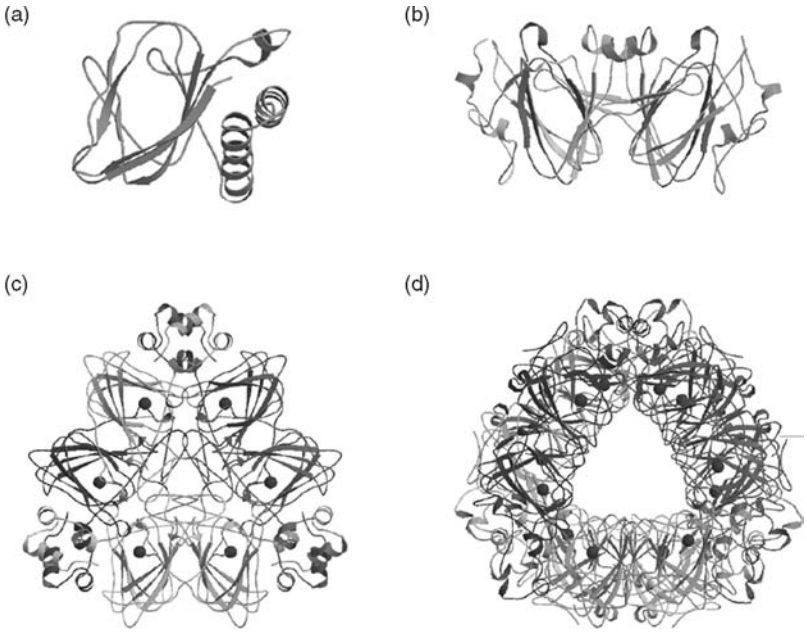

Figure 4.7 Ribbon diagrams of the three dimensional structures of cupin superfamily. (a) arabinose-binding domain of AraC transcription factor from *E. coli* (PDB code: 2ARA); (b) dimeric dTDP-4-dehydrorhamnose 3,5-epimerase from *Salmonella enterica* (1DZR); (c) hexameric germin from barley (1FI2); (d) oxalate decarboxylase from *Bacillus subtilis* (IJ58). The cupin motifs in (b) are shown in dark gray. Manganese ions are indicated by balls in (c) and (d). (From: Dunwell, J.M., A. Culham, C.E. Carter, C.R. Sosa-Aguirre, P.W. Goodenough. *Trends Biochem. Sci.* 26:740–746, 2001; and Anand, R., P.C. Dorrestein, C. Kinsland, T.P. Begley, S.E. Ealick. *Biochemistry* 41:7659–7669, 2002.)

The cupin fold is evolutionally conserved, although amino acid sequences are not conserved except the cupin motifs. This indicates that the cupin motif is essential for the formation and maintenance of the structures of glycinin and β-conglycinin.

4.4 STRUCTURAL FEATURES OF SOYBEAN PROTEINS

4.4.1 β-Conglycinin

We analyzed the structural features of the native homotrimers (α3, α'3, and β3) of the individual subunits of β-conglycinin prepared from seeds of mutant cultivars containing β-conglycinin with limited subunit compositions, the recombinant homotrimers (α3, α'3, β3, α_{core}3, and α'_{core}3) of individual subunits, and the α_{core} and α'_{core} of β-conglycinin by means of *E. coli* expression system (35–37).

On a sucrose density gradient centrifugation, three recombinant homotrimers sedimented at similar positions. However, the recombinant α3 and α'3 eluted faster than did the recombinant β3 on a gel filtration chromatography, similarly to the native glycinin hexamer. These indicate that the extension regions largely contribute to the dimensions of α3 and α'3. Therefore, the structural models indicated in Figure 4.8 can be proposed. The order of thermal stability of the recombinant and native homotrimers was $\alpha 3 < \alpha' 3 < \beta 3$, and β3 was the most stable among the three subunits. On the other hand, the α_{core}3 and α'_{core}3 exhibited similar thermal stability to those of α3 and α'3, respectively. These results indicate that the extension regions and the glycans do not affect the thermal stability, and that the core regions determine the thermal stability of the individual subunits of β-conglycinin. Further, an analysis of the thermal stability of the heterotrimers of β-conglycinin indicated that thermal stabilities of most heterotrimers are determined by that of the constituent subunit which has the lower thermal stability (38). On the other hand, the order of surface hydrophobicity was $\alpha 3 > \alpha' 3 \geq \beta 3$, and dependent on that of the core regions. Surface hydrophobicities of the heterotrimers were the arithmetic mean of those of constituent subunits. The extension regions and the glycans largely affect solubility under lower ionic strength, but not under higher ionic strength. The solubility of the trimer containing even one α or α' subunit is much higher than that of the β3, α_{core}3 and α'_{core}3, and close to that of the α3 and α'3, indicating that the extension regions contribute largely to the solubility.

Because the thermal stability of the core region determines that of the subunit, we tried to analyze the structural factors related to thermal stability by comparing the three dimensional structure of the α'_{core}3 with that of β3 in detail. Thus, five structural factors that can account for the result that β3 is more thermostable than α'_{core}3 were elucidated (39).

First, protein packs tightly but some cavities are often observed inside the molecule, resulting in a decrease in its thermal stability (40). We calculated the total cavity volume

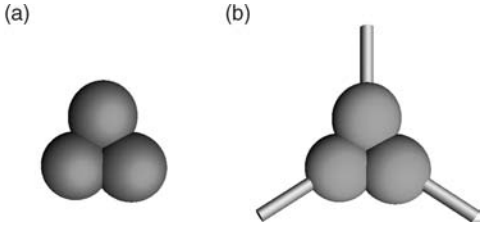

Figure 4.8 Structure models of soybean β-conglycinin. (a) β3, (b) α3 or α'3. The core and the extension regions are shown in ball and stick, respectively.

of the $\alpha'_{core}3$ (172 Å^3) to be larger than that of $\beta 3$ (79 Å^3), indicating that $\beta 3$ is more tightly packed than $\alpha'_{core}3$. The main cavities are located in the β-barrels of the N- and C-terminal modules. The cavities of the C-terminal β-barrels of $\beta 3$ and $\alpha'_{core}3$ exhibit a prominent difference between them. Twelve residues among 15 residues lining the cavity were common between the β and α'_{core}, and three residues were different. In other words, Phe233, Leu262, and Phe325 of β were substituted with Leu376, Phe405, and Val468 of α'_{core}, respectively. Because of the compensating substitutions of Leu376 and Phe405 in the α'_{core} to Phe and Leu in β, respectively, a substitution of Val468 in the α'_{core} to Phe in β contributes mainly to the difference in the cavity volume of the C-terminal β-barrel.

Second, because long ion pair networks have been found in several enzymes from hyperthermophilic bacterium (41,42), they are thought to be a common mechanism to stabilize the protein of hyperthermophiles (43). Sequence alignment of β and α'_{core} indicates that some of the charged residues in β are substituted with noncharged residues in the α'_{core}. These residues exist in the α-helix domain of the C-terminal module, and form a cluster at the intermonomer interface. The length of an ion pair network of $\beta 3$ was longer than that of the $\alpha'_{core}3$, because E353, R359, E362, R363, R379, K383, and R385 of β were replaced with S496, S502, P505, S506, N522, S526, and S528 of the α'_{core}, respectively.

Third, the hydration of nonpolar groups apparently destabilizes proteins (44). Experimental analysis of surface hydrophobicity using a hydrophobic column demonstrated that the molecular surface of $\alpha'_{core}3$ was more hydrophobic than that of $\beta 3$. Further, a comparison of three dimensional structures between $\beta 3$ and $\alpha'_{core}3$ indicated that the ratio of hydrophobic atoms (carbon and sulfur) to all atoms of solvent accessible surface of $\alpha'_{core}3$ was higher than that of $\beta 3$.

Fourth, the number of proline residues, which stabilize the protein structure by decreasing the entropy of denatured structure, is 57 in the $\alpha'_{core}3$ compared to 63 in $\beta 3$. According to Matthews et al. (45), this difference contributes 4.8 kcal/mol to the ΔG. Therefore, the difference in the number of proline residues may affect the thermal stability.

Fifth, shorter loops are one of stabilizing factors in thermophilic bacteria (46). The loop between helix 3 and strand J' is five residues shorter in β than that in α'_{core}. The electron densities of this loop region were broken in all monomers of the $\alpha'_{core}3$ and two of $\beta 3$, but appeared in one monomer of $\beta 3$, giving the clearest density map among the three monomers. Because the resolution of $\beta 3$ is lower, this may suggest relatively rigid conformation of this loop region in the β subunit. The length of the loop is also considered one of the important factors related to the structural stability of the cupin superfamily to which β-conglycinin belongs.

As described, we investigated possible factors for the difference in the thermal stability between the $\alpha'_{core}3$ and $\beta 3$ through the comparison of three dimensional structures. More hydrogen bonds were observed in each module of $\alpha'_{core}3$, which suggests more stable packing of $\alpha'_{core}3$, and is not consistent with the experimental data. This difference should be more than compensated by the accumulation of the effects of many factors which account for less thermal stability of the $\alpha'_{core}3$, such as larger cavity volumes, lack of short ion pair networks, higher surface hydrophobicity, lower number of proline residues, and a longer loop. We think that $\beta 3$ would be stabilized more than the $\alpha'_{core}3$ by the sum of the contributions of each of these factors.

4.4.2 Glycinin

Researchers of the Ministry of Agriculture, Forestry, and Fisheries of Japan have developed mutant soybean cultivars containing glycinin of limited subunit compositions, such as only group I, only group II, and only A5A4B3, in addition to only A3B4 (22,23). In collaboration with them, we prepared glycinin (group I, group II, A3B4, and A5A4B3)

from these mutant cultivars and analyzed their structural features (unpublished data). On gel filtration chromatography, subunits having the longer hypervariable region eluted faster. In other words, A5A4B3 and group II eluted faster than A3B4 and group I did, respectively. These results indicate that the variable regions influence the dimensions of glycinin similarly to the extension region of β-conglycinin. The thermal stability of A3B4 (87.2°C) was slightly lower than those of the other subunits (92.9–95.0°C), but group II containing A3B4 exhibited thermal stability similar to the others. Therefore, the effect of subunit compositions on the thermal stability is not significant. The order of surface hydrophobicity on a hydrophobic column chromatography was group I $<$ 11S $<$ A3B4 $<$ group II $<$ A5A4B3. Thus, the surface hydrophobicity of glycinin comprised of several subunits is the arithmetic mean of those of individual subunits. Further, we confirmed that the molecular surfaces of the three dimensional structures of recombinant proglycinin A1aB1b and native glycinin A3B4 corresponded to the difference of surface hydrophobicity on a hydrophobic column chromatography. However, it is difficult to discuss the difference of the thermal stability in detail, because we have only determined the three dimensional structure of A3B4 among native glycinins.

4.5 IMPROVEMENT OF NUTRITIONAL QUALITY BY PROTEIN ENGINEERING

There are two approaches to improve the nutritional quality of soybean proteins: fortify the content of a limiting amino acid such as amino acids containing sulfur, and increase the digestibility of the proteins.

4.5.1 Increasing Sulfur Containing Amino Acids

In grain legumes such as soybean, methionine is the primary limiting essential amino acid. The biological value of legume protein is limited to 55–75% of that of animal protein because of this limitation or imbalance in amino acid composition (47). Several ways to increase the content of sulfur containing amino acids have been cited (48): (1) the insertion and replacement of amino acid residues at appropriate sites in a storage protein; (2) increasing the level of endogenous methionine rich protein; (3) introduction of heterologous genes for methionine rich protein; and (4) manipulating key enzymes in the biosynthetic pathway. A description of the work done in our laboratory using the first strategy, protein engineering, follows.

Both glycinin and β-conglycinin have variable regions which are less conservative. Thus, it may be possible to replace and insert amino acids in the variable regions to enhance nutritional quality.

At the start of our research to improve glycinin by protein engineering, no data for the three dimensional structures of glycinin were available. Therefore, we attempted to modify the variable regions based on the alignment of amino acids. Five variable regions were named I, II, III, IV, and V from the N-terminus [Figure 4.9(a)]. We designed modified glycinins with five contiguous Met residues inserted into variable region IV or V (IV+4Met and V+4Met). Further, we also designed a modified glycinin whose five contiguous Glu in the variable region IV were substituted with five Met and one Leu [IV(Met)]. These modified glycinins were produced by means of an *E. coli* expression system and their folding ability was analyzed. All of them were accumulated as soluble proteins in *E. coli* at a high level, and each one self assembled. Because the modified glycinins exhibit solubility as a globulin, we concluded that the modified glycinins fold correctly. Moreover, the three modified glycinins can be crystallized, and IV+4Met and

V+4Met can be accumulated in tobacco seeds, rice seeds, and potato tubers in a way similar to the intact molecule (49–53). In other words, an insertion and a replacement in variable regions could be useful in improving the nutritional quality of glycinin.

It is difficult to insert amino acids in conserved regions, but it is possible to replace amino acids based on three dimensional structures. For example, Figure 4.10(a) shows one β-strand in the β-barrel of C-terminal module of A1aB1b. This strand contains a hydrophobic peptide, Val-Ile-Leu-Val. Based on molecular modeling, we considered that it is possible to replace these four amino acids with four Met residues [Figure 4.10(b)]. We have not examined the folding ability of this modified glycinin yet, but we think that it probably can fold correctly.

4.5.2 Increasing Digestibility

There are two approaches to improving digestibility: by introducing a cleavable site for digestive enzymes, and by destabilizing a structure. If aromatic residues recognized by chymotrypsin are introduced inside the molecule, however, its structures may be stabilized

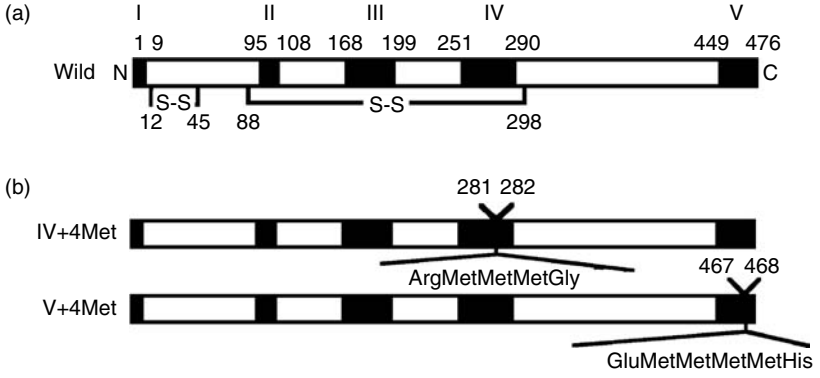

Figure 4.9 Schematic representation of the wild and modified proglycinin A1aB1b. (a) wild type, (b) tetramethionine-inserted proglycinin. White and black areas indicate the conserved and variables regions, respectively. The number of the residues from the N-terminus for the variable regions (I–V) are shown above the alignment. S-S indicates a disulfide bond.

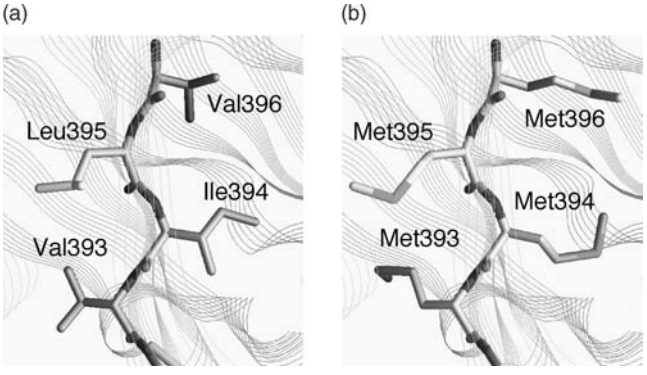

Figure 4.10 Fortification of Met into β-barrel of the proglycinin A1aB1b. (a) wild type; (b) methionine-introduced proglycinin. Backbone and side chains are indicated by bond models.

by the increased hydrophobicity inside the molecules, resulting in the lowering of digestibility. On the other hand, introduction of lysine and arginine residues recognized by trypsin inside the molecule may probably have a large influence on digestibility, because they not only add the site for cleavage, but also destabilize the structure due to the introduction of a charged residue inside the molecule. Most of the salt bridges inside molecules contribute largely to structural stability. Therefore, a substitution of an acidic residue which forms a salt bridge inside the molecule with another amino acid destabilizes a structure while keeping the site for trypsin. In glycinin A1aB1b, a salt bridge between Asp157-Arg161 exists inside the molecule. We replaced Asp157 with Ala (D157A) (54). This mutant, produced in *E. coli*, was found to fold correctly. Furthermore, we confirmed that D157A formed crystals suitable for X-ray crystallography. The T_m value of D157A was 15°C lower than that of the wild type and its sensitivity to chymotrypsin increased.

4.6 IMPROVEMENT IN PHYSICOCHEMICAL FUNCTIONS BY PROTEIN ENGINEERING

4.6.1 Structure to Physicochemical Function Relationships of Soybean Proteins

The physicochemical functions of soybean proteins are determined by solubility, degree of hydrophobicity, and hydrophilicity of a molecular surface. Their distribution and balance, structural stability, exposure of hydrophobic regions under denaturation, and interactions between the same and the different molecular species also influence physiochemical function. Therefore, elucidation of the structure to physicochemical function relationships of soybean proteins is necessary to improve rationally the physicochemical functions of soybean proteins. Such studies have mostly been done in our laboratory using mutant cultivars, and by means of protein engineering.

We prepared homotrimers of the individual subunits of β-conglycinin and analyzed their physicochemical functions (35–38). The order of emulsifying ability was $\alpha 3 > \alpha' 3 > \beta 3$ in the cases of both the recombinant and native homotrimers. In comparison with the homotrimers lacking the extension region, the order of emulsifying ability was $\alpha_{core}3 > \alpha'_{core}3 > \beta 3$, although the emulsifying abilities of $\alpha'_{core}3$ and $\alpha_{core}3$ were lower than those of $\alpha' 3$ and $\alpha 3$, respectively. This order was related to those of thermal stability and surface hydrophobicity. The heterotrimers containing two α or α' subunits ($\alpha 2\beta 1$, $\alpha' 2\beta 1$) exhibited emulsifying ability similar to those of $\alpha 3$ or $\alpha' 3$, respectively. The heterotrimers containing one α or α' subunit ($\alpha 1\beta 2$, $\alpha' 1\beta 2$) exhibited emulsifying ability similar to that of $\beta 3$. Therefore, the number of the extension regions, structural stability, and surface hydrophobicity contribute to the emulsifying abilities, but the glycans do not. The native and recombinant $\alpha 3$ and $\alpha' 3$ formed soluble aggregates without accompanying insoluble aggregates by heating at greater than their T_m values. In contrast, the native and recombinant $\beta 3$ did not form the soluble aggregates at all at greater than their T_m values, but formed insoluble aggregates. The size and the amount of the soluble aggregates of the native $\alpha 3$ and $\alpha' 3$ were smaller and fewer than those of the recombinant $\alpha 3$ and $\alpha' 3$, respectively, but $\alpha'_{core}3$ and $\alpha_{core}3$ formed insoluble aggregates without soluble aggregates similarly to that of $\beta 3$. The heterotrimers containing two α or α' subunit ($\alpha 2\beta 1$ and $\alpha' 2\beta 1$) exhibited a similar tendency about heat induced associations to $\alpha 3$ and $\alpha' 3$, but the behaviors of heterotrimers containing two β subunits ($\alpha 1\beta 2$ and $\alpha' 1\beta 2$) resembled that of $\beta 3$ rather than those of $\alpha 3$ and $\beta 3$. These results indicate that the presence and the number of the extension regions contribute to the heat induced association, but the glycans prevent such heat induced association.

Similarly, we measured the emulsifying ability of glycinin prepared from mutant cultivars having subunit compositions different from a normal one (unpublished data). Group II exhibited higher emulsifying ability than that of group I, and that of glycinin containing all subunits (normal glycinin) was intermediate between those of group I and II. A5A4B3 exhibited slightly higher ability than A3B4 did, and the ability of group II was intermediate between those of A3B4 and A5A4B3. These results indicated that A5A4B3 has the highest emulsifying ability among all subunits of glycinin, and that the heterohexamer exhibits the arithmetic mean of the abilities of constituent subunits. Variable region IV (the hypervariable region), the longest in five variable regions of glycinin, is rich in negative charges. The length of this region is different among subunits of glycinin, and that of group II, especially A5A4B3, is longer than that of group I. Therefore, it can be considered that the length of the hypervariable region is largely related to the emulsifying ability of glycinin. This resembles the effect of the extension region of β-conglycinin on the emulsifying ability. However, the order of the emulsifying ability of glycinins did not correlate with those of the surface hydrophobicity and the structural stability, in contrast to β-conglycinin. In other words, the degree of the contribution by each factor is different among the species of proteins and subunits.

To exhibit excellent emulsifying ability, proteins need the affinity for both oil and water at their interface. Therefore, flexibility and amphiphatic properties are important factors for emulsifying ability. In fact, it is pointed out that in many proteins surface hydrophobicity and structural stability are related to emulsifying ability. The contribution of surface hydrophobicity and structural stability of glycinin to its emulsifying ability is different from that of β-conglycinin, although the presence of large hydrophilic regions contributes to the emulsifying ability of both glycinin and β-conglycinin. Elucidation of the three dimensional structures of all subunits of glycinin and β-conglycinin can probably shed light on this difference. It is expected that destabilization of a structure and strengthening of hydrophilicity or hydrophobicity can improve emulsifying ability. However, the effect is probably different between glycinin and β-conglycinin.

The subunit compositions of glycinins vary among cultivars (55). Mori et al. analyzed heat induced gel forming ability of glycinins prepared from five cultivars containing different subunit compositions (56). As a result, glycinins which have larger amounts of A3B4 formed harder gel. Pseudoglycinins were reconstituted from A1aB1b, A2B1a, and A3B4 isolated on a chromatography in the presence of urea, and their heat induced gel forming abilities were analyzed (57,58). The results showed that the hardness of the gels is directly proportional to the amount of A3B4. The number of cysteine residues in A3B4 is less than those of A1aB1b and A2B1a. The topology of free sulfhydryl groups of A3B4 is different from those of A1aB1b and A2B1a. Further, A3B4 has lower structural stability than A1aB1b and A2B1a. Changes in conformation and SH/S-S interchange reactions are essential for heat induced gel forming ability of glycinin. Therefore, it can be considered that the reactivity of SH/S-S interchange of A3B4 is higher than those of A1aB1b and A2B1a due to the difference in the topology of the free sulfhydryl group and lower structural stability. As a result, A3B4 can form hard gels with fine network structures. Therefore, we can consider that a destabilization of a structure and modification of the topology of free sulfhydryl groups are an approach to improving gel forming ability of glycinin. In terms of fineness of network, the addition of a number of SH and S-S could be a strategy. We cannot describe the mechanism of gel forming ability of β-conglycinin, because analysis is still insufficient.

4.6.2 Improvement in the Physicochemical Functions of Glycinin

Variable regions of glycinin are rich in hydrophilic amino acids. Therefore, deletions of these regions can change the balance between hydrophilicity and hydrophobicity of glycinin.

There is a possibility that the deletions destabilize the molecule, because the regions exist in the intact molecule. So we designed mutants of glycinin lacking each of the variable regions (ΔI, ΔII, ΔIII, ΔIV, ΔV, ΔV36 and ΔV8) [Figure 4.9(a)] (49). Existing restriction enzyme sites were used to construct the mutants because the use of PCR was not yet popular during the time of these experiments. Therefore, some parts of conserved regions were also deleted, and glycinin lacking C-terminal 8 or 36 residues (ΔV8, ΔV36) has two extra amino acids, Leu and Asn, at its C-terminus.

If a peptide composed of four Met residues is introduced into the variable region [Figure 4.9(b)], a small hydrophobic patch is formed. This may result in structure destabilization because a small hydrophobic patch is introduced into a hydrophilic region. Therefore, it is expected that this mutation improves the protein's emulsifying ability and gel forming ability in addition to nutritional quality.

Glycinin has two disulfide bonds in each constituent subunit: one is an intraacidic chain bond (Cys12-Cys45 in A1aB1b) and another links the acidic and basic chains (Cys88-Cys298 in A1aB1b). These disulfide bonds can be confirmed in the three dimensional structure of A1aB1b (29). Because the corresponding cysteine residues are conserved in all 11S globulins whose primary structures have been determined, it is considered that these two disulfide bonds are also conserved in all 11S globulins (1). In case of the subunits of group I, it is assumed that one more disulfide bond (C271-C278 in A1aB1b) exists. However, we cannot confirm this disulfide bond in the three dimensional structure, because these residues are located in the disordered region. If one of the cysteine residues forming a disulfide bond is replaced by other amino acids, a free sulfhydryl group arises. The lack of a disulfide bond probably induces a destabilization of a structure. It is therefore expected that the emulsifying ability and gel forming ability are improved by a disruption of a disulfide bond. To test this hypothesis, mutants lacking one disulfide bond (C12G and C88S) and both disulfide bonds (C12G/C88S) were designed [Figure 4.11(b)] (59).

On the other hand, Cys53 and Cys377 in A1aB1b are free sulfhydryl groups. If an amino acid near the site of Cys53 or Cys377 is replaced by a cysteine residue, a new disulfide bond can be rationally introduced, considering the directions of the side chains of the replaced, the cysteine residues, and the distance of Cα between them shown by a simulated model. On the other hand, if two amino acids are replaced by cysteine residues by a similar method, a new disulfide bond can be introduced. Two and three mutants containing a new sulfhydryl residue and a new disulfide bond were designed, respectively (60).

These mutants were expressed in *E. coli*. Solubilities, self assemblies, and stabilities of expressed proteins indicated that ΔI, ΔV8, C88S, C12G/C88S, R161C, P248C, N116C, P248C, and N116C/P248C, in addition to IV+4Met, V+4Met. and D157A can fold correctly. In other words, modifications of the variable regions and the conserved regions based on three dimensional structure can be acceptable. Further, it was elucidated that the two disulfide bonds conserved among 11S globulins are not essential for the formation and the maintenance of the conformation of glycinin. However, it was difficult to purify C12G/C88S, because it was susceptible to attack of proteinase of *E. coli* during purification under a low ionic strength. This indicates that the removal of both disulfide bonds makes the conformation of C12G/C88S less compact than that of normal glycinin under low ionic strength.

We confirmed the expected introduction of a new free sulfhydryl group and a new disulfide bond by measuring the content of the free sulfhydryl group of the modified glycinins after blocking a free sulfhydryl group (60).

We analyzed the physicochemical functions of the modified glycinins, which can be prepared at a large scale. We compared the heat induced gel forming ability of ΔI, ΔV8, IV+4Met, V+4Met, C12G, C88S, R161C, F163C, N116C, P248C, and N116C/P248C with those of native glycinin and normal proglycinin A1aB1b. Proglycinin A1aB1b exhibits

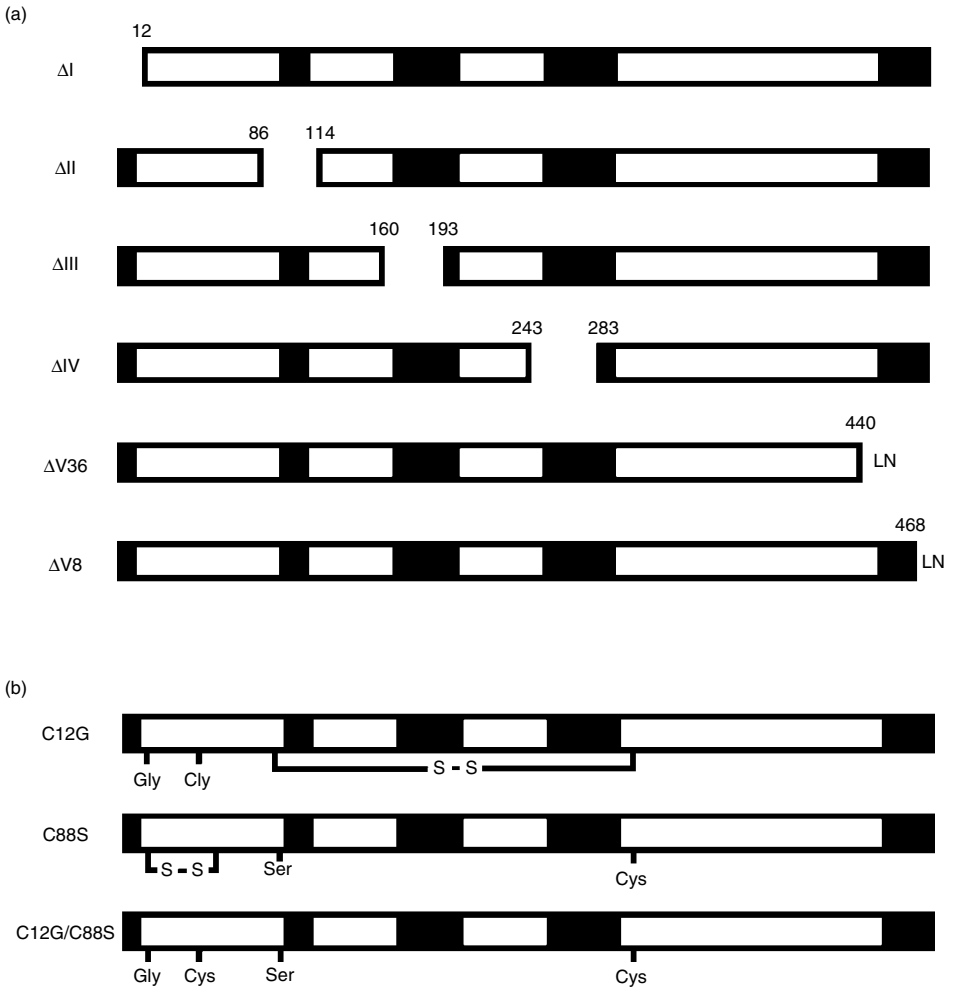

Figure 4.11 Schematic representation of modified proglycinin A1aB1b. (a) variable region-deleted mutants; (b) disulfide bond-deleted mutants. Numbers and S-S indicate the residue number from N-terminus and a disulfide bond, respectively. (From: Kim, C.S., S. Kamiya, T. Sato, S. Utsumi, M. Kito, *Protein Eng*. 3:725–731, 1990.)

gel forming ability and gel hardness similar to those of the native glycinin. On the other hand, ΔI, IV+4Met, V+4Met, C88S, F163C, N116C, P248C, and N116C/P248C formed harder gels than the normal one did. C88S and N116C/P248C showed the most prominent results. On the other hand, R161C formed harder gels than normal at protein concentrations higher than 7%, but formed gels with gel hardness similar to that of normal to one at protein concentration lower than 7%. C12G formed gels with gel hardness similar to that of normal glycinin at higher protein concentration, but could not form gel at a protein concentration lower than 5.6%. These results indicate: (1) the disulfide bond between Cys12 and Cys45 plays an important role in the initiation of a disulfide exchange reaction for a gelation; (2) introduction of a new sulfhydryl group and a disulfide bond is useful for improvement of heat induced gel forming ability and gel hardness; (3) the reactivity of the disulfide bond between Cys12 and Cys45 of ΔI, where its N-terminus is Cys12, increases; and (4) enhancement of surface hydrophobicity may improve gel forming ability.

We compared the emulsifying ability of ΔI, ΔV8, IV+4Met, V+4Met, C12G, C88S, and D157A with that of proglycinin A1aB1b. ΔI, IV+4Met, C12G, and C88S exhibited similar emulsifying ability to that of proglycinin A1aB1b. D157A exhibited worse emulsifying ability than proglycinin A1aB1b did (the details will be described elsewhere). In contrast, ΔV8 and V+4Met exhibited better emulsifying ability. These results indicate: (1) the presence of a hydrophobic region at the C-terminus increases emulsifying ability; (2) the effect of increasing hydrophobicity is different among the mutants; and (3) a destabilization of a structure does not have an effect on the improvement of the emulsifying ability of proglycinin A1aB1b. These observations correspond to the results of the analyses of glycinin having different subunit compositions described in the previous section.

Protein engineering is useful not only for the improvement of physicochemical functions, but also to elucidate the relationship between structure and physicochemical function. Therefore, the elucidation of the relationship between structure and physicochemical function at a molecular level, by protein engineering, will enable us to improve the physicochemical functions of soybean proteins effectively and rationally.

4.7 IMPROVEMENT AND ADDITION OF PHYSIOLOGICAL PROPERTIES OF SOYBEAN PROTEINS

Many kinds of bioactive peptides have been isolated from enzymatic digests of food proteins (61–64). Some proteins contain such peptides in a noncleavable form, and some contain peptides with a weak activity in a cleavable form. In these cases, physiological properties can be introduced or changed by replacement of a few amino acids. It is easy to replace a few amino acids in variable regions. Further, simulation models based on three dimensional structures enable introductions of bioactive peptides into even conserved regions. In case of the variable regions, if there is no sequence similar to that of the bioactive peptide, it is possible to introduce bioactive peptides that are not long and highly hydrophobic by replacements and insertions.

The peptide lunasin, which is the small subunit of the soybean MRP GM2S-1, has antimitotic properties and is a potential chemopreventive agent (8,10). As earlier mentioned, the soybean Bowman-Birk protease inhibitor has been shown to suppress various types of cancer: colon cancer (4), prostrate cancer (5,6), oral cancers, and cancers of the head and neck (7).

In this section, we review the research status of the improvement of physiological properties of soybean protein.

4.7.1 Fortifying the Bile Acid Binding Ability

It is well known that soybean proteins have a cholesterol lowering effect in human serum (65,66). Several mechanisms for the regulation of serum cholesterol have been proposed. As a major one, an undigested insoluble fraction of soybean protein interacts with cholesterols and bile acids in the intestine, and they are excreted into an easing (67,68). Most probably, hydrophobic interactions play an important role in these interactions. Makino et al. found that the 114–161 residues in A1aB1b, one of the peptides generated by trypsin digestion of glycinin, have a bile acid binding ability (69). On the other hand, Iwami et al. confirmed that peptides generated by hydrolysis of mild acids contain residues having highly hydrophobic properties derived from β-conglycinin, and these peptides actually bind bile acids (70).

The sequence of 114–161 residues in A1aB1b found by Makino et al. is very similar to those of the corresponding regions of the other glycinin subunits, because the region

is located in the conserved region. Further, the cleavage sites for trypsin exist at both sides of the corresponding regions of the other subunits. Makino et al. confirmed that a peptide generated from A2B1a also has bile acid binding activity. However, the activity of peptides generated from any of the subunits except A1aB1b and A2B1a has not been identified. There is a possibility that the peptide derived from A1bB2 was not detected because the sequence of the corresponding region of A1bB2 is very similar to that of A1aB1b, and the amount of A1bB2 in seeds is smaller than those of A1aB1b and A2B1a. All normal cultivars examined so far contain A3B4, whereas some normal cultivars of soybean do not contain A5A4B3. Therefore, Makino et al. probably used a cultivar containing no A5A4B3, and the activity of the corresponding region in A3B4 is weaker than those of A1aB1b and A2B1a.

Our experiments using an affinity column conjugated with cholic acid, one of the bile acids, supports this idea (71). By replacing the corresponding region in A3B4 with the region of 114–161 residues in A1aB1b, the bile acid binding ability can be increased in A3B4. Recently, we constructed deletion mutants of A1a and evaluated their bile acid binding ability by affinity column and their dissociation constants by fluorescence measurement (71). As a result, VAWWMY, the most hydrophobic sequence in the region of 114–161 residues of A1aB1b, was found to be very important in binding bile acids. We can easily fortify the bile acid binding ability of food proteins by using this peptide. For example, the sequences of A3B4 and A5A4B3 corresponding to VAWWMY of A1aB1b are VPYWTY and VPYWTY, respectively. Therefore, a replacement of three amino acids will probably enable the addition a bile acid binding ability into them. However, the folding ability of the mutants in these cases must also be considered, because the amino acids to be replaced are located inside the β-barrel. As described in the section on improvement of nutritional quality, the folding ability of the mutants can be evaluated by simulations before constructing and preparing them. On the other hand, the bile acid binding sequence (VAWWMY) can be introduced into variable regions easily, because it is easy to insert and replace amino acids in these regions. Thus, we introduced the bile acid binding sequence into two sites (M1 and M2) in the variable region IV (hypervariable region) of A1aB1b. The dissociation constants of M1 and M2 for sodium cholate were calculated by fluorescence measurements to be 30 mM and 37 mM, respectively, and that of A1a was 49 mM. These results indicate that the bile acid binding activity of A1a can be fortified as expected.

The bile acid binding peptide sequence can probably be introduced into β-conglycinin by a similar method, because β-conglycinin also has variable regions. Both glycinin and β-conglycinin have β-barrels rich in hydrophobic amino acids. Therefore, the bile acid binding ability of soybean proteins may be fortified by introduction of the bile acid binding sequence (VAWWMY) into the β-barrel based on simulation modeling.

4.7.2 Addition of Phagocytosis Stimulating Activity

Recently, Yoshikawa et al. isolated a phagocytosis stimulating peptide from trypsin digests of soybean proteins (72). This peptide, named soymetide, is derived from the α' subunit of β-conglycinin, and its primary sequence is MITLAIPVNKPGR. Met at its N-terminus is essential for the activity and MITL, the four residues from N-terminus, is the shortest peptide exhibiting phagocytosis stimulation. When the Thr, third residue from the N-terminus of the soymetide, was replaced by Phe or Trp, the activities of the modified peptides greatly increased (Thr $<$ Phe $<$ Trp) (72). Although the regions of the α and β subunits corresponding to the soymetide are highly conserved among the three subunits, and the cleavage sites for trypsin exist at both sides of the regions, their digests by trypsin do not exhibit the activity. The reason is that the residues of the α and β subunits corresponding to the

N-terminal Met in the soymetide, which is essential for the activity, are Leu and Ile, respectively. It was also found that Lys124 in the β subunit was not favorable for phagocytosis stimulation (72).

We attempted to introduce the phagocytosis stimulating peptide sequence into the β subunit by replacing Ile122 and Lys124 of the wild type with Met and Thr/Phe/Trp (I122M/K124T, I122M/K124F and I122M/K124W), respectively (73). These residues are located in the β barrel of the core region and their side chains are inside the molecule. Therefore, there is a possibility that the introduction of the phagocytosis stimulating peptide sequence into the β subunit might induce the loss of the folding ability by causing unfavorable contacts, especially in the case of the replacement of Lys with Phe or Trp, which have side chains bigger than that of Lys.

At first, we simulated the models of the three mutants using the three dimensional structure of the β subunit by the programs Insight II and Discover to confirm whether these mutants could fold correctly or not. The RMSD for the entire Cα atoms between the starting and simulated monomer models was around 0.67 Å for all the mutants. The distance of Cα atoms between the wild type and the simulated models at the positions 122 and 124 were 0.47–0.49 and 0.29–0.50 Å in all the mutants, respectively. These values mean that the position of the backbone scarcely moved. Furthermore, no unfavorable van der Waal's interactions between the side chains of the replaced residues and those of their neighboring residues were observed. Therefore, we concluded that all the mutants could fold correctly. To confirm our assumption that all the mutants could fold correctly based on the molecular modeling, we characterized the structural features of the mutants expressed in *E. coli* by circular dichroism measurement, differential scanning calorimetry, and gel filtration column chromatography. No significant difference in circular dichroism spectra was observed between the wild type and the mutants. This result indicates that the mutations for introducing the phagocytosis stimulating peptide sequence into the β subunit have little effect on the secondary structure. T_m values of all the mutants measured by differential scanning calorimetry were 1.9–3.1°C lower than that of the wild type. Although there is a hydrogen bond between Lys124 and Tyr109 in the β barrel of the wild type, all the mutants lost this hydrogen bond by the replacement of Lys124. Therefore, the loss of the hydrogen bond of the mutants might induce a slight decrease in T_m values. In gel filtration chromatography, all the mutants eluted similarly to the wild type. The results of circular dichroism measurement, differential scanning calorimetry, and gel filtration chromatography indicate that all the mutants folded correctly similar to the wild type. Further, we determined the crystal structure of I122M/K124W to investigate the effect of mutations in detail, because Trp was biggest among the introduced residues (Figure 4.12). The distances of Cα between Ile and Met (residue number 122) and between Lys and Trp (residue number 124) were 0.48 Å and 0.17 Å, respectively. Furthermore, no unfavorable van der Waal's interactions between the side chains of the replaced residues and those of their neighboring residues were observed. These results indicate that the replacement has little influence on the backbone structures and that the assumption about the conformation of I122M/K124W from the simulated model is correct. Further, all the mutants exhibited phagocytosis stimulating activity in the order of I122M/K124T $<$ I122M/K124F $<$ I122M/K124W as expected, and the wild type did not (Figure 4.13). The results confirm that we could introduce the phagocytosis stimulating peptide sequence into the β subunit with the correct folding.

When bioactive peptides are introduced into food proteins, a simulation based on three dimensional structures is a powerful tool to estimate the folding ability of the mutants. In the future, the accumulation of data on three dimensional structures of higher resolutions and on the folding abilities of mutants will make it possible to introduce bioactive peptide sequences exactly into food proteins by protein engineering.

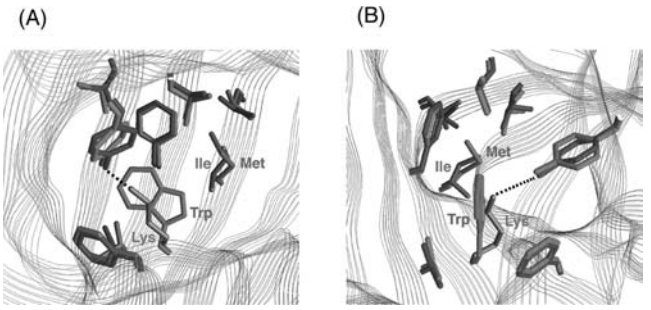

Figure 4.12 Structural comparison of the mutation site of I122M/K124W with corresponding site of the wild type. The Cα traces of wild type and I122M/K124W are represented by lines, respectively. The view in panel (b) is related to that depicted in panel (a) by a rotation of 90º. Dotted line indicates a hydrogen bond. (From: Maruyama, N., Y. Maruyama, T. Tsuruki, E. Okuda, M. Yoshikawa, S. Utsumi, Biochim. Biophys. Acta 1648:99–104, 2003.)

4.7.3 Antimitotic Activity of Lunasin

Lunasin is the small subunit peptide of a seed specific methionine rich 2S albumin (Gm2S-1) (74). It consists of 43 amino acids, and contains the cell adhesion motif Arg-Gly-Asp (RGD) followed by eight aspartic acid residues at its C-terminal end. Lunasin was found to arrest mitosis, leading to cell death, when the lunasin gene was transfected and expressed in mammalian cells (8). In addition to arresting cell division, the lunasin peptide caused abnormal spindle fiber elongation, chromosomal fragmentation, and cell lysis when transiently transfected into murine embryo fibroblast, murine hepatoma, and human breast cancer cells. Deletion of the polyaspartyl tail abolished the biological activity of lunasin. The antimitotic activity of lunasin is therefore ascribed to the binding of its polyaspartyl

tail carboxyl end to regions of hypoacetylated chromatin. Galvez et al. (10) have also shown that exogenous application of the peptide inhibits chemical carcinogen induced transformation of murine fibroblast cells to cancerous foci. When applied on the skin, lunasin (250 μg/week) reduces skin tumor incidence by 70%, tumor yield per mouse significantly, and delays tumor appearance by 2 weeks compared to the positive control.

It was estimated that commercial soy products contain about 5.48 mg lunasin/g of protein (defatted soy flour) to 16.52 mg of lunasin/g protein (soy concentrate) (10). However, it is not known whether ingestion of soy products at the FDA recommended daily consumption of 25 g of soy protein (75) will be adequate for chemoprevention. Bioavailability studies of natural and recombinant lunasin are needed to determine the physiological doses of lunasin that will be effective for preventing cancer. At present, the biological role of the methionine rich protein GM2S-1 or lunasin in soybean seeds is not known. Its allergenic potential has also not been established. Lunasin with identical structure and anti mitotic properties has also been isolated from barley (76).

Lunasin is presently produced either by recombinant DNA technology or chemical synthesis (10). It may be possible to add this biologically active peptide to one of the storage proteins of soybean based on three dimensional structure to prevent or minimize changes in structural conformation as described earlier. This can possibly increase the amount of lunasin in the soybean seeds.

4.8 FUTURE TRENDS

Understanding and use of three dimensional structures have made it possible for us to increase or add specific nutritional properties, physicochemical functions, and physiological properties to soybean proteins more accurately and rationally by protein engineering. The nutritional quality of soybean proteins can be improved by adding sulfur containing amino acids, while physiological properties can be enhanced or added by the introduction of bioactive peptide sequences. However, to improve physicochemical function, which is most important for usage as a food material, requires the elucidation of the relationship between structure and physicochemical function in detail. This can be done to a certain extent by analysis of a molecular species consisting of a single subunit prepared by means of an *E. coli* expression system and a limited number of subunits by using the mutant cultivars. However, this is still insufficient, as the relationship between the structure and the physicochemical function are different among a species of proteins. It still remains to be elucidated whether there is a general rule on structure and physicochemical function.

Protein engineering is a powerful tool for describing these subjects. If we can elucidate the relationship between structures and physicochemical functions of soybean proteins at a molecular level by protein engineering in the near future, it is expected that we can develop soybean proteins with excellent physicochemical functions in addition to nutritional and physiological properties. This will contribute to solving the food and health problems of the twenty-first century.

Genetic Modification of Plant Starches for Food Applications

Jeffrey D. Klucinec and Peter L. Keeling

CONTENTS

5.1 INTRODUCTION

Starch is a unique natural material, valued for its uses in food, feed, and industry. It is found in higher plants, mosses, ferns, and some microorganisms where it serves as an important store of energy. In higher plants, starch is deposited as transitory starch in leaves and as storage starch in specialized storage organs such as seeds or tubers. Starch is also an important component of many fruit crops such as apple, pear, melon, banana, and tomato. Storage starch is one of the main components of cereal grain (seeds) harvested from crops like wheat, maize, oats, barley, sorghum, and rice as well as of tubers harvested from crops like cassava, yam, and potato. Whether in its native state in grain or tubers, or in isolated granular form, starch is a convenient stable material, cheap to produce, suitable for long term storage without spoilage, convenient for high volume transport, and an important source of calories, retaining functional properties for use in many potential product applications. Grain and tubers are often used directly for animal feed or human food, with little or no processing, such as cooked whole cereal grain or potatoes. Cereal grain is also ground or milled to make flour or meal, which is subsequently mixed with other ingredients and cooked to make breads and pastries. Alternatively, starch may be extracted from the storage organs and the purified starch used as a key functional ingredient added to foodstuffs such as pie fillings, puddings, soups, sauces, gravies, coatings, candies, confectionary products, yogurts, and other dairy products. Extracted starch also has many nonfood industrial uses, such as paper sizing aids, textile sizing aids, molded plastics, ceramics, dye carriers, or suspension aids. Globally, starch is an essential commodity providing most (~80%) of the worlds calories. This vital commodity supply comes from just six different plant species: three cereal crops (rice, maize, and wheat) and three tuber crops (potato, yam, and cassava).

As a result of advances in genetics and biochemistry, we have discovered much about how starch is synthesized in crop plants. Furthermore we have also unraveled the biochemical and genetic basis of some useful natural genetic variations that affect starch synthesis and consequently starch structure and functionality. Some of these variants are already commercially exploited. Examples include variants that accumulate less starch and more sugar (e.g., sweet peas, sweet corn, sweet potato) and others that cook to form clear sols rather than opaque gels (e.g., waxy corn, waxy rice, waxy wheat) and yet others that are useful industrially (e.g., amylose extender corn), and finally others valued for imparting stickiness when cooked (e.g., indica vs. japonica rice). Further progress in this area depends upon improvements in our understanding of the relationship between starch synthetic genes and enzymes, starch structure and functionality. Thus, by linking these findings with further advances in our understanding of the genes required for starch synthesis, an opportunity has appeared for us to make starches with increased usefulness and value.

This paper seeks to pull together the disciplines of biochemistry, genetics, biotechnology, and food technology of plant starches. First we will review current knowledge of starch structure and how starch is synthesized in plants. The primary focus of this review will be storage starch because this provides the main source of food starch today. Next we will summarize the effects on starch composition, physical properties, and functionality due to genetic modifications that cause changes in starch biosynthetic enzymes. Finally we will focus on food applications that might benefit from genetic modifications of crop plants and discuss future opportunities coming from traditional plant breeding and modern biotechnology.

5.2 STRUCTURE

Physically, after extraction and drying, normal starch is a white powder consisting of a mixture of amylose and amylopectin in semicrystalline granules. Starch granules are

microscopic structures approximately 0.5 to 100 μm in diameter. In shape, they are spherical, elliptical, or polyhedral. The size and morphology of starch granules is characteristic of the organ and species in which they are produced (102). Starch granules appear rather similar in size and morphology with and without amylose. Under most environmental conditions, starch granules can be considered moderately inert with little capacity to hold water. These characteristics of starch granules make them ideal vessels for storage and shipping, whether in grain or tubers or from processed isolated starch.

Chemically, starch is classified as a complex carbohydrate and is a mixture of two polymers of glucose: amylose and amylopectin. Amylose is a generally linear α-1,4 glucan which is sometimes lightly branched with α-1,6-glycosidic linkages. Amylopectin is normally higher in molecular weight than amylose. It is also an α-1,4 glucan, but is highly branched with α-1,6-glycosidic linkages. The proportions on a dry weight basis of amylose and amylopectin in starches isolated from storage tissues like potato tubers or cereal grain is normally between 20 to 30 percent amylose and 70 to 80 percent amylopectin. In addition to amylose and amylopectin, granules contain small quantities of protein and lipid. Between species there is variation in the structure of amylopectin (104), the size and structure of amylose (84,207,209,211,213), and the nature and amounts of proteins (77,78,155) and lipids (154,214). Because starch physical behavior is dependent on all of these components (55,70,104,116–119) there are specific uses of starches from different species. In addition, within a given species, rare examples have been found of grains, tubers, or roots producing starches that deviate from the typical amylose to amylopectin ratio or have altered amylopectin structure. These plants have been selected because of their unique cooking behavior due to their unusual starch composition that confers unique properties to the crop storage organ. Some of these natural variants are now cultivated on a commercial scale.

Examination of starch structure began over 60 years ago (191). The first widely accepted model shows starch as a branched structure with alternating regions of higher branching density separated by more lightly branched regions (110). A more widely accepted model shows amylopectin arranged in alternating clusters (178,179). Based on the chain length profile of debranched amylopectin and a refinement of the cluster model, the amylopectin chains were categorized into type A, B1, B2, B3, B4 and a single C chain (82). Recently, three refinements for the different modes of interconnection of the amylopectin clusters were presented (82,216) (See Figure 5.1). In starch granules, some of the chains of amylopectin are believed to be associated with one another through hydrogen bonding, forming double helices. The double helices either form higher ordered crystalline structures or may exist independently of crystalline order. The double helices are oriented radially within the granule, with the reducing ends of the chains oriented toward the center or hilum of each granule. Within the granule, crystalline regions, often referred to as growth rings, are separated in a radial fashion from each other by amorphous regions. The crystalline regions are further subdivided into amorphous and crystalline lamellae, which have a periodicity between clusters of approximately 9 nm (105). The branch points in amylopectin are believed to be the primary component of the amorphous lamellae, with the ordered amylopectin side chain double helices clustered in the crystalline lamellae. Differences in the internal chain lengths of amylopectin affect starch crystallinity (163). Important new insights into how amylopectin chain architecture may affect packing have been advocated based on small angle x-ray scattering studies and analogies with liquid crystals (230–233). Using these models it is possible to discuss the mechanisms and kinetics of interchain associations in the context of visualizing starch as a liquid crystalline polymer having different degrees of crystalline order depending on physical conditions.

Amylose contributes to the overall crystallinity of normal starch through the formation of crystalline complexes of amylose with lipids and, it is believed, through participation

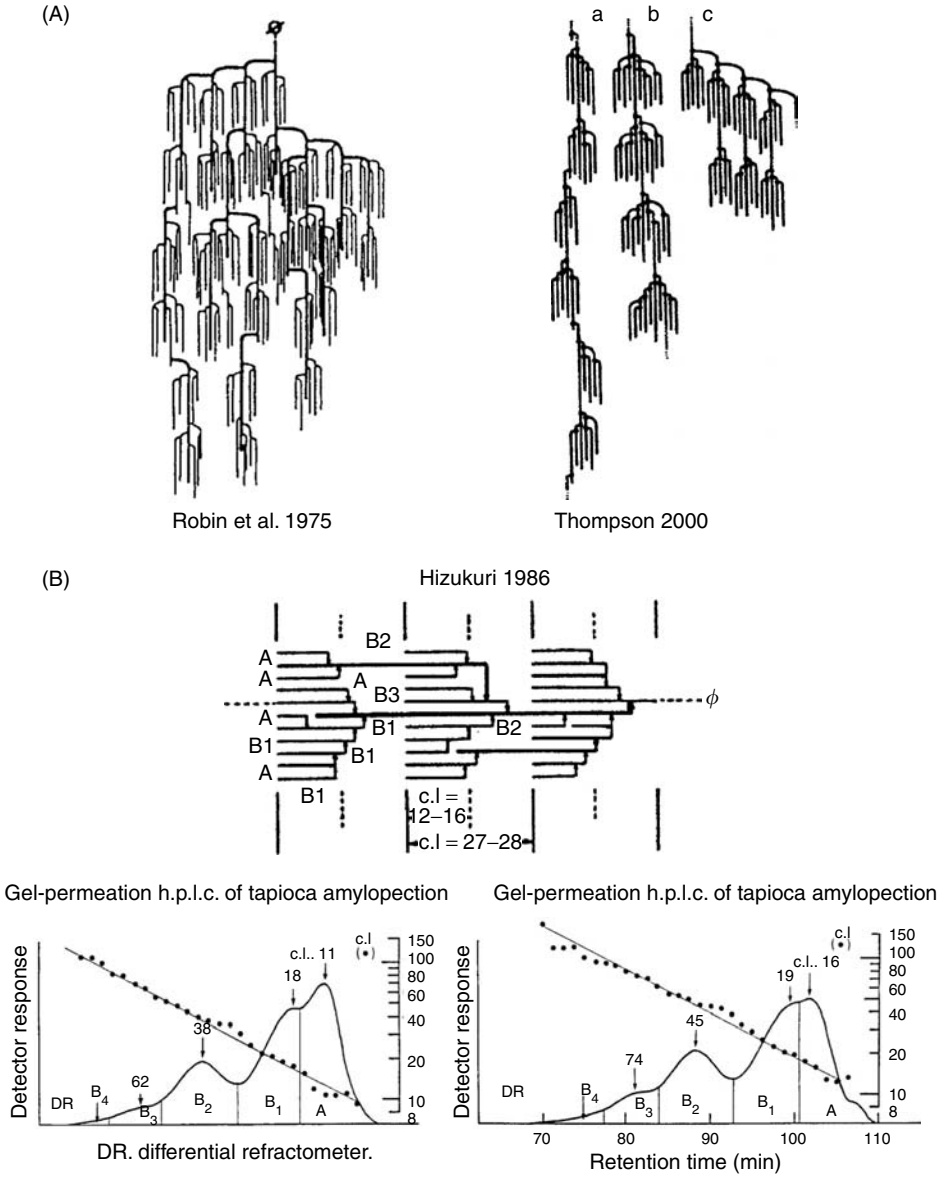

Figure 5.1 (A) Mode of Interconnection of clusters (B) Cluster models of amylopectin

in some starch double helices. However, although amylose readily forms double helices in solution, it readily leaches out of hydrated starch at granule gelatinization temperatures (68). This observation shows that amylose in starch granules does not associate in the same manner inside granules as it does outside of the granule. This observation additionally raises some intriguing questions about the nature of amylose synthesis and the kinetic trapping of amylose within starch granules.

While normal starch can be readily separated into two components, amylose and amylopectin, studies of high amylose starches have revealed what some authors describe as a third starch component, sometimes termed intermediate starch. For normal starches containing ~25% amylose, the results from quantification by iodine inclusion complex formation

(11,139,181,127), or precipitation in the presence of complexing agents (191,192,126,240,241) are in general agreement. However, for high amylose starches, these methods give different results. Thus, from detailed observations, high amylose starches were initially considered to contain either normal amylopectin and short chain linear amylose (1,2,75) or longer chain amylopectin compared with amylopectin from normal starch (148,149). Liquid chromatographic studies (140) have confirmed the latter. Additional studies of high amylose starches by differential precipitation with 1-butanol combined with Sepharose 2B chromatography (245) revealed an inability to clearly separate amylose from amylopectin. Further fractionation revealed high molecular weight material in what traditionally was the amylose fraction (8,9,209). Later studies showed that this material can be removed by repeated precipitation with 1-butanol and was most likely contaminating amylopectin (209,213), while removal of the low molecular weight material in the amylopectin fraction using differential precipitation techniques has not been successful. In summary, starch from high amylose mutants appears to contain a significant amount of an amylopectin-like component having an altered architecture. This intermediate starch component is characterized by:

1. An inability to precipitate with 1-butanol
2. An ability to eluete within the same molecular size range as amylose
3. An ability to bind iodine and having a lambda maximum between amylose and amylopectin

Estimates of intermediate material defined in this way have exceeded 55% (w/w) of the total starch of high amylose mutants (10).

Other workers (116,209,239) have defined intermediate starch to be the material that has the ability to precipitate in the presence of some complexing agents (e.g., 2-nitropropane) or mixtures of complexing agents (1-butanol with isoamyl alcohol) but not others (e.g., 1-butanol, 1-nitropropane). This type of intermediate material obtained by differential precipitation is a relatively small proportion of normal starches ($<10\%$) (116,209,220,239) irrespective of the amylose content of the high amylose starch. The molecules have been considered by some as amylopectin molecules with long external chains and a limited capacity to form clathrate complexes and precipitate (116,209,220,239). It has also been suggested (209) that this type of intermediate material could be a mixture of amylopectin and a small amount of contaminating amylose, which might be the case if the amylopectin from high amylose starch has an overall molecular size similar to that of amylose from normal starch (116).

Amylopectin molecules within granules are believed to be organized radially, with the long C-chain innermost (84). As a result of high magnification microscopy studies it was proposed that the radially oriented amylopectin clusters are organized into super helices, which may relate to the blocklets seen in microscopy studies (166). In turn the super helices may be responsible for the formation of concentric spherical rings. Although these growth rings are a characteristic of all starch granules, the mechanisms determining their formation are still not well understood (60,170). Recently, Bertoft proposed a bidirectional backbone model, where the super helix could be organized so that the longer amylopectin chains are oriented in line with the super helix, while the amylopectin clusters may be oriented radially (18) (Figure 5.2).

X-ray crystallography has shown that there are three distinct types of crystalline order in starch: A-type, B-type and V-type. V-type crystallinity is often associated with crystalline packing of amylose lipid complexes. The A-type and B-type starches differ in the organization of helices: A-type crystals are densely packed hexagonal arrays of double helices, B-type crystals, though also double helices packed in a hexagonal array, are unlike A-type

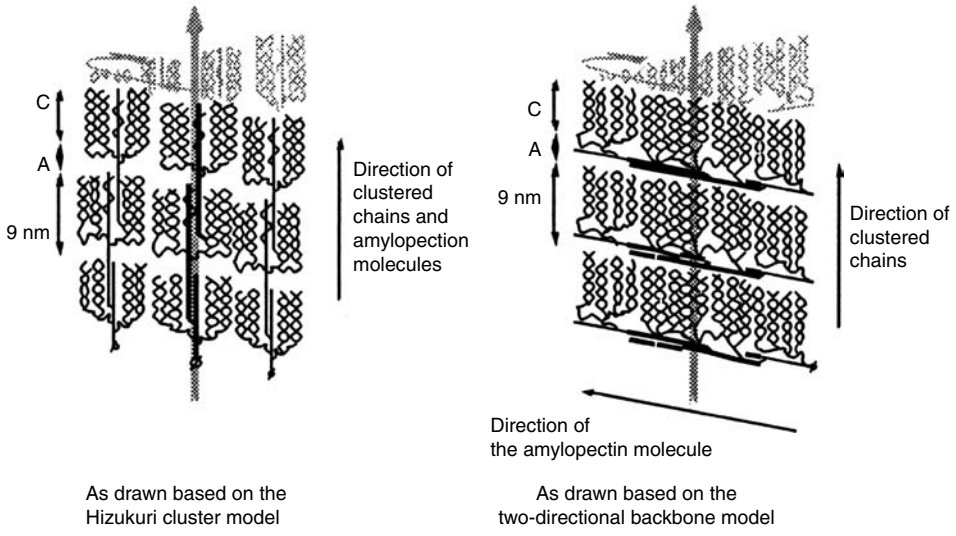

Figure 5.2 The super helix model as drawn in the Hizukuri cluster model and modified based on the two-directional backbone model.

crystals because they have an open central cavity which results in an increased water content (92). C-type starches are a mixture of A-type and B-type crystallinity (22,27,69).

5.3 SYNTHESIS

For an overview of starch synthesis, the reader is referred to recent reviews (99,151,218). In general terms, it is important to note that storage organs are composed of individual starch storing cells and each cell contains several subcellular compartments: including particularly the cytosol and amyloplast compartments. Sucrose, made in the leaves, is transported to the storage organ where it is imported into the cytosolic compartment of each cell. A well characterized pathway (see Figure 5.3) of starch synthesis achieves the enzymatic conversion of sucrose to starch. The first part of this pathway is localized in the cytosol, while the final steps of starch synthesis are located in a specialized subcellular compartment called the amyloplast.

In the cytosol, the glucosyl and fructosyl moieties of sucrose are converted into sugar phosphates. One of these types of hexose phosphates, glucose-1-phosphate is converted into ADP-glucose by the enzyme ADP-glucose pyrophosphorylase (AGPase), the first committed step in starch synthesis. In the endosperm of monocot crops, AGPase is located predominantly in the cytosol, whereas in the storage organs of dicot crops, AGPase is located predominantly in the amyloplast. Thus in monocot crops, ADP-glucose is transported into the amyloplast, while in dicot crops hexose phosphate is imported to support ADP-glucose synthesis inside the amyloplast. The conversion of ADP-glucose to starch is performed by several enzymes, which include, but may not be limited to, soluble starch synthase (SS), granule bound starch synthase (GBSS), starch branching enzymes (SBE), and isoamylase (ISA). Other enzymes that also may be involved in starch synthesis include phosphorylase (PHO), pullulanase (PU) and disproportionating enzyme (DisPE). GBSS is involved primarily in amylose biosynthesis and SSs, SBEs, and ISAs are involved in the biosynthesis of amylopectin.

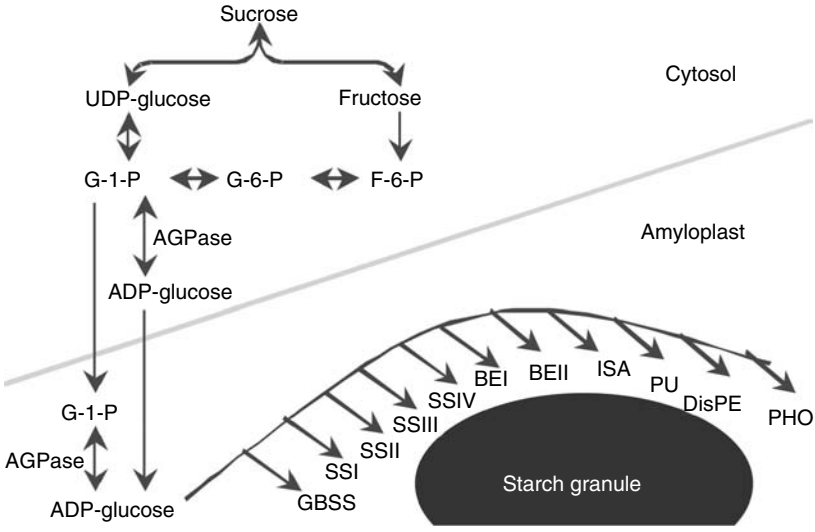

Figure 5.3 Pathway of starch biosynthesis

Across species, well conserved families of genes encode the enzymes in the pathway. Thus, diverse plant species possess similar sets of multiple forms (isoforms) of each enzyme. The conservation of isoforms suggests that each has a unique role in the process of starch synthesis. This idea has been largely confirmed in several plant species by studies of genetic modifications in which particular isoforms have been overexpressed or reduced.

5.3.1 Granule Bound Starch Synthase

Granule bound starch synthase (GBSS) is a member of the glycosyltransferase class of enzymes more generally known as starch synthases. GBSS is more formally named ADPglucose:1,4-α-D-glucan-4-α-D-glucosyltransferase (E.C. 2.4.1.21). In storage organs there are several starch synthase proteins associated with starch. However, only one isoform (GBSSI) is found predominantly associated with starch, and based on studies of amylose free mutants which lack the GBSSI protein, this isoform appears to be exclusively responsible for amylose synthesis in maize (200) and other plant species (44,88). There is a similar isoform in leaves (229). GBSSI has been identified, mapped and cloned from several species (218). The activity of GBSSI is correlated with the product of the waxy, lam, and amf locus of cereals, pea, and potato respectively (44,88,89,160,200).

As well as associating with starch granules, another key attribute of GBSSI is its ability to elongate a growing glucan chain processively. This means that the enzyme does not necessarily dissociate from the glucan chain after the addition of the first glucose but can remain associated with it to add further glucose units before finally dissociating. Soluble starch synthases enzymes in comparison add single glucose units per encounter with the glucan chain (distributive elongation). This processive mechanism of elongation by GBSSI is consistent with the proposed role of GBSSI in amylose synthesis (45,46). One of the more intriguing aspects of the function of GBSSI is that in isolated granules, its amylose synthesizing activity appears to be dependent on the presence of low concentrations of maltooligosaccharides (45,46). These experiments with isolated granules also showed that GBSSI can elongate glucan chains within amylopectin, a finding that may explain why mutants lacking GBSSI have altered amylopectin structure as well as lacking amylase (83,172,251).

5.3.2 Soluble Starch Synthase

Soluble starch synthase (SS) isoforms are all members of the glycosyltransferase class of enzymes. SS is more formally named ADPglucose:1,4-α-D-glucan-4-α-D-glucosyltransferase (E.C. 2.4.1.21). Like GBSSI, the SS enzymes are also associated with starch granules, but are also present in the stroma of the amyloplast, leading to their classification as soluble starch synthase. SS catalyses the transfer of glucose from ADP-glucose to an acceptor glucan chain, by a mechanism that has been described as distributive (46).

Four SS forms have been identified, mapped and cloned from several species (218). Although the various isoforms are believed to be present in all starch synthesizing cells, they appear to have different relative activities in different species and tissues. SS is believed to be primarily responsible for amylopectin synthesis, and there is evidence that each isoform is responsible for the synthesis of different chain lengths. SSI has been cloned and mapped from several species, but the only known mutant type described so far is in rice (159). SSI appears to be primarily responsible for synthesizing shorter chains of amylopectin based on biochemical studies of the isolated enzyme (38) and structural studies of the rice mutant (159). The SSII and SSIII isoforms appear to be involved in synthesizing the intermediate chains of amylopectin, as evidenced by changes observed with mutant and transgenic rice (40,63,221). The precise role of SSIV remains to be elucidated, and it may even be revealed that SSIV is a subclass of the SSIII isoform. All of these classifications are consistent with evidence obtained from starch isolated from potatoes transformed with antisense constructs to the potato enzymes (51,68).

5.3.3 Branching Enzyme

Starch branching enzyme (SBE) is a member of the glycosyltransferase class of enzymes. The branching enzymes are more formally and collectively named 1,4-α-D-glucan:1,4-α-D-glucan 6-α-D-(1,4-α-D-glucano)-transferase (E.C. 2.4.1.18). Like the SS enzymes, the SBEs appear to have a weak association with the starch granule as evidenced by the fact that these enzymes may be found entrapped inside starch granules. SBEs catalyze the interchain cleavage of a glucan chain with subsequent bonding of the cleaved portion to the parent glucan chain. SBEs act by cutting an α-1,4 linkage forming a new linkage between this cleaved glucan chain and an adjacent glucan chain via an α-1,6 linkage. There appear to be at least two major classes of highly conserved SBEs across plant species (SBEI and SBEII). Thus, like the soluble starch synthases, SBEs appear to have a distinct role in the mechanism of amylopectin structure development. The SBEs must also play some role in amylose synthesis, as amylose is lightly branched. All known SBEs have been mapped, cloned, and sequenced from several plant species. SBEIIb appears to be primarily responsible for transferring longer chains of amylopectin based on biochemical studies of the isolated enzyme (76,212) and structural studies of the maize and rice mutant (162,205,212). The role of SBEI and SBEIIa is less clear as mutants of SBEI in rice have reduced intermediate and long chains (159)while in maize the chain lengths are unaffected in mutants of SBEI and SBEIIa (20,21).

5.3.4 Debranching Enzyme

Debranching enzymes are members of the amylase class of enzymes. There appear to be at least four debranching enzymes in the storage organs: three isoforms of Isoamylase (ISA) and one Pullulanase (PU). Although ISA is known to catalyze the selective cleavage of α-1,6 linkages in branched glucans, their precise catalytic role in starch granule biosynthesis remains unresolved. Plants lacking ISAI accumulate higher levels of sucrose, more starch granules and phytoglycogen and have reduced amounts of starch, strongly indicating that ISAI is required for normal starch biosynthesis (28,29,59,122). Some studies have highlighted the involvement of ISA in starch granule initiation, probably mediated by degradation

of soluble glucans which would otherwise initiate granule formation (28,29,122). The role of ISAII and ISAIII in starch biosynthesis remains unresolved at the present time, as no mutants are known to exist. What little is known about their catalytic properties has led to the proposal that each isoform has retained a specific role (90). Studies in maize of the limit dextrinase/pullulanase (PUI) class of debranching enzymes has successfully identified a mutant, which on its own appears to have minimal effects on starch deposition (13,47).

5.4 MODIFICATIONS

Most of the maize starch mutants affecting starch structure were discovered before the genes and enzymes responsible for starch synthesis were known. Their names are therefore based upon the phenotypic changes observed in that storage organ or on the properties of the starch, rather than that of the gene or enzyme affected by the mutation. For example, numerous mutant phenotypes have been reported for maize (73,36) and several phenotypes (e.g., waxy, amylose extender, dull, shrunken, sugary-2, and sugary) have been described extensively with regard to their effects on carbohydrate composition and response to genetic background, allelic dosage, or interaction with other mutations (42,64,65,87). Examination of maize kernels with differing starch phenotypes has been instrumental in determining which enzymes are required for starch synthesis in this storage organ (24,194). Mutations that are responsible for most of the abnormal starch phenotypes have been located in genes encoding starch synthetic enzymes. Related isoforms, for which there are as yet no mutants available, have also been identified and characterized. Table 5.1 summarizes the enzymes

Table 5.1
Summary of individual isoforms of enzymes linked with specific mutants and the effects of these mutations on starch structure (similar genetic modifications affecting these starch biosynthetic enzymes exist in other species).

Enzyme and Specific Isoform	Mutant (Maize)	Effect on Starch
Granule Bound Starch Synthase		
GBSSI	Waxy (*wx*)	Low amylose content.
Soluble Starch Synthase		
SSI	None known	Not known
SSII	Sugary2 (*su2*)	Lacks intermediate glucan chains in amylopectin
SSIII	Dull1 (*du*)	Lacks longer glucan chains in amylopectin
SSIV	None known	Not known
Branching Enzyme		
BEI	BEI (*be1*)	None/Minimal
BEIIb	Amylose extender (*ae*)	High amylose content.
Debranching Enzyme		
ISAI	Sugary1 (*su1*)	Forms compound granules and phytoglycogen
ISAII	None known	Not known
ISAIII	None known	Not known
PUI	Pullulanase1 (*pu1*)	None/Minimal

required for normal starch synthesis in maize kernels, the associated mutant loci and the starch phenotypes of these mutants.

As a result of the great progress made in genetics in the last decade, in addition to the more traditional modifications used in plant breeding, it has become possible to modify or engineer starch synthesis enzymes using modern biotechnology. Collectively this is opening an oppurtunity to consider using all the tools of breeding, genetics and biotechnology to genetically control starch deposition in plants so as to enhance starch yield and starch quality. Thus, instead of crudely controlling enzyme activity by selecting certain mutants or selecting among different alleles of starch synthesis enzymes using plant breeding, it is possible to more precisely reduce the expression or activity of certain enzymes (such as by using antisense or RNAi technology). Alternatively the enzymes may be overexpressed: an opportunity that is unavailable using conventional plant breeding. What is additionally exciting about enzyme overexpression is that novel enzyme isoforms can be selected in order to act in concert with the existing starch pathway enzymes. With full sequencing of many homologous genes from different plants, we have begun to be able to identify domains within enzymes, which impart particular catalytic properties. This reclassification of enzymes into domain classes is an important new facet of our time, and is generating new understandings of the origins, mode of action and potential for genetic modification of different enzymes. The starch created from such work has the potential to be extremely novel and valuable. However, while the opportunities seem limitless, we are constrained by our limited understanding of the links between starch structural changes and functionality. Furthermore we are significantly constrained by our understanding of what determines the specific catalytic properties of the enzymes.

In the following sections, we will expand upon the properties and roles of the best studied of the enzymes of starch synthesis and describe the effects on the properties of starch of genetic modifications that eliminate or modify the genes encoding them.

5.4.1 Modification of GBSSI Activity

Modifications in granule bound starch synthase activity result in changes in amylose content or amylose structure. In maize, the GBSSI mutant phenotype was named waxy because the intact seed has a waxy phenotypic appearance, unlike normal seed that has a shiny and glossy appearance (194,236). No other enzyme appears to be involved in determining amylose content, as the waxy mutants of cereals (96,157), the amf mutants of potato (88), the lam mutants of pea (44), and GBSSI antisense lines of potato (4,228) show either a reduction or elimination of GBSS activity and a specific reduction of amylose in starch from tubers. Some studies have attempted to restore the production of amylose in amylose free potato plants by transforming the plants with genes for GBSSI enzymes produced by other plants. Between 3.5% and 13% amylose was restored to amylose free mutants of potato by transformation with the cassava GBSSI enzyme (183). Similarly, amylose free potatoes transformed with pea GBSSI isoforms resulted in potatoes with amylose contents of between 0.8% and 1%. Like, the other low amylose potatoes and pea starch, heterogeneity in amylose and amylopectin content was observed within the granules: the granules stained with iodine revealed amylose in concentric rings or having blue-staining granule cores (52).

Extensive work, initially in Japan, has identified wheat mutants lacking GBSSI activity (143,144,145,156,158,255). Miura and Sugawara (144) showed that substitution of genes producing functional GBSSI enzyme with the null alleles could result in starches with a 22 to 23% amylose content rather than the 25.5% amylose content of the normal control. Likewise, Miura et al. have shown that elimination of an active GBSSI enzyme at 2 of the 3 loci in wheat endosperm results in a wheat starch that has an amylose content

of 16% to 21% (143). Thus, the presence of a functional GBSSI enzyme from a single locus pair is sufficient to produce a starch with an amylose content of at least 16%. Others (164) have shown that low amylose wheat starches having amylose content between 14.1 and 16.7% can be created through ethyl methanesulphonate (EMS) mutagenesis of the seeds. Amylose free wheat starches were created using triple null combinations of GBSSI mutants (255) and using mutagenesis of a double null wheat known as Ike to generate a nonnull wheat (WO09815621) which stained red when stained with iodine.

Two functional Wx alleles of rice exist: Wx^a, which produces a large amount of amylose, and Wx^b, which produces a smaller amount of amylose. Studies of the effects of the two alleles on the gene expression at the waxy locus in rice (187) showed that the Wx^b allele resulted in an ineffective production of GBSSI enzyme and amylose in japonica rice, while the Wx^a allele produced larger quantities of GBSSI enzyme and amylose in indica rice (186). On a specific activity basis, other authors have shown that the Wx^a allele was less effective in the production of amylose than the Wx^b allele based on analysis of 40 rice varieties (226). It was observed that for two wild-type rice alleles, Wx^a and Wx^b, Wx^b had a GBSS expression tenfold lower than Wx^a at the protein and mRNA levels (97). The decrease in the expression of Wx^b compared to Wx^a was the result of a point mutation within the genetic sequence for the normal rice enzyme (Wx^a allele). The Wx^b allele resulted in the synthesis of a 3.4 kilobase pair mRNA transcript compared to a 2.3 kilobase pair mRNA transcript for Wx^a as a result of the inclusion of an intron into the mRNA sequence as a result of the point mutation (97). Amylose produced from rice plants was related to the ability of the plant to excise the intron 1 from the mRNA sequence (235). Plants expressing high levels of mature mRNA (without intron 1) and no pre-mRNA (containing intron 1) produced the highest levels of GBSSI protein and the highest levels of amylose (20.0 to 27.8% amylose). These were all indica species. With more balanced expression of mature and pre-mRNA, lower levels of GBSSI protein and amylose were observed (6.7 to 16.0% amylose). Both indica and japonica species were within this group. When all of the mRNA contained intron 1 and no mature mRNA was observed, no GBSSI protein was observed and no amylose was detected (235). This pattern relating amylose content to mature mRNA with properly excised intron 1 could be applied across 31 different rice cultivars (235). Thus, based on extensive studies (97,198,235), low amylose rice appears to be the result of a decrease in the amount of normal GBSSI through a mutation which results in problems with mRNA processing rather than due to a mutation in the mature mRNA sequence. However, some differences in the behavior of Wx^a and Wx^b may be present in different rice species.

In recent years a number of patents have been filed covering genetic modifications of granule bound starch synthase in plants, utilizing knowledge gained after cloning, sequencing and transforming plants with the GBSSIs. Examples include WO9211376, US5365016, WO09827212, WO028052, WO02018606, and WO04078983.

5.4.2 Modification of SS Activity

Modifications in starch synthase activity result in changes in amylopectin content or amylopectin structure. Starch synthase may have either a subtle or profound impact on the starch, depending on the activity or inactivity of a specific isoform on the structure and composition of the starch. Although SSI is a relatively minor isoform in potato, it is the predominant isoform of SS in the cereals. Of the starch synthases, the effects of SSIIa and SSIII on starch structure and composition are the best elucidated, especially in maize. Mutants lacking the putative SSIV isoform have not yet been reported. The first reported SSI mutant was in rice (159) and no mutants have yet been reported in other plant species. In rice, the SSI mutant has only a minor effect on starch content and quality. In maize, SSIIa maps to a locus known as Sugary-2 which when mutated produces the sugary-2

mutant. Starch from mutants lacking SSIIa lack certain intermediate amylopectin chains in maize, pea and rice (31,40,221). Wheat, null for the SSIIa enzyme in each of the A, B, and D genomes, has an increase in starch chains with a DP below 10, an elevated amylose content, and a poor x-ray diffraction pattern (246). Barley null for the SSIIa enzyme produces a starch with an apparent amylose content between 50 and 70% of the dry weight of the starch, with a concurrent increase in the proportion of short chains through a DP of 35 (150). The structural gene for SSIII in maize is known to be the Dull1 locus which when mutated gives the dull1 mutant. Starch from the dull1 mutant is relatively lacking in longer amylopectin chains (62). In potato the simultaneous antisense inhibition of SSII and SSIII resulted in a grossly modified amylopectin (51,136), with yet further changes in structure if GBSSI as well as SSII and SSIII are inhibited (108).

In recent years a number of patents have been filed covering genetic modifications of starch synthase in plants, utilizing knowledge gained after cloning, sequencing and transforming plants with the starch synthase enzymes. Examples include WO9409144, US6013861, US5824790, JP06070779, US6130367, WO9720936, EP779363, WO09726362, WO09744472, WO09745545, WO9844780, WO9924575, WO9966050, WO006755, WO031274, and WO112826.

5.4.3 Modification of SBE Activity

Modifications in branching enzyme activity result in changes in apparent amylose content which are believed to be due to an increase in amylose and to changes in amylopectin structure. The first naturally high amylose starch was reported 50 years ago when Vinyard and Bear successfully found a maize endosperm mutant termed *amylose extender* (*ae*) (12,227). Despite extensive research, kernels containing exclusively amylose as the reserve starch polysaccharide have never been found (197,201). The relationship between the Ae mutation and SBE activity was proposed nearly 30 years ago (25). We now know that the structural gene for SBEIIb is the *Ae* locus (205), which when mutated produces *ae* mutant starch having an amylose content of up to 50%. Although the biochemical basis of maize starches having amylose contents above 50% clearly requires the *ae* mutant (SBEIIb), the biochemical basis of the additional increases over 50% amylose is not clear at the present time (201). Furthermore, it does not appear as though SBI is involved, as SBI mutants do not have increased amylose alone or in combination with SBEIIb mutants (20,250). Similarly, SBEIIa mutants (21) had no detectable effects on seed starch structure.

Irrespective of the means of defining or partitioning *ae* starch into amylose and amylopectin components, it is clear that the relatively clear demarcation between amylose and amylopectin existing for normal starch is blurred for *ae* starch, giving rise to a third type of starch termed intermediate starch. Additional evidence for this comes from material collected as amylopectin from *wxae* intermediate starch which has no GBSSI activity and hence produces no true amylose, and has reduced amylopectin branching (61,104,116,135,196,254). Further, the beta-amylolysis limits for *wx* starch, *wxae* starch, and the amylopectins from normal maize and *ae* starches are all between 55 and 61% (259, 260). Thus, both the average exterior chain length and average interior chains length are proportionally longer for the amylopectin from *ae*-containing starches and the double mutant *wxae* starch than for *wx* starch and the amylopectin for normal maize starch. The combination of the absent GBSSI and BEIIb activity in the *wxae* double mutant produces an amylopectin which has sufficient linearity to have apparent amylose content approximately 20% as measured by iodine binding (25).

SBEIIb mutants also exist in rice (162) but there appear to be pleiotropic effects that complicate directly linking SBE activity with increased amylose. Rice SBEI mutants have

also been found (189) which, like maize, do not have increased amylose content and do not further increase amylose when combined with SBEIIb mutants. High amylose rice starches appear to have amylose contents between 30 and 50% of the weight of the starch (226). However, with the variability of amylose content of what may be considered normal rice varieties (19,173,210) and the recent implication that other starch biosynthetic enzymes affect the amylose content of such normal rice starch (221) with a few exceptions (146,147,225), it is difficult to know whether deficiencies in SBE are explicitly responsible for some of these high amylose rice starches. In such instances, the rice starch granules have the characteristic changes in starch properties, amylose properties, and amylopectin structure seen with high amylose maize starches (6,225,249). Similar to rice, high amylose barley starches with an amylose content between 30 and 45% of the weight of the starch clearly exist (184,203,252), although it is unknown whether these starches are a result of down regulation of SBE activity or are a result of changes in the expression and activity of other enzymes.

Reports of high amylose potato starch obtained through transgenic down regulation of multiple starch branching enzymes have been published recently (85,107,182,193). Work on development of a high amylose potato starch has been occurring for at least the past 10 years. Amylose contents as high as commercially available maize starches have been obtained in potato with a decrease in the overall molecular weight distribution.

In recent years a number of patents have been filed covering genetic modifications of branching enzymes in plants, utilizing knowledge gained after cloning, sequencing and transforming plants with the SBEs. Examples include US6013861, WO9211375, WO9214827, WO09507355, WO9634968, WO9722703, WO9720040, WO9820145, WO9837214, WO9837213, WO9914314, WO9964562, WO015810, WO031282, WO022140, JP0621767, JP06098656, JP05317057, and JP04088987.

5.4.4 Modification of DeBE Activity

Modifications in debranching enzyme activity can result in significant changes in starch granule structure. ISAI mutants accumulate starch in compound instead of simple starch granules (compound refers to amyloplasts containing many small granules, while simple refers to amyloplasts containing one major granule) and sometimes also accumulate phytoglycogen (a highly branched nongranular storage product). Mutants known in ISAI include the sugary1 locus in maize and sugary of rice (100,122) and in barley by lines named *Riso17* and *Notch-2* (28). Similar results were observed using antisense technology to reduce ISAI activity in rice (59). In potato where antisense constructs for ISAI and ISAII were combined, the tubers accumulated large numbers of small granules (28,29,122). Mutations in PUI have been identified (47), but effects on starch content are minimal. Modifications in the other isoamylase (ISAII and ISAIII) have not yet been identified, although there is some evidence that they each play distinct roles in starch synthesis (90). The maize sugary mutants are important because they are one of the main sources of producing sweet corn.

In recent years a number of patents have been filed covering genetic modifications of debranching enzymes in plants, utilizing knowledge gained after cloning, sequencing and transforming plants with the ISA and PU enzymes. Examples include WO9202614, WO09504826, WO09619581, US5750876, WO9603513, US5912413, WO09732985, WO09742328, WO9850562, WO09906575, WO9912950, WO09958690, and WO0001796.

5.4.5 Modification of Multiple Pathway Enzymes

By eliminating multiple starch biosynthesis enzymes, other alterations of the starch biosynthetic pathway can occur resulting in even more novel starches. Several patents exist

on the creation and use of such starches (US4428972, 4615888, 4767849, 4789557, 4789738, 4801470, 5009911, and 5482560). More recently, several patents and published applications have described the production and utilization of heterozygous combinations of mutations in the starch biosynthetic pathway to obtain commercially useful starches (WO9535026, US5356655, US5502270, and 5516939). The production of many of these starches involves the use of double or triple mutant plants. Due to the number of mutations required to sufficiently alter the starch (at least 2 or 3 within a single plant) many of these starches are difficult and costly to produce commercially, so many of these starches from plants with mutations in the starch biosynthetic pathway are uncompetitive with chemically modified starches. Further, these combinations of two or more mutations, whether they are combined homozygously or heterozygously in the plant endosperm, rely on the alteration of the structure of amylopectin from normal or waxy starch.

5.5 FUNCTIONALITY

The origin of wide angle x-ray scattering (WAXS) diffraction patterns from amylose fibers was determined to be due to the crystalline packing of double helices of starch chains (242,243). This work was further developed to explain the crystallinity of starch granules. When starch granules are heated sufficiently in excess water, the WAXS diffraction pattern is lost (257) and an endothermic transition is observed (39). Double helical order is additionally lost during this endothermic event, and it is this loss and not the loss of crystalline order that is believed to be responsible for the endothermic event (39). This loss of granular, crystalline, and double helical order is called gelatinization, and it is irreversible with respect to the three dimensional granule organization (7). Subsequent to gelatinization, starch chains of both amylose and amylopectin may organize into new double helical and crystalline structures in a process called retrogradation (7,70,176).

In its native granular form mixed with water, starch makes a high solids mixture, useful in making batters and doughs. During heating, starch granules swell, associating with water up to 30-fold its dry weight, to form a hydrated starch. This process is reversible provided temperatures and pressures are lower than those that lead to disruption of the organized intramolecular glucan chain associations within the granule. Above these temperatures and pressures, the granules will undergo irreversible changes and glucan chains will dissociate, permitting further swelling. With additional heating and applied shear forces, swollen hydrated granules will eventually collapse to form an unorganized paste of starch molecules. Such hydration, with heating, results in a thickening effect, imparting texture and structure. In functional terms, this process of starch granule swelling and dissociation is known as gelatinization (7,18,214,238). The glucan polymers of a gelatinized starch are able to associate with each other or other components of food to impart additional character to the food system including stickiness, tackiness or a rubbery texture (258). In addition, amylose readily leaches out of the granule during gelatinization and interacts with the other food components (17,53,165). Under mild cooking conditions, amylopectin does not so readily leach from the granule and hence is enriched inside the gelatinized granule. However, in more extreme cooking conditions, the amylopectin is much more dispersed, resulting in products with a tacky or sticky character.

Once a cooked starch is allowed to cool, the glucan chains begin to reassociate in a process resulting in a change in the functional characteristics, including a decrease in paste clarity and gelation of the paste. In functional terms, this process of reorganization is known as retrogradation (7,70,176). Normal starches are generally recognized for their ability to retrograde within hours (175) and usually form opaque gels (41). Retrogradation

of amylopectin gels occurs during days or weeks of storage. As a consequence of their different molecular weights and chain length profiles, the rates of retrogradation of amylose and amylopectin are not the same. The rapid setting of the structure of breads is believed to be due to rapid (within seconds or minutes) amylose retrogradation to form a network structure. Starch functionality is therefore a consequence of the degree of gelatinization and is influenced by retrogradation, time, temperature, concentration, and the presence of other food components or additives. In addition, modifying starch using chemical, enzymatic, or physical treatments alters and extends its functional properties.

Measuring starch functionality and applying it to food applications is problematic because the results are subject to extrapolation to systems and processes which are far more complex than laboratory testing is able to emulate. Analytical instruments (e.g., Differential Scanning Calorimetry, DSC) are frequently used to quantify the temperature range and amount of energy needed to melt crystalline starch. The amounts and molecular size of amylose and amylopectin may be measured using gel permeation or size exclusion chromatography. Granule size and shape are measured microscopically or by light diffraction techniques, and granule viscosity is measured using various rheometers. Rheological measurements may include various temperature and shear programs that attempt to mimic thermal treatments, pumping, and shearing forces that occur during food processing. Such measurements of texture provide information on adhesiveness, cohesiveness, yield stress, viscous flow, and rigidity of starch sols and gels.

5.5.1 Amylopectin Retrogradation

Because retrogradation manifests itself in many ways and over many different spatial scales, establishing relationships between the structural orders and the physical properties of the starch are complicated. Thus, a number of techniques are required for such an assessment. NMR has been used to probe the most fundamental physical order of the starch: double helical order (71), and x-ray diffraction has been used to examine the crystallinity of starches (114). However, neither of these two measures of starch order adequately represents the rheological properties of a cooked starch paste because rheology is dependent on not just the order of the starch but also the larger scale interrelationships of this order with the covalent structure of the starch molecules themselves. There are additional problems that make relationships between low level molecular order and larger scale order difficult to establish: residual granular order (41,141,153) or polymer incompatibility (49,66,112) may result in macromolecular heterogeneity in the system. To avoid these complications, many investigators interested in starch retrogradation have examined the behavior of waxy-type starches (16,30,57,134,135,144,154,175,176,195,253). Likewise, the properties of amylopectin free amylose have been studied either by preparing synthetic amylose using glucose-1-phosphate and the enzyme phosphorylase (35,68,70,180), or by studying highly pure amylose fractionated from the native starch mixtures of amylose and amylopectin (116,126,209,239). Amylopectin retrogradation has been examined by multiple techniques including DSC (57,95,137,169,196,254), WAXS (175,176,217), turbidimetry (98,176), and rheology (16,30,55,111,117,176,253).

The length of a double helix, whether in a starch granule or in a retrograded starch, is limited by the length of the external chains participating in the double helix. Linear chain lengths of amylopectin are generally shorter than the DP 40 to DP 70 lengths observed for amylose double helices (103,129,138). Amylopectin double helices are generally observed to dissociate below 70°C by DSC (39) when the starch is in excess water (<30% starch). The DSC endotherm of retrograded amylopectins containing a higher proportion of longer chains than normal amylopectin (i.e., amylopectin from some mutant starches) may extend above 100°C. The endotherms from these mutant starches are also broader than an endotherm

observed for retrograded amylopectin from normal starch, perhaps indicating that amylopectin with longer external chains has an ability to form a broader distribution of double helical lengths than amylopectin with shorter chains. The absolute lower limit for the length of a stable double helix appears to be six anhydroglucose residues (69), the length required to complete one turn of a chain in a double helix (242,243). Practically, the lower limit appears to be closer to ten anhydroglucose units, given that in systems of a pure oligosaccharide, chains with a length (or degree of polymerization, DP) less than ten anhydroglucose units could not self associate into stable double helices and crystallize (69). However, this minimum appears to be somewhat dependent on the lengths of other chains available for double helix formation, because in mixed systems of short chain oligosaccharides chains longer than a DP of 6 may form double helices with longer chains.

As with double helical and crystalline formation with oligosaccharides, the ability for amylopectin chains to retrograde is closely related to the average external chain length (ECL) of the molecules. With stubs of DP 1, 2, or 3 anhydroglucose residues as external chains, β-limit dextrins of amylopectin do not retrograde after one month of storage at 4°C (176). Shortening the average ECL by just three anhydroglucose units (from 14 to 11) by alpha-amylase was sufficient to reduce the enthalpy and solid character (assessed by DSC and pulsed NMR, respectively) to 10% of those of the native starch (12,244). Chromatography of the modified starches was instructive, because it showed that the component chains of the starch do not all need to be equally shortened to have an effect on starch retrogradation: some chains were reduce to a DP less than 5, with the remainder remaining largely unchanged (12,244).

Examination of starches with intact chains (135,196,254) has indicated that starches with high proportions of chains below a DP of 11 to 12 have a slower rate of retrogradation than those starches with fewer short chains, irrespective of concentration. The retrogradation rate of starches with higher proportions of shorter chains is also more concentration dependent than for those starches with fewer short chains (57,135). However, conclusions from these studies must be tempered by any possible confounding effects of additional changes in the fine structure of the amylopectin (e.g., branching pattern).

5.5.2 Amylose Gelation

Amylose retrogradation has been monitored by the development of supramolecular organization using turbidimetric and rheological methods (35,48,56,70,141,142). Gels of amylose have been suggested to develop within minutes through the retrogradation of amylose into double helices (35,70) or through an initial phase separation of amorphous amylose, followed by retrogradation into double helices in these concentrated amylose regions. The aggregation event is followed by an additional retrogradation event: the development of double helical crystallites within hours (91,128,141,142). Increasing the chain length and concentration of the amylose both have a destabilizing effect on amorphous amylose in solution (70).

Destabilization of amylose may lead to retrogradation in the form of gelation, precipitation, or both. The relatively long, stable double helices of amylose result in more thermally stable gels than gels of amylopectin. In the formation of amylose gels, one outcome of amylose retrogradation, gel development is understood to be related to the ability of a single molecule to interact in double helical junction zones which bind molecules together into a three dimensional network structure, and the subsequent ability for the double helices to either orient or aggregate once formed (70,128). For synthetic, completely linear amylose, the network formation is possible for amylose molecules with a DP above 100 because these molecules are able to interact with more than one additional molecule to form a network (70). Precipitation, the other outcome of amylose retrogradation, is

favored over gelation for amylose molecules below a DP of 250, gelation is favored over precipitation for amylose molecules above a DP of 1100, and both network forming (gelation) and breaking (precipitation) retrogradation phenomena are similarly favored for amylose molecules with a DP of 440 and 660 (35). The concentration of amylose also influences whether amylose will gel or precipitate. Higher concentrations of amylose result in an increased frequency for chain to chain interactions, which would both increase the rate of gel development and decrease the time required for the onset of a three dimensional network.

Amylose gels prepared in water have been described as phase separated systems consisting of a solvent rich phase and a filamentous polymer rich phase consisting of bundles of amylose chains (74,91,129,222). Portions of amylose chains that participate in the double helices residing in the crystalline regions of amylose gels have been estimated to range in length between DP 40 and DP 70 (103,128,137,138). As measured by DSC, the double helices of amylose appear to dissociate over a very broad temperature range (~50°C) with an endothermic peak temperature between 120°C and 160°C (23,37,117,129,202).

5.5.3 Gelation of Mixtures of Amylose and Amylopectin

Understanding the retrogradation behavior of normal starches, considered as mixtures of amylose and amylopectin, is even more complex than understanding amylose or amylopectin retrogradation in isolation. This is due to the possibilities for phase separation of the two types of molecules and for interactions between amylose and amylopectin to develop.

Cooked normal starches have been considered phase separated systems of swollen granules consisting of amylopectin trapped within a continuous gel matrix of leached amylose (141,153,167). In these systems, the amylose and amylopectin behaviors appear to be relatively independent of each other: the amylose forms a thermally irreversible (at $<$100°C) gel network within hours, followed by a thermally reversible increase in gel elastic modulus attributable to an increase in granule rigidity due to amylopectin retrogradation (113,141,167). In the absence of granular order, amylose and amylopectin mixtures have been shown to phase separate over time (66,111). Examination of gels of artificial mixed systems of amylose and amylopectin showed that over a small increase (10–15% w/w) in the amylose content of gels (from 25 to 40% amylose on a total starch basis), the gels developed the behavior of pure amylose gels in their rate of turbidity development (49), their elastic modulus, and their susceptibility to enzymatic and acid hydrolysis (128). Both groups suggested that a phase inversion from an amylopectin to an amylose continuous phase at an amylose to amylopectin ratio of about 30:70 or about 17:83 was the cause of the observed differences in gel characteristics at high and low amylose to amylopectin ratios. The differences may have been with the starches and concentrations used, with the methods of preparation of both the amylose and amylopectin prior to mixing, and the method of mixing the amylose and amylopectin. From examination of the fracture of gels of jet cooked high amylose maize starches prepared between temperatures of 121°C and 166°C, it was hypothesized (33)that higher processing temperatures resulted in more homogeneous mixtures of amylose and amylopectin than processing at lower temperatures, and that the more homogeneous mixtures would take longer to phase separate and gel during cooling at a constant rate. The delay in phase separation during cooling was thought to result in phase separation and gelation at lower temperatures, resulting in weaker gels due to the more rapid formation of a less perfect gel network.

Others have suggested that amylose and amylopectin interact more extensively than suggested by the relatively independent behavior of mixtures of phase separated amylose and amylopectin (101,117,168,190) and that the short chains of branched molecules interfere with the molecular association of amylose molecules (23,117). In gels prepared from reconstituted mixtures of amylose and amylopectin, the chain length distribution of the

amylopectin, the size of the amylopectin, and the amylose content appear to influence the formation and properties of starch gels. From examination of gels formed by waxy maize starch (considered amylopectin) and oligosaccharide chains with a DP of 21 or 35, linear chains as short as DP 21 appear sufficient to form junction zones with multiple amylopectin chains resulting in a gel (190). Acetylation, substitution of the hydroxyl groups of the starch with structure-inhibiting moieties, also appear to destroy the gel-forming ability of the amylopectin, and the addition of amylose instead of the oligosaccharides appears to result in stronger gels. Substitution was suggested to limit associations preventing gelation, but was not sufficiently high to prevent gelation in the presence of amylose or short, linear chains (190). Using a variety of amylopectin sources with different chain lengths and a consistent source of amylose and ratio of amylose to amylopectin ratio (20:80), the strongest gels appear to form from the mixtures containing the amylopectin with the longest chains (101). Using 25:75 or 50:50 (w/w) mixtures of amylose with either *wx* starch or small, medium, or large dextrins prepared from waxy maize starch, gels prepared with the medium sized dextrins, irrespective of amylose content, formed weaker gels than gels prepared from the other dextrins or the *wx* starch (168). Examination of starches by DSC shows that amylose appears to retrograde independently when the starch is heated to temperatures below 140°C, but does not do so when heated to temperatures above 160°C in an excess water environment (23). Further, dynamic shear rheology of these same starches indicated that the length of these double helices formed between amylose and amylopectin was dictated by the length of the external chains of the amylopectin: when gels prepared from mixtures of completely dispersed starches were heated, the decrease in the elastic modulus paralleled the decrease in the elastic modulus for the amylopectin isolated from the starch (117).

5.6 APPLICATIONS

As well as providing essential calories, starches from different crops play an important role in foods, such as improving processing, shelf life, consistency and appearance by providing texture and thickening capability for suspending solids. There are myriads of applications of starches in foods and these uses have been extended due to application work by food technologists using physical and chemical modifications (designated by E-numbers in the EU). These include oxidation (E1404, E1451), monostarch phosphorylation (E1410), distarch phosphorylation (E1412), acetylation (E1414, E1420, E1422), hydroxypropylation (E1440, E1442), and octenylsuccination (E1450). In this section, we will focus on starch applications of various genetic modifications of the major crop plants and how these modifications impact the uses of these starches in foods. In particular we will emphasize modifications in amylose and amylopectin content and molecular weight, amylopectin chain length, starch granule size and morphology, crystal structure and phosphate content. We will conclude with a discussion of new opportunities for enhanced starches resulting from new genetic modifications of plants.

5.6.1 Amylose Free Starch

The most widely used amylose free starches are obtained from waxy maize and rice and in all cases are considered non-GM natural variants of normal maize and rice. Staining starch with iodine readily identifies amylose free types: normal starch will stain blue or purple whereas the starch produced from amylose free plants will stain red or brown or brownish red in color. Amylose free maize starches are generally considered to contain zero or almost zero amylose. Amylose free rice starches have been shown to contain

between 0 and 3% amylose, though collectively these starches are referred to as amylose free or waxy rice starches (109,173,185). With these amylose free rice starches, it has been assumed that the differing cooking and paste properties are due to differences in the structure of the amylopectin of the starch rather than variations in the low levels of amylose of the starch (234). The effects of amylose and other molecular and compositional characteristics of rice starches on rice (19,34) or rice starch properties remain unclear (125).

Amylose free starches have useful functionality that has encouraged their commercial development. They are considered useful as water binders, viscosity builders, and texturizers in food as well as in industrial applications (171). However, these starches are less resistant to shear, acid, and high temperatures than are normal starches, and extended cooking results in stringy, cohesive pastes. Amylose free starches are generally recognized for their improved transparency after processing compared to normal starches (41) and have better freeze and thaw stability compared to normal starches once cooked (171,237). They are also recognized for their improved long term storage capability as they require weeks to gel if they could be considered to gel at all (15,253). To correct for some of the negative paste attributes of amylose free starch, such as poor stability to temperature, shear and acid and undesirable paste quality, most amylose free starches are chemically modified by substitution, cross linking, or both (171,238,256).

In recent years there has been significant interest in developing amylose free starches in other crops so as to take further advantage of any species specific qualities of the starch produced from that species. However, although mutants are readily found in some plant species (such as maize, rice, and barley) this is more difficult in other plant species where there are multiple copies of each gene (such as the polyploid species like potato, oats, and wheat). In the case of wheat, the advances have been made by screening for mutants (non-GM), while in potato the waxy types were made using biotechnology (GM). Applications of amylose free wheat and potato are at present still being developed. However, the most likely applications for amylose free potato include the paper, adhesive, textile, and packing industries. In the EU, certain GM varieties of modified amylose free (high amylopectin) potato have not been approved thusfar (http://europa.eu.int/comm/food/fs/sc/scp/out24_en.html), while others appear to be in the approval process (http://europa.eu.int/comm/food/fs/sc/scp/out129_gmo_en.pdf). Amylose free wheats are finding applications in foods such as noodles and baked goods including breads (5,247).

5.6.2 Low Amylose Starch

Although staining starch with iodine readily identifies amylose free starches (161), care must be taken when using this quantitatively to adequately account for the iodine binding capacity of the amylopectin (120). For example, amylopectin from an amylose free plant having an inactive GBSSI enzyme might appear to contain 5% amylose based on iodine binding, blue value, measurement (116). After carefully considering these potential problems certain low amylose starches have been identified. For example, in the early 1940s, a waxy maize mutant (wx^a) was discovered in two exotic Argentinean small seeded flint varieties that contained a starch that had an amylose content of 2.4% and stained a pale violet color with iodine (26). Additionally, the amylose content of the starch increased from 0% (full waxy) to 0.65% to 1.3% to 2.4% (full wx^a) with increasing dose of the wx^a allele (26,204). With these same crosses, the viscosity of starch pastes decreased with increasing dose of the wx^a allele. The wx^a allele was described as resulting in a 95% reduction in the amount of GBSSI protein produced and a starch with a low amylose content (174, 204,261).

Wheat starches have been produced with amylose contents of about 7.5% and 13.5% by crossing normal wheat with amylose free wheat (188). Peak viscosities of all starches

differed by less than 20% of the peak viscosity of the amylose free wheat starch, with the low amylose starches having a higher peak viscosity than both normal and waxy wheat starch. The gelatinization temperatures and enthalpy were highest for waxy wheats and decreased in the order waxy > 13.5%, amylose wheat > 7.5%, and amylose wheat > normal wheat starch. The retrogradation temperatures and enthalpy were insignificantly different for amylose free wheat, normal wheat, or any of the low amylose wheat starches. Starch granules extracted from a wheat strain derived from mutagenized Tanikei A6099 had an apparent amylose content of 1.6% and stained dark brown with dark cores compared to red-staining waxy wheat starch with 0.4% apparent amylose (115). The Tanikei A6099 mutant wheat starch had a higher initial pasting stability than an amylose free wheat starch (0.4% amylose). However, the viscosity of the low amylose starch paste decreased dramatically, to the same viscosity as the amylose free wheat, during continued cooking and remained at the same viscosity as amylose free wheat after cooking. The mutagenized Tanikei A6099 wheat is known to produce a mutant GBSSI enzyme (115,248).

By screening microtubers from plants exposed to x-ray radiation an amylose free mutant of potato was identified (88). Potato starches considered amylose free have been shown to have an amylose content varying from 0 to 7.9% (183,204,223,224). The amylose free potatoes were null for the GBSSI enzyme. Staining with iodine gave varied results: sometimes the starch stained red and other times reddish brown and blue. These results are indicative of a heterogeneous mixture of amylose free starch and amylose containing starch of unknown quality within the potato tuber. In further attempts to understand the link between function and activity of GBSSI in potato, antisense transgenic plants having amylose contents between 3.0 and 8% were produced (123,224,228). These tubers had both blue and red brown staining portions (228) again indicative of heterogeneous mixtures of amylose free starch and amylose containing starch of unknown quality. Others (123) observed additional heterogeneity at a granule level, with starch granules having blue cores surrounded by a red brown shell of starch. The size of the blue core appeared to be correlated with the amylose content of the starch**.** Starch extracted from plants produced from crosses between an amylose free potato and a normal potato had no linear correlation between GBSS activity and amylose content (58). Additionally it was observed that the swelling and rheological properties of the granules could not be clearly linked with amylose content (183).

The waxy barley starches have been shown to contain up to approximately 5% apparent amylose (215). However, this apparent amylose is due to a mixture of starch granules within the barley seeds. The amylose content of the granules typically ranges from an undetectable level up to approximately 10%, with the granules closest to the surface of the seed having the highest amylose content (3). Recent work with waxy barley starch (with amylose contents up to 6.44%) shows delayed peak viscosity development and viscosity varying during cooking under shear (132). Additionally, all of the waxy barley starches began to develop viscosity at a similar time and temperature in the cooking process.

Low amylose rice starches have been shown to have amylose contents between 7 and 15% (124). Shimada et al. (199) produced several antisense rice plants with starch having an amylose contents between 6 and 13%. The iodine staining qualities of these starch granules were not reported. Further, any cooking properties of the starches, the elastic properties and gelling abilities of pastes and the gel properties of gels produced from these low amylose rice starches produced by transgenic rice plants are unknown.

5.6.3 High Amylose Starch

Commercialized high amylose maize starch is a result of down regulation of the maize BEIIb enzyme, utilizing the *amylose extender* mutation. High amylose maize starches

bring important differentiated properties for food applications, having amylose contents between 30 and 90% of the weight of the starch. The starch imparts gelling ability to the food system, improving adhesion to water impermeable surfaces and altering product texture. These starches also have improved film forming ability and improved fat impermeability compared to the normal starch counterparts. High amylose starches provide firmness, extend cooking times and increase the crispiness of coatings.

Because of their high resistance to processing and subsequent digestion, in addition to their rapid retrogradation if gelatinization occurs, high amylose maize starches are also being utilized as a source of resistant starch in a number of food products. Reviews (43,79,93) provide an overview of resistant starch and its valued physiological benefits in foods. Commercialized resistant starches include unprocessed starches from different botanical sources (e.g., green banana, legumes, potato) as well as more highly processed forms of high amylose starches. High amylose starches from other sources are also being advocated for their resistant starch properties.

The most widely available high amylose starches originate from maize using the *amylose extender* mutation that results in a starch having 40–50% amylose. As a result of extensive breeding and selection work higher amylose contents (up to 90%) have been achieved (201). High amylose starches are also available in barley and rice.

5.6.4 Amylopectin Chain Length

As already stated, care must be taken when using the iodine binding assay for quantifying amylose content. In a more extreme example of this problem, the combination of the absent GBSSI activity and the *ae* mutation produces an amylose free maize starch that stains blue or purple and appears to have an amylose content of 15–26% (194). This is because the *ae* mutation causes a decrease in starch branching enzyme activity (24), which results in the formation of long chain amylopectin (104), which will itself stain blue with iodine. Other examples of this come from genetic modifications that affect amylopectin structure.

Loss of SSIIa activity in maize results in a starch with an amylose content near 40% of the total starch weight. This starch develops viscosity very slowly at temperatures above 90°C and forms stable gels that strengthen only very slowly compared to normal starch gels (31). The loss of SSIIa activity resulting in elevated amylose contents highlights the often observed disconnect between the viscosity development of the starch and the thermally detected gelatinization of the starch. Despite the resistance of the starch to develop viscosity, likely a consequence of the elevated amylose content, loss of SSIIa activity results in a decrease in the gelatinization temperature range of the starch from about 70°C to 80°C for normal starch to approximately 55°C to 65°C (31,21). Examination of the chain length distribution of the maize starch in combination with the absence of amylose, as a result of the inactivity of GBSSI, indicates that the starch has a elevated proportion of short component chains below a DP of 30 compared to normal starch (212) and additionally an elevated proportion of very short component chains below a DP of 10 compared to normal starch (94,134). This high proportion of very short chains imparts a decreased tendency to retrograde compared to normal starch (134,135).

Recently, potatoes have been engineered to eliminate both SSIIa and GBSSI activity, resulting in an increase in short chains below a DP of 14 compared with normal starch (108). This had the benefit of a decrease in the tendency for the starch to retrograde after cooking which may have implications for improved freeze and thaw tolerance. Potatoes engineered to have reduced SSIII activity had decreased amounts of chains longer than DP 17 (60).

The SSIIa enzyme of rice has been implicated as one of the major enzymes that affects whether the grain is of the indica-type vs. the japonica-type (221). Indica-type rices have been long known to have higher kernel integrity and higher granule stability than

japonica-type rices (131). The properties of indica rice starches have been attributed to their higher proportion of longer chains than japonica-type rice starches.

It has been known for some time that the inactivation of SSIII in the dull mutant of maize results in an elevation in the apparent amylose content to 30 to 40% (81). Beyond this, a number of chromatographic studies on dull starches, including those additionally lacking GBSSI enzyme activity, indicate that the chain distribution of maize starch is only slightly different from normal starch, with some elevation in the chains with a DP less than 30 to 50 (94,196,254). The beta-limit dextrins, starches with the exterior chains digested to stubs of maltose to maltotriose, provide a more complete picture of the changes observed with elimination of SSIII in maize. In this case the lengths of the residual chains containing all of the branching are considerably shorter when SSIII is absent during synthesis. It has been suggested (135) that this change has implications for the retrogradation of starch produced in the absence of SSIII. Thus, during gelatinization and then continued heating after gelatinization, the starch chains are less able to randomly orient themselves compared with starches having longer spacing between branch points (i.e., normal or waxy starch). Thus, the retrogradation rate of *du wx* starch is less concentration dependent than *wx* starch despite the similar chain length distributions of the two starches after debranching.

5.6.5 Novel Starches

Recent developments in biotechnology are opening ways of making novel starches in plants. Thus starches obtained from different crops having varied functionalities due to differences in composition may now theoretically be readily transferred into crops from one or another different plant species. In recent years a number of patents have been filed covering novel genetic modifications of starch in plants. Examples include WO09711188, WO008184, WO09961580, WO9814601, WO9404692, WO09601904, WO09729186, WO014246, WO9924593, WO9839460, WO047727, WO011192, WO9929875, WO9747806, WO9747807, WO9747808, and WO9822604. In general we can consider making changes in any aspect of amylose/amylopectin, phosphate, protein, phospholipids, crystallinity, gelation, and pasting characteristics, flavor and starch granule morphology. One merely has to understand the genetic basis of the differences.

One interesting example of a cross species difference that may be exploited is phosphate content in potato. Recent work (177) has shown that starch phosphate content may be attributed to a novel glucan water dikinase enzyme. This discovery opens up the possibility of creating novel genetically modified starches having varied phosphate contents. Although it is too early to conclude whether there would be useful applications in food, possibilities include changing starch digestibility or starch viscosity after cooking. Another interesting character in one species that is not available in others is associated with the genes responsible for endosperm texture in some cereal crops. In this case the puroindoline genes, described as PinA and PinB are interesting candidates (14,72,86,152). Transforming the wheat genes into rice successfully created the softness trait in the seed (121). At this time it is still too early to say how useful this character will be in food applications.

Although starch granule morphology varies extensively across species (102) and starch from different species is highly valued for certain applications, there are few specific reports that granule morphology is the attribute desired for valuable food applications. Furthermore, although there have been some reports of progress in understanding the mechanisms that control and influence starch granule size (28,29,122), for granule morphology there is little that can be defined as clear enough to arouse interest in a genetic approach. Similarly, flavor can be considered to vary extensively across species and a bland flavor of (e.g., tapioca starch) is valued over certain cereal starches that impart a mealy character. However, as with granule morphology, our understanding of the genetic components

determining this character is rather poor, making flavor a difficult target for genetic modification at the present time. Thus in these cases it is difficult to see a way of using such differences in granule morphology and flavor to exploit that character in another species.

Another novel concept has come from bifunctional domains involving cellulose and starch, which may enable developments with novel biomaterials (130). Another possibility is to explore incorporation of inulins with starch (80). Even more novel possibilities to consider include adding new functionality to starch using gene constructs containing fusion proteins (106). The fusion proteins can be proteins, which might affect starch properties or enzymes, or other bioactive proteins.

Bioprocessing of Starch Using Enzyme Technology

K. Ravi-Kumar and S. Umesh-Kumar

CONTENTS

6.1 INTRODUCTION

Starch is a polymer of glucose produced by the plants as their principal food reserve: polysaccharide. Starch is stored in seeds such as cereals and millets, and tubers such as tapioca (cassava) and potato. Starch is a major source of carbohydrates for human and animal diets. Starches, or their liquefied products, are found in almost every processed food. In the U.S.A, fructose syrups are the primary sweeteners.

In its native state, starch is crystalline; the shape of the granules varies according to the source of starch. Because starch granules have the property to swell reversibly in cold

water, they are used in industrial applications to loosen the starch protein in grain matrix. Starch irreversibly swells, forming a paste; when boiled in water this process is called gelatinization. The result increases the viscosity of a food product.

Structurally, starch can be separated into two polymers called amylose and amylopectin. Amylose is a linear polymer of D-glucose units linked together by α-1,4-glucosidic linkages, whereas amylopectin has branching at α-1,6 positions of starch. The concentration of amylose and amylopectin in each plant varies. Waxy starches from maize contain 2% amylose and 98% amylopectin, whereas most starches contain 15–30% amylose. A starch granule exists in a ring structure of amylose and amylopectin extending from the hilum toward the edge of the granule.

Starch hydrolases act either by cleaving α-1,4 and α-1,6 glucosidic bonds at random positions, releasing oligosaccharides of different chain lengths called dextrins or from the nonreducing ends of the starch molecules, successively releasing D-glucose (Figure 6.1). Smaller chain lengths of starch molecules such as disaccharides and oligosaccharides are also substrates for specific enzymes. Hence, enzyme processing of starch defines processes for the preparation of food components, substrates for the production of beverages, and industrial alcohol using microorganisms. The processing also defines technologies for modified starch components used in paper, textile, soaps, cosmetic, and pharmaceutical industries.

6.2 ENZYMES INVOLVED IN STARCH DEGRADATION

Microorganisms are the major source for starch hydrolases, generally called amylases (Table 6.1). The number of amylases produced by microorganisms in culture can be easily identified by performing enzyme zymograms after electrophoresis (Figure 6.2) in starch incorporated sodium dodecyl sulfate containing polyacrylamide gels (SDS-PAGE) under nonreducing condition (18). Amylases are classified according to the specific glucosidic bond they cleave as α-1,4-glucanases or α-1,6-glucanases. Endoglucanases act on interior bonds of starch while exoglucanases cleave the bonds successively from nonreducing ends of starch. Activities of amylases result in smaller molecules called dextrins, disaccharides, and monosaccharides. Glycosyl transferases are enzymes that synthesize cyclic molecules from starch.

6.2.1 α-Amylase (1,4-α-D-glucan Glucanohydrolase EC 3.2.1.1)

α-Amylases are α-1,4-endoglucanases that rapidly decrease starch viscosity, resulting in oligosaccharides. Some of the α-amylases produce higher concentrations of mono- and disaccharides; they are classified as saccharifing α-amylases. α-Amylases that reduce starch viscosity by producing precursor products for mono- and disaccharides are called liquefying enzymes. Though bond specificity for this enzyme is for α-1,4 linkages, some enzymes acting on α-1,6 linkages of starch molecule have also been reported (19). End products of the reaction result in oligosaccharides with α-configuration at the first carbon. Several of these enzymes, acting at temperatures above 60°C (normal gelatinization temperature of starch molecules), have been identified and characterized from bacterial sources. The enzyme most stable to high temperature, acting at temperatures above 100°C, has been described from *B. licheniformis* by Novo industries (20).

α-Amylases of bacterial origin are extracellular and act at near neutral pH. However, the pH optimum of an enzyme from *B. stearothermophilus* was reported to be dependent on temperature (10). α-Amylases active at pH as high as 9.0 and 11 have been described from alkalophilic *Bacillus spp* (21).

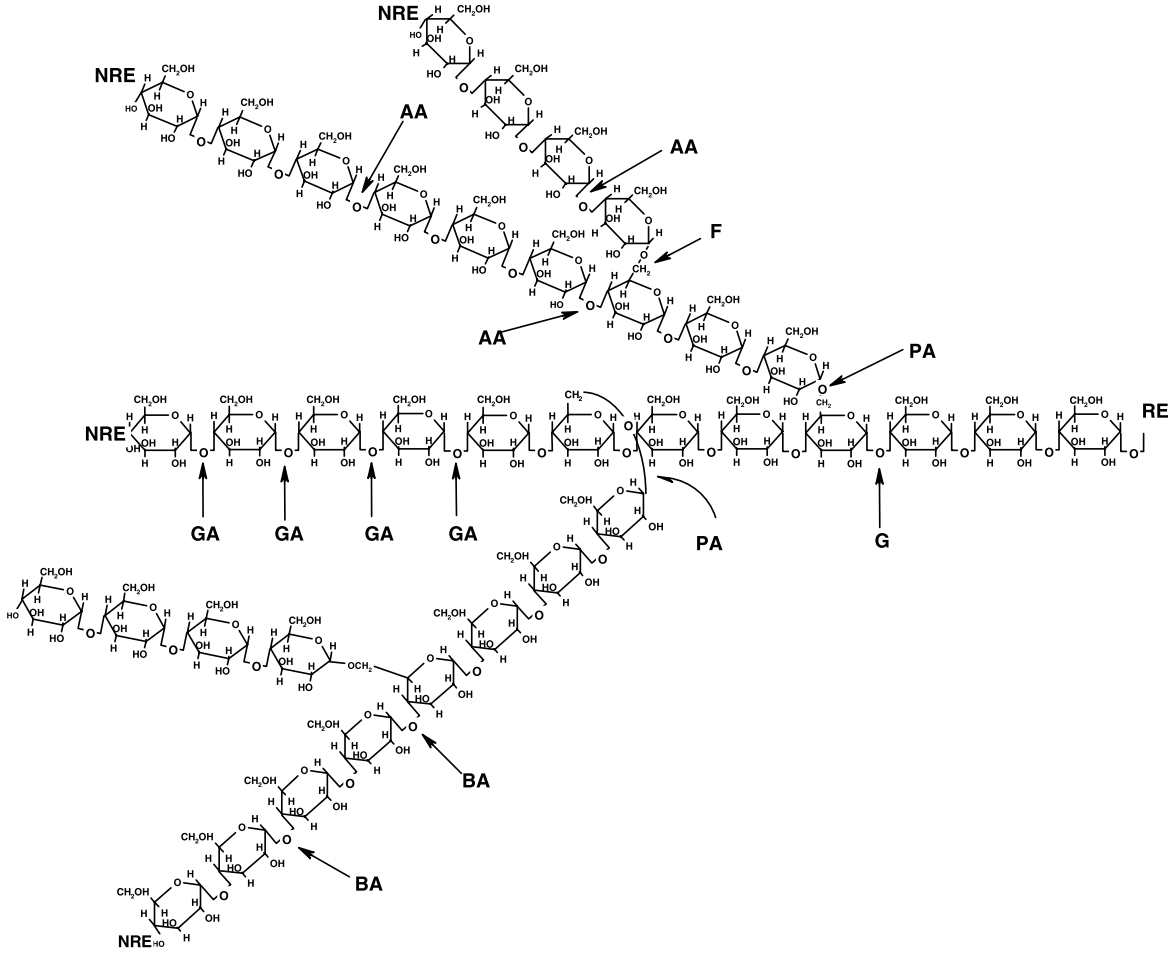

Figure 6.1 Action of different amylases on starch molecule

AA – α-Amylase (Endo 1,4-α-D-glucan glucanohydrolase), GA – Glucoamylase (Exo 1,4-α-D-glucan glucanohydrolase), BA – β-Amylase (Exo 1,4-α-D-glucan maltohydrolase), PA – Pullulanase (Endo α-dextrin 6-glucanohydrolase), RE – Reducing end, NRE – Non reducing end, F – α-1,6-glucosidic linkage, G – α-1,4-glucosidic linkage.

Table 6.1
Amylases of microbial origin

Microbial Source	Amylase Produced[a]	Activity on Starch	Ref.
Aspergillus awamori	Glucoamylase	Exo	1, 2
	α-Glucosidase	Exo	1
A. niger	α-Amylase	Endo	3
	Glucoamylase	Exo	4
	α-Glucosidase	Exo	5
A. oryzae	Taka-Amylase	Endo	6
	Glucoamylase	Exo	7
Bacillus amyloliquefaciens	α-Amylase	Endo	8
B. licheniformis	α-Amylase	Endo	9
B. stearothermophilus	α-Amylase	Endo	10
B. subtilis	α-Amylase	Endo	11
B. megaterium	α-Amylase	Endo	12
B. acidopullulyticus	Pullulanase	Endo	13
Clostridium thermosulfurogens	β-Amylase	Exo	14
Chalara paradoxa	α-Amylase	Endo	15
Lactobacillus amylovorus	α-Amylase	Endo	16
Thermomonospora viridis	Maltogenic amylase	Endo	17

[a] α-Amylases, α-Glucosidases, Taka-amylase, β-Amylase and Maltogenic amylase cleave α-1,4-glucosidic linkages; Pullulanase cleaves α-1,6-glucosidic linkages; Glucoamylases cleave both α-1,4 and α-1,6-glucosidic linkages.

α-Amylase stability at high temperatures requires calcium ions for maintaining the protein conformation at high temperatures (22). However, for *B. licheniformis* thermostable α-amylase, the calcium requirement is low (23). Inhibition of the enzyme activity by calcium ions has also been reported (24). Modeling of *Bacillus* α-amylase suggested conserved regions for calcium binding and the amino acids between 116 and 127 are involved in calcium binding in *B. subtilis* α-amylase (25). In *B. amyloliquefaciens,* calcium is bound outside the active center (26). In *B. subtilis* Taka-amylase, calcium is bound to the SH group of cysteine (27). α-Amylases of bacterial origin contain tryptophan, tyrosine, and histidine in their active sites (28).

The three dimensional structure of Taka-amylase (α-amylase of *Aspergillus oryzae*) and *Bacillus* α-amylase revealed that seven glucose units of the substrate are bound by at least two amino acids on the surface of the molecule. In this reaction, calcium binds close to the active center, apparently to stabilize the cleft in the active center (28). The catalytic site of Taka-amylase contains conserved aspartic acid at positions 206 and 297 of the protein chain. Protein engineering of *B. stearothermophilus* α-amylase revealed that aspartic acid is in the catalytic site at 331 position (28).

6.2.2 Glucoamylase or Amyloglucosidase (1,4-α-D-glucan Glucanohydrolase EC 3.2.1.3)

This enzyme catalyses release of glucose from the nonreducing ends of starch, dextrins, and maltose. Glucoamylases occur widely in microorganisms and plants with filamentous fungi as the major source of the enzyme (29). *Rhizopus* glucoamylase hydrolyses both α-1,6 and α-1,4 linkages of starch molecule with equal efficiency compared to the *A. niger* glucoamylase, which has higher affinity for α-1,4 linkages of starch (30).

Glucoamylases occur as multiple forms in several fungi. Because all fungal glucoamylases are glycoproteins, the difference in molecular mass was attributed to varying

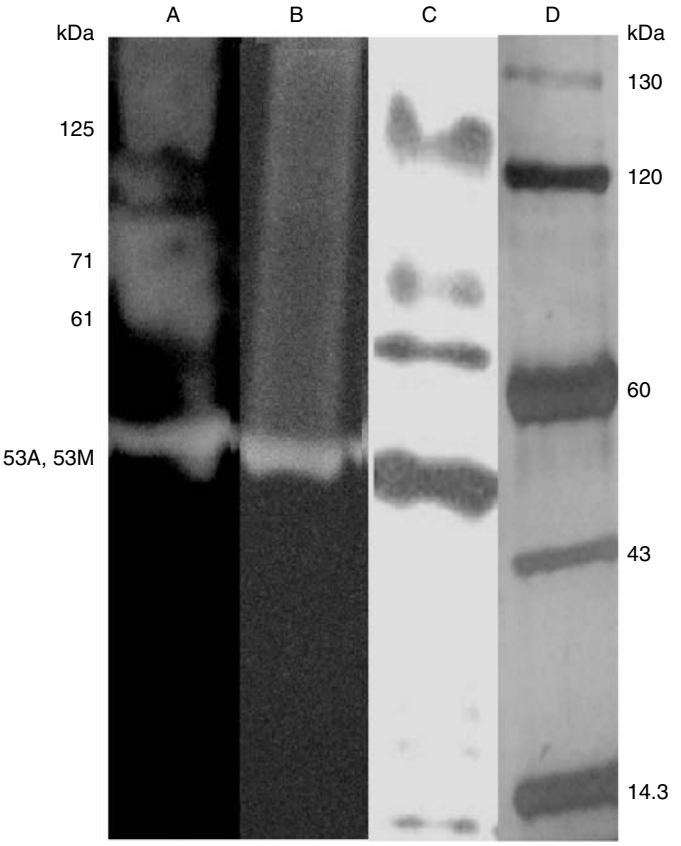

Figure 6.2 Amylases of *A. niger* identified as zymogram reactions after SDS-PAGE performed under nonreducing conditions in 10% acrylamide gels. Haloes correspond to enzyme activity as determined after iodine addition. A. Zymogram at pH 4.3; B. Zymogram at pH 6.0; C. Corresponding silver stained amylase proteins; D. Protein Standards. 125-Starch Hydrolyzing enzyme; 71 and 61-Glucoamylases; 53A-α-amylase (active at pH 6.0); 53M-Taka amylase (active at pH 4.3).

amounts of carbohydrate moieties. The glucoamylases of molecular mass 71 and 61 kDa from *Aspergillus niger,* referred to as G1 and G2, have been extensively studied. It was initially believed that there were two glucoamylases because of differential splicing of mRNA encoded by a single gene that contained a number of intervening sequences (31,32). But it was shown that the 61 kDa G2 protein came from a proteolytic splitting off of a 10 kDa peptide from the 71 kDa G1 protein C-terminus (33). The activity differences of G1 and G2 on raw starch were determined to be the C-terminus peptide. Recently it was shown that a 125 kDa precursor starch hydrolysing enzyme is the major enzyme in *A. niger* and this enzyme is apparently processed by proteases to give rise to 71-, 61-kDa glucoamylases and 53 kDa Taka amylase enzyme (18).

Glucoamylases of fungal origin contain about 28% carbohydrate, which is responsible for the maintenance of the enzyme conformation (28). The carbohydrate is *O*-glycosidically linked to serine and threonine of the protein. Glucoamylases have optimum activity at acidic pH and act at temperatures around 60°C. Tryptophan residues have been proposed to be essential for enzyme activity (34). Biochemical analysis after site directed mutagenesis of glucoamylase gene indicated that tryptophan 120 is essential for transitional state

stabilization (34). Glutamic acid 179 and 400 were identified as general catalytic acid and base catalyst respectively (35,36).

6.2.3 β-Amylase (1,4-α-D-glucan Maltohydrolase, EC 3.2.1.2)

Occurrence of β-amylase is common in plants and perhaps the best characterized enzymes of microbial origin are of *Clostridium thermosulfurogenes* (14) and *B. polymyxa* (37). β-Amylase hydrolytically cleaves the penultimate α-1,4 bond at the nonreducing ends of starch and causes the production of anomeric β-maltose. Because the enzyme cannot act on α-1,6 linkages of starch, it also produces β-limit dextrins.

Plant β-amylases are not thermostable. The enzyme of the thermophilic anaerobe *C. thermosulfurogenes* is thermostable, maintaining its activity at 80°C for two hours in the presence of 5% starch (28). Cysteine residues seem to be essential for both activity and conformation of β-amylase.

6.2.4 Isoamylase (Glycogen 6-glucanohydrolase, EC 3.2.1.68)

This enzyme predominantly degrades α-1,6-glucosidic linkages of amylopectin, glycogen, dextrins, and oligosaccharides. Its low affinity to short chains of pullulan makes this substrate less susceptible to the enzyme activity. Isoamylases have been characterized from *Bacillus spp*. (38,39). Molecular mass of the enzyme from microbial sources range from 65–121 kDa.

6.2.5 Pullulanase (α-dextrin 6-glucanohydrolase EC 3.2.1.4)

Very few organisms produce this enzyme that hydrolyse α-1,6 linkages of pullulan. Their molecular mass range from 80–145 kDa. Pullulanase of *C. thermohydrosulfuricum* and *B. acidopullulyticus* are thermostable with optimum activities in acidic pH (4.9–6.0).

6.2.6 α-Glucosidase, (α-D-glucoside Glucohydrolase EC 3.2.1.20)

α-Glucosidases are exoacting enzymes that catalyze the splitting of α-glucosyl residue from the nonreducing terminals of substrates to liberate α-glucose. Typically they are called maltases, because they hydrolyse maltose to glucose.

Fungal α-glucosidase has a wide substrate specificity degrading starch, dextrins, and maltose (5). The enzyme purified and crystallized from *A. niger* was a glycoprotein of molecular mass of about 125 kDa as estimated by SDS-Polyacrylamide gel electrophoresis. The activities of this enzyme resembled that of glucoamylase.

6.2.7 Glucose Isomerase or Xylose Isomerase (EC 5.3.1.5)

A range of microorganisms like *Streptomyces*, *Bacillus,* and *Arthrobacter* normally produces glucose isomerase or xylose isomerase intracellularly. Glucose isomerase generally act at 60°C, isomerising glucose to fructose. Because its affinity for glucose is low, a concentrated solution of substrate is used for isomerization reaction. The molecular mass of the enzyme range from 80 kDa in the case of *Actinoplanes missouriensis* to 157 kDa in the case of *Streptomyces spp*. This enzyme is strongly inhibited by Ca^{+2} and Mn^{+2}. However, it requires magnesium for activity and cobalt for maintenance of stability.

6.3 STARCH PROCESSING

Starch based derivatives are produced industrially for different applications. In its unmodified form, starch obtained from cassava is used in puddings, fruit fillings, and biscuits. Acid modified starches such as the dextrins find applications in baby food formulations.

They have also been used in the paper and textile industries. Hydrolyzed starches form substrates for sweeteners and brewing industries.

In the early years, starch was processed using concentrated acid at high temperature and pressure. By this procedure, the yield of products was inconsistent. Starch loss due to retrogradation (spontaneous precipitation of starch) was also a major constraint in the acid hydrolysis process. Advent of enzyme reactions and their suitability for application in starch processing has nearly replaced the acid hydrolysis processing of starch. Discovery of thermostable amylases and specificity of the enzymatic reactions upgraded industrial processing of starch, Product yields were in order obtain products consistent with defined end points, thereby saving on. This saved processing cost by reducing starch loss due to retrogradation.

The primary step in starch hydrolysis for processing (Figure 6.3) is its gelatinization at high temperatures followed by a thinning reaction. Discovery of bacterial α-amylases like Termamyl from *B. licheniformis,* which was stable even at temperatures as high as 104°C, completely replaced acid hydrolysis of starch, making enzyme technology a viable process. Use of this enzyme permitted, processing of even 30% starch slurries in steam jet cookers. Being a liquefying enzyme, the dextrins produced due to the activity of thermostable α-amylase constituted nearly 70% of the product. From these simple starch molecules, cyclodextrins can be created with the enzyme cyclodextrin glycosyl transferase. Cyclodextrins find applications as carriers of fragile vitamins and flavors. Only enzymatic synthesis of cyclodextrins is possible, because no chemical means exist for making this class of substance.

Two and three stage enzyme processing of starch hydrolysed with thermostable α-amylase defined clear protocols for industrial production of glucose, maltose, fructose, and limit dextrins.

6.3.1 Production of Sweeteners and Confectionaries

Enzymatically hydrolysed starch has been used in the manufacture of syrups (glucose, maltose, and fructose), baby food formulations (dextrins), and in confectionaries (maltose and β-limit dextrins).

Glucose is produced from starch in two stages. In the first stage, starch is gelatinized at temperatures ranging from 105–110°C and liquefied to reduce viscosity using thermostable α-amylase to evolve α-limit dextrins. The enzyme reaction is performed at pH approximately 7.0 to maintain the enzyme stability. In the second stage, glucoamylase or β-amylase enzymes are used to produce glucose and maltose syrups from the dextrins respectively. Glucoamylases and β-amylases act at acidic pH (3.5–5.0 and 4.8–6.5 respectively) and at temperatures around 60°C. Hence, the dextrin solution evolved from the thinning reaction is acidified to the required pH and cooled prior to enzyme action. *Aspergillus* is the major source for commercial glucoamylase. Because the enzyme is slow acting on α-1,6-linkages of dextrins, pullulanase is added along with glucoamylase to improve enzyme efficiency to evolve glucose syrups containing 95–96% glucose in shorter periods of time (40). Glucoamylases are also known to catalyze reversible condensation of glucose into isomaltose at higher concentrations of glucose. Hence, technologies describing glucose syrup production define a very low concentration of glucoamylase to prevent reversible reactions (40).

In the manufacture of maltose syrups, the dextrins obtained from gelatinized starch after α-amylase treatment is further hydrolyzed using thermostable β-amylase. Products of this enzyme activity evolve β-maltose and β-limit dextrins. α-1,6-Glucosidic bonds of dextrins are resistant to β-amylase activity. Simultaneous treatment of the dextrins with β-amylase and pullulanase improves the yield of maltose, but the process efficiency is reduced due to condensation reaction of maltose to form branched tetra-, penta-, and

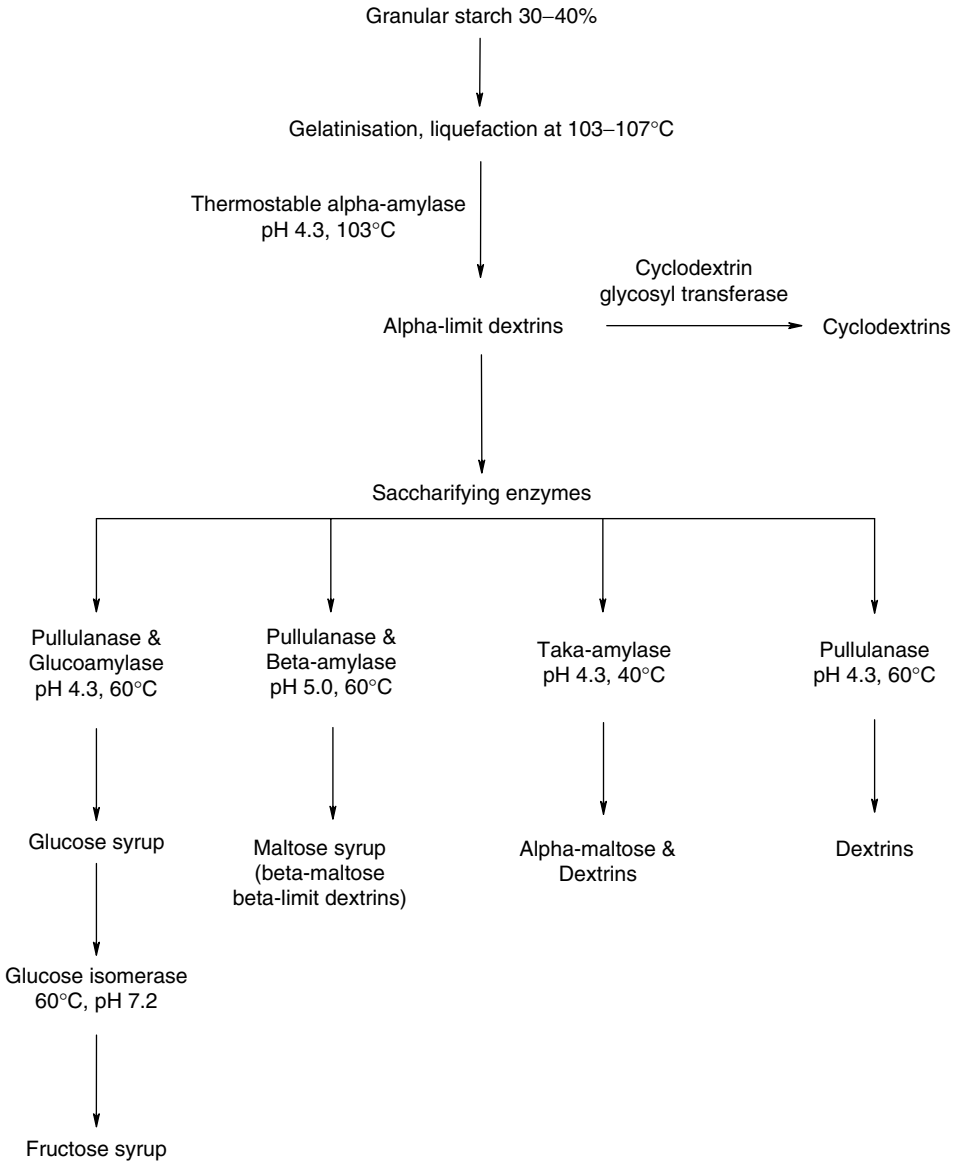

Figure 6.3 General processing steps of starch using enzymes.

hexa- saccharides. Maltose syrups are nonhygroscopic and are used in hard candies to avoid stickiness. These syrups normally contain 45–60% maltose, 3–5% glucose, and 37–55% oligosaccharides. Because maltose syrups are characterized by mild sweetness, defined enzyme technologies have attempted to make extra high maltose syrups by decreasing substrate concentrations and by using new pullulanase that lack reversible activities. In foods, rather than sweetness, the primary importance for maltose syrups is for their functional properties, such as low hygroscopicity, low viscosity in solution, resistance to crystallization, reduced browning capacity, and good heat stability. These properties of maltose syrups have applications as moisture conditioners, crystallization inhibitors, stabilizers, carriers, and bulking agents (41).

Production of high fructose syrup involves a three stage processing of starch. The first two stages of starch processing to generate glucose have been described above. In the third stage of processing, isomerization of glucose to fructose is achieved using glucose isomerase. The enzyme obtained from *B. coagulans* is most widely used (42). Calcium ions, the potent inhibitor of glucose isomerase are acquired as impurities from raw materials. Though calcium ions are important for the stability of α-amylase used to liquefy starch, they have to be removed completely prior to the isomerization reaction. Hence, the glucose syrup obtained after glucoamylase treatment is passed through ion resin columns to remove calcium. To make the process economical, glucose isomerase immobilized by cross linking with glutaraldehyde is used in column reactors to achieve isomerization. By this procedure, the need for the enzyme is considerably reduced and the process is made amenable to microprocessor control. Different immobilization procedures are described to retain high enzyme activity, as described in Table 6.2. Glucose isomerases are optimally active at pH 7.5–7.8. Hence, prior to conversion of glucose to its isomer fructose, the pH of the glucose syrup is adjusted generally with soda ash or sodium hydroxide. Because isomerization reaction does not result in high fructose syrups, industries employ chromatography columns to partially separate glucose. This gives the industries the flexibility to sell syrups with different levels of fructose. This is important because fructose is sweeter than glucose and syrups that carry a broad range of sweetness. The variety of sweeteners assists in the manufacture of many food products (43).

6.3.2 *In situ* Starch Modifications for Food and Beverage Preparations

Amylolytic enzymes are widely used in modifying texture in breads. They are an important application in biochemically modifying barley to substitute malt in the brewing process for the manufacture of beer. Staling, that makes bread hard and brittle, is thought to be due to reversion of starch granules from soluble to insoluble form (retrogradation). In bread making, thermostable α-amylase reduces the retrogradation of starch to improve the shelf life of breads. α-Amylases, due to their stability at high temperatures, are able to work after the baking process, breaking the starch to smaller length dextrins, preventing retrogradation and increasing the shelf life of bread. Also, production of dextrins from starch reduces high dough viscosity in bread and accelerates the fermentation process by yeast, thereby improving the crust formation. In brewing of beer, use of amylase, apart from thinning the mash and accelerating fermentation, also modifies barley biochemically to substitute for malt. In beer, malt has an impact on flavor and is usually used as source of β-amylase enzyme. β-Amylases of microbial origin can modify β-glucans in the barley

Table 6.2
Immobilized glucose isomerase used for fructose syrups

Immobilization Method	Enzyme Activity [b]
Whole cells	
Cross-linked *Streptomyces spp.*	121
S. violaceoniger in gelatine fiber	260
Bacillus coagulans cross-linked	200
Purified/crude enzyme	
Actinoplanes missouriensis on alumina	1350
Enzyme bound to DEAE-cellulose	1487

[b]Activity IU/g corresponds to micro moles of fructose formed min^{-1}

to lower the wort viscosity for improving flavor. Activity of this enzyme also releases maltose, which serves as a nutrient for yeast in the fermentation process.

6.4 CURRENT STATUS

Though microorganisms have been identified, which produce amylases that find direct application in starch processing industries, the demand and requirement to improve processing parameters necessitated further developments in this area. Overproduction of amylases by recombinant DNA technologies and modification of the enzyme property by protein engineering have reduced the cost of producing enzymes as well as producing enzymes designed for a particular application.

Most cloned α-amylase genes have been expressed using their own promoters in bacteria and fungi. High level production using cloned genes has been obtained for α-amylase in *B. amyloliquefaciens* and *A. oryzae* and *β*-amylase in *A. schirousami*. Glucoamylase gene has been found expressed in *Saccharomyces cerevisiae* under the control of enolase (*ENO1*) promoter (44). This study described construction of the yeast strain that hydrolyzed and simultaneously fermented starch, because of the presence of *A. awamori* glucoamylase gene.

Insight into carbohydrate binding properties of amylases and their mechanisms of action acquired by a combination of x-ray crystallography, chemical modification, inhibition studies, and site directed mutagenesis, explained functionality of amylases for specific action patterns. Replacement of histidine 238 with aspartic acid in α-amylase showed thermostability reduction but the mutant protein derived hydrolyzed starch to give rise to a different oligodextrin profile (45). In another approach, replacement of histidine 133 with tyrosine resulted in α-amylase that was more stable (45). The tryptophan 178 to arginine, and serine 119 and to tyrosine mutations in *A. niger* glucoamylase increased the cleavage of α-1,6 glucosidic bonds of starch without significantly decreasing activity toward α-1,4 bonds (45).

The extreme thermostability of *B. licheniformis* α-amylase was attributed to electrostatic interactions involving few specific lysines (46). Stabilization against irreversible thermal inactivation was achieved in a chimeric gene constructed using *B. amyloliquefaciens* and *B. licheniformis* α-amylase genes and by deleting arginine 176 and glycine 177, substituting lysine 269 with alanine and asparagine 266 with aspartic acid (47). Truncation of amylolytic enzymes has also led to the understanding of starch granule binding function. Hence, protein engineering of amylases through chemical modifications and site directed mutagenesis described the art of changing enzyme properties without losing catalytic efficiency (48). Selectivity of glucoamylase for increasing glucose yields by site directed mutagenesis of the glucose catalytic domain (49–52), modified the dimension of the active site just enough to prevent the prevalent byproduct, isomaltose, from binding the active site without affecting the binding of maltose. This was achieved by stiffening the α-helices of the protein by mutating glycine to alanine or producing disulphide bonds by substituting cysteine on adjacent loops that restricted the movement of the active site so that it did not accommodate isomaltose.

Thermostability of glucoamylase was also found to increase when amino acid substitutions were made by site directed mutagenesis. Significantly, replacement of glycine 137 with alanine was reported to stiffen an α-helix that improved the enzyme thermostability at temperatures over 70°C. This was because the mutation retarded general unfolding of the enzyme (53). Several other mutants obtained by site directed mutagenesis have also shown substantial improvement in thermostability and activity of glucoamylase (54).

While several problems of industrial processing of starch using enzymes were solved through isolation and engineering of amylases, still this technology is affected by

low thermostability of enzymes like β-amylase, glucoamylase, pullulanase, and glucose isomerase. Hence there is a continuous search for highly thermostable enzymes from microbes occurring in extreme environments (55).

pH variations described for the production of different types of sweeteners is also an important consideration in starch processing. Thermostable α-amylase of *B. licheniformis*

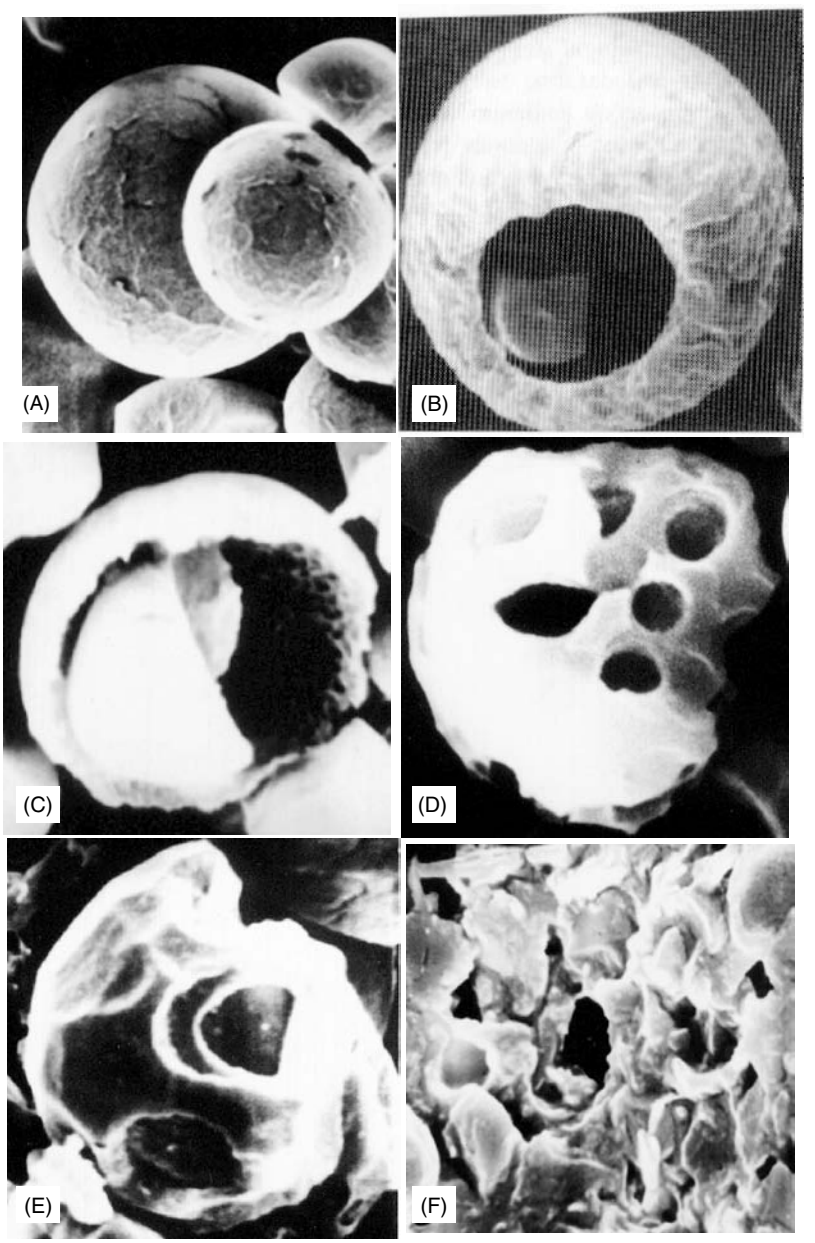

Figure 6.4 Granular starch hydrolysis by amylases of A. niger

that has an optimum pH range of 5.5 to 6.0 has been reported (9). Liquefaction of starch at low pH using this enzyme was claimed to prevent the formation of maltulose (4-α-D-Glucopyranosyl-D-fructose) precursors. In the manufacture of glucose syrups, maltulose precursors are hydrolyzed to maltulose by glucoamylase, reducing the yield of glucose.

Starch processing as described involves high energy inputs, because gelatinization of granular starch at high temperature is a primary requisite. Degradation of crystalline granular starch by amylolytic enzymes (Figure 6.4) has been widely reported. Structural studies on glucoamylases have characterized a separate globular domain that has the capacity to bind starch granules. These studies and the three dimensional structures of the enzyme proteins have identified the structure — function relationships of the enzyme and substrate — that have revealed clues for rational engineering of enzymic properties for granular starch saccharification. Granular starch hydrolysing glucoamylase of *Rhizopus* has been cloned and expressed in yeast (56). Thus, enzymatic degradation of granular starch to make syrups and sweeteners is not a distant possibility.

It has been reported that in order to improve starch processing, a transgenic potato crop has been developed that produces fructose and glucose when mashed and treated at 65°C for 45 minutes (57). This was achieved by expressing chimeric gene construct coding for *Bacillus stearothermophilus* α-amylase and *Thermus thermophilus* glucose isomerase in potatoes. The possibility of starch modification in plants apparently will revolutionize the existing technologies because it can be a solution to many problems encountered by the starch processing industries that use enzymes.

Genetic Modification of Plant Oils for Food Uses

Anthony J. Kinney

CONTENTS

7.1 INTRODUCTION

Almost 100 million metric tons of vegetable oil are produced annually, and most of it is used for food purposes. The majority of edible vegetable oil in the world (70 million metric tons) is derived from four crops: soybean, canola, palm and sunflower. About half finds its way (after refining, bleaching, and deodorizing) directly to the retail market in the form of bottled oil for cooking and salads (1). These oils tend to be rich in linoleic acid, an omega-6 polyunsaturated fatty acid, and for this reason the ratio of omega-6 to omega-3 fatty acids in the Western diet is greater than 10 moles of omega-6 to one of omega-3. Most medical experts now believe that this ratio should be about three to one, and suggest a reduction in omega-6 fatty acid consumption or an increased intake of omega-3 fatty acids (2,3).

The half of edible vegetable oil production that is not bottled directly is used by the food industry for the manufacture of shortening, confections, and margarine, and as such is usually hydrogenated to a greater or lesser degree depending upon the application (1,4). Oils are hydrogenated to remove oxidatively unstable polyunsaturated fatty acids, and thus increase the shelf life of oil containing food products. Oils are also hydrogenated to achieve solid fat functionality, by increasing the saturated fatty acid content and by the introduction of *trans* fats, which have a much higher melting point than their *cis* isomers. The relative abundance of saturated and monounsaturated (*cis* and

trans) fatty acids in the oil will determine the solid fat content (SFC) curve of the oil and thus its food application. A developing understanding of the negative health effects associated with the consumption of *trans* fatty acids is leading food manufacturers to consider alternatives to hydrogenated oils, such as fractionation and transesterification, for many food applications (5).

In recent years the importance in the diet of relatively modest concentrations of bioactive fatty acids, such as long chain omega-3 and conjugated fatty acids, especially conjugated linoleic acid (CLA), has been recognized. Currently the main dietary sources of these fatty acids are dairy products (for CLA) and fish oils (for long chain omega-3 fatty acids). Consumption of these fatty acids has been strongly correlated with a reduced risk for coronary disease and a number of other positive health benefits (2,3). There is a potential for including these bioactive fatty acids in the diet as food ingredients, although their widespread use is currently limited by the high cost of purifying and refining them to a point where they will not negatively impact the flavor of the food to which they are added. Food ingredient quality refined fish oil, for example, can cost as much as $50 per kilogram.

Biotechnology has the potential to impact both the low added value, high volume commodity oil market and the low volume, high added value specialty oil market. Changing the relative abundance of saturated, monounsaturated, and polyunsaturated fatty acids in seed oils by manipulating existing biosynthetic pathways could result in oils that have desired health and functional properties without hydrogenation, fractionation, or other modifications (6). Adding new pathways for the synthesis of conjugated or long chain polyunsaturated fatty acids represents a new direction for food oil biotechnology, and could result in lower cost, higher quality replacements for fish and microbial oils as health promoting food ingredients.

Many of the technical challenges of both these areas have been met, and the feasibility of producing a broad range of novel plant oils in the major oilseed crops has been demonstrated in both model plants and oilseed crops. Some of these oils (such as lauric acid rich canola and high oleic acid soybean oils) have even been commercialized in limited quantities. It is not expected, however, that any of these new oils will make a commercial impact until the end of the current decade. It is hard to imagine any of the major edible plant oils (with the exception of gourmet, organic, and artisanal oils) that will not have been improved, by the middle of this century, by the use of biotechnology.

7.2 FRYING OILS

The most important property of frying oils is resistance to oxidation and polymerization (4). Oxidative stability is usually measured by either the active oxygen method (AOM) or the oxidative stability index (OSI). In both cases the higher the number, the more stable the oil to oxidation and polymerization, and the two measurements normally correlate with each other. A typical refined, bleached, deodorized (RBD) vegetable oil will have an AOM in the 15–25 hour range (4). This is fine for home frying that is done in small batches and often discarded after a single use. For the kind of heavy duty, continuous frying done in the food industry, however, far more stable oils are needed, with AOMs of around 100–200 hours (4,6,7). This stability is usually achieved by either partial hydrogenation or a combination of partial hydrogenation, transesterification, and fractionation. Partial hydrogenation will remove most of the polyunsaturated fatty acids and replace them with *cis* and *trans* monounsaturated fatty acids. There is now a substantial body of evidence linking the consumption of *trans* fatty acids to coronary heart disease, and food manufacturers will

soon be required to label the *trans* content of packaged foods (8). Thus there is an incentive to remove polyunsaturated fatty acids from oils by means other than hydrogenation.

The polyunsaturated fatty acids linoleic and linolenic acid are synthesized in the developing oilseed by the action of two types of desaturase enzyme. A delta-12 desaturase inserts a second double bond into oleic acid while it is esterified to the membrane lipid phosphatidylcholine (9). This enzyme is encoded by the Fad 2 gene in plants. Linolenic acid is synthesized by the insertion of a third double bond into linoleic acid by an omega-3 desaturase, encoded by the Fad 3 gene. Again, this reaction occurs while the fatty acid is esterified to a membrane lipid. Because this synthesis of linolenic acid from oleic acid is sequential, blocking the first step by silencing the Fad 2 gene should theoretically result in blocking the formation of polyunsaturated fatty acids and result in an increase in oleic acid. This generally proves to be the case, although most oilseed plants have two or three Fad 2 genes. To achieve the maximum oleic acid content all three may have to be silenced in a seed specific manner. A small amount of polyunsaturated found in seed oils is actually synthesized in a separate pathway located in the plastid. Nevertheless, silencing of Fad 2 genes has resulted in oils with an oleic acid content up to 90%. High oleic soybean oil (HOS), which has an oleic acid content of about 85% and less than 5% total polyunsaturated fatty acids, has an AOM of 150 hours. Polymer formation in HOS oil during frying is very low, equivalent to heavy duty, hydrogenated shortening (7).

Interestingly, high oleic soybean oil has a higher AOM than other modified vegetable oils with a similar oleic and polyunsaturate content. This is most likely because soybean oil is naturally richer in tocopherols than other plant oils, and the form is predominantly *gamma*-tocopherol. When, for example, high oleic sunflower oil is stripped of tocopherols, and tocopherols are added back to the final content and composition of soybean oil, the AOM of the sunflower increases close to that of high oleic soy (7). Most of the genes that control tocopherol formation and the degree of tocol methylation have been cloned (10–12). It is now theoretically possible, therefore, to combine genetic modifications in fatty acid desaturation with modifications of tocopherol metabolism to produce very high stability frying oils from most oilseed species.

Because of concerns surrounding the consumption of genetically enhanced foods and the advent of novel, cheaper transesterification techniques, the commercial production of transgenic high oleic acid oils, even in the US, has been limited. The increasing demand for *trans* free oils created by the new labeling requirements and increased public awareness of *trans* related health issues is likely to reverse this situation. Consequently, in the near future genetically enhanced high oleic oils should become more widely available.

7.3 OILS FOR BAKING AND CONFECTIONARY APPLICATIONS

The bulk of the hydrogenated vegetable oil produced in the US is used as shortening for baking applications (4). These oils were originally developed to replace animal fats such as lard and butter. They typically need a high oxidative stability (AOM between 100 and 200 hours), a high melting point (35–60°C) and usually a SFC curve that is basically flat or very gently sloping between 10 and 40°C. The actual SFC curve requirement depends upon the application, although SFC curve requirements for piecrusts, puff pastry, and baker's margarine would be very similar (4). Consumer margarine applications, which represent about 5% of hydrogenated vegetable oil produced in the US, require very similar SFC curves and properties. Hydrogenated vegetable oils are also used for confectionary coatings, cookie fillers, and wafer fillers. These particular oils, however, need to be solid

at room temperature but liquid at body temperature, and thus have a very different SFC requirement from baking and margarine oils (4).

Producing modified plant oils with these two very different types of SFC curves can be done with similar technical approaches. Margarine type baking oils may be replicated by oils with a higher stearic acid and higher oleic acid content than regular plant oils. The coating, confectionary, and filler-type fats can be mimicked by fractionating these same oils to enrich for particular triacylglycerol species. Oils with a confectionary-type SFC curve can also be made by engineering seeds to produce structured triacylglycerols that are also rich in certain medium chain fatty acids.

High oleic, high stearic acid oils can be made by combining the Fad 2 silencing effect described with a gene for increased stearic acid. There are a number of possible approaches to increase stearic acid in oilseeds. All of these approaches involve providing more favorable flux conditions for 18:0-ACP leaving the cytoplasm (where it becomes a substrate for triacylglycerol [TAG] biosynthesis) than for it being desaturated to 18:1-ACP.

Stearic acid is the predominant fatty acid (45–55%) in the seed oil of *Garcinia mangostana* (mangosteen). This is result of the activity of an unusual FatA-type thioesterase, *GarmFatA1*, which has low activity toward 16:0-ACP but high activity toward 18:0 and 18:1-ACPs (13). When a cDNA encoding this FatA was expressed in seeds of canola, it was able to siphon away large amounts of plastidal 18:0-ACP from the acyl-ACP desaturase and transfer it to the cytoplasm as stearoyl-CoA. The resultant stearate accumulation in the seed oil was increased from 1% to 20% of the total fatty acids (13).

It is also possible to slow flux through the acyl-ACP desaturation step to allow the endogenous FatB-type thioesterase to release more stearic acid from 18:0-ACP into cytoplasm. This can be achieved by silencing the gene for one of the number of SAD genes in oilseeds that encode 18:0-ACP desaturases. Knocking out a single gene of the acyl-ACP desaturase gene family usually results in a stearic acid content of around 25% of total fatty acids (6,14).

Because, in both these cases, flux into 18:1 has been reduced, the final oleic acid content of high stearate, high oleic combinations is usually in the 55–60% range (6,9). Vegetable oils which contain 20–25% stearic acid and 55–60% oleic acid have a unique SFC functionality that makes them suitable for baking and margarine applications. This functionality may be further extended by fractionation of these oils.

It has been possible to make oils suitable for chocolate substitutes, confectionary coatings, and cookie fillings by modifying fatty acid synthesis to produce shorter chain fatty acids, from 8:0 to 12:0 carbons in length. A 12:0-ACP FatB-type thioesterase was isolated from California bay laurel. Expressing this FatB-type thioesterase in canola resulted in seed oil rich in lauric acid, up to 50% of the total fatty acids (15). The initial intent of producing this oil (which has the trade name Laurical ®) was for nonfood uses, such as soaps. Once the oil had been produced and its functionality measured, it was also found to be suitable for various food applications (16). Commercial production of this oil has been limited, however, by the availability of relatively inexpensive coconut oil. Nevertheless, the invention of Laurical was a major milestone along the road to more exotic food oils (16).

Subsequently, cDNAs encoding 8:0-ACP, 10:ACP, and 14:0-ACP FatB-type thioesterases have been isolated from *Cuphea* species with oils rich in the corresponding acyl chains. Expression of these cDNAs in canola resulted in oil rich in these medium chain fatty acids (18).

The functionality of all these medium chain oils is limited by the positions of the fatty acids on the triaclyglycerol molecule. In the bay thioesterase oil, for example, the lauric acid is found exclusively at the sn-1 and sn-3 positions. Coexpression in canola seeds of a coconut 12:0-CoA Lysophosphatidic acid acyltransferase, along with the bay

thioesterase, facilitated efficient laurate deposition at the sn-2 position resulting in the accumulation of lauric acid at all three positions of the seed triacylglycerol (19).

The cloning and expression of acyl transferases has paved the way for the production of triacylglycerols (TAGs) structured with specific fatty acids at different positions on the glycerol backbone. The utility of these structured triacylglycerols (STAGs) extends beyond the functional properties related to their SFC curve and their nutritional importance is more profound than their bulk fatty acid profile might suggest (20,21). For example, STAGS with medium chain fatty acids at positions sn-1 and sn-3 of the glycerol backbone and an essential fatty acid at the sn-2 position have been useful in the diets of patients suffering from malabsorbtion because they provide both essential fatty acids and a source of energy equivalent to soluble sugars. The medium chain fatty acids are absorbed as free fatty acids, independently of acylcarnitine, and hence faster and more efficiently than longer chain fatty acids. They thus provide a rapid source of energy without having the side effects of high sucrose supplements (21).

In another example, most of the palmitic acid in human milk is at the sn-2 position of triacylglycerol. Enriching infant formula with TAGs having palmitic acid at this position results in a food that more closely resembles natural sources and results in a number of health benefits for the infant, including reduced calcium loss (21,22).

The utility of foods containing STAGs is currently limited by the very high cost of producing the structured molecule itself. By combining the fatty acid pathway manipulation techniques described with the expression of specific acyltransferases it should be possible to directly produce relatively inexpensive plant oils enriched in specific STAGs for various food and medical purposes.

7.4 FATTY ACIDS FOR FOOD INGREDIENTS

There is an increasing body of evidence supporting the conclusion that the fatty acids in the food we eat have a major influence on our physical and mental health (23). This is particularly the case with the essential omega-6 and omega-3 polyunsaturated fatty acids (PUFAs) linoleic and linolenic acids, which are the precursors of the long chain PUFAs arachidonic acid (ARA) and eicosopentaenoic acid (EPA) in humans. In turn these long chain PUFAS are the direct precursors of bioactive eicosanoids (prostaglandins, prostacyclins, thromboxanes, and leukotrienes) and the bioactive omega-3 fatty acid docosohexaenoic acid (DHA). The eicosanoids mediate many functions in the human body including the inflammatory response, the induction of blood clotting, the regulation of mental functions such as the sleep/wake cycle, and the regulation of blood pressure (24). The balance of omega-6 and omega-3 derived eicosanoids is important in the body because those derived from omega-6 ARA are proinflammatory and those derived from omega-3 EPA are antiinflammatory (24). DHA is an important component of mammalian brain membranes and has been shown to play a role in the cognitive development of infants and the mental health of adults (25–27).

Because of dietary changes over the last century many populations, particularly those in the U.S. and Europe, now consume a high proportion of omega-6 fatty acids, mostly in the form of linoleic acid. The main source of omega-3 fatty acids in human diets is fish, the consumption of which is not consistent across any population (23). Thus many people are thought to have suboptimal concentrations of long chain omega-3 fatty acids in their bodies (28). It is no surprise, therefore, that consumption of omega-3 fatty acids, particularly the long chain PUFAs EPA and DHA, has been associated with many positive health benefits such as the prevention of cardiovascular disease in adults, improved cognitive development

in infants (25–27), and a greatly reduced risk of sudden cardiac arrest, one of the major causes of death in the U.S. (29).

It has been calculated that adding between 800mg and 1000mg of EPA per day to the human diet would redress the omega-6:omega-3 balance in the body and lead to substantially improved health (2). This is equivalent to eating a 4–12 oz serving of fresh tuna every day, depending on the EPA/DHA content of the fish itself (2). It is very difficult to persuade people to change drastically their dietary habits, particularly if the change involves eating more of a strongly flavored food such as fish. In addition, the world supply of fish (either wild or farmed, because farmed fish need fish oil from the wild to sustain them) is limited, environmentally sensitive, and subject to periodic issues of contamination with mercury and other pollutants (30).

Biotechnology has the potential to provide a sustainable source of high quality and relatively inexpensive long chain omega-3 PUFAs that could be added to many different foods, from salad dressings to high protein nutrition bars. This can be achieved by adding a long chain PUFA biosynthetic pathway to the existing fatty acid biosynthetic pathway in developing oilseeds and thus producing a PUFA enriched plant oil that could be used as a food ingredient.

There are a number of potential pathways that could be added, and a number of potential sources for the pathway genes (31). Fish make few if any long chain PUFAs, obtaining all they need from marine plankton. Over the past few years a wide range of PUFA pathways have been discovered in microbes. Certain marine prokaryotes, such as *Shewanella* species, *Moritella* species, and *Photobacter profundum*, contain significant quantities of either EPA or DHA which they synthesize via a polyketide synthase (PKS) enzyme complex (32). Some eukaryotic microbes, such as many thraustochytrids, also contain a PUFA synthesizing PKS (31,32). It is likely that PUFA PKSs make EPA or DHA from malonyl-CoA by a cyclical extension of the fatty acid chain with isomerization and enoyl reduction occurring in some of the cycles.

Many other eukaryotic microbes synthesize EPA and DHA using an aerobic pathway similar to that of humans, involving desaturases and fatty acid elongating enzymes. In these pathways EPA or DHA is made by the elongation and aerobic desaturation of linoleic and linolenic acids (31).

The PUFA synthesizing PKS was first identified in the EPA rich prokaryote *Shewanella*. The five open reading frames necessary for reconstituting this system in *E. coli* had homology to type I and II PKS components and to type II fatty acid synthase enzymes. A similar PKS from the DHA rich eukaryotic microbe *Schizochytrium* was found to contain three open reading frames (ORFs) with domains homologous to those in *Shewanella* (32). When expressed with a 4′-phosphopantetheinyl transferase, to activate the PKS ACP, the *Schizochytrium* PKS was able to synthesize DHA in *E. coli*. Current efforts are underway to engineer *Schizochytrium* PKS into oilseeds crops such as safflower and thus provide a renewable source of DHA in the seed oil (33).

In humans EPA is synthesized by the delta-6 desaturation of linolenic acid, and delta-6 elongation of the resulting stearidonic acid, followed by delta-5 desaturation to EPA. The same enzymes also convert linoleic acid to ARA (31). This pathway is also used by a wide range of microbes including fungi (e.g., *Mortierella alpina* and *Saprolegnia diclina*), mosses (e.g., *Physcomitrella patens*) and microalgae (e.g., *Phaeodactylum tricornutum*). A number of other freshwater and marine microbes (*Isochrysis galbana, Euglena gracillus*) have been shown to use an alternative aerobic pathway of EPA biosynthesis that begins with the delta-9 elongation of linoleic acid. This is followed by delta-8 and delta-6 desaturations to yield ARA, and then an omega-3 (delta-17) desaturation to EPA (34).

The synthesis of DHA from EPA in humans is complex, involving two elongation steps, a delta-6 desaturation, and β-oxidation in the peroxisome to DHA (31). Microbial DHA synthesis follows a simpler route. EPA is elongated to docosopentaenoic acid (DPA) which is then desaturated by a delta-4 desaturase to DHA.

There has also been some success in engineering both the delta-8 and the delta-6 aerobic pathways for EPA biosynthesis into plants. The delta-8 pathway was reconstructed in the model oilseed plant *Arabidopsis*, by the heterologous expression of an *I. galbana* delta-9 elongase, a *Euglena* delta-8 desaturase, and an *M. alpina* delta-5 desaturase. Significant accumulation of both ARA and EPA (7% and 3% respectively) was observed in *Arabidopsis* leaves, although the seed content of these long chain PUFAs was not reported (35). A similar EPA content was observed in flax seeds containing a delta-6 pathway transferred from *Physcomitrella patens* (36). Flax was chosen because it has a naturally abundant linolenic acid content, thus encouraging the formation of long chain omega-3, rather than omega-6, fatty acids (37). Another approach to omega-3 enrichment is to add extra omega-3 desaturase genes along with the long chain PUFA pathway (38,39). Transforming soybeans with a delta-6 desaturase and delta-6 elongase from *M. alpina*, a delta-5 desaturase from *S. diclina* and two extra omega-3 desaturases (under the control of various seed specific promoters) resulted in soybean oil containing up to 20% EPA and no ARA (40). It has also been possible to include two more genes, encoding a C20-elongase and a delta-4 desaturase, to the set for this aerobic pathway in transgenic plants, resulting in the production of small quantities of DHA in seed oils (36,40).

All of these results are very encouraging regarding future plant derived sources of long chain omega-3 fatty acids although considerable progress still needs to be made in optimizing pathway expression, producing crops with good agronomics and in stabilizing the new, highly unsaturated oil during production (to prevent oxidation).

Another bioactive fatty acid that is attracting some interest from the biotechnology world is conjugated linoleic acid (CLA). This fatty acid is normally found in dairy products, and has attracted this interest because of its reported effects on reducing body fat mass and increasing lean body mass (41). Other beneficial health related effects of CLA that have been reported in the literature include anticarcinogenic effects, and beneficial effects on the prevention of coronary heart disease, as well as modulation of the immune system (42). Most of the research on CLA, however, has been done with animals and there is not yet a scientific consensus about the human benefits of CLA consumption (42). Part of the problem may be that CLA is really a collective term signifying a group of different geometrical and positional isomers of linoleic acid and it is still unclear which isomers are the most active forms (43,44). Most natural food sources of CLA consist predominantly of the *cis-9 trans-11* isomer, while commercial CLA preparations are usually a mixture of *cis-9 trans-11* and *trans-10 cis-12* isomers. Consequently, most research has focused on these two isomers, although it is quite possible that other isomers and other conjugated fatty acids may also have some biological activity. Only very recently have researchers begun to examine the effect of purified CLA isomers in humans, and in these studies both *cis-9 trans-11* and *trans-10 cis-12* isomers have been shown to have some biological effects on blood lipids and immune function (44,45).

Attempts have been made to provide new food sources of CLA by enriching seed oils with conjugated fatty acids. One approach to this is expressing a polyenoic *cis-trans* fatty acid isomerase in developing oilseeds to convert newly synthesized linoleic acid to CLA before it is incorporated into oil (46). Isomerase genes have been cloned from algal (*Ptilota filicina)* and bacterial (*Propionium, Bacterium acnes*) sources, and attempts made to express these genes in plant cells (46,47). The substrates for these isomerases, however, are free fatty acids, which are only present in trace amounts in plant cells. Thus only trace

amounts of CLA have been observed when isomerases were expressed in plants (47). Because most fatty acids in plant cells are part of complex lipids such as phospholipids, galactolipids and triacylglycerol, it seems likely that coexpressing an isomerase in developing oil seeds with some kind of lipase might be necessary to observe useful quantities of CLA in plant oils.

Another approach to making significant quantities of conjugated fatty acids in plant oils is to use plant enzymes that operate on esterified fatty acids. Dienoic conjugated fatty acids, such as CLA, are only present in plants in trace amounts although trienoic fatty acids are abundant in some plant species. The trienoic isomer of linolenic acid, calendic acid (*trans-8, trans-10, cis-12* CLnA), is found in high relative abundance (over 65% of total fatty acids) in the seeds of the pot marigold *Calendula officinalis* (48). This conjugated linolenic acid isomer contains the *trans-10 cis-12* double bonds thought to be involved in the biological activity of commercial CLA. The *trans-8, trans-10, cis-12* CLnA is synthesized in the developing marigold seed from linoleic acid, while the fatty acid is esterified to the membrane lipid phosphatidylcholine (48). The synthesis is catalyzed by a delta-12 oleic acid desaturase related enzyme encoded by a member of the Fad 2 gene family. When the marigold Fad 2 conjugase was expressed in soybean seeds, significant concentrations of calendic acid (15–20%) were observed in the seed oil (48).

Similar delta-12 oleic acid desaturase related enzymes catalyze the synthesis of other linolenic acid isomers, such as α-eleostearic acid (*cis-9, trans-11, trans-13* CLnA) in Chinese bitter melon (*Momordica charantia*) seeds (49) and trichosanic acid (*cis-9, trans-11, cis-13* CLnA) in *Trichosanthes kirilowii* and *Punica granatum* seeds (50). Again, it is possible to produce these other CLnA isomers in plant oils by expressing the Fad 2-related gene encoding the specific linoleic acid conjugase in the developing seeds of an oilseed plant (49,50).

It is not yet known how the biological activities of various CLnA isomers compare with those of CLA isomers, although there have been a number of provocative recent studies that have even raised the suggestion that dietary CLnA may be more biologically potent than CLA (51–54). For example, it has been shown that eleostearic acid prepared from both pomegranate seed and bitter melon seeds had very potent anticarcinogenic effects in rats (51,52). In another study, chemically synthesized eleostearic acid was found to be substantially more effective at suppressing tumors in rats than was CLA (53). Other studies in rats have found calendic acid to be more effective than CLA at increasing lean body mass and reducing adipose tissue weight (54).

The biotechnology of bioactive food lipids such as long chain omega-3 PUFAs and conjugated fatty acids is still in its infancy. Nevertheless, the ability to produce these fatty acids in plant oils has now been demonstrated and has the potential to impact the long term physical and mental health of human populations in a significant and positive way.

Molecular Biotechnology for Nutraceutical Enrichment of Food Crops: The Case of Minerals and Vitamins

Octavio Paredes-López and Juan Alberto Osuna-Castro

CONTENTS

8.1 MICRONUTRIENTS: ALLEVIATING NUTRITIONAL DISORDERS BY NUTRACEUTICALS

Ever since the discovery of vitamins, there has been a great interest in deciphering the effects of food constituents on human health. The requirements for a healthy life with a balanced metabolism (metabolic homeostasis) and preservation of the body cell mass

require a protein balance having all the essential amino acids, fatty acids, carbohydrates, and micronutrients (1,2).

Approximately 40 micronutrients (the vitamins, essential minerals, and other compounds needed in small amounts for normal metabolism) are required in human diet (Tables 8.1, 8.2). Obtaining maximum health and life span requires metabolic harmony. For each micronutrient, metabolic harmony requires an optimal intake (i.e., to give maximal life span); deficiency distorts metabolism in numerous and complicated ways, many of which may lead to DNA damage (3–7). Many micronutrient minerals and vitamins act as substrates or cofactors in key DNA maintenance reactions, and the exact concentration of these in the cell may be critical. Suboptimal levels of key micronutrients will thus lead to impaired activity of enzymes needed for genomic stability in man, producing effects similar to inherited genetic disorders or exposure to carcinogens (Tables 8.1, 8.2) (3–7). In fact, a deficiency of some micronutrients (folic acid, vitamin B12, vitamin B6, niacin, vitamin C, vitamin E, selenium, iron, or zinc) appears to mimic exposure to radiation or chemicals by causing single and double strand breaks in DNA, oxidative lesions, or both (4–12). Chromosomal aberrations such as double strand breaks are a strong predictive factor for human cancer.

In adults, superoxide, hydrogen peroxide, and hydroxy radicals (produced by some 10^{10} free radicals per cell each day) can potentially cause in the order of 10^6 mutational alterations of DNA per cell per day. Fortunately, the activities of these dangerous mutagens are countered by antioxidants, DNA repair, the removal of persistent alterations by apoptosis (normally a cellular program is activated, that causes the cell to self destruct), differentiation, necrosis, and activation of the immune system so that only about one mutation per cell per day persists (13). By old age, many mutations have accumulated because the repair system is not working properly, and as a consequence, cancer may occur. However, the increased consumption of dietary antioxidants such as vitamins C and E, quercetin (flavonoid), and carotenoids (zeaxanthin and lycopene) can diminish DNA oxidation and therefore, less cancer incidence is presented (3,13–18).

The U.S. Recommended Dietary Allowances (RDAs) for micronutrients refer to daily levels of intake of essential nutrients, at or above defined minimum values, judged by the Food and Nutrition Board to be adequate to meet the known nutrients needed for practically all healthy persons and to prevent deficiency diseases. The level of daily requirement for each nutrient varies with age, sex, and physiological status (e.g., pregnancy, lactation, disease related stress) (Tables 8.1, 8.2) (19). RDAs are established by estimating the requirement for the absorbed nutrient, adjusting for incomplete utilization of the ingested nutrient, and incorporating a safety factor to account for variability among individuals (19).

Also, now it is known that vitamins, minerals, and other dietary components consumed at varying levels, higher than RDAs, are significant contributors to the reduction of risks of chronic diseases such as cancers, cardiovascular diseases, and degenerative diseases associated with aging (Alzheimer's, premature aging). Their role in maintaining human genomic stability is likely to be critical to alleviating the classical nutritional deficiency diseases which include scurvy (vitamin C), anemia (folic acid, iron), and pellagra (niacin) (Tables 8.1, 8.2) (4–7,17,20,21).

While deficiencies of dietary energy (i.e., calories) and protein currently affect more than 800 million people in food insecure regions, incredibly, micronutrient malnutrition, known as "hidden hunger", now afflicts over 40% of the world population, especially the most vulnerable being in many developing nations (resource-poor women, infants, and children), and a surprisingly large amount of people in the advanced countries, where food diversity, abundance, and supply are excellent, but also poor food eating habits are common

and in both cases the numbers are rising (4,22–25). Even though micronutrients are needed in minute quantities (i.e., micrograms to milligrams per day), they have tremendous impact on human health and well-being (Tables 8.1, 8.2) (22,26,27). Insufficient dietary intake of these microcomponents impairs the functions of the brain, the immune and reproductive systems, and energy metabolism (26,27).

At present, deficiencies of iron, vitamin A and iodine are of the most concern to the community and healthcare systems. Unfortunately, for zinc there is a lack of a simple, quick, and cheap clinical screening test for determining marginal zinc deficiency in humans. Specialists in zinc nutrition suggest that its deficiency presents similar problems as caused by a deficiency of iron (10,22,24,25,28). Iron, zinc, and vitamin A all play important roles in brain development, and when deficiencies of these micronutrients are manifest during pregnancy, or even for up to two years postpartum, permanent damage to offspring is possible. Thereafter, further loss of cognitive ability is found (10,22,24–31).

Iodine deficiency is the greatest single cause of preventable brain damage and mental retardation in the world today. More than 2 billion people around world live in iodine deficiency environments. Deficiency in iodine occurring in late infancy and childhood have been demonstrated to produce mental retardation, delayed motor development, and stunted growth, occurrence of neuromuscular disorders, and speech and hearing defects. Even mild iodine deficiency has been reported to decrease intelligence quotients by 10–15 points (22,31).

Rapid growth during fetal development, infancy, childhood, and adolescence demand greater amount of micronutrients, when their deficiency can cause developmental abnormalities (22,25). In addition to multiple micronutrient deficiencies (those of vitamin A and C, decreased iron absorption), interactions between micronutrient deficient conditions and infectious diseases may become significant. These effects can complicate health care efforts to control various diseases such as vitamin A deficiency and measles, and increased severity of measles leading to vitamin A deficiency blindness and death. Malaria and hookworm infections are also associated with Fe deficiency anemia (22,25,30,32).

Plants synthesize and accumulate an astonishingly diverse array of vitamins, and nutraceuticals that have health-promoting properties (33,34). Many naturally occurring compounds have health promoting or disease preventing properties beyond the mere provision of nutrients for basic nutrition (1,34–36). In this way, plants not only constitute the base of the human food chain but they are also important means to improve human health and well-being, with the exception of vitamin B12 and D. A diverse and well-balanced plant-based diet, that includes mixed sources of grains, fruits, and vegetables, can ensure the proper micronutrient nutrition and health at all stages of the life cycle (Tables 8.1, 8.2) (18,20,21,37–39). It is known that seeds are good sources of lipid-soluble vitamins, but tend to have low levels of bioavailable iron, zinc, and calcium, whereas leafy vegetables can supply most minerals and vitamins. Fruits provide water-soluble vitamins and several types of carotenoids but generally are minor sources of certain minerals. Thus, concentrations of very few individual plant foods are able to supply all the daily recommended intake of any micronutrient in an average or reasonable serving size (20–22,37–39). Unfortunately, many people do not consume a sufficiently diverse diet. In fact, many low-income families from the developing world subsist with a simple diet formed mainly of a staple food (i.e., maize, soybean, beans, wheat, tubers, root) that are poor sources of many micronutrients (2,16,20–25,27,37–39). Heavy and monotonous consumption of cereal-based foods with low concentrations and diminished bioavailability of iron and zinc has been considered a major reason for the current widespread deficiency of both minerals in developing countries (16,20–25,27,37–39). Furthermore, even in developed nations, the average intake of fruits and vegetables may fall below official recommendations (19,21).

Table 8.1
Minerals: Dietary allowances per day and safe upper intake limit values, sources, deficiency and importance on human genomic stability.

Minerals	Maximum Adult RDA[Φ]	Safe Upper Intake Limits (Relative to RDA)[θ]	Predominant Food Sources	Deficiency: Some Classical Nutritional Disorders and Diseases	Deficiency: DNA Damage (Negative Effecton Genomic Stability)	Deficiency: New Health Effects	Functions on Genomic Stability
Selenium	70 μg	13X	Seeds	Keshan disease, an endemic cardiomyopathy in China	DNA Oxidation (radiation mimic)	Prostate cancer, increased risk for heart diseases and other type of cancer	Retardation of oxidative damage to DNA, proteins and lipids, modulation of cellular events critical in cell growth inhibition and multi-step carcinogenesis process, cofactor of glutathione peroxidase
Iodine	150 μg	13X	Iodized salt, sea foods, plants and animal grown in areas where soil iodine is not depleted	Goiter, mental retardation, brain damage and reproductive failure	—	—	—
Chromium	50–200 μg	1X	Various	Rare	—	—	—
Molybdenum	75–250 μg	1X	Seeds	Rare	—	—	—
Copper	1.5–3 mg	1X	Organ meats, sea foods, nuts, seeds	Rare	—	—	Cofactor of cuproenzymes of antioxidant system
Fluoride	1.5–4 mg	1X	Aerial tissues	Problems with bone and teeth	—	—	—

Manganese	2.–5 mg	1X	Whole seeds, fruit	Extremely rare	—	—	—
Zinc	15 mg	1X	Meat, eggs, nut, seeds	Growth retardation, delayed skeletal and sexual maturity, dermatitis, diarrhea, alopecia and defects in immune system function with decreased resistance to infections	Elevated DNA Oxidation (radiation mimic) DNA breaks and increased chromosome damage rate	Immune and brain dysfunction, cancer	Co-factor of enzymes: Cu/Zn superoxide dismutase, endonuclease IV, zinc fingers
Iron	13–15 mg	5X	Meat, seeds, leafy vegetables	Nutritional anemia, problem pregnancies, stunted growth, tiredness and diminished food-energy conversion, poor work performance	DNA breaks, radiation mimics	Immune and brain dysfunction with lower resistance to infections and long-term impairment of neural motor development, and mental function, cancer	Fe-containing enzymes that are particularly important for gene regulation
Magnesium	350 mg	1X	Whole grains, nuts, green leafy vegetables	Rare, but when it occurs there are some problems with bone structures	—	—	—
Sodium	500 mg	5X	Common salt	Rare, but excesive intakes may lead to hypertension	—	—	
Chloride	750 mg	5X	Various	Rare	—	—	—

Vitamins: Dietary allowances per day and safe upper intake limit values, sources, deficiency and importance on human genomic stability.

Vitamins	Maximum Adult RDA[Φ]	Safe Upper Intake Limits (Relative to RDA)[θ]	Predominant Food Sources	Deficiency/Traditional Functions: Classical Nutritional Disorders and Diseases	Deficiency: DNA Damage (Negative Effects on Genomic Stability)	Deficiency: New Health Effects	Role on Genomic Stability
Fat Soluble							
Vitamin D (Chole-calciferol)	10 μg	4X	Milk and dairy products	Rickets, whose common symptoms include weak and misshapen bone, bowlegged and poor muscle tone; Required to incorporate calcium, phosphate and magnesium into bones	—	Colorectal cancer and adenoma, increase cell proliferation	—
Vitamin K	80 μg	375X	Leafy vegetables (spinach, cauliflower, cabbage), tomato and some vegetable oils	Elevated hemorrhage due to reduced prothrombin levels, particularly in premature or anoxic infants	—	—	—
Vitamin A	1 mg RE[Ψ]	5X (retinol); 100X (β-carotene)	Some pigmented vegetables and fruits	Poor night vision, eye lesions, and in severe cases, permanent blindness; elevated illness and death from infections	—	—	

(*Continued*)

Table 8.2 (*Continued*)

Vitamins	Maximum Adult RDA[Φ]	Safe Upper Intake Limits (Relative to RDA)[θ]	Predominant Food Sources	Deficiency/Traditional Functions: Classical Nutritional Disorders and Diseases	Deficiency: DNA Damage (Negative Effects on Genomic Stability)	Deficiency: New Health Effects	Role on Genomic Stability
Fat Soluble							
Vitamin E	10 mg α-TE [ϑ]	100X	Oilseeds, leafy vegetables	Increased fragility in red cells and hemolysis, as well as impaired sensation and neuromuscular activity	Increased baseline level of DNA strand breaks, chromosome breaks and oxidative DNA damage and lipid radicals adduct on DNA	Heart disease, colon cancer, immune system impairment	Prevention of lipid and DNA (radiation mimic) oxidation
Water Soluble							
Vitamin B12 (Cyano-cobalamin)	2 μg	500X	Fish, dairy products, meat	Megaloblastic anemia where proper maturation of red blood cells is hampered, among other symptoms such as anorexia, intestinal discomfort, depression and some neurological problems	Chromosome breaks	Neuronal damage also see folate	Maintaining methylation level in DNA

Biotin	30–100 μg	300X	Seeds, animal products	Rare	—	—	—
Folate	200 μg	50X	Fruits, leafy vegetables, legumes including dark and dried beans	Megaloblastic anemia, weight loss, nausea, confusion, irritability and dementia are typical.	Uracil misincorporation into DNA provoking DNA breakage (DNA hypomethylation), chromosome breaks (radiation mimic)	Colorectal cancer, most heart diseases, altered risks of birth defects (neural tube), brain dysfunction (Down's syndrome), tumorigenesis, acute lymphoblastic leukemia in children	Maintaining methylation level in DNA, efficient recycling of folate
Vitamin B1 (Thiamine)	1.5 mg	67X	Crops	Beriberi, symptoms include weak muscles, fatigue, depression, irritability, weight loss, with frequency cardiovascular complications and paralysis	—	—	—
Vitamin B2 (Riboflavin)	1.7 mg	—	Leafy vegetables (i.e., broccoli), cereals, liver, beef and cheese	Nouse dermatitis, altered coloration and texture of lips and tongue, fatigue and sensitive and vascularized eyes, bloodshot	—	—	—

The world population is expected to grow from 6 billion to around 10 billion by 2050. Virtually all of the anticipated increase in population will occur in Africa, Latin America, and Asia (23–25,30,31). These regions already face serious problems of food production and access, water scarcity, nutritional disorders, and malnutrition of macronutrients and micronutrients (23–25,30,31). Among the undernourished, children under five years of age are particularly at risk. A high percentage of children are underweight, and low birth weight becomes an important factor in child malnutrition and premature death (23–25,30). Notably, countries that have dramatically reduced the incidence of malnutrition have also concurrently reduced their birth rates dramatically over the last century.

Therefore, to ensure an adequate dietary intake of all essential micronutrients and to augment the consumption of various nutraceuticals by people around the world, great and intelligent efforts are needed to improve the nutritional and nutraceutical quality of agricultural produce, with regard to their micronutrient composition, concentration as well as their biological availability (16,17,27,38–41).

8.2 MICRONUTRIENT BIOAVAILABILITY AND APPROACHES TO REDUCE MICRONUTRIENT MALNUTRITION

The mineral and vitamin content of food crops should be considered at the same time with its bioavailability (20,42,43). The total content, or absolute concentration, of a given nutrient in a food is not always a reliable indicator of its useful nutritional quality, because not all of the nutrients in food are absorbed (20,42,43).

The human nutritionists employ the concept of bioavailability of micronutrients, which refers to the percentage of a given nutrient that is potentially available for absorption from an ingested food, and once absorbed, utilizable for normal physiological functions and even for storage in the body (25,40,44). Bioconversion is defined as the fraction of a bioavailable micronutrient (i.e., absorbed provitamin A carotenoids) that is converted to the active form of a nutrient (retinol) (44,45).

The digestive processes help to release and solubilize nutrients so they can diffuse out of the bulk food matrix into the enterocytes of the human intestine. Micronutrients can be present in several chemical species in plant foods and their quantities may vary according to growth environment, plant species and genotype, and cultural practices utilized to grow the plant (21,22,24,43,46,47). These chemical forms may have characteristically distinct solubilities and reactivities related to other plant components and other meal constituents; absorption then is a function of physicochemical properties and form of micronutrients (i.e., free, complexed, charged, dispersible). The absorption and transport of nutrients may be influenced by the presence of inhibitory (i.e., antinutrients) and promotive (i.e., promoters that can enhance absorption and utilization) substances in the food matrix (Table 8.3) (21,22,24,32,39,43,46,47).

As a result, for a complete and realistic description of the nutritional adequacy of food from dietary micronutrient viewpoint, three factors should be assessed: (1) the concentration of the micronutrients at the time of consumption; (2) the nature of chemical species of the micronutrients present; and (3) the bioavailability of these forms of the micronutrient as they exist in the meal consumed (21,22,24,32,39,42,43,46,47).

The bioavailability of normal micronutrients from plant sources ranges from less than 5% for some minerals such as calcium and iron, over 90% for sodium and potassium (20,21,43). The three most common and widely recognized strategies for reducing micronutrient mineral and vitamin malnutrition include: (1) supplementation with pharmaceutical preparations, (2) fortification, (3) and dietary food diversification (16,21,22,31,39–43,48–50).

For instance, iron and zinc supplementation has been useful in developing countries for rapid improvement of the status of both minerals in deficient individuals, but this approach is relatively expensive and often has poor compliance, particularly with medicinal Fe because of unpleasant side effects (22,43).

Commercial fortification of foods is familiar to most of us. Minerals and vitamins are added to a particular food vehicle during its processing, well after the foods have left the farm and before they are distributed through various marketing channels for consumer purchase and consumption (31). Thus, fortification refers to incorporation of nutrients at superior levels than those existing in the original (i.e., unprocessed) (42,48,49). This may include adding nutrients not normally associated with the food. Food fortification is usually the best long term strategy, but its effectiveness depends on the compatibility of fortified foods with local culinary habits. Iron is the most difficult mineral to incorporate into foods (due to technical problems related to the choice of suitable iron compounds) and to ensure adequate absorption (22,43,48,49). For example, those with relatively high bioavailability, which are water-soluble iron compounds such as ferrous sulfate, usually provoke unacceptable color and flavor changes in food. When water-soluble iron compounds are incorporated into cereal flour, they often cause rancidity; and in low grade salt, they rapidly lead to undesirable color formation. Furthermore, other compounds which are organoleptically inert, such as elemental iron powders, are so poorly absorbed as to be of little or no nutritional value (22,43,48,49).

Both supplementation and fortification have treated the symptoms of micronutrient malnutrition rather than the underlying causes. While many of these interventions have been successful in the short term, these strategies have proved to be prohibitively expensive in marginal economies, unsustainable and incapable of reaching all the individuals affected. Ironically, those segments of population at high risk (poor women, infants, and children) usually live in remote places either from a clinic and health care professionals or do not have ready access to processed and fortified foods (22,24,30,43,48,49). Finally, food diversification may also be quite difficult, but not impossible, in developing countries for economic, social, or traditional reasons, and people who avoid milk products in developed nations normally do so because they dislike or are intolerant to dairy products (16,20,38).

Within the agricultural community, conventional plant breeding efforts during the green revolution were focused on productivity and efficiency of cropping systems (mostly cereal crops), being greatly successful in supplying enough calories and macronutrients to prevent the threatening global starvation and shortage of foods predicted at the beginning of 1960s (37,51). Remarkably, the nutrition community has never embraced agriculture as a key tool to be used to fighting "hidden hunger"; paradoxically the green revolution may have contributed to some unforeseen negative consequences on human nutrition and health referent to micronutrient malnutrition (22,25,37). Thus, in some developing countries the rise in micronutrient deficiencies may be associated to changes in the patterns in cultivation toward cereals, which was paralleled by a significant decreased per capita production of traditional edible legumes that are a much richer source of micronutrients than cereals, especially after cereals have been milled and polished before consumption (22,23,25).

Plant mineral and vitamin concentrations vary among plant sources (i.e., species, cultivars) and within plant tissues (i.e., leafy structures against seeds); thereby demonstrating the existence of genetic variability, which can contribute to the plant's ability to acquire, sequester, synthesize, and accumulate micronutrients (16,21,22,33,34,37,38,52). In contrast to macronutrients which can represent up to 30 to 50% in dry weight in some tissues (g/100 g portion of food), individually, minerals and vitamins when present constitute a very tiny quantity ranging from a microgram to a milligram per 100 g of food (less than 0.1%) (2,16,21,22,33,34,37,38,52). Therefore, significant quantitative and qualitative

Table 8.3

Antinutritional and promoter substances that reduce and enhance, respectively, the bioavailability of some important micronutrients for human nutrition and health, and even genomic stability, and their food distribution.

Antinutrient(s)	Micronutrient(s) Negatively Affected (Less Bioavailability)	Common Dietary Food Sources of Antinutrient(s)	Promoter(s) [Enhancer(s)]	Micronutrient(s) Positively Affected (Improved Bioavailability)	Common Dietary Food Sources of Promoter(s)
Some tannins and other polyphenols	Iron, zinc	Pigmented beans, sorghum, coffee, tea	Meat factors (cysteine-rich polypeptides)	Iron, zinc	Animal meats (i.e., pork, beef, fish)
Hemagglutinins (i.e., lectins)	Iron, zinc	Wheat and most legumes	Some free and essential amino acids (i.e., lysine, histidine, sulfur-containing)	Iron and/or zinc	Animal meats (i.e., pork, beef, fish)
Fiber (i.e., cellulose, cutin, hemicellullose, lignin)	Iron, zinc	Whole-cereal-based products	Some organic acids and/or their salts (i.e., ascorbic acid, citrate, fumarate, malate)	Iron and/or zinc	Several fresh fruits and vegetables
Toxic heavy metals (i.e., Cd, Hg, Pb, Ag)	Iron, zinc	Contamined leafy vegetables, tubers and grains (i.e., Cd in rice) from metal-polluted soils	Plant ferritin	Iron	Legume crops, leafy vegetables

Phytic acid or phytin	Iron, zinc, magnesium, calcium	Whole legume and cereal crops	Hemoglobin	Iron	Animal red meats
Oxalic acid	Calcium	Spinach	β-Carotene, vitamin A	Iron	Green and orange vegetables, red palm oil, yellow maize
—	—	—	Iron, zinc	Vitamin A	Animal meats
—	—	—	Selenium	Iodine	Sea foods, organ meats, tropical nuts and cereals, amounts vary depending on soil levels
—	—	—	Vitamin E (α-tocopherol)	Vitamin A	Vegetable oils, green leafy vegetables

Sources: Adapted from References 22, 24, 27.

changes are feasible for minor plant components. Genetic manipulation to augment the levels of these components would require minimal diversion of precursors and some modifications in the plant's ability to store or sequester the target micronutrients (16,33,34,52,53). Interestingly, the tolerable upper intake levels in humans for minerals fluctuate between 1- and 13-fold in their RDA values, whereas those for vitamins are higher than those for minerals, and, as it has been reviewed earlier, micronutrient intakes superior to RDAs, but not higher than those tolerable levels for humans, provide health benefits including genomic stability (Tables 8.1, 8.2) (3–7).

All this raises the opportunity for the molecular biotechnology as an emerging and powerful approach with the potential for improving nutritional quality of food plants, altering the composition, content, and bioavailability of the existing micronutrients [i.e., modifying chemical forms of the stored micronutrient, removing (or reducing the level of) antinutritional compounds, or elevating the amount of promoter substances] (Table 8.3), or accumulating novel and bioavailable minerals and vitamins in edible parts (i.e., the endosperm of cereals), which usually lack these components (18,33,34,41,49,50).

8.3 MINERALS

In developing nations, cereal grains such as wheat, maize, rice, and sorghum, and some legumes such as common bean and soybean, are the primary and cheap sources of essential minerals as iron, zinc, and calcium (20,37,43). Minerals with chemical similarities can compete for transport proteins or other uptake mechanisms, as well as for chelating organic substances, hindering absorption (Table 8.3) (32,54,55). In fact, it has also been suggested that antinutritional factors that interfere with proper nutrient absorption and bioavailability account for a large proportion of world wide micronutrient deficiencies (40,55).

Thus, increasing the amount of bioavailable micronutrients in plant foods for human consumption by molecular biotechnology is a challenge that is not only important for developing countries, but also for many industrialized countries. Theoretically, it could be achieved by increasing the total level of micronutrients in the edible part of staple crops, such as cereals and pulses, while simultaneously increasing the concentration of compounds which promote their uptake, for example ascorbic acid, and by decreasing the concentration of chemicals that inhibit their absorption, such as phytic acid or some phenolic compounds (Table 8.3) (22,41,43,50).

8.3.1 Iron

Iron is both an essential micronutrient and a potential toxicant to cells; as such, it requires a highly sophisticated, coordinated, and complex set of regulatory mechanisms to meet the demands of cells as well as prevent excess accumulation (29). The human body requires Fe for the synthesis of the oxygen transport proteins hemoglobin and myoglobin and for the formation of heme enzymes and other Fe-containing enzymes that are particularly important for energy production, gene regulation, immune defense, regulation of cell growth and differentiation and thyroid function (Table 8.1) (28,29,43). The body normally regulates Fe absorption so as to replace the obligatory iron losses of about 1–1.5 mg per day. Thus, the body must be economical in its handling of iron, for example, when a red blood cell dies, its iron is reutilized, and excess level of iron can be stored by a specially designed protein, ferritin, which is used at times of increased iron metabolic requirements (28). In spite of these ingenious physiological approaches, iron deficiency is estimated to affect around 30% of the world population, making iron by far the most deficient nutrient worldwide. In general, the etiology of iron deficiency can be viewed as a negative balance

between iron intake and iron loss. Whenever there is a rapid growth, as occurs during infancy, early childhood, adolescence, and pregnancy, positive iron balance is difficult to maintain (9,28). The blood volume expands in parallel with growth, with a corresponding increase in iron requirement (9).

Dietary iron is constituted by heme iron (animal origin) and nonheme iron (inorganic salts mainly from vegetal sources); the first one is absorbed by a distinct route and more efficiently than nonheme iron (Table 8.1). Usually, nonheme iron bioavailability is very low (less than 5–10%) due to its poor solubility and interaction with other diet components known as antinutrients (28,43). Inadequate absorption of this mineral will first lead to the mobilization of storage iron, and finally to lower hemoglobin levels or anemia (29). Iron deficiency is the most common cause of anemia and is usually due to inadequate dietary intake of bioavailable iron and/or excessive loss due to physiological conditions of parasitic infections (30,32). For example, dietary iron sources in developing countries consist mainly of nonheme iron. Because cereal and legume staples are rich in phytic acid, a potent inhibitor of mineral absorption, and in addition, the intake of foods that enhance nonheme iron absorption such as fruits, vegetables, and animal muscle tissues is often limited, these conditions may serve as major factors responsible for the anemia (Table 8.3) (21,22,43,47,49,55). The major consequences of this deficiency are poor pregnancy outcome, including increased mortality of mothers and children, reduced psychomotor and mental development in infants, decreased immune functions, tiredness, and poor work performance (25,26,30–32).

Increasing ferritin, the natural iron store protein, in food crops, has been suggested as an approach to raise iron levels and bioavailability. Ferritin is a multimeric iron storage protein, composed of 24 subunits, and has a molecular structure highly conserved among plants, animals, and bacteria (56,57). This protein is capable of storing up to 4500 Fe atoms in its central cavity, which are nontoxic, biologically available, and releases them when iron is required for metabolic functions. In fact, recent studies have demonstrated that iron from animal and plant ferritin can successfully be utilized by anemic rats and humans (56,58,59).

While staple food, such as corn and wheat flours are usually fortified with iron, rice grains present much hard problems and challenges. In addition, whole brown rice is barely consumed, and its commercial milling (polishing) produces considerable loss of micronutrients, up to 30% and 67% for zinc and iron, respectively, by eliminating its outer layers where these metals are accumulated (27).

With the aim of increasing the iron content and its bioavailability in rice, two different research groups have overexpressed a ferritin gene into its endosperm isolated from either common bean or soybean (Table 8.4) (60–62). In both cases the plant ferritin is produced at high levels and correctly accumulated in the cereal endosperm. Notably, the iron content of bean ferritin rice is 22.1 μg/g dry weight whereas soybean ferritin rice stores up to 31.8 μg/g dry weight, resulting in two- and threefold greater levels, respectively, than that of the corresponding untransformed crop (10–11 μg/g dry weight). A two to three times extra iron enrichment in ferritin in transgenic grains would appear to be of nutritional significance. In fact, a daily consumption of about 300 g of the iron-rich rice by an adult would be sufficient to provide 50–75% of the daily adult requirements for this mineral, which is about 13–15 mg (Table 8.1).

Recently, Vansconcelos et al. (63), a third distinct research group, also reported the expression of soybean ferritin gene, driven by the endosperm-specific glutelin promoter, leading to higher iron accumulation in transgenic *indica* rice seed than control grains, even after commercial milling. They selected as target the *indica* rice line IR68144-3B-2-2-3, an elite line, which presents high tolerance for tungro virus and an excellent grain quality,

good yield and resistance for growing in mineral-poor soils, and high iron level in the crop (15–17 μg/g untransformed brown rice). Transgenic rice lines were obtained containing as much as 71 μg iron/g dry weight unpolished rice. This accounts for a 4.4-fold increase in iron compared with that of the control; a two- to threefold extra iron content of transformed rice with plant ferritins would already be of nutritional relevance as noted earlier (Tables 8.1, 8.4) (60–62). But when the iron levels of the rice grains (untransformed and transgenic) were assessed after the seeds were polished, they indicated that the highest iron content of transgenic lines ranged from 19–37 μg/g milled rice, versus control material of only 10 μg/g milled rice. This is the first report which shows that after commercial milling the iron concentration remains higher than that of that milled negative control, and even that of untransformed brown crop. These results with transgenic rice expressing a ferritin from either soybean or bean would imply that low iron concentration in food seeds may not result from low iron availability for transport, but rather from a lack of sequestering and storing capacity in the seeds.

In order to explore and test the potential benefit of iron-improved transgenic rice incorporating soybean ferritin in its edible tissue (60), a standard hemoglobin depletion bioassay was employed with anemic rats followed by complete diets having equivalent quantities of either iron as $FeSO_4$ (a popular compound used in anemic human beings in medical treatments) or bioengineered ferritin rice. Iron-rich rice diet was as effective as the diet containing $FeSO_4$, and it was shown that full recovery of anemia in rats occurred after 28 days of treatment with any of the iron sources (Table 8.4) (64).

It is generally agreed that nutrients are effectively utilized from breast milk and that breast-fed infants possess a lower prevalence of infections than those fed with commercial formula. Breast milk not only provides the infant with a well balanced supply of nutrients, but also several unique components that facilitate nutrient digestion and absorption, protection against pathogenic microorganisms, and promotion of healthy growth and development. It is believed that those benefits are due in part to milk proteins (41,65,66). One of such bioactive proteins is lactoferrin. Lactoferrin is an 80 kDa iron-binding glycoprotein belonging to the transferrin family and is found in elevated levels (1–2 g/l) in human milk. Proposed biological activities for this protein include antimicrobial properties, regulation and facilitating iron absorption, immune system modulation, cellular growth activity, and antivirus and anticancer activities (41).

Rice was used as an useful bioreactor to produce, in its edible endosperm, recombinant human lactoferrin to infant food because it presents a low allergenicity, and is likely a vehicle safer than transgenic microorganisms or animals. Therefore, a human milk lactoferrin linked to a rice glutelin 1 promoter was inserted into rice cells and a very high expression level was reached in a large scale field trial (5 g of recombinant human lactoferrin per kilogram of dehusked transgenic rice), being stable for four generations. In fact, the boosting expression of lactoferrin in rice endosperm turned this cereal grains pink, as a consequence of iron bound to lactoferrin (65). The gross nutrient composition of transgenic cereal was similar to that of nontransformed rice, except for a twofold increase in iron content (negative control, 8.7 μg/g dehusked rice; transgenic rice, 19.3 μg/g dehusked rice) probably because each molecule of lactoferrin is able to bind two Fe^{3+} ions (Table 8.4) (65).

Additionally, the lactoferrin purified from transgenic rice exhibited similar pI, antimicrobial activity against a human pathogen (i.e., inhibition of growth of enteropathogenic *Escherichia coli*, one of the most common causes of diarrhea in infants and children) and bind and release iron capacity at acidic gastric pH as those of native human lactoferrin (Table 8.4) (65,66). Lactoferrin-rich rice crops (as lactoferrin is bioactive and therefore, has the ability to store iron in a bioavailable manner) can be incorporated directly into infant formula or baby foods, and even to be consumed by people at any age; without purification

Table 8.4
Manipulation of selected micronutrients for human nutrition and nutraceutical uses by molecular biotechnology.

Micronutrient	Molecular Approach	Improved Plant	Results and Comments	Ref.
Mineral				
Iron	Expression of bean-ferritin- or soybean-ferritin	Rice	Both bean-ferritin- and soybean-ferritin-rice presented high levels of stored iron, in their edible endosperm being of nutritional and nutraceutical significance for fighting against anemia disease and other iron-related deficiencies. In fact, anemic rat fed with iron-rich transgenic rice had a full recovery from that disease, and thus a food with enhanced iron bioavailability.	60–63.
	Production of human milk lactoferrin	Rice	Overaccumulation of lactoferrin in rice endosperm, which turned pink; transgenic protein showed similar antimicrobial activity against a human pathogen and both bind capacity and release iron at acidic gastric pH as native human lactoferrin; also immune system modulation, cellular growth activity, antivirus and anticancer properties are expected	65, 66.
Phosphorus	Expression of microbial or plant phytase	Canola, soybean, rice, maize, wheat	Phytic acid reduced amount in crops; significant improvement in essential mineral bioavailability such as iron, calcium and zinc and in protein digestibility are expected. Low-phytic-acid maize enhanced iron absorption in humans that consumed tortillas whereas pigs fed with this cereal exhibited a higher phosphorus absorption	43, 47, 61, 68–71.
Vitamin				
Vitamin A	Production of carotenoid biosynthetic enzymes	Canola, rice, tomato	Enhanced content of provitamin A and other nutraceutical carotenoids such zeaxanthin	79–82.
Vitamin E	γ-Tocopherol methyltransferase expression	*Arabidopsis*	Increased levels of α-tocopherol, higher vitamin E activity, nutraceutical	90.
Vitamin C	Expression of rat L-gulono-γ-lactone oxidase or strawberry D-galacturonic acid reductase	Lettuce, *Arabidopsis*	Improved antioxidant and nutraceutical properties and iron bioavailability; reduction, or elimination of bisulfite utilization to prevent browning in leaf lettuce	94, 95.

this milk protein provides a convenient advantage over other heterologous protein expression systems (65,66).

These achievements have demonstrated the feasibility of producing ferritin or lactoferrin in a very important food crop as rice, as a cheap and good source of bioavailable iron (Table 8.4). However, further investigations are now needed to show biological usefulness in the human diet and their contribution to a solution to global problems of iron deficiency.

8.3.2 Zinc

Most of the zinc in the human body is in the bones and muscles. This mineral acts as a stabilizer of the structures of membranes and cellular components. Its biochemical function is as an essential component of a large number of Zn-dependent enzymes, especially in the synthesis and degradation of biomacromolecules such as carbohydrates, proteins, lipids, and nucleic acids, as well as wound healing (43). Because of a significant portion of cellular zinc is found in the nucleus, it seems that mechanistically this metal is participating in processes which include stabilization of chromatin structure, DNA replication and transcription by the activity of transcription factors and DNA and RNA polymerases, as well as playing a key role in DNA repair and programmed cell death (Table 8.1) (10).

These features give Zn an essential and unique role for healthy growth and development of human beings. In fact, its deficiency reduces appetite, growth, sexual maturity, and the immune defense system (22,30,43). Meat and seafood are good sources of Zn for people in industrialized nations, providing up to 70% of their requirements. However, its deficiency has just recently taken dimensions as a serious public health problem (10).

8.3.3 Calcium

Calcium is required for the normal growth and development of the bones. It accumulates at the rate of about 150 mg per day during human skeletal growth until genetically predetermined peak bone mass is reached in the early twenties. Bone mass is then stable until about 50 years of age in men or before menopause in women (43). After that time, Ca balance becomes negative and bone is lost from all skeletal sites, which is related with a marked rise in fracture rate in both sexes, but particularly in women. So, adequate Ca intake during adolescence is critical. Osteoporosis in old age is characterized by a microarchitectural deterioration of bone tissue, leading to increased bone fragility as well as to an increased risk of fractures (Table 8.1) (22,46). Also, during early childhood this mineral is of a significant concern as its deficiency can cause rickets (22).

Besides its structural role in humans, Ca plays major regulatory functions in several biochemical and physiological processes such as blood clotting, muscle contraction, cell division, transmission of nerve impulses, enzyme activity, cell membrane function and hormone secretion (37,46). Milk and dairy products are the most important sources of calcium, but again these foods are scarce in less developed countries; in Mexico maize tortillas are a good and important Ca source for great part of its population (20,39).

8.3.4 Phytic Acid

Seeds normally accumulate severalfold more phosphorus than that which is needed to support basic cellular functions. In the normal seed this excess P is incorporated into a single small molecule referred to as phytic acid (*myo*-inositol-1,2,3,4,5,6-hexa*kis*phosphate). Grain crops typically contain about 10 mg of phytic acid per gram of dry seed weight, representing about 60–85% of total P (47). Once synthesized, most phytic acid is deposited as a mixed phytate or phytin salt of K and Mg, although phytates also contain other mineral cations such as Fe and Zn. During germination, phytate salts are broken down by the action of phytases, releasing P and *myo*-inositol for use by the growing seedling. Phytic acid is a polyanion at

physiological pH and an effective chelator of nutritionally important mineral cations (Ca, Zn, Mg, and Fe) (Table 8.3) (22,32,40,47,54,55,67). Once consumed in human foods or animal feeds, phytic acid binds to these minerals in the intestinal tract to form mixed and unavailable salts that are largely excreted. This phenomenon contributes to mineral deficiency in human populations (40). In addition, diverse investigations suggest that phytic acid may also react with proteins making them partially unavailable for human absorption (22,67). On the other hand, phytic acid can readily be degraded in cereal and legume foods by the addition of exogenous phytases either during food processing or during digestion, increasing mineral absorption dramatically (22,43,47,50). Other interesting approach that has been proposed is for an *in vivo* decrease of phytic acid levels through raising phytase activity in crops using genetic engineering. Also, it is important that the enzyme should be able to withstand the cooking temperatures that occur during food preparation. Thus, highly important agronomic crops such as canola, soybean, rice, wheat, and even tobacco seeds have been successfully transformed with fungal phytase genes, driving their expression by either constitutive or seed-specific promoters (Table 8.4) (43,50,61,68,69). Significant enhancement on mineral bioavailability is expected in transgenic crops synthesizing and accumulating functional microbial phytases. On the other hand, consumption of natural low phytic-acid mutant maize improved iron absorption in humans fed with maize-based diets, for example tortillas prepared with this type of maize. The phytic acid level was reduced significantly representing only 35% of that found in wild-type maize and outstandingly, absorption of iron from transgenic tortillas was nearly 50% greater than from normal tortillas (Table 8.4) (70). Moreover, when pigs were fed with low phytic-acid maize, a higher P bioavailability of up to 62% than that obtained from the nonmutant, wild-type grain, was observed (71).

8.4 VITAMINS AND NUTRACEUTICALS

Vitamins are defined as a diverse group of food-based essential organic substances (relatively small molecules but comparable in size to amino acids or sugars) that are not synthesized by the human body, but by plants and microorganisms. Therefore, vitamins are nutritionally essential micronutrient for humans and function *in vivo* in several ways, including: (1) as coenzymes or their precursors (niacin, thiamin, riboflavin, biotin, pantothenic acid, vitamin B6, vitamin B12, and foliate); (2) in specialized functions such as vitamin A in vision and ascorbate in distinct hydroxylation reactions; and (3) as components of the antioxidative defense systems (vitamins C and E and some carotenoids), and as factors involved in human genetic regulation and genomic stability (folic acid, vitamin B12, vitamin B6, niacin, vitamin C, vitamin E, and vitamin D) (Table 8.2) (5,6,42).

Vitamins present in a food source, once taken up by the body, are dissolved either in water or fat (37,42). As a consequence vitamins are classified on the basis of their solubility as water-soluble or fat-soluble vitamins. Vitamins and the chemical structures of each group are presented in Figures 8.1 and 8.2.

8.4.1 Carotenoids as Food Pigment and Provitamin A

The term carotenoids summarizes a class of structurally related compounds, which are mainly found in plants, algae, and several lower organisms, bacteria, and fungi. At present, more than 600 different carotenoids have been identified (72). Saffron, pepper, leaves, and red palm oil possessing carotenoids as their main color components, have been exploited as food colors for several centuries. The color of carotenoids, together with beneficial properties such as vitamin A precursor and antioxidant activity, has led to their wide application in the food industry. They have been used for pigmentation of margarine, butter, fruit juices and

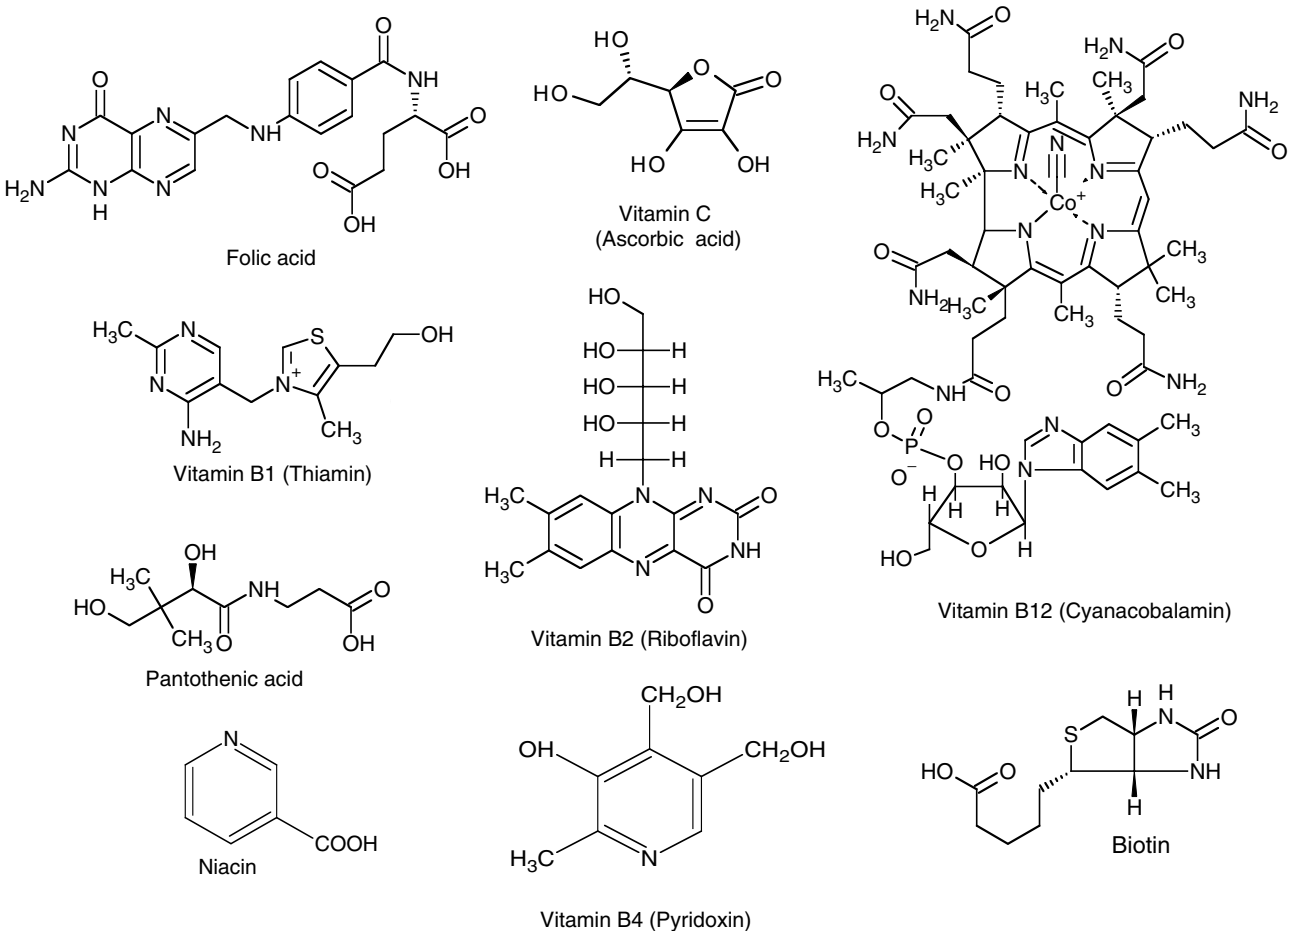

Figure 8.1 Chemical structures of water soluble vitamins.

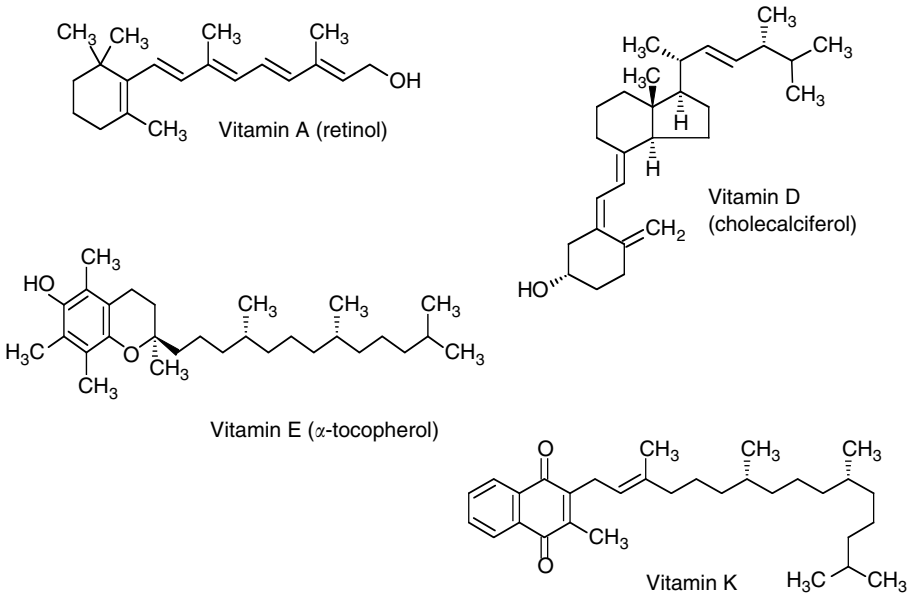

Figure 8.2 Chemical structures of fat soluble vitamins.

beverages, canned soups, dairy and related products, desserts and mixes, preserves and syrups, sugar and flour confectionery, salad dressings, meat, pasta and egg products (17,73).

Carotenoids form one of the most important classes of plant pigments and play a crucial role in defining the quality parameters of fruits and vegetables. Their function as antioxidants in plants in the prevention of photo oxidative damage shows interesting parallels with their potential roles as antioxidants in foods and humans (72). Carotenoids as food colorants take advantage of their very high stability to pH and reducing agents (ascorbic acid); their colors fluctuate from yellow to red, including orange, with variations of brown and purple (17).

Epidemiological studies suggest that the onset of chronic disease states such as coronary heart disease, certain cancers and macular degeneration can be reduced by high dietary intakes of carotenoid-rich foods (72–74). Lycopene has been shown to prevent the incidence of prostate cancer, while zeaxanthin and lutein offer protection against the occurrence of age-related macular degeneration. In addition, β-carotene is the most potent provitamin A carotenoid; α-carotene and β-cryptoxanthin also possess provitamin A activity, but to a lesser extent than β-carotene. Their deficiency can result in blindness and premature death (Table 8.2) (17,74).

Marigold (*Tagetes erecta* L.) varieties range in petal color from white to dark orange. This pigmentation of flowers is due to the massive synthesis and accumulation of carotenoids during petal development. The dark orange varieties possess concentrations of carotenoids that are 20-fold greater than those found in ripe tomato fruit (75). For this reason, marigolds are grown commercially as an important source of carotenoids and used as an animal feed supplement (73).

In our laboratory, Delgado-Vargas et al. (76) found that sunlight illumination produces a favorable equilibrium toward all *trans*-lutein isomers. Also, *trans*-isomers showed increased red hues, and the poultry fed with sunlight-illuminated marigold meal (lutein as its main carotenoid) showed a better egg yolk-pigmentation than controls. These authors also suggested that other components different from carotenoids may participate in pigmentation efficiency.

Also, the antimutagenicity activity of carotenoids from Aztec marigold has been evaluated. It was concluded that lutein was the compound with a higher activity in marigold extracts; however, the mixture of carotenoids in the marigold extract had higher antimutagenicity activity. In addition, it was suggested that lutein and 1-nitropyrene (mutagen) formed an extracellular complex that limits the bioavailability of 1-nitropyrene and consequently its mutagenicity (77).

8.4.1.1 Carotenogenesis in Tomato

In general, carotenoids are compounds comprised of eight isoprenoid units whose order is inverted at the center of the molecule. Formally, all carotenoids can be considered as lycopene ($C_{40}H_{56}$) derivatives by reactions involving hydrogenation, dehydrogenation, cyclization of the ends of the molecules, or oxidation (Figure 8.3A), which in addition to the number and location of conjugated double bonds inside their structure, influence biological action (antioxidant properties) and pigmentation efficiencies of colorants in food systems (17,74,76,78).

Based on their chemical composition, carotenoids are subdivided into two groups. Those which contain only carbon and hydrogen atoms are collectively assigned as carotene (β-carotene, α-carotene, and lycopene). The majorities of natural carotenoids have at least one oxygen function, such as keto, hydroxy, or epoxy groups and are referred to as xanthophylls (oxy-carotenoids) (17,72,74,76,78). The first step in the carotenoid biosynthetic pathway is the head-to-head condensation of two molecules of geranylgeranyl pyrophosphate (GGPP) to produce the colorless intermediate phytoene (Figure 8.3A) (17,74,75,78,79). This reaction is catalyzed by the enzyme phytoene synthase (PSY). Introduction of four double bonds convert phytoene to red lycopene. In plants, two enzymes carry out those transformations, phytoene desaturase (PDS), and ζ-carotene desaturase (ZDS). Each desaturase catalyzes two symmetric dehydrogenation steps; thus, the first enzyme catalyzes the conversion of ζ-carotene via phytofluene (phytoene to phytofluene to ζ-carotene) whereas the second transforms ζ-carotene to lycopene through neurosporene. In contrast, the bacterial phytoene desaturase (ctrl) is capable of introducing the four double bonds converting phytoene to lycopene. Subsequently, the ends of the linear lycopene can be cyclized by lycopene cyclases, resulting in the formation of β-carotene and α-carotene. Hydroxylation reactions carried out by hydroxylases [β-carotene hydroxylase (β-*Chy*) and ε-hydroxylase (ε-*Chy*)] produce the xanthophylls β-cryptoxanthin, zeaxanthin, and lutein (Figure 8.3A) (17,74,75,78,79).

Vitamin A refers to a family of essential, fat-soluble dietary compounds required for vision, growth, reproduction, cell proliferation, cell differentiation, and the integrity of the immune system (Table 8.2) (45). The most potent vitamin A compound, all-*trans*-retinol, is able to reverse signs and symptoms of vitamin A deficiency (44,45).

All vitamin A is originally derived from carotenoids, and all green plants produce carotenoids as β-carotene in their tissues as essential photosynthetic pigments. But for many staple crops, to have nutritional value from a micronutrient viewpoint, the carotenoids must also be produced in the nonphotosynthetic edible tissues consumed by humans; however traditional breeding methods have had little success in producing staple crops containing a high vitamin A concentration (17,22).

Research on carotenoid metabolic engineering in plants has focused on increasing nutritional quality, and it includes: (1) introducing variation in carotenoid products in tomato; (2) production of higher levels of preexisting carotenoids in canola; and (3) accumulation of carotenoids in normally carotenoid-free tissues, such as rice endosperm (Table 8.4) (78–83).

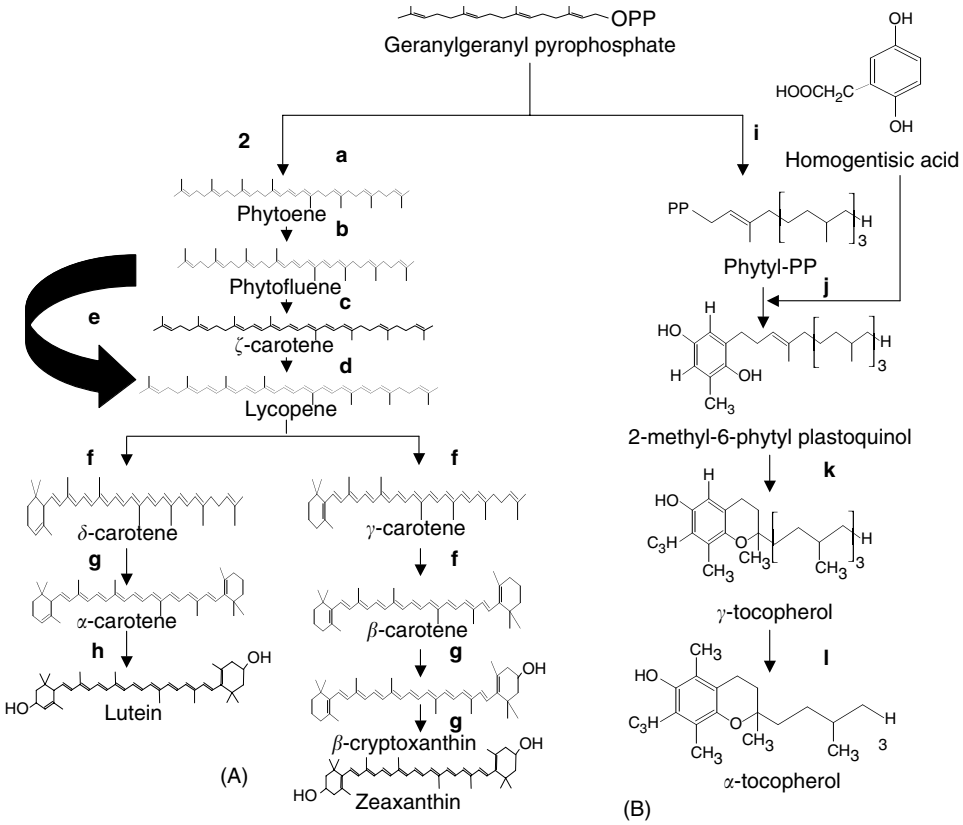

Figure 8.3 Summary of carotenoid (A) and vitamin E (B) biosynthesis pathway in plants. Enzymes carrying out specific reactions (a-h, for carotenoids and i-l, for vitamin E); are named as: a, phytoene synthase (PSY); b and c, phytoene desaturase (PDS); d, ζ-carotene desaturase (ZDS); e, the formation of lycopene through a bacterial phytoene desaturase (ctrl) is indicated with a black thick arrow; f, lycopene ε-cyclase, g, β-carotene hydroxylase (*β-Chy*); h, ε-hydroxylase (*ε-Chy*); i, hydrogenation enzyme; j, phytyl/prenyl transferase; k, methyl transferase 1 and cyclase; l, tocopherol γ-methyltransferases (γ-TMT). Adapted from Ref. 17, 21, 74, 75, 78, 79, 90.

Tomato fruit and its processed products are the principal dietary sources of lycopene, and also useful for their β-carotene content in minor amounts in the red varieties. At the green stage, tomato fruit has a carotenoid content similar to leaves (essentially β-carotene, lutein, and violaxanthin). But during fruit ripening, the genes mediating lycopene synthesis are up regulated whereas those controlling its cyclization are down regulated leading to over accumulation of lycopene in ripe fruit (up to 90% of total carotenoid, followed by β-carotene and only traces of lutein) (Figure 8.3A) (79).

Because the activity of the enzyme phytoene synthase (PSY) increases during tomato fruit ripening and when lycopene deposition occurs, it has been a preferred target to modify carotenoid profiles and levels in the fruit (Figure 8.3A). The constitutive expression of tomato PSY-1 in transgenic tomato plants led to dwarfism (plants with reduced size), due to redirecting GGPP from the gibberellins biosynthetic pathway into the carotenoid pathway, which reduced the amount of those hormones in the plants. Transgenic fruits produced lycopene earlier in development, but the final levels in the ripe fruits were lower than those in control samples, due to silencing of the endogenous gene (Table 8.4) (84). On the other hand,

Romer and coworkers (81) achieved a significant increment in the levels of β-carotene (provitamin A) in transgenic tomatoes by manipulating their desaturation activity. They produced transgenic lines overexpressing a PDS from *Erwinia uredovora* bacterium using a constitutive promoter; an enzyme capable of producing lycopene from phytoene (Figure 8.3A). Although total carotenoid concentration was not affected, ripe tomato fruits from transformed plants showed a threefold increase in β-carotene levels, accounting for up to 45% of total carotenoids. Tomato with improved provitamin A quality possessed about 5 mg/g fresh weight of all-*trans*-β-carotene (800 retinal equivalents), which satisfy 42% of the RDA, in contrast to normal fruit satisfying only 23% (Tables 8.2, 8.4).

Tomato is one of most productive based on carotenoid production per unit of cultivated area. By metabolic engineering, the large pool of red lycopene could be converted into high value added downstream carotenoids such as xanthophylls, which are an important type of target nutraceuticals, because of their antioxidant properties, their chemical stability and the difficulty in their chemical synthesis (79).

Recently, Dharmapuri et al. (79) reported the hyperexpression in tomato of an *Arabidopsis* β-lycopene cyclase (*β-Lcy*) gene with and without pepper β-carotene hydroxylase (*β-Chy)* gene under the control of the fruit-specific PD*S* promoter (Figure 8.3A). They found that the color of the ripe fruit varied from complete red as in wild-type tomato (by natural lycopene accumulation) to red-orange or to complete orange for transgenic tomatoes expressing only recombinant β-lycopene cyclase, or both recombinant β-lycopene cyclase and β-carotene hydroxylase enzymes, suggesting significant changes in carotenoid composition. The transformed fruits showed up to a 12-fold increase in β-carotene content with respect to their untransformed parental line. The transgenic tomato (containing genes *β-Lcy* + *β-Chy)* accumulated β-carotene as much as 63 μg/g fresh weight as compared to 5 μg/g fresh weight produced by the untransformed fruit. Notably, modified tomato also stored very good levels of both nutraceutical xanthophylls; β-cryptoxanthin (11 μg/g fresh weight) and zeaxanthin (13 μg/g fresh weight), but they are not detectable in control parent fruit or transformed tomato with only *β-Lcy* gene (Table 8.4). These results demonstrate that β-carotene pool can be converted into xanthophylls by the overexpression of pepper *β-Chy* and thus adding nutraceutical and commercial value to tomato.

8.4.1.2 Carotenogenesis in Other Food Crops

Another successful genetic manipulation of carotenogenesis has been reported in canola (*Brassica napus*). The bacterial (*Erwinia uredovora*) phytoene synthase with a plastid targeting sequence was overexpressed in a seed-specific manner using a napin promoter from rapeseed (Figure 8.3A) (80). Transgenic embryos were visibly orange, as compared with those green from control seeds, and the mature seed exhibited up to 50-fold more carotenoids, mainly α- and β-carotene, both presenting activities of provitamin A. Carotenoid-rich transgenic canola seed reached up to 1.6 mg per gram of fresh weight and produced an oil with 2 mg of carotenoids per gram of oil (Tables 8.2, 8.4).

Worldwide, vitamin A deficiency causes visible eye damage in around 3 million preschool children and up to 500 thousand of those children become partially or totally blind each year because of this deficiency, and approximately two thirds of them die within months of going blind. The estimates of the subclinical prevalence of vitamin A deficiency range between 100 and 200 million across the world. In developing countries several clinical trials have shown that vitamin A capsules can reduce mortality rates among preschool children by 23%, whereas improved vitamin A nutrition could prevent 1.2 million deaths annually among children aged 1–4 years (31). In addition, because vitamin A deficiency is common among vast populations of Asia, Africa, and South America, whose principal source of food

is rice, engineering these crops to produce provitamin A-type carotenoids is of great importance (72,74).

Rice is generally consumed in its polished version, as commercial milling removes the oil-rich aleurone layer which becomes rancid during storage mainly in tropical and subtropical regions. Mature rice (*Oryza sativa*) endosperm is capable of synthesizing and accumulating GGPP but completely lacks carotenoids (Figure 8.3A) (85). In rice endosperm, the additional enzymatic activities needed to produce β-carotene was genetically engineered (82). To achieve this, four plant enzymes are necessary, but alternatively the number may be reduced to three as a bacterial carotene desaturase catalyzes the introduction of four double bonds required to produce lycopene (Figure 8.3A). Therefore three new genes (a plant phytoene synthase gene from daffodil, a bacterial phytoene desaturase gene from *Erwinia uredovora* and a lycopene β-cyclase also from daffodil plant) were transferred to rice. The first and third genes were driven by the endosperm-specific promoter of the rice glutelin gene, whereas a constitutive CaMV 35S promoter was used for the phytoene desaturase gene. Interestingly, transgenic rice seeds exhibited a beautiful golden yellow color after milling and increased accumulation of β-carotene in edible endosperm; as well as the xanthophylls, zeaxanthin, and lutein were formed to some extent, resulting in a carotenoid qualitative profile somehow analogous to that of green leaves. However, golden rice showed a higher proportion of β-carotene in their endosperm than that of the other two carotenoids, with a maximum amount of 1.6 μg/g dry weight; however, this quantity only represents 1–2% of carotenoid concentration in transgenic rapeseed (80) (Table 8.4). Nevertheless, it is noteworthy that in a typical Asian diet (about 300 g of rice per day), provitamin A-rich golden rice could provide nearly the full daily vitamin A requirement (85) (Table 8.2). It has been suggested that β-carotene accumulated in golden rice endosperm can be converted to retinol easier than β-carotene in vegetables, where provitamin A is converted to retinol at a rate equivalent to 26 to 1, due to the physicochemical properties of endosperm matrix (31,85). This significant accomplishment in plant biotechnology of improving the nutritional value of rice with beneficial carotenoids can benefit human nutrition and health (83). A future project aims to join iron-rich rice lines expressing ferritin with golden rice lines because it is known that provitamin A improves the iron bioavailability (Table 8.3) (85).

Nopal cactus (its young cladodes are called nopalitos) is low in calories and since Mesoamerican times has been eaten as a vegetable and fruit source in Mexico. At present, the economic and social importance of nopal is not only because large areas are covered with wild and commercial species in all arid and semiarid Mexican regions, but also because of its remarkable nutritional and nutraceutical qualities. For example, the intake of broiled nopalitos improved glucose control in adult people with noninsulin-dependent diabetes mellitus; it is also known that nopal diminishes human cholesterol levels (35,86). On the other hand, nopal is a good source of dietary fiber, calcium, iron, zinc, and vitamin C, and thereby can also be used in treatments against scurvy. However, although β-carotene is accumulated in nopal, its amount is very low; in fact its provitamin A level depends on nopalito development stage and nopal variety (35,86).

In our laboratory, Paredes-López et al. (87) have developed a genetic transformation system for nopal cactus (*Opuntia* sp.) through *Agrobacterium tumefaciens*, obtaining regenerated transgenic nopal plants. Thus, it has been proposed to use the nopal plant as a bioreactor for improving the production and storage of provitamin A by introducing additional genes for carotenoid biosynthesis to obtain β-carotene (P. Garcia-Saucedo, O. Paredes-López, personal communication, 2004). Nopal could become an important, cheap, and accessible source of vitamin A, and other nutraceuticals such as lutein or zeaxanthin for a great part of the population in Mexico.

8.4.2 Vitamin E

The intense research efforts which have surrounded vitamin E, a lipid-soluble antioxidant, support the hypothesis that preventing free radical-mediated tissue damage, for example to cellular lipids, proteins, or DNA, may play a key role in decreasing or delaying the pathogenesis of a variety of degenerative diseases such as cardiovascular disease, cancer, inflammatory diseases, neurological disorders, cataract, and age-related macular degeneration, and a decline in the immune system function (Table 8.2) (8,21). It has been suggested that vitamin E supplementation of 100 to 400 international units (IU) or around 250 mg of α-tocopherol per day may help reduce the magnitude of occurrence of such health disorders. Vitamin E is represented by a family of structurally related compounds, eight of which are known to occur in nature, being isolated from vegetable oils and other plant materials. The eight naturally occurring compounds are α-, β-, γ-, and δ-tocopherol (which differ only in the number and position of methyl substituents on the aromatic ring), and α- β-, γ-, and δ-tocotrienols (8,33). Tocotrienols differ from the corresponding tocopherols in that the isoprenoid side chain is unsaturated at C3′, C7′, and C11′. The phenolic hydroxyl group is key for the antioxidant activity of vitamin E, as donation of hydrogen from this group stabilizes free radicals (Figure 8.2). The presence of at least one methyl group on the aromatic ring is also critical. α-tocopherol, with three methyl groups, is the most biologically active of all homologues occurring in nature as a single isomer, followed by β-tocopherol, γ-tocopherol, and δ-tocopherol (8,88). Changes in the isoprenoid side chain also influence vitamin E activity; this biological activity is defined in terms of equivalents of α-tocopherol (α-TE). (R, R, R)-α-tocopherol has an activity of 1 α-tocopherol (α-TE) equivalent per milligram of compound. The activities of (R, R, R)-β-, (R, R, R)-γ-, and (R, R, R)-δ-tocopherols are 0.5, 0.1 and 0.03 per mg of compound, respectively (8,21). Of the tocotrienols, only α-tocotrienol has significant biological activity (0.3 mg α-TE/mg). Lengthening or shortening the side chain results in a progressive loss of vitamin E activity. The previous information is based on all tocopherols which are absorbed to similar extents during digestion, however single (R, R, R)-α-tocopherol is successfully stored and distributed in the entire body, while the other species are not processed with the same efficiency. It has been estimated that one α-TE molecule is capable of protecting 2000 phospholipids (8,88).

The physiological role of vitamin E centers on its ability to react with and quench free radicals in cell membranes and other lipid environments, thereby preventing polyunsaturated fatty acids (PUFAs) from being damaged by lipid oxidation. An imbalance in the production of free radicals and the natural protective system of antioxidants may lead to oxidized products, able to harm tissue; in fact tissue damage due to free radicals has been associated to several human chronic diseases (Table 8.2) (4–8).

Refined and processed foods are usually exposed to light, heat, or metal ions that can cause structural degradation of their constituent lipids by triggering the process of lipid oxidation (42). The rate of lipid oxidation in a food depends on the concentration and type of PUFAs it contains, the amount and effectiveness of the antioxidants present in the food and the heating, processing and storage conditions to which it is subjected to. Tocopherols and tocotrienols are the most important natural antioxidants in fats and oils, acting as primary or chain breaking antioxidants by converting lipid radicals to more stable products (8,42). At normal oxygen pressure, the major lipid radical is the peroxyl radical (ROO°) which can be converted to a hydroperoxide (ROOH) by proton donors such as tocopherols and tocotrienols. The hydrogen is donated from their phenolic groups, stabilizing the radicals and stopping the propagation phase of the oxidative chain reaction.

Supplementation of α-tocopherol has been demonstrated to positively affect sensorial quality of meat as well as saving money (i.e., in the U.S. beef industry meat, color degradation provokes losses up to $1 billion each year). In poultry, the high tocopherol level

increased the stability of its meat; whereas in the case of pork and beef, vitamin E protects against rancid flavor, odor, and discoloration improving shelf life of packaged meat (89).

However, traditional plant breeding and food processing technologies have not concerned themselves with maximizing the levels of tocopherols in the human diets and even in diets for domestic animals used for meat, and the supplementation is necessary both for nutritional reasons and for the protection of fat-rich foods against oxidative rancidity (8,42). Unfortunately, synthetic α-tocopherol used as supplement is a complex mixture of stereo-isomers with less biological activity than natural single (R, R, R)-α-tocopherol (16,21,88). Significant changes in the α-tocopherol levels of major edible crops are necessary because there is a growing body of evidence to suggest that the dietary intake of vitamin E is insufficient to protect against the long term health risks associated with oxidative stress (8,16,21,88,89). Normally, the tocopherol composition of cultivated sunflower (*Helianthus annuus* L.) seed is primarily α-tocopherol, 95–100% of the total tocopherol pool. However, two mutant sunflower lines have been identified with tocopherol compositions of 95% γ-tocopherol/5% α-tocopherol, and 50% β-tocopherol/50% α-tocopherol. Although these presumed tocopherol methylation mutants showed severe alterations in their tocopherol profiles in seeds, their overall levels do not differ significantly from those of wild-type sunflower (8,89). These results suggest that it should be possible to alter the tocopherol profile of different crop species by manipulating the expression of one or both tocopherol methyltransferases (TMT), without having a detrimental effect on the total tocopherol pool size (Figure 8.3B). An exquisite and noteworthy research in the context of increasing the overall level of vitamin E activity available to consumers from plant foods was carried out by Shintani and DellaPenna (90). By overexpressing γ-TMT (Figure 8.3B), it was possible to increase α-tocopherol content in the *Arabidopsis* seed to about 85–95% of the total tocopherol, as compared with levels of 1.1% α-tocopherol and 97% γ-tocopherol in the untransformed seeds. Transgenic *Arabidopsis* showed a vitamin E activity about nine times greater than the negative control (Table 8.4). The authors speculate that if γ-TMT activity is limiting in commercially important oilseed crops such as soybean, corn, and canola, all of which have low γ-tocopherol to α-tocopherol ratios, overexpressing the γ-TMT gene in these crops should also elevate α-tocopherol amounts and improve their nutraceutical value (8,16,21,33,34,89).

8.4.3 Vitamin C

Vitamin C is used in large scale as an antioxidant in food, animal feed, beverages, pharmaceutical formulations, and cosmetic applications (91). This water-soluble vitamin, defined as L-ascorbic acid (L-AA), structurally is one of the simplest vitamins (Figure 8.1); its oxidation product is termed dehydroascorbate. It is related to the C6 sugars, being the aldono-1,4-lactone of a hexonic acid (L-galactonic or L-gulonic acid) and contains an enediol group on carbons 2 and 3 (92). In animal metabolism, including that of humans, the biological functions of L-AA are centered on its antioxidant properties and on its role to modulate a number of important enzymatic reactions. Thus, generally it acts as an enzyme cofactor, free radical scavenger and donor and acceptor in electron transfer reactions. For example, L-AA is required for collagen synthesis, and consequently in the formation and maintenance of cartilage, bones, gums, skin, teeth, and wound healing. In fact, the Fe-dioxygenases involved in collagen biosynthesis need L-AA for maximal activity, where the function of L-AA is to keep the transition metal ion centers of these enzymes in a reduced form. In the disease scurvy, which is known to be the result of vitamin C deficiency, its symptoms are directly related with the inadequate collagen formation (Table 8.2) (12,92). This micronutrient is also crucial for the normal, and enhanced, functioning of immune system, and is required for carnitine synthesis. There is now strong evidence to link high intake dietary

vitamin C with reduced risk for several oxidative stress-associated diseases such as cardiovascular diseases, various types of cancers, aging, neurodegenerative diseases, and cataract formation. Cataracts appear to be due to the oxidation of lens protein, and antioxidants such as vitamin C and E, and carotenoids seem to protect against cataracts and macular degeneration of eye in rodents and humans. On the other hand, increased oxidative damage from low vitamin C intake, chronic inflammation, smoking, or radiation, together with elevated levels of uracil in DNA, would be expected to lead to more double strand (chromosome) breaks in individuals who are deficient in both folate and antioxidant (Table 8.2) (4–7,12).

However, there is also large body literature on supplementation studies with vitamin C in humans using biomarkers of oxidative damage to DNA, lipids (its oxidation releases mutagenic aldehydes), and protein. Some studies suggest that blood cell saturation occurs at about 100 mg vitamin C/day and the evidence suggests that this level minimizes DNA damage. Both experimental and epidemiological data support that vitamin C provides protection against stomach cancer, a result that is plausible because of the role of oxidative damage from inflammation by *Helicobacter pylori* infection, which is the main risk factor for stomach cancer (4–7,12). Unfortunately, the plasma levels of L-AA in large sections of the population around the world are suboptimal for those health benefic effects of this vitamin; in fact about 15% of the population consumes less than half the RDA (60 mg/day) of ascorbate (Table 8.2).

It is thought that L-AA secreted in gastric juices in animals enhances the absorption of iron from plant foods through two mechanisms: by forming Fe(III) complexes and by reducing the less soluble Fe^{3+} to the more soluble and bioavailable Fe^{2+} valence state (Table 8.3) (12,43).

Plants and most animals (i.e., rats, dogs, cats) can synthesize their own vitamin C, but a few mammalian species, including primates, human beings, and guinea pigs have lost this capability, and thus entirely depend upon dietary sources to meet needs for this vital micronutrient. This deficiency has been localized to a lack of the terminal flavo-enzyme L-gulono-1,4-lactone oxidase (L-gulono-γ-lactone oxidase, [GuLO]); the gene encoding it was found in the human genome, but was not expressed due to the accumulation of various mutations. In vitamin C-producing animals, GuLO catalyzes the final reaction in the L-AA route corresponding to the oxidation of L-gulono-1,4-lactone, whereas in plants the enzyme L-galactono-1,4-lactone dehydrogenase employs L-galactono-1,4-lactone as a substrate for carrying out the terminal step in the vitamin C production (Figure 8.4) (92–95).

Vitamin C is the single most important specialty chemical manufactured in the world. The current world market of ascorbic acid is 60,000 to 70,000 metric tons each year and generates annual revenues in excess of US$ 500 million (91). But its industrial production is a lengthy procedure involving microbial fermentation and diverse chemical steps (38,91). Until quite recently, little focus has been given to improving the L-AA content of plant foods, either in terms of the amounts present in commercial crop varieties or in minimizing losses prior to consumption. Notably, plants and animal possess different pathway for synthesizing L-AA; the expression in transgenic lettuce plants of an animal cDNA encoding a rat GuLO under the control of CaMV 35S promoter led to accumulation up to seven times more L-AA than untransformed crops (the basal levels of L-AA varied among the three unmodified lettuce cultivars from 0.36–0.58 μmol/g fresh weight) (Table 8.4) (95). In food science and technology, vitamin C as well as bisulfites are used to prevent oxidation in peaches, potato chips, apples, potatoes, peanut butter, beer, fat, and oils (20,42). Therefore, in the future, L-AA-rich transgenic lettuce may diminish the commercial application of bisulfite to avoid browning of its leaf, as well as enhancing the nutritional and nutraceutical value of this food vegetable. A recent report also showed that the L-AA content of *Arabidopsis thaliana* (untransformed plants have a vitamin C level of about 2 μmol/g fresh weight) was increased two- and threefold by hyperexpression of a D-galacturonic acid reductase gene from strawberry

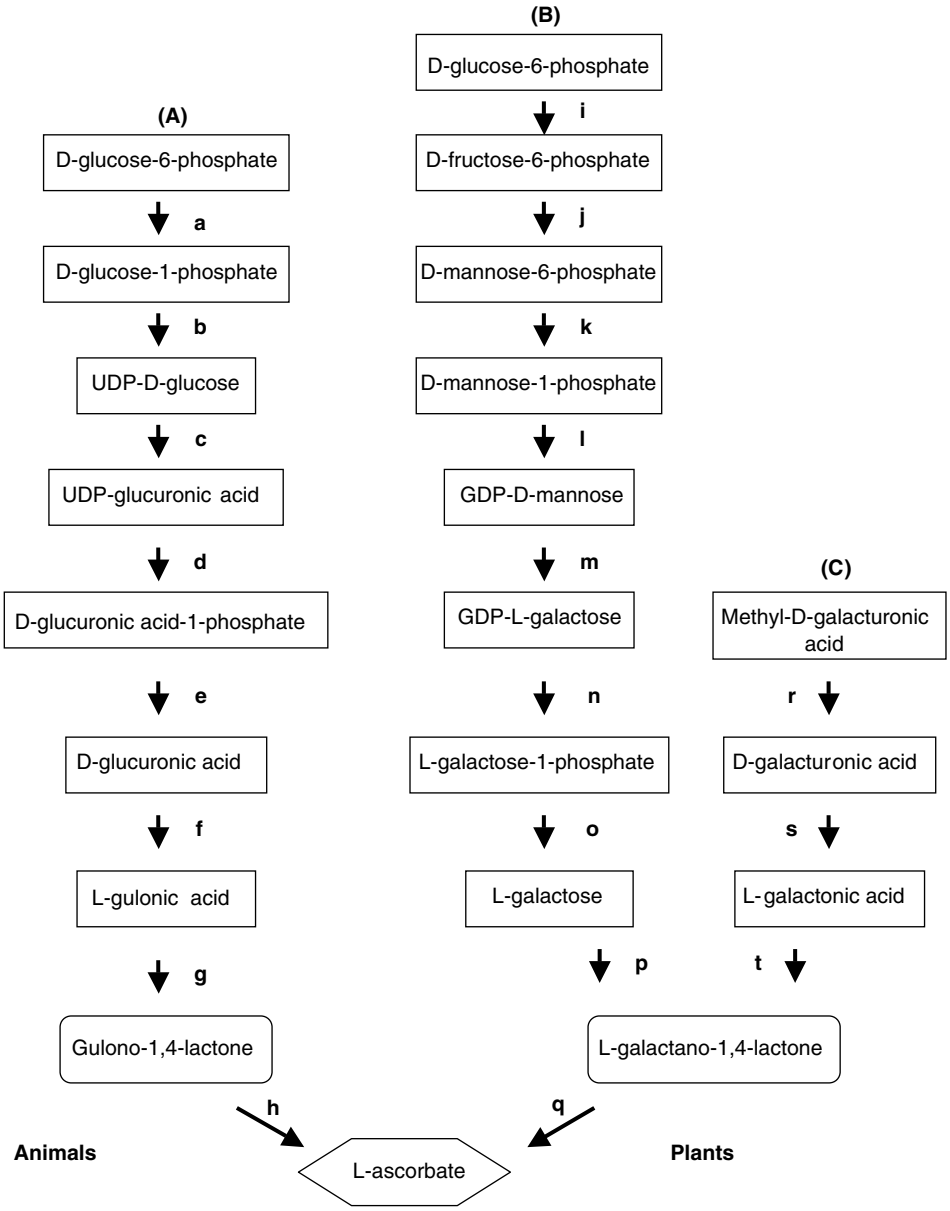

Figure 8.4 Proposed pathways for L-ascorbic acid biosynthesis in animals (A) and plants (B and C). Enzymes catalyzing the individuals reactions (a-h, for animals; i-t, for plants) are given next: a, phosphoglucomutase; b, UDP-glucose pyrophosphorylase; c, UDP-glucose dehydrogenase; d, glucuronate-1-phosphate uridylyltransferase; e, glucurono kinase; f, glucuronate reductase; g, aldono-lactonase; h, L-gulono-1,4-lactone oxidase, GuLO; i, glucose-6-phosphate isomerase; j, mannose-6-phosphate isomerase; k, phosphomannomutase; l, GDP-mannose pyrophosphorylase; m, GDP-mannose-3,5-epimerase; n, phosphodiesterase; o, sugar phosphatase; p, L-galactose-1- dehydrogenase; q, L-galactono-1,4-lactone dehydrogenase, r, methylesterase, s, D-galacturonate reductase; t, aldono-lactonase. Adapted from Ref. 92–95.

(Table 8.4) (94). This gene encodes the enzyme D-galacturonate reductase that converts D-galacturonic acid into L-galactonic acid, which is readily transformed to L-galactono-1,4-lactone, the immediate precursor of L-AA (Figure 8.4C).

The previous works demonstrate the possibility that the basal content of minerals and vitamins in important food crops can be augmented by metabolic engineering, and therefore raise the realistic possibility that such increases may substantially benefit vulnerable populations in their daily dietary intakes, without the need for fortification or for a change in dietary habits as a whole.

Potential Health Benefits of Soybean Isoflavonoids and Related Phenolic Antioxidants

Patrick P. McCue and Kalidas Shetty

CONTENTS

9.1 INTRODUCTION

Soybeans are a well-known dietary staple of Asian countries such as Japan and are now consumed worldwide (1). Unlike string beans or snap peas, soybeans cannot be eaten raw, because they contain trypsin inhibitors, which can disrupt digestion activities in the stomach, leading to cramping and associated discomfort. Soybeans are usually fermented to produce distinct cultural or ethnic foods or food ingredients, or sometimes are sprouted for use in salads, as are mungbean and alfalfa sprouts. In Japan, soybeans are sometimes blanched (i.e., boiled for about five minutes), cooled, and then consumed readily with beer as a snack. The Japanese also process soybeans to produce a protein rich meat substitute, tofu. In Indonesia, soybeans are fermented by a food grade fungus of the *Rhizopus* species to produce an alternative protein rich meat substitute called tempeh (1).

9.2 CONSUMPTION OF SOYBEAN AND REDUCED INCIDENCE OF DISEASE

East Asian populations that regularly consume soybeans as a part of their dietary intake seem to have lower incidences of cancers and oxidation linked diseases of old age than are prevalent in Western populations. Numerous epidemiological studies have demonstrated an association between the consumption of soybeans and improved health, particularly as a reduced risk for cancers or diseases, such as breast cancer, cardiovascular disease, and atherosclerosis (2–8). Consumption of soy foods has also been associated with a reduced risk of prostate cancer (9,10).

Although soybean protein was first suspected to potentiate the health-promoting benefits of soybean consumption, these properties have more recently been linked to the biological activities of a specific group of phenolic compounds, found mainly in soybeans, known as isoflavonoids (5). While the chemopreventive properties of purified and synthetic isoflavonoids have been heavily investigated, a fermented soybean extract was recently shown to perform better at reducing the incidence of mammary tumor risk than a similar mixture of its constituent isoflavonoids, suggesting that the food background may play a positive role in the chemopreventive actions associated with soybean consumption, in addition to that of isoflavonoids (11–16).

9.2.1 Soybean Isoflavonoids

Isoflavonoids are a unique subgroup of the flavanoids, one of the largest classes of plant phenolics, with more than 5000 compounds currently identified. Isoflavonoids are found mainly in soybeans, and possess a chemical structure that is similar to the hormone estrogen (1). The chief isoflavonoids found in soybeans are genistein and daidzein. Because their structures resemble estrogen and they can interact with the estrogen receptor, soybean isoflavonoids are sometimes referred to as phytoestrogens (17).

Isoflavonoids are flavanoid variants in which the location of one of the phenolic rings is shifted. As diphenolic secondary metabolites, isoflavonoids are synthesized from products of the shikimic acid and malonyl pathways in the fusion of a phenylpropanoid with three malonyl CoA residues (1). Isoflavonoid content in soybeans ranges from 0.14 to 1.53 mg/g, and in soy flour from 1.3 to 1.98 mg/g (18). The Japanese are estimated to consume 25–100 mg of isoflavonoids per day (19). Chinese women are estimated to consume 39 mg of isoflavonoids per day (20). The consumption of isoflavonoids in Western diets is much lower, at less than 1 mg/day in the U.S. and U.K. (18,21).

Phenolic compounds normally occur as glucoside bound moieties called glycones (22,23). However, it is the aglycone (glucoside free) form that is metabolically active (24). After consumption, probiotic enzymes in the intestine cleave the glycoside moieties from glycone isoflavonoids and release the biologically active health-promoting aglycone isoflavonoids. Aglycone phenolic compounds possess higher antioxidant activity and are absorbed faster in the intestines than glucoside bound forms (23,25,26). Interestingly, fermented soy foods are rich in phenolic aglycones due to microbial bioprocessing during fermentation (27,28). However, once inside the bloodstream, biologically active aglycone genistein travels to the liver were it is converted back into an inactive glycone (β-glucuronide) (24). Cellular glucuronidases must remove the glycone moiety before genistein can exert its biological activity (24).

Isoflavonoids have been well studied and possess numerous biological activities (1). For example, genistein possesses inhibitory activity against topoisomerase II, tyrosine kinase, NF-κB, cancer cell proliferation, and nonoxidative pentose–phosphate pathway ribose synthesis in cancer cells (29–33). Many of the health-promoting benefits of isoflavonoids have been linked to the ability of phenolics to serve as antioxidants (34–37).

9.2.2 Major Bioactivities of Soybean Isoflavonoids

9.2.2.1 Phytoestrogenic and Postmenopausal Activity

The structure of soybean isoflavonoids is uniquely similar to that of estrogen (17) and may account for their weak ability to act as agonists at estrogen receptors (38). Many have speculated that soybean isoflavonoids may be useful for the treatment of somatic, mood, and cognitive disturbances associated with the onset of menopause (39). Diet supplementation with soybean phytoestrogens has been reported to ameliorate hot flashes and other symptoms of menopause (40–43).

Soybean isoflavonoids may also have potential in natural chemoprevention therapies against long term health problems associated with menopause, particularly for osteoporosis (44–47). After menopause, the ovaries stop producing estrogen. Because estrogen positively affects the metabolism of calcium, lack of sufficient estrogen can lead to bone loss and osteoporosis (48). Hormone replacement therapy (HRT) can reduce bone loss and the risk of osteoporosis in postmenopausal women, but unfortunately appears to also increase the risk for certain estrogen linked cancers (49–51).

Current osteoporosis prevention research is focused on the development of estrogen-like compounds (selective estrogen receptor modulators, or SERMs) that can selectively act against bone loss without causing negative estrogenic action against the uterus (52). The soybean isoflavonoid genistein has shown SERM activity in ovariectomized mice (53). When provided at optimal dosages, soybean isoflavonoids (especially genistein and daidzein) have been shown to improve bone mass and reduce bone resorption (54,55).

9.2.2.2 Cancer Chemoprevention

Soybean isoflavonoids also possess various biological activities that may help to explain the cancer chemopreventive properties associated with the consumption of soybean foods (3,8,49,56). In *in vitro* studies, daidzein was reported to activate the catalase promoter, to stimulate caspase-3 and apoptosis, and to down regulate the activities of Bcl-2 and Bcl-xL (57,58). Genistein can stimulate p53, antioxidant enzyme activities, BRCA2, caspase-3 and apoptosis, and chloride efflux (59–63). Genistein has also been reported to suppress activation of NF-κB, matrix metalloproteinases, lipogenesis, and COX-2 (31,64–66).

The exact mechanism by which these compounds exert their chemopreventive properties is not yet clear.

9.2.2.3 Prevention of Cardiovascular Disease

Soybean consumption has also been linked to a reduced risk for cardiovascular disease (47). Addition of soybean to foods has been shown to result in reduced cholesterol (67). In 1999, the US Food and Drug Administration reported that the consumption of soy protein as part of a healthy diet could help reduce the risk of coronary heart disease by lowering blood cholesterol levels (68). Soy protein isolates typically contain soybean isoflavonoids, which are believed to be largely responsible for the health benefits assigned to soy protein. Related herbal flavanoids prevented *in vitro* platelet aggregation and *in vivo* thrombogenesis in mouse arteries (69). Inclusion of isoflavonoid rich soybean in diets was also reported to protect against coronary heart disease by causing reductions in blood lipids, oxidized LDL, homocysteine, and blood pressure (7).

9.2.3 Approaches Toward Isoflavone Enrichment of Soybean

9.2.3.1 Genetic Modulation of Soybean

Throughout recorded history, man has used conventional breeding and selection techniques to improve crop species for desired traits. When modern genetic engineering techniques became available, agricultural scientists sought to improve crop species' phenolic content through the use of genetic technologies. At first, progress was slow, as knowledge of the biosynthetic pathways responsible for producing beneficial phenolic phytochemicals was limited.

One of the most studied pathways is the anthocyanin biosynthesis pathway, as phenotypic changes in flower color aided genetic analysis and metabolic understanding. Study of anthocyanin biosynthesis has also aided in the understanding of isoflavonoid biosynthesis as both pathways share a dependence on substrate flux through the flavanoid biosynthetic pathway. The isoflavonoid biosynthetic pathway is now almost completely characterized and genetic manipulation techniques have matured enough that it is now possible to alter synthesis at many different stages (70).

Knowledge of key enzymes involved in isoflavonoid biosynthesis in legumes led to attempts to engineer isoflavonoid biosynthesis in nonlegumes through genetic manipulation, in order to expand the delivery of dietary isoflavonoids as well as to develop new sources for their isolation (1). Unfortunately, initial attempts to incorporate key enzymes involved in isoflavonoid synthesis, such as soybean isoflavone synthase (IFS) and alfalfa chalcone isomerase in *Arabidopsis*, corn, and tobacco resulted in little to no formation of genistein or daidzein, the major isoflavonoids produced by soybean (71–73). Significant accumulation of isoflavonoids in nonlegumes was thought to be hindered by limited activity of the introduced IFS enzyme, by precursor pool limitations, and by competition (flux partitioning) between IFS and other enzymes that use the flavanoid naringenin as a substrate (73,74). More recent attempts to engineer flavanoids in bacteria and increased isoflavonoid content in soybean have been more successful, with the latter largely by coengineering the suppression of the naringenin-utilizing enzyme flavanone-3-hydroxylase to block competing pathways (72,75).

Dietary safety of genetically engineered foods remains a major concern of potential consumers. Although genetically modified (GM) foods appear no more harmful than conventionally produced foods, concerns remain as to the safety of the newly added DNA, its gene product, the overall safety of the rest of the food, the potential toxicology of the

expressed protein, potential changes in allergenicity, changes in nutrient composition, unintended effects that could give rise to allergens or cause toxicity, and the safety of antibiotic resistance marker encoded proteins included with the transgene (76).

9.2.3.2 Enrichment of Soybean Isoflavone Content via Nongenetic Approaches

The technological challenge of stably introducing a foreign gene into a food crop and having that gene product function as desired, the problems of controlling substrate flux partitioning to drive a desired biosynthetic pathway, and the potential risks posed by transgenic food crops are troublesome issues that have underscored the need for continued research on and development of nongenetic approaches for the enrichment of isoflavonoids in soybean foods and food ingredients (1). Major nongenetic approaches for increasing phenolic content in dietary plants include bioprocessing of soybean substrates and stimulation of the plant defense responses, which is known to result in the stimulation of phenolic synthesis. Both of these approaches could potentially be used to increase isoflavonoid content in soybeans.

Bioprocessing of various plant based foods by dietary fungus is a technology that has been used throughout history in the context of producing fermented foods, such as tempeh. Currently, this technology is being utilized in conjunction with specific dietary fungi to produce certain desired products. In this context, fungal bioprocessing (also known as solid-state fermentation) has been employed to enrich various solid food substrates such as grape pomace, cornmeal, mango, date, wheat bran, and wine for products such as protein, C/N ratio, β-glucan, and pectinase (77–81). The use of dietary fungal bioprocessing of fruit and legume food substrates for enrichment of aglycone phenolic antioxidants such as ellagic acid in cranberry and isoflavonoids from soybeans has been reported (27,28,82–84). Enhanced isoflavonoid content in soybeans and soybean meal following bioprocessing by *Aspergillus* species has also been reported (85,86). The number of different microbial species and substrates available for isoflavonoid and other phenolic enrichment by fungal bioprocessing is likely to grow as knowledge of dietary microbial species increases.

One of the results of elicitor mediated activation of the plant defense system is an increase in phenolic secondary metabolite biosynthesis (87,88). Exogenous application of salicylic acid, a phenolic metabolite thought to act as a chemical signal in the defense response system, can stimulate phenolic content in peas (89). Similarly, pure dietary phenolics and phenolic rich extracts have been reported to stimulate phenolic content in legumes (90–96). Further, application of bacteria, bacterial polysaccharides, and UV and microwave radiation (all of which are known inducers of plant defense responses) have been shown to stimulate plant phenolic content (96–99). The type of phenolics elicited by activation of the defense response is largely determined by the nature of the treated plant (i.e., phenolic profiles vary from plant to plant). Therefore, application of plant defense response elicitors to soybean may potentially stimulate higher isoflavonoid content without the need for genetic manipulation.

9.2.4 Toward a Model Mechanism for Action of Soybean Isoflavonoids and Related Phenolic Antioxidants against Cancer

9.2.4.1 Metabolism of Dietary Isoflavonoids

As stated earlier, genistein and daidzein occur in soybeans as glucoside conjugates that must be converted into aglycones to be metabolically active (22,24). In humans, this can be performed by intestinal flora. Interestingly, fermented soy foods are rich in phenolic aglycones due to microbial bioprocessing during fermentation, which may allow for rapid intestinal absorption upon consumption (27,28).

9.2.4.2 *Control of Energy Metabolism and Oxidative Stress in a Healthy Cell*

In cells, the production of energy adenosine triphosphate (ATP) occurs in mitochondria by reduced nicotinamide adenine dinucleotide (NADH)-mediated oxidative phosphorylation (oxPHOS) (100). The tricarboxylic acid (TCA) cycle produces NADH to support mitochondrial ATP synthesis. Although some reactive oxygen species (ROS) are generated during mitochondrial oxPHOS, cells possess an extensive antioxidant response system which operates to scavenge ROS and protect cellular components from oxidative damage (100,101).

Antioxidant enzymes play a key role in cellular antioxidant response (100). Chief among these enzymes are superoxide dismutase (SOD) and catalase. SOD converts superoxide (O_2^-) into hydrogen peroxide (H_2O_2), which is less reactive. Catalase converts H_2O_2 into water (H_2O) and oxygen (O_2). Manganese superoxide dismutase (MnSOD) occurs within mitochondria to protect the organelle from oxidative damage, while copper–zinc SOD (CuZnSOD) and catalase occur in the cytosol, both to protect cytosolic bound cellular components from oxidative damage and to maintain a proper redox environment, because redox imbalances can activate certain cellular activities (102).

It has been proposed that phenolic antioxidants may have chemopreventive potential through modulation of the antioxidant enzyme response through the proline linked pentose–phosphate pathway (103). Exogenous antioxidants, such as dietary plant phenolic compounds, have been shown to scavenge ROS in cells *in vitro* and may help protect cells against oxidative damage *in vivo* (103,104).

9.2.4.3 *Control of Energy Metabolism and Oxidative Stress in a Tumorigenic Cell*

Many of the diseases for which a reduced risk of incidence has been associated with soy food consumption are oxidation linked diseases, such as cancer and cardiovascular disease (100). Oxidation linked diseases have been linked to a general breakdown in the regulation of cellular activities (such as growth or energy production), an accumulation of ROS such as superoxide and hydrogen peroxide, a cellular redox imbalance, and accumulated oxidative damage in normal cells (106).

Evidence indicates that, similar to healthy cells, tumor cells obtain much of their ATP for energy requirements via NADH linked mitochondrial oxPHOS (107). However, in tumorigenic cells, energy generation is inefficient as mitochondrial respiration activities are defective compared to healthy cells (108–110). Interestingly, in many cancer cells the activity of glucose-6-phosphate dehydrogenase (G6PDH), the key regulatory enzyme of the oxPPP, is reduced by up to 90%, while the nonoxidative pentose–phosphate pathway (nonoxPPP) flux is increased, possibly to support higher glycolytic flux toward the TCA cycle to support additional demand for NADH (111,112).

In addition to an abnormal energy metabolism, tumor cells possess a reduced antioxidant response system. Catalase and CuZnSOD activities, important for controlling cytosolic ROS levels, are decreased in numerous cancer cell lines (113,114). Low activity of antioxidant enzymes leaves cancer cells particularly susceptible to increased oxidative damage upon ROS accumulation, and eventually apoptosis (cell death) or necrosis (113,114).

9.2.5 Stress Response and the Proline Linked Pentose–Phosphate Pathway

Healthy cells possess a mechanism that couples increased mitochondrial ATP synthesis to increased glucose flux through the oxPPP for biosynthetic substrates (glucose phosphates, reduced nicotinamide adenine dinucleotide phosphate ($NADPH_2$) that support cellular energy demands during times of stress (100). In this mechanism, mitochondrial ATP generation and

oxPPP activity are coupled through the biosynthesis of proline (115). Proline biosynthesis provides a mechanism for the transfer of reducing equivalents from $NADPH_2$ into mitochondria (via proline oxidation) and is linked to glucose oxidation in the oxPPP by $NADPH_2$ turnover, a coupling known as the proline linked pentose–phosphate pathway (PL-PPP) (116). Notably, in this mechanism mitochondrial oxPHOS switches its dependence on NADH to proline as a source of reducing equivalents to support ATP synthesis while maintaining cellular $NADPH_2$ biosynthesis for anabolic reactions. Increased proline metabolism has been shown to stimulate oxPPP activity via NADP mediated redox regulation (117).

As the activity of several antioxidant enzymes depends on the availability of $NADPH_2$, activity of the cellular antioxidant response system in stressed cells may depend directly upon flux through the oxPPP and, therefore, indirectly upon the activity of a functional proline cycling mechanism (100). Increased oxPPP activity has been shown to protect cells against H_2O_2 and NO stresses (118,119). Similarly, a phagocyte derived ROS increase occurs during the immune response and is followed by an increase in G6PDH activity (120). G6PDH and oxPPP activity protected cells from oxidant and radiation induced apoptosis (121). Recently, antioxidant enzymes were found to be essential for protecting cells against ROS mediated damage (122).

9.3 A HYPOTHETICAL MODEL FOR THE CANCER CHEMOPREVENTIVE ACTION OF THE SOYBEAN ISOFLAVONE GENISTEIN

The mechanistic coupling of mitochondrial ATP generation and oxPPP through proline metabolism that supports normal cells during stress and which appears to be dysfunctional in many tumorigenic cells provides a foundation for a possible model mechanism for the chemopreventive action of phenolic antioxidants, such as genistein, against certain cancers (100).

When soybean is consumed, its main phenolic phytochemical, the isoflavone genistein, is converted by intestinal flora bioprocessing and subsequent hepatic activities into a β-glucuronide conjugate. In an interesting twist of fate, the expression of β-glucuronidase is low or not detected in normal tissues, but is high in tumors (123). Therefore, in tissues that take up the genistein-β-glucuronide from the bloodstream, free and biologically active genistein is most likely to occur in a higher amount in tumor cells than in healthy cells due to the selective nature of β-glucuronidase expression in these tissues.

Once activated by glucuronidase, free genistein may stimulate proline metabolism through the activation of proline dehydrogenase (PDH) via p53. Genistein can induce p53 expression in colorectal cancer cells (124). The mechanism for stimulation of p53 by genistein is not clear, but other dietary antioxidants can activate p53 by a ref1 dependent redox mechanism (125,126). The transcription factor p53 can activate PDH, as well as ROS and apoptosis in cancer cells (127–129).

Stimulation of mitochondrial PDH in the tumor cell by phenolic antioxidants such as genistein should cause a demand for proline (117) that would have several major metabolic effects: (1) increased mitochondrial oxPHOS supported by proline oxidation would generate increased ROS that could leak into the cytosol and damage essential cellular components; (2) proline would be shunted to the mitochondria and away from collagen biosynthesis, potentially crippling tumor growth, expansion, and proliferation activities; and (3) energy metabolism would be redirected toward proline mediated mitochondrial ATP synthesis and away from TCA linked, NADH mediated oxPHOS via activity of the PL-PPP. An occurrence of these metabolic effects would be uniquely detrimental to the functioning of a tumor cell because, by all reported indications, normal cellular metabolism, including

the antioxidant response system, in tumor cells is dysfunctional at mitochondrial and cytosolic levels.

First, increasing the activity of PDH would drive mitochondrial oxPHOS toward ATP synthesis, and produce increased ROS levels in the process. In a normal cell, increased ROS production by increased mitochondrial activity would likely be countered by activation of the cellular antioxidant enzyme response system, but in cancer cells antioxidant enzymes appear to be less active and may be less able to adequately protect tumor cells from oxidative damage, and potentially promote apoptosis (109,110,122,130). Because tumor cell mitochondria are already dysfunctional, increased respiration activities activity driven by genistein stimulated PDH activity should produce increased amounts of cytosolic ROS into the cytosol, endangering numerous essential cytosolic components such as proteins and organelles. MnSOD is expressed at low levels in normal cells, but at high levels in tumors, perhaps in response to high ROS levels (131). However, expression of catalase, glutathione peroxidase (GPx), and CuZnSOD is greatly diminished, which may facilitate accumulation of excessive oxygen radicals and oxidative damage in tumor cells (109,110). Although dietary antioxidants, such as curcumin, ascorbic acid, and flavanoids, have been shown to stimulate antioxidants and important phase II antioxidant enzymes such as SOD and catalase, genistein did not stimulate catalase or SOD in prostate cancer (132–135). In fact, genistein and soy isoflavone extracts have been shown to stimulate caspase-3 and apoptosis in cancer cells (58,62). Thus, phenolic antioxidants such as genistein may stimulate apoptosis linked activities that support the generation and accumulation of oxygen radicals and oxidative damage in tumor cells. The action of genistein could be further enhanced synergistically by other soluble phenolics from a food system. This is further supported by recent evidence that fermented soymilk and whole soy extracts inhibit tumor growth better than genistein alone (16,136,137).

Second, the stimulation of PDH activity by genistein and synergistic phenolic profiles would cause a metabolic demand for proline as a reductant to support mitochondrial oxPHOS (energy production) and may derail tumor growth supporting collagen biosynthesis by redirecting a necessary substrate (e.g., proline). Genistein has been shown to inhibit the growth and proliferation of cancer cells *in vitro* (32). If genistein activates of mitochondrial PDH and the proline cycle as part of a key stress response mechanism, proline cycle demand for proline may have higher cellular priority than collagen biosynthesis during times of stress (117).

Finally, and perhaps most importantly, induction of mitochondrial PDH activity and proline cycling by genistein would shift cellular energy metabolism in the tumor cell away from NADH linked mitochondrial oxPHOS to a proline linked mitochondrial oxPHOS system (100). Dysfunctional tumor cell mitochondria may produce increased ROS generation via increased mitochondrial respiration that may lead to mitochondrial membrane damage, caspase activation, and eventually apoptosis. In support of this idea, genistein has been shown previously to inhibit nonoxPPP ribose synthesis and cell proliferation in cancer cells (32,33). In healthy cells, stress induced stimulation of the proline cycle also drives the oxPPP via G6PDH recycling of $NADPH_2$, and G6PDH (and thereby the stress induced PL-PPP) can be inhibited by high $NADPH_2$ levels. In contrast, in tumorigenic cells G6PDH is dysfunctional (with activity decreased by up to 90%) and is no longer inhibited by high $NADPH_2$ (105,117,38). Therefore, while genistein stimulated PDH activity may be supported by $NADPH_2$ cycling between proline biosynthesis and G6PDH activity, a dysfunctional G6PDH enzyme may not allow the tumor cell to disengage the stress response mechanism in the presence of high levels of $NADPH_2$. Because the dysfunctional enzyme operates at such a low efficiency (~10%) and likely does not produce high $NADPH_2$ levels, there may not be enough $NADPH_2$ produced to support the anabolic

demands of the antioxidant enzyme response system which would further hinder the tumor cell to defend itself against oxPHOS derived ROS.

Further, genistein possesses other biological activities that may help to promote apoptosis in tumor cells. Aside from the stimulation of caspase-3 which could result from mitochondrial PDH activation, genistein can inhibit NF-κB (13), which can block apoptosis (139).

9.4 SUMMARY AND IMPLICATIONS

Starvation is an efficient way to kill a living organism, even a diseased cell. An effective strategy to starve a tumor cell could be to potentiate a switch in energy metabolism from a dysfunctional and inefficient TCA/NADH linked mechanism to an even more dysfunctional alternative pathway (100). In tumor cells, mitochondrial ATP-generating activities are known to be negatively altered and to function inefficiently (103,104,140). If the energy metabolism could somehow be forced to revert back to the dysfunctional mitochondria, the inefficiency of the system may starve the tumor cell of chemical energy (ATP) for cellular activities (100). For a tumor cell to knowingly switch a core metabolism to favor a pathway or mechanism that would be detrimental to its survival seems unlikely, but it is possible that just such an action may occur through the activation of an underlying key stress response mechanism that functions in normal, healthy cells, for which activation triggers may still remain even after the normal cell transitions into a tumorigenic cell (100).

Here we describe a potential mechanism by which phenolic antioxidants such as the isoflavone genistein may act to promote tumor cell death by inducing the diseased cell to switch its energy metabolism from growth-promoting TCA cycle/ NADH linked system to a dysfunctional proline linked system through the activation of a key stress response mechanism involving the PL-PPP, whereby the cell is essentially starved of chemical energy (100). As the PL-PPP in plants can be stimulated by dietary (89,92,93,41), the same may be true in animal (e.g., human) cells. We have described how p53 mediated activation of PDH by genistein may create a metabolic demand for proline, therein activating the PL-PPP and causing a shift in energy metabolism to facilitate mitochondrial ATP generation, even though components of the stress response mechanism in tumor cells may be dysfunctional. A mitochondrial demand for proline might divert proline away from collagen biosynthesis, which may explain the interrupted tumor growth and proliferation activities observed in cancer cells treated with phenolic compounds. It is unknown whether or not tumor cell PDH is dysfunctional (100).

ROS accumulation precipitated by increased activity of leaky mitochondria should stimulate activity of antioxidant enzymes and the oxPPP for $NADPH_2$ to support reductant cycling systems (100). However, in tumor cells G6PDH is also dysfunctional and inefficient, such that the generation of adequate $NADPH_2$ levels to support the demands of both proline synthesis and the antioxidant enzyme response system is unlikely. Further, as the dysfunctional G6PDH is no longer inactivated by high $NADPH_2$, it is likely that once the PL-PPP mediated stress response mechanism is activated, the tumor cell may not be able to disengage it, and may become locked in its fate and thus prevented from returning to TCA cycle/ NADH linked energy metabolism (100).

Further, our hypothetical model helps to explain how phenolic antioxidants such as genistein could have both detrimental effects against tumor cells and beneficial effects on healthy cells. In healthy cells, addition of a phenolic antioxidant that can stimulate mitochondrial activity and the antioxidant enzyme response system (i.e., SOD, catalase, GPx) may aid in protection against oxidative damage and thus promote healthy cellular

conditions (102,142). Furthermore, as normal G6PDH can be inactivated by high $NADPH_2$ levels, the PL-PPP-mediated stress response mechanism can be turned off as needed, something that a tumor cell may be unable to do and which may, ultimately, lead to the death of the diseased cell (100).

Numerous dietary phenolic antioxidants have been shown to inhibit cancer cell growth and proliferation, but until now no overall cellular mechanism that integrates the many observed phenolic linked activities has been put forth. We believe our hypothetical model for the chemopreventive actions of the soybean isoflavonoid genistein as described here offers a logical mode of action for dietary phenolic antioxidants based on key cellular metabolism linked to alternative energy and redox management. This model merits further experimental investigation in conjunction with genetic and signal transduction mechanisms associated with cancer biology (107). As various dietary phenolic compounds have been reported to possess activities that may facilitate apoptosis, our model provides a core mechanism by which many of these compounds could act, and a mechanism that could be supported by other such anticancer properties, such as NF-κB inhibition and related signal pathways.

Functional Phytochemicals from Cranberries: Their Mechanism of Action and Strategies to Improve Functionality

Dhiraj A. Vattem and Kalidas Shetty

CONTENTS

10.1 INTRODUCTION: PHENOLIC PHYTOCHEMICALS

Phenolic compounds or phenolic phytochemicals are secondary metabolites of plant origin which constitute one of the most abundant groups of natural compounds and form an important component of both human and animal diets (1,2,3). These phenolic metabolites function to protect the plant against biological and environmental stresses and are therefore synthesized in response to pathogenic attack, such as fungal or bacterial infection, or high energy radiation exposure, such as prolonged UV exposure (4,5). Because of their important biological functions, phenolic phytochemicals are ubiquitous in plants and therefore find their place in almost all food groups. Common fruits such as apples, cranberries, grapes, raspberries, and strawberries, and fruit beverages like red wine and apple and orange juices, are rich sources of phenolic phytochemicals. In addition to fruits, vegetables such as cabbage and onion, and food grains such as sorghum, millet, barley, peas, and other legumes (6) are also described as important sources of phenolic phytochemicals. Varied biological functions of phenolic phytochemicals in plants have led to the evolution of diverse types of phenolic compounds. Depending on the evolutionary pressures experienced, plants have evolved a constituent profile of inducible phenolic phytochemicals, usually characteristic of a particular species of fruit or vegetable (6,7). For example, the most abundant phenolic compound in fruits and their products are flavonols. Cereals and legumes are rich in flavonoids, phenolic acids, and tannins (6,7). The major phenolic phytochemicals in wine include phenolic acids, anthocyanins, tannins, and other flavonoids (6,7).

10.2 CHEMICAL NATURE AND BIOSYNTHESIS OF PHENOLIC PHYTOCHEMICALS

The International Union for pure and applied chemists (IUPAC) defines phenol as hydroxybenzene. The term phenolic compounds refers to a relatively wide range of chemical compounds that contain at least one aromatic ring and usually one or more hydroxyl substituents (8). There are numerous different types of these phenolic phytochemicals, classified according to their ring structure and the number of carbon atoms substituting the ring and linking them together (Table 10.1).

Metabolic processing of phenolic phytochemicals in plants for their final biological function has led to chemical variations in basic phenolic structure. Differences in substituent groups and linkages have resulted in a wide variety of chemical structures having distinct properties. More than 8000 different phenolic structures, categorized into 10 classes, have been identified. They vary structurally from simple molecules (e.g., phenolic acids with a single ring structure), to biphenyls and flavonoids having 2–3 phenolic rings (9,10) (Figure 10.1). Another abundant group of phenolic phytochemicals in fruits and vegetables, often referred to as polyphenols, contain 12–16 phenolic groups and approximately 5–7 aromatic rings per 1000 relative molecular mass (Figure 10.1). These polyphenols are classified as condensed proanthocyanidins, tannins which include galloyl and hexahydroxydiphenoyl (or ellagoyl) esters and their derivatives, or phlorotannins (9,10) (Figure 10.1).

All the phenolic phytochemicals are derived from a common biosynthetic pathway, incorporating precursors from the shikimate or the acetate–malonate pathways or both (1,11) (Figure 10.2). Simple phenolic acids such as cinnamic acid and its derivatives are widespread in fruits and vegetables. They are derived primarily from the shikimate pathway via phenylalanine or tyrosine (1). Other phenolics of biological importance that are formed in this manner include coumaric acid and caffeic acid. Chemical modification of side chains by processes such as oxidation produce another group of compounds, such as protocatechuic

Table 10.1
The major classes of phenolic compounds in plants

Number of Carbon Atoms	Basic Skeleton	Class
6	C_6	Simple phenols
		Benzoquinones
7	C_6-C_1	Phenolic acids
8	C_6-C_2	Acetophenones
		Tyrosine derivatives
		Phenylacetic acids
9	C_6-C_3	Hydroxycinnamic acids
		Phenylpropenes
		Coumarins
		Isocoumarins
		Chromones
10	C_6-C_4	Naphthoquinones
13	C_6-C_1-C_6	Xanthones
14	C_6-C_2-C_6	Stilbenes
		Anthraquinones
15	C_6-C_3-C_6	Flavonoids

	$(C_6)_n$	Catechol melanins
	$(C_6$-C_3-$C_6)_n$	Flavolans (Condensed Tannins)

acid and its positional isomer gentisic acid, which are referred to as benzoic acid derivatives (Figure 10.2). To increase the solubility and target the phenolics to specific parts of the plant, and to prevent their enzymatic and chemical degradation, phenolic phytochemicals are often esterified with sugars and other chemical components such as quinic acid through the hydroxyl groups of the phenolic ring. The esters are sugars and phenolic phytochemicals are called glycosides. A majority of glycosides contain glucose, but the glycosides of phenolics with galactose, sucrose, and rhamnose have also been described (11).

Flavonoids and biphenyls are another important class of phenolic phytochemicals that are especially rich in fruits and legumes. Flavonoids like quercetin constitute the most abundant group of phenolic phytochemicals. Their common structure consists of two aromatic rings linked through three carbons that usually form an oxygenated heterocycle; this type of chemical arrangement is often described as diphenylpropanes (C_6-C_3-C_6) (2,11). Structural variations within the rings resulting in an alteration in the extent of hydroxylation, methylation, isoprenylation, dimerization, and glycosylation (producing O- or C-glycosides) subdivide the flavonoids into several families: flavonols, flavones, isoflavones, antocyanidins and others (Figure 10.2).

10.2.1 Phenolic Phytochemicals from Berries

Phenolic phytochemicals are ubiquitous in nature and are especially rich in fruits (12,13). Fruits such as berries (14,15) are known to be good sources of phenolic antioxidants having protective health benefits. Fruit beverages such as wines have been shown to

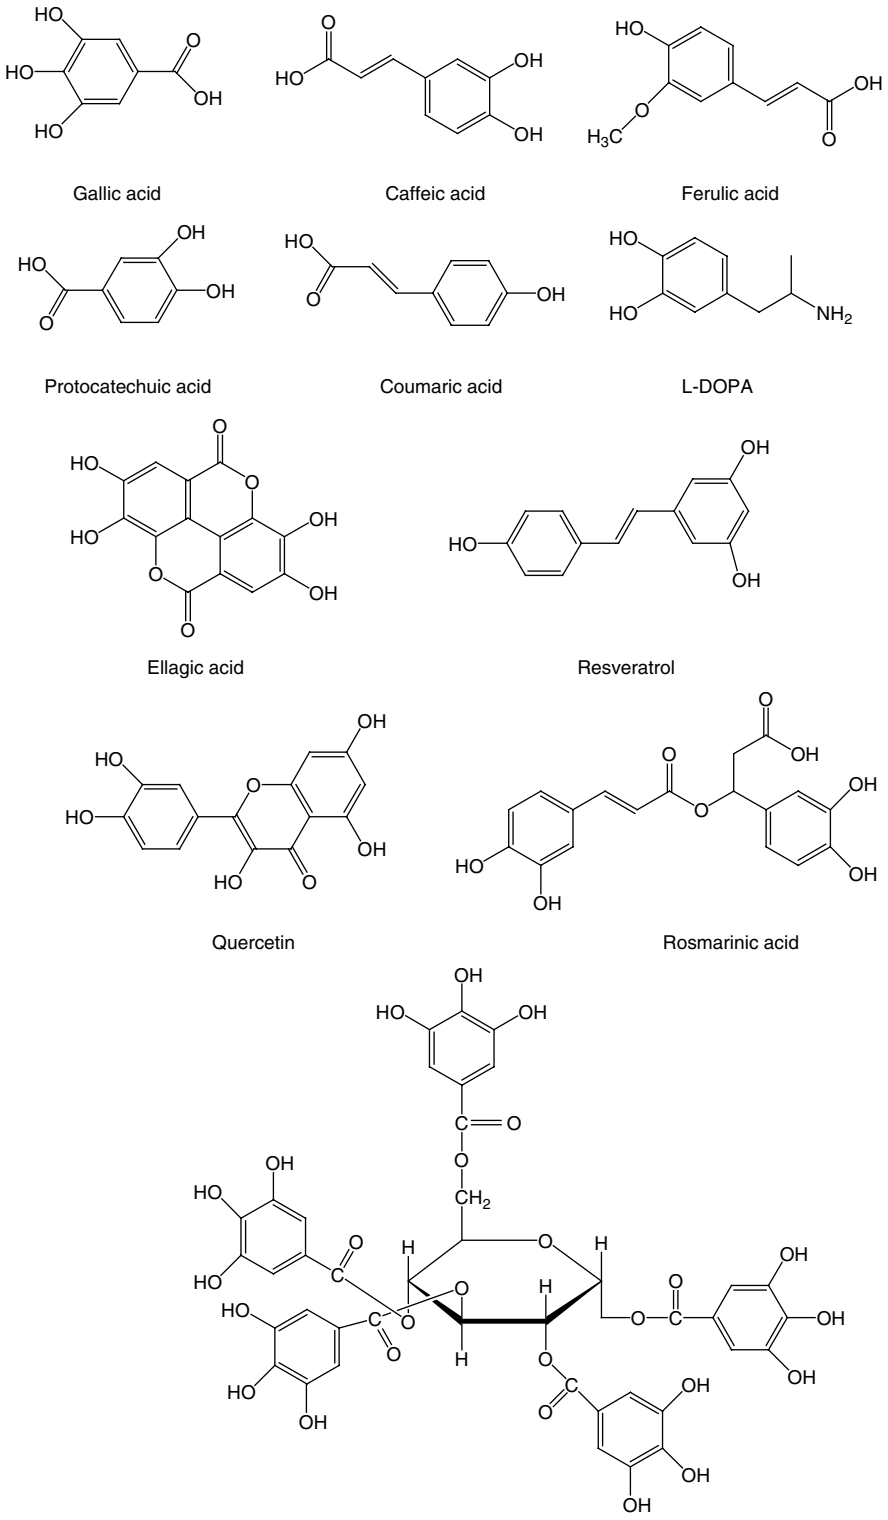

Figure 10.1 Common simple phenol, biphenyls, flavonoids, and tannins in plants.

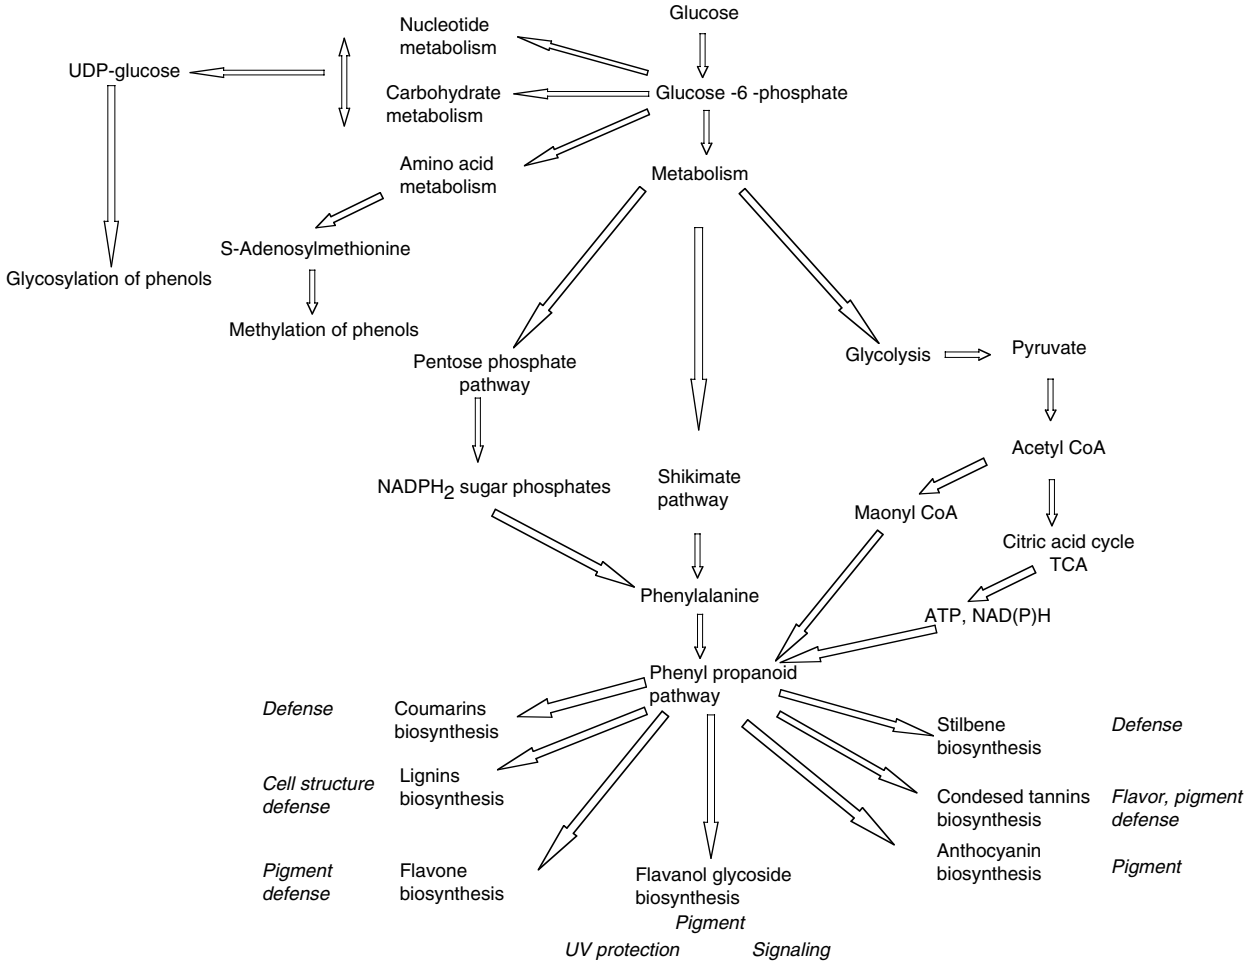

Figure 10.2 Biosynthesis of phenolic phytochemicals.

contain a variety of polyphenolic compounds, the most abundant being flavonoids such as anthocyanins (16,17,18).

Berries, like many other fruits, are rich in phenolic compounds, including diphenyls, flavonoids and phenolic acids, which exhibit a wide range of biological effects, including antioxidant (19,20,21) and anticarcinogenic properties (22). A high free radical scavenging activity of berry extracts toward chemically generated active oxygen species has been described in several studies (19–21). Increased fruit consumption in daily diets has shown to significantly reduce the incidence and mortality rates of cancer, cardiovascular disorders, and other degenerative diseases caused by oxidative stress (22–25). Epidemiological evidence suggests that high consumption of flavonoids, which are an important component of berries, may provide protection against coronary heart disease, cardiac stroke (26–28), lung cancer (22,28,29), and stomach cancer (30).

Berries are typically rich in flavonoids and diphenyls such as ellagic acid (Figure 10.1), and represent a large group of secondary plant metabolites (31). The diversity and complexity of the flavonoids found in berries depends on at least two factors: different variety of aglycones and the high number of glycosides, sometimes in acylated form; and condensation into complex molecules. Recent research has determined the antioxidant activity of different phenolic compounds (32–34) and attempted to define the structural characteristics which contribute to their activity (33,35). Phenolic acids present in berries are hydroxylated derivatives of benzoic acid and cinnamic acid (36). The other simple phenolics in berries include caffeic, chlorogenic, ferulic, sinapic, and *p*-coumaric, acids (37).

10.2.1.1 Cranberry

The cranberry *(Vaccinium macrocarpon),* also known as American cranberry, belongs to the family Ericaceae, which also includes blueberry (*V. angustifolium*) and bilberry (*V. myrtillus*). Even though cranberries have been historically associated with positive health benefits, scientific investigation into the positive health benefits of the cranberry has received little attention (38,39). Many studies have demonstrated high phenolic content in fruits such as grapes, apples, oranges, prunes, and berries (31). The American cranberry is a prominent agricultural food crop produced in Massachusetts, Wisconsin, Michigan, Canada, New Jersey, Oregon, and Washington. The crop size is approximately 500 million pounds annually and is processed into three basic categories: fresh (5%); sauce products, concentrate, and various applications (35%); and juice drinks (60%) (40).

10.2.1.2 Cranberry Pomace

Cranberry pomace is the byproduct of the cranberry juice processing industry with limited applications. Once the juice is extracted from the fruit, the remaining product is called cranberry pomace. Pomace is mainly composed of the skin, flesh, and seed of the fruit. It is rich in fiber and has relatively small amounts of protein and carbohydrates (41). Traditionally it has been used as an ingredient in animal feed, however, due to its low protein and carbohydrate content, it has little nutritive value. Its disposal into the soil or in a landfill poses considerable economic loss, and causes potential environmental problems due to its low pH (41).

Agricultural and industrial residues are attractive sources of natural antioxidants. Potato peel waste (42,43), olive peel (44), grape seeds, and grape pomace peels (45,46) have been studied for their use as cheap sources of antioxidants. Increased antioxidant activity in rat plasma after oral administration of grape seed extracts was reported recently (47). Identification of polyphenolic compounds from apple pomace (48) has also been reported. Phenolics are ubiquitous in plants, but seeds and skins are especially rich sources of phenolics (42,47,49–51), probably because of the role they play in protecting the fruit

and the seed to ensure healthy propagation of the species. Pomace, which mainly consists of fruit skins and seeds, is also a rich source of phenolic compounds (47,48). However, several phenolics that are found in pomace and other plant products exist in conjugated forms either with sugars (primarily glucose), as glycosides, or as other moieties. This conjugation occurs via the hydroxyl groups of the phenolics, which reduces their ability to function as good antioxidants, because availability of free hydroxyl groups on the phenolic rings is important for resonance stabilization of free radicals. Lowered antioxidant capacity has direct implications on decreasing health functionality when these phenolics are ingested via food or as nutraceuticals. Therefore, if free phenolics are released from their glycosides or other conjugates, then the antioxidant, and thus the health functionality of these phytochemicals could be improved. Enzymatic hydrolysis of these phenolic glycosides appears to be an attractive means of increasing the concentration of free phenolic acids in fruit juice and wines to enrich taste, flavor, and aroma, also potentially increasing nutraceutical value (52–54).

10.2.2 Oxidative Stress Mediated Pathogenesis

Emerging evidence suggests that free radical mediated oxidative stress is responsible for the induction of pathogenicity in biological systems. The primary manner in which oxidative stress is mediated in cellular systems is by the generation of reactive oxygen species (ROS). Oxygen in its ground state is often described as a biradical, as it contains two electrons in its outer shell having the same spin. When one of the electron changes its spin, the oxygen is transformed into a singlet, and becomes a powerful oxidant and undergoes reduction. However, in biological systems, incomplete reduction of molecular oxygen occurs due to errors in metabolism, or due to controlled reduction of oxygen, resulting in the formation of what are now known as ROS. These ROS are highly reactive molecules, and include the hydroxyl radicals (HO^-), superoxide anions (O_2^-) and hydrogen peroxide (H_2O_2) (Figure 10.3). The superoxide anion is the precursor of most ROS in biological systems, and is formed by the one electron reduction of molecular oxygen. Spontaneous or enzymatic dismutation of superoxide anion produces the peroxide radical, which can undergo a complete reduction to form water or an incomplete reduction to form the highly reactive hydroxyl radical (55). Singlet oxygen can also react with nitric oxide (NO) in a diffusion limited reaction to form peroxynitrite which is a powerful

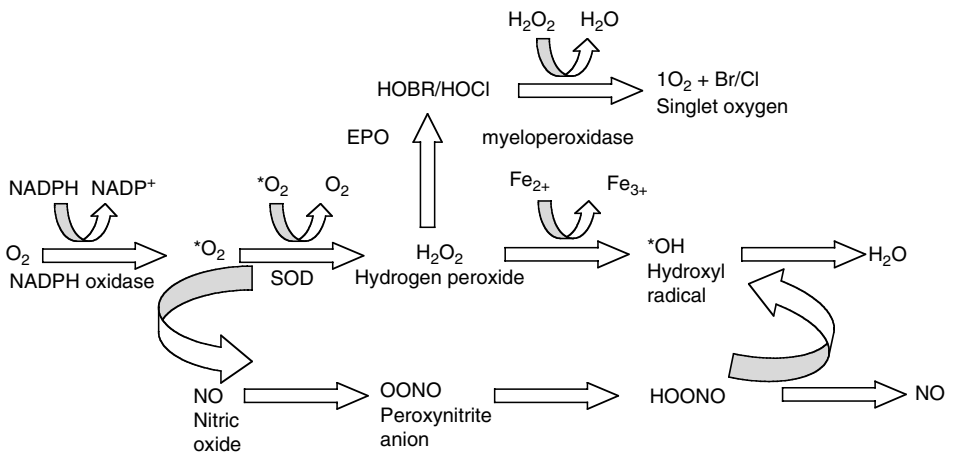

Figure 10.3 Biological mechanisms for ROS formation.

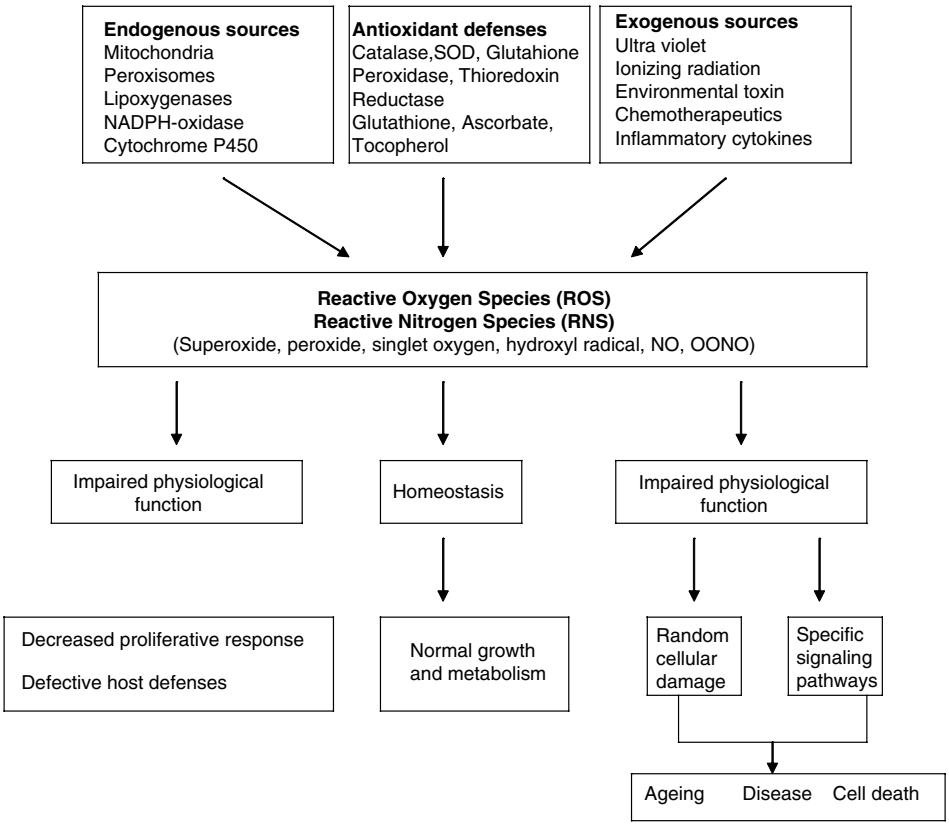

Figure 10.4 Reactive oxygen species mediated pathogenecity.

oxidant (56,57). The oxidants derived from NO are often referred to as reactive nitrogen species (RNS) (Figure 10.3).

Reactive oxygen species and reactive nitrogenspecies (RNS) are constantly produced in aerobic organisms both enzymatically and non-enzymatically. Many sources for the formation of ROS have been identified in cellular systems of living organisms (58,59). Superoxide is formed upon the one electron reduction of oxygen mediated by enzymes such as NADPH oxidase located on the cell membrane of polymorphonuclear cells, macrophages, and endothelial cells (60–62); from xanthine oxidase or from the respiratory chain (63). Superoxide radicals can also be formed from the electron cycling carried out by the cytochrome P450 dependent enzymes (64,65). Mitochondrial leakage of electrons or direct transfer of electron to oxygen via coenzymes or prosthetic groups such as flavins and Fe-S centers constitute another important source of ROS in cellular systems (58,59). The homolytic cleavage of water, or the breakdown of hydrogen peroxide in a high energy radiation (e.g., x-rays, UV) or metal catalyzed process, forms the hydroxyl radical which is the most reactive oxygen species (Figure 10.3, Figure 10.4). Another ROS, the hypochlorite ion, is formed by the macrophage myeloperoxidase, or related peroxidase activities, which catalyze the halide driven reduction of hydrogen peroxide to form the oxidant hypochlorous acid (HOCl) to kill invading microorganisms (63). Biological conversion of L-arginine to L-citrulline by nitric oxide synthase forms a cytotoxic oxygen species, nitric oxide (NO), which is involved in the cellular defense against malignant cells, invading fungi, and protozoa (56,57). Nitric oxide is also involved critically in

signaling mechanisms in the vasculature controlling the vascular force in the blood vessels by vasodilation and inflammation (66).

Reactive oxygen species are ideally suited to be signaling molecules, as they are small, can diffuse small distances, and have several mechanisms of production that can be controlled and regulated. Low levels of ROS therefore have been implicated in many cellular processes, including intracellular signaling responsible for proliferation or apoptosis (67), for modulation of immune response (68), and for mounting a defense response against pathogens (69) (Figure 10.4). Even though the exact mechanism of action of ROS in effecting these physiological processes is not very well understood, there is growing evidence that ROS at some level are capable of activating or repressing many biological effector molecules (70). It has been shown to activate or repress transcription factors by directly activating them by oxidizing the sulphydryl groups present, or by modulating a complex array of kinases and phosphatases, which are important in signal transduction. Many ions that maintain the electrostatic balance of the cell required for many physiological processes such as cell growth and cell death are also now shown to be regulated by ROS. Another important mechanism by which ROS are now shown to be regulating the cell function is by altering the redox status of the cell, often by regulating the levels of oxidized and reduced glutathione (GSH/GSSG) (71).

10.2.2.1 Antioxidant Defense Systems

Redox regulated physiological processes are inevitably sensitive against excessive ROS production by any source. Such excessive levels of ROS may be generated either by overstimulation of the otherwise tightly regulated NAD(P)H oxidases or by other mechanisms that produce ROS in a nonregulated fashion, including the production of ROS by the mitochondrial electronic transport chain (ETC) or by xanthine oxidase. Diets rich in saturated fatty acids, and carbohydrates; and environmental factors such as exposure to high energy radiation, and ingestion of or exposure to toxins and carcinogens can also overstimulate metabolic systems resulting in the formation of ROS, which are beyond the cellular need for their regular functions (63–65) (Figure 10.4).

Several antioxidant systems are in place in the cell that can quickly remove the ROS from cellular systems. Biological defenses against ROS comprise a complex array of endogenous antioxidant enzymes, endogenous antioxidant factors including glutathione (GSH) and other tissue thiols, heme proteins, coenzyme Q, bilirubin and urates, and a variety of nutritional factors, primarily the antioxidant vitamins and phenolic phytochemicals from diet (72–74) (Figure 10.4, Figure 10.5).

Glutathione is the most abundant intracellular reductant in all aerobic cells. Tissue GSH and other tissue thiols exist at millimolar concentrations and are important systems to protect the cell against oxidative stress and tissue injury (71). Glutathione acts as a redox sensor and as a sulfhydryl buffer in cellular systems. Upon generation of ROS, GSH preferentially reacts with ROS in an almost sacrificial manner to form oxidized glutathione (GSSH) to prevent the oxidation of other biological molecules. Enzymes such as glutathione peroxidases (GPX) reduce soluble peroxides and membrane bound peroxides to the corresponding alcohols, at the expense of GSH, which is oxidized to GSSG and ascorbic acid, which is then oxidized to dehydroascorbic acid (71–73). Another class of proteins, called glutaredoxins (GRx), are reduced by GSH, and are capable of reducing protein disulfides from oxidative stress (Figure 10.4, Figure 10.5). However, for this antioxidant response to continue, cellular systems have to regenerate GSH constantly (74). Tissue GSH/GSSH ratios are maintained in the reduced state by the concerted action of antioxidant vitamins such as ascorbate and tocopherols using many antioxidant enzyme systems

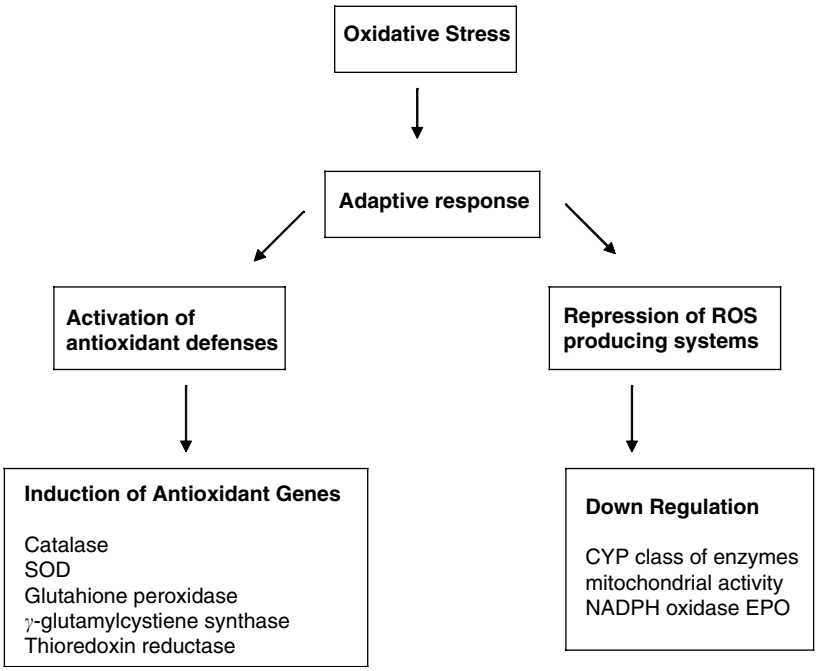

Figure 10.5 Biological adaptive responses to manage oxidative stress. (Morel, Y., R. Barouki, *Biochem. J.* 342(3): 481–496, 1999).

involving several oxidoreductases (72–74). The cascade of endogenous antioxidant enzymes requires energy to maintain the living system in the reduced state. Glutathione reductase and ascorbate peroxidase maintain the tissue GSH in the reduced state at the expense of $NADPH_2$ and $FADH_2$ (72–74) (Figure 10.6). Enzymatic reactions of the thioredoxin system contain a set of oxidoreductases with wide range substrate specificity that reduce the active site disulfide in thioredoxin (Trx) and several other substrates, directly under the consumption of $NADPH_2$. Reduced Trx is highly efficient in reducing disulfides in proteins and peptides including glutathione disulfide (GSSG).

Another biological defense against superoxide free radicals is the superoxide dismutase (SOD) enzyme, which is often considered the most effective antioxidant system.

Superoxide dismutase is an enzyme that catalyzes dismutation of two superoxide anions into hydrogen peroxide and molecular oxygen

$$2O_2^{\cdot -} + 2H^+ \rightarrow H_2O_2 + O_2 \qquad (10.1)$$

The importance of SOD is that it is a very efficient enzyme system in removing superoxide radicals from biological systems. The function of SOD is so imperative for the protection of cells that it represents a substantial proportion of the proteins manufactured by the body (72,73). One of the contributing factors for the high efficiency of SOD is that its dismutation is always coupled to another enzyme system called catalase (CAT). Catalase is involved in removing hydrogen peroxide molecules, which are byproducts of the reactions created by SOD (72,73) (Figure 10.6). Catalase is also abundantly present in the body and is integrated into all the cellular systems that operate in an oxidant environment. Red blood cells, which transport oxygen to different cellular systems, have high levels of CAT and help to remove hydrogen peroxide from tissues to prevent both cellular damage and propagation

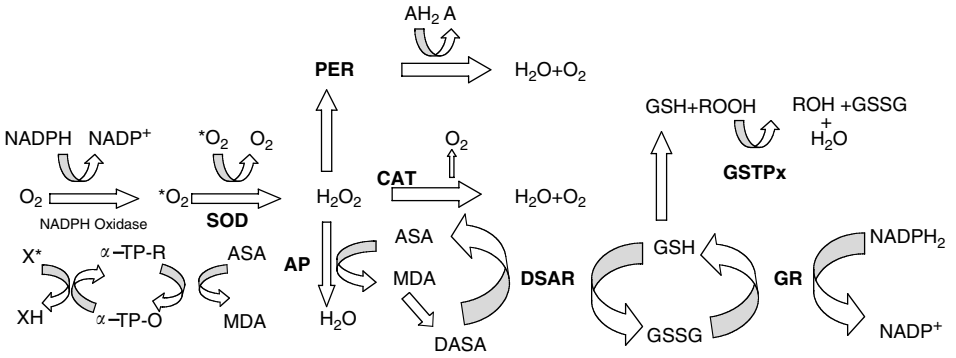

Figure 10.6 The antioxidant defense response of the cell carried out by enzymatic as well as the nonenzymatic antioxidants.

of free radicals. This natural interaction synergy between these two antioxidant enzymes constitutes the most effective system of free radical control (72,73).

Imbalance in the generation of ROS can occur, and deficiency of biological systems to control such an imbalance can result in conditions of oxidative stress, which is now believed to be a primary cause for the induction of many chronic diseases. Small fluctuations in the concentration of ROS may actually play a role in intracellular signaling (67). Uncontrolled increases in the concentrations of these oxidants lead to free radical mediated chain reactions that indiscriminately target proteins (75), lipids (76), and DNA (77,78), which can impair their normal biological functions (Figure 10.4).

Excessive generation of ROS can result in activation or repression of several key signaling pathways and transcription factors, which can impair normal physiological responses, resulting in impaired host defenses. These can lead to impaired cell growth and cell death, which have been shown to develop into cancer and diseases related to aging (67,70,79).

Pathogenesis mediated by virus and *Helicobacter pylori* are also now linked to oxidative stress and are associated with lower responses of CAT and SOD (80,81). Recent experimental findings suggest that overproduction of ROS and RNS lowered antioxidant defense; and alterations of enzymatic pathways in humans with poorly controlled diabetes mellitus can contribute to endothelial, vascular, and neurovascular dysfunction (82). Neurodegenerative disorders such as Alzheimer's disease, Parkinson's disease, and dementia have also been associated with the oxidation of carbohydrates and proteins by ROS, and reduced activities of the enzymes involved in the antioxidant defense response: GPX, SOD and CAT (83).

10.2.2.2 Phenolic Phytochemicals in Nutritional Management of Antioxidant Defense

Association of ROS with manifestation of several diseases has led to an increase in the management of oxidation linked diseases such as cancer, cerebrovascular disease, and diabetes by supporting the body's antioxidant defense system through consuming dietary antioxidants such as ascorbic acid, tocopherols, and carotenoids (82,84,85). Recent epidemiological studies have shown that diets rich in fruits and vegetables are associated with lower incidences of oxidation linked diseases such as cancer, cerebrovascular disease, and diabetes. These protective effects of fruits and vegetables are now linked to the presence of antioxidant vitamins and phenolic phytochemicals having antioxidant activity.

The ability of dietary antioxidants in managing diseases manifested by oxidative stress is not clearly understood. Most phenolic phytochemicals that have positive effects on health are believed to function by countering the effects of ROS species generated during cellular metabolism. Consumption of natural dietary antioxidants from fruits and vegetables has been shown to enhance the function of the antioxidant defense response mediated by GSH, ascorbate, SOD, CAT and GST interface (86–89). This was observed in systemic sclerosis and rheumatoid arthritis patients (90). It was observed that consumption of fruits and vegetables led to a direct increase in scavenging ROS, and prevented polymorphonuclear leukocytes from generating hydroxyl radicals (91).

10.2.3 Biological Function of Phenolic Phytochemicals

Chronic and infectious diseases have become the primary cause of mortality and are expected to become a major public health challenge. These chronic diseases such as cardiovascular disease, hypertension, diabetes mellitus, and some forms of cancer, have now been associated with changes in diet and lifestyle associated with calorie sufficiency. These include excessive dietary carbohydrate and fat intake, low intake of fruits and vegetables, smoking, lack of physical activity, and exposure to environmental toxins (92).

Compelling epidemiological and scientific evidence has led to an understanding that oxidative stress, as a consequence of an imbalance of prooxidants and antioxidants, is a key phenomenon in the manifestation of chronic diseases (90). Powerful strategies to control oxidative stress related pathogenicities are gaining prominence. Epidemiological evidence showing that populations consuming diets rich in fruits and vegetables have lower incidences of many chronic diseases such as cancer, cardiovascular diseases and diabetes has led to an interest in the use of diet as a potential tool for the control of these oxidative diseases (86–89). Recent *in vitro* and clinical studies have shown that diets rich in carbohydrates and fats induced oxidative stress, which was decreased by consuming fruits, vegetables, and their products (93). Among all the dietary components, fruits and vegetables have especially been shown to exert a protective effect (23–26). Phenolic phytochemicals with antioxidant properties are now widely thought to be the principle components in fruits and vegetables which have these beneficial effects. Phenolic phytochemicals exhibit a wide range of biological effects and can broadly be divided into two categories. The first and the most well described mode of action of these phenolic phytochemicals in managing oxidation stress related diseases is due to the direct involvement of the phenolic phytochemicals in quenching the free radicals from biological systems. It is well known that free radicals cause oxidative damage to nucleic acids, proteins, and lipids. Oxidation of biological macromolecules as a result of free radical damage has now been strongly associated with development of many physiological conditions which can develop into disease (67,70,79–83). Phenolic phytochemicals, due to their phenolic ring and hydroxyl substituents, can function as effective antioxidants due to their ability to quench free electrons. Phenolic antioxidants can therefore scavenge the harmful free radicals and inhibit their oxidative reactions with vital biological molecules (19).

The second and more significant mode of action is a consequence of their ability to modulate cellular physiology both at the biochemical or physiological level and at the molecular level. This mode of action is a result of the structure to function phenomenon linked to metabolic pathways. Because of their structural similarities with several key biological effectors and signal molecules, phenolic phytochemicals are able to participate in induction or repression of gene expression; or activation or deactivation of proteins, enzymes, and transcription factors of key metabolic pathways (67,71–73). They can critically modulate cellular homeostasis as a result of their physiochemical properties such as size, molecular weight, partial hydrophobicity, and ability to modulate acidity at biological pH through

enzyme coupled reactions. As a consequence of many modes of action of phenolic phytochemicals they have been shown to have several different functions. Several studies have demonstrated anticarcinogenic properties of phenolic phytochemicals such as gallic acid, caffeic acid, ferulic acid, catechin, quercetin, and resveratrol (94–96). It is believed that phenolic phytochemicals might interfere with several of the steps that lead to the development of malignant tumors, including inactivating carcinogens and inhibiting the expression of mutant genes (97). Potential anticarcinogenic functions of phenolic phytochemicals have also been shown due to their ability to act as animutagens in the Ames test (94–96). Many studies have also shown that these phenolic phytochemicals can repress the activity of enzymes such as the CYP class of enzymes, involved in the activation of procarcinogens. The protective functions of the liver against carbon tetrachloride toxicity (98) have shown that phenolic phytochemicals also decrease the carcinogenic potential of a mutagen and can activate enzymatic systems (Phase II) involved in the detoxification of xenobiotics (2). Antioxidant properties of the phenolic phytochemicals can also prevent oxidative damage to DNA which has been shown to be important in the age related development of some cancers (99). Other phenolics such as caffeic and ferulic acids react with nitrite *in vitro* and inhibit nitrosamine formation *in vivo*. They inhibit the formation of skin tumors induced by 7,12-dimethyl-benz(a) anthracene in mice (100). Important biphenyls such as resveratrol (Figure 10.1) which is found in wine has been shown to inhibit the development of preneoplastic lesions in rat mammary gland tissue in cultures in the presence of carcinogens, and it was also shown to inhibit skin tumors in mice (101,102).

Another well described function of phenolic phytochemicals is the prevention of cardiovascular diseases (CVDs). The lower incidences of CVDs in populations consuming wine as part of their regular diet is well established, and is often referred to as the French paradox (103). Recent research into the beneficial effects of wine has led to an understanding that resveratrol, which is a phenolic phytochemical, is the active component in wine responsible for its beneficial effects. Resveratrol and other phenolic antioxidants have also been shown to prevent development of CVDs by inhibiting LDL oxidation *in vitro* (104) and preventing platelet aggregation. Phenolic phytochemicals have also been able to reduce blood pressure and have antithrombotic and antiinflammatory effects (105,106). Phenolic phytochemicals have also been shown to inhibit the activity of α-amylase and α-glucosidase, which are resposible for postprandial increase in blood glucose level, which has been implicated in the manifestation of type II diabetes (107,108).

In addition to managing oxidation, several studies have indicated the ability of phenolic phytochemicals to manage infectious diseases. Antibacterial, antiulcer, antiviral, and antifungal properties (109–112) of the phenolic extracts have been described. Immune modulatory activities of phenolic phytochemicals such as antiallergic properties as a result of suppressing the hypersensitive immune response have also been defined (113). Antiinflammatory responses mediated by suppression of the TNF-α mediated proinflammatory pathways have also been shown to be mediated by phenolic phytochemicals (114).

10.2.3.1 Biological Functionality of Cranberry Phenolics

Cranberries and their products have been part of North American and Western European cuisines for many centuries. Foods that contain cranberries and their products have been associated historically with many positive benefits on human health. For many decades, cranberry juice has been widely used, particularly in North America, as a folk remedy to treat urinary tract infections (UTIs) in women, as well as other gastrointestinal (GI) disorders (115,116). These infections have now been shown to be caused by the infections of the GI tract by *Escherichia coli* and other pathogens. Recent clinical studies have established a positive link

in prevention of urinary tract infection with the consumption of cranberry juice (117). Cranberry, like other fruits and berries is rich source of many bioactive components including phenolic phytochemicals such as phenolic acids, flavonoids, anthocyanins and their derivatives (118). p-Hydroxybenzoic acid, a phenolic acid present at high concentrations in cranberry, was believed to be the primary bioactive component in preventing urinary tract infections (38). This was believed to be due to the bacteriostatic effect of hippuric acid which is formed from metabolic conversion of p-Hydroxybenzoic acid in the liver. Hippuric acid, when excreted into the renal system, causes acidification of urine and thus prevents the growth of *Escherichia coli* on the urinary tract (38). It is now well established that adherence of the pathogen to the host tissue is also one of the most important steps required for the colonization of the bacteria and their subsequent infection. A majority of infectious diseases, including UTIs that are caused by microorganisms, have now been shown to involve the adherence of the pathogen to the host tissue (119,120). Investigations into the mechanism of adherence to host tissue has led to an understanding that these are mediated by specific glycoprotein receptors called fimbriae or lectins on the bacterial cell surface which can specifically bind to sugars present on the mucosal or intestinal cell surfaces of the host tissue (119,120). Many soluble and nondigestible sugars and oligosaccharides, such as fructose and mannooligosaccharides, can act as decoy sugars, forcing the bacteria to bind to them instead of the host cell. Inability of the pathogen to bind to the cell surface causes the microorganism to be washed away by the constant peristaltic motion in the intestine. This type of binding however, occurs only via a specific type of fimbriae called type 1 (mannose sensitive) fimbriae (119,120). Recent investigations have shown that type P fimbriae [α-Gal(1$\rightarrow$4)β-Gal] mediated adhesion, which is mannose resistant, is also involved in bacterial adhesion. Components of fruit juices, including cranberry juice, have been proposed to inhibit bacterial adherence to the epithelial cells by competing to bind with both these fimbriae (119,120). In addition to the extensive studies done on the inhibition of the adherence of components of *Escherichia coli* to host mucus cells, recent *in vitro* studies indicate a high molecular weight component in cranberry to inhibit the siallylactose specific (S-fimbriae) adhesion of *Helicobacter pylori* strains to immobilized human mucus, erythrocytes, and cultured gastric epithelial cells. It is suspected that these high molecular weight components from cranberries can inhibit the adhesion of *Helicobacter pylori* to the stomach *in vivo* and therefore may have a potential inhibitory effect on the development of stomach ulcers (121,122). Certain high as well as low molecular weight preparations of cranberry juice were also effective in decreasing the congregation and salivary concetration of *Streptococcus mutans,* which causes tooth decay (123,124). The formation of catheter blocking *Proteus mirabilis* biofilms in recovering surgical patients was also significantly decreased by the consumption of cranberry juice (125). Adherence of *Fusobacterium nucleatum* to buccal cells was also reduced by the high molecular weight extract from cranberry juice (123,124). Low and high molecular weight components from cranberry are also suspected to have antiviral properties because of the ability of tannins and other polyphenols to form noninfectious complexes with viruses. Cranberry and its products are also known to inhibit many fungi belonging to *Candida* species, *Microsporum* species and *Trycophyton* species (126,127).

Recent studies have reported on the radical scavenging activities of the various flavonol glycosides and anthocyanins in whole cranberry fruit and their considerable ability to protect against lipoprotein oxidation *in vitro*. The flavonoid and hydrocinnamic acid derivatives in cranberry juice reduced the oxidation of LDL and LDL mobility (128). In an *in vitro* study cranberry samples significantly inhibited both H_2O_2 and TNFα induced vascular endothelial growth factor (VEGF) expression by the human keratinocytes (129). Matrigel assay using human dermal microvascular endothelial cells showed that edible cranberries impair angiogenesis (129). It is therefore believed that cranberry juice may also have beneficial effects on cardiovascular health (130,131).

Cranberry and cranberry extracts have been shown to have anticancer properties. Phenolic extracts from berries of *Vaccinium* species were able to modulate the induction and repression of ornithine decarboxylase (ODC) and quinone reductase that critically regulate tumor cell proliferation (132). Cranberry extracts showed *in vitro* antitumor activity by inhibiting the proliferation of MCF-7 and MDA-MB-435 breast cancer cells. Cranberry extracts also exhibited a selective tumor cell growth inhibition in prostate, lung, cervical, and leukemia cell lines (132,133). Solid-state bioprocessing of natural products including cranberry pomace had shown to enhance its functionality. The antioxidant activity of the cranberry pomace was improved significantly after solid-state bioprocessing with fungi. Bioprocessing of cranberry pomace was found to release phenolic aglycones and enhance the phenolic profile of the pomace with important functionally relevant diphenyls such as ellagic acid. The antimicrobial properties of the pomace extract against foodborne and human pathogens such as *Listeria monocytogenes, Eschereschia coli O157: H7, Vibrio parahemolyticus* and *Helicobacter pylori* significantly improved after solid-state bioprocessing (134).

10.2.3.2 Ellagic Acid

Ellagic acid is a naturally occurring phenolic lactone compound found in a variety of natural products (Figure 10.1). Ellagic acid is present in plants in the form of hydrolyzable tannins called ellagitannins as the structural components of the plant cell wall and cell membrane. Ellagitannins are esters of glucose with ellagic acid which, when hydrolyzed, yield ellagic acid. Ellagic acid is seen at high concentrations in many berries including strawberries, raspberries, cranberries, and grapes (38,39). Other sources of ellagic acid include walnuts, pecans (135), and distilled beverages (136). Recent studies have indicated that ellagic acid possesses antimutagenic, antioxidant, and antiinflammatory activity in bacterial and mammalian systems (137–140).

Ellagic acid has been shown to be a potent anticarcinogenic agent. One of the main mechanisms by which ellagic acid is proposed to have anticancer benefits is by modulating the metabolism of environmental toxins and therefore preventing initiation of carcinogenesis induced by these chemicals (141). It is also proposed to show antimutagenic activity by inhibiting the direct binding of these carcinogens to the DNA (142).

Ellagic acid was found to inhibit the mutagenesis induced by aflatoxin B1 in *Salmonella* tester strains TA 98 and TA 100 (143). On oral administration, ellagic acid exhibited hepatoprotective activity against carbon tetrachloride both *in vitro* and *in vivo* (144). Ellagic acid inhibited the DNA binding and DNA adduct formation of N-nitrosobenzylmethylamine (NBMA) in cultured explants of rat esophagus (145). Related studies have shown that ellagic acid inhibited both the metabolism of NBMA and the binding of NBMA metabolites to DNA (146). In human epithelial cells ellagic acid also inhibited the binding of carcinogenic benzo[a]pyrene metabolites to DNA (142), and dibenzo[a,l]pyrene-DNA adduction in human breast epithelial cell line MCF-7 (147). Smith et al. (148) also showed that ellagic acid resulted in substantially reduced (>70%) DNA binding of 7,12-dimethylbenz[a]anthracene (DMBA) and suggested that possible mechanisms for the observed adduct reduction include direct interaction of the chemopreventive agent with the carcinogen or its metabolite, inhibition of phase I enzymatic activity, or formation of adducts with DNA, thus masking binding sites to be occupied by the mutagen or carcinogen (142). Ellagic acid also significantly increased the GST enzyme activity, GST isozyme levels, and glutathione levels, and therefore is proposed to show strong chemoprotective effects by selective enhancement of members of the GST detoxification system in the different cancerous cells (142).

Ellagic acid was also found to significantly reduce the number of bone marrow cells with chromosomal aberrations and chromosomal fragments as effectively as alpha tocopherol (149). Moreover, administration of ellagic acid inhibited radiation induced DNA strand

breaks in rat lymphocytes. Ellagic acid induced G1 arrest, inhibited overall cell growth, and caused apoptosis in tumor cells (150). One of the studies reported a better protection by ellagic acid than vitamin E against oxidative stress (151). Ellagic acid reduced cytogenetic damage induced by radiation, hydrogen peroxide, and mitomycin C in bone marrow cells of mice (149,152). Chen et al. (153) suggested that the antitumor promoting action of ellagic acid and other related phenolics may be mediated in part by inducing a redox modification of protein kinase C (PKC) which serves as a receptor for tumor promoters. Ellagic acid is also suggested to carry out its antimutagenic and anticarcinogenic effects through the inhibition of xenobiotic metabolizing enzymes (141), and by the induction of antioxidant responsive element (ARE) mediated induction of NAD(P)H: quinone reductase and glutathione S-transferase (GST) genes, which can detoxify carcinogens and reduce carcinogen induced mutagenesis and tumorigenesis (154,155). Wood et al. (140) showed that ellagic acid is a potent antagonist to the adverse biological effects of the ulimate carcinogenic metabolites of several polycyclic aromatic hydrocarbons, and suggested that this naturally occurring plant phenolic, normally ingested by humans, may inhibit the carcinogenicity of polycyclic aromatic hydrocarbons.

Studies have shown that ellagic acid is a potent inhibitor of DNA topoisomerases, which are involved in carcinogenesis. Structure and activity studies identified the 3,3′-hydroxyl groups and the lactone groups as the most essential elements for the topoisomerase inhibitory actions of plant phenolics (156). Some recent studies have shown that ellagic acid was found to be better than quercetin for chemoprevention (139). When the effect of both of these compounds on reduced glutathione (GSH), an important endogenous antioxidant, and on lipid peroxidation, was investigated in rats, both ellagic acid and quercetin caused a significant increase in GSH and decrease in NADPH dependent and ascorbate dependent lipid peroxidation. However, ellagic acid was found to be more effective in decreasing the lipid peroxidation and increasing the GSH (139). This suggested that it may be more effective in inducing the intracellular synthesis of GSH and may be more capable of regenerating the oxidized GSH. This may be one of the reasons for the well documented anticarcinogenic activity of ellagic acid compared to quercetin (139). When the ability of vitamin E succinate and ellagic acid to modulate 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD)-induced developmental toxicity and oxidative damage in embryonic or fetal and placental tissues was compared in C57BL/6J mice (151), ellagic acid provided better protection than vitamin E succinate and decreased lipid peroxidation in embryonic and placental tissues.

10.2.3.3 Alternate Model for the Function of Ellagic Acid and Related Phenolic Phytochemicals from Cranberries

Recent research has shown that phenolic phytochemicals such as ellagic acid from cranberries and other fruits have several health benefits. Several studies have suggested many mechanisms as the mode of action of ellagic acid and several other related phenolics. Primarily the mechanism of action has been defined as being able to counter the negative effects of stress at late stages of pathogenecity by aiding the regeneration of cellular antioxidants such as GSH and ascorbate, and by activation or induction genes responsible for expressing enzymes such as superoxide dismutase (SOD), catalase (CAT), glutathione-S-transferase (GST), Quinone: NADPH oxidoreductase (QR), and others which are involved in managing the oxidative stress (141,155). Control of oxidative stress induced diseases is also believed to be brought about by repressing certain genes such as the cytochrome P450 dependent Phase I enzymes (157,158), inhibition of NADPH oxidase, and other systems that generate ROS (63). Though these proposed mechanisms are valid and justified with experimental findings, however, they do not explain the larger, more comprehensive, functions of

cranberry phenolics such as ellagic acid and other phenolic antioxidants in maintaining specific cellular homeostasis, which contribute to its preventive mode of action. The mechanisms and models proposed so far only explain a particular specific response mediated by ellagic acid or related phytochemicals in a disease such as preventing the binding of a carcinogen to the DNA (141), or repressing the activity of Phase I enzymes in the liver (154,155). These observations often explain the beneficial effect of phenolic phytochemicals based on either one mechanism of action such as a free radical scavenging activity, or by explaining consequences on end results such as activation or repression of some genes. These models, however, do not explain several different effects mediated by a single phenolic phytochemical and the synergistic actions of phenolic phytochemicals in foods. Biological antioxidant protection is believed to occur through an adaptive response (Figure 10.5, Figure 10.6), wherein the cell shifts its functions in a manner that induces genes and transcription factors such as AP1, NFκB and *cfos* (70), which in turn stimulate the antioxidant enzyme response mediated by GSH, SOD/CAT and GST interface, and also reduces mitochondrial function to prevent ROS generation (67,70). One drawback of these models is that they are limited in explaining the several upstream metabolic processes that ultimately contribute to manifestation of the adaptive response that maintains the cellular homeostasis. The adaptive response, which comprises the cascade of antioxidant enzyme activity, is an energy intensive process and therefore requires a constant supply of ATP and reducing equivalents ($NADPH_2$) (74). For this antioxidant response to function in an efficient manner, the cell would have to constantly replenish its energy. It would, therefore, be imperative for the mitochondria to function efficiently to replenish the energy needs. Also, a specific mode of functionality of the individual phytochemical does not explain other functionality such as antimicrobial activity in preventing *Helicobacter pylori* or *Escherichia coli* infections for maintaining gastrointestinal health. It is challenging to explain, using existing models, the reason for the same phytochemical to promote survival in eukaryotes and discourage the survival of pathogens. These apparently conflicting modes of action of phytochemicals have prompted a need to understand the functionality of phenolic phytochemicals such as ellagic acid in a much broader sense. There is a need to understand the mechanism of action of these phenolic phytochemicals at the early stages of stimulating the antioxidant response mediated cellular homeostasis in the cell (159,160). Therefore, in addition to the described mechanisms of action of phenolic antioxidants, an alternative model has been proposed for the mode of action of dietary phenolic phytochemicals. The antioxidant homeostasis in the cell occurs via the functioning of a diverse array of redox processes, primarily carried out by cellular antioxidants such as glutathione, ascorbate, tocopherols, and an array of antioxidant enzymes such as SOD, CAT and GST (72). However, to maintain high efficiency of this system it is important to regenerate the oxidized substrates such as glutathione disulfides (GSSG), dehydroascorbate, and other proteins with oxidized sulfhydryl groups. The regeneration of oxidized glutathione, ascorbate and tocopherol occurs by a group of oxidoreductases which use cellular reducing equivalents such as $FADH_2$ and $NADPH_2$, and therefore are energy intensive processes (72–74). In order to meet the cellular requirement for these reducing equivalents, in this model, it is proposed that phenolic antioxidants aid the antioxidant response of the cell not only by themselves acting as redox modulators by virtue of their antioxidant (free radical scavenging) activity, but also able to stimulate pathways in the cell that can replenish the needs for reducing equivalents. One such pathway that could be up regulated by phenolic phytochemicals such as cranberry phenolics, and ellagic acid could be the pentose and phosphate pathway (PPP) (Figure 10.7). The pentose phosphate pathway is an important pathway that commits glucose to the production of ribose sugars for nucleotide synthesis and, in the process, also produces reducing equivalents ($NADPH_2$) (161–163). Phenolic phytochemicals, especially biphenyls and polyphenols, are structurally similar to many biological signaling molecules which

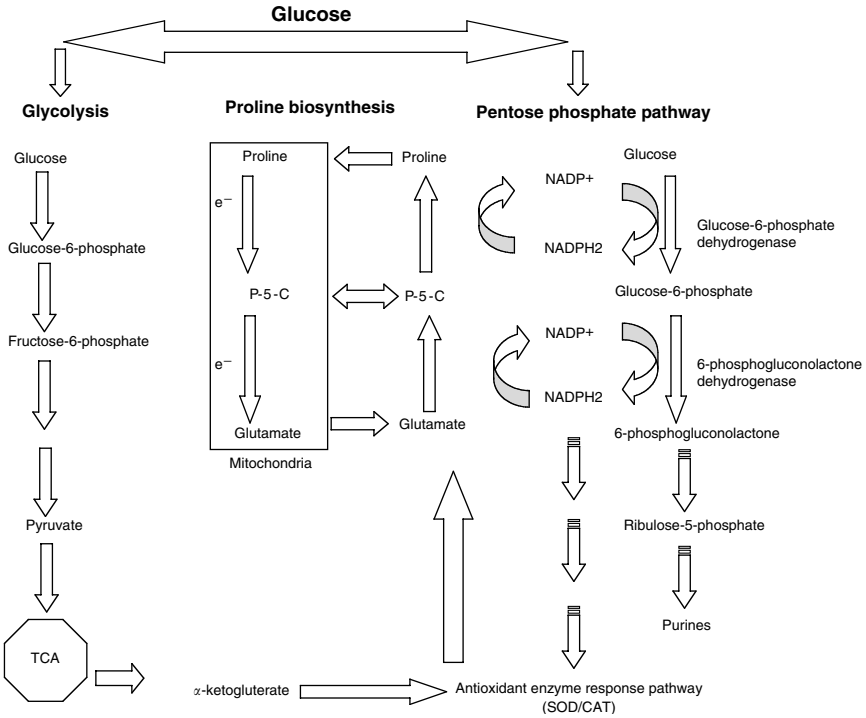

Figure 10.7 Proline linked pentose–phosphate pathway in eukaryotes for regulating antioxidant response.

interact with the receptors on the cell surface responsible activating biological signal transduction processes. Recent empirical evidence has now shown that some phenolic phytochemicals can also mimic the functions of biological signaling molecules and trigger the signal transduction (153,164,165). Phenolics from cranberry, especially biphenyls and flavonoids are large and partially hydrophobic, and can be perfect candidates for the activating signaling pathways responsible for the stimulation of PPP (153,164,165). In addition, phenolic phytochemicals such as ellagic acid and flavonoids from cranberry have been known to be good chelators; these phytochemicals can effectively chelate the ions such as calcium in the extracellular matrix (ECM) or in the cytosol and alter the net concentration of free calcium (8,166,167). Calcium in the cytosol and extracellular matrix is critical for maintaining cellular homeostasis and is an important factor in regulating cell division and cell death, and is often regulated by the calcium sensing receptor (168–172). Many cellular signaling cascades are sensitive to a calcium gradient across the cell membrane (171,172). An apparent modulation in the concentration of calcium, either by calcium binding or by the modulating the calcium sensing receptor, can activate these cellular signaling cascades which can result in changes in many physiological pathways including the stimulation of the PPP (161, 171–173). Phenolic phytochemicals such as ellagic acid and flavonoids have been shown to interact with proteins and alter their configuration. These phytochemicals can therefore directly interact with the cell surface receptors and ion pumps, and directly activate signaling cascades by inducing structural changes in the membrane receptor proteins and pumps (174–177). Phenolic phytochemicals, especially phenolic acids, are weak acids and are capable of dissociating at the cell membrane at a biological pH of 6.8–7.2 (178). This dissociation can create a proton gradient across the cell membrane which can alter the function

of many proton pumps on the cell membrane (159,160). The partially hydrophobic ellagic acid and flavonoids can also directly interact with the proton pumps and modulate their function. In addition, phenolic phytochemicals, especially flavonoids, have been shown to be able to interact with the membranes (179,180). Such an interaction can alter the permeability of the cell and cause changes in the electrochemical gradient across the cell membrane, causing rapid influx of protons into the cytosol and activation of many signal cascades leading to the stimulation of PPP (Figure 10.7). The stimulation of PPP which results in the $NADPH_2$ synthesis can help in decreasing the excess protonation of the cytosol by the phenolic phytochemical, by combining the protons with $NADP^+$ to make $NADPH_2$ through dehydrogenases. Stimulation of the pentose phosphate pathway could be an important cellular mechanism in managing antioxidant stress response and may be closely linked to stimulation of antioxidant response pathways (160,181). The availability of reducing equivalents in the cell could now further stimulate the antioxidant stress response managed by GSH, ascorbate, SOD, CAT, and GST, which require $NADPH_2$ for their effective functioning (72–74). Phenolic phytochemicals are now known to modulate gene expression either by activating or repressing transcription factors or by directly binding to the DNA (164,182,183). The phenolic phytochemicals such as ellagic acid and other cranberry flavonoids can aid in the cellular antioxidant defense response by activating the expression of enzymes involved in antioxidant defense and repressing the expression of oxidative stress producing pathways such as NADPH oxidase and cytochrom-P450 dependent phase I enzymes.

The stimulation of the pentose phosphate pathway could further be coupled to the biosynthesis of proline made from glutamic acid using $NADPH_2$ (184–186). Phenolic phytochemicals can stimulate the biosynthesis of proline and subsequently create a demand for the tricarboxylic acid (TCA) cycle intermediates such as α-keto glutarate to be channeled to glutamic acid and then to $NADPH_2$ requiring proline biosynthesis (Figure 10.7). This channeling of the TCA cycle intermediates to proline biosynthesis can generate a cellular demand for $NADPH_2$ and can therefore stimulate the pentose phosphate pathway (160,181). This coupling of proline biosynthesis with PPP can generate more $NADPH_2$ which can be used by the proline biosynthesis pathway, antioxidant response pathways, and anabolic reactions (160,181). The cellular demands for reducing equivalents are coupled to the needs for ATP, which is the source of energy in biological systems. ATP is synthesized by oxidative phosphorylation of ADP by an enzyme, ATPase, in the mitochondria by reduction of molecular oxygen to water with the help of electrons from reducing equivalents such as NADH and $FADH_2$. Excessive cellular requirement for ATP usually results in incomplete reduction of oxygen to make reactive oxygen species, which have implications in manifestation of various oxidative stress related diseases (187,188). Proline has been shown to be able to function as a reductant in cellular systems (189,190). Therefore, it has also been proposed that proline can function as an alternative reductant (instead of NADH) (Figure 10.7) for mitochondrial oxidative phosphorylation to generate ATP (159,160). This can reduce the cellular need for NADH linked ATP synthesis, which can reduce excessive mitochondrial oxidative burst limit leakage of reactive oxygen species into the cytosol during oxidative phosphorylation.

10.2.3.4 A Model for Antimicrobial Activity of Ellagic Acid and Related Phenolics Against Bacterial Pathogens

Ellagic acid and other related phenolics can also have a different mode of action that can be used to explain their other functionalities, such as antimicrobial activity. Phenolic phytochemicals and phenolic acids are weak acids, and therefore are capable of dissociating

at the plasma membrane at biological pH (178). This weak dissociation of the phenolics is proposed to be an important mechanism by which ellagic acid and other phenolic antioxidants exert their antimicrobial effect. The dissociation of a proton from the carboxyl or the hydroxyl substituent on the phenolic phytochemical may result in hyperacidification at the plasma membrane interface of the microorganism (160,191). The hyperacidification of the plasma membrane by the phenolic antioxidant could change the resting potential of the membrane, as it results in increased positive charges outside of the membrane. Disruption in the proton and electrostatic gradient across the membrane can have several implications. Many ion pumps and channels such as Na^+/K^+ or at Ca^+ pumps are responsible for critically regulating many cellular functions such as motility, cell division, and cell death. Impairment of calcium homeostasis or calcium signaling can cause disruption in the normal cellular function of the microorganism and therefore death. Phytochemicals such as tannins, and their hydrolyzed products such as ellagic acid, can inhibit the growth of microorganisms by sequestering metal ions critical for the microbial growth and metabolism (192–195), or by inhibiting critical functions of the bacterial membrane such as ion channels and proteolytic activity (196), which are all dependent on pH and ionic strength. Many key proteins and receptors on the membrane are responsible for receptor mediated transport of nutrients and cofactors. These proteins are sensitive to the pH and ionic strength. Disruption of the electrochemical gradient and phenolic induced acidity at the membrane could cause inactivation of the receptors involved in uptake of the nutrients and thus cause death of the target bacteria.

The cell membrane is a site of electron transport and ATP generation in prokaryotes. Ellagic acid related phytochemicals are phenolic chemicals and have an ideal chemical structure to function as antioxidants. Presence of phenolic moieties confers upon them an excellent ability to quench the electrons from free radicals and delocalize them within the phenolic ring. Consequently, they can easily quench the electrons from the electron transport chain (ETC) along the bacterial membrane. This could disrupt the flow of the electrons at the level of cytochromes and inhibit the growth of bacteria by disrupting oxidative phosphorylation (160,181,191). Localized protonation and reduced plasticity of the membrane can diffuse the proton gradient essential for the functioning of H^+-ATPase required for ATP synthesis. The diffusion in the proton gradient results in lowered efficiency of the H^+-ATPase, and therefore the organism will synthesize reduced ATP, or no ATP at all. This can force the microorganism to switch to an anaerobic metabolism to generate ATP. The reduced intake of nutrients because of disruption in the membrane transport induced by ellagic acid and other related phenolics, increased demand for ATP, and disruption of the ATPase activity could prove fatal to the microorganism. For a phenolic to function effectively as an antimicrobial, it should be able to function at the lipid to water interface and therefore has to be partially hydrophobic. Biphenyls such as ellagic acid and other polymeric phenoics are partially hydrophobic, making them effective to act efficiently at the membrane to water interface of microorganisms. Molecules such as ellagic acid can possibly stack or embed themselves in the membrane. Stacking and or embedding of phenolic phytochemicals such as ellagic acid (160,181,191) at the surface of the membrane can induce a change in the membrane structure by creating an environment of hydrophobicity around the cell, and may result in inactivation of proteins by inducing protein unfolding or by the exclusion of the polar and hydrophilic component from the membrane such as water polar lipids and surface proteins (179,180). This can result in changes in the composition of the membrane and therefore can severely impair the plasticity of the membrane (179,180). A rigid membrane destabilizes the cell by weakening membrane integrity, which may result in the disruption of critical transport processes and sometimes collapsing of the bacterial membrane. This could be an important mechanism of antimicrobial activity

in Gram-negative bacteria such as *Eschereschia coli* which have an external lipopolysaccharide layer and additional minor membrane components besides an intact plasma membrane. This gives them potentially more buffering capacity and hydrophobicity and couls, therefore, create an unfavorable environment for simple phenolics to exert their hyperacidification effect.

10.3 INNOVATIVE STRATEGIES TO ENRICH FRUITS WITH PHENOLIC ANTIOXIDANTS

A large variety of phenolic phytochemicals that have several beneficial functions on human health are present in plants and especially in fruits. The phenolic phytochemicals are generally present in their glycosidic and nonglycosidic forms. The glycosides are mainly confined to hydrophilic regions in the cells, such as in vacuoles and apoplasts, probably because of their higher water solubility (197,198). Glycosylation of the hydroxyl groups on the phenolic ring of a phenolic phytochemical renders the molecule more water soluble and less reactive toward free radicals (6). Glucose is the most commonly involved sugar in glycoside formation, although phenolic glycosides of galactose, rhamnose, xylose, and arabinose; and disaccharides such as rutinose, have also been reported in plants (6). Polymeric phenolics such as tannins exist primarily as condensed tannins or proanthocyanidins and are formed biosynthetically by the condensation of single catechins and flavonols. They are present either as soluble tannins or bound to the cell wall. Hydrolysable tannins are esters of a sugar with either gallic acid (gallotannins) or ellagic acid (ellagitannins). Tannins, even though they have higher antioxidant properties than individual simple phenolics, are usually not bioavailable, and are to some extent antinutritive in their function because of their ability to bind and precipitate biological macromolecules such as proteins and carbohydrates (109). The total phenolic phytochemical content in plant foods also varies greatly. Their presence in plant foods is largely influenced by genetic factors and environmental conditions. Other factors, such as cultivar, variety, maturity, processing, and storage, also influence the content of plant phenolics (199–201). The effects of processing and storage on the changes and content of polyphenols in cranberry (202), plum (203), and grape juice (204) have been evaluated.

As a consequence of evidence that consumption of fruits and vegetables has been linked to decreased manifestation of chronic diseases, there has been a constant increase in the demand for diets rich in phenolic phytochemicals. Vast variation in the amounts of phenolic antioxidants available via diet (205) coupled with reduced bioavailability and functionality has led to an urgent need to develop innovative strategies to enrich diets with phenolics and specifically phenolic antioxidants with consistent phytochemical profile for enhanced health functionality.

Among many strategies, two are important to enrich phenolic antioxidants. The first is genetic modification of cultivars to produce plants that will yield fruits and vegetables with higher phenolic concentration. Currently, in terms of genetic improvement, breeding strategy coupled with micropropagation using tissue culture is being developed (206–208). These strategies, along with genetic modification, could be directed toward phytochemical enrichment and quality improvement. However, this method presents important issues, such as regulation of key metabolites by multiple genes and biochemical pathways, acceptance of genetically modified foods, and relative time and economic considerations that are involved (209). Another exciting strategy that can be used is the bioprocessing of botanicals using solid-state bioprocessing and synergies to generate phytochemical profiles with enhanced health functionality. This strategy can be used for juice and pulp as well as pomace that

remains after the juice is extracted from the fruits. Fermentation of fruit juices, such as grape juice to wine, has already been shown to improve nutritive and health promoting activities (210–212). Solid-state bioprocessing done on the pulps using food grade fungi can result in enrichment of the pulps with phenolic antioxidants and functionally important phenolic phytochemicals, and also improve phytochemical profile consistency.

10.4 SOLID-STATE BIOPROCESSING

Fermented foods have been consumed by humans all over the world for centuries. Most fermentation processes are conducted with liquid nutrient broths. Well known examples in the food industry are the production of yogurt, beer, wine, lactic acid, and many food flavors (213). However, partial fermentation and aerobic microbial growth based bioprocessing has also been used for processing food and food wastes. Here, instead of a nutrient broth, moist solid nutrients with minimal water are used as a substrate for microbial growth. This process is referred to as solid-state bioprocessing. Microbial fermentation and aerobic microbial growth on foods in solid state, for preservation of food and flavor enhancement, has been done for centuries and some of the common examples for these processes include manufacture of cheese and bread (214). Other wellknown examples are the production of microbe laced cheeses such as Roquefort, and the production of fermented sausages. In Asia, solid-state bioprocessing has been used for food fermentation for over 2000 years, for the production of fermented foods such as tempeh, natto, and soy sauce (193). The preservation of fish and meat by solid-state bioprocessing has also been reported to be carried by early human civilizations (193,214). Fruit wastes have been extensively used as substrates for solid-state bioprocessing. These wastes have mostly been used for the production of fertilizers, animal feed, as a growth substrate for mushrooms, ethanol production, production of organic acids such as citric acid, tartaric acid, and lactic acid, and for the production of various kinds enzymes such as pectinases (41,213). Solid-state bioprocessing of fruit substrates has also been carried out for several decades to produce compounds like gallic acid and vinegar (193,214). Recent research has also shown that consumption of fermented foods, especially solid-state bioprocessed foods is beneficial for health (215,216). Solid-state bioprocessing of fruit wastes such as cranberry pomace using the food grade fungi *Rhizopus oligosporus* and *Lentinus edodes* has been shown to enrich phenolic antioxidants and improve phytochemical consistency. These studies have shown that during the course of solid-state growth, the antioxidant activity and phenolic content of the pomace extracts increase several fold (52,53). The process resulted in enrichment of functional phenolics to a level found usually in fresh fruits and their juice products (217). The antimicrobial activity of the extracts against pathogens such as *Escherichia coli O157:H7, Listeria monocytogenes, Vibrio parahemolyticus* and *Helicobacter pylori* of cranberry pomace was also enhanced by solid-state bioprocessing. It is suspected that the increase in phenolic and antioxidant activity could have been due to the production of various hydrolyzing enzymes by the fungi during the course of solid-state growth. These fungal hydrolases such as glucosidase and fructofuranosidases could possibly be hydrolyzing the glycosidic linkages between the phenolic moieties and sugars. A similar observation in the increase in phenolic aglycones was observed during the fermentation of soy milk for the production of tofu (218). The fungus, in adapting itself to utilize the fruit substrates, may produce various other types of hydrolases such as laccases and lignocellulases. The activity of these enzymes is suspected to responsible for the increase in the polymeric phenolics, and potentially to contribute to the enhanced bioavailability of such phenolic antioxidants. Enrichment of the solid-state bioprocessed fruit wastes such as cranberry pomace with ellagic acid after bioprocessing has been reported (52,53). This may have

resulted due to the hydrolysis of ellagotannins by tannin hydrolyzing enzymes produced by the fungus. Further, it is suspected that phenolic enrichment could also occur through contribution from the growing fungal species. The endogenous phenolics present in the fruit wastes could be toxic to the growing fungus. In an attempt to adapt and utilize the substrate for growth, the fungus could be detoxifying the phenolics biochemically using a variety of enzymatic systems present in the fungus. The fungal detoxification can occur by a variety of mechanisms including methylating or demethylating the pheniolic ring, or by hydroxylation (219,220). Recent studies have shown methylated phenolic phytochemicals have excellent antibacterial properties against Gram-positive bacteria (221). Hydroxylation of the phenolic ring by the fungal system during its growth increases antioxidant properties (19) and therefore, phenolics resulting from biotransformation occurring during the solid-state bioprocessing may improve their functionality and be beneficial for human health. The advantage of this strategy is that the fungi, such as *Rhizopus oligosporus* and *Lentinus edodes* and other fungi used in this solid-state growth process are food grade and are generally recognized as safe (GRAS). This approach can easily be adapted to different substrates as well as be extended to liquid fermentation of juices to develop food and ingredients with enhanced functionality.

10.5 CRANBERRY SYNERGIES WITH FUNCTIONAL PHYTOCHEMICALS AND OTHER FRUIT EXTRACTS

Recent research has documented the evidence that whole foods, and not single compounds, have a better functionality in maintaining our health against many of the antioxidant diseases. Recent work on the effect of wine has shown that resveratrol is responsible for the decrease in atherogenesis in rats (101,102). However, when resveratrol was used as a supplement in diet such an effect was not seen. Other researchers have shown that the combination of resveratrol and quercetin exerts a synergic effect in the inhibition of growth and proliferation of human oral squamous carcinoma cells (221). Carbonneau et al. (223) during *in vivo* antioxidant assays with red wine, observed that different phenolics in wine could play a coantioxidant role, similar to that described for vitamin C, and a sparing role toward vitamin E, which increases due to supplementation with phenolics. Synergistic interactions between wine polyphenols, quercetin, and resveratrol were found to decrease the inducible nitric oxide synthase (iNOS) activity in cell culture systems (224). This suggests that the phytochemical profile in which the specific functional phenolic is present plays an important role in determining its functionality. Synergy can be defined as the ability of two or more functional components, such as antioxidants in a phytochemical background, to mutually enhance their functionalities. Typically, in a whole food background such as red wine, resveratrol is present in a background containing several simple as well as polyphenols, such as gallic acid, protocatcheuic acid and hydrolyzed tannins. Each phenolic phytochemical has its own mode of action against a particular target. These modes of actions could be due to their ability to function as classical antioxidants or because of their ability to modulate cellular physiology by disrupting membrane functions or by altering the redox balance and energy metabolism of the cell (160). However, when they are present together, their ability to function together rapidly improves the overall result of maintaining the cellular homeostasis, especially in eukaryotes, or killing the pathogen in prokaryotes. Also, it was observed that coadministration of coffee with ellagic acid enhanced the antigenotoxic effect compared with that of either coffee or the ellagic acid alone, suggesting that there is a significant synergistic interaction between coffee and the dietary constituents for antigenotoxic effects against different mutagens (225). The conditions created due to the mode of action of one phenolic significantly improves the

chances of the other phenolics being able to function effectively, thereby reducing the overall dosage required to observe the desired positive effect. This may be one of the reasons why whole foods have a better functionality in maintaining human health compared to the consumption of supplements. This synergy concept can also be artificially duplicated, and this provides another way to significantly enhance the functionality of foods. Synergistic supplementation of foods such as fruit beverages with flavonoids and other functional phenolic phytochemical can drastically improve their functionality.

In a recent study the potential antimutagenic properties of cranberry phenolics, ellagic acid, rosmarinic acid, and their synergistic interactions on enhancing antimutagenic properties in *Salmonella typhimurium* tested the system against mutagens sodium azide and N-methyl-N′-nitro-N-nitrosoguanidine (MNNG) was investigated (226). Ability of these phytochemical treatments to prevent oxidative damage to DNA was also investigated, using the supercoiled DNA strand scission assay. Results showed that ellagic acid was most effective in inhibiting the mutations in *Salmonella typhimurium* system, whereas rosmarinic acid and ellagic acid were equally effective in protecting the DNA from oxidative damage. The antimutagenic functionality of cranberry powder made from juice extracts was significantly enhanced when 30% (w/w) of phenolics in cranberry powder were substituted with rosmarinic acid and ellagic acid possibly due to synergistic redox modulation which can influence mutagen function. It was suggested that the synergistic mixture of cranberry phenolics with rosmarinic acid could also be protecting the cell from mutations by modulating DNA repair systems.

Phenolic antioxidant and α-amylase inhibition activity of cranberry, wild blueberry and grape seed extracts and their synergistic mixtures were investigated in a recent study to develop an additional strategy to manage type II diabetes (227). The results indicated that all the extracts had α-amylase inhibition activity which correlated to the presence of specific phenolic phytochemicals such as chlorogenic acid, ellagic acid, and rosmarinic acid, suggesting a possible structure related inhibition of α-amylase. Among the fruit juice powders the cranberry powder had the highest α-amylase inhibition activity. A mixture containing 75% cranberry, 15% blueberry and 10% grape showed a synergistic mode of action and was the most optimal mixture to control α-amylase activity.

A similar study investigated the effect of cranberry, blueberry and grape seed extracts on inhibiting *H. pylori* (228). The results showed that the anti-*H. pylori* activity of cranberry juice extract was significantly improved by its synergistic blending with blueberry or grape seed extract. In both the studies, the lower efficacy of purified phenolics in inhibiting α-amylase or *H. pylori* compared with fruit powder at similar dosage levels suggests a synergistic mode of functionality of these individual phenolics in whole food background.

Consumption of blends of fruit juices with biologically active biphenyls or other fruit as well as herb extracts can impart unique functional attributes and could be a more effective strategy in developing diet based management of *H. pylori* infections, as well as other oxidation linked diseases, including diabetes and mutagen and DNA damage induced carcinogenesis.

10.6 CONCLUSIONS

Emerging epidemiological evidence is increasingly pointing to the beneficial effects of fruits and vegetables in managing chronic and infectious diseases. These beneficial effects are now believed to be due to the constituent phenolic phytochemicals having antioxidant activity. Cranberry, like other fruits, is also rich in phenolic phytochemicals such as phenolic acids, flavonoids and ellagic acid. Consumption of cranberry has been historically been linked to

lower incidences of urinary tract infection and now has been shown to have a capacity to decrease peptic ulcer caused by *Helicobacter pylori*. Isolated compounds from cranberry have been shown to reduce the risk of CVD and cancer. Functional phenolic antioxidants from cranberry such as ellagic acid have been well documented to have antimutagenic and anticarcinogenic functionality. Even though many benefits have been associated with phytochemicals from cranberry, such as ellagic acid, their mechanism of action is still not very well understood. Emerging research exploring the mechanism of action of these phytochemicals from cranberry usually follows a reductionist approach, and is often focused on the disease or pathological target. These approaches to understanding the mechanism of action of phytochemicals have limitations as they are unable to explain the overall preventive mode of action of phenolic phytochemicals. The current proposed mechanisms of action of these phenolic phytochemicals have also overemphasized the antioxidant activity of phenolic phytochemicals associated with free radical quenching capacity. This mechanism of action is unable to explain the nonantioxidant (free radical scavenging) role, as well as sometimes contradictory modes of action of phenolic phytochemicals across different species, such as being protective in eukaryotes while being inhibitory to prokaryotes. The often promising results seen at laboratory scale have very rarely been successful at clinical levels in terms of seeing the beneficial effects of these phenolic phytochemicals. All these limitations of the present understanding strongly suggest the involvement of phenolic phytochemicals much earlier in the cellular response towards maintaining antioxidant stress response. A current line of investigation after a newly proposed integrated model suggests the involvement of phenolic phytochemicals in critically regulating energy metabolism of the cell by stimulating the PPP in order to supply the cell with reducing equivalents necessary for the efficient functioning of antioxidant response. A coupling of the proline biosynthesis with PPP has been suggested, which can further stimulate the PPP. Proline can also function as an alternative reductant to participate in the oxidative phosphorylation for ATP synthesis. This would effectively reduce the cellular needs for NADH, which could contribute to reducing oxidative stress as a result of reduced oxidative burst in the mitochondria. This model emphasizes the structure and function aspect of phenolic phytochemicals in their ability to cause hyperacidification, alter membrane permeability to ions, and interact with the membrane proteins and receptors to activate many signaling pathways which can be responsible for their beneficial mechanism of action in both prokaryotes and eukaryotes. Recent evidence suggests the ability of whole foods in being more effective in managing human health compared to individual phenolic phytochemicals. This suggests that the profile of phenolic phytochemicals determines the functionality of the phenolic phytochemical as a result of synergistic interaction of constituent phenolic phytochemicals. Solid-state bioprocessing using food grade fungi, as well as cranberry phenolic synergies with functional biphenyls such as ellagic acid and rosmarinic acid, and other fruit extracts have helped to advance these concepts. These strategies could be further explored to enhance cranberry and cranberry products with functional phytochemicals and further improve their functionality.

2.11

Rosmarinic Acid Biosynthesis and Mechanism of Action

Kalidas Shetty

CONTENTS

11.1 INTRODUCTION

Rosmarinic acid (RA) (Figure 11.1) is commonly found in substantial amounts in the family Lamiaceae, which has many important species such as oregano (*Origanum vulgare*), thyme (*Thymus vulgaris*), rosemary (*Rosmarinus officinalis*), holy basil (*Ocimum sanctum*), perilla or shiso (*Perilla frutescens*), spearmint (*Mentha spicata*), and several other species that have food and medicinal applications. This chapter highlights various sources of rosmarinic acid and their functional effects, RA biosynthesis in cell cultures and pathways associated with RA biosynthesis. In addition, investigations from my own research group have been summarized, where we have developed methods for RA biosynthesis through generation of high RA clonal lines using tissue cultures for field production and regulation of RA biosynthesis through a proposed critical control point (CCP), proline linked pentose–phosphate pathway. In terms of applications we have developed

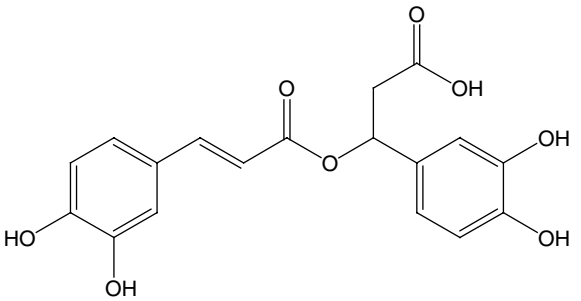

Figure 11.1 Rosmarinic acid

new applications for RA such as for amylase inhibition, which has potential for hyperglycemia management and antimicrobial effects of high rosmarinic acid-containing herbal extracts. Further, we have proposed a model of how RA can regulate human health relevant antioxidant response through the CCP, proline linked pentose–phosphate pathway of human cells.

11.2 ROSMARINIC ACID SOURCES AND FUNCTIONAL PHARMACOLOGICAL EFFECTS

Rosmarinic acid (RA) is an important caffeoyl ester (phenolic depside) with proven medicinal properties and well characterized physiological functions. Rosmarinic acid is found in substantial sources in the family Lamiaceae (1,2). *Salvia lavandulifolia* is used as choleretic, antiseptic, astringent, and hypoglycemic drug in Southern Europe and contains high levels of RA (3). Rosmarinic acid-containing *Ocimum sanctum* (holy basil) is used to reduce fevers and against gastrointestinal disorders in India and has antioxidant properties (2,4). In Mexico, high RA-containing *Hyptis verticillata* is widely used by Mixtec Indians against gastrointestinal disorders and skin infections (5). In Indonesia and several countries in Southeast Asia, RA-containing *Orthosiphon aristatus* is known for diuretic properties and is also used against bacterial infections of the urinary system (6). *Salvia cavaleriei*, a high RA-containing species is used in China for treatment of dysentery, boils, and injuries (7). The antioxidative, antimicrobial, and antiviral effects of *Prunella vulgaris* indicate its potential as a medicinal herb (8). Rosmarinic acid-containing *Origanum vulgare* (oregano), *Thymus vulgaris* (thyme), *Ocimum basilicum* (sweet basil), and *Rosmarinus officinalis* (rosemary) are important sources of antioxidants in food preservation (9–11) and for stability and enhancement of anthocyanin and related pigment color in berry based juices (12,13) and have potential health benefits as dietary amylase inhibitor in diabetes management (14).

Many pharmacological effects of RA are known. Rosmarinic acid inhibits several complement dependent inflammatory processes and has potential as a therapeutic agent for control of complement activation diseases (15,16). Rosmarinic acid has been reported to have effects on both the classical C3-convertase and on the cobra venom factor and ovalbumin/antiovalbumin mediated passive cutaneous anaphylaxis (15). Rosmarinic acid also inhibits prostacyclin synthesis induced by complement activation (17,18). Rosmarinic acid is also known to have complement independent effects, such as scavenging of oxygen free radicals and inhibiting elastase and is known to be safe (19). Other actions of RA are antithyrotropic activity in tests with human thyroid

membrane preparations, inhibition of complement dependent components of endotoxin shock in rabbits, and the ability to react rapidly to viral coat proteins and so inactivate the virus (15). Rosmarinic acid also inhibits Forskolin induced activation of adenylate cyclase in cultured rat thyroid cells (20) and inhibits external oxidative effects of human polymorphonuclear granulocytes (21).

Recent research has indicated other benefits of RA containing *Perilla frutescens* on the reduction of lipopolysaccharide (LPS) induced liver injury in D-galactosamine sensitized mice (22). High RA *P. frutescens* also inhibited lung injury in mice induced by diesel exhaust particles (23) and also had antiallergic effect (24). The antiallergic titer of rosmarinic acid was more effective than tranilast, which is a widely used antiallergic drug (24). Rosmarinic acid also has potential antidepressive-like effect in mice based on a forced swimming test (25). Another interesting study has shown that RA inhibits calcium dependent pathways of T-cell antigen receptor mediated signaling (26). However, investigations so far on pharmacological effects of RA have not clarified the antiinflammatory effects but more evidence suggests RA's ability to block complement activation (27) and to inhibit cyclooxygenase (4).

Research findings on pharmacological potential of RA have substantially increased since 2000. RA synergistically inhibited LDL oxidation in combination with lycopene indicating its potential against atherosclerosis (28). In relation to HIV type 1, RA in addition to being an integrase inhibitor also inhibited reverse transcriptase (29,30). In mice studies, *Perilla frutescens* rich in RA reduced allergenic reactions using mice ear passive cutaneous anaphylaxis (PCA) reaction (24,31). In another mice model, RA in *Perilla* extract inhibited allergic inflammation induced by mite allergen (32). In a human clinical study related to allergy reduction, RA enriched *Perilla frutescens* proved to be an effective intervention for mild seasonal allergic rhino-conjunctivitis (SAR), partly through inhibition of polymorphonuclear leukocytes (PMNL) infiltration into the nostrils, which could contribute to reduction in treatment costs for allergic diseases (33). In mice studies, oral and intraperitoneal administration of RA had antidepressive effects and mechanism was suggested to not involve inhibition of monoamine transporters and monoamine oxidase (25,34). In relation to improvement of kidney related functions, RA has shown suppressive effects on mesangioproliferative glomerulonephritis in rats (35). Inhibitory effect of RA on the proliferation of cultured murine mesangial cells was previously reported (36). In this study, RA inhibited cytokine induced mesangial cell proliferation and suppressed PDGF and c-myc mRNA expression in PDGF mediated mesangial cells (36). Suppressive effects of RA enriched *Perilla frutescens* on IgA nephropathy in HIGA mice were also observed (37). In other pharmacological studies, RA reduced the defensive freezing behavior of mice exposed to conditioned fear stress (38). In relation to signal transduction, RA inhibited Ca2+ dependent pathways of T-cell antigen receptor mediated signaling by inhibiting the PLC-gamma 1 and Itk activity (26). RA is also known to inhibit TCR induced T cell activation and proliferation in an Lck dependent manner (39–41) and can also influence Lck dependent apoptotic activity (42). In other T cell studies, RA alone and in conjunction with currently used immunosuppressive drugs, inhibited *in vitro* splenic T-cell proliferation (43). RA enriched herb extract was also shown to have beneficial effects on suppression of collagen induced arthritis (44) and showed significant reduction in tumorigenesis in a murine two stage skin carcinogenesis model (45). Herbal extracts enriched in RA yielded higher inhibition of amylase than purified RA, suggesting RA in synergy with other phenolic compounds may contribute to amylase inhibition for potential modulation of hyperglycemia (14). Recently it was shown that oregano clonal extracts high in RA also have antimicrobial activity against *Listeria monocytogenes* (46) and *Helicobacter pylori* (47).

11.3 RA BIOSYNTHESIS IN CELL CULTURES

Rosmarinic acid has been targeted for production using undifferentiated cell suspension cultures in several species (6,48–56). Further, elicitors such as yeast extract and methyl jasmonate were used to stimulate RA content in cell cultures (6,51,57,58). The biosynthesis of RA were also evaluated and stimulated in hairy root cultures by elicitors (59). The main purpose of cell suspension cultures for production of RA is the potential for large scale production in bioreactors (60,61). Although large scale production in bioreactors is feasible for RA (62), undifferentiated cell suspension cultures are generally not practical for metabolites produced in differentiated structures (e.g., anethole in seeds of anise, curcumin in rhizomes of turmeric, eugenol in barks of cinnamon, and thymol in glandular cells of leaves). In a comparison of nodal shoot cultures and callus cultures of *Ocimum basilicum* L in airlift bioreactors, RA production in cell suspension cultures was 29 μg/g dry weight compared to 178 μg/g dry weight for shoot cultures (63). An additional disadvantage of undifferentiated callus based suspension cultures is that the DNA is more error prone and therefore more genetically unstable (64). Further, bioreactor based production requires high initial operating costs.

In terms of regulation of RA in cell cultures it is constitutively expressed in *Coleus blumei* without any medium manipulation (65). Plant cell cultures are known to accumulate 8–10% of their dry weight as RA, a content much higher than parent plants (53,66), contradicting the callus and shoot culture comparisons of the *Ocimum* study (63). The pathway of RA biosynthesis is through the aromatic amino acids, phenylalanine, and tyrosine (65). Cell suspension cultures of *C. blumei* (66), *Rosmarinus officinalis*, *Salvia officinalis* (67), and *Anchusa officinalis* (68,69) have been used to produce RA in cell suspension cultures. The influence of various macronutrients and growth regulators on growth of *A. officinalis* has been investigated (68,69). Concentrations of 3% sucrose, 15 mM nitrate, 3 mM phosphate, and 0.25 mM calcium were best for increasing both biomass and RA contents with yields in the range of 10–15% (68). Similar nitrogen, potassium, and phosphate optimizations proved useful for RA enhancement in *Lavandula vera* MM cell suspension cultures (70). When auxin effects were tested, they maintained growth and integrity of the cell suspensions, whereas cytokinins alone did not, suggesting that the culture of *A. officinalis* was auxin dependent (69). Among auxins, NAA had the most pronounced effect on RA content (69) and was confirmed in other recent studies where NAA at levels of 2 mg/l induced maximum RA level of 355 mg/l in cultures of *Zataria multiflora* (71). The kinetics of growth and RA production suggested that the increase in the final RA content and initiation of the period of biosynthesis was in the exponential, rather than the linear growth phase (69). Other studies have shown that increased sucrose concentrations stimulate RA content (72). The highest RA content reported so far was 36% of the cell dry weight in suspension cultures of *Salvia officinalis* at 5% sucrose (49), which is unusually high and never been reproduced.

11.3.1 Pathways Associated with Rosmarinic Acid Biosynthesis

The amino acids phenylalanine and tyrosine have been shown to be precursors of RA biosynthesis (52,73–75). Phenylalanine is transformed to an activated hydroxycinnamic acid by the enzymes of the general phenylpropanoid pathway, which are already well known for biosynthesis of flavonoid or lignin (75). Using radioactive phenylalanine and tyrosine, it was established that these two amino acids are incorporated into caffeic acid and 3,4-dihydroxyphenyllactic acid moieties, respectively (73). Steps in RA biosynthesis originating from phenylalanine and tyrosine have been characterized (Figure 11.2)

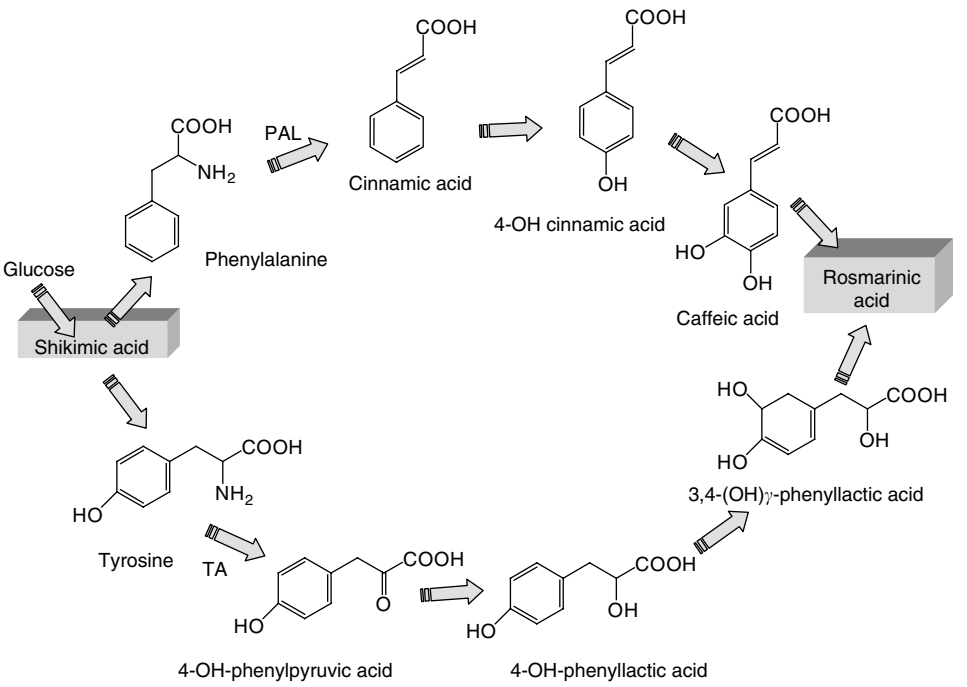

Figure 11.2 Rosmarinic acid biosynthesis from shikimic acid through tyrosine and phenylalanine

(6,52,65,76,77). In several cell suspension cultures, activity of phenylalanine ammonia-lyase (PAL) was correlated to RA (6,77). Basic characteristics of this enzyme were determined in protein preparations from suspension cell suspension cultures of *Coleus blumei* (78). The reaction, following formation of cinnamic acid, is the hydroxylation in the position 4 to 4-coumaric acid by cytochrome P450 monooxygenase cinnamate 4-hydroxylase (74). Generally, coenzyme A thioester, or glucose or chlorogenic acid have been shown to serve as donors of hydroxycinnamic acid moieties (75). Further, using *A. officinalis* cell suspension cultures, it was reported tyrosine amino transferase catalyzes the first step of the transformation of tyrosine to 3,4-dihydroxyphenyllactic acid. Several isoforms of tyrosine aminotransferase were found to be active in cell suspension cultures of *A. officinalis* (76,77). Prephenate aminotransferase in *A. officinalis* cell suspension cultures was found to be important, and its activity was affected by 3,4-dihydroxyphenyllactic acid (79). Other enzymes of late steps in the RA biosynthesis pathway, like hydroxyphenylpyruvate reductase and RA synthase (hydroxycinnamoyl-CoA, hydroxyphenyllactate, hydroxycinnamoyl transferase), were isolated and characterized in cell suspension cultures of *C. blumei* (80–82). Under the release of coenzyme A, the ester linkage is formed between carboxyl group of 4-coumaric acid and the aliphatic hydroxyl group of 4-coumaric acid and the aliphatic hydroxyl group of 4-hydroxyphenyllactate (75). Other studies have isolated microsomal hydroxylase, later confirmed as cytochrome P450 monooxygenases (74,83), whose activities introduce hydroxyl groups at position 3 and 3′-hydroxyphenyllactate to give rise to the aromatic rings of ester 4-coumaroyl-4′-hydroxyphenyllactate to give rise to RA (52). A number of cDNAs encoding cytochrome P450s, which can hydroxylate 4-coumaric acid or 4-coumaroyl moiety in an ester, have been isolated (84–86). This enzyme isolation led to the proposal that the complete biosynthetic pathway for RA biosynthesis originates from phenylalanine and tyrosine (52,75).

11.3.2 RA Biosynthesis and Generation of High RA Clonal Lines

High RA production can be achieved at low cost by incorporating superior varieties in traditional agronomic systems. Superior varieties can be isolated using tissue culture techniques using shoot based clonal lines of single seed origin (1). The major limitation of using dietary herbs for pharmacological applications from traditional wild collections and heterogeneous seeds is the inconsistency of phenolic phytochemicals such as RA due to the heterogeneity resulting from the cross pollinating nature of their breeding characteristics, and especially species in the family Lamiaceae (1). Plants which originate from different heterozygous seeds in a given pool of extract are phenotypically variable, resulting in the substantial phytochemical inconsistency, and therefore leads to unreliable clinical effects as well as inconsistent health benefits and functional value. In order to overcome the problem of phytochemical inconsistency due to genetic heterogeneity, plant tissue culture techniques have been developed to isolate a clonal pool of plants originating from a single heterozygous seed (87,88). A single elite clonal line with superior RA and phenolic profile can then be screened and selected based on tolerance to *Pseudomonas* sp. (89–91) and proline analogs (92–94). These elite clonal lines (each clonal line originating from a different heterozygous seed), following large scale clonal propagation (micropropagation) and evaluation of functionality, can be targeted as dietary sources of phenolics (with focus on RA compared in diverse total phenolic clonal backgrounds) for diverse food and pharmaceutical applications.

11.3.3 Role of Proline Linked Pentose–Phosphate Pathway in RA Biosynthesis in Clonal Systems

The hypothesis that synthesis of plant phenolic metabolites is linked to the critical control point (CCP), proline linked pentose–phosphate pathway (PLPPP) (1,95,96) (Figure 11.3) was developed based on the role of the PLPPP in regulation of purine metabolism in mammalian systems (97). Proline is synthesized by a series of reduction reactions from glutamate. In this sequence, P5C and proline known to be metabolic regulators function as a redox couple (97,98). During respiration, oxidation reactions produce hydride ions, which augment reduction of P5C to proline in the cytosol. Proline can then enter mitochondria through proline dehydrogenase (99) and support oxidative phosphorylation (alternative to NADH from Krebs/TCA cycle). This is important because shunting the TCA cycle toward proline synthesis likely deregulates normal NADH synthesis. The reduction of P5C in the cytosol provides $NADP^+$, which is the cofactor for glucose-6-phosphate dehydrogenase (G6PDH), an enzyme that catalyzes the rate-limiting step of the pentose–phosphate pathway. Proline synthesis is therefore hypothesized, and has been partly shown to both regulate and stimulate pentose–phosphate pathway activity in erythrocytes (100) and cultured fibroblasts (101) when P5C is converted to proline. This was shown to stimulate purine metabolism via ribose-5-phosphate, which affects cellular physiology and therefore function (97,102). Therefore, understanding the CCP, PLPPP is important for designing high RA clonal extracts isolated from single seed genetic origin among a heterogeneous seed population.

From the above insights Shetty (1,95,96) first proposed a model that CCP, PLPPP could stimulate shikimate and phenylpropanoid pathways and hypothesized that stress linked modulation of this pathway can lead to the stimulation of phenolic phytochemicals, including RA (1,95,96) (Figure 11.3). Using this model, proline, proline precursors, and proline analogs were effectively utilized to stimulate total phenolic content and RA in clonal shoot cultures (103,104). Further, it was shown that proline, proline precursors, and proline analogs stimulated somatic embryogenesis in anise, which correlated with increased soluble phenolic content (105). It was also established that during *Pseudomonas* mediated stimulation of total soluble phenolics, RA and proline content was stimulated in

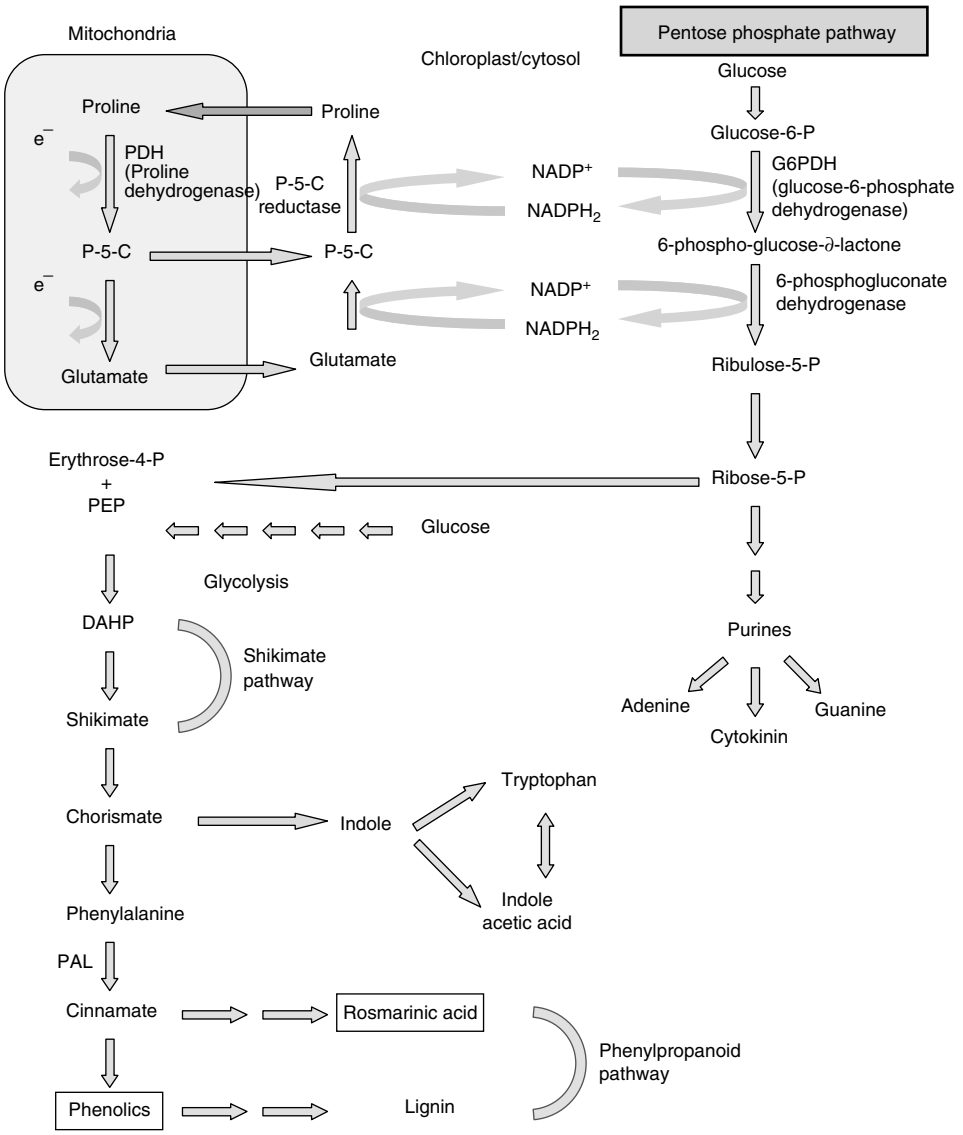

Figure 11.3 Model for RA biosynthesis through the proline linked pentose–phosphate pathway and its utilization to screen high RA and phenolic-producing clonal lines using microbial interaction and proline analogs (targeted at proline dehydrogenase-PDH)

oregano clonal shoot cultures (106). Therefore, it was proposed that $NADPH_2$ demand for proline synthesis during response to microbial interaction and proline analog treatment (1) may reduce the cytosolic $NADPH_2$/ $NADP^+$ ratio, which should activate G6PDH (107,108). Therefore, deregulation of the pentose–phosphate pathway by proline analog and microbial induced proline synthesis may provide the excess erythrose-4-phosphate (E4P) for shikimate and, therefore, the phenylpropanoid pathway leading to RA (95). At the same time, proline and P5C could serve as superior reducing equivalents (RE) reductant, an alternative to NADH (from Krebs/TCA cycle) to support increased oxidative phosphorylation (ATP synthesis) in the mitochondria during the stress response (97,98).

Therefore, proline analog, azetidine-2-carboxylate (A2C), and proline stimulating *Pseudomonas* interactions were used to isolate high RA clonal lines (1,92–95). A2C is an inhibitor of proline dehydrogenase (109) and is also known to inhibit differentiation in Leydig cells of rat fetal testis, which can be overcome by exogenous proline addition (110). Another analog, hydroxyproline, is a competitive inhibitor of proline for incorporation into proteins. According to the model of Shetty (1,96), either analog at low levels should deregulate proline synthesis from feedback inhibition, and stimulate proline synthesis (1). This would then allow the proline linked pentose–phosphate pathway to be activated for $NADPH_2$ synthesis, and concomitantly drive metabolic flux toward E4P for biosynthesis of shikimate and phenylpropanoid metabolites, including RA (Figure 11.4). Proline could also serve as a RE reductant for ATP synthesis via mitochondrial membrane associated proline dehydrogenase (99). Therefore, any high RA clonal line with a deregulated proline synthesis pathway should have an overexpressed pentose phosphate pathway which allows excess metabolic flux to drive shikimate and phenylpropanoid pathway toward total phenolic and RA synthesis. Similarly, such proline overexpressing clonal lines should be more tolerant to proline analog, A-2-C (95,96). At the same time if the metabolic flux to RA is overexpressed, it is likely to be stimulated in response to *Pseudomonas* sp (95). Therefore, such a clonal line is equally likely to be tolerant to *Pseudomonas* sp. Further, such a clonal line should also exhibit high proline oxidation and RA content in response to A2C and *Pseudomonas* sp. In addition, in the presence of A2C or *Pseudomonas* sp., increased activity of key enzymes G6PDH (pentose–phosphate pathway), P5C reductase (proline synthesis pathway), proline dehydrogenase (proline oxidation pathway), 3-deoxy-D arabino-heptulosonate-7-phosphate synthase (shikimate pathway), and phenylalanine ammonia-lyase (phenylpropanoid pathway) should be stimulated (96). As mentioned earlier, the rationale for the PLPPP model for RA biosynthesis is based on the role of the pentose–phosphate pathway in driving ribose-5-phosphate toward purine metabolism in cancer cells (97), differentiating animal tissues (110), and plant tissues (111). The success of this CCP, PLPPP strategy (89–94) provides ready access to critical interlinking metabolic pathways associated with RA biosynthesis and will allow more detailed analyses, which could lead to large scale greenhouse and Agronomic based field production systems for efficient RA biosynthesis. This strategy for investigation and production of RA can be the foundation for designing other dietary phenolic phytochemicals from cross pollinating, heterogeneous species (1,95,96).

11.4 MECHANISM OF RA ACTION THROUGH STIMULATION OF HOST ANTIOXIDANT RESPONSE

Investigations so far in food grade clonal herb systems (1) and legume sprouts (112–114) led to the development of the model that activity of CCP, proline linked pentose–phosphate pathway is important for stress induced phenolic biosynthesis such as RA and phenolics and that this stimulation of phenolics is likely closely linked to stimulation of antioxidant response pathways (Figure 11.4) (96,112–114). Further research has indicated that the proline biosynthesis pathway coupled to stress induced antioxidant response pathways could be also stimulated in legume sprouts using exogenous treatment of phenolic extracts from clonal oregano (113,115,116). Phenolic extracts from these clonal oregano lines have high free radical scavenging activity (47). Proline linked stimulation of antioxidant enzyme response pathways may also be stimulated by low pH and salicylic acid (117). Further, exogenous seed treatment with oregano phenolic antioxidant extracts enhanced endogenous phenolic content, GPX activity, and consequently, enhanced seeding vigor during germination (116). From these initial plant studies and plant PLPPP model (Figure 11.4), a human/mammalian cell PLPPP model has been developed (Figure 11.6) wherein a proton donation by phenolic antioxidants

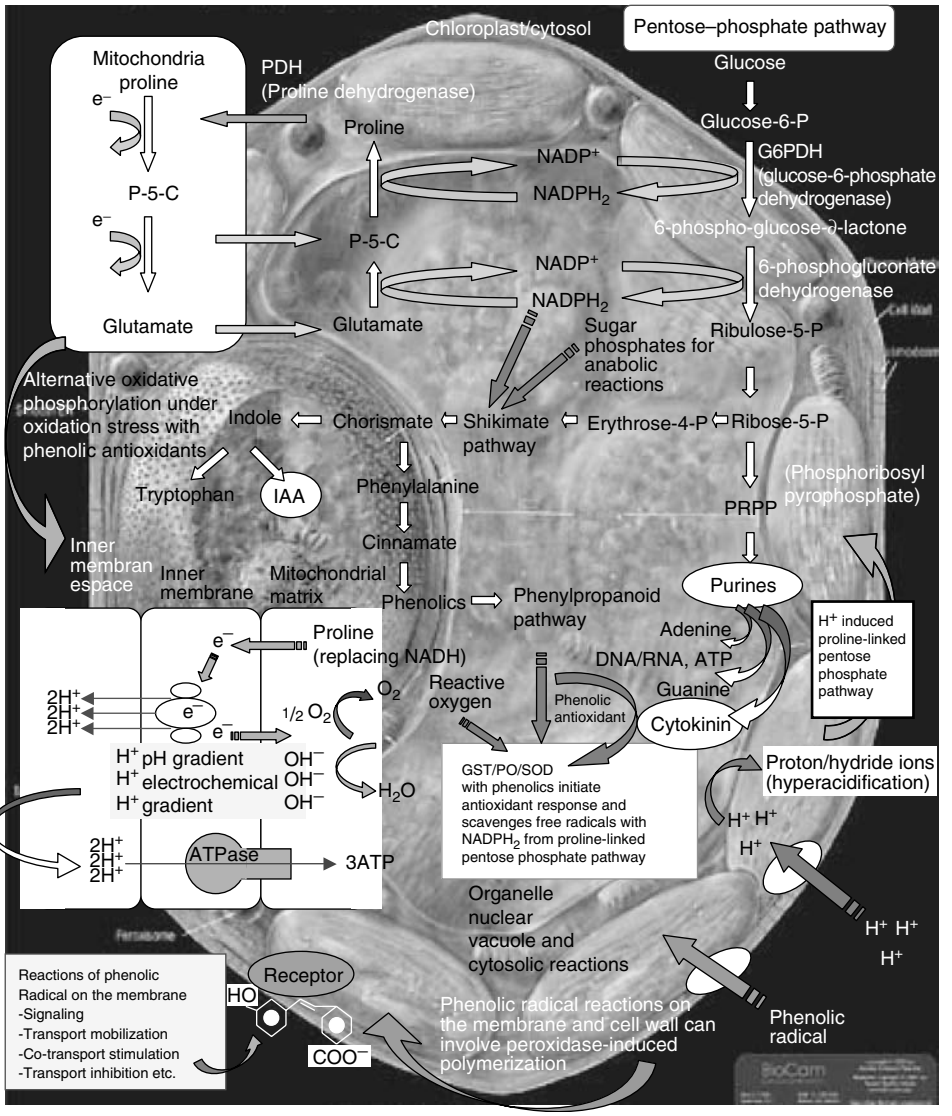

Figure 11.4 Expanded Model for the role of proline linked pentose–phosphate pathway in regulating phenolic biosynthesis, which also accommodates the mechanism of action of external phenolic phytochemicals such as RA from herbal extracts to trigger an endogenous antioxidant enzyme response. (Abbreviations: P5C: pyrroline-5-carboxylate; IAA: indole acetic acid; GST: Glutathione-s-transferase; PO: peroxidase; SOD: superoxide dismutase)

such as RA at the outer plasma membrane initiates a proton/hydride ion influx into the cytosol which activates an antioxidant response through the stimulation of the, CCP, proline linked pentose–phosphate pathway (95,96). Demand for $NADPH_2$ by stimulated proline biosynthesis also drives the production of precursors for phenolic (only in plants and fungi), purine and antioxidant pathways. In this host response PLPPP model, proline can also be used as a reducing equivalent (RE) reductant to support oxidative phosphorylation for ATP synthesis. Using this approach and rationale, we first developed several RA and phenolic overexpressing plant clonal systems for functional food and agro-environmental applications. Subsequently, PLPPP linked and optimized phenolic phytochemical clonal profiles can be

used as sources of antioxidants and antimicrobials in biological systems based on host PLPPP response and have implications for human health and wellness.

Human health applications have been developed with additional insights based on the animal antioxidant response model (Figure 11.7) and the plant antioxidant response model (Figure 11.5). From these insights an innovative model for the mechanism of

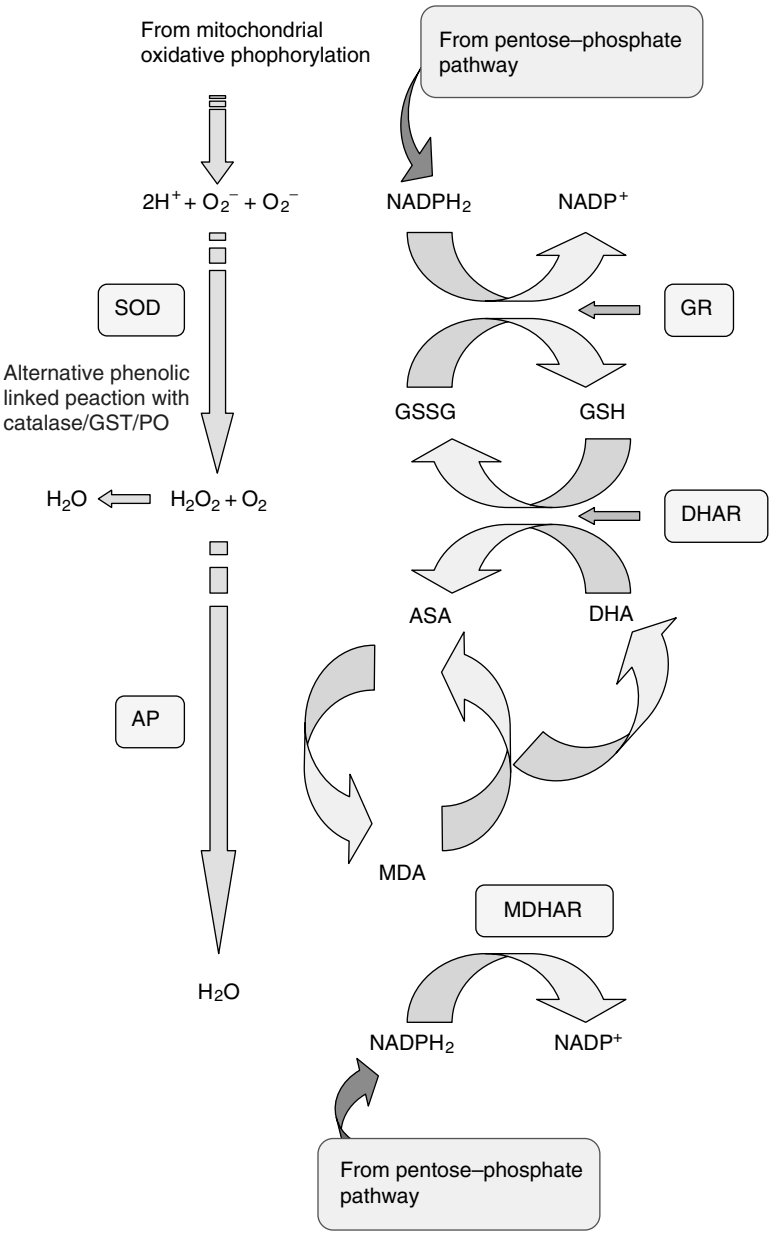

Figure 11.5 Model for specific steps in antioxidant enzyme response pathway in plants. Figure 11.6 Extension of plant proline linked pentose–phosphate pathway model for the effect of external phenolic phytochemicals in human and mammalian systems. (Abbreviations: P5C: pyrroline-5-carboxylate; GST: Glutathione-s-transferase; SOD: superoxide dismutase)

action of phenolic antioxidants like RA for improving human health through protection against oxidation linked diseases involving the host proline linked pentose–phosphate pathway has been proposed (Figure 11.6). The major diseases afflicting humans today, related to excess calories, obesity, and environmental pollutant exposure, are oxidation linked chronic diseases such as cancer, cardiovascular disease, arthritis, cognition diseases, and diabetes. Oxidation linked immune dysfunction and the inability to fight pathogenic infection under a very low calorie and protein diet still remains a problem in several parts of the world and the challenge has to be addressed. Oxidation linked and infectious diseases involve free radical reactions. Free radicals are potential

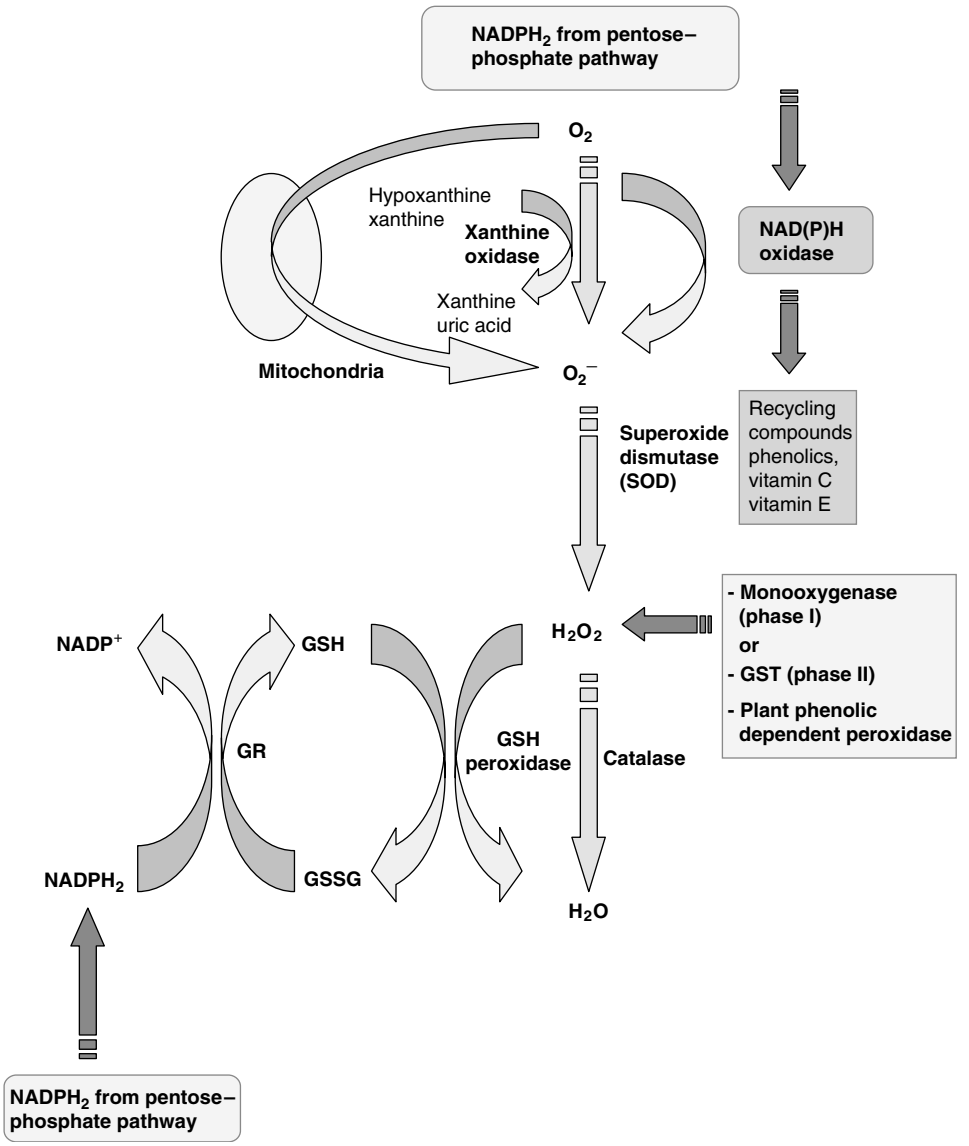

Figure 11.7 Model for specific steps in antioxidant response pathways in human and mammalian systems. (Abbreviations: SOD: superoxide dismutase; GST: glutathione-s-transferase; GR: glutathione reductase; PO: peroxidase; GP: glutathione peroxidase; GSSG: oxidized glutathione; GSH: reduced glutathione)

carcinogens because they can facilitate mutagenesis, tumor promotion and progression (118–120). For example, in the case of cardiovascular diseases, free radicals are implicated in the pathogenesis of atherosclerosis, which is characterized by the hardening of the arterial wall (118,121,122). Rheumatoid arthritis is a systemic autoimmune disease characterized by chronic joint inflammation with infiltration of macrophages and activated T cells. Production of free radicals at sites of inflammation is thought to contribute to the pathogenesis (118,123,124). Free radicals are implicated in the pathogenesis of Alzheimer disease (118,125). As significant amounts of lipid peroxidation in brain

tissues have been observed and may help explain the progressive decline in cognition function and excessive neuronal loss in afflicted patients. The brain tissue shows numerous amyloid plaques. Free radicals have been implicated in diabetes mellitus (118,126,127). These oxidative stress linked disease conditions are associated with a prooxidative shift of glutathione redox state in the blood (118,128). Elevated glucose levels are also associated with increased production of free radicals by several different mechanisms (118,129,130).

Diet, environment, and lifestyle influence oxidation linked diseases and improvement of diet is an important part of the preventive management of these diseases (95,96). It is evident that a variety of plant based phenolic antioxidants have a positive impact on the prevention and modulation of various oxidation linked diseases (16,131–135) and must be considered important part of the dietary management of these diseases. Currently the modes of action and early stage effects of these phenolic antioxidants in positively modulating and preventing various diseases are not completely clear (95,96). Extensive research is underway to ascertain how free radicals modulate physiological control of cell function at the level of cell proliferation and deterioration (118) and at the level of gene expression (136). Phenolic antioxidants such as RA have been targeted to control the free radical linked cellular deterioration that can otherwise lead to major oxidation linked chronic diseases. We have proposed in this chapter that an understanding of RA biosynthesis through CCP and PLPPP could help to not only design the right RA profile through functional foods, but the host response to this RA profile could also operate effectively through an antioxidant enzyme response regulated by host (human) PLPPP.

Therefore, an important strategy to develop diet based interventions is through design of functional foods (conventional foods with clinically defined health promoting components) based on the understanding of phenolic antioxidant biosynthesis, such as RA in food plants (Figure 11.4) and the effect of RA in human and mammalian systems (Figure 11.6). In order for diet based interventions (through functional foods) to be effective, it is also important to understand the early stage modes of action of these functional compounds such as RA and how to deliver RA at consistent levels and with no toxicity problems. In the antioxidant enzyme response model for human health, proposed previously (95,96), a consistent and defined phytochemical profile of RA and in high phenolic background can be developed using clonal shoot systems using various dietary botanicals from the family Lamiaceae. In the human model (Figure 11.6), the early stage mode of action of RA in human cells has parallels to the models for plant systems (Figure 11.4), but within the scope of human cellular physiology, function, and diversity (95). By this model, plant extract enriched RA similarly initiate an inward proton flux at the outer human cell membrane, which increases the cytosolic proton/hydride ion concentration and activates the PLPPP. Some phenolic antioxidant radicals in the total phenolic background or hydrolyzed RA, depending on their size, may penetrate the plasma membrane along with the proton/hydride ion flux (cotransport) into the cytosol. The cytosolic proton/hydride ion flux then drives PLPPP generating $NADPH_2$, sugar phosphates for anabolic reactions and proline as an alternative RE reductant to generate ATP via oxidative pentose–phosphate pathway (95,96). The products of the pentose–phosphate pathway are important for purine biosynthesis and for stimulating antioxidant enzyme response pathways in conjunction with action of the dietary phenolic antioxidants (Figure 11.6). The control of free radicals that is likely associated with proline or TCA cycle generated NADH linked mitochondrial oxidative phosphorylation at this early stage could have a positive effect on any subsequent oxidation linked cellular deterioration and consequent oxidation linked chronic disease

development. Other roles for RA or RA hydrolyzed phenolic radicals that penetrate the membrane could involve:

1. Stability and protection of organelle membranes and proteins from free radical damage
2. Participation in the antioxidant response pathway to quench super oxide and peroxide radicals
3. Protection of DNA and protein stability
4. Stimulation of proline linked pentose–phosphate pathway activity to satisfy demand for $NADPH_2$ in reactions involving penetrating phenolic radicals (95,96)

In specific cases where RA or phenolic radicals cannot normally penetrate the outer plasma membrane, other conceivable roles could include:

1. Stability and protection of the outer membranes and membrane proteins from free radical damage
2. Modulation of membrane transport
3. Inhibition of specific membrane proteins, including those involved in PMF and electron transport chain in Prokaryotes
4. Modulation of signal transduction
5. Modulation of membrane receptors
6. Co-transport with H^+, sugars or amino acids
7. Passive membrane transport through damaged membranes

An inward proton flux to the cytosol could be created even without phenolic radical penetration, which then could stimulate the proline linked pentose–phosphate pathway and couple its action to the various reactions and roles that may be initiated and modulated through interactions of phenolic radicals at the outer plasma membrane (95,96).

11.5 SUMMARY

It is clear that RA containing herb extracts have wide potential applications for functional food and pharmacological applications. In optimizing RA biosynthesis for such applications the potential role of microbial elicitation and proline linked pentose–phosphate pathway (PLPPP) has been exploited to develop clonal tissue culture systems of single seed genetic origin that can be grown in traditional and efficient greenhouse and agronomic systems. Such clonal systems allow the screening of phenotypic specific RA enriched herbal herbs extracts that offer potential for consistency for various applications and design of health specific functional foods. Further, using clues about the role of proline linked pentose–phosphate pathway as a CCP in relation to RA biosynthesis in herb clonal systems (Figure 11.4), a model has been developed for the mode of action of RA in mammalian and human systems (95,96) (Figure 11.6). In this model for animal systems, RA has been hypothesized to stimulate host antioxidant enzyme response and enhance free radical scavenging to counter oxidation pressure. Efficient operation of this free radical scavenging system requires the proper functioning of pentose phosphate pathway. Further, pentose phosphate pathway could be optimally stimulated by coupling it to proline biosynthesis. This coupled proline linked pentose–phosphate pathway in normal human cells

could be stimulated by RA enriched herb extracts, thereby providing critical precursors like $NADPH_2$ for antioxidant enzyme response and therefore serving as a critical control point (CCP). Through this antioxidant response regulation and other specific RA related structure and function activity at the cellular gene and signal pathway levels, protective chemopreventive functions of RA can be potentially enhanced.

Bioprocessing Strategies to Enhance L-DOPA and Phenolic Antioxidants in the Fava Bean *(Vicia faba)*

Kalidas Shetty, Reena Randhir, and Preethi Shetty

CONTENTS

12.1 INTRODUCTION AND ROLE OF PHENOLIC SECONDARY METABOLITES

In plants, primary products such as carbohydrates, lipids, proteins, photosynthetic components, and nucleic acids are common to all; they are involved in the primary metabolic processes of building and maintaining cells. In contrast, secondary metabolites do not appear to have such a vital biochemical role, but studies have indicated a role of these chemicals in defense and stress response of plants. Some of the most abundant stress

induced secondary metabolites synthesized by plants are phenolics and their derivatives. Phenolic compounds include a large array of chemical compounds possessing an aromatic ring bearing one or more hydroxyl groups, together with a number of other side groups. Plant phenolics are a chemically heterogeneous group (1–3). These phenolics usually occur in conjugated or esterified form as glycosides (1,2,4). The diverse arrays of plant phenolics have many roles in plant growth and development. Therefore, emergence of dietary and medicinal applications for phenolic phytochemicals, harnessing especially their antioxidant and antimicrobial properties, for the benefit of human health and wellness is not altogether surprising. As stress damage at the cellular level appears similar among eukrayotes, it is logical to suspect that there may be similarities in the mechanism for cellular stress mediation between eukaryotic species. Plant adaptation to biotic and abiotic stress involves the stimulation of protective secondary metabolite pathways (5–7), resulting in the biosynthesis of phenolic antioxidants. Studies indicate that plants exposed to ozone responded with increased transcript levels of enzymes in the phenylpropanoid and lignin pathways (8). Increase in plant thermotolerance is related to the accumulation of phenolic metabolites and heat shock proteins that act as chaperones during hyperthermia (9). Phenolics and specific phenolic like salicyclic acid levels increase in response to infection, acting as defense compounds or serving as precursors for the synthesis of lignin, suberin, and other polyphenolic barriers (10). Antimicrobial phenolics, called phytoalexins, are synthesized around the site of infection during pathogen attack and, along with other simple phenolic metabolites, are believed to be part of a signaling process that results in systemic acquired resistance (5–7). Many phenylpropanoid compounds such as flavonoids, isoflavonoids, anthocyanins, simple phenolics, and polyphenols are induced in response to wounding (11), nutritional stress (12), cold stress (13), and high visible light (14). Ultraviolete (UV) irradiation induces light-absorbing flavonoids and sinapate esters in *Arabidopsis* to block radiation and protect DeoxyriboNucleic Acid (DNA) from dimerization and cleavage (15). In general, the initiation of the stress response arises from certain changes in the intracellular medium (16) that transmits the stress induced signal to cellular modulating systems, resulting in changes in cytosolic calcium levels, proton potential as a long distance signal (17), and low molecular weight proteins (18). Stress can also initiate free radical generating processes and shift the cellular equilibrium toward lipid peroxidation (19). It is believed that the shift in prooxidant antioxidant equilibrium is a primary nonspecific event in the development of the general stress response (20). Therefore, phenolic compounds are ubiquitous and have important roles in all vascular plants, and as a result are integral part of the human diet (21–23). These phenolic secondary metabolites that are synthesized through the shikimic acid pathway vary from simple phenolics such as the hydroxy benzoic acids and levodopa (L-DOPA) to biphenyls such as resveratrol and rosmarinic acid to large condensed tannins and hydrolysable tannins with high molecular weights (23,24). The polymers formed from plant phenolics in the cell wall provide structural support and form barriers to prevent moisture loss diffusion and pathogen encroachment. The phenolics also function in defense mechanisms with UV protectant, antifungal, antibacterial, antifeedant, and antimitotic properties, and in morphogenesis (25,26). When exposed to air, most phenolics readily undergo oxidation to colored quinone containing products. This response is frequently observed as a browning reaction of plant tissues as a part of a healing response. The oxidation of these compounds by polyphenoloxidase (PPO) has been suggested to be the main cause of apple browning (27). Therefore, protective phenolic metabolites involved in such secondary metabolite linked stress responses in food plant species can be targeted as a source of therapeutic and disease-preventing functional ingredients, especially in oxidation disease linked diets (diets containing foods with a high glycemic index and saturated fats) and environmentally (physically, chemically, and biologically) influenced chronic disease problems (23).

12.2 PLANT PHENOLICS IN HUMAN HEALTH AND AS ANTIOXIDANTS

It is evident that plant phenolic compounds constitute one of the most numerous and widely distributed groups of substances with more than 8000 phenolic structures currently known (28). In addition to stress linked phenolics coming only from the shikimate and phenylpropanoid pathways, a number of the phenolic compounds are found in plants, including the flavonoids that contribute to the characteristic flavor and fragrance of vegetables, fruits, tea, and wine. These compounds, which come from phenylpropanoid and polyketide (acetate–malonate) pathways, also have biological properties that are beneficial to human health.. Flavonoids such as quercetin and catechin and isoflavonoids, genistein for example, are being investigated for properties which may reduce the incidence of cancer(22,23). Flavonoids and isoflavonoids are a class of phenolic compounds that have appeared sequentially during plant evolution and are simple aromatic compounds generated from both the phenypropanoid and acetate–malonate (polyketide) pathways (24). From a functional health point of view, it is suggested that such phenolics, for example, through the consumption of tea, may provide protection against certain cancers; soybeans may provide protection against breast cancer and osteoporosis (22). The Japanese and Chinese frequently used plants rich in polyphenol tannins in their folk medicines for the treatment of inflammation, liver injury, kidney ailments, hypertension, and ulcers. Oregano extracts have been shown to inhibit lipid peroxidation by their flavonoid fractions such as flavone apigenin, the flavanone, eriodictoyl, dihydrokaempferol, and dihydroquercetin (29). Rosmarinic acid-containing *Ocimum sanctum* (holy basil), derived from the phenylpropanoid pathway, is commonly used in India to reduce fevers and gastrointestinal disease (30). Essential oils from thyme (*Thyme vulgaris* L.) have phenolic linked antioxidant properties, which may result from the presence of free radical scavengers in these oils (31–33). These diverse phenolic compounds in thyme are unusually derived from phenylpropanoid, polyketide, and terpenoid pathways. Many other phenolic compounds have the ability to inhibit platelet aggregation, block calcium influx, and protect low density lipoproteins (LDL) from oxidation (34). L-DOPA from the fava bean, that is the focus of this chapter, has been evaluated in Parkinson's management (35–37); it is derived from L-tyrosine of the phenylpropanoid pathway (Figure 12.1).

Among many functional roles, the most important function assigned to phenolics is their antioxidant activity. Antioxidants may be defined as substances, which when present in low concentrations compared with those of an oxidizable substrate, such as proteins, carbohydrates, and fats, delay or prevent the oxidation of the substrate (38). Phenolic antioxidants from dietary plants can be useful to counter reactive oxygen species related to human diseases. Reactive oxygen species (ROS) are able to oxidize cellular components such as DNA, lipids, and proteins (23). Dysfunction of oxidative phosphorylation at the mitochondrion has been recognized as a major physiological source of ROS (39). Lipid peroxidation damages the structural integrity of the mitochondria, which can result in organelle swelling, resulting in increased permeability to cations, decreased membrane potential, and damage to electron transfer activities (40). This form of tissue damage can ultimately lead to some of the major diseases such as cancer, cardiovascular disease, immune dysfunction, diabetes, and neurodegeneration (23). To deal with ROS, the biological systems, including human cellular systems, have an effective defense system, which includes enzymes such as superoxide dismutase (SOD), catalase (CAT), high molecular weight antioxidants, and an array of low molecular weight antioxidants such as ascorbic acid, α-tocopherol, β-carotene, and glutathione (41). The endogenous antioxidant responses, both enzymatic and nonenzymatic could also be enhanced by dietary intake of

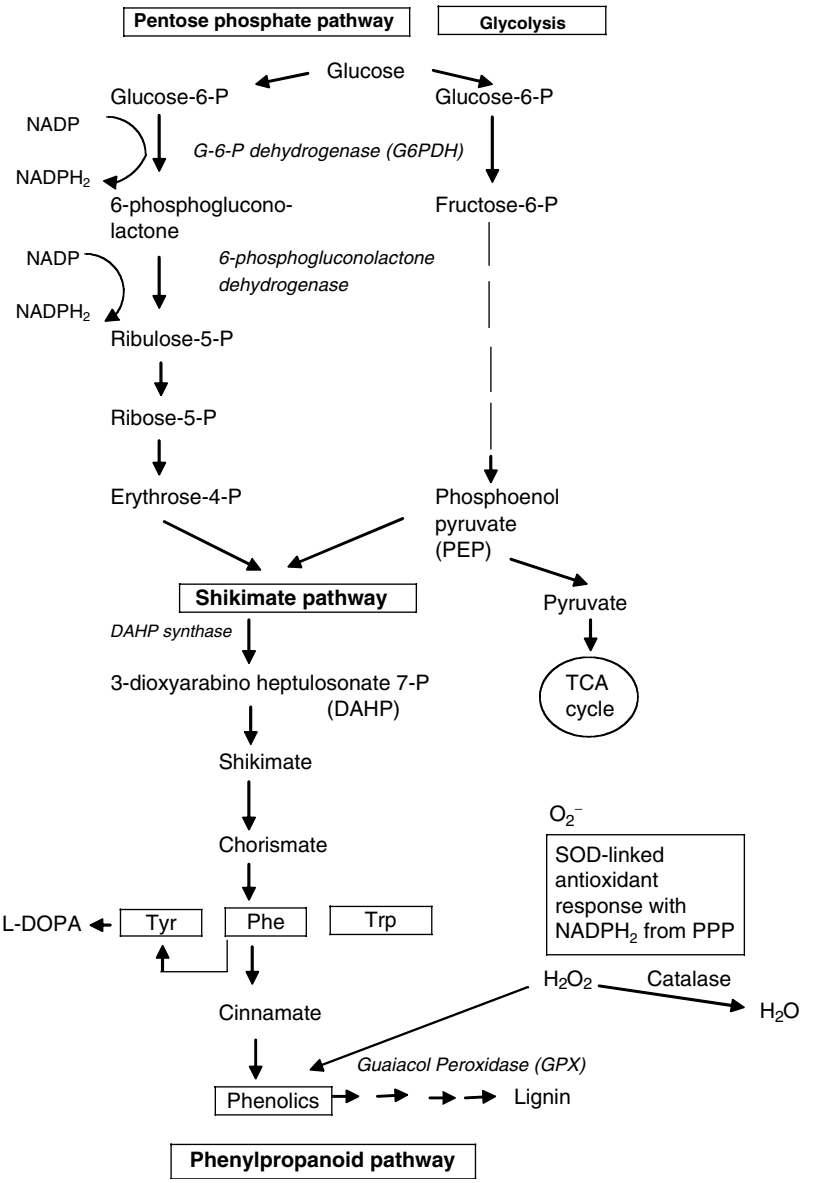

Figure 12.1 Pentose–phosphate pathway and L-DOPA biosynthesis in plants

phenolic antioxidants from plant foods (23,42). Therefore phenolic antioxidants, through design and use of functional foods, are receiving increasing interest from consumers and food manufacturers due to their synergistic roles as antioxidants, antimutagens, and scavengers of free radicals (23,43). They have the potential to function as antioxidants by trapping free radicals generated in the oxidative chemistry, which then normally undergo coupling reaction leading to polymeric or oligomeric products (43) or by enhancing host antioxidant enzyme response through a stimulation of antioxidant enzyme response through SOD, peroxidases, and CAT (23). Epidemiological studies have also suggested associations between the consumption of phenolic antioxidant rich foods or beverages and the prevention of diseases (44–49).

12.3 BIOSYNTHESIS OF PHENOLIC METABOLITES AND L-DOPA

Plant phenolics are synthesized using several different routes. This constitutes a heterogeneous group from a metabolic point of view. Two basic pathways are the shikimic acid pathway and the acetate–malonate (polyketide) pathway. The shikimic acid pathway represents the principal mode of accumulation of plant stress related phenolic compounds. The acetate–malonate pathway is also an important source of phenolic secondary products for biosynthesis of flavonoids and isoflavonoids that have many human disease protective chemoprevention properties.

The shikimic acid pathway requires substrates such as erythrose-4-phosphate (E4P) from the pentose phosphate pathway (PPP) and phosphoenol pyruvate (PEP) from glycolysis (Figure 12.1). The oxidative pentose phosphate pathway in plants is thought of as comprising two stages (50). The first is an essential irreversible conversion of glucose 6 phosphate (G6P) to ribulose-5-phosphate (Ril5P) by the enzymes glucose-6-phosphate dehydrogenase (G6PDH), 6-phosphogluconolactonase, and 6-phospho gluconolactonate dehydrogenase (6 PGDH). This oxidative stage provides reductant in the form of $NADPH_2$ for a wide range of anabolic pathways including the synthesis of fatty acids, the reduction of nitrite, and synthesis of glutamate (51,52). The second stage is the irreversible series of interconversions between phosphorylated carbon sugars. The function of this stage of the pathway is to provide a carbon skeleton for the shikimate pathway via erythrose-4-phosphate (E4P), nucleotide synthesis utilizing ribose-5-phosphate, as well as recycling of sugar phosphate intermediates for use in the glycolytic pathway (53).

The shikimate pathway is often referred to as the common aromatic biosynthetic pathway, even though in nature it does not synthesize all aromatic compounds by this route (54). The shikimic acid pathway converts the simple carbohydrate precursors to aromatic amino acids phenylalanine, tyrosine, and tryptophan. The flux from this pathway is critical for both auxin and phenylpropanoid synthesis (23,30). Auxins are plant hormones that regulate plant development (2). Up to 60% of the dry weight in some plant tissue consists of metabolites derived from the shikimate pathway. Activity of the distinct isoenzyme of 3-deoxy arabinose heptulosonate-7-phosphate (DAHP) synthase in the shikimate pathway is dependent on metabolite flux from E4P. This enzyme has been shown to be subject to feedback inhibition by L-phenylalanine, L-tyrosine, and L-tryptophan (54,55). Therefore, this enzyme controls the carbon flow into the shikimate pathway.

The most abundant class of secondary phenolic compounds in plants is derived from phenylalanine via the elimination of an ammonia molecule to form cinnamic acid. This reaction is catalyzed by phenylalanine ammonia lyase (PAL). This is the branch point between the primary (shikimate pathway) and the secondary (phenylpropanoid pathway) (6). Studies with several different species of plants have shown that the activity of PAL is increased by environmental factors such as low nutrient levels, light (through the effect of phytochrome), and fungal infection (11). Fungal invasion triggers the transcription of messenger RNA (mRNA) in the plant, which then stimulates the synthesis of phenolic compounds (6). Many phenylpropanoid compounds are induced in response to wounding or in response to microbial pathogens, insect pests, or herbivores. Anthocyanins increase in response to high visible light levels and it is thought that they attenuate the amount of light reaching the photosynthetic cells (6).

The product of PAL, *trans*-cinnamic acid, is converted to *para*-coumaric acid by the addition of a hydroxyl group on the aromatic ring in *para* position. Subsequent reactions lead to the addition of more hydroxyl groups and other substituents. These are simple phenolic compounds called phenylpropanoids because they contain a benzene ring and a

three carbon side chain. Phenylpropanoids are building blocks for more complex phenolic compounds (1,3).

As previously discussed, phenolic compounds have wide ranges of functions. The synthesized phenolics can be either antioxidant in nature or they may function in lignification of the plant cells. Depending on the requirements, the type of the phenolics synthesized and their complexity vary from species to species in different environmental niches. Flavonoids, tannins, caffeic acids, curcumin, gallic acids, eugenol, rosmarinic acid, and many more have antioxidant properties (56,57). These ranges of phenolics provide plants with defense mechanisms and act as scavengers of free radicals as described earlier. Other functions of phenolics include their ability to provide structural stability to the plants by lignins and lignans. These are complex phenolics are formed from the polymerization of simple phenols (58). Figure 12.2 illustrates the origins of varied phenolic compounds from simple phenols.

Lignin is a polymer of aromatic subunits usually derived from phenylalanine. It serves as a matrix around the polysaccharide components of some plant cell walls, providing additional rigidity and compressive strength, as well as rendering the walls hydrophobic for water impermeability (59,60). The final enzymatic steps of lignin biosynthesis, the production of mesomeric phenoxy radicals from cinnamoyl alcohol, is catalyzed by peroxidase and must occur outside the cell to allow these short lived radicals to polymerize *in situ* (61). Phenol polymerization is catalyzed by the peroxidase enzyme (62) and a specific enzyme, Guaiacol peroxidase (GPX), is suggested to be important in the metabolic interconversion of phenolic antioxidants. The same phenylpropanoid pathway also supports the synthesis of L-DOPA, which is a simple phenolic compound found in many seeded legumes such as fava beans and velvet beans with relevance for Parkinson's therapy (37,63–66). This pathway

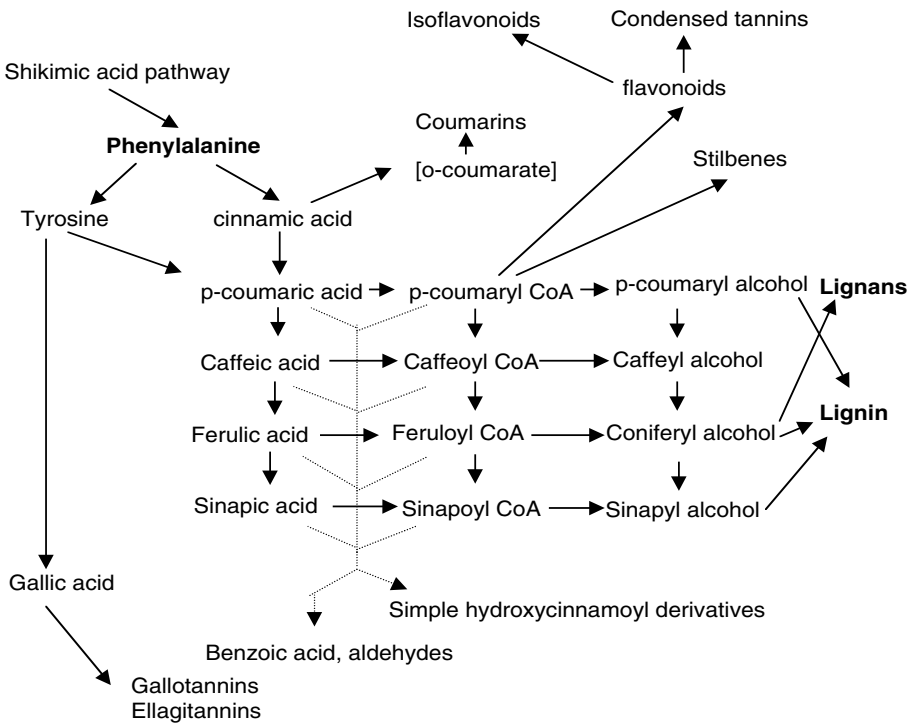

Figure 12.2 General phenolic flux through the phenylpropanoid pathway from the shikimic pathway

provides the precursor chorismate, which oxidizes to L-phenylalanine, before going through a hydroxylation step to form L-tyrosine and than L-DOPA (Figure 12.1).

12.4 L-DOPA AND PARKINSONIAN SYNDROME

The Parkinsonian syndrome has long held the interest of psychologists, psychiatrists, and other behavioral investigators. Lately, the field of cerebral monoamines has received increased attention; first with the serotonin hypothesis of Brodie, then the noradrenaline hypothesis of Schildrant, in relation to neuron function, is receiving particular attention. (67). Dopamine is postulated to be the key neurotransmitter responsible for the origin of human intelligence (67). Dopamine, the direct precursor for noradrenaline, has a specific distribution pattern within the brain (Figure 12.3). It is concentrated mainly in the striatum and substantia nigra. It is deficient in patients with Parkinson's diseases (PD). L-DOPA has been studied as a treatment for neurological disorders such as Parkinson's disease (68,69).

Parkinson's disease is a common neurological disorder, affecting 1% of the people over the age of 60 years; it is a disease with the signs of rigidity, resting tremor, postural instability, which is due to underproduction of the neurotransmitter dopamine (DA) (70). One of the factors leading to PD is the marked loss of melanized nigrostriatal dopamine neurons, one of the principal components responsible for the normal control of movement. Signs of PD do not appear until a large majority of the nigrostriatal DA neurons have been damaged. Another factor that may mitigate the loss of nigrostriatal DA neurons in PD is a reduced rate of DA activation (71). Also, mitochondrial swelling was noticed as a result of low concentrations of DA, causing a mitochondrial damage triggering neurodegenerative process and PD (72). DA receptors are expressed not only in the central nervous system (CNS), but also in several peripheral tissues including arteries, heart, thymus, and peripheral blood lymphocytes (73). Unconjugated DA represents only 20–40% of the total DA excreted in human urine, with the remainder being mainly excreted in the form of phenolic sulfate (74). It has been suggested that a low level of DA excretion is associated with hypokinesia and normal or excess rate of excretion with hyperkinesia and associated renal dysfunction (74). Overproduction of this catecholamine appears to be associated with the psychological disorder schizophrenia (68).

Introduction of L-DOPA has improved the clinical status of patients with Parkinson's disease (75). Levodopa (L-DOPA — synonym: levo-dihydroxyphenylalanine) therapy in Parkinson's disease was initiated after the suggestion of the role of dopamine in the neuronal system (71,76–81). Dopamine is also known to have a role in renal function, through its action on renal dopaminergic receptors and improved concentration of intrarenal area is dependent on L-DOPA availability (82). The biosynthesis dopamine is considered to start from tyrosine. obtained from dietary sources (82) (Figure 12.3). Blood borne tyrosine is taken into the brain to effect the functioning of dopaminergic neurons. When tyrosine has entered the neurons, L-DOPA (dihydoxyphenylalanine) is made using the cytsolic enzyme tyrosine hydroxylase (71). Subsequently, another cytosolic enzyme aromatic amino acid decarboxylase converts L-DOPA to dopamine (71). In the neurons, striatum is one of the main components of basal ganglia that are responsible for normal control of movement and role of dopamine is essential for this action (71). In Parkinson's disease, the importance of dopamine for striatum is clear due to the motor abnormalities seen in patients, which is characterized by a marked loss of melanized nigrostriatal dopamine neurons (71). Dopamine release in the striatum modulates activity in direct and indirect circuits, which are important for voluntary control of movement (71). Signs of Parkinson's

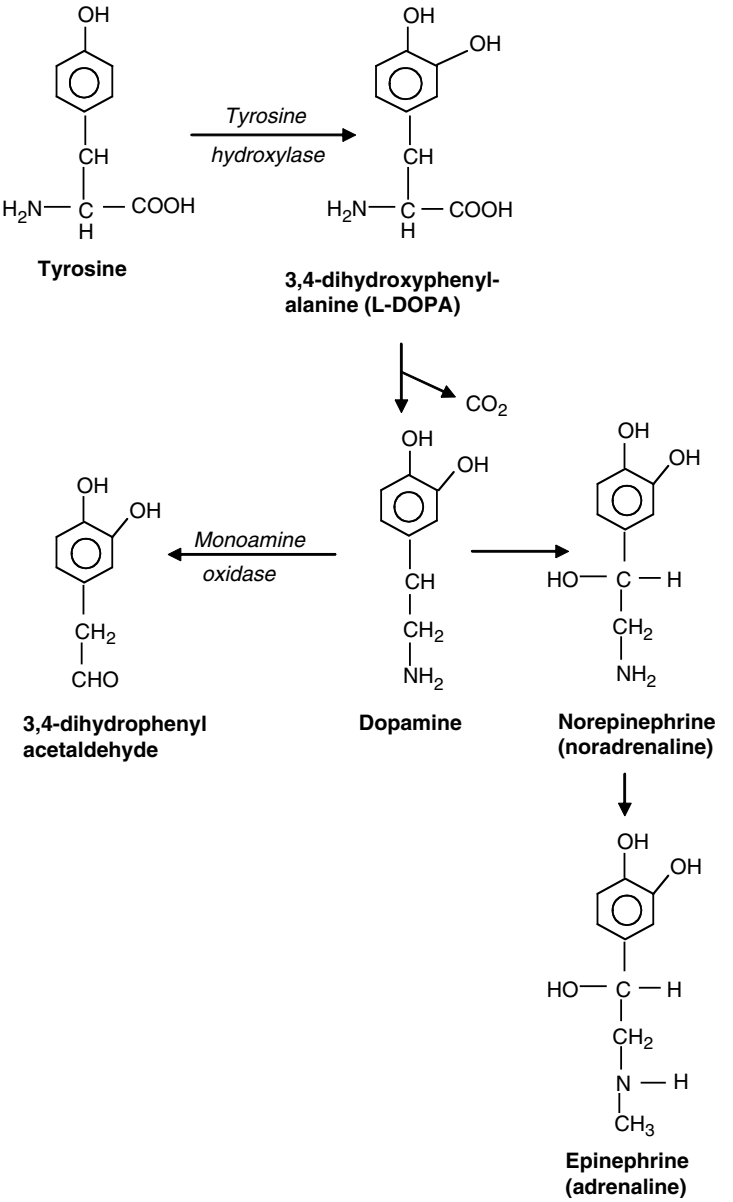

Figure 12.3 Dopamine pathway in neuronal cells

disease are observed after damage to majority of nigrostriatal dopamine neurons when 80% of striatal dopamine loss has occurred (71).

However, declining efficacy is observed over the course of L-DOPA treatment for Parkinson's (75). In addition, the L-DOPA therapy is associated with a variety of side effects such as dyskinesias, fluctuations in motor performance, confusion, hallucinations and sensory syndrome (37,75). To reduce the side effects, L-DOPA dosage is reduced, which limits the antiParkinsonian benefits (75). The benefits of lower dosage and short absence of L-DOPA intake to reduce side effects has had limited success (75) and therefore L-DOPA from fava beans is promising as an alternative Parkinson's therapy (35,37,69).

12.4.1 l-DOPA from Natural Sources

L-DOPA is present in certain food, and L-DOPA glycoside has been extracted from the broad bean (fava bean) *Vicia faba* (83). The fava bean is one of the best plant sources of L-DOPA; clinical studies have shown that seed sprouts have antiParkinson's effects without any of the side effects seen from the pure synthetic form (74). Fava beans are a widely cultivated legume and commonly consumed in the Mediterranean region (37). L-DOPA was identified in the seedling, pods, and beans of broad bean (fava bean) initially by Guggenheim in the early 1930s (37,69,74). Fava bean ingestion correlated with a significant increase in levels of L-DOPA in plasma and with an improvement in motor performance (35). As discussed earlier, exogenously synthesized L-DOPA is not effective in all PD patients and has side effects (37). The mechanism of efficiency of the natural source of L-DOPA may be due to the amino acid milieu generated in broad fava beans that may favor the selective transport of L-DOPA across the blood brain barrier (37). Fava beans seedling ingestion is useful in the treatment of PD patients, especially those in low income societies, where limited resources do not allow the purchase or manufacture of expensive drugs. Fava beans are available cheaply in all seasons and can be easily grown. Furthermore, fava beans serve as natriuretic agents (82). Other natural sources of levodopa, besides broad bean, have also been reported in *Stizolobium deeringianum* and *Mucuna pruriens*. *Mucuna pruriens* beans have been used as an efficacious herbal drug for PD treatment in India for many years (37).

12.4.2 l-DOPA from Fava bean

Studies have shown that ingestion of *Vicia faba* (fava bean) fruits (pods and seeds) improved substantially the clinical features in Parkinson's patients (35,36). In further studies the benefits from fava bean seedlings, which had 20-fold higher L-DOPA than fruit was even better, with higher plasma L-DOPA and substantial clinical improvement (69). In a limited clinical case study, fava beans as a source of L-DOPA, prolonged the "ON" periods in patients with Parkinson's disease who have "ON-OFF" fluctuations (37). In these studies, patients had been previously administered higher doses of L-DOPA, up to 800–100 mg per day, which failed to optimize the "ON" time and resulted in peak dose dyskinesias, but the fava bean showed beneficial effects by prolonging the "ON" time and shortened "OFF" time (37). Other studies using L-DOPA from *Mucana pruriens* beans have been used as an effective drug for Parkinson's disease in India for many years (84). In a clinical study of 60 patients over 12 weeks, an extracted powder from *M. pruriens* mixed with water significantly improved Parkinsonian motor scores, and from the studies authors speculated that the extract benefits may be a result of other antiParkinsonian compounds besides L-DOPA (Parkinson's study group for HP-200). The observation from these limited legume studies indicates that there may be additional complementary compounds that may work in conjunction with L-DOPA. Our hypothesis is that these additional complementary compounds could be other phenolics that have antioxidant benefits and amino acid cofactors. Therefore, the rationale for enhancing biosynthesis of L-DOPA and total phenolic profiles in various stages of fava bean seedlings following elicitation with physical and elicitor stress has merit. Further, because seedlings were shown to be the best source of L-DOPA (69), its biosynthesis is being investigated in light and dark germinated fava bean seedlings and correlated to total phenolic content and fava bean antioxidant activity at the metabolite and enzyme level. From this understanding of L-DOPA phenolic content and antioxidant response, the goal is to use various stages of the seedlings with different optimized levels of L-DOPA and total phenolics and to confirm that these ratios will affect the antioxidant enzyme response in a Parkinson's neuronal cell model system. This

approach not only helps to optimize the best stage for L-DOPA biosynthesis in fava bean seedlings but will also confirm whether the additional factors that contribute to the benefits of L-DOPA from the fava bean is potentially the result of " phenolic antioxidant" and "amino acid" factors.

12.5 LINKING L-DOPA SYNTHESIS TO THE PENTOSE PHOSPHATE AND PHENYLPROPANOID PATHWAYS

L-DOPA in the seed is potentially derived from the phenylalanine. As mentioned earlier, phenylalanine is synthesized in the plant from the pentose phosphate pathway and the shikimate pathway, which forms the starting material of the phenylpropanoid pathway for the synthesis of phenolic acid (Figure 12.1). PAL catalyses its further conversion to cinnamate, which leads to the secondary metabolite synthesis. An alternative route for phenylalanine modification is the synthesis of tyrosine by phenylalanine hydroxylase. Tyrosine, in turn, is the precursor for L-DOPA production in the seed.

It is hypothesized that synthesis of free soluble phenolics and L-DOPA is regulated via the proline linked pentose–phosphate pathway (PLPPP), shikimate pathway, and phenylpropanoid pathway (23,30) (Figure 12.1). PPP is an alternate route for the breakdown of carbohydrates generating $NADPH_2$ for use in anabolic reactions and for providing erythrose-4-phosphate for the shikimate pathway (23,30). This route is vital for the biosynthesis of phenylpropanoid secondary metabolites, including L-DOPA (Figure 12.1). Glucose-6-phosphate dehydrogenase (G6PDH) catalyses the first committed and rate-limiting step of PPP (85). A putative correlation has been observed between proline levels and total soluble phenolics in thyme, oregano, seeds of *Pangium edule*, and pea, which suggests that proline accumulation may be linked to the regulation of the phenylpropanoid pathway (86–88). The stimulation of PPP, purine, (89) and soluble phenolic (23,30) synthesis is believed to occur through a redox cycle. Cytosolic pyrroline-5-carboxylate (P5C) is reduced to proline and $NADPH_2$ is oxidized to $NADP^+$ (89). The enzymes G6PDH and 6-phosphogluconate dehydrogenase utilize the generated $NADP^+$ as cofactors in PPP for their reactions. In many plants, free proline accumulates in response to the imposition of a wide range of biotic and abiotic stresses (90). The stimulation of L-DOPA through the proline linked pentose phosphate pathway (PLPPP) could also serve as the critical control point (CCP) for generating $NADPH_2$, not just for proline synthesis (as an alternative reductant for energy), but it could also meet the reductant needs of antioxidant enzyme response through superoxide dismutatse (SOD) and catalase (CAT) (Figure 12.4)(23,30).

Current investigations using fava bean sprouts indicate that under various biotic and abiotic elicitors, L-DOPA content is enhanced in the early stages of germination, which then gradually gets reduced and the total soluble phenolics steadily increases with germination, reaching highest synthesis in the later stages (63,64,66). Further, it is evident that stimulation of soluble phenolics in the late stages is regulated through the pentose phosphate pathway as reflected in the activity of glucose-6-phosphate dehydrogenase. This is likely coupled to proline synthesis (63,64). It is likely that as soon as germination takes place L-DOPA content is mobilized rapidly in early stages, and once germination leads to hypocotyl development, the phenolic flux is redirected for structural development with maximum demand for the pentose phosphate pathway because elicitor stress demand increases soluble phenolics in late stages (63,64,66). This late stage soluble phenolic stimulation in response to stress factors could be as important as

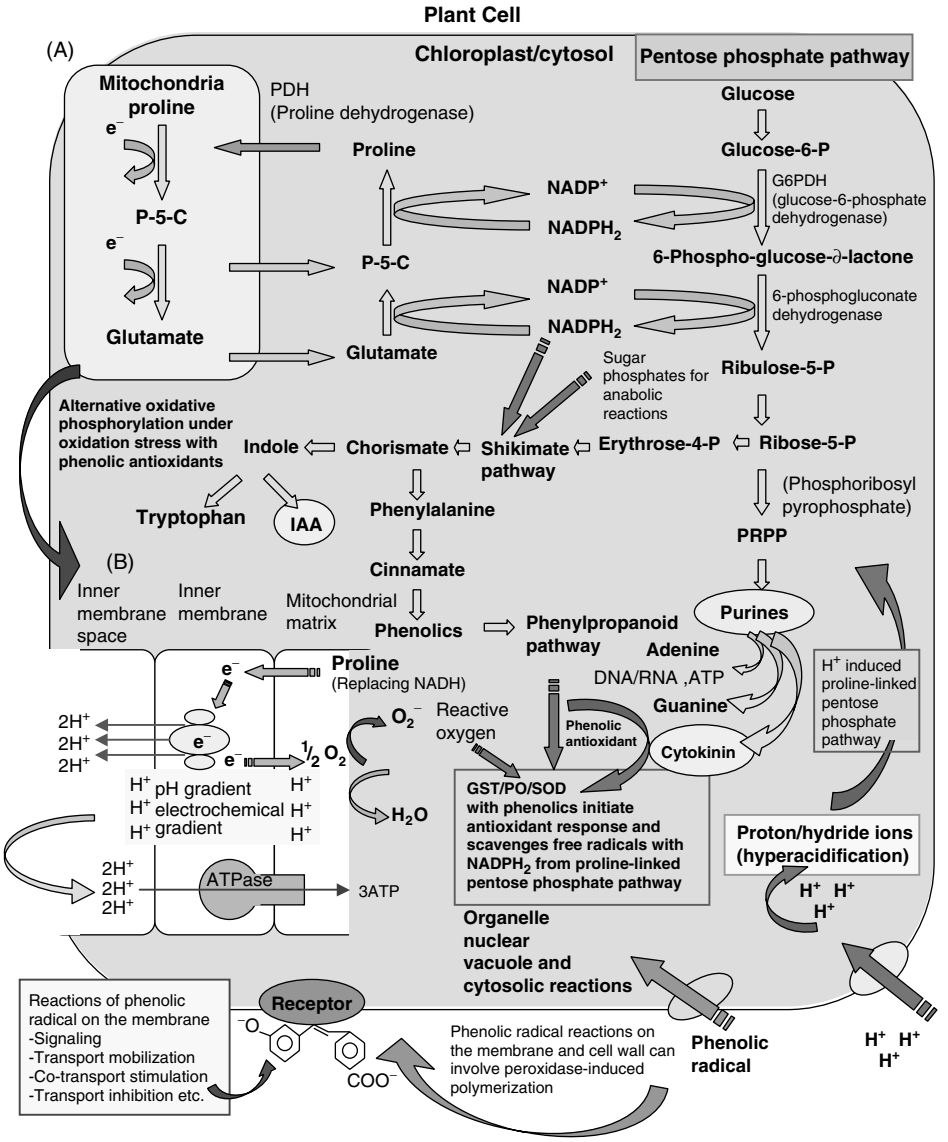

Figure 12.4 Improved model for the role of praline linked pentose–phosphate pathway in phenolic biosynthesis, which also accommodates the biosynthesis and mechanism of action of L-DOPA in a high phenolioc background from fava bean sprouts, and the effect of external elicitors like oregano phenolics. (Abbreviations: P5C: pyrroline-5-carboxylate; IAA: indole acetic acid: GST: Glutathione-s-transferase: PO: peroxidase; SOD: superoxide dismutase)

L-DOPA for Parkinson's management, as this could provide additional "phenolic antioxidant" and "amino acid" factors that could moderate the L-DOPA insensitivity often seen with pure synthetic L-DOPA treatments (37). These additional phenolic antioxidant and amino acid factors such as glutamic acid and proline could contribute soluble factors for proper redox management of neuronal cells as proposed for human and mammalian cells (23,91) (Figure 12.5).

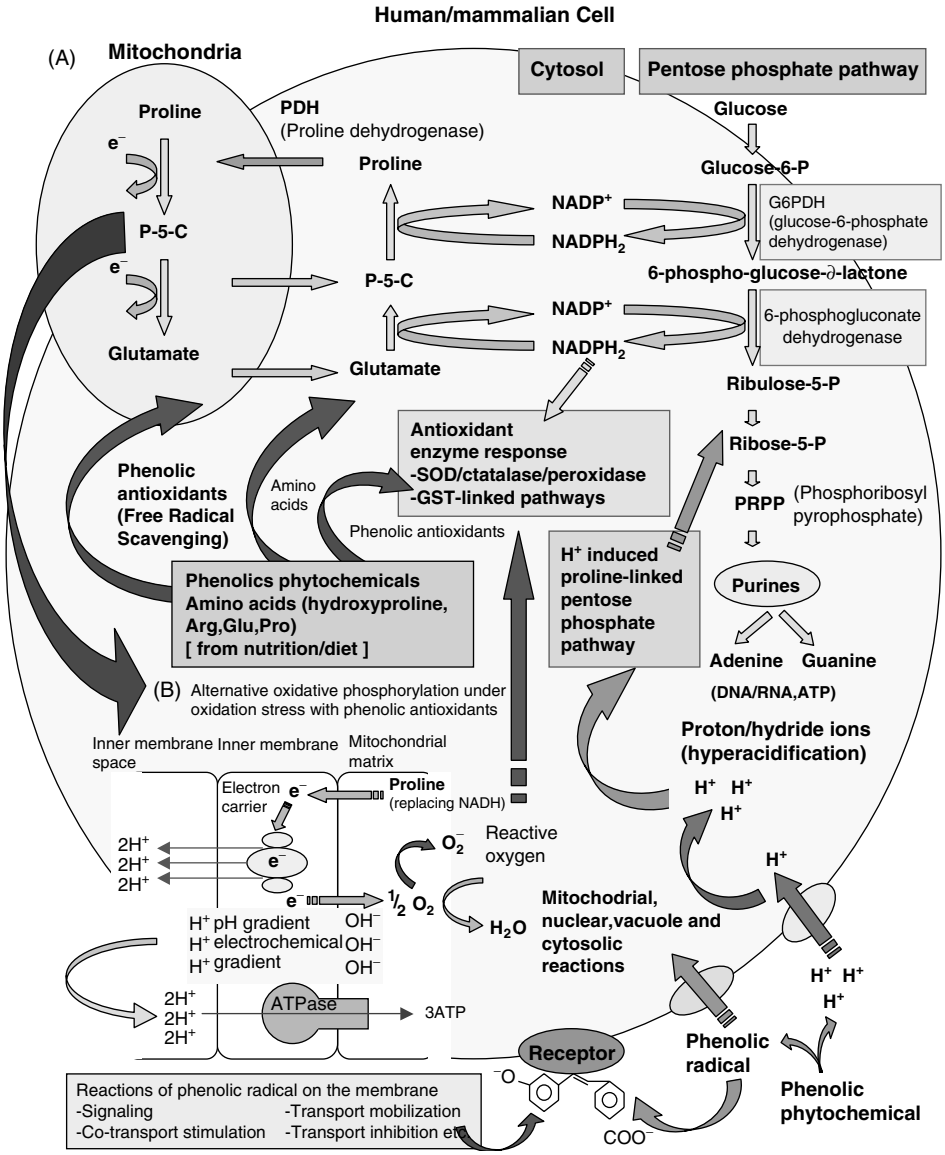

Figure 12.5 Extension of plant praline linked pentose–phosphate pathway model for the effect of external phenolic phytochemicals like L-DOPA in a high total phenolic background from fava bean sprouts or fermented extracts in human and mammalian systems. (Abbreviations: P5C: pyrroline-5-carboxylate; GST: Glutathione-s-transferase; SOD: superoxide dismutase)

12.6 RECENT PROGRESS ON ELICITATION LINKED BIOPROCESSING TO ENHANCE L-DOPA AND PHENOLICS IN FAVA BEAN SPROUTS

We have developed biotic and abiotic induced elicitation techniques to enhance L-DOPA, total phenolics, and antioxidant activity during sprouting of fava beans (63,64,66,92–94). The rationale for this approach is based on the understanding that pretreatment in the dry presoak stage or soak stage enhances critical stress responses as the seed germinates and

that this will alter the stress related phenylpropanoid pathways linked to soluble phenolic and L-DOPA biosynthesis. This also likely mobilizes free amino acid from protein stored in the cotyledons. In our earliest work we investigated the stimulation of L-DOPA, total soluble phenolics, and related antioxidant activity in dark germinated fava bean seeds in response to bacterial polysaccharides from *Pseudomonas elodea* (gellan gum) and *Xanthomonas campestris* (xanthan gum) (92). Results indicated that gellan gum stimulated a ninefold increase in total soluble phenolics, compared to control. and this stimulation may be regulated via the pentose phosphate pathway based on the stimulation of glucose-6-phosphate dehydrogenase (92). The L-DOPA content was high in the initial days in the hypocotyl in all treatments and steadily reduced over the later stages. This approach allowed the development of two kinds of extracts, an early stage high L-DOPA with low soluble phenolics, and later stage medium L-DOPA with high soluble phenolics. The relative antioxidant activity based on the β-carotene assay did not change over the sprouting phase (92). Subsequent studies explored the stimulation of L-DOPA and total soluble phenolic in response to phytochemical and peptide elicitors in dark and light germinated conditions (93,94). Under dark germination conditions, the elicitors stimulated soluble phenolic content, with fish protein hydrolysates, lactoferrin, and oregano phenolic extracts stimulating the highest phenolic contents of 2.9–5.2 mg/g fresh weight (FW) during early stages of germination (93). The stimulation of primary metabolism through the pentose phosphate pathway occurred on day 5 for fish protein hydrolysates, and early stage of day 3 for lactoferrin and oregano phenolics (93). L-DOPA was stimulated from 20–40% for all elicitors immediately after treatment on day 1 and declined steadily. Under these conditions, fava extracts with any of the foregoing elicitations could be suitable for designing a dietary source of L-DOPA with high soluble phenolics between 2–5 days, depending on the elicitor. The same elicitors were tested for stimulation of light modulated seed vigor response and it was clear that L-DOPA content in seedlings was stimulated to over 80–100% by fish protein hydrolysate and oregano phenolics, which was followed by a change in flux toward higher soluble phenolics and enhanced antioxidant activity on day 20 (94).

In another study, UV treatment of seeds for 15 hours after overnight soaking stimulated highest L-DOPA content on day 1 and highest total soluble phenolic content day 6. The stimulation of soluble phenolic content was correlated to glucose-6-phosphate dehydrogenase, the first committed step in the pentose phosphate pathway. Further, proline content was slightly elevated compared non-UV treated control, indicating that soluble phenolic synthesis in late stages may be driven through the proline linked pentose–phosphate pathway (63). In another very exciting abiotic stress study, 30 seconds of microwave treatment of dry seed prior to overnight soaking and dark germination, resulted in over 50% stimulation of L-DOPA on day 1 and over 700 % stimulation of total soluble phenolics on day 7 (66). Each of these stages correlated to higher antioxidant activity both in terms of free radical scavenging assay as well as stimulation of superoxide dismutase (SOD) (66). Further, it was clear that late stage soluble phenolic stimulation correlated strongly to the stimulation of the pentose phosphate pathway (66). Additional studies using proline analog and proline combinations were used as elicitor treatments to confirm that the stimulation of soluble phenolics in the late stages of dark germination correlated with simultaneous stimulation of glucose-6-phosphate dehydrogenase and proline, further supporting the hypothesis that the proline linked pentose–phosphate pathway may be involved in the stress induced stimulation of phenolics (64). These studies support the model that PLPPP may be a critical control point (CCP) that not only stimulates the pentose phosphate pathway to support proline as an alternative reductant for energy through oxidative phosphorylations (alternative to NADH), but could also provide the critical $NADPH_2$ for supporting antioxidant enzyme response through SOD and CAT (Figure 12.4). The

optimization of these steps during sprouting and seedling development could help to generate fava bean extracts with optimum L-DOPA with additional soluble phenolics and amino acid factors that could better modulate neuronal antioxidant enzyme response (Figure 12.5) and help to overcome any L-DOPA insensitivity seen with extended use of pure synthetic L-DOPA.

12.7 RECENT PROGRESS ON SOLID-STATE BIOPROCESSING OF THE FAVA BEAN TO ENHANCE L-DOPA AND PHENOLICS USING FOOD GRADE FUNGAL SYSTEMS

A solid-state bioconversion system using the food grade fungus *Rhizopus oligosporus* was developed to enrich the fava bean substrate with phenolic antioxidants and L-DOPA (65). The L-DOPA content in the fungal grown fava bean increased significantly to approximately twice that of control, accompanied by moderate soluble phenolic linked antioxidant activity based on free radical scavenging assay and higher fungal SOD activity during early stages of growth. This indicated that L-DOPA can be mobilized and formed from fava bean substrates by fungal bioconversion, conributing to the antioxidant functionality of such extracts (65). A high superoxide dismutase (SOD) activity during early and late growth stages indicates the likely oxidation stress of initial fungal colonization and during later growth stages due to nutrient depletion. High levels of soluble phenolics were observed during late growth stages. During the course of solid-state growth there was an increase in β-glucosidase activity, which correlated to an increase in total soluble phenolic content during the late stages. This suggests that the enzyme may play an important role in the release of phenolic aglycones from fava bean substrate, thereby increasing the soluble phenolic content and accompanying antioxidant activity (65). The implication from this study is that solid-state bioconversion of the fava bean by *R. oligosporus* can significantly improve the phenolic antioxidant activity and Parkinson's relevant L-DOPA content.

12.8 IMPLICATIONS AND SUMMARY

It is clear that elicitor induced sprout systems and fungal based solid-state bioprocessing systems can be used for specific stimulation of L-DOPA. In the case of sprouts, the L-DOPA increase was observed immediately after elicitor and soaking treatment on day 1, but was observed over an extended growth phase when using a fungal solid-state system, The contents were consistently higher over the middle growth stage from days 4–12. In contrast, the total soluble phenolics were substantially stimulated concurrent with high proline in late stages of sprout growth with general stimulation of the pentose phosphate pathway supporting this total soluble phenolic metabolite production. In the solid-state fungal bioprocessing system, soluble phenolic content was observed in the later stages. The extent of antioxidant activity based on free radical scavenging generally coincided with higher L-DOPA content in the early stage, and with total soluble phenolics in the late stage in both elicitor stimulated sprouts and fungal bioconversion system. These bioprocessing approaches provide avenues to optimize L-DOPA content in the fava bean system with optimum "phenolic antioxidant" and "amino acid" profiles that could be more effective than the current approaches observed for pure synthetic L-DOPA drug treatments. Insights provided by studies so far also indicate that the L-DOPA content and total soluble

phenolic contents are likely stimulated through an alternative proline liked pentose–phosphate pathway (Figure 12.4). In this model under elicitor stress, soluble phenolic synthesis is enhanced to counter the stress, which likely involves both direct free radical scavenging using the produced phenolics as well as antioxidant enzyme response through SOD. Further, an alternative proline linked pentose–phosphate pathway more efficiently facilitates $NADPH_2$ and sugar phosphate flow for anabolic pathways, including phenolic and antioxidant response pathways, while proline meets the reductant need for oxidative phosphorylation replacing NADH from TCA Krebs cycle (Figure 12.4) (23). Extending this model into animal systems, we have hypothesized fava bean extracts with optimum total soluble phenolics, L-DOPA, and proline could better maintain the cellular homeostasis and function of neuronal cells by modulating host antioxidant response through a proline linked pentose–phosphate pathway (23) (Figure 12.5). This mode of alternative regulation could facilitate better management of cellular redox environment through dehydrogenases and antioxidant enzyme response through SOD and CAT under which L-DOPA can work effectively.

Phytochemicals and Breast Cancer Chemoprevention

Sallie Smith-Schneider, Louis A. Roberts, and Kalidas Shetty

CONTENTS

13.1 INTRODUCTION

13.1.1 Background

According to the National Cancer Institute, approximately 13% of American women will develop breast cancer during their lifetimes. There are approximately 216,000 newly diagnosed cases of breast cancer each year, and breast cancer is second only to lung cancer in cancer related deaths among women in the USA (American Cancer Society). Despite a gradual decline in deaths due to breast cancer (likely attributable to increased screening), there is a rise in the incidence of newly diagnosed breast cancer. Numerous pharmaceuticals exist to prevent breast cancer growth, and several drugs are used chemopreventatively to block the formation of new tumors in previously diagnosed patients. Several plant derived compounds have been identified that may offer promise as chemopreventative agents that can be used routinely by the general population. However, in order to develop improved strategies aimed at preventing breast cancer, a better understanding of the cellular and molecular mechanisms that contribute to breast cancer initiation and protect epithelial cells against initiation or progression to cancer is needed.

During normal development of the mammary gland, controlled cell growth and changes in differentiation that resemble the unchecked cell proliferation that is a hallmark of breast cancer occur in response to hormones (1,2). In particular, the signaling pathways used during development and cancer initiation or growth are the same, with the loss of regulation over normal signals representing the most significant difference in initiation of cancer. Early in fetal development an extended epidermal mammary ridge forms and subsequently regresses, producing one nipple per breast with a bud of epithelial cells that essentially remains dormant and unchanged in females until puberty. Pubertal hormones (i.e., estrogen) initiate rapid division, branching, and migration of epithelial cells to form a system of ducts which extend to the limits of the fat pad, with lobules surrounded by stroma and microvascularized connective tissue. The ends of the lobule are referred to as terminal end buds, which maintain the ability to proliferate when triggered by pregnancy hormones (including estrogen and progesterone). During pregnancy the cells of the terminal end buds rapidly divide, then differentiate during lactation into milk producing alveoli. Upon weaning, rapid apoptosis of the alveoli ensues (termed involution), and the breast is then virtually indistinguishable from those of nulliparous females. However, the epithelial terminal end buds retain the ability to proliferate, invade the stroma, and differentiate in response to hormones produced during pregnancy and lactation. Thus, mammary gland development is a highly ordered and controlled process that directs epithelial cell proliferation, differentiation, and apoptosis.

A vast majority of breast cancers initiate from the ductal and lobular epithelial cells already described. Initially, the cells that comprise ductal carcinoma *in situ* (DCIS) are still hormone responsive (express estrogen and progesterone receptors), but often display hormone independent growth upon progression to more metastatic tumors. Additionally, growth factor receptors are often overexpressed in aggressive metastatic tumors that further promote unrestrained proliferation, inhibition of apoptosis, and vascularization of the growing tumor (3). Many chemopreventative strategies are based upon promoting or restoring normal signaling mechanisms within these ductal and lobular epithelial cells to

reduce the likelihood of breast cancer initiation. Interestingly, pregnancy exerts a protective effect on the breast, such that a full term pregnancy lowers breast cancer risk by ~50% (4). This effect appears to be mediated in part by sensitizing the tumor suppressor protein p53, and in part by altering growth factor signaling (5–9). Chemoprevention using dietary phytochemicals aims to mimic the protective effect of pregnancy hormones by modulating such signaling pathways (Figure 13.1).

13.1.2 Susceptibility and Chemoprevention: Molecular Pathways

There are numerous factors and molecular events that can increase or decrease the susceptibility toward developing breast cancer. Understanding the molecular basis of this disease often relies on identifying the signal transduction pathways whose activation (or inhibition) directly regulates the development of breast cancer or acts as a marker for breast cancer susceptibility or protection. Once these pathways are identified, development of chemopreventative strategies to decrease the risk of breast cancer and chemotherapeutic regimens to treat existing cancers will be greatly facilitated.

p53 is a tumor suppressor protein that when activated acts as a transcription factor to induce expression of a host of genes involved in responses to DNA damage (triggered by ultraviolet light, ionizing radiation, or carcinogenic chemicals) (6,10). The central function of p53 is to induce cell cycle arrest and decide if DNA damage can be fixed (arrest followed by resumption of the cell cycle), or is irreparable (activation of the apoptotic pathway). p53 thus plays a critical role in preventing genotoxic initiation of precancerous lesions. Mutation of the *p53* gene or loss of p53 responsivity is one of the most common events identified in human breast cancer (detected in ~50% of cases), and loss of the p53 allele in mouse models predisposes them to cancer. In fact, transformation of normal ductal epithelium to DCIS typically progresses to the formation of a malignant, invasive cancer of the breast, and is frequently linked to mutation of p53 (2). p53 can be sensitized, i.e., made more responsive, by the pregnancy hormones estrogen and progesterone (11) and many dietary phytochemicals (12). Sensitization of p53 minimizes cancer initiation by increasing the likelihood that cells with activated p53 will either repair damaged DNA, or will be removed by apoptosis.

The estrogen biosynthetic and signaling pathways have been very well studied in normal development of the breast (i.e., directing proliferation of ductal epithelial cells during puberty), as well as in breast cancer (13). The enzyme aromatase (itself a popular target of estrogen responsive breast cancer) (14,15) converts androgen into estrogen, produced distally by the ovaries and locally in the breast. Estrogen is highly mitogenic, and directs cell proliferation by binding to estrogen receptors and activating transcription. Estrogen also may ultimately lead to the release of epidermal growth factor (EGF), itself a mitogenic factor, and may be converted into hydroxylated estrogens which in turn can act to stimulate cell division. Inappropriate signaling through the estrogen response pathway can lead to unchecked cell proliferation, and breast cancer.

Upregulation of signaling through the aryl hydrocarbon receptor (AhR) has recently been closely linked with breast cancer initiation, likely by inducing hyperplasia in epithelial breast tissue. Environmental toxins such as dioxin bind to cytosolic AhR, which then acts as a transcription factor to induce the expression of several genes, including the monooxygenase CYP1A1. Protoxins are then metabolized into mutagenic substances by CYP1A1. With respect to breast cancer specifically, CYP1A1 is capable of generating hydroxylated estrogens (i.e., 16α-hydroxyestrone) with mitogenic activity, and variant or increased CYP1A1 activity is associated with an increased risk of breast cancer (16). Additionally, AhR activation leads to the upregulation of other genes that regulate the antioxidant response and the cell cycle.

Many phytochemicals have been shown to modulate AhR activation and CYP1A1 expression and activity, including polyphenols, flavonoids, and phytoalexins, and may have a role in breast cancer prevention.

Signaling by growth factors [such as insulin-like growth factor (IGF), vascular endothelial growth factor (VEGF), transforming growth factor beta (TGF-β), and EGF represents an important area of focus in cancer initiation and development. Increased signaling through IGF can inhibit apoptosis (likely by upregulating the protein kinase Akt and the transcription factor NF-κB) (17), and some correlation exists between high circulating blood levels of IGF and the risk of premenopausal breast cancer (18). Epithelial growth factor, signaling through its receptors epidermal growth factor receptor (EGFR) and HER-2/neu plays a significant role in stimulating cell proliferation in the mammary gland (19). Vascular endothelial growth factor expression is regulated by NF-κB as well as cyclooxygenase and lipoxygenase metabolites of arachidonic acid (AA), and signaling it increases the growth and migration of endothelial cells that leads to vascularization of growing tumors (20). In contrast, TGF-β acts as a negative regulator of cell growth, as disruption of TGF-β signaling is correlated with cancer development (21). Additionally, crosstalk amongst growth factor signaling networks exists. For example, both IGF and EGF are capable of regulating the expression of VEGF. Antagonistic effects are also seen. IGF activation can down regulate TGF-β signaling (22), while TGF-β can decrease the circulating levels of IGF. Modulation of growth factor signaling obviously represents a complex yet important area of research in the development of chemopreventative strategies.

The aberrant metabolism of arachidonic acid by cyclooxygenases (COX) and lipoxygenases (LO) has recently been shown to be a predictive marker for initiation and progression

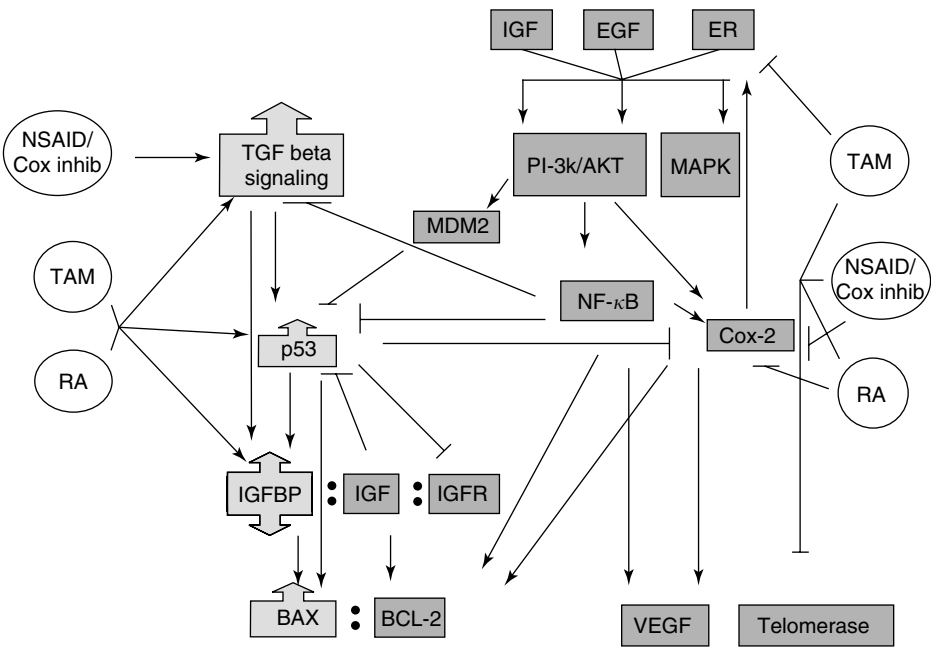

Figure 13.1 Signaling pathways which promote cell growth, survival, and metastasis and stimulate angiogenesis (dark grey) exist in a balance with signals that suppress growth, sensitize cell to apoptosis, and induce differentiation (light grey). Chemopreventive agents appear to have common overlapping roles in their ability to control growth signals through TGF beta family signaling, inhibit cyclooxygenase activity, regulate IGF, control oxidation, and sensitize or activate p53. (RA = retinoic acid, TAM = tamoxifen, NSAID = nonsteroidal antiinflammatory drug)

of a variety of cancers, and has been correlated with ultimate outcome in patients with breast cancer. COX-2 upregulation was first associated with a predisposition for colon cancer development, and COX-2 expression and activity are increased in breast cancer cells (23). The upregulation of COX-2 is indicative of, and is at least partially responsible for, increased cell growth and migration and decreased apoptotic rate. The AA metabolizing enzymes 5-lipoxygenase and 12-lipoxygenase are also overexpressed in many cancerous tissues, while decreased expression of 15-lipoxygenase is observed in many carcinomas. Recent studies have correlated increased expression of COX-2, 5-LO, and 12-LO with poor clinical outcome of breast cancer patients (24–26). Pharmacological COX inhibitors are currently in clinical trials as chemopreventative or chemotherapeutic agents (27), and the discovery and application of plant derived inhibitors of COX and LO represent an intense area of scientific and clinical research (28).

Many plant derived compounds either have been shown, or offer promise, to act as chemopreventative agents that block the development of breast cancer (29). These phytochemicals include but are not limited to the flavonoids, catechins, lignans, (poly)phenolics, and organosulfones. Interestingly, a subset of these phytochemicals act on multiple signaling pathways to coordinately suppress breast cancer initiation and progression, often by acting on a common signaling intermediate. Additionally, many of these plant derived compounds exert their protective effects by acting as antioxidants, which minimize oxidative stress and DNA damage. Several of the specific signaling pathways through which phytochemopreventative agents are known to act are detailed in the following (Figure 13.2).

	Estrogen signals	EGF signals	IGF signals	VEGF	COX2	TGF beta family signals	p53	Antioxidant enzyme response	AhR/ CYP1A1	LOX

Figure 13.2 Numerous phytochemicals have been shown to regulate the balance of signals that promote cancer as well as the signals that control growth and sensitivity to DNA damaging agents. The (+) symbol indicates that in certain cell lines the phytochemical has been shown to activate or promote this pathway in some manner. The (−) symbol indicates that the phytochemical has been shown to have repressive or inhibitory effects on the signaling pathway at some level.

13.2 MOLECULAR PATHWAYS OF BREAST CANCER CHEMOPREVENTION

13.2.1 p53

p53 is a protein that activates transcription in response to a wide range of genotoxic stresses. Activation of p53-induced genes (i.e., p21, 14-3-3, bax, killer/DR5, GADD45, and NAG-1) results in execution of a cell cycle checkpoint important for the repair of DNA, cellular differentiation, or engagement of the apoptotic pathway. Loss of p53 activity due to mutation or viral inactivation results in immortalization of cells, and can represent one factor in the multihit process required for the progression to cancer.

The importance of proper control of p53 is underscored by its highly intricate regulation at numerous levels. The phosphorylation of p53 is complex and cooperative. Phosphorylation at specific residues are required for DNA binding, oligomerization, and transactivation. Ataxia telangiectasia mutated/ATM and Rad3 related kinase (ATM/ATR) are kinases which are believed to act as sensors of genotoxic stress. Ataxia telangiectasia mutated kinase appears to respond to double stranded DNA breaks, while ATR responds to stalled replication. These sensors transport signals of genotoxic damage through downstream targets such as Chk2 kinases, p53, and Brca. Activity of ATM/ATR is believed to be responsible for the phosphorylation of numerous N-terminal p53 residues such as serines 9, 15, and 46 as well as indirectly regulating the phosphorylation states of serines 20 and 376 (30). The phosphorylations of serines 15 and 20 control the binding of the ubiquitin ligase, MDM2, which regulates stability and cellular localization of p53 (31). Phosphorylated serine 15 (along with cooperative phosphorylations at serines 33, 37, 392) is believed to regulate the transcriptional activity of p53 to allow recruitment of general transcription factors (32–34). MAP kinase family members, in particular the stress activated members p38 and c-Jun N-terminal kinase (JNK), can also phosphorylate p53. c-Jun N-terminal kinase can phosphorylate threonine 81 to regulate p53 stability, transcriptional activity, and ability to initiate apoptosis (35), while p38 can phosphorylate serines 33 and 46 in response to UV radiation (36). The stability and cytoplasmic localization of the p53 protein is regulated by sequestration through interaction with the MDM2 protein, a ubiquitin ligase. The MDM2 protein can block p53 activity by binding to the N-terminus of p53 and either targeting p53 for degradation through ubiquitination, or by sequestering p53 in the cytoplasm. The regulation of MDM2 through the PI3k pathway is one mechanism by which deregulated signals through receptor tyrosine kinases can repress p53 activity and thus increase genetic instability (37,38). p53 can also be regulated by sumoylation and protein to protein interactions mediated through oxidative stress. The redox state of the cell determines the activity of thioredoxin reductase, which can control the activity of ref-1, which in turn can bind to and regulate transcriptional activity of p53 (39).

The mammary gland appears essentially normal in mice with a null deletion of p53, suggesting that p53 is not required for normal development. However, these mice are more prone to tumors in general and die at a relatively young age, mostly due to lymphomas. The loss of a single allele in the breast cancer susceptible mouse strain BALB/c results in 55% developing breast cancer by one year of age (40). A spectrum of p53 mutations has also been detected in cases of human breast cancer, and p53 appears to be inactivated by mutation in approximately 40% of human breast cancer cases (41,42).

A relatively new and interesting observation is that the mammary glands of virgin rodents are refractile to the activation of p53 by gamma radiation, while parous glands are sensitive (43). This offers a possible explanation for why the virgin rodent mammary gland is more susceptible to cancer induced by carcinogen exposure than the parous gland. The implications of pregnancy induced sensitization of p53 are obvious, as cells with DNA

damage can be eliminated or repaired in the glands of parous mice, but may not be cleared or corrected in virgin mice. The importance of this pathway in humans remains to be determined; however, it is known that women who undergo pregnancy at an early age have a significantly reduced risk of breast cancer. Chemopreventative agents such as tamoxifen and retinoic acid have also been shown to sensitize p53 activity and the mammary gland (Tu, Schneider, and Jerry, unpublished). This suggests that the sensitization of p53 and the gland utilizes a common and important pathway in the protective response.

The ability to sensitize the mammary gland to repair and death via p53 represents an excellent target in the search for dietary phytochemicals which might act as strong chemopreventative agents. To date, numerous phytochemicals have been identified that can activate p53 and thus the apoptotic pathway in tumor cells. These agents include the organosulfur compounds phenethyl isothiocyanate (PEITC) (44) and diallyl disulfide (45); the phenolic compounds resveratrol (46), ellagic acid (47), and curcumin (48); and the plant isoflavonoids apigenin, kaempferol, luteolin (49), and genistein (50). While the mechanisms of p53 induction by most of these agents is not known, the flavonoids appear to induce p53 through the activation of ATM/ATR and the p38 stress related kinase; and some data suggest that genistein can alter Chk2 kinase activity which controls the activity of cdc25, a dual specificity kinase (49).

13.2.2 Estrogen Signaling

13.2.2.1 Background

Ovarian hormones have dichotomous effects when applied to the biology of the breast. On one hand, prolonged exposure through early menarche, belated menopause, or postmenopausal hormone replacement therapy increases the risk of breast cancer. On the other hand, an early full term pregnancy can significantly reduce breast cancer risk to humans (51), and in rodents pregnancy levels of estrogen and progesterone will impart a significant protection against carcinogen induced breast cancer (52,53). The context and duration of the signaling is likely to be the important determinant in the effects of estrogen. There is no doubt, though, that estrogen remains one of the critical hormones that regulate both normal and malignant development of the mammary gland.

13.2.2.2 Estrogen Regulation

Androgen is converted to estrogen by aromatase. Estrogen is produced primarily in the ovaries and released into the bloodstream, though aromatase activity has been identified in the stroma of the mammary gland. Estrogen is highly mitogenic, and regulates transcription of a variety of genes by activating several distinct signaling pathways within the cell. Estrogen specifically binds to estrogen receptors (ERα or ERβ) and activates transcription. Alternatively, recent data suggests estrogen may also bind a G-protein coupled plasma membrane receptor, which signals through Src, leading to matrix metalloproteinase (MMP) activation. Matrix metalloproteinase activavtion in turn cleaves heparin bound EGF such that EGF is released and can signal through EGF receptors (54). Finally, estrogen may also signal through metabolites generated by cytochrome P450 enzymes. 16a-hydroxyestrone has been shown to exert agonistic and proliferative effects upon mammary epithelial cells (55).

Estrogen is critical for the normal development of the mammary gland during puberty and pregnancy. Proper regulation of estrogen receptor (ER) signaling is important for directed proliferative events. During puberty proliferation of ductal epithelial cells increases dramatically in response to hormones, leading to extension of the ductal network through the stroma toward the limits of the fat pad. Mice with a targeted deletion of ERα exhibit a very

prevalent phenotype in which the ducts are severely stunted. Estrogen is also partially required for differentiation and development of lobuloalveolar structures during pregnancy.

13.2.2.3 Protection and Susceptibility Duality of Estrogen Signaling

Ovariectomy in humans and mice (which reduces estrogen levels) substantially reduces the risk of breast cancer. A subset of potent chemopreventative and chemotherapeutic agents has the ability to inhibit certain ER activities (e.g., selective estrogen receptor modulators [SERM]) or inhibit estrogen synthesis (e.g., aromatase inhibitors). Tamoxifen (the best studied SERM) has partial ER antagonistic properties, and has been very popular as adjuvant therapy in humans to reduce the risk of recurrent breast cancer. Some of the documented successes of tamoxifen may be due to its pleiotropic effects. Tamoxifen decreases IGF signaling, increases TGF-β secretion, prevents oxidative damage, inhibits protein kinase C, and induces apoptosis. However, tamoxifen has agonistic effects on endometrial tissue, and because of its potential side effects long term use is discouraged. Raloxifene is a newer member of the SERM family which is also an ER antagonist, but lacks some of the side effects associated with tamoxifen. Preliminary studies with Raloxifene have yielded comparable preventative features. Furthermore, the aromatase inhibitor Letrozole decreases levels of estrogen and has also shown promising initial results.

Paradoxically, pregnancy or prolonged treatment with pregnancy levels of estrogen and progesterone (E+P) result in a significant reduction in the susceptibility to breast cancer. In humans, a full term pregnancy at a relatively young age results in approximately a 50% reduced risk of getting breast cancer (51,56). In rodents, a similar response is noted. Exposure to pregnancy levels of estrogen and progesterone for extended periods alters proliferative responses in untreated and carcinogen treated glands (5). Proliferation in the mammary glands of virgin estrogen and progesterone treated animals was overall lower than in untreated animals. Interestingly, the proliferation in ER positive cells was 10 times lower, suggesting that exposure to hormones that mimicked pregnancy altered important signaling pathways in a population with proliferative potential. The carcinogen n-nitroso methyl urea (NMU) induced a much more significant mitogenic response in virgin animals as compared to the hormone treated population. These hormones have also been shown to be the vital agent needed to sensitize p53 in ductal epithelial cells to make them responsive to DNA damage (5,7).

13.2.2.4 Estrogenic Phytochemicals

Epidemiological studies of populations with low versus high risk of breast cancer note that female Asian populations experience a much lower percentage of breast cancer cases (57). This protection is lost once the women relocate to the USA, suggesting that it is a difference in diet which imparts this protection. Analysis of the Asian diet indicates a higher amount of soy is consumed in comparison to a typical North American diet. Interestingly, soy contains significant amounts of estrogenic activity stemming from isoflavone components (specifically genistein and diadzein). Chemoprevention studies in rodents have indicated that soy can delay tumor development, and that administration of either diadzein or soy protein with isoflavones results in some protection (58,59). Genistein has been shown to have a chemopreventative effect on prepubertal rats (60). Besides the antiestrogenic ability of isoflavones, these compounds can enhance the antioxidant enzyme response, inhibit NF-kB and Akt activity, prevent angiogenesis, and reduce levels of IGF-I, ER-α, and PR (61,62).

Additional studies focusing on food benefits have identified a number of phytoestrogens, compounds found in plants that have both agonistic and antagonistic effects on the estrogen receptors. These phytoestrogens include the lignans found in flaxseed, the

coumestans in alfalfa sprouts, and the polyphenolic catechins found in teas (63). Chemopreventative studies in rodents examining phytoestrogens indicate that at high concentrations, these agents can impart protection in the mammary gland, which can be hoped will translate into human chemoprotection.

13.2.3 CYP1A1 and Aryl Hydrocarbon Receptor (AhR)

The CYP1A1 p450 monooxygenase enzyme has recently been identified as a target of chemopreventative strategies. The protoxin dimethylbenz[a]anthracene (DMBA) is metabolized by CYP1A1 (and CYP1B1) into a DNA damaging agent that is a potent initiator of breast cancer (64). The CYP1A1 gene also catalyzes the conversion of estradiol to form hydroxylated estrogen; high estrogen levels are associated with an increased risk of breast and ovarian cancers. The CYP1A1 enzyme is capable of metabolizing arachidonic acid into 19-OH-AA (major product) and 14,15-EET (minor product) (65), but no link between these metabolites and breast cancer initiation or progression has been uncovered. Additionally, CPY1A1 expression is upregulated by a wide array of environmental toxins such as dioxins (most notably TCDD) and polychlorinated biphenyls (PCBs). The CYP1A1 gene is induced by the AhR, which is translocated to the nucleus upon ligand binding to act as a transcription factor. Dioxins act as ligands of AhR to induce expression of a class of genes (including CYP1A1) that possess a dioxin responsive element upstream of the coding sequence. In a screen of 90 vegetable derived compounds that may act as AhR antagonists, 37 were found to block dioxin mediated induction of AhR (16). The aryl hydrocarbon receptor also induces genes that regulate the cell cycle and the antioxidant response, two pathways that affect breast cancer development. Additionally, allelic variation or polymorphisms of the CYP1A1 gene may be correlated with an increased risk of breast cancer. For these reasons, identifying phytochemicals that modulate AhR/CYP1A1 signaling may be of significant value as chemopreventative agents.

The best characterized function of phytochemicals as chemopreventative agents is their role as antioxidants. Such plant derived compounds are divided into distinct classes: phenolics, flavonoids, and phytoalexins. Polyphenols are present at high levels in foods such as olives or olive oil (66) and fresh cut potatoes (67). Several polyphenolics (caffeic acid, syringic acid, and sinapic acid) have been shown to inhibit the growth of the human breast cancer cell line T47D (68). Caffeic acid was the most potent anti proliferative agent in these studies, and was capable of stimulating apoptosis of T47D cells. Induction of the apoptotic program in MCF-7 cells by the phenethyl ester of caffeic acid is mediated by inhibition of the transcription factor NF-κB and activation of Fas by a p53- and p38-dependent mechanism (69). Additionally, caffeic acid was able to bind to AhR antagonistically, and decrease CYP1A1 activity by inhibiting the activation of CYP1A1 transcription (68). Thus, polyphenols like caffeic acid are promising chemopreventative agents with respect to decreasing the likelihood of developing breast cancer.

The flavonoids have also received a great deal of attention for their potential as chemoprotective agents, especially with regards to their proestrogenic and antiestrogenic activity (70). Flavonoids are a diverse class of compounds that can act as either AhR agonists or antagonists, depending on the specific phytochemical and cell type. Focusing on the AhR responsive MCF-7 cell line, four compounds have been identified that act as AhR agonists by their induction of CYP1A1 gene expression: cantharidin (a lactone derived from insect extract); baicalein (an isoflavone that also is an inhibitor of 12-LO); chrysin (a flavonoid); and emodin (an herbal laxative) (71). Additionally, baicalein and emodin increase the protein level of CYP1A1, while baicalein and cantharidin increase the level of AhR protein. However, as dietary components it has not been shown the flavonoids would act as AhR agonists, due to their relatively low serum concentrations (16). Conversely, luteolin acts as a

potent AhR antagonist in MCF-7 cells, while quercetin, kaempferol, and myricetin can act as mild AhR antagonists (71). Genistein and baicalein also are capable of inhibiting the conversion of environmental protoxins (like DMBA) into DNA damaging agents by blocking CYP1A1 activity (72).

Another class of plant derived compounds that modulate AhR/CYP1A1 functions and have potential applications as chemopreventative agents are the phytoalexins. These primarily stress induced compounds can act as antifungal agents in plants, but possess additional activities that make them attractive chemopreventative agents. For example, resveratrol (3,5,4′-trihydroxystilbene) is a polyphenolic phytoalexin found in red wine that has a wide spectrum of inhibitory properties (73). Resveratrol has been shown to induce apoptosis in established human breast cancer cell lines that have wild-type p53 tumor suppressor protein but not mutant p53 (46). In addition to its ability to inhibit cyclooxygenases, resveratrol is a competitive antagonist of AhR that causes nuclear translocation of AhR but does not induce CYP1A1 (74). Thus, resveratrol may act to prevent cancer initiation by inhibiting signaling through AhR and blocking the upregulation of CYP1A1.

In addition to these phytochemicals, other plant derived compounds affect the expression and activity of CYP1A1. Curcumin, a major component of the spice turmeric, binds to and activates AhR and can bind to the xenobiotic response element upstream of CYP1A1(75). However, several studies suggest that curcumin partially blocks DMBA induced CYP1A1 activity, as well as the conversion of procarcinogens into DNA damaging agents in breast and squamous cell carcinoma cells (75,76), and *in vitro* (77). Curcumin also inhibits 5-HETE (78) and prostaglandin formation (79), and has antioxidant properties; thus, its role as a tumor repressor or chemopreventative agent may be due to its effects on more than one single pathway. Indole-3-carbinol (derived from cruciferous vegetables) is also antitumorigenic, likely resulting from its ability to inhibit the activity of CYP1A1, blocking the hydroxylation of estradiol and resulting in the repression of estrogen signaling.

13.2.4 Growth Factor Signaling

13.2.4.1 Background

Growth factors are very important in the normal and malignant development of the mammary gland, and include epidermal growth factor (EGF), platelet derived growth factor (PDGF), hepatocyte growth factor (HGF), amphiregulin (AR), insulin-like growth factor (IGF), vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), transforming growth factor alpha (TGF-α), and transforming growth factor beta (TGF-β). These factors have diverse effects and work on different cell types, but ultimately their activities (in concert with hormones and other factors) regulate the architecture of the mammary gland. These growth factors bind receptor kinases on the surface of the plasma membrane. The deregulated expression or activity of these receptors often results in a susceptibility to breast cancer. Among them, EGF, IGF, TGF-β, and VEGF are particularly interesting with regards to chemoprevention due to their ability to regulate homeostasis in the mammary gland.

13.2.4.2 Epidermal Growth Factor (EGF)

Epidermal growth factor is secreted from cells and can act in an autocrine or paracrine fashion. Epidermal growth factor is one of approximately ten ligands (including amphiregulin and TGF-α) that bind to and activate a family of EGF receptors (HER1, 2, 3, and 4) found on the surface of the epithelial cells. These receptors are tyrosine kinases and play a strong role in the proliferation and differentiation of the mammary gland. The EGFR and HER-2 receptors are frequently upregulated or activated in breast cancer. New advances in

breast cancer treatments of ER negative tumors target this family of receptors. Herceptin (Trastuzumab) is a humanized antibody to the HER-2 receptor which has been found to be successful in clinical trials of patients with very high expression of HER-2 (80,81).

Numerous dietary phytochemicals have been identified that can inhibit EGFR or HER-2/neu signaling. Typically these agents do not block the binding of the ligand to the receptor, but instead inhibit the autophosphorylation of the receptor and downstream signaling. Flaxseed has been shown to down regulate EGF receptor levels (82). Curcumin can inhibit EGFR activity and proliferation in A431 epidermoid carcinoma cells (83). Phase 1 clinical trials indicate curcumin is nontoxic up to 8 g/day, and patients with precancerous growths often saw stability of the disease or a histological improvement (84) with this curcumin regimen. However, trials with higher numbers of patients are needed.

Black and green teas have also been shown to have constituents which will decrease EGFR activity. Epigallocatechin-3-gallate (EGCG) or theaflavin-3,3′-digallate (TF-3) in particular can inhibit the autophosphorylation of the EGF receptor and inhibit proliferation. EGCG in prolonged treatment could enhance the apoptotic response by upregulating p53 (85), while TF-3 was better at blocking the binding of EGF to its receptor (86). Fruit derived anthocyanidins are structurally similar to EGCG and can also inhibit EGF receptor activation in A431 epidermoid carcinomas cells. Cyanidin and delphinidin have been shown to inhibit growth and block MAPK phosphorylation of ELK, and in turn inhibit EGF induced transcription though the ELK transcription factor (87).

13.2.4.3 Insulin-Like Growth Factor (IGF)

Insulin-like growth factor is a mitogen and a prosurvival factor which can act through autocrine and paracrine pathways. Signaling through the IGF axis is highly regulated at numerous levels, including expression of the IGF receptor (IGFR), the regulation of IGF binding protein (IGFBP) expression (which modulate the ability of IGF to bind to and activate receptors), regulation of IGFR autophosphorylation, and transmission of downstream signals through insulin receptor substrate-1 (IRS-1). The activation of the IGF receptor results in phosphorylation and activation of IRS, which in turn signals to the nucleus. The inositol triphosphate kinase (PI3k) pathway is one of the major pathways elicited by IGF in mammary epithelial cells.

Production of IGF occurs both systemically and locally. Growth hormone regulates the levels of IGF generated by the liver, the major site of IGF production. Increased serum levels of IGF are critical for the proper maintenance of terminal end bud structures in the mammary gland. The role of IGF in prevention of or susceptibility to breast cancer stems largely from correlative evidence in human studies and direct evidence in rodent studies. Epidemiological studies analyzing possible roles for IGF in breast cancer have indicated that premenopausal women with serum IGF levels in the highest quartile have an increased incidence of breast cancer. Conversely, well established protective therapies such as tamoxifen, fenretinide, and caloric restriction are associated with a decrease in IGF serum levels. However, the most convincing evidence that high IGF levels and signaling may be related to breast cancer is obtained from genetically defined rodent models with alterations in the IGF signaling pathway. Mice overexpressing IGF-I are sensitized to TPA induced tumor development (88). Mice that have a 25% reduction in serum IGF levels have a significantly delayed onset of breast tumor occurrence and a reduction in the number of tumors induced by C3(1)/SV40-LTA or in response to DMBA treatment (89). Interestingly, the reduced levels of IGF had no effect on the levels of hyperplasia induced in these models, but a significant difference in metaplasia, suggesting that the serum levels of IGF affect the progression, rather than the initiation, of breast cancer. Serum IGF levels also

appeared to affect the growth of the tumors, as differences in tumor size were noted, especially in the early weeks after tumor detection (89).

The mechanism by which IGF predisposes mammary epithelial cells to tumorigenesis is unknown, but studies on various cell types indicate that signaling through this pathway counteracts most of the pathways important for the protective response. IGF has been shown to activate the PI3k pathway, which often leads to survival by activating Akt and NF-kB, or by phosphorylating and activating MDM2, which will degrade or sequester p53 in the cytoplasm (90). The PI3k pathway also can regulate the expression and localization of β-catenin, which will activate TCF/LEF signaling. In renal mesangial cells and colon carcinoma cells, IGF enhances cyclooxygenase activity (91,92). In certain cell types IGF has also been shown to down regulate the level of the progesterone receptor and TGF-β (22), suggesting pathways by which IGF might upset the balance of homeostasis. Furthermore, IGF has been shown to upregulate telomerase activity (93). Cancer cells have higher telomerase activity, which allows a bypass of naturally occurring senescence that limits the number of cell division cycles. Agents that inhibit telomerase thus represent a new potential target for cancer therapy.

Known chemopreventative agents appear to regulate IGF signaling at multiple levels. Retinoic acid (RA) inhibits growth of the MCF-7 breast cancer cells through inhibition of IRS and PI3k signaling (94), which in turn regulates c-fos expression (83). Retinoic acid also induces the secretion of IGFBPs in a cultured cancer cell line (95), which decreases the serum level of IGF-I. Data also suggests that in normal mammary epithelial cells RA will upregulate other binding proteins, such as IGFBP7 (96). Inhibitors of cyclooxygenase activity also upregulate IGFBP3 in immortalized breast epithelial cells, and tamoxifen and TGF-β inhibit the IGFBP3 protease to stabilize IGFBP3 in MCF-7 cells. In addition to decreasing plasma levels of IGF-I and upregulating IGFBP3, tamoxifen also decreases the levels of IRS-1 and Akt signaling in MCF-7 cells (97).

Dietary phytochemicals aimed at reducing IGF signaling have only recently been utilized in human chemoprevention. Flaxseed can inhibit growth of mammary tumors in rats, and has recently found favor in humans to prevent breast cancer. In addition to its antiestrogenic activity, flaxseed can inhibit IGF-I plasma levels in rats and IGF receptor levels in breast cancer cells (82,98). In prostate cancer cells genistein, biochaninA, quercetin, and kaempferol downregulated the activity and reduced phosphorylation of IRS as well as downstream Akt (99). In a different prostate cancer cell line black tea phenolics were also shown to reduce IGF signaling by decreasing the phosphorylation of the IGFR-I and Akt (100).

13.2.4.4 Transforming Growth Factor Beta (TGF-β)

The TGF-β growth factor is a cytokine with growth inhibitory properties for many cell types, including epithelial cells. Numerous members of the TGF-β family exist, with TGF-β1, 2, and 3 the most studied. Other family members include activin, BMP, and the more distantly related NAG-1 (also known as MIC-1, PLAB, PTGF-β, or GDF15). The three main forms of TGF-β have some overlapping properties and specific roles, and are expressed in response to different stimuli. All three (TGF-β 1, 2, and 3) are upregulated during involution, but TGF-β 3 expression is increased to the highest extent (101). Furthermore, mammary gland tissue from mice null for TGF-β 3 display a significant inhibition of involution, suggesting that this form is responsible for the apoptosis that occurs after weaning (102). The TGF-β growth factor is secreted in a latent form as part of a complex with other proteins, and is retained as such in the extracellular matrix until activation. Proteolytic cleavage is required to release the active form of TGF-β, and occurs in the mammary gland in response to estrogen and progesterone,

as well as radiation(103,104). The active form of TGF-β then binds to one of three types of TGF-β receptors which either heterodimerize or homodimerize. Some receptors have higher affinities for particular TGF-β subtypes and some transduce signals more efficiently. Type I and type II receptors have cytoplasmic serine or threonine kinase domains responsible for downstream signaling events.

Cytokines of TGF-β are required for the normal development of the mammary gland. They are expressed at high levels in the stroma and can act in a paracrine fashion to control the growth and branching of ductal epithelium. Animal studies have also indicated that they have a role in regulating lobular alveolar development and involution. Pregnancy has been shown to upregulate the transcription of all three TGF-β isoforms. In rats, TGF-β 2 is increased late in pregnancy, and TGF-β 3 increases with milk stasis induced by weaning. Interestingly, TGF-β 3 remains at relatively high levels even after weaning, and is one of the few differences observed between the glands of virgin and parous females (9).

The loss of the TGF-β antiproliferative response is observed in many cases of breast cancer and appears to be an early hallmark of the immortalization of cells in culture. Intriguingly, the expression of TGF-β in tumor cells increases while the levels of TGF-β receptors are decreased. However, the lack of responsivity may be due to defects at multiple levels, such as loss of SMADs, mutation of receptors, or loss of other cooperative factors needed for growth arrest. Genetic manipulation of the genes encoding TGF-β and its receptor has demonstrated that modulation of this complex pathway within the mammary gland can impact the balance between a protective or susceptible phenotype. A constitutively active form of TGF-β crossed onto a mouse which has a TGF-α oncogene reduces breast cancer development (105). In mice that overexpress a dominant negative type II TGF-β receptor in the mammary gland, there is increased susceptibility to breast tumor development (21,106). These experiments suggest that properly regulated TGF-β can function as a tumor suppressor in the mammary gland.

Numerous chemopreventative agents regulate TGF-β expression. Natural and synthetic retinoids will induce TGF-β 1 or 2 in a number of cell types (107–109). Retinoic acid and tamoxifen will increase the expression of latent TGF binding proteins (LTBPs) (110). Tamoxifen upregulates the expression of TGF-β 2 (111,112) and activates TGF-β 1 in MCF-7 cells (113–115). The upregulation of TGF-β family members may be responsible for controlling the proliferation in response to growth factors and hormones, and may play a role in regulating cell death in response to ionizing radiation. Death by ionizing radiation requires TGF-β in concert with p53. It is also known that TGF-β inhibits telomerase activity (116).

The activation of TGF-β by dietary phytochemicals (such as perillyl alcohol) has been observed in mammary carcinomas (117). In addition, NAG-1 (NSAID activated gene) is a newly identified and more distant relative of TGF-β that is currently receiving significant attention. The NAG-1 gene was first identified as a factor that is expressed at high levels in the placenta, prostate, and brain(118,119); and is synthesized as a latent proenyzme which is cleaved to generate a 28kDa active form. Like other members of the TGF-β family, NAG-1 can inhibit tumor development and activate apoptosis. The upregulation of the NAG-1 protein is controlled by at least two different pathways: a p53-independent mechanism, which stabilizes Nag-1 RNA; or a p53-dependent transcriptional increase in expression. Expression of Nag-1 is induced by known chemopreventative agents like NSAIDs (120,121) and retinoids (122), but has also been shown to be upregulated by dietary phytochemicals such as diallyl disulfide, genistein, and resveratrol (120,121,123). These agents appear to induce NAG-1 through the p53-dependent mechanism. The role of NAG-1 in protection of the mammary gland is still under investigation, and its growth inhibitory and proapoptotic properties make it worthy of further study.

13.2.4.5 Vascular Endothelial Growth Factor (VEGF)

Oxygen is required for the sustained growth of tumors, and is delivered by an induced and directed growth of vascular tissue. Angiogenesis of tumors is controlled primarily by the tumor and growth factors released from the stoma, most notably VEGF and FGF. Vascular endothelial growth factor has been found to be released by breast tumor cells, and its expression is regulated by IGF, as well as by products of cyclooxygenase and lipoxygenase. In a synergistic fashion with FGF, VEGF binds receptors on the endothelial cells and stimulates growth and neovascularization. The targeting of angiogenesis has become a major focus of cancer research. In animal models significant inhibition of tumor development is observed; however, these results have not yet translated as successfully in human studies. Inhibitors that block VEGFR signaling (Neovastat), as well as monoclonal antibodies to VEGF are being examined. Drugs are also being developed that resemble endogenous angiogenesis inhibitors such as endostatin and angiostatin.

Phytochemicals may provide a partial defense against angiogenesis. Green tea, flaxseed, and numerous berry extracts decrease the expression of inducible VEGF. Green tea (in particular epigallocatechin gallate (EGCG) has been extensively studied in numerous cell types including the MDA-MB-231 breast cancer cell line, which constitutively expresses high levels of VEGF(124,125). EGCG ultimately blocks VEGF expression through the inhibition of the EGF receptor, which regulates NF-κB and STAT-3, two signaling proteins which have been demonstrated to impact the VEGF promoter. Green tea catechins in endothelial cell lines also appear to block VEGF induced tubule formation through the regulation of VE-cadherin and the inhibition of Akt activity (126). Fruits such as *Gleditsia sinensis* effectively control VEGF in the MDA-MB-231 breast cancer cell line (127), and other berries (cranberry, raspberry, strawberry, blueberry, elderberry, and bilberry) appear to significantly reduce VEGF expression in HaCaT cells (128). While most of the studies looking at phytochemical reduction of VEGF have used cell lines, a flaxseed study corroborated these findings *in vivo*. A diet that was supplemented with flaxseed reduced tumor formation in a breast cancer xenograft model and decreased the expression of VEGF (129).

13.2.5 Arachidonic Acid Metabolism

13.2.5.1 Background

Arachidonic acid and its metabolites play key roles in cell growth, signaling, and adhesion, and are key mediators of the inflammatory and immune responses. Arachidonic acid is released from plasma membrane phospholipids (i.e., phosphatidylcholine) by phospholipase A_2, where it can serve as a signaling molecule (autocrine or paracrine), or alternatively be metabolized by the monooxygenase (MO), lipoxygenase (LO), or cyclooxygenase (COX) enzymes. Natural product and pharmacological inhibitors of AA metabolism have been successfully employed to inhibit cell proliferation, transformation, and migration. Additionally, human breast cancer tissues overexpress 12-lipoxygenase and cyclooxygenase-2 (26). Thus, phytochemicals blocking AA and its metabolites offer great promise in chemopreventative strategies against a variety of cancers, including breast cancer (130,131). The COX and LO branches of AA metabolism are discussed in the following, and plant derived agents that block each of these pathways are presented.

13.2.5.2 Cyclooxygenase (COX)

Arachidonic acid can be metabolized by cyclooxygenase (COX) to produce prostaglandins (PGs), thromboxanes (TXs), and prostacyclins. These prostanoids have physiological roles in reproduction, pain response, fever, cell growth, and inflammation (23). There is much

interest in prostaglandin E_2 (PGE_2), which is a potent mediator of the inflammatory response. PG synthesis can be achieved by two functionally distinct isoforms of cyclooxygenase: COX-1 and COX-2. Cyclooxygenase-1 is generally regarded as a constitutively expressed housekeeping gene used to synthesize PGs for necessary, routine functions, and is present in most cell types. In contrast, COX-2 is normally expressed only when induced by growth factors, cytokines, or upon viral transformation as an immediate early gene (132). Upregulation of COX-2 activity increases PGE_2 levels, which acts as a signaling molecule in an autocrine or paracrine manner to stimulate cell proliferation.

Constitutive expression of COX-2 (but not COX-1) and high PGE_2 levels have been detected in a variety of epithelial derived tumors, including cancers of the breast, colon, esophagus, and skin (23), and in human breast cancer cell lines (133). Several lines of evidence suggest that COX-2 overexpression may be important in breast cancer initiation. Cyclooxygenase-2 was typically overexpressed in invasive carcinomas (134), in adjacent DCIS (134,135), and in normal epithelium surrounding DCIS (135). Overexpression of COX-2 was sufficient to cause tumorigenesis in mice (136). Additionally, COX-2 overexpression was found to correlate with markers for premalignant breast cell transformation (137), and may be of prognostic significance in patient outcome (24,25). Prostaglandin E_2 has also been shown to be required for cell migration and metastasis by signaling through cAMP dependent protein kinase (PKA) (138,139), and along with TXA_2 and PGI_2 is involved in angiogenesis to supply blood to established tumors (140,141). Many oncogenes also stimulate COX-2 expression, including HER-2/neu (142), which directs EGF signaling leading to cell proliferation. Recently it has been determined that PGE_2 increases the expression of HER-2/neu, indicating that a positive loop drives overexpression of both genes in breast tumors (143). Increased COX-2 activity also has been shown to lead to a decrease in apoptosis, primarily through upregulation of the antiapoptotic factor Bcl-2 (144). The tumor suppressor protein p53 has also been shown to down regulate COX-2 expression (145). Thus, inhibition of COX-2 activity may serve to decrease breast tumor initiation and development.

The relationship between COX inhibition and cancer was first noted when links between frequent use of nonsteroidal antiinflammatory drugs (NSAIDs) that block COX activity, and decreased colon cancer incidence were identified (146). However, many of the first generation COX inhibitors used to treat pain and inflammation (e.g., aspirin, indomethacin) are nonselective; i.e., the activity of both COX isoforms are blocked, leading to many undesirable side effects, most frequently gastrointestinal discomfort or bleeding (23). Currently, there are many pharmacological selective COX-2 inhibitors (e.g., celeCOXib, SC-236, NS-398) available that possess potent antiinflammatory properties, lower colon cancer incidence when used regularly, and have greatly reduced side effects. There are many reported studies of NSAID use and breast cancer (147), most recently linking aspirin use to a reduced risk of hormone receptor positive breast cancer (148). However, more clinical studies are required to conclusively establish the use of aspirin or other NSAIDs in breast cancer chemoprevention.

Several scientific studies have demonstrated that inhibition of COX-2 activity and PGE_2 secretion may offer promise in breast cancer prevention and treatment. Using established human breast cell lines, indomethacin (nonselective COX inhibitor) is capable of inhibiting the proliferation of MCF-7 and MDA-MB-231 cancer cells and of normal human mammary epithelial cells (HMEC) (149,150). Treatment with the selective COX-2 inhibitor NS-398 was capable of inducing apoptosis in MDA-MB-231 cells (151). Treatment with NS-398 also increased sensitivity to radiation in COX-2 expressing rat intestinal epithelial cells (152). These scientific studies indicate a potential role may exist for COX-2 inhibitors in chemoprevention of breast cancer.

In addition to these pharmacological inhibitors of COX, many phytochemicals are capable of blocking COX activity. The best studied plant derived compound that inhibits COX is the phytoalexin polyphenol resveratrol, found in red wine, peanuts, and many herbs. Resveratrol induces growth arrest and apoptosis in several human cancer cell lines, including the breast cancer line MCF-7 (153). Treatment of mouse mammary glands with resveratrol inhibited the development of preneoplastic lesions (154), thus demonstrating resveratrol has chemopreventative functionality. Most of the initial research indicated that resveratrol was selective for inhibiting COX-1; however, it has since been shown in mammary epithelial cells to inhibit the both the expression and the activity of COX-2 (155,156). Resveratrol likely blocks COX-2 expression by a protein kinase C-dependent mechanism (155).

Several other phytochemicals have demonstrated the ability to inhibit COX-2 transcription and activity. Curcumin (a significant component of turmeric) prevents lipopolysaccharide and phorbol ester mediated upregulation of COX-2 gene expression, likely by blocking signaling through extracellular signal regulated kinase (ERK) and decreasing NF-κB and activator protein 1 (AP-1) binding to the COX-2 promoter (157,158). Curcumin also directly inhibits the enzymatic activity of COX-2 (159), indicating that curcumin acts on multiple levels to decrease PGE_2 levels. The phytochemical baicalein (flavone isolated from the roots of *Scutellaria baicalensis* that is also a 12-lipoxygenase selective inhibitor) is capable of inhibiting both cell growth and the production of PGE_2 in breast and prostate cancer cell lines (160). Additionally, various flavonoids such as EGCG (green tea) and apigenin (vegetables and fruits) block COX-2 gene expression by suppressing NF-κB (161).

13.2.5.3 Lipoxygenase (LO)

Three main branches of the lipoxygenase pathway give rise to specific products of AA, including leukotrienes (LTs) and hydroxyeicosatetraenonic acids (HETEs). Arachidonic acid can be metabolized by 5-lipoxygenase (5-LO) to LTs (key mediators of asthma and anaphylactic shock) or 5-HETE. 12-LO converts AA into 12-HETE. Metabolism of AA by 15-LO generates 15-HETE, which acts as a ligand for the growth controlling nuclear receptor PPARγ (162). Both 5-HETE and 12-HETE act as a mitogen to cultured breast and prostate cancer cells (163). Interestingly, studies with colon cancer cells indicate that unlike 5-LO and 12-LO, 15-LO activity is antiproliferative (164). Tissue samples taken from breast cancer patients indeed show that 15-LO expression is decreased in tissues taken from patients with breast cancer as compared to paired normal tissues. Therefore, the application of phytochemicals that block the activities of 5-LO or 12-LO or both in combination may be useful in the treatment of several cancers, including breast cancer. While 15-LO activity can be blocked by several flavonoids such as luteolin (165), the antiproliferative activity of this enzyme makes inhibition undesirable.

Increased metabolism of AA to 5-HETE by 5-LO has been observed in a variety of cancers (166), and overexpression of 5-LO in cancerous breast tissue has been correlated with poor clinical outcomes in patients with breast cancer (26). Application of exogenous 5-HETE to the breast cancer cell lines MCF-7 and MDA-MB-231 increased cell proliferation (167). Accordingly, treatment of these cell lines with the 5-LO inhibitor Rev-9501 induced apoptotic events, such as cytochrome *c* release and decreasing levels of antiapoptotic proteins. Several researchers have attempted to identify the signal pathways utilized by which 5-HETE exerts its mitogenic effect. In pancreatic cancer cell lines, 5-HETE was shown to induce tyrosine phosphorylation, and work through Erk and Akt to induce cell proliferation (168). Many pharmacological inhibitors of 5-LO activity exist (e.g., AA-861, MK-866, and the antiallergenic drugs montelukast, zafirlukast, and zileuton), but are not

used for cancer chemoprevention. Natural phytochemicals that selectively inhibit 5-LO include the COX and CYP1A1 inhibitor curcumin (78), the prenylated flavanones sigmoidins A and B (isolated from *Erythrina sigmoidea hua*) (169), the dual 5-LO/12-LO inhibitor 2-(3,4-dihydroxyphenyl)ethanol from olive extracts (170) and hyperforin, a lipophilic component of *Hypericum perforatum* (St. John's wort) extract (171).

When normal breast tissue was compared to lobular and ductal carcinomas taken from the same sets of patients, cancerous tissues exhibited increased expression of 12-LO. Additionally, prognostic value of relating clinical outcome with the degree of increased 12-LO expression existed, where higher mortality rates were directly correlated with higher overexpression of 12-LO (26). Baicalein is a potent and selective inhibitor of 12-LO activity, and inhibits proliferation and induces apoptosis in MCF-7 and MDA-MB-231 cells, two well established breast cancer cell lines (160,167). Additionally, baicalein may be antiestrogenic in ER-alpha expressing MCF-7 cells and better at inducing apoptosis than the soy isoflavone genistein (172). Expression of 12-LO and levels of 12-HETE increase with progression of prostate cancer, and a similar correlation may also exist for breast cancer. Therefore, the use of baicalein as a chemopreventative agent against the development and progression of breast cancer may be of significant value as it inhibits both 12-LO and COX-2, two enzymes upregulated in breast cancer.

13.3 STRATEGIES FOR PHYTOCHEMICAL ENRICHMENT FOR CHEMOPREVENTION

13.3.1 Consistency of Phytochemicals

The major challenge in developing and characterizing phytochemicals for chemopreventative applications lies in the inconsistency of phytochemicals from botanicals. Additionally, in many cases a whole extract or food phytochemical profile provides more effective protection than individual phytochemicals in the profile. Soybeans are an example of this complication. Epidemiological studies have associated high soy intake with a reduced risk for certain types of cancer (173). Soybeans are a rich source of phenolic antioxidants known as isoflavonoids. The functionally active isoflavonoid found in soybeans is genistein, which has weak estrogenic activity that appears to antagonize the action of estradiol at the estrogen receptor in breast cells, and thus may protect against breast cancer development (174,175). While the chemopreventative properties of purified and synthetic genistein have been demonstrated (58,61,176–178), recent research has shown that fermented soy products performed better at reducing incidence of mammary tumor risk as compared to a similar mixture of soy constituent isoflavonoids (179). This suggests that the food background may play a positive role in the chemopreventative actions of its resident isoflavonoids (particularly genistein). The challenge posed by inconsistency of phytochemicals is even greater in highly cross pollinating botanical species, such as those belonging to *Lamiaceae*. These species are the source of rosmarinic acid (180), which in proper phenolic profiles has chemopreventative potential through inhibition of COX (181). However, each extract is likely to vary in content from source to source and batch to batch (180).

Development of consistent and optimized phytochemicals and whole extract profiles is critical for consistent dosage that is clinically relevant and safe for chemoprevention. Attempts to address this need include the development of approaches such as clonal screening from heterogeneous botanical sources, elicitor and stress induced sprouting of phytochemicals from seedlings, solid-state and liquid bioprocessing and fermentation of botanical extracts. By combining various optimized dietary phytochemicals, synergistic enhancement of chemoprevention can also be attempted.

13.3.2 Clonal Screening of Phytochemicals from a Heterogeneous Genetic Background

Rosmarinic acid is a phenolic biphenyl found in several species in the family *Lamiaceae* with many pharmacological effects. Rosmarinic acid inhibits several complement dependent inflammatory processes and thus has potential as a therapeutic agent for control of complement activation diseases (182,183). Rosmarinic acid has been reported to have effects on both the classical C3-convertase and on the cobra venom factor and ovalbumin and antiovalbumn mediated passive cutaneous anaphylaxis (182). Recent research has indicated other benefits of rosmarinic acid containing *Perilla frutescens* on the reduction of lipopolysaccharide (LPS)-induced liver injury in D-galactosamine sensitized mice (184). Additional evidence suggests that rosmarinic acid inhibits COX (181), and therefore represents a good candidate for chemoprevention of oxidation linked diseases, including cancer.

High rosmarinic acid producing, shoot based clonal lines originating from a single heterozygous seed amongst a heterogeneous bulk seed population of oregano, rosemary, lavender, spearmint, and thyme have been isolated. These lines were screened based upon tolerance to the proline analog A2C and a novel *Pseudomonas* species isolated from oregano (185–187). This strategy for screening and selection of high rosmarinic acid clonal lines is additionally based on the model that the proline linked pentose phosphate pathway is critical for driving metabolic flux (i.e., E4P) toward the shikimate and phenylpropanoid pathways (188). Any clonal line with a deregulated proline synthesis pathway should have increased pentose phosphate pathway activity, which would allow excess metabolic flux to drive the shikimate and phenylpropanoid pathways toward total phenolic and rosmarinic acid synthesis. This model hypothesizes that the same metabolic flux from increased activity of the proline linked pentose phosphate pathway also regulates the interconversion of ribose-5-phosphate to E4P, driving the shikimate pathway. Shikimate pathway flux is critical for both auxin and phenylpropanoid biosynthesis, including rosmarinic acid. High rosmarinic acid producing clonal lines selected by these approaches (185,186,189–191) are being targeted to produce consistent dietary phenolic phytochemicals from cross pollinating, heterogeneous species for functional foods and for chemoprevention strategies (180,191).

13.3.3 Stress and Elicitor Induced Sprouting

In many legumes such as soy (192), pea (193), fava bean (194), mung bean (195) and fenugreek (196), sprouting in combination with biological, chemical, and physical stress linked elicitation can stimulate phytochemicals relevant in chemoprevention. Preliminary results have provided empirical evidence for a link between proline biosynthesis and oxidation, as well as stimulation of G6PDH during phenolic phytochemical synthesis (180,188,197–199). In light mediated sprout studies in peas (*Pisum sativum)*, acetylsalicylic acid in combination with fish protein hydrolysates (a potential source of proline precursors) stimulated phenolic content and guaiacol peroxidase (GPX) activity during early germination, with corresponding higher levels of proline and G6PDH activity (200). In other light mediated studies in peas, low pH and salicylic acid treatments stimulated increased phenolic content and tissue rigidity, with concomitant stimulation of G6PDH and proline (199). This work supports the hypothesis that pentose phosphate pathway stimulation may be linked to proline biosynthesis, and that modulation of a proton linked redox cycle may also be operating through the proline linked pentose phosphate pathway. In dark germinated studies in peas, high cytokinin containing anise root extracts stimulated phenolic content and antioxidant activity, which correlated directly with increased proline content but inversely with G6PDH activity (193).

In dark germination studies in mung bean (*Vigna radiata*), dietary grade microbial polysaccharide, oregano phenolics and peptide elicitor treatments stimulated phenolic

content and G6PDH and GPX enzyme activities compared to controls (193,195,201,202) with concomitant stimulation of proline content. In addition, specific elicitors xanthan gum, oregano phenolics, yeast extract, and yeast glucan stimulated antioxidant activity. The hypothesis that stimulation of proline linked pentose phosphate pathway would stimulate phenolic metabolism under elicitor and stress response was tested using dark germinated fava bean. In polysaccharide elicitor studies, gellan gum stimulated fava bean total phenolic content by ninefold in late stages of germination with a corresponding increase in proline content and GPX activity. However, the effect on antioxidant and G6PDH activity was inconclusive (203). In the same fava bean system, UV mediated stimulation of phenolic content in dark germinated fava bean sprouts indicated a positive correlation to G6PDH and GPX activities with a concomitant increase in proline content (204). It was further confirmed that the proline analog A2C also stimulated phenolic content in fava bean, with positive correlation to G6PDH and GPX activities as well as proline content (205). Similar to studies in clonal shoot cultures of thyme (197) and oregano (198), the proline analog mediated studies in fava bean confirmed that proline overexpression was not only possible, but involved stimulating G6PDH, and therefore likely diverted the pentose phosphate pathway toward phenylpropanoid biosynthesis. The late stage stimulation of phenolic content and GPX activity in response to microwave mediated thermal stress in dark germinated fava bean strongly correlated with stimulation of free radical scavenging activity of free phenolics as measured by the quenching of 1,1-diphenyl-2-picrylhydrazyl (DPPH) and stimulation of SOD activity (202). Recent studies have extended this concept of elicitor induced stimulation to fenugreek (196). These strategies and insights have allowed the development of a technology platform where stress induced elicitation can be used to capture and optimize the production of phytochemicals with chemopreventative potential in germinating seeds, which would not be otherwise possible. This approach could theoretically capture protective phytochemical profiles that are specifically produced under stress to protect the emerging young embryo and seedling, at a stage when respiration and oxidation stress during the sprouting process is high.

13.3.4 Solid-State Bioprocessing

Solid-state bioprocessing using dietary microbial systems under minimal water conditions has been used for over 2000 years in many parts of the world to develop specific foodstuffs such as soy based products like tempeh in Indonesia, tofu and related foods in East Asia, several legume products in India and cheese in Europe (206,207). In the context of chemoprevention, enhanced isoflavonoid content in soybean and soybean meal following bioprocessing by *Aspergillus* species has been reported (208,209). Dietary fungal bioprocessing of fruit and legume substrates to enrich aglycone phenolic antioxidants such as ellagic acid (cranberry), isoflavonoids (soybean) and L-DOPA (fava bean) have been similarly developed (210–215). Critical microbial enzymes that are involved in the optimal release of these phenolic phytochemicals have recently been identified (194,215–217). A better understanding of growth and enzyme regulation during phenolic phytochemical mobilization and release would help to optimize the desired phytochemical profile with maximum chemopreventative potential. In noncancer related chemoprevention investigations, results indicate that cranberry and soybean bioprocessing by solid-state methods not only stimulated free radical scavenging antioxidant activity, but also increased phenolic content in specific stages and inhibited foodborne pathogens (217–219) and the ulcer associated *Helicobacter pylori* (217,219). Such extracts are now being targeted for breast cancer chemoprevention and diabetes through modulation of the antioxidant enzyme response (207,220).

13.3.5 Liquid Fermentation

Recent research has shown that fermented soymilk performed better at reducing incidence of mammary tumor risk than a similar mixture of its constituent isoflavonoids, suggesting that the food background may play a positive role in the chemopreventative actions of soy based products (179). Fermented soymilk is rich in phenolic aglycones (which are more active and more readily taken up than their (β–glycosides), thus increasing the free phenolic content of soy based food through microbial bioprocessing may positively affect its medicinal and nutritional value (221–224). The role of lignin degrading enzymes in phenolic antioxidant mobilization during yogurt production from soymilk by active probiotic kefir cultures was investigated (225). Total soluble phenolic content and free radical scavenging antioxidant activity were measured every 8 hours for a 48 hour period. The activity of several enzymes (β-glucosidase, laccase, and peroxidase) associated with the microbial degradation of polymeric phenolics and lignin and previously linked to phenolic mobilization from soybean during solid-state bioprocessing by dietary fungi were also investigated. Soluble phenolic content initially increased with culture time and was strongly correlated to total peroxidase and laccase activity. However, phenolic content dropped sharply at 48 hours. Antioxidant activity increased with culture time and was strongly correlated to decreased soluble phenolic content over the same time period. This research has important implications for the optimization of functional phytochemicals in commercial soymilk based yogurts, which can be targeted for chemoprevention strategies (225).

2.14

Biotechnology in Wine Industry

Moustapha Oke, Gopinadhan Paliyath, and K. Helen Fisher

CONTENTS

14.1 INTRODUCTION

Wine is a product of the alcoholic fermentation of grape juice, which is stored in a manner to retain its wine like properties (1). Clear evidence of winemaking dates from 5000 years ago, although archaeological records on wine date back to 6000 B.C. (2,3). It is believed that winemaking technology was first developed in Caucasia (currently part of Turkey, Iraq, Azerbaijan, and Georgia). The domestication of the commercial grape cultivar *Vitis vinifera* is also assumed to have originated in the same area (4). Some researchers believe

that domestication of grapes may have independently occurred in Spain (5). From Caucasia, grape growing and winemaking spread toward Palestine, Syria, Egypt, Mesopotamia, and around the Mediterranean. In southern Spain however, there is evidence that extensive grape cultivation existed before the colonization of the region by the Phoenicians (6). It is not until the seventeenth century that modern winemaking technology became established. The quality of the wine was improved by the use of sulphur in barrels, glass bottles, and corks.

The grape growing regions of the world are located between 10°C and 20°C isotherms, (lines drawn around the earth connecting the average yearly temperatures). It is also possible to grow grapes in cooler and subtropical regions, but on those regions viticultural practices are limited because of less than ideal conditions. Currently, grapes are important fresh fruit crops globally, with production reaching over 60 million metric tons (second only to bananas, with a production level of 68.6 million metric tons in 2001) (7). Italy, France, and Spain produced more than 35% of the total world production of grapes. More than 80% of the grapes grown each year are fermented, and the rest are used for fresh consumption or dried for raisins. World wine production has varied from 250 to 330 million hectolitres since 1970, with the production level reaching 282 million hectolitres in 2001. Italy, France, and Spain produce about 50% of the world's wine. Other major wine producers include the USA, Argentina, South Africa, Germany, Australia, Portugal, and Chile.

Wine consumption varies in different regions of the world. Wine consumers are found primarily in European countries. For centuries, wine has been an integral part of daily regional food consumption and an important source of calories. The political conditions and religious beliefs of certain regions, and alcohol abuse in other countries, have resulted in increased restriction in alcohol consumption. It has long been accepted that excessive alcohol consumption is detrimental to human health, although recent studies support the beneficial effects of moderate wine drinking (8,9). There has been a noticeable decline in world wine consumption due possibly to the shift toward the use of less, but better quality, wine. The production of high quality wines involves the use of excellent quality grapes, and of ideal strains of yeasts called superyeasts. The objective of this chapter is to evaluate the current technologies for improving wine quality.

14.2 GRAPE CULTIVARS AND WINE TYPES

There is no unanimous classification for grapevine cultivars even though there are nearly 15,000 of them. Growers in France use ecogeographic associations based on ampelographic (structural) and physiological properties of grapes, while others use aroma profiles to assess the relationship between cultivars (10). Numerical taxonomy is another way of classifying grapevine cultivars (11). The common disadvantage of these methods is the subjectivity of data interpretation. Grouping of cultivars based on evolutionary evidence may be obtained using modern techniques such as DNA fingerprinting (restriction fragment length polymorphisms and amplified fragment length polymorphisms -RFLP and AFLP) (12). The application of microsatellite (SSR) markers is now available to *Vitis* species (13–18). Raisins and grape berries have been typed by microsatellites (19,20), and clonal line diversity has been investigated with such markers (21,22). Many authors have evaluated these markers for cultivar identification, and parentage studies (14,19,23–30). AmpeloCAD, a computer aided digitizing system for determining ampelographic measurements is another means of simplifying the identification (31).

Generally the classification of grape cultivars is based on their specific or interspecific origin. Currently there are four majors groups of grapevine cultivars that include the

pure line of *Vitis vinifera*, the French–American hybrids, the American hybrids (*Vitis labrusca*), and some interspecific cultivars (1).

14.2.1 *Vitis vinifera* Cultivars

The genus *Vitis* is divided into two distinct subgenera, *Vitis* and *Muscadinia*. Except for *V. rotundifolia* and *V. popenoei*, all the rest of the species are members of the largest subgenus *Vitis*. The difference between the two genera is in the number of their chromosomes; 38 for *Vitis* against 40 for *Muscadinia* (32). Crossing between species of *Vitis* and *Muscadinia* is possible, but often result in nonfertile progenies, due to the imprecise pairing and unequal separation of the chromosomes during meiosis. The genetic imbalance creating infertility is probably caused by the synthesis of inhibitors such as quercetin glycosides in the pistil (33). However, interspecies crossings among *Vitis* and *Muscadinia* are relatively easy and often yield fertile progeny. This, on the other hand, complicates the classification of grapevine species, because the differences in shoot and leaf morphological characteristics such as hairiness are strongly dependent on environmental conditions.

Most commercial cultivars belong to the species *V. vinifera*. Their reputation comes from their fine wines with distinctive, balanced, and long aging potential. Their weakness, however, is the low productivity and demanding cultivation practices. *Vitis vinifera* cultivars are used to produce both white and red wines. There is room for improving quality attributes of *V. vinifera* cultivars using modern techniques such as genetic engineering.

14.2.1.1 White Cultivars

Chardonnay is the most prestigious white French cultivar, and does well in most wine producing regions of the world. It also yields one of the finest sparkling wines. Under optimal conditions, chardonnay produces wine with an aroma reminiscent of apple, peach, and melon. The cultivar is susceptible to powdery mildew and bunch rot.

Riesling (White Riesling or Johannesburg Riesling) is Germany's most appreciated variety, popular also in the U.S. and in Australia. Wines made from these varieties of grapes have the characteristics of a fresh, aromatic, and well aged wine, reminiscent of roses. Fruit clusters possess small to medium size berries. Although a cold hardy variety, the yield is moderate, and it is also susceptible to powdery mildew and bunch rot.

Parellada is a Spanish variety from Catalonia, producing white wine with apple to citrus like aromas, and sometimes with hints of licorice or cinnamon. Pinot Blanc and Pinot Gris are popular in France, Germany, and other cool regions of Europe, and are used mostly in the production of dry, botrytised, and sparkling wines. They yield wines with the fragrances of passionfruit and hard cheese, respectively.

Sauvignon Blanc is originally from Loire Valley in France, but is also grown in California, Eastern Europe, Italy, and New Zealand. Some clones possess a floral character, but most Sauvignon Blanc wines have an herbaceous aspect, and the aroma of green peppers. Clusters produce small size berries, resistant to bunch rot and downy mildew. Sauvignon Blanc is susceptible to powdery mildew and black rot.

Muller-Thurgau variety was developed by H. Muller-Thurgau in 1882, presumably as a cross between Riesling and Silvaner. However the DNA fingerprint showed that it was more likely a cross between Riesling and Chasselas de Courtillier (34). Muller-Thurgau is probably the best known modern *V. vinifera* in Germany, but is also extensively grown in cool regions of Europe and in New Zealand. It is a high-yielding cultivar, producing a light wine with fruity fragrance and mild acidity. The fruits are susceptible to powdery and downy mildew and bunch rot.

Traminer is an aromatic cultivar, grown throughout the cooler regions of the world. It is used to produce dry and sweet white wines. Gewürztraminer is a clone with an intense

fragrance and litchi fruit aroma. Savagnin, in France, is a clone of Traminer with a mild aroma. The basic characteristic of Traminer is the relatively small size of the fruit and their tough skin. The modest clusters are susceptible to powdery mildew, bunch rot, and coulure.

Muscat Blanc is mostly used in the production of dessert wines. Muscat grapes are extensively grown throughout the world because of their marked and distinctive muscaty aroma. They also possess high levels of soluble proteins and flavanoids. Muscato Bianco is used for the production of sparkling wine in Asti, Italy.

Another well known white varietie is Viognier, from the Rhône Valley of France, which is characterized by the smaller size of the fruit and its Muscat character. The wine matures quickly and has a peach or apricot fragrance. Viura, cultivated in Rioja, Spain is another white cultivar, with excellent attributes. Generally, clusters are few and fruits are large. The wine has a floral aroma with aspects of citron when produced in cooler regions, and a rich butterscotch or banana fragrance, after aging in wood. Some *V. vinifera* cultivars that are regionally popular, but less well known are Fiano, Garganega, and Torbato, in Italy; Malvasia, in Spain; Arinto, in Portugal; Tãmîoasa Romînească, in Romania; and Furmint, in Hungary.

14.2.1.2 Red Cultivars

Cabernet Sauvignon is the most well known red variety, because of its association with Bordeaux, one of Europe's finest red wine producing areas. The wine has a black currant aroma under favorable conditions or a bell pepper aroma otherwise. The berries are small, seedy, and acidic, with darkly pigmented tough skin. The microsatellite study of Cabernet Sauvignon suggests a crossing between Cabernet Franc and Sauvignon Blanc (35). In order to accelerate the maturation of wine produced by Cabernet Sauvignon, it is blended with Merlot or Cabernet Franc. The cultivar is susceptible to several fungal diseases including powdery mildew, *Eurypa* and *Esca* wood decays, and phomopsis.

Merlot is a red variety grape, similar to Cabernet Sauvignon, which has the advantage of growing in cooler regions and moist soils. The ability to mature more quickly has made Merlot a popular substitute for Cabernet Sauvignon. The clusters are susceptible to coulure.

Pinot Noir is a famous French variety from Burgundy, suitable for the production of rosé and sparkling wines. Under favorable conditions it produces a wine with a distinctive aroma, which some researchers attribute to peppermint, beets, or cherries. Pinot Noir has a large number of clones such as Pinot Gris, Pinot Blanc, Meunier, Pinotage, (crossed with Cinsaut), and the California varietal Gamay Beaujolais (12,36). The clusters are compact with small to medium size fruits susceptible to bunch rot.

Barbera, ranked third after Sangiovese and Trebbiano in Italy, is also grown in California and in Argentina. The clusters possess long green stalks, and are susceptible to leaf roll and sometimes to bunch rot. Because of its high acidity, Barbera is often blended with some low acidic cultivars, but can also be used to make fruity wines by itself.

Gamay Noir à jus Blanc (Gamay with white juice), is mostly used in the production of Beaujolais wines. It produces fruit with medium size and tough skins. Gamay is a high yielding cultivar giving light red wines with little aroma. The fruity aroma of Beaujolais comes from the carbonic maceration technique. Gamay is susceptible to most fungal diseases.

Zinfandel is mostly grown in California and produces a wide range of wines varying from ports to light blush. The predominant aroma in rosé wines is reminiscent of raspberry. The full bodied wines possess berry flavors. The main problem with Zinfandel is that the fruits ripen unevenly.

Nebbiolo is basically grown in Northwestern Italy and adapts well in a wide range of soil pH and types. The wine produced from Nebbiolo is high in tannin and is acidic with a good aging potential. This cultivar is susceptible to powdery mildew and to bunch rot.

Tempranillo (Ull de Llebre) is the famous red variety in Spain, which is also grown in Argentina and in California under the name of Valdepeñas. Under optimal conditions it yields a fine wine with a complex berry jam fragrance with nuance of citrus. Tempranillo is sensitive to powdery and downy mildew.

Another important red variety of *V. vinifera* is Graciano, a Spanish variety with relatively low yield, but resistant to most fungal diseases and drought. Sangiovese is grown in central Italy and consists of a number of clones. It produces light to full bodied wines with nuances of citrus. The clusters are small to medium in size with oval fruits sensitive to bunch rot, powdery mildew and downy mildew. Syrah is a cultivar of the Rhône Valley in France, characterized by a low yield and high tannin content, allowing a good aging potential. It is also cultivated in Australia, where it is known under the name of Shiraz. The clusters are elongated with oval or small round fruits susceptible to drought, bunch rot, and berry moths.

Touriga National, mostly grown for the production of Port wine, is one of the famous Portugaese red cultivars. The clusters contain small berries and produce wine with a rich flavor and deep color. Ramisco, in Portugal, and Corvina and Dolcetto, in Italy, are nationally popular varieties with less international recognition.

14.2.2 French–American Hybrids

French–American hybrids are the second largest group of cultivars, and are derived from crosses between *V. vinifera* and one or more of the following: *V. riparia*, *V. rupestris*, and *V. aestivalis*. Primarily developed in France, their expansion was banned in the European Economic Community (EEC) in the late 1950s, because of their high yield and their nontraditional fragrance. Extensively grown in some South American countries and Asia as well, French–American Hybrids have been widely used by North American wine industries since 1960. These hybrids were developed in order to overcome the difficulties and high expenses of grafting *V. vinifera* onto *Phylloxera* resistant rootstocks. The hybrids obtained are easy to grow with high yielding characteristics, and show reduced sensitivity to most of leaf pathogens. These varieties are used in Europe by the breeding programs as sources of disease resistance. The most popular French–American hybrids are:

Baco Noir, resulting from a cross between Folle Blanche and *V. riparia,* yields wine with a specific flavor and a very good aging potential. This hybrid is unfortunately sensitive to bunch rot, and several soil borne viruses.

Marechal Foch, derived from a cross between *V. riparia* and *V. rupestris* selections, with Goldriesling (Riesling $\times$ Courtiller Musqué). This hybrid has characteristics such as early maturation, winter hardiness, high productivity, and resistance to downy mildew, which makes it popular in North America.

Chambourcin is a Johannes Seyve hybrid of unknown parentage, and is presumed to be one of the best French–American hybrids. The cultivar was popular in France in the 1960s and 1970s, and also in Australia, because of its long growing season. Chambourcin is characterized with resistance to downy and powdery mildews and produces wines with a rich flavor.

Vidal Blanc has excellent winemaking and viticultural properties including tough skin and long maturity, making it suitable for the production of high quality ice wines. Vidal Blanc yields wine with Riesling like character, under favorable conditions. It is a cold hardy cultivar, but susceptible to soil borne virus diseases, as are many other French–American hybrids (37).

De Chaunac, once extensively grown in Eastern North America, has lost its importance nowadays, due to its sensitivity to soil borne viruses and the neutral character of the produced wines. De Chaunac is a Seibel cross of unknown parentage.

Seyval Blanc is a Seyve-Villard hybrid of *V. vinifera*, *V. rupestris,* and *V. aestivalis lincecumii*. It is a cold hardy cultivar, which produces wine with a pomade fragrance and fairly bitter finish. Seyval Blanc is sensitive to bunch rot, but tolerant to many soil types.

Delaware, which is a cross between *V. labrusca, V. aestivalis,* and *V. vinifera*, is another important French–American hybrid In the past, it has been used in the production of sparkling wines. Delaware needs well drained soils to grow and tends to crack. It is susceptible to various fungal pathogens, such as *Phylloxera*. Duchess, which produces wine with a mild fruity aroma, is a cross between *Vitis labrusca* and *V. vinifera*, and is difficult to grow. Magnolia and Noble are self fertile strains of muscadine cultivars, which yield sweet bronze colored and dark red fruits, respectively.

14.2.3 American Hybrids

American hybrids are cultivars bred in North America, from hybrids between indigenous grapevines, and hybrids between these and *V. vinifera*, or both. Most important American hybrids are derived from *V. labrusca*. The major characteristics of American hybrids are low sugar content and high acidity, and abundant flavor, e.g., Niagara, Concord and Catawba. A method of reducing the intense labrusca flavor is early picking and cold fermentation. Norton and Cynthiana, derived from *Vitis aestivalis* (38), are grown in Arkansas and Missouri, and are resistant to indigenous diseases and pests. The group of American hybrids derived from *V. rotundifolia* have low sugar content, but are resistant to indigenous diseases, especially to Pierce's disease. American hybrids are extensively grown in Eastern North America, South America, Eastern Europe, and Asia, although their significance has decreased in North America.

Another group of hybrids are interspecific cultivars derived from crossing *V. vinifera* and species such as *V. amurensis*, *V. riparia*, *V. armata,* and *V. rotundifolia,*. Orion, Regent, and Phoenix are new hybrids developed in Germany, with winemaking properties equal or superior to most *V. vinifera*. Veeblanc was developed in Ontario from complex parentage and generates mild quality wine. Cayuga White from New York is a new hybrid with excellent winemaking attributes and resistance to fungal diseases. Its fragrance resembles apples and tropical fruits, with a rich mouth feel. The quality attributes of wine grapes can be improved by genetic engineering and clonal or somaclonal selection.

14.3 GENETIC ENGINEERING OF WINE GRAPES

The goal of grape breeding is to enhance agronomic properties of rootstock varieties and to improve winemaking attributes of fruit-bearing cultivars. There are a number of ways by which this can be accomplished, including simple cross and backcross between appropriate varieties. The improvement often involves the addition of novel qualities such as drought tolerance and disease resistance to established cultivars.

Standard breeding techniques are time consuming and expensive. Genetic engineering introduces the genes of choice without disrupting varietal characteristics of cultivars. The steps involved in genetic engineering include the isolation, amplification, and insertion of the target gene into the intended organism. An example is the insertion of a protein coat gene for the grapevine fanleaf virus (GFLV) into rootstock varieties in order to enhance their resistance (39). There are several laboratories around the world working on

gene transfer technologies in grape vines. It has been reported that several transformed grape varieties are being evaluated in France (40) and the U.S. In Geneva, New York, a Thompson Seedless variety with an incorporated gene for resistance to tomato ringspot virus is being evaluated. Experiments in France include evaluation of rootstocks and Chardonnay carrying resistance genes to fanleaf virus; and another variety, Richter 1110, with an incorporated gene for resistance to chrome mosaic virus (CMV) (41). Attempts have also been made to introduce the chitinase gene into embryonic cultures of Merlot, Chardonnay, Pinot Noir, Concord, and Niagara varieties, through biolistic transformation. Increased chitinase activity may afford protection from fungal pathogens, such as *Botrytis,* which causes bunch rot, and *Uncinula necator,* which causes powdery mildew (42). These varieties are being evaluated for increased disease resistance. Superoxide dismutase is a key enzyme involved in the detoxification of active oxygen species and it is believed that a higher superoxide dismutase activity will confer added protection to grapevines during extreme cold conditions. A gene for superoxide dismutase was isolated from *Arabidopsis thaliana* and inserted into scion varieties in order to improve their cold resistance. A problem associated with these techniques is the uncertainty of the transfer and expression of traits under multigene control in another organism. Although genetic engineering requires isolated cells or tissues grown in tissue culture to develop into whole plants, the induction of embryos from grape tissue or cells is difficult. For transformed cells to be of value, they must be able to form embryos and differentiate into whole plants. The phenotypic variability of the progeny is another problem with propagating vines that originate from cells grown in tissue culture. The variability decreases with vine age or repeated propagation. Using buds from the fortieth node and onward from the stem apex, and grafting them onto desirable rootstocks, is a way to circumvent this problem (43). Progress has been made in both augmenting the proportion of embryonic tissue that develops into vines (44), and in understanding the origins of poor plantlet yield from grape cells (45).

14.3.1 Clonal Selection

Clones are forms of cultivars, derived vegetatively from a single parental plant, such that all derivatives are initially genetically identical (1). Clonal selection is a series of procedures designed to provide a premium stock of known characteristics. Basically, cuttings are multiplied and repeatedly assessed for their viticultural and fruit-bearing characteristics and their winemaking properties, as well as their resistance to systemic pathogens. Clonal selection is the primary means by which cultivar characteristics can be modified without significantly changing varietal attributes. Variations in monoclonal varieties consist of mutations accumulated since the origin of the cultivar which are reproduced unchanged in cuttings of the mutated clone, whereas in polyclonal varieties, variation occurs because the cultivar exists as a group of closely related strains. The difference between related clones may be phenotypical, such as color variants of Pinot Noir, Pinot Gris, and Pinot Blanc, or biotypical (almost genotypical), such as Sangiovese strains (46). Clones are grouped according to the combination of traits they possess. For example, among Pinot Noir cultivars, Pinot Fin, with trailing low yielding vines having small fruit clusters; Pinot Droit, having a high yielding vine with upright shoots; Pinot Fructifer, which has high yielding strains; and Mariafeld-type strains, with loose clustered, moderate yielding vines, show the variability in phenotypic characteristics (47). The main objective of clonal selection is the elimination of all systemic infectious organisms including pathogens. This is not always possible, as some systemic agents are not known to cause disease, and reinfection is always possible. The weakness of clonal selection is the resulting phenotypic variability, which is difficult to eliminate. In order to control the desirable variations, some breeders suggest planting several clones rather than just one (48).

Often, clonal instability is due to chimeric mutations, which occur in embryonic cells, and, as a result, cause vine tissues to differ from one another. Another important goal of clonal selection is the improvement in yield and grape quality. There is a negative association between yield and quality, but this can be overcome through rigorous viticultural practices such as more open canopy, increased plant density, and basal leaf removal. An exception to this rule is the Weinberg 29 clone of Riesling, which gives a high yield and shows a high level of sugar content in the fruits (49).

The assessment of quality is complex, time consuming, and costly. There is no unanimous criterion for quality. However, some parameters such as, º Brix, pH, and acidity are used to assess maturity. Parameters such as the level of glycosyl glucose (G-G) in the must, the polyphenol content, and the color density and hue are commonly used as potential indicators of wine quality (50). The presence of specific flavor impact compounds such as 2-methyl-3-isobutylpyrazine in Cabernet Sauvignon is also another important characteristic. Unique varietal aromas can be integrated into clonal selection. Examples of this kind include the Muscat nuance of Chardonnay 77 and 809; the difference in wine making potential of Gamay 222 versus Gamay 509 in the production of Beaujolais cru vin de garde and vin nouveau (48). Because properties of a clone are dependent upon environmental conditions, some desirable traits may not be expressed, which requires vineyard growers to make their own assessment of a given clone.

14.3.2 Somaclonal Selection

Although clonal selection has reduced viral infection in grapes, more advances may come from incorporation of new genetic information through genetic engineering or induced mutations. Mutations can be created by exposing meristematic tissue or cells in tissue culture to mutagenic chemicals or radiation. Somaclonal selection enhances the expression and selection of clonal variation. It also involves the selective growth enhancement of cell lines. For example, isolation of transgenic vines or lines possessing tolerance for salinity or fungal toxins (51) is done by exposing cells to mutagenic agents, such as chemicals and radiation, during cell culture (39,52). However, the tolerance shown by tissue in culture may not always be expressed at the whole plant level (53).

14.3.3 Biotechnology in Viticulture

Biotechnology has been extensively applied in viticulture since the early work of breeders like F. Baco, B. Seyve, and A. Seibel. The main goal then was to develop cultivars with enhanced wine-producing characteristics of *Vitis vinifera* and the *Phylloxera* resistance of American species. Breeding has focussed on developing rootstocks resistant to drought, salt, lime, viruses, and nematodes. For example, *V. cinerea helleri* can donate resistance to lime induced chlorosis; *V. champinii* can supply tolerance to root knot nematodes; *V. vulpine* can provide drought tolerance under shallow soil conditions. Improvements have also been made in developing new pest and disease resistant fruit varieties. There is also a trend in producing grapevine varieties that produce fruits having increased nutritional value, such as antioxidant and vitamin contents, thereby improving the quality of the grapes and wine. Unfortunately, consumers are still sceptical of genetically modified organisms, which limits their acceptance. The benefits of such resistant varieties are their reduced production costs and use of pesticides. Their disadvantages however, are legal restrictions against interspecies crosses in the production of Appellation Contrôlée wines in most European countries. Recently 40 out of 60 Masters of Wine voted against any introduction of genetically modified (GM) vines or geneticallk modified organisms (GMOs) in any step of the wine making process (54). Despite these controversies, genetic engineering appears to be the most efficient way of successfully developing disease resistant cultivars.

Researchers are experimenting with the isolation and insertion of specific genes for resistance such as genes regulating the activities of chitinase, β-glucanase, and peroxidase isoenzymes.

14.4 GENETIC ENGINEERING OF YEAST FOR FERMENTATION

The two main organisms involved in fermentation are *Saccharomyces cerevisiae* and *Leuconostoc oenos*. Traditionally, indigenous yeasts conduct the fermentation, but induced fermentation with selected yeast strains is a standard procedure in most parts of the world (55). The reason for using specific yeasts is to avoid the production of off flavors sometimes associated with wild yeasts. New techniques such as mitochondrial DNA sequencing (56) and gene marker analysis (57) allow identification of strains responsible for fermentation. Regardless of yeast inoculation, red and white grape musts contain a significant amount of wild yeast, but their metabolic activity during induced fermentation is unknown. Thus, their significance in vinification is not clear. *Kloeckera apiculata* is the most frequently isolated wild yeast in grapes, believed to contribute greatly to the complexity of the wine. Other yeasts occasionally isolated are: *Brettanomyces*, *Candida*, *Debaryomyces*, *Hansenula*, *Kluyveromyces*, *Metschnikowia*, *Nadsonia*, *Pichia*, *Saccharomycodes,* and *Torulopsis* (58). *Saccharomyces cerevisiae* is the most important yeast species, because it may function as wine yeast, baker's yeast, distiller's yeast, and brewer's yeast. The original habitat of the yeast is uncertain (59), and only one healthy grape out of a thousand carries ideal wine yeasts (60). *Saccharomyces paradoxus* (*S. cerevisiae tetrasporus*), isolated from oak tree exudates, is assumed to be the ancestral form of *Saccharomyces cerevisiae*. Although *S. cerevisiae* is sometimes isolated from the intestinal track of fruit flies, the importance of insects in dispersal of *Saccharomyces* is not clear (59,61). *Saccharomyces* species such as *S. uvarum* and *S. bayanus* also can effectively conduct fermentations, and they are used in special applications; e.g., *S. uvarum* ferments well at temperatures down to 6°C and synthesizes desirable sensory components, whereas *S. bayanus* is well adapted for the production of sparkling wines and fine sherries. Other wild yeasts of sensory significance are *Candida stellata*, *Torulopsis delbruekii* and *Kloeckera apiculata. Candida stellata* persists in fermenting juice (62), and produces high concentrations of glycerol, increasing the mouth feel in wine. *Torulopsis delbruekii* positively influences sensory attributes of wine by producing low concentrations of acetic acid and succinic acid. *Kloeckera apiculata*, however, can produce up to 25 times the typical amount of acetic acid produced during induced fermentations (63), and is capable of producing above threshold amounts of 2-aminoacetophenone, giving a naphthalene like off odor to wines (64). *Kloeckera apiculata* may inhibit *S. cerevisiae* from completing fermentation (65). *Kloeckera apiculata* and *C stellata* normally produce only 4 to 10% alcohol, but can survive higher alcohol concentrations (66,67). Most of the other members of indigenous yeasts found on grapes are suppressed by low pH, high alcohol, oxygen deficiency, and sulphur dioxide concentrations. Most bacteria are inhibited by *S. cerevisiae*, except lactic acid bacteria. Commercially available strains of *S. cerevisiae* possess a wide range of winemaking characteristics such as low production of acetic acid, hydrogen sulphide (H_2S), and urea; the ability to produce fruit esters in abundance; and to enhance varietal flavorants. Yeasts can also be selected for their alcohol tolerance, fermentation speed, ability to restart stuck fermentation, production of specific wine styles (such as after carbonic maceration), resistance to killer factors, ability to ferment glucose or fructose selectively, fermentation at high pressure and at low temperature, and their ability to flocculate rapidly and completely after fermentation.

14.4.1 Ideal Yeast

Taking into account that each type of wine requires different types of yeast, it may be difficult to find an ideal type of yeast. However, the following are major characteristics of high quality wine yeasts:

1. Fermentation Speed: An ideal type of yeast should be able to initiate and complete the fermentation as quickly as possible after inoculation. The higher sugar content of the must, which creates an elevated osmotic pressure, is a limiting factor for most wine yeasts.
2. Alcohol tolerance: Yeast should be able to ferment all the sugars in the must in less than 3 weeks and be able to withstand up to 15% ethanol. Most fermentations stop at 1–2% sugar content creating conditions for spoilage. There are commercial strains of yeasts available that have the ability to restart stuck fermentations or to perform the second fermentation during sparkling wine production.
3. SO_2 Tolerance: Most of the yeasts are sensitive to SO_2, and sulphites are used as an antioxidant and a microbial inhibitor. The allowed concentration of SO_2 in the finished product is 70 parts per million in free state, and 350 parts per million in combined state, respectively. An ideal type of yeast should be able to dominate the fermentation even at this level of SO_2.
4. Cold tolerance: Cold tolerant yeasts are used especially for white wine production in order to keep the loss of the bouquet to a minimum. The fermentation temperature is often below 14ºC.
5. Low foaming activity: Ideal yeasts should have a low foaming activity. High foaming yeasts spoil the quality of wine by producing off odors and off flavors.
6. Efficient conversion of sugar into alcohol: Ideal yeasts have the ability to convert sugar primarily into alcohol and produce low levels of other metabolites.
7. Production of desirable metabolites: Several secondary products of yeasts are components of the bouquet and flavor of the wine. The quality of a given wine is therefore dependent upon the production of the right amount of these metabolites. This is particularly important for those types of wines with low aging potential such as the Gamay Nouveau wines of Ontario, consumed within three months after production.
8. Low production of undesirable metabolites: The selection of yeasts is based on their ability to synthesize low levels of undesirable metabolites such as acetaldehyde, acetic acid, sulphur dioxide, hydrogen sulphide, and mercaptans.
9. Resistance to "Killer" yeasts: Most of the commercial yeasts are killer strains with the ability to ferment sugars completely and to resist toxins of contaminating killer yeasts. Killer yeasts are wild yeasts that possess the ability to synthesize and excrete proteins that kill other strain of yeasts. This is the reason why the yeast breeders breed yeasts containing the killer genes.
10. Flocculation: An ideal yeast strain should flocculate at the end of the fermentation, leaving the wine clear and requiring less rigorous filtration. Filtration negatively influences the complexity of wine.
11. Producing or reducing certain organic acids: Yeast strains are selected on the basis of their ability to deplete malic acid and other organic acids found in wine. This is very important taking into account the net difference in the acid content of grapes grown in hot and cool climate regions. Hot growing regions are ideal for the production of low acid grapes having high sugar content, whereas cool climate regions tend to produce high acid grapes.

14.4.2 Yeast Breeding and Wine Quality

The use of genetic engineering is very limited for improving wine yeasts, compared to yeasts used for other industrial fermentations. The reason for this is that more importance has been given to grape variety, fruit maturation, and fermentation temperature. Also, during genetic improvement, features controlled by one gene are easily influenced by other genes. For example, the expression of flocculation ability in yeasts is regulated by several genes, including epistatic genes and, possibly, cytoplasmic genetic factors (68). On the other hand, inactivating the gene that encodes sulphites reductase restricts the conversion of sulphites to sulphide (H_2S). Genetic improvement is attainable, although this may take time to achieve because many important enological attributes, such as the ability to ferment at low temperature and alcohol tolerance, are controlled by a combination of several genes. The consequences of changing the direction of a metabolic pathway on other characteristics of the yeasts are not very clear at present. For example increasing ester production could interfere with the alcohol tolerance ability of the strain (69). It is easier when the compound concerned is the end product of a pathway. There were no apparent undesirable side effects when genes for terpene synthesis were incorporated from a lab strain into a wine strain of *S. cerevisiae* (70). Rainieri and coworkers (71) found that thermotolerant *Saccharomyces cerevisiae* strains possess oenological potential and provide an important genetic resource for yeast improvement programs. In the search for a substitute for sulphite in winemaking, Suzzi and coworkers (72) selected a strain of *Saccharomyces cerevisiae* No 10278, able to form 30 to 80mg/L of sulphite, with an excellent stabilizing power. Techniques available for researchers for improving wine yeast qualities include selection and modification of the genetic makeup of the yeast. Simple selection is easy, if a selective medium is developed so that only cells containing the desirable trait can grow; otherwise, cells must be randomly isolated and individually studied for the presence of the desired trait. Modifying the genetic makeup involves procedures such as hybridization, mutagenesis, backcrossing, transformation, somatic fusion, and genetic engineering. To incorporate single traits into a desirable strain, backcross breeding is the preferred technique. Combined with a selection, backcross eliminates undesirable donor genes accidentally incorporated in the original cross.

Somatic fusion is used if a desirable feature missing in *S. cerevisiae* is found in another yeast species. This procedure requires enzymatic cell wall dissolution and mixing of protoplasts generated in the presence of polyethylene glycol, which enhances cell fusion. Instability is the major problem with somatic fusion, because fused cells often revert to one or the other of the original species.

On the other hand, the advantage of genetic transformation is that donor and recipient need not be closely related. The procedure involves bathing yeast protoplasts in a solution containing DNA from the donor organism. By this technique, the malolactic gene from *Lactococcus lactis* was transferred into *S. cerevisiae* along with the malate permease transport gene from *Schizosaccharomyces pombe* (73–76). Other genes of interest are pectic lyase to increase fruity flavor and β- (1-4)- endoglucanase to increase aroma. Boone and coworkers (77) integrated the yeast K1 killer toxin gene into the genome of laboratory and commercial yeasts by a gene replacement technology that generated recombinants containing only yeast DNA. The integration of the K1 killer gene into two K2 wine yeasts generated stable K1/K2 double killer strains, which have a wider spectrum of killing and a competitive advantage over other sensitive and killer strains of *Saccharomyces cerevisiae* in wine fermentations. Genetic engineering is useful if specific traits are desired, but not when multigenic characteristics are involved. However, the ethics of releasing genetically modified organisms that could enter the environment is questionable.

The main problem in breeding *S. cerevisiae* is its diploid character, which means each cell contain two copies of the genes. The diploid nature complicates improvement by

masking the potentially desirable genes. More difficulties occur due to the low frequency of sexual reproduction, poor spore germination, and rapid return to the diploid form (75). Stability is the fundamental requirement for the yeast strain, which means that, for instance, flocculant strains should not loose their ability to flocculate.

14.4.3 Wine as a Functional Food

The beneficial effects of wine on human health may originate from their nonalcoholic components, such as flavanoids and phenols. Some phenolic compounds can be protective, whereas others have been found to be mutagenic at high doses in laboratory studies. Fazel and coworkers (78) found that quercetin can induce mutation during *in vitro* culture of animal cells, but is an anticarcinogen in whole animal dietary studies. This anomaly may be due to the differences in the concentrations of quercetin used and the low level of metal ions and free oxygen found in the animal body. Subbaramaiah and coworkers (79) observed that resveratrol, a member of the stilbene family found in wine, can inhibit the production of cyclooxygenase-2, thought to be important in carcinogenesis. As well, flavanols and flavones strongly reduce the action of the common dietary carcinogens such as the heterocyclic amines (80). In this regard, it is important to note that wines made from fruits such as cherry, blackberry and blueberry, and red grape show a very high complement of superoxide and hydroxyl radical scavenging ability due to the presence of several phenolic components (81). The flavanoids are also strong inhibitors of calcium second messenger function in animal systems, and the biological activities of wines may, to a large extent, result from this activity. Recently, during *in vitro* culture, the flavonoid wine components have been shown to be specifically cytostatic and cytotoxic to MCF-7 cells, which are estrogen receptor positive breast cancer cells. Under similar conditions, the normal human mammary epithelial cells were unaffected (82). Thus, by enhancing the components in the wine that afford health beneficial effects, the functional food value of the wine can be enhanced. Even though moderate wine consumption is believed to be beneficial to cardiovascular health, its effect on breast cancer development is still controversial. Several biotechnological approaches such as *in vitro* culture, genetic engineering of grapes for enhanced secondary metabolite biosynthetic pathways, and conditions of fermentation could ultimately enhance the functional food value of the wine.

14.5 CONCLUSIONS

It is possible to improve the quality attributes of wine using modern techniques such as selective breeding, hybridization, somatic fusion, transformation, and genetic engineering. They can be applied both to wine grapes and to yeasts. Although the safety of genetically modified food is an issue, the advantages of adapting these technologies are enormous; as they may help provide better yield, environmental protection and high quality wine products.

Biotechnology of Nonnutritive Sweeteners

Reena Randhir and Kalidas Shetty

CONTENTS

15.1 INTRODUCTION

Consumer preference for sweetness in a diet with reduced calories has created a marketplace for sweeteners with few or no calories. Sweeteners are broadly classified as providing energy (nutritive) or not providing energy (nonnutritive). Nutritive sweeteners (e.g., sucrose, fructose) are generally recognized as safe (GRAS) by the Food and Drug Administration (FDA). The Code of Federal Regulations states that nonnutritive sweeteners are "substances having less than 2 percent of the calorie value of sucrose per equivalent unit of sweetening capacity" (1,2). By increasing the palatability of nutrient dense foods and beverages, sweeteners can promote health. Scientific evidence supports neither that intake of nutritive sweeteners by themselves increase the risk of obesity, nor that nutritive or nonnutritive sweeteners cause behavioral disorders. However, nutritive sweeteners

increase risk of dental caries. High fructose intakes may cause hypertriglyceridemia and gastrointestinal symptoms in susceptible individuals (1,2).

Nonnutritive sweeteners are used to:

1. Expand food and beverage choices for those who want to control calorie, carbohydrate, or specific sugar intake
2. Assist weight control or reduction
3. Aid in the management of diabetes and hyperlipemia
4. Assist the control of dental caries
5. Enhance the usability of pharmaceuticals and cosmetics
6. Provide sweetness when sugar supply is limited
7. Assist the cost effective use of limited resources

These concerns are shaping the need for manufacturers and food and beverage processors to reconsider what additives they use in their products, and what alterations need to be made to meet consumer demand for something sweet, low calorie, and affordable (1,2). The search for noncarbohydrate nonnutritive sweeteners from natural sources has led to the discovery of many intensely sweet tasting substances. The characteristics of an ideal nonnutritive sweetener are:

1. A sweetness quality and profile identical to that of sucrose
2. Sensory and chemical stability under the relevant food processing and storage conditions
3. Compatibility with other food ingredients and stability toward other constituents in the food
4. Complete safety, shown as freedom from toxic, allergenic and other physiological properties
5. Complete freedom from metabolism in the body
6. High specific sweetness intensity (2)

Most sweet compounds, including all popular sweeteners, are small molecular weight compounds of different chemical nature, but there are also sweet macromolecules, both synthetic and natural, such as sweet proteins. Sweet molecules elicit their taste, in humans and other mammals, by interacting with the recently discovered T1R2–T1R3 taste receptors (3–5). The sequence of this protein indicates that it is a metabopromic 7 transmembrane G-protein coupled receptor with a high homology to the mGluR subtype 1 (4). The structure of the N-terminal part of the mGluR has been recently determined by x-ray diffraction and has been used as a template to build a homodimeric T1R3–T1R3 receptor model (4). It is very likely that small molecular weight sweet molecules occupy a pocket analogous to the glutamate pockets in the mGluR (5), possibly similar to the active site models predicted by indirect receptor mapping studies (6–8). These significant investigations have facilitated the understanding of sweetness perception in humans; and have also made it possible to modify genetically the sequence of the natural sweet proteins as necessary. The following review is a brief summary of the current nonnutritive sweeteners, namely Saccaharin, Acesulfame K, Sucralose, Aspartame, Neotame, Stevioside, Monellin, Brazzein, Thaumatin, and Manbinlin, which, although they are permitted food ingredients under different national statutory regulations, are not universally accepted. The evaluation of the sweetness of a given substance in relation to sucrose is made on a weight basis. Table 15.1 provides the relative sweetness of the nonnutritive sweeteners discussed in this chapter.

Table 15.1
Relative sweetness of nonnutritive sweeteners

Nonnutritive Sweetener	Approximate Sweetness (Sucrose = 1)
Saccharin	300
Acesulfame K	200
Sucralose	600
Aspartame	180–200
Neotame	8000
Stevioside	200
Monellin	1500–2000
Brazzein	2000
Thaumatin	1600
Mabinlin	100

15.2 SACCHARIN

Saccharin, commonly known as Sweet n Low™, was first discovered in 1879 by Remsen and Fahlberg and has been used commercially since then (9). It is 300 times as sweet as sucrose, produces no glycemic response in humans, synergizes the sweetening power of nutritive and nonnutritive sweeteners, and its sweetness is thermostable. It occurs as a white crystalline powder with a molecular formula of $C_7H_5NO_3S$ and molecular weight of 183.18 (Figure 15.1). It has been widely used to sweeten foods and beverages without calories or carbohydrates for over a century (10,11). It was widely used during the sugar shortages of the two world wars. Research also has shown that saccharin is beneficial to people with diabetes and obese people, and helps to reduce dental cavities (12). It is used in products such as soft drinks, tabletop sweeteners, baked goods, jams, chewing gum, canned fruit, candy, dessert toppings, and salad dressings. It is also used in cosmetic products, vitamins, and pharmaceuticals (10).

Although extensive research indicated that saccharin was safe for human consumption, there has been controversy over its safety. The basis for the controversy rests primarily on findings of bladder tumors in some male rats when fed high doses of sodium saccharin (13–18). Other saccharin research, however, indicates safety at human levels of consumption with no detectable metabolism using analytical techniques. The vast majority of the data on the biotransformation of saccharin demonstrate that this compound is excreted unchanged, predominantly in the urine of all lab animals tested (20–22). The production of saccharin is simple, inexpensive, and can be done in bulk. The production process uses the basic route described by Remsen and Fahlberg. Methyl anthranilate is diazotized by treatment with sodium nitrite and hydrochloric acid to form 2-carbomethoxybenzenediazonium chloride. Sulfonation of this compound produces 2-carbomethoxybenzenesulfinic acid, which is converted to 2-carbomethoxybenzenesulfonyl chloride with chlorine. Saccharin is synthesized by amidation of this sulfonychloride, followed by acidification. This is then treated with either sodium hydroxide or sodium bicarbonate to produce sodium saccharin (23).

15.3 ACESULFAME-K

Acesulfame-K, commonly known as Sunette™ or Sweet One™, was discovered by Clauss and Jensen, 1967 (24). It was approved by the FDA as tabletop sweetener and as an additive in a variety of desserts, confections, and alcoholic beverages. It is 200 times sweeter

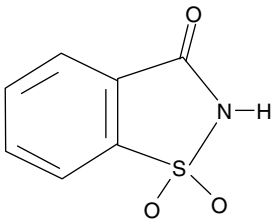

Figure 15.1 Chemical structure of saccharin

than sucrose, is noncarcinogenic and produces no glycemic response (25). Its chemical name is potassium salt of 5,6-methyl-1,2,3-oxathiazin-4(3H)-one-2,2-dioxide and its chemical formula is $C_4H_4KNO_4S$ (Figure 15.2). Its sweetening power is not reduced by heating, and can synergize the sweetening power of other nutritive and nonnutritive sweeteners. It does not provide any energy, is not metabolized in the body, and is excreted unchanged (12,26,27). However, toxicology research performed on albino mice for the genotoxic and clastogenic potential of acesulfame-K revealed chromosome aberrations in the bone marrow cells. In view of this significant *in vivo* mammalian genotoxicity data, it is advised that acesulfame-K should be consumed with caution (28).

Synthesis of acesulfame-K starts with the reaction of acetoacetic acid tert-butyl ester with fluorosulfonyl isocyanate (29). Both compounds form the intermediate of α–N-fluorosulfonylcarbamoyl acetoacetic acid tert-butyl ester. This compound is unstable, and by releasing CO_2 and isobutene is converted to N-fluorosulfonyl acetoacetic acid amides (30). This reaction can be accelerated by heating the compound slightly. In the presense of potassium hydroxide it cyclizes to the dihydrooxathiazinone dioxide ring system by separating out fluorides. Because these are highly acidic compounds, salts of this ring compound are formed in reactions with KOH, NaOH or $Ca(OH)_2$ (30).

15.4 SUCRALOSE

Sucralose is also known by the brand name Splenda™ and is 600 times sweeter than sucrose. It is the only low calorie sweetener made from sugar, with a chemical formula of $C_{12}H_{19}C_{l3}O_8$ and molecular weight of 397.64 (Figure 15.3). It was discovered in 1976 and scientific studies conducted over a 20 year period have conclusively determined that sucralose is safe for everyone to consume (31,32). It was approved by the FDA, and by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) in 1990. Sucralose has been approved by prominent regulatory authorities throughout the world, and has been consumed by millions of people internationally since 1991.

It can be used in place of sugar to eliminate or reduce calories in a wide variety of products, including beverages, baked goods, desserts, dairy products, canned fruits, syrups, and condiments. Heating or baking does not reduce its sweetening power. It has no calories, and the body does not recognize it as a carbohydrate (33). Clinical research showed that it produced no glycemic response in the human body; approximately 15% of sucralose was passively absorbed in the body, and the majority was excreted unchanged (34–36). The small amount that was passively absorbed was not metabolized and was eliminated within 24 hours. The FDA concluded that it does not pose a carcinogenic, reproductive, or neurological risk to humans, and this is supported by clinical research (35,37). However a few controversial investigations indicate the potential hazards of sucralose on human health (38).

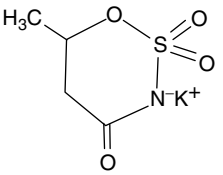

Figure 15.2 Chemical structure of Acesulfame-K

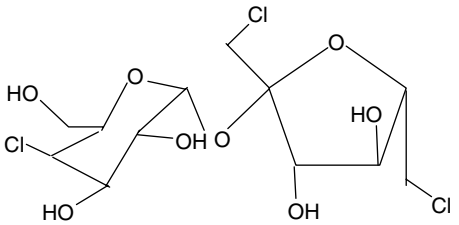

Figure 15.3 Chemical structure of Sucralose

Production of sucralose starts with a cane sugar molecule, then three hydrogen-oxygen groups are substituted with three tightly bound chlorine atoms, which makes it inert. A high yielding bioorganic synthesis of sucralose (4,1′,6′-trichloro-4,1′,6′-trideoxy-galactosucrose) involves the chemical chlorination of raffinose to form a novel tetrachlororaffinose intermediate (6,4′,1″,6″-tetracyhloro-6,4′,1″,6″-tetradeoxygalactoraffinose; TCR) followed by the enzymatic hydrolysis of the α-1-6 glycosidic bond of the TCR to give sucralose and 6-chlorogalactose. The most active enzyme was produced by a strain of *Mortierella vinacea* and had a maximum rate of 118 μmol sucralose/g dry weight cells/hour, which was approximately 5% of the activity toward raffinose, and a Km of 5.8 mM toward TCR. The enzyme was used in the form of mycelial pellets in a continuous packed bed column reactor. Synthesis of raffinose was achieved from saturated aqueous solutions of galactose and sucrose using a selected α-galactosidase from *Aspergillus niger*. (39).

15.5 ASPARTAME

Aspartame was discovered by accident by James Schlatter, a chemist at G.D Searle Co. in 1965, when he was testing an antiulcer drug. Its chemical name is N-L- aspartyl-l-phenyl-alanine-1-methyl ester and marketed as Nutrasweet™, Equal™, Spoonful™, and Equal Measure™. It is an odorless, white crystalline powder that has a sweet taste (40,41). It is widely used as a flavor enhancer, and to sweeten foods and beverages (42). It provides the same energy as any protein (4 calories per gram) because it is a combination of phenyl-alanine and aspartic acid (two amino acids), which is then combined with methanol (Figure 15.4). It is 180–200 times sweeter than sucrose, so the small amount needed to sweeten products does not actually contribute a significant number of calories (40,41). Clinical studies on the safety of aspartame have been widely conducted on animals and humans (43,44). The data demonstrated a substantial margin of safety for aspartame and its metabolites at reasonable levels of consumption. However, the product is required to display a warning label about the possibility of Phenylketonuria, a genetic disease where the body cannot produce the enzyme necessary to use the amino acid phenylalanine, which is one of the breakdown metabolites of aspartame (45,46).

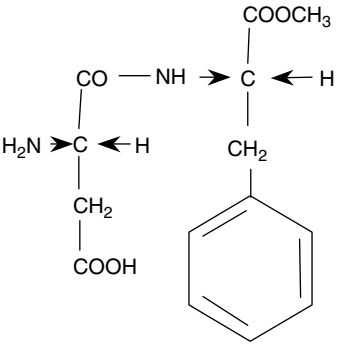

Figure 15.4 Chemical structure of Aspartame

The two primary components of aspartame (phenylalanine and aspartic acid) are chiral, which means that they have two isomers that are mirror images that cannot be superimposed upon each other. This means that the final aspartame molecule will have two stereogenic centers. If the wrong enantiomers are used, the aspartame molecule will not have the correct shape to fit the binding site of the sweetness receptors on the tongue (47). In the synthesis of aspartame, the starting materials are a racemic mixture (equal quantities of both enantiomers) of phenylalanine and aspartic acid. Only the L-enantiomer of phenylalanine is used: this is separated from the racemate by reacting it with acetic anhydride and sodium hydroxide. If the product of this reaction is then treated with the enzyme porcine kidney acylase, and an organic extraction with H^+ carried out, the L-enantiomer is found in the aqueous layer and the D-enantiomer remains in the organic layer (48,49).

Treatment of L-phenylalanine with methanol and hydrochloric acid esterifies the $-CO_2H$ group, and this ester is then reacted with aspartic acid to give the final product. It is important that the amine group on aspartic acid be protected with carbobenzyloxy groups, and the acid group nearest the amine protected with benzyl groups, to prevent the L-phenylalanine reacting with these and giving unwanted byproducts. The acid group that is required to react is activated with Castro's reagent. Castro's reagent is displaced as L-phenylalanine is added, but the protective groups must be removed after the reaction. Carbobenzyloxy is removed by a reaction with hydrogen and platinum(IV) oxide with methanol and chloroform; benzyl is removed by reaction with hydrogen, palladium, and carbon, plus methanol and chloroform, completing the aspartame synthesis (48,49).

Another method for the synthesis of this high intensity sweetener is a very simple example of how proteases may be used in peptide synthesis. Most proteases show specificity in their cleavage sites, and may be used to synthesise specific peptide linkages (50–53). Aspartame is the dipeptide of L-aspartic acid with the methyl ester of L-phenylalanine (L-aspartyl-L-phenylalanyl-O-methyl ester). The chemical synthesis of aspartame requires protection of both the carboxyl group and the amino group of the L-aspartic acid. Even then, it produces aspartame in low yield and at high cost. If the carboxyl group is not protected, a cost saving is achieved, but about 30% of the isomer is formed and must subsequently be removed. When thermolysin is used to catalyze aspartame production, the regiospecificity of the enzyme eliminates the need to protect this carboxyl group, but the amino group must still be protected (usually by means of reaction with benzyl chloroformate to form the benzyloxycarbonyl derivative, i.e., BOC-L-aspartic acid) to prevent the synthesis of poly-L-aspartic acid. More economical racemic amino acids can also be used, as only the desired isomer of aspartame will be formed.

If stoichiometric quantities of L-aspartic acid and L-phenylalanine methyl ester are reacted in the presence of thermolysin, an equilibrium reaction mixture is produced giving relatively small yields of aspartame. However, if two equivalents of the phenylalanine methyl ester are used, an insoluble addition complex forms in high yield at concentrations above 1 M. The loss of product from the liquid phase due to this precipitation greatly increases the overall yield of this process. Later, aspartame may be released from this adduct by simply altering the pH. The stereospecificity of the thermolysin determines that only the L-isomer of phenylalanine methyl ester reacts but the addition product is formed equally well from both the D- and L-isomers. This allows the use of racemic phenylalanine methyl ester, the L-isomer being converted to the aspartame derivative and the D-isomer forming the insoluble complex shifting the equilibrium to product formation. D-phenylalanine ethyl ester released from the addition complex may be isomerised enzymically to reform the racemic mixture. The BOC-aspartame may be deprotected by a simple hydrogenation process to form aspartame (51).

15.6 NEOTAME

Neotame is the FDA approved sweetener developed by Monsanto Chemical Corporation, and was discovered by Nofri and Tinti. It is reported to be approximately 8,000 times sweeter than sugar. Neotame has approximately 40 times the sweetness potency of aspartame (54). Its chemical name is N-[N-(3,3-dimethylbutyl)-L-aspartyl]-L-phenylalanine 1-methyl ester (Figure 15.5). It was designed to overcome some of the problems with aspartame. It is more thermostable and does not break down during processing, which is a major drawback of aspartame. It is suggested for use as a tabletop sweetener, to sweeten frozen desserts, chewing gum and candy, baked goods, fruit spreads, and readymade cereals (55,56).

Neotame is a derivative of aspartame dipeptide made of amino acids: aspartic acid and phenylalanine (54). It is quickly metabolized and fully eliminated through normal biological processes. The dimethylbutyl part of the molecule is added to block the action of peptidases which are enzymes that break the peptide bond between the aspartic acid and phenylalanine. This reduces the availability of phenylalanine, eliminating the need for a warning on labels directed at people with phenylketonuria, who cannot properly metabolize phenylalanine (57,58).

15.7 STEVIOSIDE

Stevioside is a nonnutritive sweetener extracted from the leaves of the plant *Stevia rebaudiana*, which belongs to the Asteraceae family and was rediscovered by Bertoni in 1888 (59–61) (Figure 15.6). It is native to Brazil, Venezuela, Colombia, and Paraguay where the native Guarani tribes have used *caa-ehe* (stevia) for over 1500 years to sweeten otherwise unpalatable medicinal drinks. It is a herbaceous perennial, which is normally used as a natural herbal sweetener (59). The glycosides are found between the veins of the leaves which can be up to 200 times sweeter than sucrose. The sweetness is mainly attributed to the two compounds, namely stevioside (3–10% of dry leaf weight) and rebaudioside A (1–3%) (62–66). Research conducted at the College of Pharmacy at the University of Illinois found that when a bacterium was exposed to stevioside, the DNA of the bacteria was genetically altered (67). Mutagenic effects of steviol, the aglycone of stevioside, were

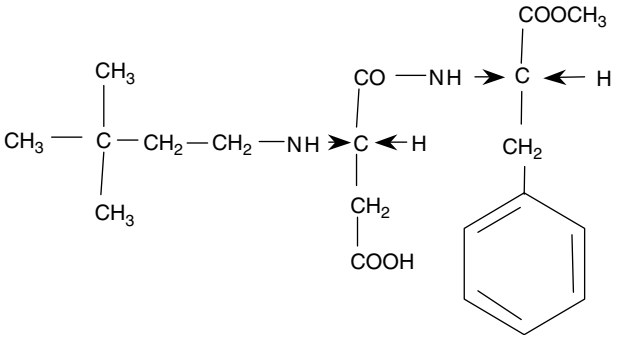

Figure 15.5 Chemical structure of Neotame

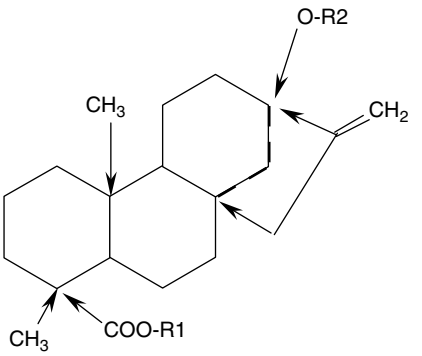

Figure 15.6 Chemical structure of Stevioside

also reported in *Salmonella typhimurium* TM677. After metabolic activation, it was shown that so far unknown steviol metabolites caused mutations in *Salmonella typhimurium* TM677, includiing transitions, transversions, duplications, and deletions at the guanine phosphoribosyltransferase (*gpt*) gene (67,68). Stevia, or stevioside, has not been granted GRAS status by the FDA, but the Dietary Supplement Act of 1994 allows stevia to be sold in the US as a dietary supplement. However, it has been used as a sweetener in South America for centuries, and in Japan for over 30 years.

The other uses for the plant and its extracts are in weight loss programs, because of its ability to reduce the cravings for sweet and fatty foods. The plant has also been used to treat diseases such as diabetes, hypoglycemia, candidiasis, high blood pressure, skin abrasions, and for inhibiting growth and reproduction of bacterialike plaque (69). The advantages of stevioside as a dietary supplement for human subjects are manifold: it is stable, it is noncalorific, it supports good dental health by reducing the intake of sugar, and opens the possibility for safe use by diabetic and phenylketonuria patients, and by obese persons. Stevioside has a few advantages over artificial sweeteners, in that it is stable at high temperatures (100°C) and a wide pH range (3–9), and does not darken with cooking. It is suggested in the use of sweetening soft drinks, ice cream, cookies, pickles, chewing gum, tea, and skin care products.

The biosynthesis of stevioside is via the recently discovered 2-C-Methyl-D-erythritol-4-phosphate pathway (MEP) due to the *ent*-kaurene skeleton of stevioside (69). The genes of the enzymes catalyzing the first two steps of this pathway, 1-deoxy-D-xylulose-5-phosphate synthase (DXS) and 1-deoxy-D-xylulose-5-phosphate reductoisomerase

(DXR) were cloned using reverse transcriptase polymerase chain reaction (PCR). The DXS and DXR from *Stevia* both contain an N-terminal plastid targeting sequence and show high homology to other known plant DXS and DXR enzymes. Furthermore, it was demonstrated through heterologous expression in *Escherichia coli* that the cloned cDNAs encode these functional proteins (70–73).

15.8 MONELLIN

Monellin is a sweet tasting protein isolated from the tropical African fruit *Dioscoreophyllum cumminsii*. Inglett and May first reported the isolation of a sweet substance from the berries in 1967. The unusual protein possesses the interesting property of having a very high specificity for the sweet receptors in the tongue (74). Monellin is made up of two dissimilar polypeptide chains, which are noncovalently associated. It consists of two peptide chains, the A chain of 44 residues and the B chain of 50 residues (75–80). These two chains, A and B, are linked by noncovalent interactions (Figure 15.7). Single chain mutants of monellins in, which the two chains are covalently linked, retain all their sweetening power and have greatly increased thermal stability (81). The first single chain monellin is obtained by joining the C-terminal residue of the B chain directly to the N-terminal residue of the A chain. The second single chain monellin is obtained by linking B and A chains *via* the Gly-Phe dipeptide. It has a molecular weight of 11,000 and is approximately 1500–2000 times sweeter than sugar on a molar basis and several thousand times sweeter on a weight basis. It does not contain carbohydrates or modified amino acids. Monellin is extracted from the fruit by removing the skin, leaching the fruit into water, and concentrating the product by salting out with ammonium sulphate. It shows little promise as a commercial sweetener because of taste qualities, stability, and difficulties in propagating the plant (74).

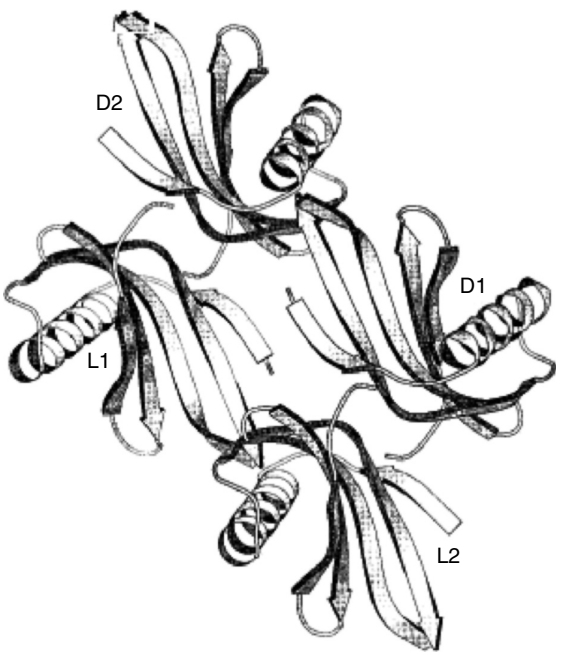

Figure 15.7 Schematic diagram of the spatial relationship of the two D-and two L-monellin molecules. Adapted from Hung L, M. Kohmura, Y. Ariyoshi, S. Kim. *J. Mol. Biol.* 285:311–321, 1999

The heterologous expression of the monellin gene in the yeast *Candida utilis* has been investigated. A single chain monellin gene was expressed under the control of the glyceraldehyde-3-phosphate decarboxylase gene promoter from *C. utilis* (80). A promoter deficient marker gene allowed high copy number integration of vectors into either the rDNA locus or the URA3 gene locus. Monellin was produced at a high level, accounting for 50% of the soluble protein. No significant decrease in the production level of monellin was detected in transformants after 50 generations of nonselective growth (80,81).

15.9 BRAZZEIN

Brazzein is a sweet tasting protein found in the fruit of the African plant *Pentadiplandra brazzeana* (82). It contains no carbohydrate, and its structure bears no structural resemblance to sucrose, small molecule chemical sweeteners, or the other sweet tasting proteins monellin and thaumatin. Moreover, members of the class of sweet proteins contain no conserved stretches of amino acids (83). It is the smallest, most heat stable and pH stable member of the set of proteins known to have intrinsic sweetness. These properties make brazzein an ideal compound for investigating the chemical and structural requirements of a sweet tasting protein. It is 2,000 times sweeter than sucrose and has a molecular mass of 6,473 Da (83,84).

Brazzein is a single chain polypeptide of 54 amino acid residues with four intramolecular disulfide bonds, no free sulfhydryl group, and no carbohydrate (82). It is rich in lysine, but contains no methionine, threonine or tryptophan. It exists in two forms in the ripe fruit. The major form contains pyroglutamate (pGlu) at its N-terminus; the minor form is without the N-terminal pGlu (des-pGlu1). Taste comparisons of chemically synthesized brazzein and des-pGlu1 brazzein revealed that the latter protein has about twice the sweetness of the former (85). It is highly water soluble with an isoelectric point (pI = 5.4) lower than those of other sweet proteins (82). It is remarkably heat stable, and its sweet taste remains after incubation at 80°C for 4 h (86). Chemical modification studies suggested that the surface charge of the molecule is important and led to the conclusion that Arg, Lys, Tyr, His, Asp, and Glu are important for brazzein's sweetness. The structure of brazzein was determined by nuclear magnetic resonance (NMR) spectroscopy in solution at pH 5.2 and 22°C (86,87). The study revealed that brazzein contains one short α-helix (residues 21–29) and three strands of antiparallel β-sheet structures (strand I, residues 5–7; strand II, residues 44–50; strand III, residues 34–39) held together by four disulfide bonds (Figure 15.8). It is proposed that the small connecting loop containing His31 and the random coil loop around Arg43 are the possible determinants of the molecule's sweetness (88,89). Brazzein can be synthesized by the fluoren-9-yl-methoxycarbonyl solid phase method which produces a compound identical to natural brazzein as demonstrated by high performance liquid chromatography, mass spectroscopy, peptide mapping, and taste evaluation. The D-enantiomer of brazzein, which is a mirror image of brazzein, was also synthesized, but was devoid of any sweetness and was essentially tasteless (85).

15.10 THAUMATIN

Thaumatin is a sweet tasting protein isolated from the arils of *Thaumatococcus daniellii* (Benth), a plant native to tropical West Africa (90). It is approved for use in many countries and has application as both a flavor enhancer and a high intensity sweetener. The

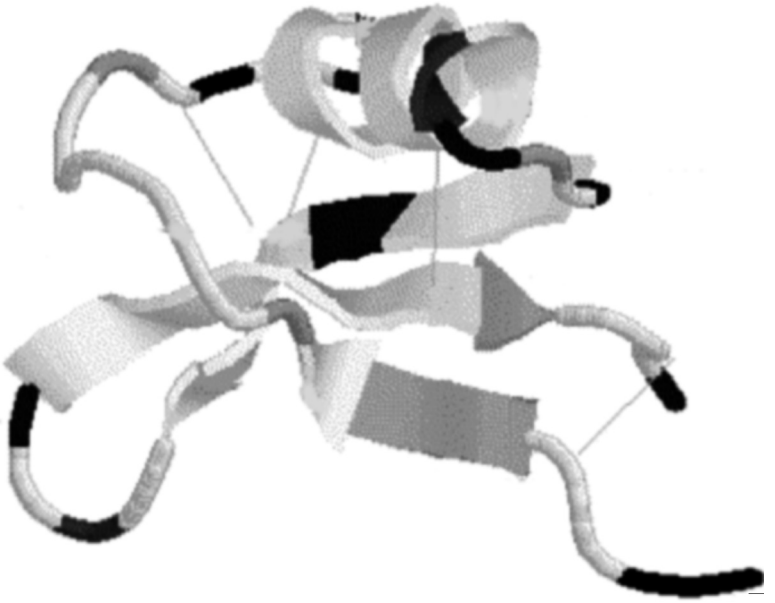

Figure 15.8 Diagram showing the three-dimensional backbone of brazzein. Adapted from Jin, Z., V. Danilova, P. Assadi, M. Fariba, D.J. Aceti, J.L. Markley, G. Hellekant. *FEBS Lett.* 544(3):33–37, 2003

availability of thaumatin of plant origin is very limited (91), and it is notoriously difficult to produce thaumatin by recombinant DNA methods (92). Production has been attempted with *Escherichia coli* (93), *Bacillus subtilis* (94), *Streptomyces lividans* (95), *Saccharomyces cerevisiae* (96), and *Aspergillus oryzae* (96). A synthetic gene for thaumatin with fungal codon usage has been synthesized, but expression in *Aspergillus niger* gave poor yields (97). Expression could be limited by a weak promoter, copy number, insertion location, inefficient processing of the prepropeptides, or bottlenecks in protein traffic and translocation through the membrane systems of the protein secretory pathway (98,99). Efficient production of a heterologous protein is usually achieved by increasing gene dosage, although overloading of the secretory pathway may result in abnormal folding and protein degradation.

Naturally occurring thaumatin consists of six closely related proteins (I, II, III, a, b, and c), all with a molecular mass of 22 kDa (207 amino acids) (90). Neither protein contains bound carbohydrate or unusual amino acids. The proteins have an isoelectric point of 12 (90). The sweet taste of thaumatins can be detected at threshold amounts 1600 times less than that of sucrose on a weight basis. The three dimensional structure of thaumatin I has been determined at high resolution (99,100), revealing that the protein consists of three domains: an 11 strand, flattened ß-sandwich (1–53, 85–127 and 178–207, domain I); a small, disulfide rich region (54–84, domain III); and a large disulfide rich region (128–177, domain II) (Figure 15.9). The five lysine residues, modification of which affected sweetness, are separate and spread over a broad surface region on one side of the thaumatin I molecule. These lysine residues exist in thaumatin, but not in nonsweet thaumatinlike proteins, suggesting that these lysine residues are required for sweetness. These lysine residues may play an important role in sweetness through a multipoint interaction with a putative thaumatin receptor (100,101).

Thaumatin was also secreted by the methylotrophic transgenic yeast *Pichia pastoris*. The mature thaumatin II gene was directly cloned from Taq polymerase amplified PCR

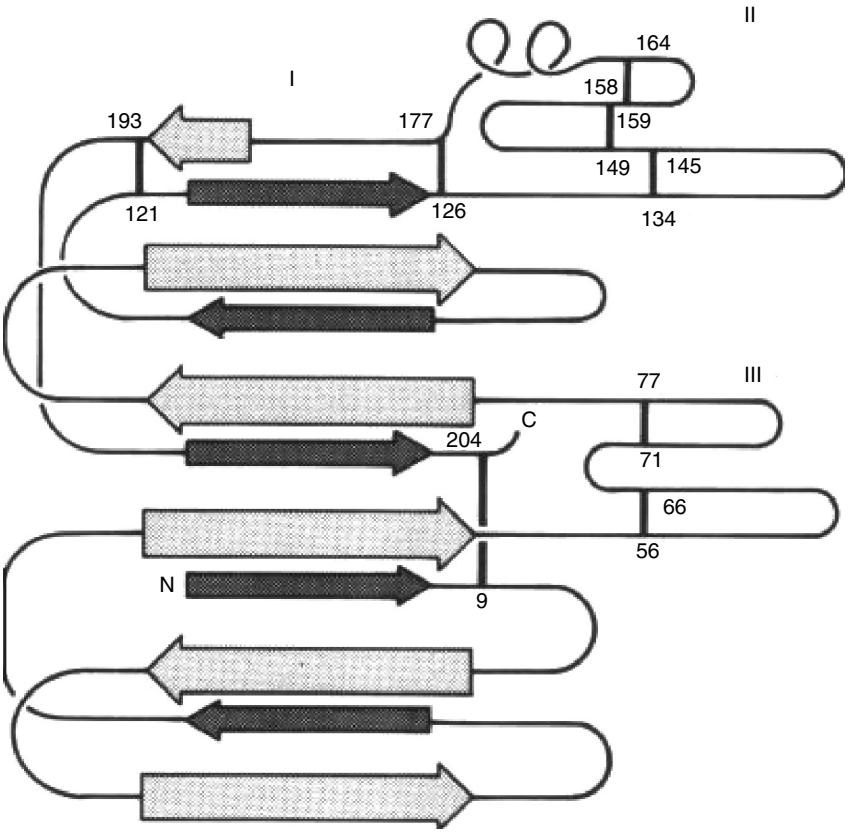

Figure 15.9 Topological structure of thaumatin. There are two beta sheets in the structure. The beta strands of the top sheet are indicated by broad arrows and those of the bottom sheet by narrow arrows. Also shown are the three domains of the protein and a crystallographic assignment of the disulphide bonds shown in black vertical bars. Figure adapted from: Vos, A.M., M. Hatada, H. Van der Wel, H. Krabbendam, A.F. Peerdeman, S.H. Kim. *Proc. Natl Acad Sci USA* 82(5):1406–1409, 1985

products by using cloning methods, and fused the pPIC9K expression vector that contains *Saccharomyces cerevisiae* prepro alpha mating factor secretion signal (101,102). Several additional amino acid residues were introduced at both the N- and C-terminal ends by genetic modification to investigate the role of the terminal end region for elicitation of sweetness in the thaumatin molecule. The secondary and tertiary structures of purified recombinant thaumatin were almost identical to those of the plant thaumatin molecule. Recombinant thaumatin II elicited a sweet taste just as native plant thaumatin II; its threshold value of sweetness to humans was around 50 nM, which is the same as that of plant thaumatin II. These results demonstrated that the functional expression of thaumatin II attained by *Pichia pastoris* systems and that the N- and C-terminal regions of the thaumatin II molecule did not play an important role in eliciting the sweet taste of thaumatin (102).

Research indicated that obtaining of thaumatin producing strains by transformation with an expression cassette containing a synthetic thaumatin gene (with an optimized codon usage) and the inactivation of a specific protease resulted in a significant increase of

extracellular thaumatin (99). An alternative method for reduction of expression of a particular gene is the use of antisense RNA. Although the technique is simple, the effectiveness of the method is influenced by many factors (103). This technique has been successfully used to silence the *creA* gene in *Aspergillus nidulans* (104). It was, therefore used to silence the *pepB* gene in *A. awamori* by the antisense RNA technique, as a first approach to elimination of the negative effect of the presence of aspergillopepsin B on thaumatin accumulation. Research revealed that significant amounts of antisense RNA of the *pepB* gene are formed by using a strong fungal promoter, but that the aspergillopepsin B is not completely removed from the broths. On the other hand, *pepB* gene disruption by replacement using the double marker selection procedure led to the complete loss of aspergillopepsin B and to a 100% increase in thaumatin accumulation under optimal fermentation conditions (105).

15.11 MABINLIN

A new sweet tasting protein named mabinlin II was extracted from the seeds of *Capparis masaikai*. It was purified by ammonium sulfate fractionation, carboxymethylcellulose to Sepharose ion exchange chromatography, and gel filtration. The sweetness of mabinlin II was unchanged by at least 48 h incubation at nearly boiling temperature (106). Purified mabinlin II thus obtained gave a single band having a molecular mass of 14 kDa on SDS/PAGE (Sodium Dodecyl Sulphate-Polyacrylamide Gel Electrophoresis). In the presence of dithiothreitol, mabinlin II gave two bands having molecular masses of 4.6 kDa and 5.2 kDa on SDS/PAGE. Two peptides (A chain and B chain) were separated from reduced and S-carboxamidomethylated mabinlin II by HPLC. The amino acid sequences of the A chain and B chain were determined by the automatic Edman-degradation method. The A chain and B chain consist of 33-amino acid and 72-amino acid residues, respectively. The A chain is mostly composed of hydrophilic amino acid residues and the B chain also contains many hydrophilic residues. High similarity was found between the amino acid sequences of mabinlin II and 2S seed storage proteins, especially 2S albumin AT2S3 in *Arabidopsis thaliana* (106,107).

15.12 CONCLUSION

The pursuit for the ideal sweetener continues. The ideal sweetener is expected to taste like sucrose, and be colorless, odorless, noncariogenic, and nontoxic; and to present a pleasant, untainted taste without a delayed onset of persistence in sweetness; but at the same time be noncaloric and low cost. The long term safety of the nonnutritive sweeteners, which is of prime importance to consumers, has yet to be thoroughly investigated. However, the wide variety of sweeteners available today enables the development of a much wider range of new, good tasting, low calorie products to meet consumer demand. A variety of low calorie sweeteners also provides products with increased stability, improved taste, lower production costs, and more choices for the consumer. The search for noncarbohydrate sweeteners from natural sources has led to the discovery of many intensely sweet tasting substances. The occurrence of sweet tasting proteins has provided a new approach to the potential treatment of diabetes, obesity, and other metabolic disorders. Such choices allow a person to control their caloric intake in a manner best suited for their health conditions.

Biotechnological Approaches to Improve Nutritional Quality and Shelf Life of Fruits and Vegetables

Reena Grittle Pinhero and Gopinadhan Paliyath

CONTENTS

16.1 INTRODUCTION

Fruits and vegetables, which can be consumed as fresh and as processed products, are important ingredients of a healthy diet. They are valuable sources of vitamins, minerals, antioxidants, and fiber. The important quality factors of fruits and vegetables are their color, flavor, texture, and nutritive value. Consumers always prefer to buy fruits and vegetables of high quality. As used by the industry, quality is a concept involving measurable attributes: degree of purity, firmness, flavor, color, size, maturity, condition, or any other distinctive attributes or characteristics of the product (1). The qualities of the produce bought by the consumer are influenced by many factors, such as the cultivar, the environmental conditions affecting growth, cultural practices, exposure to pests and diseases, time of harvesting, and postharvest and storage conditions used. Today, with the advancement of technology in several areas, the only factor on which the grower has no control of is the environment of the field conditions. Heredity (the identity of the cultivar) plays a major role in determining the quality of fruits and vegetables, as evidenced by the various varietal differences in quality. Even though traditional crop breeding is still being used as one means of crop improvement, continuing advances in knowledge and technology have dramatically expanded the biotechnological tools available for genetic improvement and production of vegetables and fruits. The term biotechnology is broad, encompassing a wide range of disciplines in science. In this chapter, the focus will be on plant transformation, where genes are modified or transferred by molecular means, and the resulting improvements in fruit and vegetable quality. Because this chapter is focused on genetic engineering, we will be discussing only the parameters and mechanisms that affect nutritional quality and shelf life (other than pests and diseases), and which can be improved or modified by genetic engineering. The discussion will also be based on two important crops; potatoes and tomato.

16.2 POTATOES

Potatoes are ranked fourth in production of all agricultural commodities in the world and yield more dry matter and protein per hectare than the major cereal crops (2). They are consumed as fresh and processed products, and used as raw material for many industrial purposes such as starch extraction. Potato chips and french fries are two of the most popular processed potato products. The consumer preference for these products is influenced by the color and crispness of these products. The primary problem associated with potato processing is the nonenzymatic browning of the product that occurs under the high temperature conditions used during frying, when reducing sugar levels are high in the tissue, a phenomenon known as Maillard reaction (3). The reducing sugars, glucose and fructose, combine with the α-amino groups of amino acids at the high temperatures used in frying operations, resulting in darker and more bitter flavored french fries and chips that are unacceptable to

the consumer. The ideal content of reducing sugars is 0.1% of the tuber fresh weight; 0.33% is the upper acceptable limit (4). A four year study was conducted to determine the compositional differences during low temperature storage between low sugar accumulating and high sugar accumulating cultivars in relation to potato chip processing quality (5). Pearson analysis of the above data showed that chip color was most closely correlated with reducing sugar concentration. Multiple regression analysis revealed that the relative contribution of each of the parameters studied, such as sucrose, reducing sugars, nitrogen, protein, ascorbic acid and dry matter content, varied greatly among cultivars and selections evaluated and from season to season (5).

16.2.1 Factors Affecting Accumulation of Reducing Sugars in Potatoes

The factors that affect the sweetening or breakdown of starch into sucrose and its component reducing sugars glucose and fructose are drought, excess nitrogen during growth, high temperature at harvest, handling, aging, identity of the cultivar, anaerobic conditions, and low temperature during post harvest storage (6).

16.2.2 Low Temperature Sweetening in Potatoes

Low temperature sweetening (LTS) in potato tubers is a phenomenon that occurs when tubers are stored at temperatures below 10°C in order to minimize respiration and sprouting. LTS results in the accumulation of starch breakdown products, primarily sucrose and the reducing sugars glucose and fructose (7), which cause Maillard browning during potato chip frying operations (3,8). Fry color of Russet Burbank and Shepody potatoes has been shown to be more closely associated with glucose concentration than with fructose, total reducing sugars, sucrose, or total sugars (9). In order to avoid Maillard browning, processing potatoes are generally stored at temperatures around 10°C; but at this storage temperature potato tubers will sprout. To prevent sprouting during storage, the processing tubers are treated with chemical sprout inhibitors. However, due to health and environmental concerns, there is increasing pressure to reduce the use of chemical sprout inhibitors. The only solution to avoid this problem is using cultivars that are resistant to LTS.

Low temperature storage of potato tubers has many advantages, such as control of sprout growth and senescent sweetening, reduction of physiological weight loss due to decreased respiration and losses associated with bacterial and fungal pathogens, and extended marketability. Low temperature storage has several advantages, but the main drawback associated with it is the accumulation of reducing sugars and the resulting browning of processed products such as chips and fries.

The mechanism responsible for the initiation and subsequent regulation of LTS in potato tubers has not been fully elucidated. Many theories have been proposed to explain LTS based on starch metabolism, sucrose metabolism, glycolysis and the oxidative pentose phosphate pathway (PPP), and mitochondrial respiration (10,11), as well as membrane instability, lipid peroxidation, and electrolyte leakage (12–15). It has been suggested that in mature, cold stored potato tubers, the glycolytic or respiratory capacity plays a key role in the ability of potatoes to regulate their sugar concentration (16). Although LTS has not been elucidated at the molecular level, many factors may play a role in it. For example, chilling may influence compartmentation and membrane permeability by altering the phase transition of lipids in the bilayer, resulting in the leakage of key ions such as inorganic phosphates. This can alter the activity and synthesis of key enzymes involved in the metabolic pathways, ultimately resulting in LTS (17).

Many theories have been postulated and documented to explain LTS at the level of carbohydrate metabolism in stored potato tubers (7,11,12,17,18). The mechanism is complex and may involve the interaction of several pathways of carbohydrate metabolism and the

genes that regulate these pathways. This discussion focuses on a theoretical model of the mechanisms involved in LTS based on information available about the roles of the major tuber carbohydrate metabolic pathways as well as changes in membrane stability (Figure 16.1).

16.2.3 Metabolism of Starch in Tuber

Starch is the major component in the main crop plants of the world, as well as an important raw material for many industrial processes. Potato tubers contain 60–80% starch, of which sugars represent only a small fraction (up to 3% on a dry weight basis) (19). There is evidence that the principal event in LTS is the cold induced synthesis of sucrose (7,12). The carbon needed for the synthesis of sucrose and reducing sugars for LTS is generally, but not always, provided by a net breakdown of starch. An increase in potato tuber sugar content occurs early during cold storage; over two to three months at storage temperatures of 1–3°C, tubers can convert as much as 30% of their starch content (20). In mature King Edward tubers stored at 2°C, the sugar content increased from 0.3 to 2.5% in three months, with the initial appearance of sucrose followed by reducing sugars (19). Coffin et al. (21) found that sucrose content increased within two days of 5°C storage for both mature and immature tubers of four cultivars, while fructose and glucose content increased more slowly. Pollock and ap Rees (22) reported an increase in both sucrose and reducing sugar content within 5 days in tubers stored at 2°C, and after 20 days storage, the sugar content was approximately

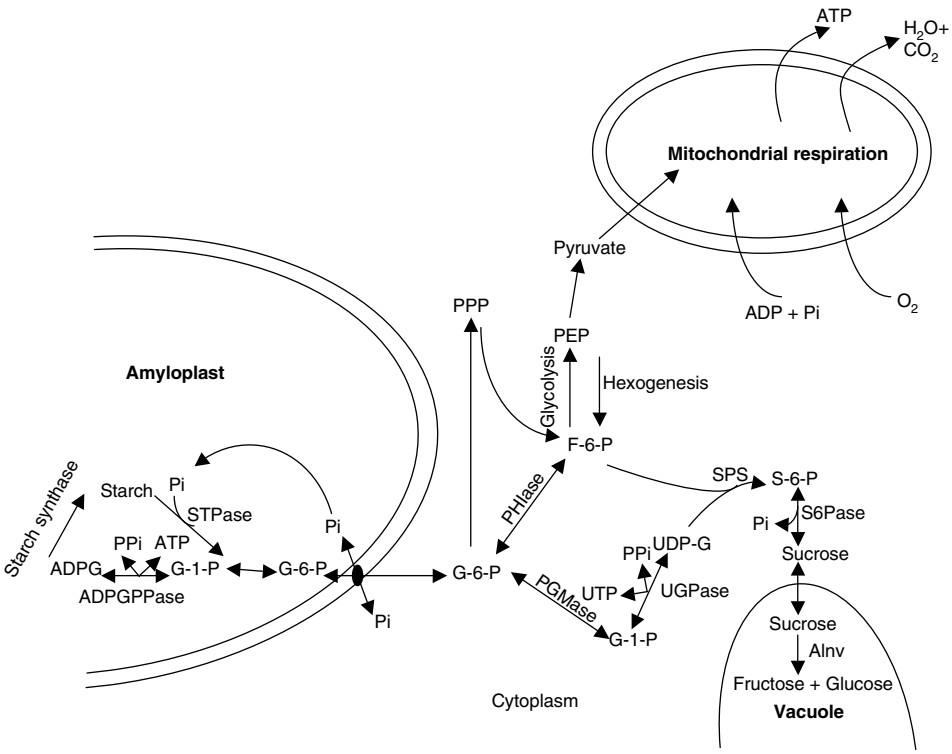

Figure 16.1 Starch-sugar interconversion in potato tubers. six times greater than at day 0. The sweetening response of tubers to low temperatures is fairly consistent, but is influenced by cultivar, locality, and conditions prior to cold storage. Isherwood (19) related energy requirements to possible biosynthetic pathways and concluded that sucrose was formed from starch when potato tubers were moved from 10° to 2°C and that starch was reformed when tubers were moved back from 2° to 10°C, although different metabolic pathways were involved. Reconditioning of tubers is sometimes used to improve chipping quality by decreasing the level of reducing sugars (20). After cold storage, potatoes are reconditioned at 18°C where sugar content decreases and starch content increases as sugars are resynthesized to starch. However, the response to reconditioning is neither consistent nor completely restorative, and tends to be cultivar dependent.

Preconditioning treatment has been used to lessen chilling injury in chilling sensitive plants. Storage at 10°C prior to cold storage can acclimatize tubers and lessen the LTS effect (8). Katahdin tubers preconditioned at 15.5°C for one to four weeks before 0°C storage did not show a change in sugar accumulation patterns or respiration rates (23). The use of intermittent warming (15.5°C for one week following 0°C for three weeks) decreased sugar levels and respiration rates to levels lower than those of tubers stored continuously at 0, 1 and 4.5°C, although sugar levels were not low enough for desirable chipping potatoes.

16.2.3.1 Starch Synthesis

Starch is synthesized in plastids (amyloplasts) upon tuber initiation, and both the number of starch grains and the grain size increase during tuber growth (Figure 16.1, Figure 16.2). Starch consists of two types of glucose polymers, the highly branched amylopectin, and relatively unbranched amylose. Potato starch is comprised of 21–25% amylose and 75–79% amylopectin (24). Starch is synthesized from ADPglucose by the concerted action of ADPglucose pyrophosphorylase (ADPGPase), starch synthase, and the starch branching enzymes (25). Following the conversion of sucrose into hexose phosphates in the cytosol, glucose-6-phosphate is transported into the amyloplast where it is converted into glucose-1-phosphate. A study involving antisense inhibition of plastidial phosphoglucomutase supported the theory that carbon from the cytosol was imported into potato tuber amyloplasts in the form of glucose-6-phosphate (26). Glucose-1-phosphate is subsequently converted to ADPglucose by ADPGPase. The starch synthases catalyze the polymerization of the glucose monomers into α-1,4-glucans using ADPglucose as a substrate, while the starch branching enzyme catalyzes the formation of the α-1,6-linkages of amylopectin (25).

ADPGPase is often referred to as a rate-limiting step in starch synthesis (25). It is subjected to allosteric activation by 3-P-glycerate and inhibition by inorganic phosphate (27). Strategies to alter the starch metabolism in tubers by genetic manipulation of ADPGPase may be helpful in reducing the accumulation of reducing sugars during LTS. It has been reported that transgenic tubers with an 80–90% reduction in ADPGPase activity have reduced starch content relative to wild type tubers (28,29). The reduction in ADPGPase activity resulted in a major reduction of carbon flux, with increased flux to sucrose and decreased flux to starch. Stark et al. (30) have reported that hexose accumulation was greatly reduced in cold stored tubers with overexpression of the mutated ADPGPase gene, glgC16, from *E. coli*. The glgC16 gene produces a mutant form of ADPGPase that is less responsive to allosteric effectors. It has been suggested that the observed decrease in hexose concentration could be due to the higher starch biosynthetic capacity of the transgenic tubers. Lorberth et al. (31) developed transgenic potatoes with decreased levels of R1 protein, a starch granule bound protein capable of introducing phosphate into starch-like glucans. By reducing the activity of the R1 protein using antisense technology, the phosphate content of starch was reduced, resulting in a starch that

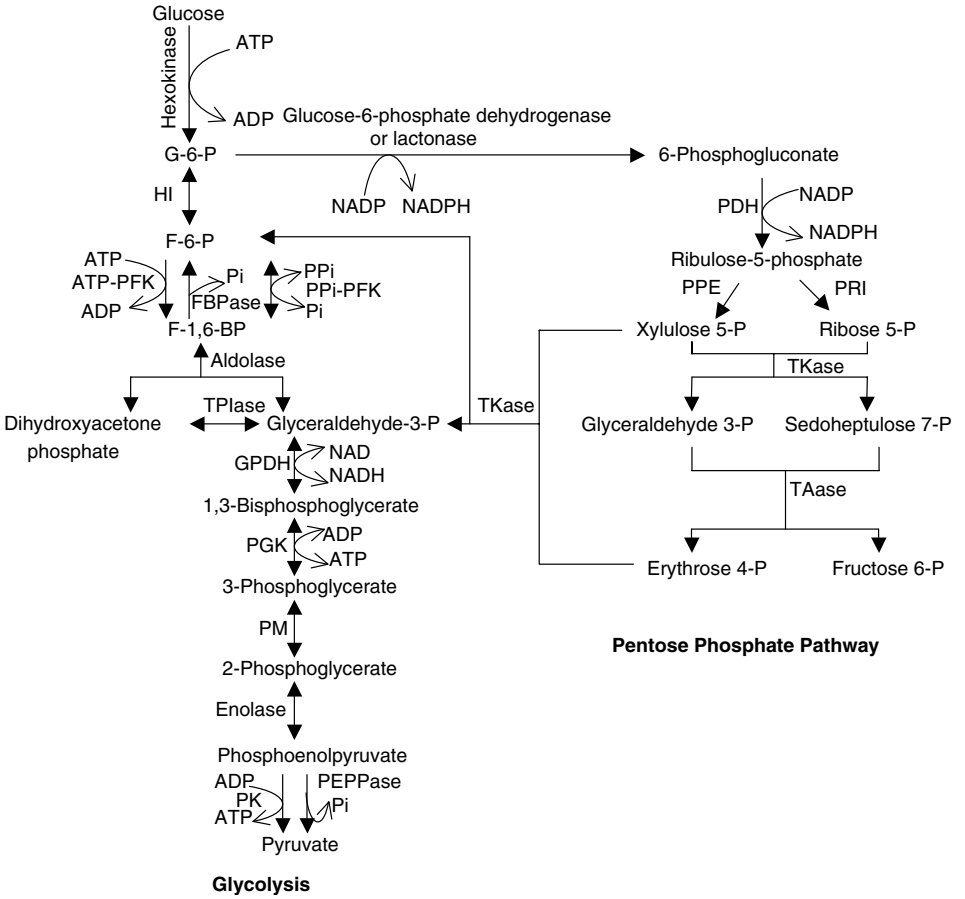

Figure 16.2 Interactions between glycolysis and pentose phosphate pathway. was less susceptible to degradation at low temperatures relative to the starch of wild type tubers. It has been observed that after two months of storage at 4°C, the transgenic tubers contained up to ninefold lower concentrations of reducing sugars compared to the wild type. However, the commercial value of the modification of starch could not be assessed because the authors did not analyze the processing quality of transgenic tubers.

16.2.3.2 Starch Degradation

The differential response of potato cultivars to LTS may be the result of starch properties that affect the ability of enzymes to degrade it. The various starch properties ascribed are:

1. Chemical modifications of glucose units by attachment of covalently bound phosphate. Phosphate esters are attached to C3 or C6 glucosyl residues of amylopectin

in the larger interbranch chains and are absent around the branching points. This affects the cleavage sites and degradation product patterns (32).

2. Surface property alteration caused by the negative surface charge from surface phosphate, lipid, or protein can affect the properties of enzymes and other soluble compounds (33).
3. Association with starch-metabolizing enzymes such as endoamylase activity in cotton leaves (34) and starch synthase in potato tubers (35).
4. Physical characteristics of starch. Isolated starch grains from two cultivars differing in their sensitivity to LTS showed an increase in starch grain size over time with the disappearance of smaller starch grains while ND860-2, the resistant cultivar had a consistently smaller mean starch grain size (36,37). Higher levels of amylose in ND 860-2 were believed to be responsible for a more ordered crystallinity within the starch granule, decreased thermomechanical analysis swelling, increased resistance to gelatinization and decreased susceptibility to α-amylase hydrolysis.

In addition to the various properties of starch, which affect its degradation, other factors such as enzymes responsible for starch degradation during LTS have been studied. The pathway of starch breakdown during LTS is not well established. The degradation of starch is believed to occur in the amyloplast (38). The widespread distribution of α-glucan phosphorylase, α-amylase, *β*-amylase, and maltase (39) suggests that starch breakdown could be phosphoryltic, hydrolytic, or both. However it is assumed that starch breakdown in cold stored potato tubers is mainly conducted by starch phosphorylase, because sucrose is the first sugar to accumulate upon transfer of tubers to chilling temperatures (19). Amylase activities are too low at such cold temperature to catalyze the required rate of starch degradation (40), and no increase in either maltose or polymers of glucose larger than maltose, the common products of amylolytic starch degradation (41), have been observed during LTS (42).

Two types of potato phosphorylases are recognized based on glucan specificity, monomer size, and intracellular location. They are noninterconvertible proteins with different primary structures and different immunological properties (38). Type 1 isozyme, also known as type H, is localized in the cytoplasm, has a low affinity for maltodextrins, has a high affinity for branched polyglucans, and cross reacts with type H phosphorylase from potato leaves. Type 2 isozyme, also known as type L, is located in the amyloplast, has a high affinity for maltodextrins, has a low affinity for branched polyglucans, and cross reacts with type L enzyme from the leaf (38,43). Type L and type H isozymes do not cross react immunologically. The function of these isozymes in starch degradation and LTS is unknown. There are reports which suggest that starch breakdown during LTS is phosphorylitic. Kumar et al. (44) have demonstrated that although the activities of cytosolic and plastidic isozymes of starch phosphorylase were reduced by up to 70% in transgenic potatoes expressing antisense cDNA constructs of starch phosphorylase, this did not affect the accumulation of reducing sugars during 4°C storage.

Other studies suggest that starch breakdown in potato tubers during cold storage is not solely due to the activity of starch phosphorylase. Cochrane and coworkers, (45) using a modified amylase assay, found that α- and *β*-amylases and α-glucosidase activities were much higher in tubers stored at the colder temperature (4°C) than those stored at 10°C, and in cultivars known to be more susceptible to LTS. It was considered inappropriate to correlate reducing sugar content and amylase activity, because the formation of reducing sugars is influenced by many other cold labile processes in the tuber. Reducing sugar content and the

activities of α- and β-amylases and debranching enzymes were measured by Cottrell et al. (46) over 139 days in five cultivars of potato tuber stored at 4 and 10°C. The activities of these enzymes were always greater at 4 than at 10°C, but cultivars that accumulated high levels of reducing sugars did not always display the greatest level of hydrolytic enzyme activity (46). It has been reported that the onset of sugar accumulation in tubers during low temperature storage coincided with an increase in the activity of one specific isoform of amylase, the β-amylase in the cultivar Desirée (47–49). β-Amylase activity was present at low levels in tubers stored at 20°C, and increased from four- to fivefold within 10 days of storage at 3°C. However, no specific role has been established for this cold induced β-amylase in LTS.

16.2.3.2.1 Effect of Inorganic Phosphates The intracellular compartmentalization of Pi has been suggested to influence carbon partitioning in nonphotosynthetic potato tubers in a manner similar to its role in photosynthetic tissues. It has been observed that increased inorganic phosphate in the amyloplast shifted metabolic activities toward starch degradation rather than accumulation (Figure 16.1) (17). Increased Pi concentration inhibits ADPGPase and enhances starch breakdown by α-glucan phosphorylase. A high concentration of Pi was found in tuber amyloplasts (50), and Pi in cold stored tubers was later found to be cleaved off from starch (51). Higher levels of Pi were found in Russet Burbank potatoes stored at 5.5 than at 15.5°C (52). A highly significant correlation was found between the Pi content and the accumulation of reducing sugars. Amyloplasts were found to have high concentrations of Pi, citrate, Cl^-, and K^+. It was suggested that Pi leaks from the amyloplast to the cytoplasm during cold storage and induces higher sugar concentration levels in tubers during LTS (53).

Another source of Pi in plant cells is the vacuole (54). The major portion of Pi is stored in potato tuber vacuoles where it is compartmentalized away from the cytoplasm. Loughman (55) examined the respiratory changes of potato tuber slices and found that the larger part of Pi in the cell was localized in the vacuole, and did not take part in the steady state metabolism of the cell. However, the Pi in the vacuole may become available for metabolism in the cytoplasm during cold storage when ionic pumps that utilize ATP in the tonoplast become unable to maintain ionic gradients (56). This scenario could happen by passive leakage of Pi into the cytoplasm or when the membrane becomes leaky due to changes in the properties of the lipid bilayer. Increased Pi in the cytoplasm could affect the metabolism by mobilizing carbon from the amyloplast into the cytoplasm in exchange for Pi transported into the amyloplast by the hexose phosphate translocator (Figure 16.1) (57). Inside the amyloplast stroma, Pi can serve as a substrate for the continued phosphorlysis of starch, via α-glucan phosphorylase, forming additional molecules of G-1-P.Elevated cytoplasmic levels of Pi initiated by leaky membranes, coupled with reduced levels of fructose 2,6,bisphosphate during cold stress, would direct carbons away from glycolysis and favor the buildup of hexose phosphates for gluconogenic reactions (17).

16.2.4 Starch–Sugar Balance

The close relationship between starch and sugar levels when potatoes are cooled from 10 to 2°C and then rewarmed from 2 to 10°C after an interval, has given rise to a misleading concept of a starch to sugar balance in which the overall change between the two compounds is seen as being reversible (19). All the available evidence suggests that sucrose is formed from starch by an irreversible pathway, and that starch is formed from sucrose by separate, but likewise irreversible, routes. The very close relationship between starch and sucrose in stored potatoes may be due to the fact that starch is the only possible source of carbon for sugar synthesis in the cold (7,11,12,17). There is a strong evidence to indicate that G-6-P is transported into the amyloplast of potato tubers to support starch synthesis (26). Thus the pathways of starch and sugar biosynthesis compete for the same pool of precursors.

A net flux of carbon from starch synthesis into sucrose occurs in cold stored tubers as evidenced from the use of radiolabels in experiments (4,58). The coexistence of the pathways of sucrose synthesis and starch breakdown in stored tubers may be regulated by fine control mechanisms. In potato discs incubated with ^{14}C glucose at 3°C and 15°C, a large proportion of label is recovered in starch. At low temperature, in a cold sensitive, high sugar-accumulating cultivar, the ratio of ^{14}C recovered in sucrose to that recovered in starch increased (4,58), but was unaffected in a cold tolerant, low sugar-accumulating cultivar (4,58). This suggests that genotypic variation in the capacity to maintain an active starch synthesizing system may help in alleviating the rate of sucrose accumulation.

16.2.5 Sucrose Metabolism

Sucrose is the first sugar to accumulate during LTS. Its accumulation in potato tubers has been recorded within hours of their placement at LTS inducing temperatures, with the accumulation of reducing sugars occurring a few days later (19). Sucrose synthesis occurs in the cytoplasm of the tuber either by sucrose 6-P synthase (SPS), or by sucrose synthase (SS) and the hexose phosphates required for this are transported from the amyloplast via a phosphate translocator (Figure 16.1) (26,59).

Pressey (60) reported that SS activities decreased after harvest, and continued to do so under low temperature storage conditions. SPS activity also decreased if tubers were held at warm temperatures but rapidly increased when tubers were held at low temperatures. This observation indicates that SPS is the enzyme responsible for sucrose synthesis at low temperatures. Pollock and ap Rees (22) reported that sucrose synthesis during LTS is catalyzed by SPS and not by SS. This was also confirmed by ^{13}C NMR studies (61).

The increase in sucrose synthesis upon transferring the tubers to low temperature has been associated with the increased expression of an isoform of SPS (SPS-1b, 127 kDa) (62). The cold induced increase in the SPS-1b isoform was found to correlate well with the change in the kinetic properties of the enzyme. The major isoform found in tubers stored at room temperature is a 125-kDa protein (SPS-1a). Reconditioning of the tubers at 20°C resulted in the disappearance of the cold induced SPS isoform after 2–4 days (49). An increase in the total amount of SPS transcript was observed at low temperature in each of these studies. SPS from potato tubers has been shown to be subject to fine regulation by allosteric effectors and protein phosphorylation (63). Potato tuber SPS is allosterically activated by G-6-P and inhibited by protein phosphorylation.

Antisense technology has been used as an effective tool to investigate the roles of enzymes that lead to the production of sucrose, as well as reducing hexoses such as glucose and fructose in LTS. Many researchers investigating LTS mechanisms have used this technology to substantiate the role of enzymes in the carbohydrate metabolic pathway. For example, in experiments involving transgenic tubers where the SPS activity was reduced by 70–80% either by antisense or cosuppression, cold sweetening was reduced by inhibiting the increase of the cold induced isoform of SPS (64). The authors also observed that the V_{max} of SPS was 50 times higher than the net rate of sugar accumulation in wild type tubers, and found that SPS is strongly substrate limited, particularly for UDP-G (Figure 16.1). These results indicate that the rate of cold sweetening in wild type tubers is not strongly controlled by the overall SPS activity or the overall amount of SPS protein. Alterations in the kinetic properties of SPS during cold temperature storage were more effective in stimulating sucrose synthesis than changes in SPS expression. The observation that changes in the kinetic properties of potato tuber SPS coincide with the onset of sugar accumulation points to the fact that the fine regulation of SPS may be more important than coarse regulation in controlling the ability of a cultivar to sweeten during cold storage.

However, it should be noted that SPS may not be the only candidate that regulates sugar accumulation during LTS, because other factors that affect the availability of hexose phosphates, such as glycolysis and the pentose phosphate pathway, may have key roles to play (Figure 16.1, Figure 16.2).

UDP-glucose pyrophosphorylase (UGPase) is a cytosolic enzyme that catalyzes the formation of UDP-G, one of the substrates required for the synthesis of sucrose (Figure 16.1). Depending on the physiological state of the tubers (i.e, growth or post harvest storage), the UGPase reaction may be directed toward the synthesis or degradation of starch (10). During the process of cold sweetening, it has been suggested that UDP-G and PPi have regulatory roles in directing carbon flux into glycolysis, starch synthesis, hexose formation, or a combination of the three (17,65). The activity of UGPase has been correlated with the amount of glucose that tubers of different cultivars accumulate in cold storage (12), leading to the assumption that this enzyme might be a control point for low temperature sweetening, as it regulates the rate of SPS and sucroneogenesis by controlling the levels of UDP-G (17,66).

Genetic manipulation to down regulate the expression of UGPase in potato tubers has resulted in contrasting results based on the physiological stage of the tubers. In two separate experiments in which the UGPase activity was reduced by 30–50% compared to their wild types, the transgenic tubers accumulated lower levels of sucrose during storage relative to wild type tubers at 4°C and 12°C (67) and at 6°C and 10°C (68). It has been suggested that by limiting the rate of UDP-G synthesis, UGPase may exert control over the flux of carbon toward sucrose during the cold storage of tubers. These observations are supported by the results of Hill et al. (47) who observed that following the initiation of cold sweetening, the concentration of UDP-G changed in parallel with the concentration of sucrose.

In contrast to the above results, Zrenner et al. (69) observed that carbohydrate metabolism of growing tubers was not affected when the transgenic plants had a 96% reduction in UGPase activity as compared with the wild type plants. No significant changes were observed in the levels of fresh mass, dry mass, starch, hexose phosphates, or UDP-G at harvest relative to the wild type tubers. It was reported that 4–5% of UGPase activity was still in considerable excess compared to the activity of other glycolytic enzymes in the tuber, and the antisense construct may have to reduce UGPase to negligible levels in transgenic potatoes before any phenotypic differences are noticeable (70).

It should be noted that the flow of carbon is different based on the physiological state of the tuber. In the growing tuber, most of the incoming sucrose is used for the synthesis of starch, while in the stored tuber the hexose–phosphate produced from starch degradation is converted into sucrose. This explains the different responses obtained by Zrenner et al. (69), Spychalla et al. (67), and Borovkov et al. (68). In cold stored tubers, when the rate of starch breakdown exceeds the rates of glycolysis and respiration, the conversion of G-1-P to UDP-G is the only means of controlling the level of hexose phosphates. Hence it is possible that a significant effect of reduced UGPase activity may be observed only in tubers acting in the direction of sucrose synthesis, such as during post harvest storage.

Two UGPase alleles have been identified in potato tubers: UgpA and UgpB (67). In a survey conducted on a number of American and European cultivars and selections stored at 4°C, it was observed that a relationship existed between the allelic polymorphism of UGPase and the degree of sweetening. The genotypes that resist sweetening during cold storage have demonstrated a predominance of the allele UgpA; the genotypes susceptible to sweetening have a predominance of the allele UgpB (68).

In order to assess the role of UGPase in LTS, Sowokinos (13) cloned UGPase from 16 American potato cultivars and selections that have varying degrees of cold sweetening ability during storage at 3°C. It was observed that cultivars that were resistant to LTS possessed

a UgpA: UgpB allelic ratio of 4:0 or 3:1. The cultivars demonstrating LTS revealed a ratio of 1:3 or 0:4 in favor of the UgpB allele. Sowokinos (13) also observed that the cold sensitive potato cultivars expressed up to three acidic isozymes of UGPase (UGP1, UGP2, UGP3) with UGP3 being the most abundant. In addition to the three isozymes present in the sensitive cultivars, the cold resistant cultivars possessed another two isozymes, UGP4 and UGP5 that were more basic in nature. Sowokinos (18) studied the physicochemical and catalytic properties of the purified UGP4 and UGP5 isozymes, and suggested that the differences in sugar accumulation between the cultivars and selections that are either sensitive or resistant to LTS may be partially due to the unique nature of expression and catalytic properties of the isoforms in resistant lines, including pH optimum, substrate affinities for G-1-P and UTP, V_{max}, and the magnitude of product inhibition with UDP-G. The overall effect of these differences in isozyme expression is that it may decrease the rate of UDP-G formation, resulting in a lower accumulation of reducing sugars in the cold resistant clones.

16.2.5.1 Sucrose Degradation

Sucrose plays a pivotal role in plant growth and development because of its function in translocation and storage, and the increasing evidence that sucrose (or some metabolite derived from it) may play a nonnutritive role as a regulator of cellular metabolism, possibly by acting at the level of gene expression (71). As mentioned earlier, sucrose is the first sugar to form during LTS, and the source of glucose and fructose accumulation appears to be the degradation of sucrose (72). Sucrose is broken down by two types of enzymes in plants. By invertase action, it is hydrolyzed into glucose and fructose; whereas by the action of SS, it is converted into UDP-G and fructose in the presence of UDP (73).

Potato tubers are known to possess both alkaline and acid invertases. Acid invertase is localized in vacuoles, whereas alkaline (neutral) invertase is localized in the cytoplasm (72,74). Acid invertase isoforms that are ionically bound to the cell wall have also been identified (74). Alkaline invertases are sucrose specific, while acid invertases cleave sucrose at the fructose residue but can also hydrolyze other β-fructose containing oligosaccharides such as raffinose and stachyose (74).

Based on several observations of sucrose synthase and acid invertase activities in developing, mature, and cold stored tubers, and given the fact that sucrose is stored mainly in the vacuole, it is believed that sucrose synthase is responsible for sucrose degradation in developing tubers, whereas acid invertase is the principal enzyme responsible for the breakdown of sucrose into hexoses during LTS (60,70,73,75–77). Based on the widely established inverse correlation between sucrose content and vacuolar acid invertase activity, it is strongly believed that sucrose is broken down by acid invertase in the vacuole and the resulting glucose and fructose are transported into the cytosol for the formation of hexose phosphate by hexoskinase (72,78–80). It has been reported that glucose concentrations are frequently higher than fructose concentrations in stored potato tubers (81). Zrenner et al. (82) evaluated the glucose to fructose ratio of 24 different cultivars and found that the ratios were between 1.1 and 1.6, which is a strong indicator that invertase is the key enzyme responsible for the conversion of sucrose to hexose.

Zrenner et al. (82) studied the effect of soluble acid invertase activity in relation to the hexose to sucrose ratio in 24 different potato cultivars and observed a strong correlation between the hexose to sucrose ratio and the extractable soluble invertase activity. They also isolated a cold inducible acid invertase cDNA from potatoes and developed transgenic potatoes expressing the invertase cDNA in an antisense orientation. The subsequent 12–58% reduction of acid invertase activity compared to the wild type tubers resulted in an accumulation of sucrose and a decrease in the concentration of hexoses. The hexose to

sucrose ratio was found to decrease with decreasing invertase activities; however, the total amount of soluble sugars did not significantly change. Based on these observations, it was concluded that invertases do not control the total combined amount of glucose, fructose, and sucrose in cold stored potato tubers, but are involved in the regulation of the ratio of hexoses to sucrose (82). Greiner et al. (83) strongly inhibited the activity of cold induced vacuolar invertase in potato plants by repressing the activity, or by the expression of a putative vacuolar invertase inhibitor from tobacco (Nt-inh), in potato plants under the control of the CaMV 35S promoter. It was possible to decrease the cold induced hexose accumulation up to 75% without affecting tuber yield. Although the concentration of sugar produced during cold induced sweetening was decreased, the level of hexose accumulated was still in excess of what is commercially acceptable for the production of potato chips and fries. The observation that antisense expression of acid invertase did not control the total amount of soluble sugars in cold stored potato tubers (82) indicates that other factors in the carbohydrate metabolism may influence the regulation of the total amount of sugars accumulated, and that acid invertase could be only one of the enzymes involved in starch–sugar conversion.

Metabolism is more rigorously regulated by intracellular compartmentalization in plants than in animals (84), and compartmentalization of the pathways of carbohydrate catabolism is realized to be a distinct feature of plant respiration (70). It is now believed that a "futile" cycling (simultaneous synthesis and degradation) of sucrose functions continuously to allow plants to respond rapidly to demand for carbon (85). This metabolic cycle may also be involved in LTS. For instance, it has been observed that in the first two weeks of 4°C storage, the initial rates of sucrose accumulation corresponded closely with the estimated rates of sucrose synthesis (47). The rate of total soluble sugar accumulation decreased with increasing duration of cold storage. It is suggested that sugar accumulation decreased because the rate of recycling equalled the rate of synthesis.

16.2.6 Glycolysis

The effects of cold exposure on the metabolism of potato tubers indicate that cold induced sweetening may at least in part be due to differential sensitivity to low temperature of the enzymes in the glycolytic pathway (86). The available data suggest that phophofructokinase (PFK) and pyruvate kinase are more sensitive to cold than are the other enzymes involved in the metabolism of hexose-6-phosphates (Figure 16.2), and by lowering the temperature, divert the latter to sucrose (Figure 16.1) (22,86,87). Another glycolytic enzyme that has been studied in relation to LTS is fructose-1,6-bisphosphatase (FBPase). Plants possess ATP dependent (ATP-PFK) and PPi dependent (PPi-PFK) phosphofructokinases (88).

PPi-PFK is a cytosolic enzyme and experiments to examine the role of PPi-PFK during the aging of tissue slices from potato tubers (starch-storing tissue) and carrot roots (sucrose-storing tissue) showed that both vegetables showed the same pattern of changes of phosphorylated metabolites and fructose 2,6-bisphosphate. But, the consumption of PPi by tubers and the production of PPi in carrots indicated PPi-PFK control of the glycolytic flux in tubers and catalysis of the opposite reaction in carrot roots (89). PPi-PFK is activated by fructose-2,6-bisphosphate which does not affect ATP-PFK (90). The activity of PPi-PFK is often equal to or exceeds that of ATP-PFK (72,90). It has been reported that the activity of PPi-PFK was ten times that of ATP-PFK in developing potato tubers, and hence it is suggested that glycolysis may proceed regardless of the activity of ATP-PFK (91). The maximum activity of PPi-PFK has also been shown to be greatly reduced in tubers stored at a low temperature of 5°C due to a decrease in PPi-PFK affinity for fructose 2,6-bisphosphate, an increase in sensitivity to fructose 2,6-bisphosphate as an activator,

and a decrease in fructose 2,6-bisphosphate concentration at decreasing temperature (92). By contrast, in another study, no evidence was found for a cold induced inhibition of PPi-PFK in tubers stored at 2°C and 8°C (93). Hence it was postulated that PPi-PFK contributes to LTS by regulating the PPi concentration below inhibitory levels, facilitating the formation of UDP-G and subsequent synthesis of sucrose (Figure 16.1 and Figure 16.2).

ATP-PFK has been implicated in the regulation of LTS (94,95). It is responsible for the irreversible ATP dependent conversion of fructose-6-phosphate to fructose-1,6-bisphosphate. Potato tubers have been reported to possess four isozymes of ATP-PFK (96). It has been reported that the temperature coefficient (Q_{10}) of three of the four isoforms were higher at 2–6°C than at 12–16°C, indicating the cold lability of these isoforms and their roles in the accumulation of hexose phosphate and sucrose synthesis in LTS (95). This result supports the suggestion of Bryce and Hill (97) that ATP-PFK dominates the control of glycolysis, and thereby respiration, in plants. However, the observation that respiration of potato tubers increases concomitantly with the initial increase in sugar concentration (19,98), and the fact that the conversion of fructose-6-phosphate is also catalyzed by PPi-PFK (ure 16.2) indicate multiple regulatory controls in the biosynthesis of sugar phosphates.

Genetic manipulation of the two PFKs was carried out further to explore their roles in LTS. About 88–99% inhibition of PPi-PFK expression was obtained in stored tubers by antisense expression of PPi-PFK cDNA (99). Even though the transformation resulted in higher levels of hexose phosphates in transgenic tubers compared to their wild type tubers, no difference was observed between these tubers in the rates of sucrose and hexose accumulation, and the total amounts of sugars accumulated at 4°C. Besides, no change was observed in the maximum catalytic activities of ATP-PFK or other enzymes of glycolysis (pyruvate kinase) or sucrose breakdown (invertase and sucrose synthase) in the antisense tubers. This observation suggests that compensation occurs at the level of fine metabolic regulation rather than gene expression. The above results indicate that PPi-PFK may not control the rate of glycolysis at low temperatures, and that tubers possess excessive capacity to phosphorylate fructose-6-phosphate. The results are also not in agreement with the theory proposed by Claassen et al. (93), that PPi-PFK is involved in regulating the PPi concentration, as no evidence was observed to substantiate that the antisense and wild type tubers contained different PPi concentrations (99).

Expression of the *E. coli* pfkA gene in potato tubers resulted in a 14- to 21-fold increase in the maximum catalytic activity of ATP-PFK, without affecting the activities of other glycolytic enzymes (100). It was also found that no corresponding decrease in the concentration of hexose phosphate was observed, while the pool sizes of other glycolytic intermediates increased three- to eightfold. In another study, it was reported that a substantial increase in ATP-PFK activity did not affect the flux through glycolysis or a flux between glycolysis and the PPP (101). The above results suggest that ATP-PFK may not limit the rate of respiration of potato tubers. ATP-PFK is potently inhibited by phosphoenolpyruvate, and hence ATP-PFK activity may be dependent upon the activity of enzymes that metabolize phosphoenolpyruvate (PEP) such as pyruvate kinase and phosphoenolpyruvate phosphatase. The above contention is in agreement with the findings of Thomas et al. (102). Using metabolic control analysis (MCA) on tuber glycolysis, Thomas et al. (102) observed that ATP-PFK exerts little control over glycolytic flux, while far more control of flux resides in the dephosphorylation of PEP.

Fructose 1,6-bisphosphatase is localized in the plastids and in the cytosol. Cytosolic FBPase is involved in hexogenesis, converting fructose-1,6-bisphosphate to fructose-6-phosphate, which is used by SPS as one of the substrates for the production of sucrose-6-phosphate (Figure 16.1 and Figure 16.2). FBPase is potently inhibited by fructose-2,6-bisphosphate (90,103), a metabolite which is also a potent activator of PPI-PFK (104). In a study to

investigate the role of FBPase in LTS, it was observed that there was a rapid increase in the levels of sucrose and reducing sugars in tubers stored at 2°C, but no change in FBPase activity, relative to 8°C storage.

In a study carried out to identify the regulatory steps in glycolysis, a decline in phosphoenolpyruvate and a rise in pyruvate were observed when potato tubers were stored under anoxic conditions (86). As this step is preceded by phosphofructokinase, pyruvate kinase cannot regulate glycolytic flux directly as it cannot control the entry of glucose-6-phosphate into glycolysis. However, pyruvate kinase could play a role in the regulation of the movement of carbon out of glycolysis and into the oxidative pentose phosphate pathway. It has been suggested that the cold lability of phosphofructokinase and pyruvate kinase could lead to a rapid reduction in hexose phosphate consumption, which could cause their diversion to sucrose (86).

The theory that the cold lability of enzymes in the glycolytic pathway diverts hexose 6-phosphate for sucrose production and thus to LTS cannot fully explain LTS, as it takes time for potatoes to sweeten fully (7). From the results of a study carried out by Marangoni et al. (16), by comparing LTS resistant (ND860-2) and LTS susceptible (Norchip) potato cultivars, it has been suggested that tubers with decreased invertase activity along with increased glycolytic or respiratory capacity, should be more tolerant to low temperature stress.

16.2.7 Oxidative Pentose Phosphate Pathway (PPP)

Although the PPP is usually depicted as being separate from glycolysis, the two pathways are intimately linked (Figure 16.2). They share the common intermediates glyceraldehyde 3-phosphate, fructose 6-phosphate and glucose 6-phosphate, and flow through either of the pathways will be determined by the metabolic needs of the cell. The main function of PPP is to generate NADPH for various biosynthetic reactions (105). It was proposed by Wagner et al. (106) that for low sugar accumulating cultivars, the PPP may provide a means of preventing the accumulation of high levels of sugars when tubers are stored below 10°C (by bypassing phosphofructokinase). However, no differences were observed in the specific activities of glucose 6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase among LTS resistant and LTS susceptible potato cultivars stored at 4°C and 12°C, respectively (107). It was observed that the LTS resistant cultivars exhibited higher activities of G6PDH and 6PGDH, relative to the LTS susceptible cultivars.

16.2.8 Mitochondrial Respiration

During storage of potato tubers below 5°C, in addition to changes in sugar accumulation patterns, respiration changes have also been observed (108). It has been reported that the cold resistant potato clone ND860-2 has shown a higher respiration rate throughout storage compared to the cold susceptible Norchip (109). Respiration decreases as storage temperature decreases, but at storage below 5°C, respiration is stimulated. There is a brief respiratory burst attributed to the combined effect of cyanide resistant (alternative pathway) and cytochrome mediated pathways (108), followed by a subsequent decrease in respiration rate to a new steady state (19,99).

It has been suggested that during chilling stress, an alternative oxidase pathway may play a protective role in the mitochondrion by preventing both an over reduction of the respiratory chain and the consequent production of reactive oxygen species that cause cellular damage (110). It has been suggested that the alternative pathway operates only during periods of high cellular energy charge, or when there is an imbalance between the supply of carbohydrates and the requirement for carbohydrates for structural growth, energy production, storage, and osmoregulation (111,112). There is also evidence which suggests

that physical characteristics of the cellular membrane (i.e., mitochondrial membranes) may activate the alternative pathway (113). In a study carried out by Amir et al. (99) to study the relationship between respiration rate, sugar content, and ATP levels in cold stored tubers, an immediate decrease in respiration rate was observed upon storage at 4° C. The respiratory minimum was concomitant with an ATP maximum which is followed by a respiratory burst and a rapid decline in ATP content. This evidence suggests the presence of an active alternative pathway in cold stressed tubers. Expression of the alternative pathway is known to increase with decreasing temperatures (114). It has been suggested that sucrose formation could serve as an effective sink for excess ATP via the alternative pathway (113). In agreement with Solomos and Laties (113), it was observed that low O_2 levels, which inhibit the alternative pathway, were effective in suppressing sugar accumulation in tubers stored at 1°C (115) which suggests that LTS may be directly linked to the onset of cyanide resistant respiration.

16.2.9 Compartmentation and Stress Induced Membrane Changes

Membranes play an integral role in the response of plant tissues to chilling and freezing. It has been proposed that the thermotropic phase transition of membrane lipids might play an initiative role in the chilling sensitivity of plants (116–118). With further exposure to chilling, the phase separated biomembranes become incapable of maintaining ionic gradients and cellular metabolism becomes disrupted. The occurrence of phase separation as the initial event in chilling injury has been demonstrated in cyanobacterium *Anacystis nidulans* (119). It has been argued that such a phase separation would not occur in plant cells because they contain high levels of polyunsaturated fatty acids in their membranes. However, a positive correlation has been observed between chilling sensitivity of herbaceous plants and the level of saturated and transmonounsaturated molecular species of phosphatidylglycerol in thylakoid membranes (120,121).

It is likely that the regulation of starch breakdown and of sucrose synthesis is to some extent achieved by compartmentation. Therefore, it is possible that low temperature sweetening is, at least in part, due to effects of cooling on such compartmentation (7). In potatoes, studies have been performed on the effects of cold storage on lipid composition and membrane permeability (122,123), the associated biophysical changes of amyloplast membranes (124,125) and mitochondrial membranes (126), and lipid peroxidation (15,127–129). The results of these studies are described below.

16.2.9.1 Lipid Composition

Phospholipids and glycerolipids are the major potato lipids (130). It has been found that the combined proportion of polyunsaturated fatty acids (linoleic and linolenic) for all potato varieties examined consistently represents 70–76% of the total fatty acids, which help maintain membrane fluidity at lower temperatures (130).

In plants stressed by low temperature or other factors, the survival of the plant is based on the ability of the plant to maintain or reestablish membrane fluidity (131). Fatty acid desaturases play a central role in regulating the level of unsaturation of fatty acids in membrane lipids, which helps maintain membrane fluidity or refluidizes the membranes that have become rigid due to low temperature exposure (132). Bonnerot and Mazliak (133) reported cold induced oleyl-PC desaturase activity in microsomes from 16 h aged slices of potato tubers stored at 4°C for 3 months. Spychalla and Desborough (134) reported that the total amount of linoleic and linolenic acids remained constant, but the ratio of linolenic to linoleic increased over storage time for both tubers stored at 3°C and 9°C. Low temperature storage of potato tubers has been shown to increase the levels of

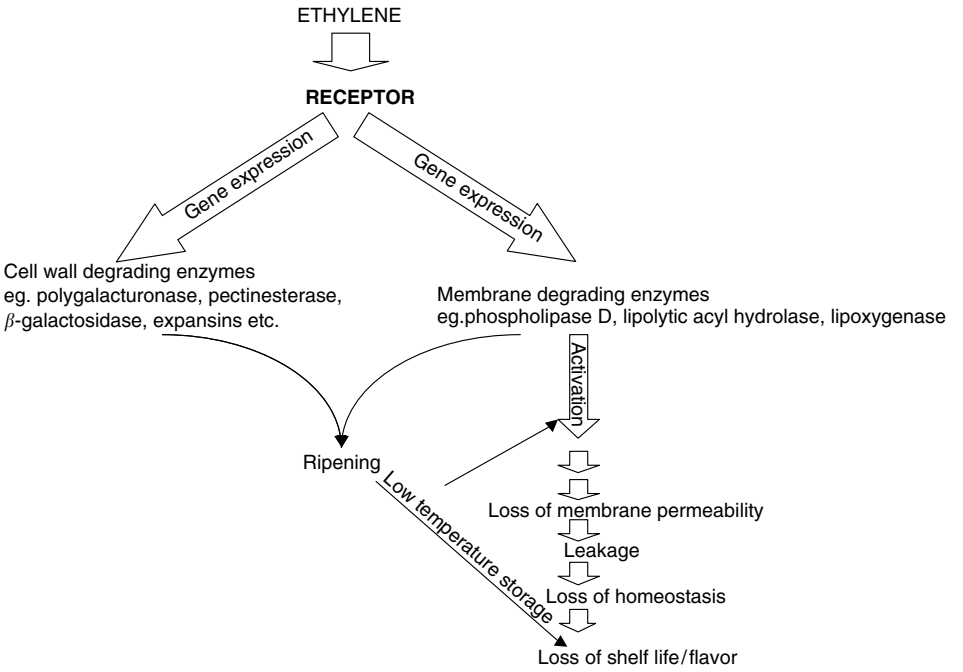

Figure 16.3 Schematic diagram illustrating the early events in the membrane and cell wall degradation during fruit ripening.

monogalactosyl diacylglycerol and digalactosyl diacylglycerol (135–137). Hence, it is possible that one or more of the low temperature induced changes in the lipid composition of the membrane may contribute to LTS or confer resistance to LTS.

16.2.9.2 Membrane Permeability

Several studies have reported that cold temperature damages membranes, resulting in the loss of compartmentation and homeostasis of the cell (138–140). As temperature decreases, membrane lipids undergo a phase transition from a liquid crystalline to a solid gel phase that results in cracks in the membrane, increases the membrane permeability and leakage of ions, and alters metabolism (141). The temperature range for the phase change in membranes is specific for each horticultural commodity and is a function of the heterogeneity of the lipid content, the ionic environment, and the presence of sterols and proteins (142).

From the earlier discussions, it is believed that LTS is caused by the effect of low temperature on many pathways of carbohydrate metabolism at the level of starch synthesis and breakdown, sucrose synthesis, hexogenesis, glycolysis, the PPP, and mitochondrial respiration. These pathways are also compartmentalized in the plant cell, and involve amyloplasts, the cytoplasm, vacuoles, and mitochondria. For the maintenance of homeostasis in normal cells, a tight control of the movement of the substrates or intermediates of these pathways is in place. However, when the plant, or a cell of the plant, experiences stress (such as low temperature stress as in the case of LTS), the normal metabolism of the cell will be lost, which might make the cell a candidate for readjustment at various levels. It is assumed that the changes caused by low temperature at the membrane level might be one of the factors contributing to LTS.

16.2.9.2.1 Tonoplast Membrane Permeability The "leaky membrane theory" of LTS suggests that the cause of LTS may be a leaky tonoplast membrane that allows Pi to be

leaked into the cytoplasm from the vacuole (17). A high concentration of Pi in cytoplasm is believed to mobilize carbon from the amyloplast to the cytoplasm, while cytoplasmic Pi participates with G-1-P in a reversible exchange across the amyloplast membrane. Increased Pi concentration in the amyloplast favors the α-glucan phosphorylase activated starch breakdown and inhibits ADPGPase mediated starch synthesis (17). In addition Pi affects fructose 2,6,-bisphosphate, phosphofructokinase, sucrose synthase, and UGPase (see section 16.2.3.2.1). The leaky membrane theory is been supported by subtle changes in fatty acid composition of potato membranes as well as by increases in electrical conductivity, which is an indicator of electrolyte leakage and membrane permeability. It has been reported that the relative change in electrical conductivity of four cultivars of potato paralleled the increase in sugar concentration when temperature was dropped from 20°C to 0°C (143). A difference in electrical conductivity was noticed among cultivars that had accumulated similar amounts of sugars. It was concluded that the increased electrical conductivity was not due to the increase in the accumulation of sugars, particularly because respiration rates were found to increase before the increase in sugar concentration and electrical conductivity.

Knowles and Knowles (122) studied the relationship between electrolyte leakage and degree of saturation of polar lipids in Russet Burbank seed tubers stored at 4°C, and observed an inverse linear relationship between the double bond index (DBI) and electrical conductivity ($r = -0.97$). The DBI revealed that the proportion of unsaturated fatty acids in membranes decreased over storage time with an accompanying increase in electrical conductivity. The authors concluded that the ability to increase membrane lipid unsaturation in storage could confer resistance to electrolyte leakage by maintaining the fluidity of the membranes. This result was supported by another study, in which it was observed that tubers stored at 3°C had greater increase in sugar content, total fatty acid saturation, and membrane permeability, as compared to tubers stored at 9°C (123). These studies suggest that high initial or high induced levels of lipid unsaturation could prevent increased membrane permeability during low temperature storage. It has been reported that cyanobacteria transformed with *des*A gene, which encodes a 12 acyl-lipid desaturase in *Synechocystis* PCC6803, did not show any significant changes in photosynthetic activity below 10°C, whereas in the wild type cells, the photosynthetic activity was decreased irreversibly (132).

16.2.9.2.2 Amyloplast Membrane Permeability It has been suggested that the low temperature induced defects in amyloplast membrane allow α-glucan phosphorylase from the cytoplasm to enter the amyloplast and degrade starch, resulting in the accumulation of sugars during LTS (144,145). Electron spin resonance study, used to examine the amyloplast membrane in potato tubers stored at 5.5 and 15.5°C, showed a strong relationship between membrane permeability and starch to sugar conversion (146). Studies using spin labeled probes revealed that at low temperatures, membranes exhibited decreased lipid fluidity. O'Donoghue et al. (125) observed that membrane lipid phase transitions were higher for Norchip (an LTS susceptible cultivar) than ND 860-2 (an LTS resistant cultivar) at both 4 and 12°C storage, and Norchip amyloplast membranes were more ordered at 4 than 12°C. The drop in double bond index (DBI) was 93% for Norchip while only 70% drop was observed for ND 860-2 due to loss of linoleic and linolenic acid. It was suggested that low temperature caused Norchip membranes to undergo deterioration to a greater extent than ND 860-2 membranes and this could have contributed to LTS. By contrast, it has been reported that the amyloplast membrane breaks down during senescence but remains relatively intact during LTS (147–149). Based on TEM examination of membranes from LTS resistant and LTS susceptible cultivars of potatoes stored at 5 and 10°C, Yada et al. (149) concluded that LTS is not the result of amyloplast membrane breakdown. However, it is likely that changes in membrane can take place at the molecular composition or organizational level, which can affect the permeability or transport properties, or both, and can contribute to LTS.

16.2.10 Free radicals and Antioxidant Enzymes

Evidence from several lines of research suggests that a variety of toxic oxygen species such as superoxide radicals, hydrogen peroxide, and hydroxyl radicals are produced in plants exposed to various environmental stresses such as high and low temperatures, drought, light, and exposure to pollutants causing oxidative damage at the cellular level (150). Lipid peroxidation is considered to be one of the reasons for membrane deterioration during senescence and chilling injury (140), and results from the activity of lipoxygenase, resulting in the formation of lipid peroxides and free radicals (151). In a study to analyze the relationship between sugar accumulation and changes in membrane lipid composition associated with membrane permeability in early stages of LTS, sucrose cycling and accumulation were greatest for Norchip, a LTS susceptible cultivar at 4°C as compared to LTS tolerant ND 860-2 (15). No significant changes were observed in phospholipid, galactolipid, free sterol levels, or phospholipid to free sterol ratio. However, the double bond index obtained from the fatty acid profiles of the total lipid fraction decreased significantly (decreased unsaturation) for Norchip tubers at 4°C over time. Free fatty acid and diene conjugation values fluctuated and increased over time for both Norchip and ND 860-2 stored at 4°C and 12°C, with greater amplitude of fluctuations observed for Norchip stored at 4°C. From the results, it has been suggested that these effects may be due to the high levels of lipid acyl hydrolase and lipoxygenase found in potato tubers, and the observed peroxidation products could relate low temperature stress and the resultant LTS to chilling injury and drought stress (15). However, Fauconnier et al. (152) could not observe a correlation between cold sweetening and membrane permeability or lipid saturation status. They studied the effect of three storage conditions: at 4°C, at 20°C with sprout inhibitors, and at 20°C without sprout inhibitors, and observed that during storage at 20°C without sprout inhibitor, the increase in membrane permeability is inversely correlated to sucrose accumulation. It was also observed that lipoxygenase activity and gene expression are not correlated with the fatty acid composition of the membrane. It was also observed that the lipoxygenase activity and fatty acid hydroperoxide content are low in older tubers, irrespective of the storage conditions and the varieties. Spychalla and Desborough (134) studied the antioxidant potential of potato tubers stored at 3 and 9°C and observed that tubers stored at 3° C had higher superoxide dismutase activities than their 9°C counterparts and demonstrated time dependent increases in superoxide dismutase, catalase, and α-tocopherol during the 40 week storage period. They also observed that low sugar clones had significantly higher levels of superoxide dismutase and catalase than high sugar clones but significantly lower levels of α-tocopherol. The increased antioxidant responses could be due to increased free radical production as manifested by the higher levels of superoxide dismutase, catalase, and peroxidase activities in seed tubers stored at 4°C for 20 months as against those stored for 8 months (129).

From the above discussion, it can be concluded that LTS is not the result of a single cause. The sugar balance in potato is regulated by many intermediate carbohydrate metabolic pathways, which are subject to genetic and environmental control. It might be possible that the low temperature effects on enzymes involved in carbohydrate metabolism result in an imbalance in the normal metabolism combined with its effect on membrane fluidity, thus diverting or leaking the intermediates, or both, in the biosynthetic or respiratory pathway for sucrose and reducing sugar production. Hence, even though genetic engineering has great potential in manipulating or improving crop productivity and the quality of horticultural crops, because of the complexity of LTS, in depth research on various molecular and biochemical properties and their correlation to LTS need to be conducted before we can fully exploit that potential. The existence of cultivars resistant to LTS with several molecular, biochemical, or compositional characteristics, or combinations of

these, might provide a better tool in understanding the mechanism that is responsible for resisting LTS in those cultivars. We can therefore be hopeful that the coordinated efforts of plant biochemists, molecular biologists and traditional plant breeders would help to better understand and control LTS, thus eliminating the use of chemical sprout inhibitors and their harmful safety issues.

16.3 TOMATO

Tomatoes rank second to potatoes in dollar value among all vegetables produced in the USA and in other parts of the world where they are grown (1). In terms of per capita consumption, processed tomato products lead all the other processed vegetables. The main factors in determining the postharvest deterioration of fruit and vegetable crops are the rate of softening of the fruit which influences quality, shelf life, wastage, infection by postharvest pathogens, and frequency of harvest, and which limit the duration of transportation and storage. Damage to the structure and function of the membrane affects the post harvest shelf life and quality of fruits, vegetables, and other food sources by causing leakage of ions from cellular storage compartments into the cytosol, thereby disrupting the homeostasis of the cell (153,154). A major problem faced by the fruit and vegetable fresh market and processing industry in the Northern Latitudes is the lack of a year round supply of high quality material. Even though cold storage can be used for long term storage of fruits and vegetables, in the case of tomatoes it is not effective due to the sensitivity of tomatoes to being chilled. Many factors affect the shelf life of tomato products, but our discussion will be based mainly on membrane changes during cold storage and the genetic manipulation to circumvent these factors.

16.3.1 Role of Membrane in Shelf life

The development of fruit in many plants can be interpreted as following a two step process. During the first phase, the ovary or hypothalamus within the flower expands and develops into a full sized fruit. During the second phase, the full sized fruit undergoes ripening, a complex set of molecular and physiological changes in the fruit. The ripening process brings dramatic changes to the fruit: softening, biosynthesis of pigments, and increase in sugar content, flavor, and aroma. In climacteric fruits such as tomatoes, and many other fruits, ripening begins with increased respiration and ethylene biosynthesis (155). Fruit ripening can be considered as the beginning of senescence of the fruit (156).

Senescence can occur at various levels, from cellular to whole plant levels, and is regulated by genetic, hormonal, and environmental factors (140,157). The plant hormone ethylene plays a major role in the ripening and senescence processes, and extensive work has been conducted in the past two decades on the role of ethylene in fruit ripening and signal transduction. Genetic manipulation to increase the shelf life of fruits, especially tomatoes, has been extensively undertaken, resulting in several new transgenic varieties with improved storage and quality characteristics (158–164).

Senescence is characterized by membrane deterioration resulting from the catabolism of membrane lipids and proteins. The pathway of the catabolism of phospholipids has been elucidated from several senescing systems and involves the sequential action of enzymes that include phospholipase D (PLD, phosphatidyl choline hydrolase, EC 3.1.4.4, PLD), phosphatidate phosphatase (3-*sn*-phosphatidate phosphohydrolase, EC 3.1.3.4), lipolytic acyl hydrolase and lipoxygenase (linoleate, oxygen oxidoreductase, EC 1.13.11.12) (140). In most systems studied, the first step in the lipid catabolic pathway is the conversion of phospholipid to phosphatidic acid by PLD, even though phosphatidylinositol and

its phosphorylated forms may be acted upon by both phospholipase C and PLD (165,166). Phosphatidic acid does not accumulate, as it is immediately converted to diacylglycerol by phosphatidate phosphatase. Diacylglycerol is deacylated by lipolytic acyl hydrolase, liberating free fatty acids. Among the free fatty acids, unsaturated fatty acids with 1–4 pentadiene systems (18:2 and 18:3) serve as substrates for lipoxygenase, resulting in the formation of fatty acid hydroperoxides. Fatty acid hydroperoxides undergo a variety of reactions by virtue of their active unstable structure, including the generation of free radicals. The free radicals damage the protein as well as the membrane, giving rise to the characteristics features of senescence. The above reactions are deemed autocatalytic, as the reaction products increasingly contribute to the formation of gel phase and nonbilayer lipid structures resulting in the destabilization of the membrane and eventually in the loss of homeostasis. Similar changes occur in the membrane in response to chilling injury, but also involve the effect of low temperature on the catalytic activity of enzymes involved as well as the effect on the phase transition temperature of the lipids (see section 16.2.9). Here we will be emphasizing the role of PLD and lipoxygenase in enhancing the shelf life of tomatoes during cold storage.

16.3.2 Phospholipase D Gene Family

Phospholipids provide the backbone for biomembranes and serve as rich sources of signaling messengers. Phospholipase D (PLD, EC 3.1.4.4) catalyzes the hydrolysis of structural phospholipids to generate phosphatidic acid and a free head group. PLD has been grouped into three classes based on their requirements for Ca^{2+} and lipids in *in vitro* assays: the conventional PLD that is most active at 20 to 100 mM levels of Ca^{2+} ; the polyphosphoinositide (PI) dependent PLD that is most active at micromolar levels of Ca^{2+}; and the phosphatidylinositol (Ptdln) specific PLD that is Ca^{2+} independent (167). PLD has been cloned from a number of plants (168), animals (169), and fungi (170) and found to constitute a supergene family of many isoforms (171). The PLD isoforms from *Arabidopsis* have been divided into five groups: PLDα, β, γ, δ, and ε. (168). The PLDα gene product is responsible for the conventional PLD activity and differs physiologically from the PLDβ, and PLDγ isoforms based on Ca^{2+} requirements and pH (172). From tomatoes, three PLDα forms and two PLDβ classes have been cloned (173). Different expression patterns were observed in different plant tissues and organs for each PLD. In fruit, PLDα3 appeared to be transiently accumulated during early ripening, whereas PLDα2 was accumulated throughout fruit development and maturation (173).

16.3.2.1 Role of PLD in Senescence and Chilling

PLD activities have been observed in many cellular functions during seed germination, aging, various abiotic and biotic stresses, and senescence (140,167,174). In membranes of tomato fruit stored at low temperature, an accumulation of phospholipid catabolites occurs due to differential effects of reduced temperature on the activities of lipid degrading enzymes (175). Destabilization of membranes has been suggested as one of the causes of chilling injury (176). In ripening tomato fruits, rigidification of microsomal membranes has been reported to activate PLD and increase membrane catabolism (177). Increased PLD activities during and after chilling are suggested to result in chilling injury in maize (139) and cucumber fruits (178). In *Arabidopsis*, cold stress increased the expression of PLDα, but not PLDβ or PLDχ, implying that PLDα has a role in plant responses to low temperature stress (174). Recently the many roles of PLD in signal transduction have been reported (167). In tomatoes, PLDβ is suggested to have a role in signal transduction due to its low abundance, activation by micromolar concentration of Ca^{2+}, a concentration

range that arises locally during signaling (173), whereas a metabolic role has been assigned for the various forms of PLDα. Our studies on the role of PLD during fruit ripening in cherry tomatoes showed that the soluble and membrane associated PLD activities increased during fruit development, which peaked at the mature green and orange stages (178a). It was reported by Jandus et al. (179) that PLD activity decreased slightly between the mature green and orange stages when the tomatoes ripened on the plants, but increased between the orange and red stages to values higher than at the mature green stage. However, when tomatoes were harvested at the mature green stage and left to ripen at room temperature, PLD activity decreased by about 40% between the mature green and red stages. It has been reported that phosphatidic acid increased as much as twofold while total phospholipids decreased about 20–25% during ripening of tomato pericarp (180,181). Treatment with lysophosphatidylethanolamine, which acts as a specific inhibitor of PLD activity (182) retarded senescence in tomato fruits and leaflets (183). From the observations on PLD activity at low temperature, ripening and senescence, it is conceivable that the quality of tomatoes, which is highly chilling sensitive, may be affected to a large degree by the modulation of PLD activity.

16.3.2.2 Regulation of PLD Activity

The activities of PLD are affected by a number of factors such as Ca^{2+} concentration, substrate lipid composition, pH changes, and mastoparan, a tetradecapeptide G-protein activator (167). Sequence analysis indicates that plant PLDs contain a Ca^{2+} to phospholipid binding fold, called the C2 domain at the N terminus. The C2 domains of PLDα and PLDβ have been demonstrated to bind Ca^{2+}, with PLDβ having a higher affinity for Ca^{2+}, whereas the Ca^{2+} requirement of PLDα is influenced by pH and substrate lipid composition (167). PLDα is active at near physiological, micromolar Ca^{2+} concentrations at an acidic pH of 4.5–5 in the presence of mixed lipid vesicles. PLDβ and PLDχ are optimally active under physiological micromolar concentration of Ca^{2+} concentrations at neutral pH and may play an active role in signal transduction. The relative distribution of PLD between the soluble and membrane fractions changes during development and in response to stress (184,185). It has been shown that Ca^{2+} binding increases the affinity of the C2 domains for membrane phospholipids (186). This shows that the C2 domain in PLD is responsible for mediating a Ca^{2+} dependent intracellular translocation between the cytosol and membranes. An increase in cytosolic Ca^{2+}, as well as a decrease in cytosolic pH, has been reported to occur in response to stress (187), which are favorable conditions for the activation of PLDα. PLDs associated with microsomal membranes are correlated with stress induced activation of PLD mediated hydrolysis (184,185). The increased association of preexisting PLD in the cell with membranes may represent a rapid and early step in PLD activation during stress responses (185).

16.3.2.3 Antisense Suppression of PLD Activity

In order to study the role of PLD in fruit ripening and senescence of fruits, we have developed transgenic tomatoes expressing antisense PLDα cDNA. The fruits from antisense Celebrity tomato (a fresh eating type) were smaller than the control fruits and showed a 30% decrease in PLD activity during development (178a). After storage for two weeks at room temperature, the control fruits developed wrinkles, indicative of senescence and dehydration, whereas the transgenic fruits appeared to be relatively normal. The transgenic fruits were also firmer, possessed a higher level of red pigmentation and increased level of soluble solids (178a). Transgenic Celebrity fruits showed a decrease in PLD expression as evidenced from Northern blot. Even though very few transcripts were detected at the mature

green, orange and red stages in the antisense PLD celebrity fruits, PLD activity was present at these stages suggesting a very low turnover rate of PLD, and that PLD synthesized at young or intermediate stages remains functional even at the red stage (178a). These results suggest that for effective inhibition of PLD using antisense suppression, PLD expression has to be reduced at an early stage of fruit development using an appropriate fruit specific promoter. In our experiments we have used a constitutive promoter (CaMV 35S) for tomato transformation. The antisense Celebrity fruits also showed low levels of PLD activity during ripening, suggesting that the natural senescence process was retarded, which was translated into increased firmness in these fruits. This observation was contrary to earlier results in *Arabidopsis* where antisense suppression of PLDα resulted in retardation of ABA and ethylene promoted leaf senescence, without affecting the natural senescence of leaves (188). It has been reported that the phospholipid content of tomato fruit declines during ripening (180). This decrease in phospholipid content could be due to a high PLD activity. It was interesting to note that antisense suppression of PLDα in an ornamental cherry tomato cultivar, Microtom, did not show any significant reduction of PLD activity (178a). However, ethylene climacteric of the transgenic fruits was delayed by nearly six days, as compared to the control fruits. In Microtom, PLD activity declined during ripening in the control fruits, whereas transgenic fruits retained much higher levels of PLD activity. This may be related to the delayed climacteric in the transgenic fruits, indicating a slower rate of deterioration. *In situ* localization of PLD by immunolabeling followed by electron microscopy also supports this observation. These results suggest that fruits from different cultivars may differ in their pattern of senescence and the relative role of PLD may differ between fruits and leaves. It is unclear why PLD activity in transgenic Microtom was higher compared to control plants during ripening, as opposed to the observation in Celebrity. It has been reported that in PLDα suppressed *Arabidopsis*, the expression and activities of other PLD isoforms are not altered (189) which means that the other PLD members cannot compensate for the loss of PLDα.

16.3.3 Lipoxygenase

Lipoxygenases (LOX, EC 1.13.11.12) are a class of enzymes that catalyze the hydroperoxidation of *cis-cis*-1,4-pentadiene moieties in polyunsaturated fatty acids and that occur widely in both plant and animal kingdom. LOX pathways in higher plants and mammals are different in two main respects: in mammals the main LOX substrates are arachidonic and eicosapentaenoic acids whereas linoleate and α-linolenate are the most important LOX substrates in plants; and the hydroperoxide metabolizing enzymes are different in plants and mammals (190). Although LOX isoforms occur in most plant cells, the tissue specific expression level of LOX within a plant can vary substantially depending on developmental and environmental conditions (191). Plant lipoxygenases have been implicated as having a role in the loss of membrane integrity associated with senescence, flavor and odor formation, response to pest attack, and wounding (192). Products of the LOX pathway such as traumatin, jasmonic acid, oxylipins, and volatile aldehydes, are supposed to play a key role in signal transduction in response to wounding, as antimicrobial substances in host–pathogen interactions, as regulators of growth and development, and as aromatic compounds that affect food quality (191).

16.3.3.1 Role of Lipoxygenase in Membrane Deterioration

Lipid peroxidation is an inherent feature of senescence and generates a variety of activated oxygen species such as singlet oxygen and the alkoxy and peroxy radicals. Alkoxy and peroxy radicals are formed directly as decomposition products of lipid peroxides and singlet

oxygen is formed through the interaction of lipid peroxy radicals (157). Lipid peroxidation is initiated either by the action of reactive oxygen species or enzymatically by the action of lipoxygenases (LOX). LOX appears to play an important role in the deterioration of membranes during senescence by initiating lipid peroxidation, and also by forming activated oxygen independently (193). Increasing data suggests that LOX is activated by various stresses such as wounding (194), water deficit (195), thermal stresses (196), and ozone stress (196). It is known that the primary site of action of various stresses is the biomembrane (151), which results in the liberation of free linoleic and linolenic acids (197). Some results also suggest the direct oxygenation of membrane lipids and biomembranes by LOX (195,198–200). The role of LOX in membrane deterioration is evident from its association with membrane in tomato fruits (192,201) and carnation petals (202) as a membrane bound LOX can attack the membrane lipids more readily than a soluble one. This is supported from the observation that LOX can oxygenate esterified polyenoic acids in complex lipids and biomembranes, in addition to free polyenoic fatty acids such as linoleic and linolenic acids (190). Yamauchi et al. (198) reported the oxygenation of dilinolenoyl monogalactosyldiacylglycerol in dipalmitoylphosphatidylcholine liposomes by a crude soybean LOX preparation containing all the three isozymes, thus demonstrating that plant LOX catalyzes the oxygenation of both free polyunsaturated fatty acids and monogalactolipids. Brash et al. (199) observed that soybean LOX-1 oxidizes fatty acid residues within phoshatidylcholine and other phospholipids such as phosphatidylinositol lipids and_phosphatidylethanolamine. Similar results were reported by Kondo et al. (200) from their studies on LOX action in soybean seedlings and Maccarrone et al. (195) on soybean LOX during water deficit. It has been proposed that the role of soybean cotyledon LOX during the early stages of seedling growth is the disruption of storage cell membranes, enhancing their permeability (203). These evidences corroborate the role of LOX in membrane deterioration. However, there is controversy regarding the role of LOX in senescence, as its activity increases during senescence in *Pisum sativum* foliage (204), whereas in soybean cotyledons, total LOX activity has been shown to decrease with advancing senescence (205). The occurrence of LOX activity in young and expanding tissues as well as the observation that soybean LOX is not induced in senescing tissues, argues against the role of LOX in senescence (191). However, soybean seedlings subjected to water stress showed an increase in specific activity of their major lipoxygenases, LOX-1 and LOX-2, which was paralleled by the increase of LOX content and mRNA, indicating that osmotic stress modulates the expression of LOX genes at the transcriptional level (195). Osmotic stress also increased the oxidative index of biomembranes by increasing the hydroperoxide content of the lipid ester fraction. Water deficit has been reported to impair cell membrane functioning (206). Based on the observed enhancement of both LOX activity and membrane oxidative state in response to water deficit, the authors suggested that their results corroborate the hypothesis of a role of LOX in plant membrane deterioration. Studies of the effects of thermal injury (heat shock and cold) and ozone treatment on LOX activity of soybean seedlings have shown that cold stress decreased the specific activities of LOX1 and LOX2, which is attributed to at least in part to a down regulation of gene expression at the translational level (196). Both heat shock and ozone treatment enhanced the LOX-specific activities, acting at the level of transcription of the genes. It is proposed that LOX-1 and LOX-2 are involved in the thermotolerance of soybeans and in the precocious aging induced by ozone. It has been suggested by the authors that cold, heat shock, and ozone can ultimately act on cell membranes. This corroborates the hypothesis for a major role of LOX in the control of membrane integrity. It has been observed that during ripening in tomato fruit pericarp, two distinct LOXs were identified based on their pH optima and their sensitivity to the LOX inhibitor nordihydroguaiaretic acid (207). Both these activities increased sharply during early ripening stages, and decreased after the fruit had ripened

fully. It has been shown that the LOX require free fatty acids as their substrate and the timing and extent of peroxidative reactions initiated by LOX are determined by the availability of these substrates which are made available through the action of lipolytic acyl hydrolase (157,201). All these results suggest that a method of enhancing shelf life and quality of fruits could be by the regulation of LOX activity.

16.3.3.2 Tomato fruit Ripening and Lipoxygenases

Studies on LOX genes during tomato fruit ripening using a low ethylene producing fruit containing an ACC oxidase (*ACO1*) sense suppressing transgene, and tomato fruit ripening mutants such as *Never-ripe* (*Nr*), and *ripening-inhibitor* (*rin*), have demonstrated that expression of three LOX genes *TomloxA, TomloxB* and *TomloxC* is regulated differentially during fruit ripening, and that ethylene and a separate developmental component are involved (208). The expression of *TomloxA* declines during ripening and this is delayed in the *ACO1* transgenic low ethylene and *Nr* fruit, indicating that this phenomenon is ethylene regulated. Transcript abundance also declines during *rin* fruit development indicating that developmental factors also influence the expression of *TomloxA*. *TomloxB* expression increases during fruit ripening, which is also stimulated by ethylene. TomloxC gene expression is up regulated in the presence of ethylene and during ripening. The principal substrates of LOX in tomato fruit are the linoleic and linolenic acids, and the action of the 13-lyase on the 13-fatty acid hydroperoxide products of these substrates results in the production of hexanal and hexenal respectively. Release of these aldehydes following disruption of the tissue results in the production of the typical aroma characteristic of fresh tomatoes (209). As the ripening process continues, the thylakoid membranes break down as the chloroplasts are transformed into chromoplasts. It has been suggested that LOX may be the trigger for the chloroplast to chromoplast transition (210), and the polyunsaturated fatty acids in the thylakoid may be acted upon by LOX, and subsequently by a lyase, to release hexanal and hexenal, which in turn influence the flavor and aroma characteristics of the fruit (209). It has been suggested that the various LOX genes in tomato fruit may aid either in the defense mechanisms early in unripe fruit, or flavor and aroma generation and seed dispersal mechanism in the later developmental stages (208).

16.3.3.3 Regulation of LOX by Genetic Manipulation

With the genetic tools available today, it is possible to identify the role or function of a particular gene or gene product either by over expressing or down regulating the gene. Overexpression of LOX2 gene from soybean embryos fused with the enhancer of alfalfa mosaic virus under the control of a duplicated CaMV 35S promoter in transgenic tobacco increased the fatty acid oxidative metabolism as evidenced by a 50–529% increase in C_6 aldehyde production (211). The impact on C_6 aldehyde formation was greater than the effect on production of fatty acid hydroperoxides, which is consistent with other studies indicating the greater involvement of soybean embryo LOX2 in generating C_6 aldehydes than that of other well characterized LOX isozymes. To evaluate the role of LOX in the onset of plant defense, transgenic tobacco plants expressing the antisense tobacco LOX cDNA were developed which showed strongly reduced elicitor and pathogen induced LOX activity (212). A linear relationship was observed between the extent of LOX suppression and the size of the lesion caused by the fungus, *Phytophthora parasitica*. The antisense plants also showed enhanced susceptibility toward the compatible fungus *Rhizoctonia solani*. The authors suggested that their results demonstrate the strong involvement of LOX in the establishment of incompatibility in plant–microorganism interactions, consistent with its role in the defense of host plants. Antisense tomato plants were developed with

TomloxA under the control of fruit specific promoter 2A11 and ripening specific promoter of polygalacturonase (213). Reduced levels of endogenous *TomloxA* and *TomloxB* mRNA (2–20% of wild type) were detected in transgenic fruit containing 2A11 promoter compared to nontransformed plants, whereas the level of mRNA for *TomloxC* was unaffected. LOX enzyme activity was also reduced in these transgenic plants. However, no significant changes were observed in flavor volatiles. The transgenic plants with PG promoter were less effective in reducing endogenous LOX mRNA levels. The authors concluded that either very low levels of LOX are sufficient for the generation of C_6 aldehydes and alcohols, or a specific isoform *TomloxC* in the absence of *TomloxA* and *Tomlox*B is responsible for the production of these compounds. Transgenic tomato and tobacco plants were developed by transformation using the chimeric gene fusions of *TomloxA* and *TomloxB* promoter with β-glucuronidase (GUS) reporter gene. GUS activity in *tomloxA-gus* plants during seed germination peaked at day 5 and was enhanced by methyl jasmonate whereas no GUS activity was detected in *tomloxB-gus* seedlings (214). During fruit development, GUS expression in *tomloxA-gus* tobacco fruit increased 5 days after anthesis and peaked at 20 days after anthesis. In *tomloxB-gus* tobacco GUS activity increased at 10 days after anthesis and peaked at 20 days after anthesis. In *tomloxA-gus* tomato fruit, GUS activity was observed throughout fruit ripening, with highest expression at the orange stage, and the expression was localized to the outer pericarp during fruit ripening. In *tomloxB-gus* fruit, GUS activity was detected at the mature green stage, while expression was localized in the outer pericarp and columella. It has been shown that antisense transgenic potato plants with reduced levels of one specific 13-LOX isoform (LOX-H3) largely abolished the accumulation of proteinase inhibitors upon wounding, indicating that this LOX-H3 plays an important role in the regulation of wound induced gene expression (215).

The genetic manipulation studies on LOX show a specific role of LOX in various developmental processes and defense mechanisms. However, considering the presence of various isoforms in tomatoes and the roles they play, it is very important to characterize the specific role of each isoform before regulating its expression for a specific intent. For example, from the results of Beaudoni and Rothstein (214), it appears that antisense suppression of *TomloxA* may be helpful in enhancing the shelf life of the tomato fruit during storage without affecting the flavor of the fruit.

16.3.4 Cell Wall Metabolism and Fruit Softening

Tomato fruit ripening is a highly regulated developmental process requiring expression of a large number of gene products (216). Enzymes involved in the degradation of cell walls, complex carbohydrates, chlorophyll, and other macromolecules must be coordinately expressed with enzymes that make the fruit desirable nutritionally and aesthetically. Polyglalacturonases [PGs, poly (1→4-α-D-galacturonide) glycanohydrolases] are enzymes that catalyze the hydrolytic cleavage of galacturonide linkages in the cell wall, and are the most widely studied among cell wall hydrolases. PG has been implicated as an important enzyme in fruit softening based on its appearance during ripening, corresponding to the increase in fruit softening. In a number of cultivars, there is a correlation between levels of PG activity and the extent of fruit softening; it degrades isolated fruit cell walls *in vitro* in a manner similar to that observed during ripening and several ripening mutants that have been described with delayed or decreased softening are deficient in PG activity (217). Results on the genetic manipulation of PG has suggested that PG activity alone is not sufficient to affect fruit softening (218), and other enzymes such as pectin-methylesterase, β-galactosidase, and expansins are involved in fruit softening. This discussion is not intended to cover this area, as it has been reviewed recently by Brummell and Harpster (218) and through another chapter in this book.

16.4 CONCLUSION

Fruit color, texture, nutritional value, and flavors are the most important parameters that affect the quality of fruits and vegetables. The post harvest storage conditions of fruits and vegetables also affect these parameters as well as the shelf life, and the type of fruit and vegetables determines the extent of the effect. In the case of potatoes and tomatoes, it is apparent from the above discussion that chilling induced changes affect the above parameters even though preharvest factors and cultivar identity also contribute to this effect. While damages to membranes are attributed to be responsible for these changes in both crops, in the case of potatoes, carbohydrate metabolism also plays a major role. Our understanding of the genes involved in the membrane deteriorative processes as well as carbohydrate metabolism have resulted in the alleviation of these effects to a certain extent. Considering the roles of PLD and LOX in the membrane deteriorative pathway, it might be possible to enhance the shelf life of tomato by generating a double transgenic plant with suppressed activities of PLD and LOX.

Genetic Modification of Peanut as a Solution to Peanut Allergy

Hortense Dodo, Koffi Konan, and Olga Viquez

CONTENTS

17.1 PREVALENCE AND IMPACT OF ALLERGIC DISEASES

Allergic diseases rank fourth among world diseases as recorded by the World Health Organization and they are becoming an increasing public health issue worldwide (1). Allergies are the 6th leading cause of chronic diseases in the US, costing the health care system, $18 billion per year (American Academy of Allergy, Asthma, and Immunology, The allergy report 1996–2001: Allergy Statistics http://www.aaaai.org/media/resources/media_kit/allergy_statistics.stm). Food allergy is a rapidly increasing phenomenon in industrial countries. Up to 25% increase every 10 years has been reported within children, as well as adult, populations. Food allergy is the leading cause of anaphylaxis treated in American hospital emergency rooms. It is estimated that in the US, food allergies affect 6 to 8% of the children and 1% of the adult population. In France, about 5% of the population is affected, and in the UK, about 2% (1). Food allergy is defined as an allergy that occurs when the immune system mistakenly responds defensively to a specific food protein that is not harmful to the body.

17.1.1 Peanut is One of the Most Potent Sources of Food Allergy

Peanut allergy is responsible for the majority of severe food induced anaphylaxis reactions. It is an immunoglobulin E (IgE) mediated hypersensitivity reaction (2) which is persistent, life threatening, and rarely outgrown, unlike allergy to egg and cow's milk (3). Reports of the exact prevalence of peanut allergy vary from countries to countries. Sicherer et al. (4) estimated that 1.1% of American children and adults (about 4.4 million people) suffer from allergy to peanut and tree nuts. Peanut allergy is characterized by more acute and severe symptoms and a higher rate of symptoms on minimal contact than other food allergies (5). Reports indicate that peanut allergies are responsible for half of the annual emergency room visits and approximately 63 to 67% of deaths due to anaphylaxis (6). Food anaphylaxis is defined as a life threatening sudden and severe allergic reaction to a foreign antigen mediated by IgE antibodies.

17.1.1.1 The Symptoms

The symptoms associated with peanut allergy may appear throughout the body. The most common sites are the mouth (swelling of the lips or tongue, itching lips), the digestive tract (stomach cramps, vomiting, diarrhea), the skin (hives, rashes, or eczema), and the airways (wheezing or breathing problems), and can progress to become systemic (dizziness, loss of consciousness, anaphylactic shock, coma) and sometimes deadly. As little as a trace amount of peanut can cause death. Anaphylaxis can quickly produce severe symptoms within as little as 5 to 15 minutes, although life threatening reactions may progress over hours.

17.1.1.2 Accidental Ingestion of Peanut Is Increasing

Accidental ingestion of peanuts in unsuspected food is increasing because of its ubiquitous use as an ingredient in processed foods, and the presence of peanut in the increasingly

expanding diet in most industrial countries. One of Britain's most promising athletes died in June of 1999 at the age of 21, after a seizure triggered by accidentally ingesting peanuts in a chicken sandwich (*The Independent*, London, June 21, 1999). In Huntsville, AL, a high school student lost his life to peanut allergy. Despite the seriousness of peanut allergy, to date, there is no cure. Epinephrine and antihistamines are administered to reverse the symptoms. The most effective management strategy available to the allergic population is total avoidance of peanuts and peanut-containing products. However, avoiding peanuts in food products is difficult. In a recent study, 75% of patients with peanut allergy still failed to avoid peanuts in food products even if they were carefully trying to do so (John Weisnagel, 2002, http://www.allerg.qc.ca/peanutallergy.htm). This insecurity leads to severe psychological and emotional distresses for peanut allergic individuals and their families, and a considerable disruption of their daily activities and family relations (7).

17.1.1.3 Nutritional Impact of Peanut

Peanut (*Arachis hypogaea* L.*)* is not a nut as the name might imply but a legume and a member of the *Leguminosae* family just like soybean and garden peas. Peanut is a highly nutritious, popular, and inexpensive food worldwide. Peanut consumption is steadily increasing in industrialized countries. For example, peanut butter is an integral part of Americans' national culture and America's favorite protein rich sandwich. Peanut and peanut butter are protein powerhouses containing 15% of the Reference Daily Intake (RDI) of protein per serving.

Peanut is rich in proteins, monounsaturated and polyunsaturated fatty acids, carbohydrates, and fibers. Peanut is a good source of vitamins E, B1, B2, B6, folic acid, thiamin, niacin, and minerals such as copper, manganese, phosphorous, iron, magnesium, calcium, selenium, and zinc. Peanut has been linked to many health benefits. For example, it contains mostly heart healthy mono unsaturated fat, which has been shown to lower blood cholesterol and reduce the risk of heart diseases; fiber, which reduces the risk of some types of cancer, and controls blood sugar levels. Peanut is also a good source of folic acid, which helps prevent neural tube defects, and phytosterols which may offer protection from colon, prostate, and breast cancer. Resveratrol, another naturally occurring phytochemical found in peanut and in grape, is associated with reduced cardiovascular diseases and reduced cancer risks (www.peanut-institute.org).

17.1.1.4 Economic Impact of Peanut Allergy

Peanut is the #1 snack nut consumed in the US, accounting for two thirds of the total snack nut market. Half of the top ten selling candy bars in the US contain peanut or peanut butter. Peanut contributes over four billion dollars annually to the US economy. Americans eat more than 600 million pounds of peanuts and 700 millions pounds of peanut butter each year (www.nationalpeanutboard.com). About 70% of the total domestic consumption of peanut is in direct food use (peanut butter, snack peanut, peanut candy, salted peanut). Peanut is also valued when crushed, as high protein, and as vegetable oil, preferred for its long shelf life and cooking qualities. Domestic food use of peanut represents 2.34 billion pounds in 2001 and 2002 (Economic Research Service/USDA; Agricultural Outlook/March 2002). Although the trend of peanut consumption slightly rebounded for the years 1997 and 1998, the government purchases of peanut butter and roasted peanuts for its food programs have tremendously fallen. This is mainly due to the prevalence of peanut allergys (http://www.ces.uga.edu/Agriculture/agacom/outlook/peanuts/pnut2000.htm). In addition, there has been a reduction in household and institutional demands (e.g., by airlines and schools) of peanuts. For example, as of May, 2001, several major U.S. airlines, including

United, USAir, and TWA, have elected not to serve peanut snacks. (http://www.foodallergy.org/topics_archive/flying.html).

World peanut exports are approximately 1.3 million metric tons (shelled basis). The major peanut exporters are the US, China, and Argentina. The US exports about one fourth of the world peanut trade. Sixty percent of its raw peanut exports are destined to the European Union (EU). The major markets within the EU are the United Kingdom, the Netherlands, and Germany. The largest US export market for processed peanut butter is Saudi Arabia, followed by Canada, Japan, Germany, and Korea. Major snack nut markets are the Netherlands, Spain, the United Kingdom, France, and Germany (http://www.peanutsusa.com/trade/uspexp.html).

17.1.1.5 Peanut Allergy is a Liability to the Peanut and Food Industry

Peanut allergy has become a major problem for the peanut and the food industries because of the potential liability. The FDA has stepped up inspection of food manufacturing plants to make sure that no peanuts are getting into products that are not supposed to have them (8). Yet, the number of food allergy alerts and food recalls by manufacturers is increasing. For example, in the US, between May 10 and August 8, 2002, thirty-five foods were recalled for potential contamination with allergen containing foods, and 6 were due to undeclared peanuts. In 2002, in a landmark case, 10 million dollars were granted for the first time in a food allergy case to a boy who suffered permanent brain damage after going into shock while eating a candy bar laced with peanuts (9). This case will set a costly trend not only for the peanut industry and the American economy, but also for the peanut allergic individuals and their families.

17.1.2 Attempted Solutions to Peanut Allergy

Over the years several research teams have investigated and proposed a variety of ways to reduce or eliminate peanut allergy, including: thermal processing, immunotherapy, and anti-IgE and -DNA vaccines.

17.1.2.1 Thermal Processing

Studies conducted to eliminate allergens from peanut using thermal processing failed. Scientists at the USDA/ARS showed that peanut allergens are heat stable and that roasting and cooking enhanced the allergenic properties of peanuts due to protein cross linking and other nonenzymatic biochemical reactions (10–12).

17.1.2.2 Immunotherapy

Allergic individuals are desensitized with a series of injections of peanut extracts, which can sometime result in increased tolerance. However, such tolerance is not usually maintained (13–15). To date, immunotherapy is not recommended for peanut allergy because of the dangers involved during treatment. These dangers include severe anaphylactic reactions with reported deaths. In fact in one editorial comment to the *Canadian Journal of Allergy & Clinical Immunology,* Dr. Sussman (1998) warns that peanut immunotherapy may be an extremely dangerous procedure, which can create a false sense of security.

17.1.2.3 Anti-IgE Vaccine

This approach uses the recombinant protein technology to modify peanut proteins to prevent them from binding to IgE. They will still be able to stimulate an immune response

when an unmodified peanut protein is introduced in the organism. The effect of anti-IgE therapy in patients with peanut allergy was studied. Leung et al. (16) concluded that TNX-901, a genetically engineered humanized IgG1 monoclonal antibody against IgE significantly increased the threshold of sensitivity to peanut, on oral food challenge, from half a peanut to almost nine peanuts. Another anti-IgE antibody, Xolair®, is also being tested for subcutaneous use in peanut allergy. (http://www.foodallergy.org/Research/antiigetherapy.html). A drawback to this approach, if successful, is the requirement for monthly injection of the drug which will affect the lifestyles of allergic patients.

17.1.2.4 DNA Vaccine

Researchers from Johns Hopkins School of Medicine have reported hope of effective prophylaxis against peanut allergy. Using a murine model they were able to induce tolerance using an oral vaccine made of DNA from the most offending peanut allergen Ara h 2 gene complexed with nanoparticles of chitosan, a natural polysaccharide, which acts as a vector for the DNA and protects it from digestion. They found that the chitosan-DNA vaccine did protect susceptible mice from developing an allergic response to Ara h 2. Control mice, fed nonencapsulated DNA, were not protected. The effect on peanut allergic individuals is not known, and the road between mice and human may be long (17).

It is important to stress that although encouraging, none of these approaches has led to a commercial solution for peanut allergy. To date, there is still no cure to peanut allergy and complete avoidance is the only proven management practice available to peanut allergic individuals. Therefore, a novel solution is offered the peanut allergic population via the genetic engineering of a hypoallergenic peanut.

17.1.3 Search for a Naturally Occurring Hypoallergenic or Allergen Free Peanut Variety

Before attempting to engineer an allergen reduced or hypoallergenic peanut plant, it was pertinent to ask if there was a naturally occurring hypoallergenic or allergen free peanut variety. A literature search made at the time revealed no data. We therefore proceeded to screen peanut germplasm in search of a null or hypoallergenic or allergen free peanut germplasm which could be used as the parent in peanut breeding programs and could also serve as a model plant to design genetic engineering experiments targeting at down regulating and silencing allergen genes in peanut.

Because this search for an allergen free Plant Introduction (PI) was the first of its kind it was critical to select a peanut germplasm which could provide a wide source of genetic diversity. It would be limiting to choose peanut varieties commercially grown in the US because the germplasm base of the US peanut cultivars is narrow. About half of the genes of all US cultivars are from two original cultivars (18). The ideal approach would be to screen peanut germplasm grown in its center of origin in Latin America. PI from countries such as Bolivia, Brazil, Paraguay, Peru, and Venezuela would provide a greater source of genetic diversity and variation. An indirect Enzyme Linked Immunosorbent Assay (ELISA) procedure was performed to detect the presence of peanut antigens or allergens in pooled sera of allergic patients (19).

The results of the ELISA revealed no naturally occurring allergen free peanuts. Two hypoallergenic germplasms, PI261942 and PI338386, were identified. Between the two, however, variation in the allergen content of the other peanut lines were not significantly different ($p < 0.05$) (Figure 17.1).

Hypoallergenic peanuts were defined as those PI which contain a significantly low ($p < 0.05$) amount of antigens capable of eliciting IgE production and thus, with a lower

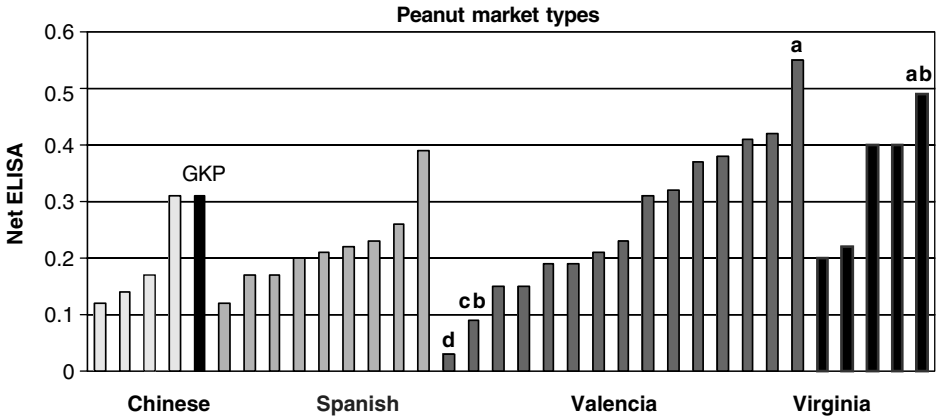

Figure 17.1 Distribution of allergen contents in four peanut market types. The PI are originating from peanut center of origin in South America. ELISA was performed using pooled sera of peanut allergic patients. Letters a, b, c and d are significantly different at $p \leq 0.05$.

likelihood of triggering an allergic reaction from peanut sensitive individuals, especially if the antigen present is a minor allergen. The significantly low optical density (OD) was set to be $OD < 0.05$ under the conditions of this experiment (19).

In addition, no significant difference was found in allergen content when comparing the four peanut market types used in the study (Figure 17.1). However, a wider range of variation was observed within the Valencia market type (0.020–0.550) compared to the Chinese (0.120–0.310) and Spanish market types (0.115–0.380). Breeding for a hypoallergenic or allergen free peanut variety might require the crossing of a null wild relative, essentially diploid ($2n = 2x = 20$), with a cultivated peanut which is an allotetraploid ($2n = 4x = 40$). The difference in ploidy level is an important criterion, making it difficult to successfully cross cultivated peanut with its closest wild relatives. In addition, plant breeding is long, tedious, laborious, and uncertain.

17.2 STRATEGY TO DEVELOP A GENETICALLY MODIFIED HYPOALLERGENIC PEANUT

Following advances made by the green revolution, genetic engineering will make it possible to improve agricultural crop in the areas of nutrition, medicine and environment. Genetic engineering holds one of the greatest potential to benefit global health. We embarked on this revolutionary projects with the goal to use a genetic engineering approach to dovelop a hypoallergenic and/or allergen-free peanut for the well being of peanut allergic patients and to boost the croded peanut Economy.

17.2.1 The Gene Silencing Principles

17.2.1.1 Posttranscriptional Gene Silencing (PTGS) Strategies to Produce a Hypoallergenic Peanut

Most of the allergen proteins in plants are present as isoforms encoded by genes which belong to multigene families (20,21). Isoforms for peanut allergens were identified for Ara h 1 (22,23), Ara h 2 (24,25), and Ara h 3 (26,27). Consequently any strategy that focuses on

silencing single genes is unlikely to lead to a significant reduction in allergen production. Therefore, posttranscriptional gene silencing (PTGS) technologies, such as the use of antisense and RNA interference (RNAi) based constructs, which selectively inhibit gene expression by base-pairing to complementary regions or target sites on mRNA transcribed from the target genes, will provide the only effective approaches to eliminated allergens from peanut.

The RNA induced gene silencing phenomenon was first identified in the analysis of transgenic plants (28,29), in which transgenes were found to silence homologous endogenous genes. The phenomenon was initially called cosuppression to indicate that a transgene could not only suppress the expression of the homologous endogenous gene, but also silence itself. Cosuppression was later defined to happen at the transcriptional as well as posttranscriptional level (30). RNA directed transcriptional silencing involves histone H3 methylation and formation of heterochromatin (31), while posttranscriptional gene silencing (PTGS) is based on mRNA degradation.

The antisense RNA mediated gene silencing is a similar PTGS phenomenon based on hybridization of antisense sequence to complementary sequences in mRNA molecule coding for a specific protein. Both the cosuppression and the antisense methods have been extensively used to down regulate genes in plants. Of particular interest is the successful engineering of hypoallergenic varieties of important plants such as rice (32), soybean (33), and ryegrass (34).

17.2.1.2 Mechanism of PTGS

Meins (35) reviewed the speculative models for PTGS in which a double stranded RNA (dsRNA) molecule has been identified as the main silencing signal. This molecule has a dual role: it is able to trigger de novo methylation of homologous DNA sequences in the nucleus (36) and to induce the sequence specific degradation process responsible for PTGS (37). Sources of dsRNA molecule include: (1) pairing of transcripts transcribed from inverted repeats (IRs) transgenes, (2) pairing of the normal sense RNAs and antisense RNAs (asRNA) arising from aberrant transcription of the same trans (genes), (3) pairing of complementary regions of RNA degradation products, and (4) pairing of transcripts with asRNA produced by RNA directed RNA polymerase (RdRP), RNA viruses, transposons, or short endogenous hairpin RNAs (35,38).

Geley and Muller (39) divided the PTGS process into two distinct phases, (Figure 17.2) an initiation and an execution phase. The initiation phase involves processing of dsRNA into small RNA molecules, called small interfering RNAs (siRNA) by Dicer, a conserved member of the RNAse III gene family (40), which is found in many organisms including fission yeast, plants, *C. elegance*, Drosophila, mice, and human, suggesting all organisms use the same basic mechanism to initiate the PTGS pathway.

In the execution phase, Dicer generated siRNAs are incorporated into a large multiprotein complex called RNA induced silencing complex, or RISC (41,42). After unwinding of the siRNA duplex, a single RNA strand becomes incorporated into a RISC complex (43). In the siRNA mediated mRNA degradation pathway, the antisense strand of the siRNA is used to target the cognate mRNA for degradation (44). This process involves specific base pairing between the antisense strand of the siRNA and the target mRNA, endonucleolytic cleavage of the mRNA strand across the middle of the siRNA strand, and subsequent degradation of the now unprotected mRNA.

In a related pathway, short noncoding single stranded RNAs, called micro RNAs or miRNAs, which are derived from partially complementary dsRNA precursor molecules, regulate the translation rather than the stability of their complementary mRNA target. Micro RNAs are RNA precursors processed in the nucleus into pre miRNAs (45) of 60 to

70 nucleotides (nt) long. Pre miRNAs form stem loop structures, or hairpins. These noncoding pre miRNAs are then exported into the cytoplasm to be further processed by Dicer (46). Mature miRNAs are of similar size to siRNAs (20–25 nt), but single stranded, and they recognize sequences in the 3' UTR of their target mRNAs. Depending on the extent of homology to their target sequence, miRNAs can initiate mRNA degradation or block translation by an as yet poorly defined mechanism (47).

17.2.1.3 PTGS for Crop Improvement

Because of the dominant silencing properties of IR transgenes, they are being exploited for research purposes and practical applications. Phenotype suppression using IR transgenes, cosuppression, or antisense RNA can persist in vegetatively growing plants, and in some cases, it can be meiotically transmitted to progeny. However, silenced genes can return to an expressed state, indicating that the stable changes are potentially reversible (48).

For crop improvement, trait stability from one generation to the next is essential. Therefore, the gene silencing technologies have been improved for stable heritability of the silenced phenotype. Very few reports have described the stability of phenotype suppression by IR transgenes. This involved the use of hairpin RNA (hpRNA) transgene constructs (49). The authors reported that phenotype suppression by hpRNA transgenes was stably inherited at least as far as the T5 generation. Although no data are available beyond T5, the authors however expected the transgene to persist. In rice, the mutant line LGC-1 (Low Glutelin Content-1) was the first commercially useful cultivar produced by RNAi (50). It is low protein rice, and is useful for patients with kidney disease whose protein intake is restricted. This dominant mutation produced hpRNA from an inverted repeat for *glutelin*, the gene for the major storage protein glutelin, leading to lower glutelin content in the rice through RNAi. Interestingly, this mutant was isolated in the 1970s and the mutant trait appears to have been stable for over 20 generations. These examples suggest that the suppression of gene expression by hpRNA induced RNAi would be inherited stably.

hpRNA induced RNAi has also been shown to be much more efficient than antisense and cosuppression–mediated gene silencing (51). In an hpRNA producing vector, the target gene is cloned as an inverted repeat spaced with an unrelated sequence and is driven by a strong promoter such as the CaMV 35S promoter for dicots or the maize ubiquitin 1 promoter for monocots. When an intron is used as the spacer, which is essential for stability of the inverted repeat, the silencing efficiency becomes very high, almost 100% (52,53). Recently, Makoko (54), hypothesized that, hpRNA induced RNAi is inherited more stably than "conventional" PTGS because hpRNA induced RNAi does not require the generation of dsRNA mediated by RdRP for the suppression of the expression of the gene (Figure 17.3).

17.2.2 Application of the Gene Silencing Principles to Peanut

We designed genetic engineering protocol which incorporated several steps and included the isolation of allergen genes, cloning of the genes in carefully selected vectors, transformation of peanut tissues in culture via microprojectile bombardment or *Agrobacterium tumefaciens* and regeneration of transgenic issues to full maturity (Figure 17.4).

17.2.2.1 Step 1: Identification and Isolation of Peanut Allergens Genes

A prerequisite to silencing peanut allergen genes is the acquisition of DNA fragments encoding the target proteins and their use as transgenes in the construction of transformation cassettes. Peanut allergens are seed storage proteins and constitute about 5% of the total protein of a cell. Three major peanut allergens have been identified and characterized at the amino acid, cDNA, and genomic DNA levels. They are Ara h 1, Ara h 2, and Ara h 3

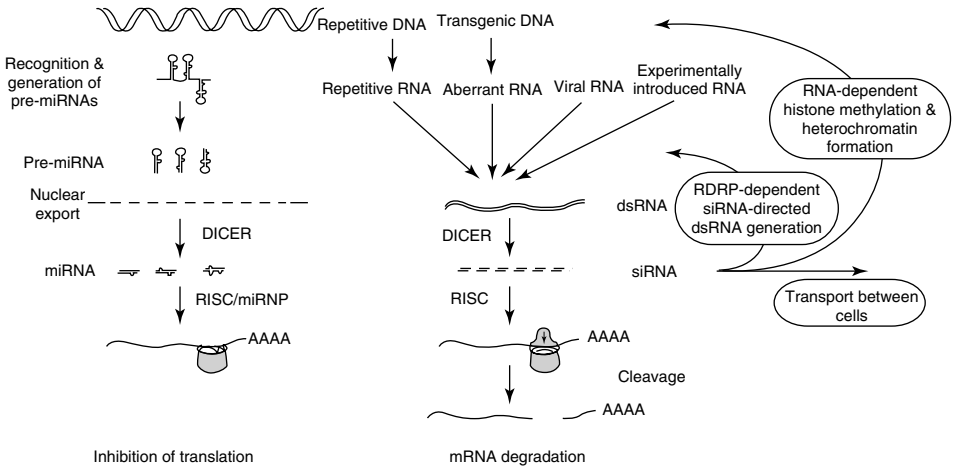

Figure 17.2 dsRNA-directed gene silencing mechanism adapted from Geley and Muller, 2004. Short dsRNA molecules can either be expressed by endogenous genes, invading viruses, or by experimental means, and are funneled into one of two different silencing mechanisms. The miRNA-dependant pathway, which mainly controls the translation of mRNAs, involves imperfect base pairing of the miRNA to its mRNA target, while siRNAs are perfectly complementary to their cognate mRNA species and induce their endonucleolytic cleavage and degradation.

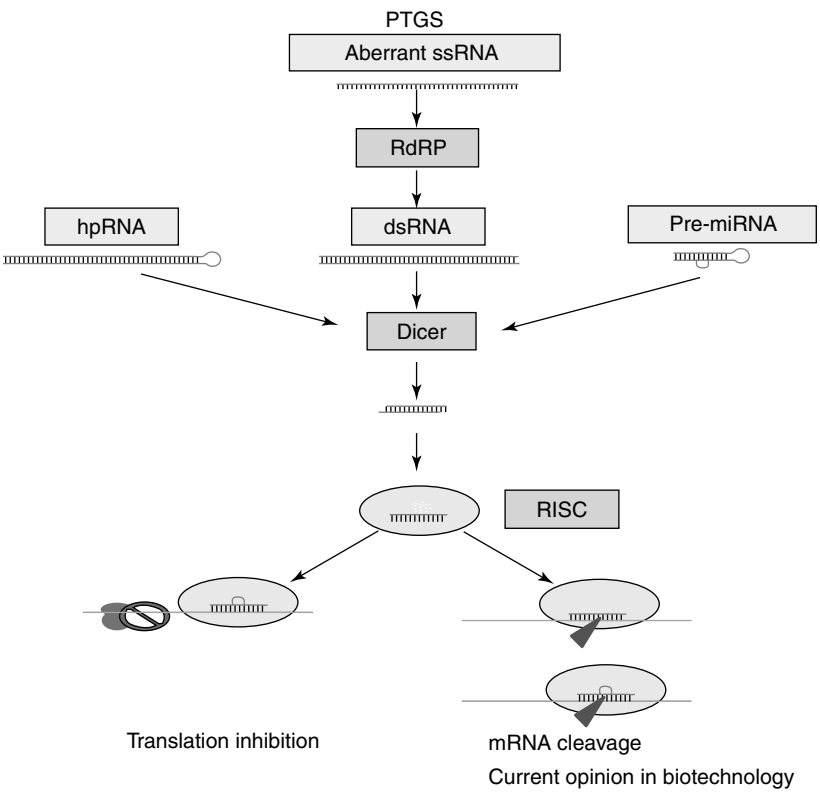

Figure 17.3 dsRNA, hpRNA, and pre-miRNA are processed by Dicer into 21 nt RNA duplexes and the unwound ssRNA is then incorporated into RISC (adapted from Makoto, 2004).

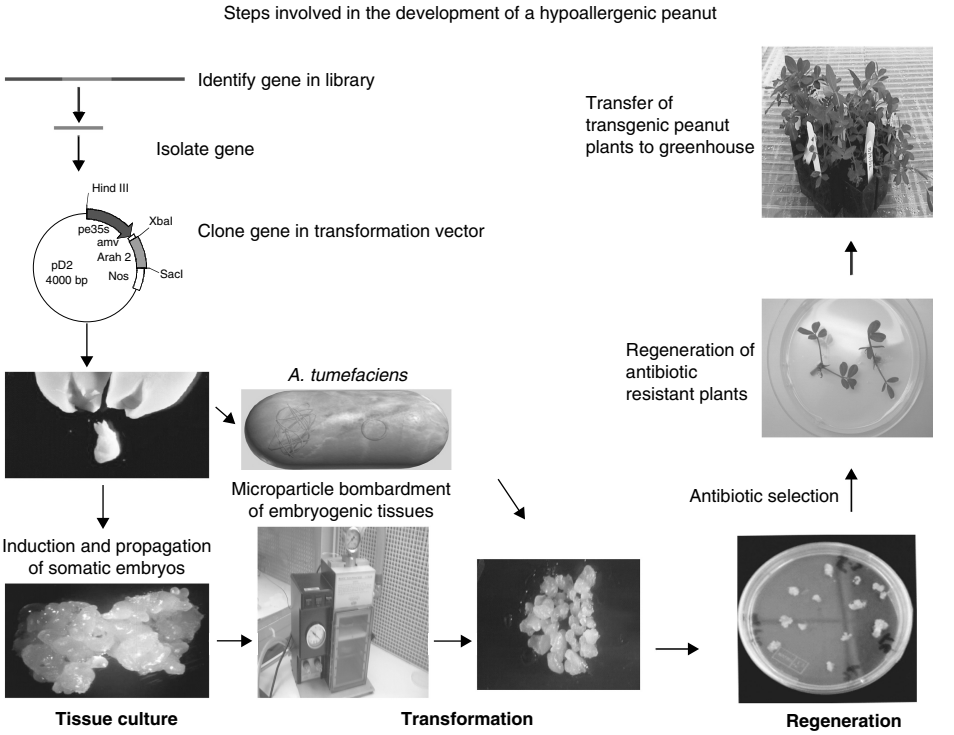

Figure 17.4 Schematic representation of steps involved in producing transgenic peanut via microprojectile bombardment or *Agrobacterium*–mediated transformation. The gene encoding peanut allergens are identified, isolated and cloned into a transformation vector. Somatic embryos initiated from peanut zygotic embryos are co-bombarded with plasmid DNAs containing the peanut allergen gene and an antibiotic selection marker gene. A binary vector containing the peanut allergan gene is mobilized into *A. tumerfaciens* for transformation in peanut tissues. Antibiotic-resistant cell lines are propagated for plant regeneration.

(23–25,55–57). Allergens are classified as "major" when they trigger a reaction in over 50% of the hypersensitive population. Although cDNA clones of major allergens were published, we made the decision to isolate and sequence the genomic clone of target allergens for several reasons. In addition to the basic information provided by a cDNA clone such as the size and coding region of the gene, a genomic clone will provide information on the features of the promoter, other regulatory regions, and the presence and sequences of introns. Introns can be used in the construction of intron hairpin RNA transformation cassette to facilitate dsRNA formation in the process of triggering RNAi. All of which are important contribution to the understanding of the structure of peanut allergen genes.

Ara h 1 encodes a 63.5 kDa protein recognized by serum IgE from over 90% of peanut sensitive individuals (55). At the protein level, it shares approximately 40% homology with vicilins from soybean and pea. The Ara h 1 transcript is about 2.3 kb and is an abundant message in mature peanut cotyledons. Ara h 1 contains 23 IgE binding epitopes that are evenly distributed along its linear sequence. A molecular model of Ara h 1 reveals that it is a homotrimer with IgE binding epitopes located in the area of monomer–monomer contact (58). This quaternary structure of Ara h 1 may be critical for its allergenicity as the epitopes appear to be structurally protected from digestive enzymes. The genomic clone of Ara h 1 was isolated and characterized in our Laboratory. Sequence analysis revealed a full length Ara h 1 gene with an open reading frame (ORF) of 2275 bp, and 3 introns (23).

Ara h 2 is the smallest of the three major allergen genes encoding a 17.5 kDa protein, and it is also the most potent allergen. At the DNA level it shares 39% amino acid homology with conglutinins from soybean and pea (57). Ara h 2 is recognized by serum IgE from 90% of allergic individuals tested. Ten antigenic (IgE binding) sites have been identified by screening overlapping peptides. Three out of these ten epitopes have been characterized as being immunodominant. A partial cDNA sequence for Ara h 2 (460 bp) has been published (55). The genomic clone of the Ara h 2 gene was isolated and sequenced by Viquez et al. (22). Sequence analysis revealed a full length genomic clone with an ORF of 622 nucleotides including a signal peptide and no intron. In the 5′ untranslated region (UTR) of the promoter, there is a TATA box TATTATTA. In the 3′ UTR there is a polyadenylation signal AATAAA (Figure 17.5). Two regions of sequence homologies were identified between major allergen Ara h 2 and two minor allergens Ara h 6 and Ara h 7 (59). The two regions present an opportunity to isolate the three genes together and also to silence them in concert during a single transformation event. Downregulating, or silencing, the most offending allergen Ara h 2 will considerably reduce the allergenicity of transgenic peanuts.

Ara h 3 encodes a 60 kDa preproglobulin (preprolegumin; arachin polypeptide); however, it is considered a minor allergen relative to Ara h 1 and Ara h 2 because it is recognized by less than 50% of peanut allergic individuals (56). The coding region of Ara h 3 is 1,530 nucleotides long coding for 510 amino acids that share 62% to 72% homology with glycinins (legumins) from soybean and pea. The protein contains four major epitopes represented by amino acid residues 33–47, 240–254, 279–293, and 303–317. One epitope, epitope 3, is considered to be immunodominant, being recognized by 100% of those individuals who are allergic to Ara h 3. The genomic Ara h 3 clone was also isolated in our laboratory. It is a 1614 bp clone with 3 introns (27).

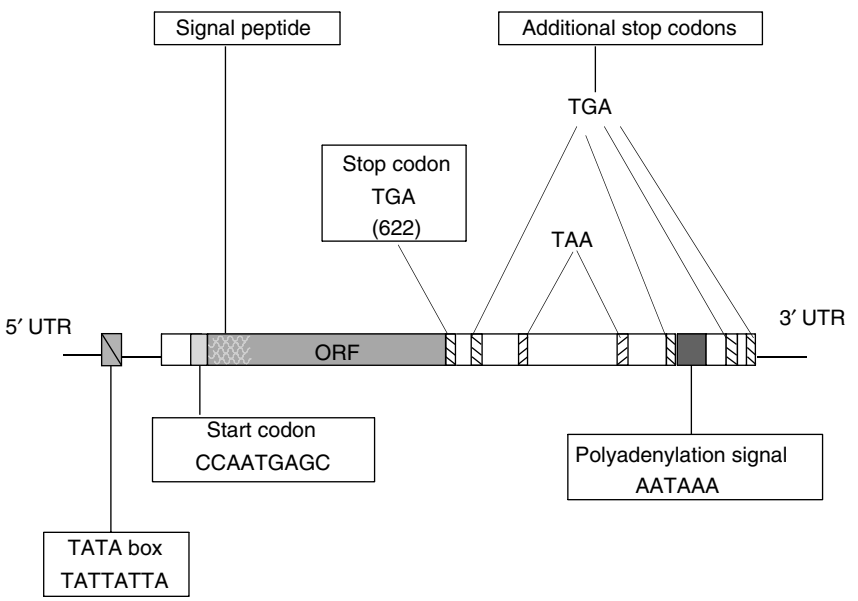

Figure 17.5 Genomic structure of peanut allergen Ara h 2 gene. The Open Reading Frame (ORF) of 622 bp is shown in grey and includes a signal peptide. In the 5′ UTR promoter region there is a typical TATA box and in the 3′ UTR a polyadenylation signal. Other features such as start and stop codons are listed.

17.2.2.2 Step 2: Construction of Peanut Ara h 2 Inverted Repeat Vectors

Ara h 2 is one of the most offending allergenic proteins in peanut (60). Silencing this major allergen is a critical step in the process of engineering an allergen free peanut variety. Peanut allergen Ara h 2 was therefore, selected as a model gene to be used to provide proof of the allergen gene silencing concept. The elimination of this protein alone will significantly reduce the allergenicity of the plant and result in the production of a hypoallergenic peanut.

According to the PTGS model, an inverted repeat construct made of Ara h 2 gene fragments targeting regions of sequence homologies with Ara h 6 and Ara h 7 would induce dsRNA for the specific degradation of Ara h 2, Ara h 6, and Ara h 7 mRNA. Two PCR fragments of a 430 bp region of the Ara h 2 gene were mounted as inverted repeats (IR) in the pUC18 vector which contains an enhanced version of the Cauliflower Mosaic Virus 35S promoter (CaMV 35S), and the Nopaline Synthase (NOS) terminator of *A. tumefaciens*. The IR transgene was fused to the 35S promoter and to the NOS term to construct plasmid pDK2 as shown in Figure 17.6.

17.2.2.3 Step 3: Induction of Peanut Somatic Embryos

The first protocol for successful transformation of peanut using particle bombardment of somatic embryos was developed by Ozias-Akins and coworkers (61). This protocol is today one of the most widely used because it presents the advantage of overcoming the genotype barrier, and allows the successful transformation of different peanut genotypes. Mature peanut embryonic axes were removed from seeds and cultured on Murashige and Skoog (MS) medium (62) containing 3 mg/l picloram to initiate somatic embryos. Embryogenic tissues were subcultured for three to four months for tissue increase, and to produce homogenous embryogenic tissues.

17.2.2.4 Step 4: Transformation and Regeneration of Transgenic Peanut

Plasmid pDK2 (Figure 17.6) was cobombarded with plasmid pCB13, a selection plasmid harboring the hygromycin resistance gene to transform peanut embryogenic tissues. Five independent bombardment experiments were performed, using embryogenic callus initiated from the peanut variety "Georgia green", a variety commonly used during particle bombardment mediated peanut transformation. Tissues were cobombarded by mixing at a 1:1 ratio plasmids pDK2 and pCB1, and bombarded tissues were subcultured for 2 to 3 months on the embryo induction medium supplemented with 10 mg/l hygromycin. Antibiotic resistant cell lines were independently propagated on the same medium for an additional 2 to 3 months for tissue increase. Transgenic embryos were produced on picloram free MS medium and germinated by supplementing the medium with 2 mg/l Naphthalene acetic acid

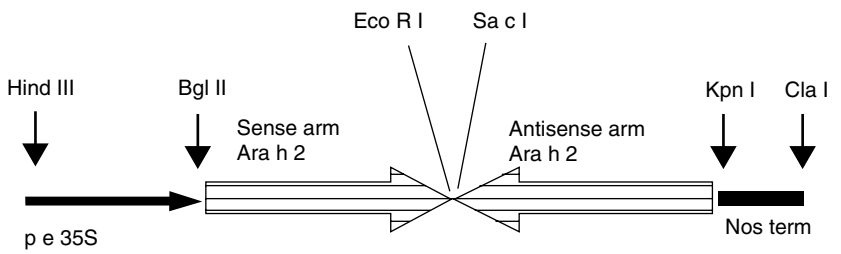

Figure 17.6 Inverted Repeats plasmid pDK2 constructed using Ara h 2 DNA fragments for transformation of peanut embryogenic tissues. Restriction sites are inserted for the restriction map of the transformation cassette.

(NAA) and 1 mg/l Benzyl Adenine Purine (BAP). Regenerated plants were transferred to the greenhouse.

No apparent phenotypic difference was detected between plants derived from somatic embryogenesis (transgenic as well as nontransgenic) and the control obtained from direct nontransgenic seed germination. However, the rate of flowering of most somatic embryo derived plants was lower and failed to seeds properly, while control plants from direct germination of nontransgenic seeds produced seeds within 3 months of transfer to greenhouse. These data suggest that the low level of flowering in tissue culture derived peanut plants resulted from the culture conditions, especially the lengthy time involved in the process. Therefore, a shorter tissue culture protocol was adopted.

17.2.3 Molecular Analyses

17.2.3.1 PCR Analysis

PCR analysis was performed to detect the presence of two foreign DNA fragments (the CaMV 35S promoter fragment, and the hygromycin gene) in transgenic peanut cells. PCR analyses were performed on all 48 hygromycin resistant callus lines produced. Two sets of primers were designed based on the nucleotide sequence of the DNA fragments to amplify the 35S promoter and the hygromycin selection gene which are DNA fragments not naturally present in peanut, but will be present in transgenic peanut. The primers amplified the expected 0.6 kb fragment of the promoter in 36 out of 48 (75%) of the callus lines. Using the same primers targeting the promoter, no amplification was observed in the two controls composed of the nontransgenic callus line, and the line transformed with the pCB13 selection plasmid only. To confirm the transgenic status of the control pCB13 callus line, amplification using the primers targeting the hygromycin gene was performed and the expected 0.7 kb fragment was generated.

17.2.3.2 Southern Hybridization

Southern hybridization was performed to confirm the stable integration of the transgene into the peanut genome. The target sequence was the CaMV 35S promoter. DNA was extracted from both transformed and nontransformed callus lines, and digested with *Hind*III/*Bgl*II to release the 0.6 kb promoter fragment. The hybridization probe was a ^{32}P labeled PCR product of the pe35S promoter. The hybridization bands (Figure 17.7) confirmed the stable integration of the transgene in the peanut genome (63).

17.2.3.3 Northern Analysis

Northern hybridization was performed to detect Ara h 2 inverted repeat transcripts in transgenic plants. Total RNA was extracted from callus, roots, petioles, and leaves of transgenic and nontransgenic plants, and hybridized with the 430 bp Ara h 2 transgene fragment. Data in Figure 17.8, show hybridization bands corresponding to the accumulation of the Ara h 2 transgene transcript is in the leaves and roots of transgenic peanut plants (Figure 17.8). These transcripts were also detected in the transgenic callus. All together, the data confirm (1) the constitutive expression of the pe35S promoter and (2) the stable and functional integration of the Ara h 2 transgene throughout the development of the transgenic plants (63).

17.2.2.4 Accumulation of Endogenous Ara h 2 Transcripts

In a parallel experiment total RNA extracted from different organs (roots, leaves, petioles, and seeds) of control nontransgenic peanut plant was hybridized with the 430 bp Ara h 2

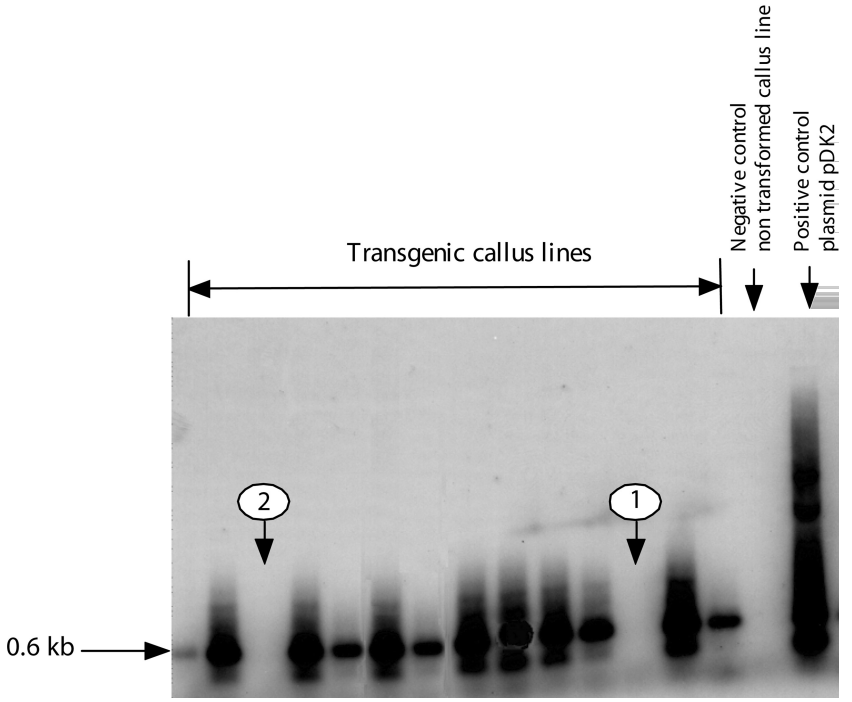

Figure 17.7 Southern hybridization in transgenic callus lines of peanut transformed with plasmid pDK2, showing the 0.6 kb band of the promoter region of the transgene. The probe was a ^{32}P labeled PCR product of the pe35S. Circled lanes 1 and 2 correspond to transgenic callus lines positive to hygromycin only.

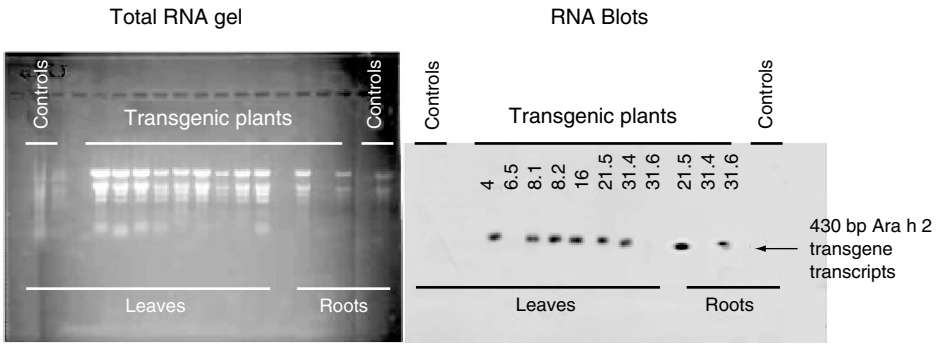

Figure 17.8 Northern analyses performed on total RNA extracted (A) from callus, and (B) from leaves and roots of mature peanut plants regenerated from transformed somatic embryos. Hybridization was performed using the 430 bp Ara h 2 transgene fragment labeled with ^{32}P.

transgene fragment to detect endogenous Ara h 2 transcripts. Figure 17.9, shows that endogenous Ara h 2 is expressed only in seed but not in vegetative tissues. These data suggest that although Ara h 2 transgene transcripts were accumulated in different organs of transgenic plants, the level of down regulation and silencing of Ara h 2 transcripts could not be assessed in the vegetative tissues but only in the seed (63). Therefore, experiments are ongoing to take the transgenic Ara h 2 hypoallergenic peanut to maturity. Nutritional

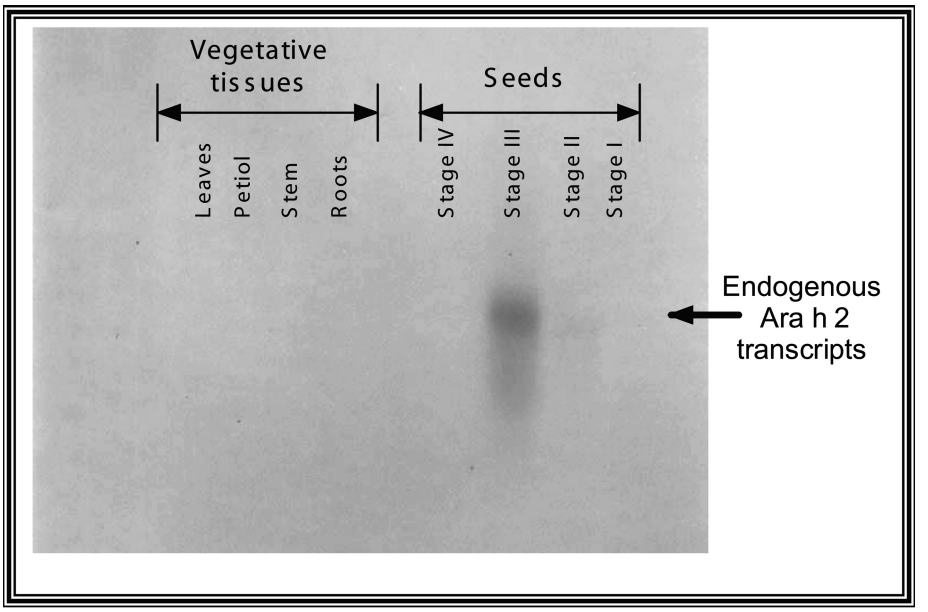

Figure 17.9 Northern analysis from leaves, roots, petioles, stems, and seeds of nontransformed peanut plants obtained by seed germination. Hybridization was performed using the 430 bp Ara h 2 transgene fragment labeled with ^{32}P.

content of the transgenic seeds will be evaluated and immunological analysis performed to determine the level of down regulation of allergen Ara h 2 in transgenic peanut seeds.

17.2.4 Current and Future Prospects: Production of Fertile Transgenic Peanut with Ara h Introns Hairpin RNA (ArahihpRNA) Constructs

Research groups using transgenic technologies for the development of improved peanut have experienced limited success mainly due to the increase sterility of transformed plants. However, only few articles have reported on this problem (64). Our personal experience and discussion with colleagues working on peanut tissue culture and transformation has confirmed that it is a common problem. The lengthy tissue culture and transformation procedures (12–17 months) currently used to produce transgenic peanut via somatic embryogenesis (61) is unanimously indexed as the major cause of sterility. These problems have prompted some researchers to adopt a nontissue culture based approach to generate transgenic peanut plants (65). Unfortunately, this procedure is inefficient ($<1\%$ transformation), labor consuming, and inadequate to produce a large number of independent transformants.

Alternative organogenesis-based protocols to produce fertile transgenic peanut plants were developed via *Agrobacterium tumefaciens* mediated transformation (66–69). However, one major disadvantage with these protocols are the problems associated with genotype and tissue specificity of *A. tumefaciens* strains. Cells which are susceptible to *A. tumefaciens* infection are restricted to certain positions within certain type of tissues and peanut susceptibility to *Agrobacterium* infection varied greatly among peanut genotypes (70).

Our preliminary experiments using *Agrobacterium* strain EHA105 to transform hypocotyls (66) and embryonic axe (67) transformation have shown good reproducibility. Therefore, future emphasis will be to optimize these transformation protocols for the production of fertile transgenic hypoallergenic peanut.

It is critical to understand that our goal in developing a hypoallergenic or allergen free peanut is not to encourage peanut allergic individuals to eat peanuts, but to promote the utilization of the transgenic peanuts in food products containing peanuts, such that in the event of an accidental ingestion of peanuts by an allergic individual, no severe allergic reactions will be triggered. In the unlikely event of an allergic reaction, it will at the most be very mild, without endangering human life. In addition the negative perception associated with peanut consumption, as well as the economic, emotional, and psychological impacts of peanut allergy, will be reduced and eventually dissipated. The development and marketing of a hypoallergenic peanut will give rise to a number of new enterprises including seed producers, processors, millers, and other allied businesses involved in the marketing of the value added products. Those who choose to market a safe hypoallergenic or allergen free peanut product for human consumption will have a competitive advantage.

Recombinant Lipoxygenases and Oxylipin Metabolism in Relation to Food Quality

Rod Casey and Richard K. Hughes

CONTENTS

18.1 INTRODUCTION

Lipoxygenases (LOX) (EC 1.13.11.12) are nonheme, iron containing dioxygenases that catalyse the formation of *Z, E* conjugated hydroperoxides from polyunsaturated fatty acids (PUFAs), or any other molecules containing one or more *Z, Z*-1, 4-pentadiene structures.

LOXs are widely distributed throughout Nature. Their presence has been recorded in higher and lower plants and animals, including fungi, corals, algae, sea urchins, clams, and slime mold (Table 18.1). The presence of LOX has also been proposed in the brown alga *Laminaria angustata* (21), the diatom *Thalassiosira rotula* (22), the hydroid *Hydra vulgaris* (23), the barnacle *Balanus balanoides* (24), and the crab *Carcinus maenas* (25), but LOX sequences are absent from yeast and typical prokaryote genomes.

There are very many sequences within DNA databases that have been proposed as encoding LOX, but only a small number of these have been demonstrated to encode a functional, active enzyme. Despite considerable sequence diversity between and within plant and animal LOX sequences, the amino acids that are critical to catalysis, particularly the histidine residues that act as ligands to the active site iron, are generally highly conserved, and the amino acids that form part of the substrate (O_2 and PUFA) binding site show a greater degree of conservation than the rest of the sequence.

LOX are significant in food biotechnology for a number of reasons:

1. Their activity destroys PUFAs, which are essential components of human diet.
2. The fatty acid hydroperoxides that result from their activity can be further metabolized by other enzymes into compounds, such as six- or nine-carbon aldehydes and alcohols, that represent key flavor and aroma components of a wide range of fruits and vegetables.

Table 18.1
Examples of the recorded presence of LOX within lower organisms in Nature

Species
Fungi
Fusarium oxysporum (1,2)
Gäumannomyces graminis (3)
Saprolegnia parasitica (4)
Lagenidium giganteum(5)
Pityrosporum orbiculare (6)
Mushrooms
Psalliota campestris (7)
Psalliota bispora (7)
Agaricus bisporus (8)
Agaricus campetris (9)
Pleurotus ostreatus (10)
Others
Algae
Ulva lactuca (11)
Enteromorpha intestinalis (12)
Chlorella pyrenoidosa(13)
Miscellaneous
Plexaura homomalla (coral) (14)
Pseudoplexaura porosa (coral) (15)
Strongylocentrotus purpuratus (sea urchin) (16)
Pennaeus japonicus (shrimp) (17)
Dictyostelium discoideum (slime mold) (18)
Starfish and clam oocytes (19,20)

3. Some of the secondary products from fatty acid hydroperoxides, such as *n*-hexanal, impart off flavors to a number of vegetable derived, particularly legume derived, products (the so-called grassy-beany odor of soybean based products is a good example).
4. As a consequence of their reaction mechanisms, some LOX promote cooxidation processes that can have either positive or negative effects. An example of a positive effect is the improvement of bread dough rheology resulting from the LOX mediated formation of disulphide bonds in wheat gluten. The destruction of pigments, antioxidants, and vitamins by LOX mediated cooxidation would generally be regarded as negative, but pigment bleaching by cooxidation is a positive aspect in the production of white bread or pasta.
5. Plant LOX play important roles in defense against insect damage and fungal invasion. Although somewhat outside the scope of this article, plant health and the quality of foods derived from plants are obviously interrelated, and LOX activity clearly affects food quality in this more general sense.

The purpose of this chapter is to describe the nature, distribution, and activity of LOX, concentrating almost exclusively on plant LOX since these are most significant in food technology; and to describe how the production and analysis of recombinant LOX has led to a deeper appreciation of the action of the enzymes and their current and future roles in food biotechnology.

18.1.1 LOX Isoforms and Heterogeneity

Early studies of seed LOX assumed them to be a single molecular species. The realization that LOX can exist as a number of isoforms within a given plant organ came from work on soybean seed LOX (26,27), that demonstrated four isoforms: LOX-1, -2, -3a, and -3b. Subsequent studies, including analyses of genetic variants that lack LOX-3 (28), suggested that LOX-3a and -3b are derived from the same parent molecule and that there are actually only three major isoforms of soybean seed LOX. LOX-1 differs markedly from LOX-2 and -3 in a number of properties, including stability, but most notably in the pH for optimum activity, which is centred around 9.0 for LOX-1 and 6.5–7.0 for LOX-2 and -3. LOX-1 also shows a marked preference for charged fatty acids and little reactivity with esterified fatty acids. Most plant LOX reported to date are more similar to soybean LOX-2 and -3 in their properties; in this sense LOX-1, with its three dimensional structure and action mechanism which is known in some detail, is atypical of plant LOX.

Multiple forms of seed LOX have been recognized in several other species, including barley (29), broad beans (30), chickpeas (31,32), kidney beans (33), maize (34,35), peas (36,37), peanuts (38), rapeseed (39), rice (40), wheat (41), and winged beans (42). Isoforms are recognized on the basis of a number of parameters, including their amino acid sequence, their pH for optimal activity, differences in net surface charge that permit their separation by ion exchange chromatography, isoelectric focusing or chromatofocusing, sensitivity to Ca^{2+}, substrate preference, turnover numbers, apparent K_m values, the ability to cooxidize pigments and to generate carbonyl compounds, heat stability, and the nature of their products, which is a consequence of their regiospecificity (the position along the fatty acid chain where oxygen is inserted). Although it is clear from defense responses and from studies of developmental regulation that different vegetative LOX isoforms can play different physiological roles (43,44), it is not obvious why seeds should contain several LOX isoforms. Several mutants that lack one or more seed isoforms exist in soybean (28,45,46), pea (47), and rice (48) and, at least in the case of soybeans, would appear to have unimpaired agronomic performance (49,50), suggesting that some seed LOX may be dispensable for normal growth and development.

The genome of *Arabidopsis thaliana*, which is one of the smallest within the plant kingdom, contains six genes encoding LOX that fall into two classes; those with and those without N-terminal sequence extensions that suggest targeting to the chloroplast. In at least one instance, LOX has been shown to be targeted to the chloroplast . Those LOX that are associated with chloroplasts have markedly different sequences from those that lack such targeting peptides, and which are assumed to be located elsewhere within the cell. Shibata et al. (51) have classified those LOX that contain such a targeting sequence as *Lox2* gene products, and all others as *Lox1*.

Other plant LOX exhibit greater heterogeneity. Soybeans, as mentioned, have three major seed isoforms (LOX-1, -2, and -3); and at least three other vegetative (nonseed) isoforms (LOX-4, - 6) have been recognized. Peas have multiple LOX isoforms, with as many as five different seed forms, and other, different, LOX in leaves, stems, flowers, and roots (52). Furthermore, even a single isoform, such as pea seed LOX-2 or LOX-3, can comprise two or three very similar polypeptides from slightly divergent members of a small gene family. One consequence of this microheterogeneity is that the measured properties of pure preparations from plant sources will often be an average of the properties of the individual components, even for an apparently pure single isoform preparation; recombinant forms of such isoforms will, however, comprise just one type of polypeptide and may therefore differ slightly in properties from the corresponding plant derived preparation, but have many advantages.

18.1.2 The Value of Recombinant LOX

At present, the only large scale sources of LOX are crude sources such as enzyme active soybean flour; and these, as discussed, are limited because they contain a mixture of isoforms with different properties. The production of LOX as recombinant enzymes in microbial hosts such as *E. coli*, yeasts, or *Aspergillus* has several advantages: recombinant production systems from cloned enzymes are an effectively inexhaustible resource for enzyme production; cloned enzymes are a single type of recombinant protein, free of other isoforms; such systems produce very high biomass for high level production; and quality control over sterility and purity is simplified. Enzyme preparations from plant materials will have variable properties depending on the plant variety used as the enzyme source and the conditions under which the plant is grown. There are, for instance, plant varieties that lack particular LOX isoforms (53,54), and LOX enzyme levels can increase dramatically in response to the stresses encountered by plants growing in the field (55).

The benefits of using recombinant DNA technology for the industrial production of enzymes for use in food production are well established. A good example of its successful application is recombinant chymosin for vegetarian cheese. Production of enzymes in this way also has spinoff advantages, in that recombinant enzymes permit facile determination of kinetic and other properties on highly purified preparations, providing information that can be used in several ways. Purification, processing, and storage systems can be optimized, based on such information, but what is more important, enzyme properties can be improved (often dramatically) through the production of mutants, either by directed mutagenesis or by forced evolution. Thus, it becomes important to understand the properties of LOX through the use of recombinant enzymes in relation to their various uses in food biotechnology (56).

To date, a wide range of plant LOX have been produced, as whole or partial molecules, in microorganisms; some examples are given in Table 18.2. These have been produced for many different reasons: in some cases (65) to simply understand the nature of enzyme specificity, in others to establish a role in the aroma of foods (79), and in others still to produce LOX in sufficient amounts (gram quantities) for industrial use (56). In all

Table 18.2
Recombinant plant LOXs of known positional specificity. All positional specificities were determined with linoleate (18:2), except for potato 9-LOX, maize 13/9-LOX, potato 13-LOX-1 and potato 13-LOX-2 with linolenate (18:3), and rice 13-LOX RCI-1, which was with both. Figures shown are those published or calculated.

Source	Accession Number	Ref.	Positional Specificity[a]	Ref.	Designation

[a]Ratio of 13-*Z*,*E*-H(P)ODE:9-*E*,*Z*-H(P)ODE (no discrimination of *R* and *S* stereoisomers)

cases, there is an important interplay between understanding the structure and activity of plant LOX in relation to their uses in food biotechnology and the role in plant physiology for which they have naturally evolved.

18.2 THE STRUCTURE OF LOXs

All LOX so far examined are monomeric and, with the exception of the manganese-containing LOX from *Gäumannomyces graminis* (the "take all" fungus) (81), contain a single atom of nonheme, nonsulphur, high spin iron per polypeptide chain of Mr 75,000–95,000. In the resting or ground state, the catalytically inactive form in which LOX is usually prepared, the iron ion is ferrous [Fe(II)]; activation to the ferric [Fe(III)] ion is required to start the catalytic cycle, during which the iron undergoes redox shuffling.

Determinations of the crystallographic structures of soy LOX-1 (82,83) and LOX-3 (63) were conducted on the unliganded enzyme in the resting state. That of rabbit 15-LOX (84) was obtained in the presence of a bound inhibitor that had superficial similarity to arachidonic acid. The structure of the metastable product oxidized purple form of soy LOX-3 (85) has revealed an unexpected mode of fatty acid binding and identified amino acid residues that may play significant roles in catalysis, regiospecificity, and stereospecificity.

Recently, structures of soy LOX-3 complexed with (-)epigallocatechin gallate and curcumin have been determined (86,87). The soy LOX-1 and LOX-3 enzymes have two domains: an N-terminal β-barrel (146 residues in LOX-1) and a C-terminal helical bundle catalytic domain (693 residues in LOX-1). Mammalian LOX, such as rabbit 15-LOX, are considerably shorter than plant LOX, with 839 residues in soy LOX-1 compared to 662 in rabbit 15-LOX. Sequence comparisons, particularly of the highly variable N-domain, showed little similarity between plant and animal LOX, because of this, it was thought for some time that the N-terminal β-barrel of plant LOX was absent from the mammalian enzymes. The structure of rabbit 15- LOX (84), however, made it clear that the mammalian LOX has the same folds as its plant counterparts, achieving this through molecular parsimony (88), whereby the plant and mammalian enzymes have common core secondary structural elements but the mammalian form has fewer dispensable elements such as surface loops (Figure 18.1).

There are clear differences between soy LOX-1 and LOX-3, in and near the three cavities that connect the active site iron with the molecule surface (63), which form a theoretical basis for the difference in the profile of products from the two enzymes.

The iron in soy LOX-1 is coordinated to six ligands (Figure 18.2). Three of the coordination positions are occupied by histidine Nε atoms. A fourth ligand is oxygen from the carboxylate of the C-terminal isoleucine, and a fifth position is occupied by a water molecule. There is spectroscopic evidence to suggest that this water changes to a hydroxide upon oxidation, which is proposed to function as the active site base. The octahedral coordination sphere also includes an asparagine (Asn^{694}), which in the resting enzyme is involved in a number of labile polar interactions with other groups but is just beyond the maximum bonding distance to be a strong iron ligand; in rabbit 15-LOX this asparagine is a histidine, which has a larger side chain and is a stronger ligand. The distance between Fe

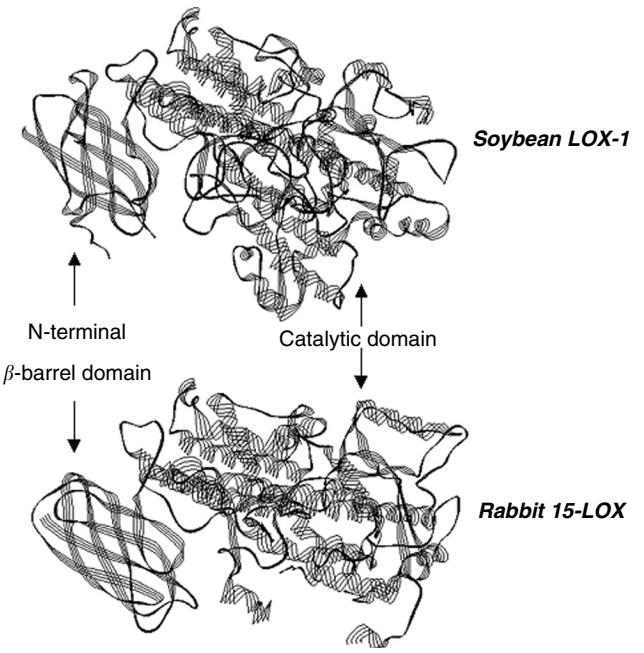

Figure 18.1 Diagram of the three dimensional structure of soybean LOX-1 and rabbit 15-LOX, showing the N-terminal β-barrel and the helical catalytic domain

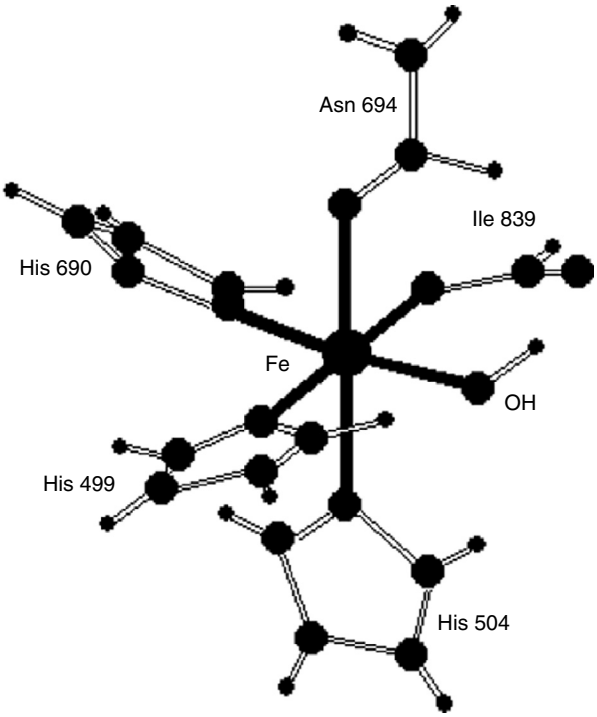

Figure 18.2 Digrammatic representation of the ligand geometry of the iron in the ferric (active) form of soybean LOX-1 (89)

and Asn^{694} depends on whether product is present or not — it is weak, or nonligand, in the Fe(II) form, giving 5-coordination geometry, but may shift position in the active, Fe(III) form to give 6-coordination geometry (Figure 18.2). Also, the bond to Wat^{842} is weak, but the strength and length of the Fe-O(Wat^{842}) bond changes noticeably on oxidation, becoming shorter and stronger as the character of the ligand changes from neutral water to the negatively charged OH group (89). The six ligands are referred to as the first coordination sphere (90). Asn^{694} is part of an important hydrogen bonding network that may provide a structural link between substrate binding and iron coordination (91). Glutamine residue Gln^{495}, which lines the putative substrate cavity wall, forms hydrogen bonds with Gln^{697}, which in turn is hydrogen bonded to Asn^{694}. This H-bond between Asn^{694} and Gln^{697}, is thought to play a key role in the modulation of the coordination flexibility of Asn^{694}, which in turn modulates activity (92). The two glutamines are referred to as the second coordination sphere. The hydrogen bond network plays a role in the hydrogen bond rearrangement of the enzymatic mechanism and steric interaction with the side chain of Gln^{495} is important in the proper positioning of the substrate (91).

18.3 LOX REACTION MECHANISM

There are several reasons to better understand the action mechanism and specificity of LOX in the context of food biotechnology. Substrate specificity will determine which PUFAs are preferentially destroyed by LOX activity in foods, and will influence the nature of the final metabolites from the LOX pathway; this in turn will influence aromas

and tastes. Similarly, positional specificity — whether 9- or 13-hydroperoxides are produced — will determine the nature of subsequent taste and aroma compounds; 9-LOX activity will give rise to 9-carbon, and 13-LOX to 6-carbon, aldehydes, and alcohols, with their characteristic aroma properties. In addition, the ability of particular LOX to carry out cooxidation reactions has a major influence in a number of spheres of food biotechnology, including the stability of vitamins and antioxidants and the use of enzyme active soybean flour in bread making. Both of these characteristics — substrate and product specificity and cooxidation potential — depend on the exact nature of the LOX reaction, which differs according to the source of the enzyme, the specific LOX isoform involved, and the reaction conditions.

Isoform 1 of soybean seed LOX (soy LOX-1) is by far the most extensively studied and best understood LOX in terms of reaction mechanism, but with its high pH optimum and degree of thermal stability it is probably not typical of most LOX. Studies of soy LOX-3 as a product oxidized purple form (85) largely support the conclusions drawn from work on soy LOX-1, but differ in a number of details.

The substrate requirement of LOX is at least one 1,4-diene with at least one of the olefins in the *Z* geometry (93). In biological terms, this translates into polyunsaturated fatty acids (PUFAs) that contain *Z,Z*-pentadiene systems: linoleic (18:2), α- and γ-linolenic (18:3) acids in plants, and arachidonic (20:4) and higher order PUFAs in animals (Figure 18.3). With linoleic acid as substrate, the predominant reaction of soy LOX-1 involves formal abstraction of the *pro*-S hydrogen atom from methylene carbon C-11, a rearrangement of the double bond system, and the stereospecific addition of the peroxy group at C13 to form the 13-*S* (*Z,E*) product (Figure 18.4). With α-linolenic acid, hydrogen removal is in principle possible either at C-11 or C-14, or both, but it seems that plants

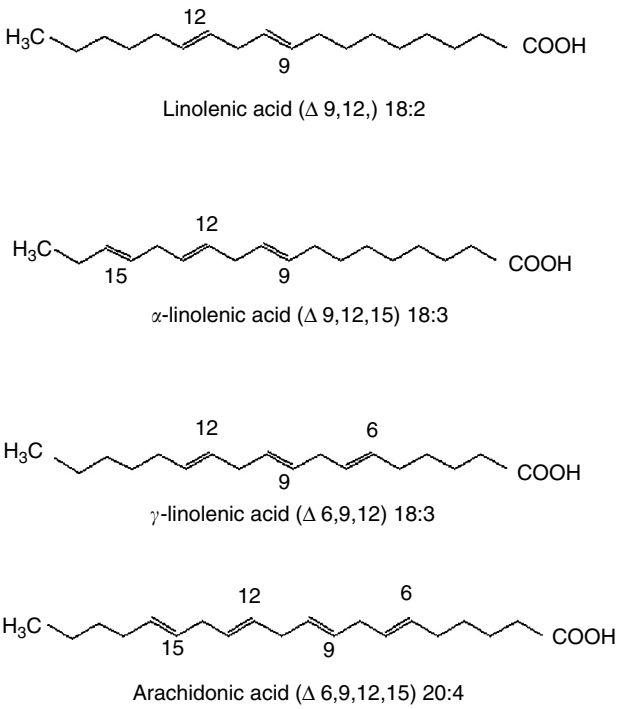

Figure 18.3 The major polyunsaturated fatty acids from plants (18:2, 18:3) and animals (20:4)

use only the one doubly allylic methylene group at C-11 in linoleic and α-linolenic acids (94). The enzyme activates the substrate PUFA for combination with molecular oxygen by this hydrogen abstraction reaction. The results of kinetic isotope effect experiments implicate a tunnelling mechanism for this key step (95), and steady state kinetics have shown that oxygen interacts with the enzyme only after hydrogen abstraction from the substrate (96). The water ligand may act as the Fe (III) bound hydroxide that serves as the effective base for hydrogen abstraction, and it has been suggested that an Fe(III)-OH^- active site base is formed as part of the mechanism, leading to a C-H bond cleavage transition state (Figure 18.5). This transition state requires that the substrate be positioned close enough to the Fe(III)-OH^- species to allow for tunnelling of the substrate hydrogen atom to the metal-bound hydroxide, leading to the fatty acid carbon based radical intermediate $L^{\cdot}$ [plus Fe(II)-OH_2]. The radical intermediate reacts with O_2 to regenerate Fe(III)-OH and generate a peroxyl radical, which is subsequently reduced and protonated to form the final 13(*S*)-hydroperoxide product (Figure 18.6). As with most reactions between carbon radicals and O_2, the soy LOX-1 reaction is very rapid, but it is also stereospecific and regiospecific, forming almost exclusively the 13(*S*) product. The radical intermediate $L^{\cdot}$ has generally been depicted as a pentadienyl radical, in which radical character is spread over C-9 - C-13, generating greater stability than for an allyl radical. This would make C9 and C13 equally reactive to O_2 attack, barring accessibility differences. However, the side

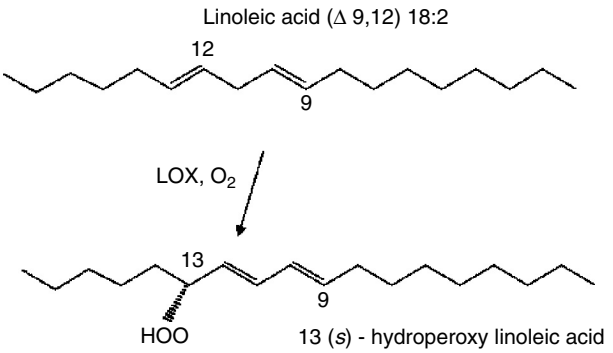

Figure 18.4 Formation of 13-(*S*)-hydroperoxy linoleic acid by soybean LOX-1

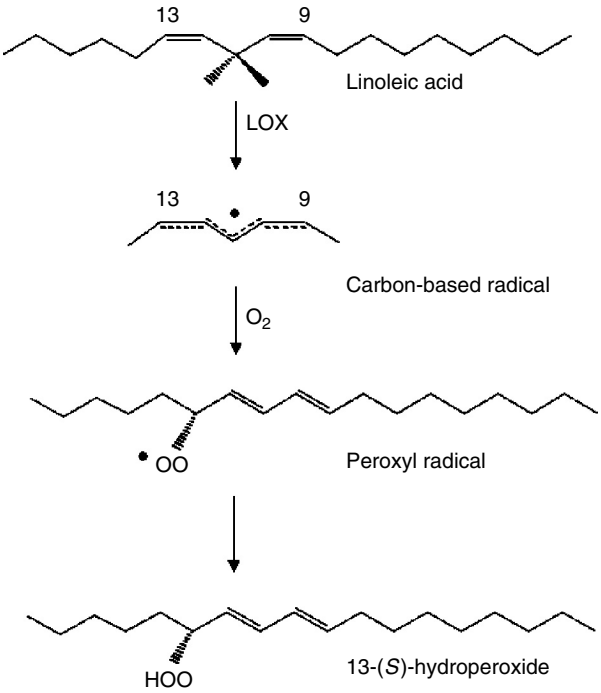

Figure 18.6 Generation of hydroperoxide from linoleic acid *via* carbon based and peroxyl radicals

chains of Ile^{538} and Gln^{495} in soy LOX-1 provide sufficient bulk to disfavor the planar pentadienyl intermediate, raising the possibility that $L^{\cdot}$ is an ene-allyl radical. If the unpaired electron density of $L^{\cdot}$ were localized near C13, in the form of a Δ^9-[11,12,13] allyl radical, then O_2 would be expected to selectively react at C13. However, electron paramagnetic resonance (EPR) investigations into the nature of $L^{\cdot}$ suggested that radical character is localized near C-9. The $Gln^{495} \rightarrow$ Ala and $Ile^{538} \rightarrow$ Ala mutations (97) should each reduce the amount of strain that might favor a localized ene-allyl radical, but they have only modest effects on the rate of oxygenation, suggesting that either an ene-allyl radical is not formed during turnover, or there is rapid interconversion between the Δ^{12}-[9,10,11] and Δ^9-[11,12,13] radicals. There is, therefore, still some doubt over the exact nature of the carbon based radical that reacts with O_2.

The observed stereochemistry requires that hydrogen atom removal and oxygen attack occur antafaracially, on opposite faces of the pentadiene unit. There is some evidence that the enzyme engenders specificity by requiring a relatively specific approach of dioxygen through steric interference or other means, rather than the specific location of an Fe bound dioxygen (97). Mutation of soy LOX-1 $Ile^{553} \rightarrow$ Phe greatly reduces the rate of oxygenation chemistry, while leaving k_{cat} (the overall rate of catalysis, which is probably limited by H abstraction) relatively unchanged. This suggests that $Ile^{553} \rightarrow$ Phe impedes O_2 access to the carbon radical intermediate and supports the view that O_2 enters the active site through the channel that passes residue 553 (97). The studies of Knapp et al. (97) suggest that O_2 in soy LOX-1 requires a discrete, separate access channel, which is a departure from typical views of substrate-activating oxygenases. It seems that the primary role of the Fe^{3+} cofactor is to generate an enzyme bound radical, whereas the protein controls the stereochemistry and regiochemistry of O_2 encounters with this radical (98).

18.4 SUBSTRATE SPECIFICITY

Some LOX have quite specific substrate requirements, others less so. The two LOX (-2 and -3) from pea seeds, for instance, have markedly different substrate specificity despite having a high degree of sequence identity; pea seed LOX-3 is highly specific for linoleic acid, whereas pea seed LOX-2 is also active with linolenic acid and shows reasonable activity with arachidonic acid. Pea seed LOX-2 is almost equally active with linoleic acid and its methyl ester, whereas the latter is not a substrate for pea seed LOX-3 (58). The basis of such specificity is poorly understood, although Hornung et al. (99) used site-directed mutagenesis to change a single amino acid in cucumber lipid body LOX [which normally forms 13(*S*)-hydroperoxides from linoleic acid (100)] and generate a species that was active on γ-linolenic and arachidonic acids. This illustrates the value of recombinant enzymes to carry out such studies.

Although the majority of plant LOX strongly prefer free fatty acids as substrates, at least three – soy LOX-1, Arabidopsis and cucumber root LOX – are capable of using PUFAs esterified to phospholipids (101,102,103); and the LOX from cucumber lipid bodies and from barley seedlings are active with PUFAs that are esterified in neutral lipids such as triacylglycerols (104,76). It will be very relevant to biological function to discover how LOXs interact with substrates in these forms.

18.5 PRODUCT (REGIO- AND STEREO-) SPECIFICITY

As discussed, soy LOX-1 produces almost exclusively the 13(*S*)-hydroperoxide of linoleic acid under the appropriate conditions. Other LOX, such as those from potato tubers or tomato fruits (65,105), produce largely the 9-*S* hydroperoxide, whereas still others [soy LOX-3, pea seed LOX-3, (58)] produce mixtures of 9-*S*- and 13-*S*-hydroperoxides, in different ratios. There is, in addition, a class of LOX, from coral, sea urchin eggs, crabs, barnacles, marine and freshwater hydroids, and oocytes of starfish and clams, that naturally form (*R*)-hydroperoxides and are related in primary structure to the *S*-LOX (106).

It is not yet completely clear how the enzyme controls the regioselectivity and stereoselectivity of catalysis, or what factors govern the outcome of the peroxidation reaction and the formation of possible products. Such information may in principle be gleaned from comparisons of the structures and sequences of enzymes with different specificities. Soy LOX-1 and LOX-3 provide an interesting study in contrast, since their mechanisms lead to both single (LOX-1) and multiple (LOX-3) products of the 9/13 peroxidation of linoleic acid. A comparison of the structures of "native" soy LOX-3 and its 13-hydroperoxide product complex (85) shows few differences, with the only amino acid dislocated in a significant way from its original place being Gln^{514}, which in the native enzyme participates in a hydrogen bonding network which connects $His^{518}\rightarrow Gln^{514}$, $Gln^{514}\rightarrow Gln^{716}$, $Gln^{716}\rightarrow Asn^{713,}$ and $Asn^{713}\rightarrow Leu^{773}$. Atoms C5-C6-C7 from the fatty acid occupy the place taken up by the Gln^{514} side chain in the native enzyme; in the complex with HPOD (hydroperoxy dienoic acid) this Gln^{514} side chain is disordered. This could be the basis for an explanation for the lack of regioselectivity in LOX-3 catalysis (85). If Gln^{514} were in its original hydrogen bonding network, the passage for the carboxyl end of the fatty acid would be blocked. If the COOH group of a fatty acid substrate could be stabilized by an interaction with the hydrogen bonding network around Gln^{514}, this would bring the C9, instead of the C13, atom from the fatty acid near the Fe^{3+} cofactor during the catalysed reaction. The binding site in general appears to be more flexible in soy LOX-3 than in LOX-1 as a consequence of amino acid differences in the aligned sequences: (LOX-1/LOX-3) Ser^{747}/Asp^{766}; Thr^{756}/Arg^{775}; Gln^{256}/Thr^{274}.

Although such comparisons give useful insights into the factors that may control specificity, they are limited and need further experimentation to check the hypotheses that they generate. Such experimentation is usually in the form of production of site directed mutants of recombinant enzymes; thus, the generation of recombinant LOX extends well beyond their utility as a production vehicle for biocatalysts, into the realms of improved understanding for the generation of improved activities. The production of site directed mutants, based on crystallographic structures and homology modelling, has been particularly useful in furthering our understanding of the basis of product specificity as well as the nature of the reaction mechanism.

Early mutagenesis experiments with human 15-LOX, based on sequence comparisons of mammalian 12- and 15-LOX (107), identified Met^{418} as a primary determinant of positional specificity. Mutagenesis of Met^{418} to Val converted the wild-type enzyme, which produces almost exclusively 15(*S*)-hydroperoxide from arachidonic acid, into a species that makes equal amounts of 12(*S*)- and 15(*S*)-hydroperoxides. It was proposed that this change in specificity was the consequence of a change in the bulk of the side chain at position 418, such that the substrate could move further into the active site, shifting the site of hydrogen abstraction from C13 to C10 and leading to 12-, rather than 15-, lipoxygenation. This particular amino acid became known as the Sloane determinant of mammalian LOX positional specificity. The suggestion that further translation of the fatty acid into the active site could lead to 5-LOX activity (84) was challenged (108) on the grounds that such further translation will not produce 5-LOX products with the correct stereospecificity of H^+ abstraction and oxygen addition. In addition, Borngräber et al. (109) made a strong argument that Phe^{353}, which also forms part of the binding pocket in 15-LOX, is a further key determinant of positional specificity of oxygenation, a residue that is referred as the Borngräber determinant (99). Borngräber et al. (110) extended their studies to include Ile^{593} of rabbit 15-LOX, amongst other residues, and suggested that enlargement of the substrate-binding pocket favored 12-lipoxygenation, whereas a smaller active site favored 15-lipoxygenation. They concluded that the overall size and shape of the substrate binding pocket is important to defining the specificity of the LOX reaction.

The equivalent position to mammalian 15-LOX Met^{418} is His^{608} in cucumber lipid body 13-LOX (100). Alteration of the bulky His to a less space-filling Val converted the enzyme to a 9-LOX. It was suggested that the alteration may unmask the positively charged guanidine group of Arg^{758}, which in turn may force an inverted head to tail orientation of the fatty acid substrate that leads to 9-, rather than 13-lipoxygenation. The equivalent mutation in pea seed LOX-3 and a specific potato tuber LOX, both of which have 9- and 13-LOX activity, however, did not alter positional specificity (66,111), suggesting that the determinants of specificity may vary from one LOX to another.

Overall, there are two hypotheses that rationalize the mechanistic differences between LOX with different positional specificities; the "orientation based" hypothesis and the "space based" hypothesis (Figure18.7). It is likely that each is correct for a particular circumstance, and the two, in any case, are not mutually exclusive in the sense that changes in the bulk of amino acid residues within the active site can influence both the degree of penetration of the substrate and its orientation.

Recent mutagenesis experiments with soy LOX-1 (97) suggest that steric restraints placed on the approach of oxygen to the enzyme bound substrate by the surrounding amino acid side chains culminate in the observed regioselectivity and stereoselectivity. Replacing bulky leucine residues with Ala at LOX-1 546 and 754 (= LOX-3 565 and 773), which created a constriction in the substrate cavity IIa, resulted in less 13-hydroperoxide, more 9-hydroperoxide, and a lower level of stereoselectivity at both positions. This indicated that the constriction in cavity IIa formed by Leu^{546} and Leu^{754} sterically

prevents O_2 access to the C9 position of soy LOX-1 within the pentadiene radical, thus imparting selectivity.

18.6 COOXIDATION

The complete catalytic mechanism (Figure 18.6) involves the formation of a fatty acid peroxyl radical which is reduced, protonated, and released as hydroperoxide. Some LOX, including pea seed LOX-3, produce keto and hydroxy fatty acids that have been proposed (58) to be the consequence of dismutation of a prematurely released peroxyl radical (Figure 18.8). There are other routes to hydroxy fatty acids from hydroperoxides (94), but the production of hydroxy and keto fatty acids seems to be associated with the capacity of the enzyme to carry out cooxidation reactions such as the bleaching of β-carotene (112), which would be consistent with the premature release of a highly oxidizing peroxyl radical or its dismutation into singlet oxygen or both. It has been suggested that such LOX are "imperfect by design" in that the nature of their active site has a flexibility that allows both dual positional specificity and the premature release of a peroxyl radical. Pea seed LOX-3 is such an enzyme; whereas pea seed LOX-2 has a single positional specificity, does not produce hydroxy and keto fatty acids (58) (Figure 18.9) and does not efficiently cooxidize β-carotene. Whatever the mechanism, this ability to carry out cooxidation is highly significant to food quality.

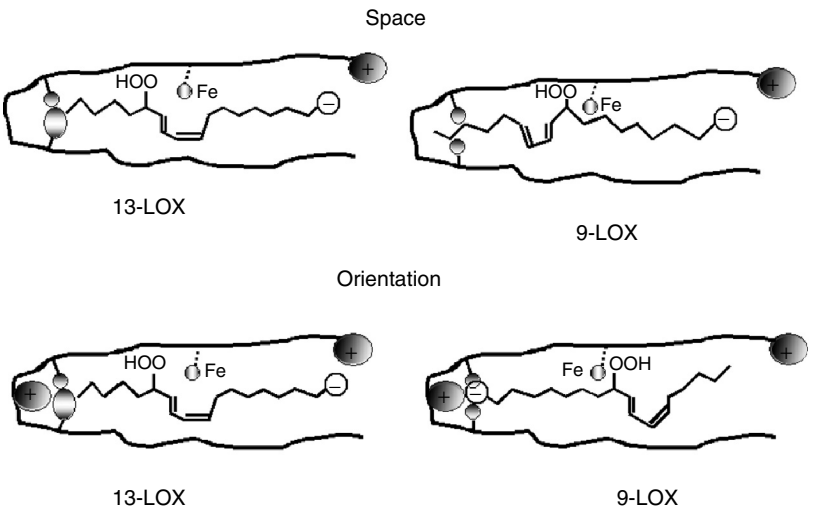

Figure 18.7 Representation of the "space" and "orientation" hypotheses of LOX positional specificity. In both cases the sizes of particular amino acids within the active site cavity play critical roles, but the underlying basis is different in the two hypotheses

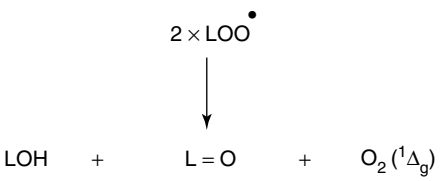

Figure 18.8 Dismutation of fatty acid peroxyl radical to produce hydroxy- and keto- fatty acids and singlet oxygen (58)

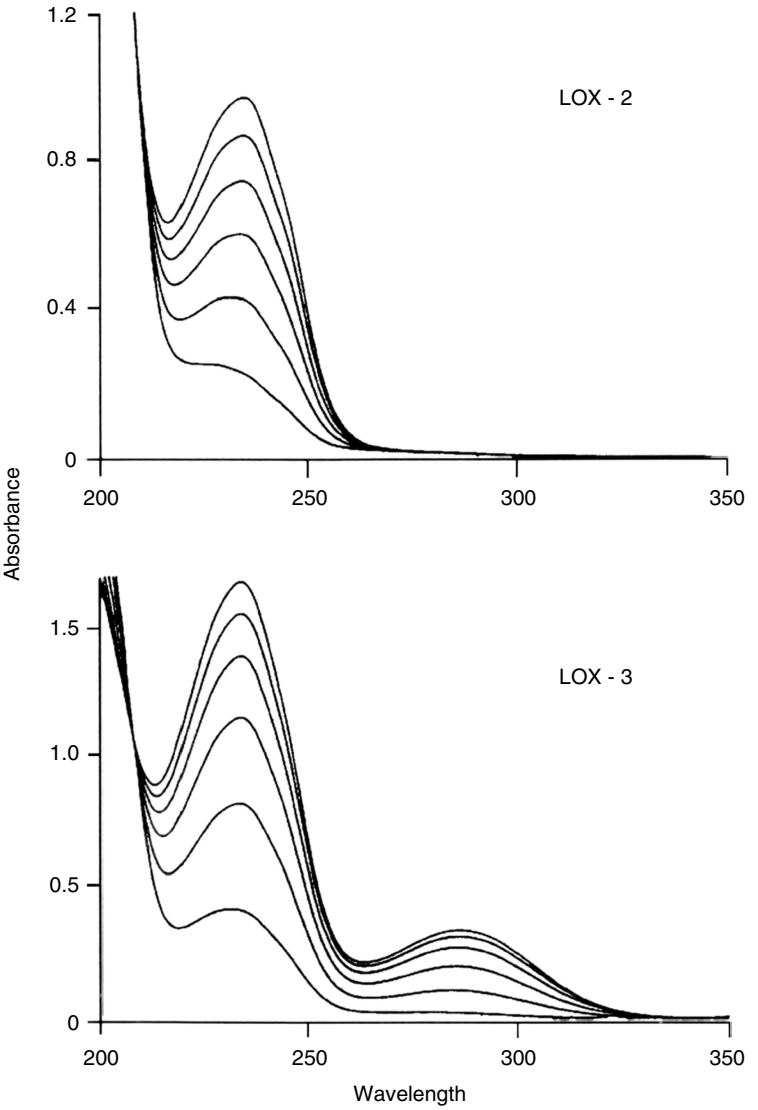

Figure 18.9 Pea seed LOX-3, but not LOX-2, generates carbonyl (keto) compounds that absorb at 280nm

18.7 APPLICATIONS OF LOX TO FOOD QUALITY

18.7.1 Flavors and Aromas

Fatty acid hydroperoxides are toxic compounds that are metabolized *in planta* by a range of enzyme activities (94), including several unusual members of the cytochrome P450 family known as CYP74s. These include allene oxide synthase (AOS), hydroperoxide lyase (HPL), and divinyl ether synthase (DES) (Figure 18.10). All three activities produce compounds that play direct or indirect roles in plant defense. AOS is the first committed step in the synthesis of jasmonate, an important signalling compound that activates defense gene expression upon wounding (113). DES in potato produces divinyl ether fatty acids,

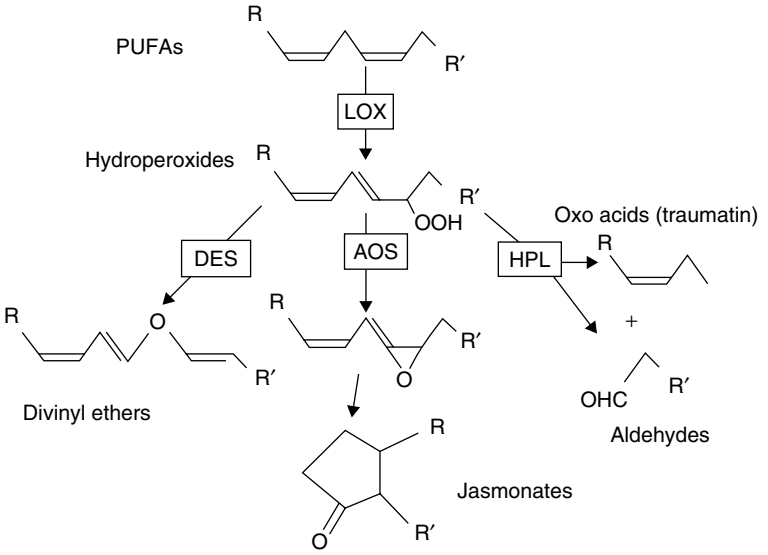

Figure 18.10 The formation of oxylipins from fatty acid hydroperoxide by CYP74 activity

which have been shown to act as protectants against *Phytophthora infestans*, the causative agent of late blight disease (114). HPL cleaves fatty acid hydroperoxides into 6- or 9-carbon volatile aldehydes, depending on enzyme specificity and, in the case of 13-HPL, acting on the 13-hydroperoxide of linolenic acid, traumatin (otherwise known as wound hormone). Traumatin plays a direct role in plant defense by accelerating cell division at wound sites, whereas volatile 6-C aldehydes can act directly as antimicrobial agents (115), or indirectly as defense signalling compounds (116). A number of plant HPL have been produced as recombinant molecules (Table 18.3) that may have a role to play in the production of fresh, green aromas (127).

Clearly, any compound which acts as a phytoprotectant will have an impact on food quality through reduced insect damage and diminished spoilage due to pathogen invasion. The volatile 6-C and 9-C aldehydes produced by HPL activity, and the alcohols derived from them by dehydrogenase action, however, have profound direct consequences for food quality in the form of taste and aroma compounds; the "green notes" (Figure 18.11) of fresh fruits and vegetables (53). They form the basis of the pleasant and distinctive aromas of tomatoes, potatoes, mushrooms, melons, cucumbers, bananas, and avocados, for instance. *E*-2-hexenal is one of the major flavor volatiles of fresh tomatoes (131) and is almost certainly derived from the action of a 13-HPL on the 13-hydroperoxide of linolenic acid. Aldehydes tend to provide green notes to tomato fruits, whereas their corresponding alcohols impart a more ripe aroma, and the balance between aldehyde and alcohol plays a major role in tomato flavor perception (132). Not all C-6 aldehydes are perceived as pleasant, however, a good example being *n*-hexanal, which is the grassy-beany flavor associated with soybean and other legume seed products. Thus the chemical difference between a pleasant and unpleasant aroma is very small (Figure 18.11).

Soybean seed has three major LOX isoforms, and genetic removal of LOX-2 reduces *n*-hexanal production and improves the consumer acceptability of soymilk and soy flour (133). LOX-2 is a 13-LOX and therefore a major source of *n*-hexanal via HPL activity, although subsequent studies have suggested that removal of both LOX-2 and LOX-3 has the greatest effect on off flavor reduction (134). Pea seeds contain two major LOX that are

Table 18.3

Recombinant plant HPLs of known substrate specificity. Functionality of all cDNA sequences were determined using purified enzymes after heterologous expression in *Escherichia coli*, with the exception of the potato sequence whose functionality was determined using crude extracts from untransformed and transgenic (antisense) plants.

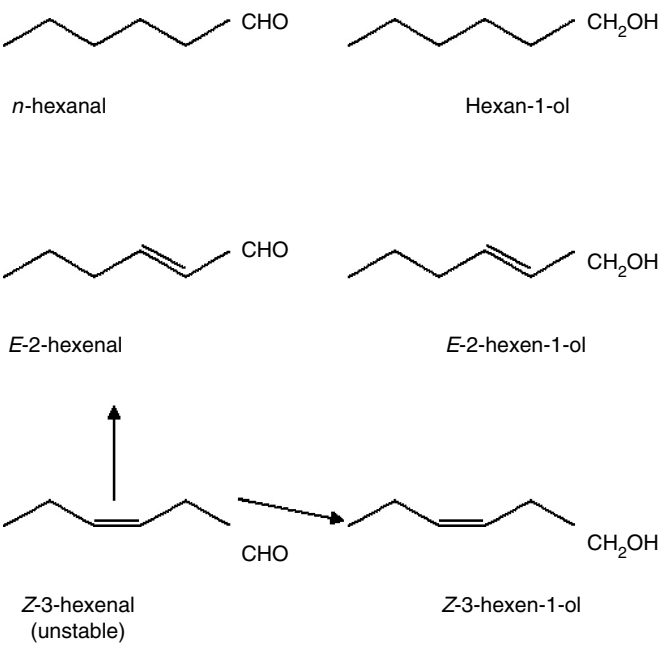

Figure 18.11 Some C-6 aldehydes and alcohols, formed by the combined action of LOX and HPL, that contribute to flavor aromas in fruits and vegetables

equivalent to LOX-2 and LOX-3 from soybean, and genetic variants have been produced that lack LOX-2. The properties of the LOX preparations from such seeds (54) are consistent with the loss of this particular isoform, based on our understanding of the properties of the two isoforms as recombinant enzymes (58). Thus, information gained from the study of recombinant enzymes can guide plant breeding processes. The recombinant enzymes can also be used as biocatalysts for the production of value added chiral chemicals; the advantage of such syntheses is control of stereochemistry. In the case of plant LOX, under the appropriate conditions virtually all of the hydroperoxide product will have (*S*) stereochemistry, whereas autoxidation products, for example, are a racemic mixture of (*S*) and (*R*) isomers, with implications for subsequent conversions. A combination of LOX and HPL can be used to produce aldehydes in industrial amounts to be used either as aroma additives or, in the case of *n*-hexanal, antimicrobial fumigants for postharvest crop protection.

18.7.2 Cooxidation and Food Quality

The ability of some LOX to prematurely release fatty acid peroxyl radicals is correlated with their capacity to carry out cooxidation reactions that catalyse the oxidation of sensitive molecules such as protein thiol groups, pigments, vitamins, and other anti-oxidants. The term "cooxidation" refers to the fact that the antioxidant or protein itself is not a direct LOX substrate, and cooxidation will not take place in the absence of PUFA, which is a mandatory part of the reaction. In general terms, cooxidation has a negative impact on food quality, destroying valuable antioxidants, decolorizing foods, and diminishing vitamin content.

18.7.2.1 Destruction of Vitamins

The adverse effect of LOX activity on antioxidant vitamins is well documented. In the presence of soybean LOX, vitamin E, vitamin C, and lutein are rapidly destroyed (135).

The antioxidants were scarcely affected by soybean extracts from lines in which the three seed LOX had been genetically removed, however, suggesting that soybeans that lack LOX could become a superior food ingredient which would improve not only the flavor of soybean products but also their nutritional quality and functionality (135). In frozen peas, the presence of LOX with cooxidizing potential may compromise vitamin C content, and genetic removal of pea seed LOX-2 (54), by conventional breeding using natural biodiversity may lead to an increased retention of vitamin C on processing (136). This principle of removing LOX to improve vitamin content can be applied generally to fruits and vegetables; the effect should be more pronounced if the LOX is a strong cooxidizer, and in this context it may be more effective to remove LOX-3, rather than (or as well as) LOX-2 from pea seeds because LOX-3 is better at cooxidation.

18.7.2.2 Pigment Bleaching

There are a large number of reports of the destruction of pigments as a consequence of LOX activity, including the loss of carotenoids from peppers (137), the bleaching of carotene and crocin by soybean LOX (138) and the cooxidation of β-carotene by potato (139) and pea (112) LOXs. The cooxidation process can be very rapid; LOX can quickly cooxidize β-carotene, even at 0°C in a predominantly organic solvent, to produce a range of breakdown products, some of which may themselves have flavor or aroma properties. The recombinant pea seed LOX-3 has a greater cooxidation to activity ratio than LOX-2 (112). Such pigment cooxidation obviously will have an impact on food quality, but this is not always negative. Commercial bread making includes the addition of enzyme active soybean flour for two reasons, both of which involve LOX. The cooxidation potential of LOX results in the bleaching of carotenoids and other pigments in the dough, leading to a brighter white loaf. The major application, however, is to brinng about the beneficial effect on dough rheology that results from the cooxidation of wheat flour proteins.

18.7.2.3 Bread-Making and Dough Rheology

It is common practice in commercial white bread making to add soybean LOX, as part of an enzyme active improver, to improve dough rheological and baking properties, by imparting tolerance to over mixing (140,141) (Figure 18.12), probably through the cooxidative formation of disulphide bonds between wheat flour proteins. The protein component of dough, gluten, is a complex mixture of glutenins, gliadins, and other proteins that interact through hydrogen bonding, disulphide bridges, and hydrophobic interactions (142). The high molecular weight (HMW) glutenin polypeptides (143) have a predicted β-spiral structure (144) that plays an important role in the viscoelastic behavior of gluten, possibly by acting as molecular springs. The HMW glutenin polypeptides have terminal cysteine residues and it is proposed (145) that the addition of LOX and PUFA, in the form of soybean flour, promotes the cooxidative formation of intermolecular disulphide bonds to generate a network of larger, stronger springs (Figure 18.13). Although wheat has endogenous grain LOX (41), they either are present in insufficient amounts, or have inappropriate effects, or both, to play this role in bread making.

There are several ways in which recombinant LOX can be used to provide the necessary cooxidation potential which are alternatives to the addition of soybean:

1. Engineer the yeast used in baking to produce and secrete a cooxidizing LOX during dough production

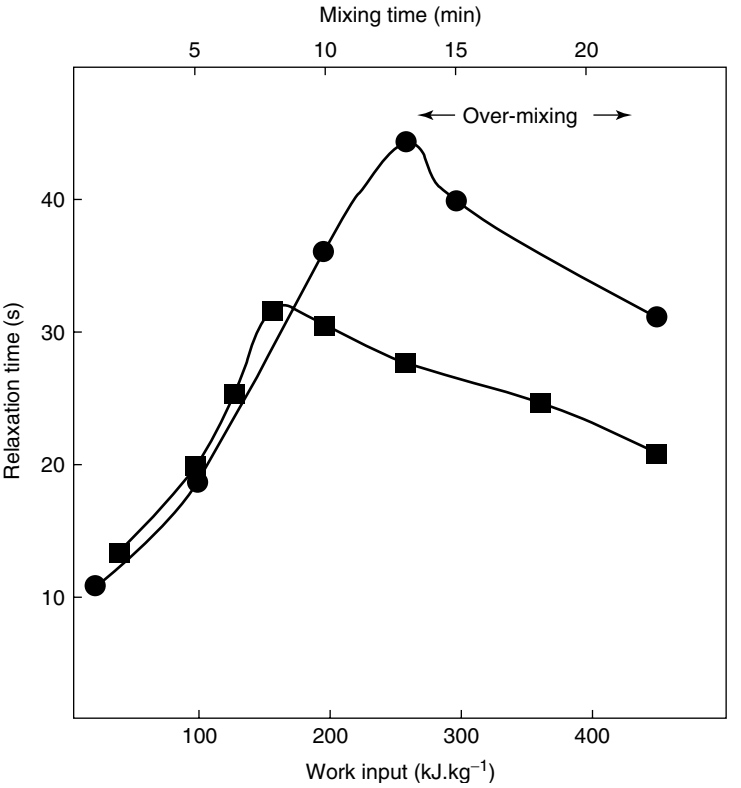

Figure 18.12 The effect of adding enzyme active soybean flour during high-power mechanical mixing of dough. Relaxation time equates to elasticity. ■, without and ●, with soybean flour (140)

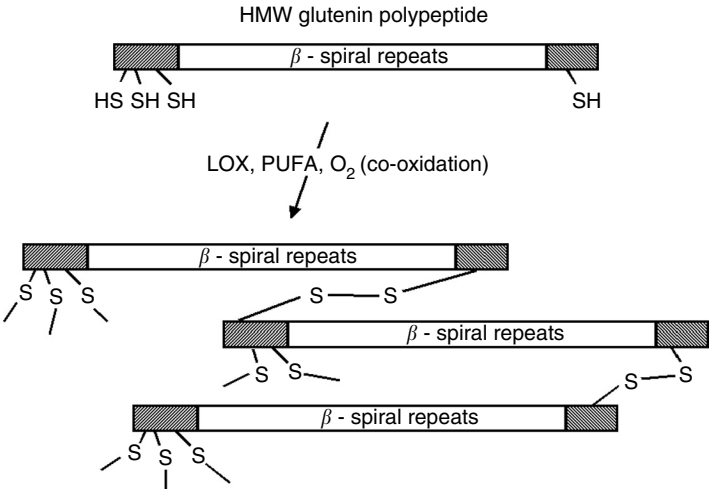

Figure 18.13 Diagrammatic representation of the cooxidative disulphide cross linking of HMW glutenin polypeptides

2. Use microbial fermentation in bacterial, fungal, or other, hosts to produce industrial amounts of cooxidizing LOX
3. Genetically modify wheat through recombinant DNA technology to produce a cooxidizing legume LOX within the developing wheat grain

18.7.2.3.1 Engineering Baker's Yeast to Secrete Recombinant LOX Active pea seed LOX-2 and -3 have been expressed in *Saccharomyces cerevisiae* using a constitutive phosphoglycerate kinase gene promoter (146), but secretion into the medium was not obtained, even with a yeast invertase signal sequence attached to the N-terminus of the enzyme. It appears that the signal sequence directed the pea seed LOX into the yeast secretory pathway, but potential cryptic vacuolar targeting sequences within the LOX coding sequence led to retention of the enzyme within the cell. The system has not been further exploited.

18.7.2.3.2 Production of Recombinant LOX by Fermentation in Microbes As indicated earlier, a large number of plant (and animal) LOX have been produced by over expression in *E. coli*, as tagged, fusion, or native proteins. For industrial use in the food industry, however, a number of criteria will need to be addressed. The enzymes will need to be produced in high yield and highly active form, and it is not clear whether LOX production by fermentation could ever be competitive with soybean products, unless it offers other advantages. Furthermore, if the recombinant enzyme is to be introduced directly into food, as opposed to being used as a biocatalyst for the production of food ingredients, then it should be identical to that from natural sources. This was the case for the high level expression of pea seed LOX in *E. coli*, which were produced as nonfusion proteins (147,56). The enzymes will need to have good cooxidation capacity if they are to be used in bread making, and there is considerable potential here for experimentation and improvement. Individual LOX vary a great deal in their cooxidation potential and their effects on the bread making process (148), and there are simple tests, such as carotenoid bleaching, that allow the screening of recombinant LOX and their site directed mutants for improved activity. Such high throughput assays also open up the possibility of forcing the evolution of LOX with greatly enhanced cooxidation potential. In addition, it is important that the enzyme activity does not generate aldehydes that impart off flavors to the product, which can easily be tested *in vitro*. The amount of soybean flour that can be added to the product is currently limited by the formation of off flavors (149), and recombinant activities that are effective cooxiders but do not generate the 13-hydroperoxides that give rise to C-6 aldehydes could be valuable. The stability of the enzyme preparations will be important to their production, purification and storage; pea seed LOX-3, which has the better cooxidation potential, is considerably more stable than LOX-2 (150).

18.7.2.3.3 Production of Recombinant Legume Lipoxygenase in Wheat Seeds The ability to transform wheat affords the possibility of expressing novel genes in wheat seeds, and this could certainly include a cooxidizing legume LOX. Other pea seed proteins have been successfully synthesized in transgenic wheat endosperm (151), the part of the seed in which the gluten proteins reside, using specific promoters to accomplish high level, seed specific expression. The *in planta* production of such recombinant LOX may or may not obviate the need for the addition of soybean improver during bread making, but it could widen the options available to plant breeders. The same considerations, in relation to cooxidation potential and the nature of the final LOX product, would apply to the production of recombinant LOX in wheat seeds under microbial fermentation, as was discussed.

18.8 FUTURE TRENDS AND APPLICATIONS OF RECOMBINANT LIPOXYGENASES AND OXYLIPIN METABOLISM

Recombinant enzymes offer immense opportunities for the development of new activities through site directed mutagenesis and forced evolution. As crystal structures for LOX become available, it becomes easier to understand the underlying bases of catalytic specificity and to test hypotheses through the production of site directed mutants. Many such experiments have been performed with plant and animal LOX, and have enhanced our understanding of regiospecificity of catalysis, but have not especially clarified the basis of substrate specificity, or the factors that influence cooxidation ability. The current lack of a structure with bound substrate is a disadvantage; that of a product bound complex (85) has proved enlightening, but will differ in detail from an enzyme substrate complex.

Site directed mutagenesis, based on three dimensional structures and predictive modelling, and aimed at altering catalytic behavior, nonetheless has some limitations. It necessarily makes assumptions about the role of specific amino acid residues in catalysis. Sequence differences within the active sites of similar enzymes with different specificities can be used as a basis for mutagenesis, as has been done for soy LOX-1 and LOX-3, but the outcomes of this may or may not be productive; in fact, often they are not. An alternative approach is to use forced evolution, or DNA shuffling, to generate altered activities. The original technique of forced evolution, pioneered by Stemmer (152), relied on the production and shuffling of PCR generated random mutants of single sequences and effective high throughput assays to select new molecules with altered, improved activities. The most effective way of carrying out forced evolution, however, is through the shuffling of naturally existing, closely similar sequences, such as LOX from soybean or pea, rather than random mutants generated by error prone PCR, because it takes advantage of sequence space that has already evolved to produce active molecules and avoids the wasteful production of nonactive mutants associated with random mutagenesis (153). Forced evolution makes no structural assumptions and, provided that the initial DNA shuffling has provided an appropriate substrate for subsequent evolution, guarantees changes that have a productive outcome in terms of altered catalytic behavior and can give great insights into the underlying basis of activity and specificity. The products of DNA shuffling or forced evolution do not necessarily reflect the properties of the parent molecules, which merely serve as sequence variants for recombination to force the emergence of new, positively selected, variants. Analysis of these variants can then be used to guide profitable, focussed site directed mutagenesis that can further the understanding of catalytic specificity or mechanism. Forced evolution can also provide new activities that are very unlikely to result from site directed mutagenesis.

There are a number of possible targets for the forced evolution of LOXs in the context of food biotechnology. Improvement of thermal stability is helpful and would benefit industrial scale purification and processing of recombinant enzymes; some LOX are much more thermostable than others, so there is potential not only for improvement through forced evolution, but also to better understand the underlying basis of the differences. Some LOX have relatively stringent requirements for substrate; forcing the evolution of activities that have a much broader specificity, or that will efficiently catalyse the lipoxygenation of novel substrates, could open up new opportunities in the production of aromas and flavors. Those LOX that catalyse cooxidation reactions are effectively mild, biological bleaching agents that require only a small amount of PUFA to decolorize specific pigments and break down antioxidants. It would be relatively straightforward to force the evolution of LOX that are much more efficient at cooxidation, and that may have application in the

specific areas of decolorisation of food products. Such activities may also have potential in food applications that require cooxidation, such as bread making.

Although only loosely related to recombinant enzymes, the ability to modulate enzyme activity by plant genetic engineering has significant implications for food biotechnology, offering both a better understanding of the biochemistry that underlies a particular aspect and the opportunity to modify the organoleptic properties of foods. The LOX pathway plays an important role in the determination of the profile of PUFA derived volatiles (oxylipins) in fruits and vegetables (131), through the combined action of specific LOX, HPL, and alcohol dehydrogenase (ADH). To date, attempts to reduce the activity of the major tomato fruit LOX (TomloxA and -B) through antisense knockouts have not significantly altered the profile of C-6 volatiles (154), suggesting that either very low levels of LOX are sufficient for the generation of C-6 aldehydes and alcohols, or that a specific isoform such as TomloxC, in the absence of TomloxA and -B, is responsible for the production of these C-6 volatiles.

Alterations in the amounts of ADH in tomato fruits, on the other hand, have been more productive. ADH, which interconverts the LOX/HPL derived aldehydes and alcohols, has been shown to accumulate during tomato fruit ripening and is thought to play an important role in flavor development. Transgenic tomato fruits in which ADH activity had been increased or decreased showed alterations in the proportions of C-6 aldehydes and alcohols that were consistent with the changes in activity (132), albeit dependent on the method used to homogenize the fruits (155).

18.9 LIPOXYGENASES, OXYLIPIN METABOLISM, PLANT DEFENSE, AND FOOD QUALITY

There is no question that the lipoxygenase pathway plays a critical role in plant defense against pests and pathogens, including biting and sucking insects, bacteria, and fungi. Plant–insect interactions in turn can lead to virus infection. Any of these can seriously compromise food quality, through damage that diminishes product quality or even makes it unsaleable, severe reduction in yield, or reduced postharvest life. Experiments with transgenic plants in which specific components of the pathway of oxylipin metabolism have been knocked out have clearly shown a role for LOX in defense against fungal invasion (156) and damage by chewing insects (157,158), and for HPL in defense against aphids (128). In each case, reduction in enzyme activity led to increased susceptibility to the disease or pest. The corollary, in which increased expression leads to improved resistance in appropriate plant organs (and, by implication, potential improvement in food quality), has been demonstrated just once; the over expression of LOX in tobacco led to decreased susceptibility to virulent races of *Phytophthora parasitica nicotianae* (159).

The nature of the LOX pathway based defense mechanism varies from instance to instance. In the case of chewing insects, the response is through AOS, the synthesis of jasmonate and subsequent production of proteinase inhibitors (113) that interfere with insect digestive processes (157). In addition, HPL cleavage products play a dual role on wounding: the C-6 aldehydes protecting the wound site from infection and the C-12 products promoting wound healing. Divinyl ether fatty acids, from DES activity, are inhibitory to the growth of *Phytophthora infestans* and may, like the C-6 aldehydes, act as direct antimicrobial agents. All of these compounds are derived from CYP74-catalysed metabolism of fatty acid hydroperoxides, but there may be a role for the peroxides themselves in defense; the role of LOX in the incompatibility between certain cultivars of tobacco and particular races of *Phytophthora parasitica*, for instance (156), may have hydroperoxide-promoted local

cell death as its underlying basis. Fatty acid hydroperoxides have been shown to be potent inducers of plant cell death (160), and may play an important role in restricting the spread of invading pathogens as part of a hypersensitive response (161).

18.10 CONCLUSIONS

LOX are widespread throughout plants, animals, and lower organisms. They, together with the enzyme activities that metabolize their oxylipin products, play key roles in defense but also have significant implications for food biotechnology. These latter include the production of flavors and aromas, the destruction of vitamins, pigments, and other antioxidants, and improvement of dough rheology during baking. Production of LOX and other enzymes of oxylipin metabolism in recombinant forms is important to food biotechnology in several respects: it provides large amounts of homogeneous biocatalysts for industrial processes; it leads to a better understanding of the mode of enzyme action; and it enables the production of new biocatalysts through directed mutagenesis or forced evolution.

Genetic Modification of Production Traits in Farm Animals

Vernon G. Pursel

CONTENTS

19.1 INTRODUCTION

As we begin the twenty-first century, those involved in food production may find it useful to think about the future. With the world's population increasing by more than 70 million people each year, it boggles the mind to think about how all these people are going to be fed. Most certainly, if this ever increasing population is going to avoid massive waves of starvation or wars over agricultural resources, we will need to harness all the advantages that modern agricultural methods have to offer; and plant and animal biotechnology will certainly be part of that methodology.

Some people will argue that as the world population continues to increase there will be no place for animal agriculture. However, the trend over several decades indicates quite the opposite. In some western countries animal products contribute about two thirds of the total protein in the food supply and provide almost three fourths of the eight essential amino acids (1). While people in the developed countries in recent years have attempted to reduce their consumption of animal protein, quite the reverse is seen in developing countries. It is well recognized that as per capita income increases so does the consumption of animal products; the same trend occurs as urbanization increases (2). Data from around the world show that on the whole the percentage of the population that can afford to consume animal products is increasing. Thus, unless this trend is reversed, we should expect to see the demand for animal products to increase tremendously during the coming decades. The use of genetic modification will be instrumental in providing a way for the animal industry to satisfy the increased demand for animal food and fiber products.

The following sections review the progress on genetic manipulation of productivity traits in farm animals as well as some of the areas that offer promise for manipulation in the future. These areas include stimulation of growth rate; increased efficiency of animal production; development of new or improved meat, milk, and fiber products; enhanced resistance to diseases; and reducing environmental pollution. At the outset it should be noted that progress on manipulation of animal traits is far slower than originally envisioned by the early proponents of this technology. The main reasons for this slow progress are: (1) Most economically important traits are controlled by multiple genes, which are largely unknown at this time, and are, understandably, not amenable to manipulation. (2) The low efficiency of gene transfer in farm animals makes research on transgenesis quite costly, so preliminary investigations are usually conducted in mice. Unfortunately, in many cases results obtained in mice are not directly applicable to farm animals. (3) The ability to regulate expression of transgenes is still far from adequate, even in mice, and frequently the regulation of expression obtained in transgenic mice is lacking when the same transgene is used in farm animals.

19.2 INCREASING GROWTH RATE AND FEED EFFICIENCY

Much of the earlier transgenic farm animal research was conducted using growth hormone (GH) or growth hormone releasing factor (GRF) genes because these peptide hormones regulate many of the physiological processes that influence growth rate and feed efficiency. This early work was fuelled by results that indicated transgenic mice expressing excess GH grew much faster and to a larger size than control mice (3). However, for farm animals, increased size or growth rate is not nearly as important as are improved efficiency of feed utilization or an increase in the proportion of lean body mass, which are economic traits that are altered when growth hormone is elevated.

19.2.1 GH and GRF Transgenics

A number of transgenic pigs and sheep were produced with human, bovine, rat, porcine, or ovine GH under the control of several gene promoters as is shown in Table 19.1. Vise and coworkers (14) reported that one pig expressing porcine GH (pGH) grew at an exceptionally rapid rate compared to littermates (1273 vs. 781 g/day), while Ebert and coworkers (6) reported two transgenic pigs expressing pGH grew at the same rate as littermates. In a study that compared two lines of transgenic pigs expressing bovine GH (bGH) with their sibling controls, Pursel and coworkers (17) found the transgenic pigs had an 11–14% faster growth rate and an 18% increase in feed efficiency. However, reduction in carcass fat as transgenic pigs approached market weight was the most consistent and dramatic effect of elevated GH, as is shown in Figure 19.1.

Unfortunately, pigs that continuously expressed excess GH exhibited several notable health problems, which included lameness, susceptibility to stress, gastric ulcers, parakeratosis, lethargy, anestrus in gilts, and lack of a libido in boars (10,17,18). In contrast, no increase in the incidence of these pathological conditions was observed in transgenic pigs carrying nonfunctional copies of GH transgenes or in transgenic pigs that expressed only low levels of bGH (10,22).

In contrast to the GH transgenic pigs, transgenic lambs expressing high levels of ovine GH (oGH) or bGH did not grow faster or utilize feed more efficiently than control lambs, but they were much leaner (11,12). In transgenic lambs, the lack of body fat may

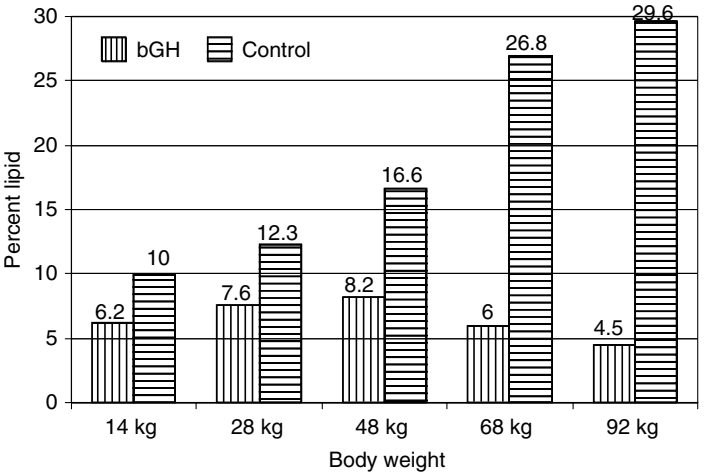

Figure 19.1 Least-squares mean total carcass lipid for four to six MT-bGH transgenic and sibling control pigs at each body weight. (From: Pursel, V.G., M.B. Solomon, *Food Rev. Int*. 9:423–439, 1993)

have been the result of hyperglycemia and glycosuria (5,11). Severely bowed front legs were a frequent anatomical abnormality observed in the transgenic lambs. More recent research with a modified oGH transgene that provided only a slight increase in circulating level of oGH resulted in lambs that grew faster and were leaner, but had significantly lower depth of eye muscle than their siblings (28).

Transfer of a GRF transgene is an alternative approach to obtain elevated GH that has been investigated in swine and sheep. Transgenic lambs that expressed GRF had continuously elevated GH and were phenotypically indistinguishable from GH transgenic lambs (11). In contrast, GH concentrations were not elevated in pigs that expressed GRF because the GRF in blood plasma was the 3–44 metabolite rather than the 1–44 native peptide (26).

It was recognized from the outset that regulation of transgene expression would be required to circumvent deleterious effects from continuous exposure of animals to elevated GH. While oGH transgenic mice expressed minimally without addition of zinc in their drinking water, the same construct produced high concentrations of constitutive expression in sheep (12) and swine (13). Similarly, expression of phosphoenolpyruvate carboxykinase-bGH (PEPCK-bGH) in mice could be regulated by altering the ratio of carbohydrate to protein in the diet (29). However, dietary manipulation did not control the level of GH expression when PEPCK-bGH was transferred into swine (27). Recently, tetracycline regulated and ecdysone regulated systems to switch transgene expression on and off in mice have been developed (30,31,32). These transgene switch systems show great promise, but are not yet perfected. When improved gene switch constructs become available there is little doubt that additional research with GH or GRF transgenes will be conducted.

19.2.2 IGF-I Transgenics

Recently transgenic pigs have been produced with a fusion gene composed of avian skeletal α-actin promoter, first intron and 3'-noncoding flanking regions, and human insulin-like growth factor-I (hIGF-I) coding region (33). Coleman and coworkers (34) previously reported that this fusion gene directs high levels of expression specifically in striated muscle in transgenic mice, and elicits myofiber hypertrophy. In the 12 founder transgenic pigs that were investigated, muscle insulin-like growth factor-I (IGF-I) concentrations

varied from 20 to 1702 ng/g muscle compared to less than 10 ng/g muscle in nontransgenic control pigs (25). In marked contrast to previous experiences with GH transgenic pigs, definitive phenotypes for the IGF-I transgenic pigs were not detected, and no gross abnormalities, pathologies, or health related problems were encountered.

The founder transgenic pigs were then mated to nontransgenic pigs to produce G1 transgenic and sibling control progeny to investigate their growth potential and carcass composition. Neither average daily gain nor feed efficiency differed for transgenic and control pigs. At 120 kg body weight, 20 transgenic and 22 control pigs were sacrificed to evaluate carcass composition. The back fat measurements were 10% lower and the loin eye areas were 18% greater in transgenic than control pigs (35).

Subsequently, one of the transgenic founder boars with a hybrid damline background was mated to 12 nontransgenic gilts from two hybrid sire lines to test more fully the potential of the IGF-I transgene to function in a crossbreeding program. Pigs were provided feed ad libitum until they reached 120 kg body weight. Average daily gain was similar for transgenic and control pigs. At 120 kg body weight 33 transgenic and 42 sibling control pigs were sacrificed and their carcass composition evaluated. Transgenic gilts and barrows had significantly more carcass lean tissue, less total carcass fat, larger loin eye areas and lower average back fat thickness than sibling control pigs (Figure 19.2). While many of the carcass characteristics differed significantly for progeny of the two sire lines, IGF-I transgene expression had a beneficial effect on progeny of both lines. Based on these results the investigators concluded that enhancing IGF-I specifically in skeletal muscle had a positive effect on carcass composition of terminal cross market swine (36).

The enhanced carcass characteristics provided by the IGF-I transgene serves as an excellent prototype for a transgene that might be economically advantageous to the swine industry. Because society in general will not embrace use of a human gene for food products destined for consumption, porcine IGF-I gene should replace the human IGF-I gene used in these studies to make the transgene acceptable for public consumption. In addition, use of a gene switch that would enable IGF-I expression to decline to endogenous levels

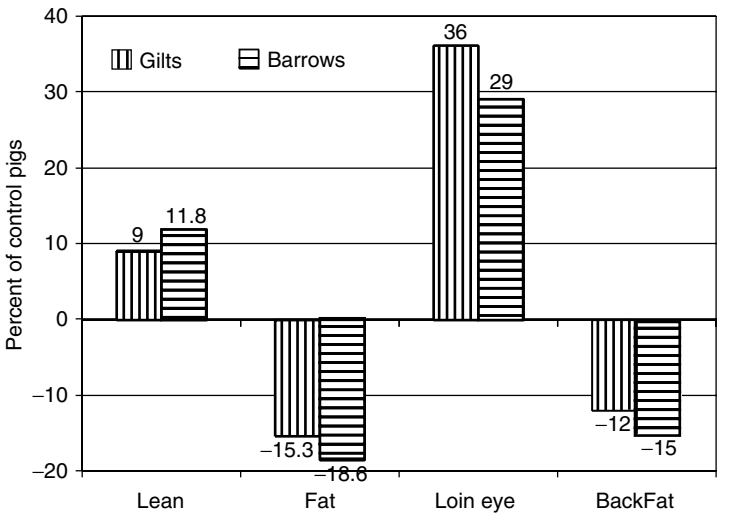

Figure 19.2 Percentage increases in carcass lean and loin eye area, and percentage decreases in carcass fat and back fat thickness for IGF-I transgenic barrows and gilts compared to sibling control barrows and gilts. (From Pursel, V.G., A.D. Mitchell, R.J. Wall, M.B. Solomon, M.E. Coleman, R.J. Schwartz, in: *Molecular Farming,* Toutant, J.P., E. Balazs eds., Paris: INRA, 2001, pp 77–86)

in striated muscle prior to harvest may be essential to overcome regulatory roadblocks that will accompany any transgenic animal that is destined for the marketplace.

19.3 MODIFICATION OF MILK COMPOSITION

Milk is widely considered one of nature's most perfect foods because of its high content of essential amino acids, essential fatty acids, vitamins, and bioavailable calcium. Because of this rich source of nutrients, dairy products provide about 20% of the protein in the diet of several western countries (37). Alteration of milk composition offers the dairy industry considerable potential for the future but has thus far received little research emphasis. A list of potential changes in milk components that have been suggested by various investigators is shown in Table 19.2.

About 80% of the protein in cow's milk is made up of the caseins (αS_1, αS_2, β and κ) while the whey fraction makes up the remainder. The caseins form the curds in cheese production, and for that reason they are extremely important for dairy manufacturing. In contrast, the whey proteins (β-lactoglobulin, α-lactalbumin, serum albumin and γ-globulin) make up only 20% of the milk proteins and represent a less valuable by product in the manufacture of cheese. Selective elimination of β-lactoglobulin, which makes up about one half of the whey,

Table 19.2
Some proposed modifications of milk constituents[1]

Change	Consequence
Increase α- and β-caseins	Enhanced curd firmness for cheese-making, improved thermal stability, and increased calcium content
Increase phosphorylation sites in caseins	Increased calcium content, improved emulsification
Introduce proteolytic sites in caseins	Increased rate of textural development to improve cheese ripening
Increase κ-casein concentration	Enhanced stability of casein aggregates, decreased micelle size, decreased gelation and coagulation
Eliminate β-lactoglobulin	Decreased high temperature gelation, improved digestibility, decreased allergenic response, decreased primary source of cysteine in milk
Decrease α-lactalbumin	Decreased lactose, increase market potential of fluid milk, decreased ice crystal formation, compromise osmotic regulation of mammary gland
Add human lactoferrin	Enhanced iron absorption, protect against gut infections
Add human lysozyme	Increase antimicrobial activity, reduce rennet clotting time, and increase cheese yield
Add proteolytic sites to κ-casein	Increased rate of cheese ripening
Decrease expression of acetyl CoA carboxylase	Decreased fat content, improved nutritional quality, reduce milk production costs
Express immunoglobulin genes	Protection against pathogens such as salmonella and listeria
Replace bovine milk proteins genes with human equivalents	Mimic human breast milk

[1]Adapted from Jimenez-Flores, R., T. Richardson, *J. Dairy Sci.* 71:2640–2654, 1985; H.-C. Yom, R.D. Bremel, *Am. J. Clin. Nutr.* 58:299–306, 1993; Maga, E.A., J.D. Murray, *Bio/Technology* 13:1452–1457, 1995.

would be beneficial to cheese production, because its presence in milk inhibits rennin's action on κ–casein (39). Because β-lactoglobulin is responsible for some of the allergic reactions to cow's milk, its elimination from fluid milk would also be advantageous for some consumers. Removal of β-lactoglobulin from cattle would require use of knockout technology that is now technically feasible by transfection of fetal fibroblasts *in vitro* (41,42,43).

19.3.1 Caseins

Because caseins are extremely important to the manufacture of cheese, modification of the relative amount or composition of the caseins may offer considerable economic value. One meritorious manipulation that has been suggested is to introduce extra copies of the αS_1-casein gene in cows to increase its proportion in milk. Jimenez-Flores and Richardson (38) suggest that such an alteration would enlarge the micelles and enhance textural development and curd characteristics. Alternatively, introduction of a chymosin sensitive region in the αS_1-casein gene by site specific mutagenesis may accelerate the rate of textural development (38).

Increasing the ratio of κ-casein to β-lactoglobulin might also be accomplished by inserting additional copies of the κ-casein gene. Such an alteration may be effective in reducing the size of casein micelles and improving the thermal stability of proteins in canned, sterilized milk products.

In addition, Jimenez-Flores and Richardson (38) suggest deletion of a phosphate group from β-casein would yield a softer cheese with higher moisture content, while addition of a phosphate group would yield a firmer cheese with less moisture and provide improved emulsifying properties. Each change would result in milk with characteristics that would be advantageous for specific market products.

19.3.2 Reduction in Butterfat

Nutrition conscious and diet conscious consumers are increasingly shunning products that have high fat levels. As a result of this declining demand, either surplus butterfat accumulates or the price declines sufficiently to stimulate consumption. Reduced butterfat production would provide a solution to this problem. Traditional genetic selection is not a suitable means of reducing fat content in milk because the genetic and phenotypic correlations for fat and protein yields are estimated at .86 and .93, respectively (44). Bremel, Yom and Bleck (45) suggest *de novo* fat synthesis from acetate might be reduced by blocking acetyl CoA carboxylase gene expression. The potential of this concept has been tested by transfecting preadipocytes with a ribozyme gene directed against acetyl CoA carboxylase mRNA (46). The rate of fatty acid synthesis in transfected cells was 30 to 70% that of the control adipocytes. If transfer of this ribozyme gene had a similar effect on butterfat production in the mammary gland, there would be the potential for a dramatic influence on the fat content of milk. Because a gram of fat has 2.25 times the amount of energy as a gram of carbohydrate or protein, reduction in the fat output in milk would greatly reduce the energy required to produce milk. Yom and Bremel (39) have suggested that reducing the fat content of milk from 3.8% to 2% would permit dairy farmers to increase the proportion of forage in the diet from about 60% to 83%. Consequently, the concentrate portion of the lactation ration would be reduced by 50%, and the farmers' feed bill for lactating cows would be reduced by 22%.

19.3.3 Lactose

Lactose is a major component of cow's milk that makes it an unacceptable food source for a sizable portion of the adult human population deficient in β-galactosidase and therefore unable to hydrolyze lactose (47). In addition, the low solubility of lactose is responsible

for grittiness defects in ice cream. These problems might be alleviated by the partial inhibition of the α-lactalbumin gene, which is an essential cofactor in the synthesis of lactose. Because lactose is responsible for the movement of water through the secretory cells, a reduction in α-lactalbumin and lactose would partially reduce total milk volume, with no reduction in overall production of milk protein. Such an inhibition of lactalbumin expression might be accomplished by transfer of an antisense sequence of the α-lactalbumin gene ligated to a mammary specific promoter (39).

Conversely, Bleck and coworkers (48) have suggested that enhanced expression of α-lactalbumin in sow's milk may increase milk production and boost preweaning growth rates in piglets. An increase in α-lactalbumin should elevate the lactose synthase activity in the mammary gland and stimulate lactose content in sow milk. An increase in lactose content early in lactation might provide a valuable energy source for the newborn piglet. In addition, the increased lactose content should increase the total quantity of milk produced. Transgenic pigs overexpressing the milk protein bovine α-lactalbumin were subsequently developed at the University of Illinois. First parity α-lactalbumin gilts had higher milk lactose content in early lactation and 20–50% greater milk yield on days 3–9 of lactation than did nontransgenic gilts. Weight gain of piglets suckling α-lactalbumin gilts was greater (days 7–21 after parturition) than that of control piglets. Thus, transgenic overexpression of milk proteins provides a means for improving the lactation performance of pigs (49).

19.3.4 Human Milk Proteins

The introduction of several human milk protein genes into dairy cows, or replacement of these bovine genes with human genes, may one day play an important nutritional role in human infants that are now unable to receive milk from their mother. Milk from cows and humans differs considerably, and consequently cow's milk is not an ideal source of food for human infants. Total protein content of human milk is low (0.9%) and whey proteins predominate, while cow's milk contains about 3.3% protein with 80% of it being casein (50). In addition, bovine β-lactalbumin is quite allergenic to many human infants, and the concentration of lactoferrin in human milk is three times that of cow's milk.

Lactoferrin has long been known to provide antimicrobial activity to the human infant and may be an important source of bioavailable iron and other minerals (47). More recently, human lactoferrin has been reported to also have antifungal, antiendotoxin, and antiviral properties (51,52,53).

Therefore, enhancing the concentration of lactoferrin in cow's milk, or expression of human lactoferrin in cow's milk, may result in a milk product that is highly suitable for production of lactoferrin for the biopharmaceutical industry. Recently van Berkel and coworkers (54) reported the production of four lines of transgenic cattle that produce between 0.4 and 3.0 g of human lactoferrin per liter of milk. The iron binding and antibacterial activities of the lactoferrin protein were shown to be highly similar to that of natural human lactoferrin.

Human milk contains about 3,000 times as much lysozyme as is present in cow's milk. Although the biological function of lysozyme in human milk is not known, its antimicrobial activity is considered to be part of the natural defense against food microorganisms, and it may protect the mammary gland against bacterial infection (40). In addition, other research has showed that addition of lysozyme to cow's milk was beneficial for rennet clotting time, yield, and syneresis in cheese processing (55). Therefore, enhanced expression of lysozyme in milk may be beneficial for infant formulations and cheese production.

The antimicrobial properties of standard human lysozyme and the milk of transgenic mice expressing human lysozyme were investigated using bacterial strains important to the dairy industry (56). Milk from transgenic mice that secreted human lysozyme in

their milk at an average concentration of 0.3 mg/mL was found to be bacteriostatic against *Pseudomonas fragi* and *Lactobacillus viscous*, which are cold spoilage organisms, and a mastitis causing strain of *Staphylococcus aureus*, but not against a pathogenic strain of *E. coli*. These results suggest that transgenic animals that produce human lysozyme in their milk may enhance the antimicrobial nature of milk.

19.4 IMPROVED WOOL PRODUCTION

Australia and New Zealand have large expanses of grazing lands that are used to convert forage to wool, which is a high quality textile fiber that is a valuable exportable commodity. The importance of wool to the economies of these countries has led investigators to attempt to improve the efficiency of wool production and enhance its characteristics as a textile fiber. Thus far three research approaches have been undertaken to improve wool production.

19.4.1 Synthesis of Cysteine

Production of high quality wool is dependent upon an abundant supply of amino acids in general and cysteine in particular. Keratins are the major structural proteins of the wool fiber, and a large amount of cysteine is required to form the extensive disulphide bridges that link the keratins as the fibers grow. Cysteine is the rate limiting amino acid for the production of wool. Addition of cysteine to the diet does not increase wool production because the rumen degrades proteins, and sulphur is lost as hydrogen sulphide. Bacterial genes are capable of synthesizing cysteine from the hydrogen sulphide and serine, both of which are available in the rumen. This limitation for wool production has led Australian investigators to attempt a genetic engineering approach to overcome this obstacle.

Serine transacetylase (*cys E*) and o-acetylserine sulfhydrylase (*cys M or K*) are required for the synthesis of cysteine from rumen substrates, hydrogen sulphide, and serine. Bacterial genes for these enzymes have been isolated, sequenced, and cloned for *Escherichia coli* (57) and *Salmonella typhimurium* (58). These linked bacterial genes (*cys E-cys M or K*) were used to form transgenes with three gene promoters that give broad expression, sheep metallothionein-Ia (oMT), Rous sarcoma virus long terminal repeat (RSVLTR) and mouse phosphoglycerate kinase-1(mPgk-1).

The *cys E-cys M or K* transgenes with oMT, RSVLTR and mPgk-1 promoters were first tested *in vitro* in tissue culture cells, and then in transgenic mice. While these transgenes expressed well in cultured mammalian cells (59), only the transgenic mice with the oMT promoter or the mPgk promoter expressed sufficient enzyme levels in stomach and intestines to support significant cysteine synthesis *in vitro* (60). Concurrently, these fusion genes were transferred into sheep zygotes and the resulting transgenic lambs were evaluated for expression of the enzyme genes (60,61). These three promoters were ineffective in directing expression of the bacterial enzymes in the rumen of the transgenic sheep. However, low levels of expression were detected in skeletal muscle of three of 23 RSVLTR lambs and one of 10 mPgk-1 lambs (60).

Subsequently, Rogers and coworkers (61) isolated a rumen specific gene from a sheep rumen cDNA library. This gene encodes a small proline rich protein (oSPR) that is highly expressed specifically in the ruminal epithelium. The *cys E-cys M or K* transgene with oSPR promoter was then transferred into sheep zygotes. Of seven transgenic sheep evaluated, only one expressed the transgene in the rumen at a low level at three months of age, and it lacked expression when reevaluated at six months of age.

19.4.2 Wool Keratin Proteins

The second approach to improved wool production that has been undertaken is to modify the protein composition of the wool fibers. The genes for many of the keratin proteins have been sequenced (61,62). Transgenic mice have been produced with three different wool keratin fusion genes expressed in the hair follicles. Two of these transgenes have produced visible phenotypic changes in the hair coat (63,64).

Subsequently, researchers at the University of Adelaide and the South Australian Research and Development Institute have produced a number of transgenic sheep in attempts to improve wool fiber quality by altering expression of wool fiber keratin and keratin associated protein genes in the wool follicle cortex (65). These investigations found: (1) Increasing the quantities of cysteine rich protein in the cortical karatin associated protein pool reduced the intrinsic strength of the wool fibers in transgenic sheep. (2) Expression of the human keratinocyte transglutaminase enzyme within the cortex increased isopeptide cross linkage but also weakened the fiber. (3) Enhanced expression of a glycine or tyrosine rich protein in the cortex also appeared to reduce the load bearing capacity of wool fibers. (4) The most promising results have been obtained with overexpression of a wool keratin intermediate filament gene in wool follicles. Using this approach, Bawden and coworkers (66) demonstrated that a high level of cortical specific expression of a wool type II intermediate filament keratin gene, K2.10, lead to marked alterations in both the microstructure and macrostructure of the wool fibers that yielded a higher luster and reduced crimp. Up to the present time only the sheep expressing the highest levels of the various transgenes have been evaluated. Transgenic sheep expressing low to moderate levels of these transgenes have been produced, but have not yet been fully evaluated (65).

19.4.3 IGF-I for Wool Follicle Growth

The third approach to improve wool production is to stimulate fiber growth by expression of insulin-like growth factor (IGF-I) in wool follicles. Several investigators reported that exogenous treatment of sheep with growth hormone stimulated wool growth (67,68,69). Subsequently, Harris and coworkers (70) reported that local infusion of sheep skin with IGF-I increased blood flow, oxygen uptake, and amino acid uptake. Because IGF-I mediates many of the actions of growth hormone and has mitogenic properties, study of its potential as a stimulator of follicle growth in transgenic sheep was undertaken in New Zealand.

Damak and coworkers (71) reported the production of transgenic sheep with a transgene composed of a mouse keratin promoter and ovine IGF-I cDNA. Two of five founder transgenic lambs expressed the IGF-I in their skin. The expressing transgenic ram was then bred to nontransgenic ewes, and 85 lambs were born of which 43 were transgenic. When shorn at 14 months of age, the clean fleece weight of the transgenic animals was 6.2% higher ($P = .028$) and the bulk was significantly higher ($P= .042$) than for the nontransgenic half sibs. Other fiber characteristics were unchanged, except that staple strength was lower for transgenic males than transgenic and nontransgenic females. Expression of the transgene did not have detectable negative physiological effect on these animals. Unfortunately, additional investigations with the second generation of transgenic animals failed to confirm the wool production enhancement that had been found in the first generation (72).

19.5 ENHANCED ANIMAL HEALTH

Economic losses from diseases of farm animals have been estimated to amount to 10 to 20% of the total production costs (73). Molecular biology and genetic manipulation may be useful in augmenting conventional breeding techniques to provide animals with

improved resistance to some of these diseases, thereby reducing these costs and enhancing animal welfare. Several approaches under investigation include transfer of genes for providing naturally occurring disease resistance, preformed antibodies, viral envelope proteins, and antimicrobial peptides.

19.5.1 Naturally Occurring Disease Resistance

Only a few genes for disease resistance have thus far been identified (74). Mice carrying the autosomal dominant Mx1 allele are resistant to influenza viruses. Transfer of the Mx1 gene into mice that lacked the Mx1 allele was successful in conferring resistance to influenza-A viruses (75,76). Subsequently, three Mx1 fusion genes were transferred into swine to test their effectiveness (77). Two of five transgenic pigs harboring the Mx1 regulatory and structural sequences were found to respond to interferon induction of Mx1 mRNA. However, the response was insufficient to produce detectable amounts of Mx1 protein in the tissues. The other two fusion genes that were transferred into pigs were rearranged during integration, so they were not functional. In retrospect the investigators believe uncontrolled expression of Mx1 during embryogenesis was lethal, thus only animals with low levels of transgene expression of rearranged genes were produced (74). Once again the necessity of tight transgene regulation was crucial to the outcome, and results were not consistent for mice and pigs.

19.5.2 Preformed Antibodies

Genes encoding mouse α heavy and κ light chains from antibodies against phosphoryl choline (PC) were coinjected into ova to produce two transgenic pigs and three transgenic lambs (78). In the transgenic pigs, the mouse immunoglobulin A (IgA) was detected in the serum despite the failure of an intact mouse transgene to integrate. Transgenic progeny from both founders demonstrated high levels of serum mouse IgA starting at about five weeks of age. Average levels of mouse IgA were 630 μg/mL in one line and 1,293 μg/mL in the other. In both cases, IgA levels in progeny were higher than in the founders. However, mouse IgA showed little binding specificity for PC, presumably because secreted chimeric antibody included endogenous light chains with mouse heavy chains. In transgenic sheep, mouse IgA was detectable in peripheral lymphocytes but not in serum. These studies need to be expanded to obtain conclusive proof that the IgA transgene would be protective against pathogenic bacteria.

In a similar study, Brem and coworkers (79) produced two transgenic pigs and three transgenic rabbits that harbored mouse λ heavy and κ light chain transgenes from antibodies directed against the hapten 4-hydroxy-3-nitrophenylacetate. Titres of 100 to 300 μg IgG/mL in transgenic rabbits and up to 1,000 μg IgG/mL in one transgenic pig were present in the serum of founders and transgenic progeny. Further evaluation of the antibody composition indicated xenogenic antibodies had formed by association of light chains of rabbit and pig with heavy chains of mouse.

Most recently, Enjuanes and coworkers (80) generated 18 lines of transgenic mice secreting a recombinant monoclonal antibody (Mab) neutralizing transmissible gastroenteritis coronavirus (TGEV) into their milk. The genes encoding a chimeric Mab with the variable modules of the murine TGEV-specific Mab 6A.C3 and the constant modules of a human IgG, isotype Mab were expressed under the control of regulatory sequences derived from whey acidic protein (WAP), which is an abundant milk protein in mice. Antibody expression titers of 10^6 were obtained in the milk of transgenic mice that reduced TGEV infectivity by a factor of 10^6. The antibody was synthesized at high levels throughout lactation. These results suggest that generation of transgenic swine producing virus neutralizing antibodies in milk could provide an effective approach for protection against neonatal infections of the enteric tract.

19.5.3 Intracellular Immunization

A transgenic approach may be effective for producing farm animals that are genetically resistant to specific pathogenic viruses. Salter and Crittenden (81) produced transgenic chickens that were highly resistant to infection with the subgroup A avian leukosis virus (ALV) by introducing an ALV gene that encoded a viral envelope glycoprotein. Normally, ALV enters chicken cells by attachment of the envelope glycoprotein to cell membrane receptors. However, in the transgenic chickens the subgroup A ALV virus could not enter the cells because the membrane receptors were presumably occupied with envelope protein that had been produced by the transgene. These chickens were not resistant to infection by subgroup B ALV because a different receptor is used for entry.

A similar experiment was initiated in sheep with the envelope gene from visna virus. The sheep population is widely infected with visna virus, which is an ovine lentivirus similar to equine infectious anaemia virus, caprine arthritis encephalitis virus, and bovine, feline, simian, and human immunodeficiency virus. Visna viruses are usually transmitted to lambs in colostrum or milk, where they infect the macrophages or monocytes, and establish lifelong infections. The clinical disease in sheep is ovine progressive pneumonia, arthritis, mastitis, and occasionally paralysis (82). Immunizations with vaccines have not been effective in control of visna virus or other lentiviruses.

Three transgenic sheep were produced by microinjection of a visna virus fusion gene into pronuclei of sheep zygotes (83). The fusion gene was composed of a visna virus long term repeat (LTR) regulatory region fused to the coding region for visna virus envelope protein. All three lambs expressed the envelope glycoprotein in the macrophages as well as in fibroblasts isolated from the skin. These animals remained healthy and expression of the viral gene had no observable detrimental effect. Two of the three sheep produced antibodies to the envelope protein, which possibly indicated the viral gene was expressed relatively late in development and was not recognized as a self antigen. Transgenic progeny from these founders were subsequently challenged with an Icelandic strain of visna virus to test their abilities to resist infection. This challenge resulted in several of the transgenic lambs becoming infected with the virus in the same manner as the control sheep that were also challenged (C. E. Rexroad, Jr., personal communication, 1998). These results do not rule out the possibility that these transgenic sheep would have been resistant to infection if they had been challenged by natural exposure to visna virus under field conditions.

19.5.4 Anti Bacterial Peptides

As a first step toward enhancing mastitis resistance of dairy animals, researchers at the University of Vermont and the Beltsville Agricultural Research Center in Maryland generated transgenic mice that secrete a potent antistaphylococcal protein, lysostaphin, into milk (84). Lysostaphin is a peptidoglycan hydrolase normally produced by *Staphylococcus simulans* that is active against *Staphylococcus aureus* bacteria. *Staphylococcus aureus* is the major contagious mastitis pathogen, accounting for more than 15% of mastitis infections, and has proved difficult to control using standard management practices. Three lines of transgenic mice were produced with an ovine β-lactoglobulin gene directing the secretion of lysostaphin into milk. Progeny of these mice exhibited substantial resistance to an intramammary challenge of *S. aureus*, with the highest expressing line being completely resistant to infection. These results clearly demonstrated the potential of genetic engineering to combat the one of the most prevalent disease of dairy cattle, and as a consequence, the same transgene has now been used to produce transgenic dairy cattle that have not yet been fully evaluated.

19.6 REDUCING ENVIRONMENTAL POLLUTION

Researchers at the University of Guelph initially developed a transgenic mouse model to determine whether endogenous expression of phytase transgenes in the digestive tract of monogastric animals could increase the bioavailability of phytate, a major indigestible form of dietary phosphorus. Forsberg and coworkers (85) constructed a phytase transgene to provide expression in salivary glands and found that expression of salivary phytase in transgenic mice reduced fecal phosphorus by 11%. These results suggested that the introduction of salivary phytase transgenes into monogastric farm animals might offer a promising biological approach for relieving the requirement for dietary phosphate supplements and for reducing phosphorus pollution from animal agriculture.

Subsequently, these researchers used the phytase transgene to generate phytase transgenic pigs (86). The saliva of these pigs contained the enzyme phytase that allowed the pigs to digest the phosphorus in phytate, which is the most abundant source of phosphorus in the pig diet. Without this enzyme, phytate phosphorus passes undigested into manure to become the single most important manure pollutant of pork production. Their research showed that salivary phytase provided essentially complete digestion of dietary phytate phosphorus, relieved the requirement for inorganic phosphate supplements, and reduced fecal phosphorus output by up to 75%. These pigs offer a unique biological approach to the management of phosphorus nutrition and to reducing one of the major environmental pollutants generated on swine farms.

19.7 CONCLUSIONS

From the foregoing material it is clear that animal scientists are gradually making inroads toward harnessing the power of transgenic technology to improve economically important productivity traits of farm animals. In the past few years research on altering carcass composition, enhancing disease resistance, increasing milk production in sows, and reducing excretion of phosphate in pigs have shown the greatest progress. Modification of productivity traits in dairy cattle offers considerable potential, but much of this research awaits improved efficiencies of producing transgenic cattle through the use of nuclear transfer. For many productivity traits, further progress seems highly dependent on finding more effective regulatory systems that permit precise control of transgene expression. As people search for solutions to these problems, they will make unexpected discoveries, find new approaches, and expand fundamental knowledge. Then, at some time in the future, as superior plant and animal products resulting from genetic engineering become available, such items will be more appropriately called “Fantastic Foods” instead of “Frankenfoods”.

Enzyme Technology for the Dairy Industry

Kieran Kilcawley

CONTENTS

20.1 INTRODUCTION

The application of enzymes in dairy technology is well established and the use of enzymes to coagulate milk in cheese making is probably the earliest use of enzyme technology in the food industry (1). In comparison to other industries, the use of exogenous enzymes in the dairy industry is limited to a few major and some minor applications. However, enzymes have a role in many dairy applications as they are inherently present in milk or are incorporated through the addition of, or advantageous growth of, microorganisms. This chapter is a summary of the role enzymes play in the dairy industry, with emphasis on indigenous and exogenous enzymes.

Enzyme technology in the dairy industry can be divided into two main areas: indigenous enzymes in milk and their impact on dairy products, and the use of exogenous enzymes in the manufacture of dairy products.

20.2 INDIGENOUS ENZYMES OF BOVINE MILK

Bovine milk consists of mainly of water, protein, fat, lactose, salts, and microorganisms (the extent of which depend upon its quality). These microorganisms are a potential enzymatic source that can have positive or negative impacts in dairy applications. Most microorganisms do not survive pasteurization and therefore their potential is limited to products produced mainly from raw milk. The microflora of raw cold stored milk is dominated by Gram-negative, nonlactose fermenting psychrotrophic bacteria, with more than 70% of milk microflora consisting of *Pseudomonas* species. Only after prolonged storage or poor hygienic handling will bacterial enzymes exert an effect on the quality of pasteurized milk. The composition of the microflora of pasteurized cold stored milk is less predictable than that of cold raw milk. The microflora of pasteurized cold stored milk contains psychrotrophic thermoduric bacteria from the raw milk and from post pasteurization contamination, as well as psychrotrophic nonthermoduric post pasteurization bacteria (2).

Numerous indigenous enzymes are present in raw milk; approximately sixty have been reported to date. Indigenous milk enzymes arise mainly from three potential sources; blood, secretary cell cytoplasm, and the milk fat globule membrane. Most indigenous enzymes are inactive in milk due to inappropriate environmental conditions or lack of suitable substrates

on which to act, and therefore do not present a major concern in milk itself; however, depending upon the application of the milk, these enzymes can exert an effect. Most indigenous milk enzymes and sources of enzymes, such as microorganisms, are destroyed by pasteurization to create a standardized product (3).

This section deals with those indigenous enzymes that can be exploited to aid certain dairy applications, or those that could have a major negative impact in dairy applications if not controlled.

20.2.1 Lipases

Tainting of milk can be a serious problem for its market acceptability. A main source of taints is hydrolytic rancidity. Lipolysis in milk has been widely studied and is due to the hydrolytic degradation of milk triacylglycerols or triglycerides, or mono- and diglycerides producing free fatty acids (FFAs). Due to their high volatility and low flavor thresholds, FFAs can impart specific flavors at low concentrations, Therefore, in certain instances, low levels of lipolysis can have a marked impact on flavor (4). In general the lower chain FFAs ($C_4 - C_8$) impart rancid flavors, while longer chain FFAs impart soapy flavors. The terms lipase and esterase are widely used to describe enzymes which degrade fat, and it is generally accepted that these enzymes are identical apart from the nature of their catalytic site which governs their selectivity (5). In summarizing esterase and lipase activities it is assumed that esterases act on soluble fat substrates with ester linkages of fatty acids of less than 8 carbon atoms, while lipases release fatty acids with ester linkages of more than ten carbon atoms in emulsified systems. The term lipase is used to represent both lipases and esterases in this chapter.

Milk has been described as an oil-in-water emulsion, where the fat globules are evenly dispersed in the serum phase. The fat globules are surrounded by a thin membrane called the milk fat globule membrane (MFGM), and it is this membrane which acts as a barrier between the lipolytic enzymes and the fat (Figure 20.1). The MFGM can be damaged by agitation, homogenization, foaming, or poor handling, which can result in the rapid interaction of enzyme and substrate, causing the development of off flavors (4).

20.2.1.1 Lipoprotein Lipase

The source of lipase or esterase activity in milk is mainly a milk lipase known as lipoprotein lipase (LPL) (EC 3.1.1.3). Indigenous LPL is present in milk via leakage through the

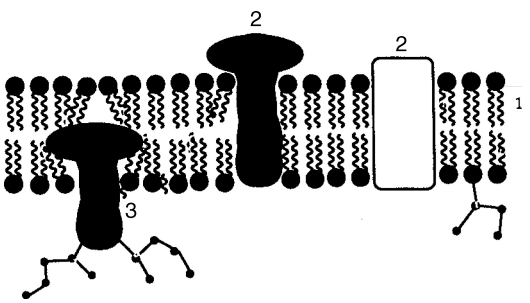

Figure 20.1 Schematic representation of a trilaminar cell membrance which is from the apical membrance of the mammary cell and forms the outer layer of the milk fat globule membrane following expression from the mammary cell, but which is more or less extensively lost on ageing.
1. Phospholipid/glycolipid
2. Protein
3. Glycoprotein

mammary cell membrane from the blood where it is involved in the metabolism of plasma triglycerols (6). LPL is activated by an apolipoprotein activator, apo-CII, and is present in high enough concentrations in milk to be of real danger in terms of its spoilage capability. LPL is mainly associated with casein and therefore is compartmentalized away from the fat by the MFGM. LPL has been shown to have 1, 3 regio-selectivity with little or no acyl specificity (7). LPL is susceptible to standard high temperature short time (HTST) pasteurization; however it is thought that it is not completely inactivated and may be active in some milk products (8). The fact that most LPL is inactivated by pasteurization is demonstrated by the fact that routine homogenization of milk immediately after or prior to pasteurization disrupts the MFGM and does not cause hydrolytic rancidity. The levels of LPL in milk are subject to variations, and are dependent upon levels in the blood serum in milk. It is thought that these levels vary in relation to the stage of lactation of the cow. For a more detailed description of LPL, see Olivecrona & Bengtsson-Olivecrona (1991) (6).

20.2.1.2 Bacterial Lipases

Extracellular lipases produced by psychrotrophic bacteria have the potential to cause hydrolytic rancidity in milk and milk products as these dominate in typical cold bulk milk storage conditions. Lipases of psychrotrophic bacteria have varying heat stability and some can survive pasteurization, however lipolytic spoilage rarely occurs in pasteurized milk (4). Studies have shown that lipases from psychrotrophs which survived pasteurization affected cheese quality if counts were reported to be greater than 10^6 cfu ml^{-1} in the raw milk (9).

20.2.1.3 Phospholipases

Phospholipase activity has been identified in milk LPL and in several bacteria. Phospholipases are potentially very important in milk as they degrade the phospholipids of the MFGM, thereby making the fat susceptible to hydrolysis. These enzymes are also quite heat stable and are not destroyed by pasteurization (4).

20.2.2 Proteinases

A few indigenous milk proteinases have been identified in bovine milk, but only two appear to be of importance in the dairy industry.

20.2.2.1 Plasmin or Milk Alkaline Proteinase

Plasmin (EC 3.4.21.7) is an alkaline serine proteinase and is secreted as plasminogen that is activated in blood and milk. Its role in blood is to break down blood clots and is a part of a complex system consisting of activators and inhibitors. In milk, there is about four times as much plasminogen as plasmin, and both, as well as plasminogen activators, are associated with the casein micelles. The inhibitors of plasmin and plasminogen activators are present in the milk serum. The concentration of plasmin and plasminogen in milk increases with advancing lactation, mastitic infection, and number of lactations (3).

Plasmin has a high specificity for peptide bonds with a carboxyl group supplied by lysine or arginine. It has an optimum activity at pH 7.5 and 35°C, and still exhibits about 20% activity at 5°C. It is active over a wide pH range from pH 4 to 9 and is quite heat stable. Its activity in milk increases after HTST pasteurization, probably due to inactivation of its inhibitors, and partly survives ultra high temperature (UHT) sterilization. Plasmin is associated with casein micelles in milk and degrades β-, α_{s1}-, and α_{s2}-caseins to γ-caseins, proteose–peptones, and possibly λ-caseins (3).

Plasmin can have a positive or negative effect on cheese making as it is involved in proteolysis during ripening, and is also linked to poor curd formation in cheese made from late lactation milks (8). Plasmin is also associated with the generation of "gluey" and "bitter" off flavors during storage of UHT milks and is a major factor affecting their shelf life (10). Plasmin aids in the initial hydrolysis of the major milk caseins, and recent studies suggest that the addition of urokinase to cheesemilk can accelerate cheese ripening by the activation of plasminogen to plasmin in the cheese (11).

For a more detailed review of plasmin activity in milk and dairy products see Fox and Stepaniak (1993); Fox (1992) and BastianBrown (1996) (8,12,13).

20.2.2.2 Cathepsin D or Acid Milk Proteinase

Cathepsin D (EC 3.4.23.5) is a lysozomal enzyme that has a similar specificity to chymosin, but has very poor milk clotting activity. It is relatively heat labile as it is inactivated by 70°C for 10 min, and may contribute to proteolysis in cheese, but not significantly (14).

20.2.3 Phosphatases

Milk contains a number of phosphatases, two of which are of technological significance.

20.2.3.1 Alkaline Phosphomonoesterase (Phosphatase)

Alkaline phosphatase (EC 3.1.3.1) occurs in the milks of all mammals, although the levels present may vary considerably. This enzyme is of technological importance to the dairy industry as the test for its presence in pasteurized milk is universally used as an index of the efficiency of HTST pasteurization. This is because alkaline phosphatase is always present in raw milk at easily measurable levels and its heat stability profile closely follows that required for adequate pasteurization (15). Alkaline phosphatase is concentrated in the fat globule membrane and has an optimum activity in the alkaline pH range of pH 9–10.5 at 37°C, and will hydrolyze most phosphate ester bonds, releasing inorganic phosphate including adenosine monophosphate, glycerophosphate, phosphates of glucose, serine, threonine, and phosphoproteins. The enzyme can be reactivated, particularly in the presence of magnesium and zinc ions, and this is of practical significance, because regulatory tests for pasteurization assume the absence of phosphatase activity. Generally bulk HTST milk does not show reactivation of phosphatase activity, however it is often observed in UHT treated milk. This problem is usually overcome by HTST pasteurization after UHT treatment. Overall alkaline phosphatase activity does not have a direct significance in milk or milk products (2).

20.2.3.2 Acid Phosphomonoesterase (Phosphatase)

Acid phosphatase (EC 3.1.3.2) is present in milk at approximately 2% of the level of alkaline phosphatase, but is quite heat stable, as 30 min of heating at 88°C is required for complete inactivation. The enzyme is a glycoprotein and has a lower optimum pH than that of alkaline phosphatase (pH 5). Acid phosphatase hydrolyses aromatic phosphomonoesters. Acid phosphatase has broad substrate specificity, and has a very different substrate specificity compared to milk alkaline phosphatase. The enzyme is active against caseins, although the major caseins act as competitive inhibitors, probably due to binding of the enzyme to the casein phosphate groups. Therefore, the effectiveness of the caseins as inhibitors is related to their phosphate content. The presence of this enzyme in milk and dairy products may be of significant importance as it affects casein micelle formation through dephosphorylation of casein, which destroys interchain bridging via phosphate

groups between casein polypeptides and calcium ions. Because many of the technologically important properties of milk depend upon the presence of casein micelles and the maintenance of their integrity, the significance of acid phosphatase in the gelling of UHT milk, coagulation of milk by chymosin, curd structure, and cheese ripening have all been investigated (15). Overall, acid phosphatase has the potential to affect the quality of dairy products, but its effect has not been fully elucidated. Some dephosphorylated peptides have been found in certain cheese varieties, but they may be the result of action by phosphatases produced by bacteria. It may be that the low activity and ease of inhibition of acid phosphatase may impinge on its overall effect (3).

20.2.4 Lactoperoxidase

Peroxidases (EC 1.11.1.7) are present in high quantities in bovine milk and have been shown to be involved in antibacterial activity. Lactoperoxidase requires hydrogen peroxide (H_2O_2) and thiocyanate to cause bacterial inhibition by forming hypothiocyanite and other unidentified antibacterial agents. The mode of action of this system is well understood and has been used to cold pasteurize milk in situations where refrigeration or thermal pasteurization is unavailable. Lactoperoxidase is added to milk replacers for calves or piglets to reduce the incidence of enteritis. Lactoperoxidase inhibits starter cultures, which accumulate H_2O_2 through their oxygen metabolism, but has also been shown to stimulate some strains of Lactococci. Lactoperoxidase can cause nonenzymatic oxidation of unsaturated fatty acids (3,16).

20.2.5 Lysozymes

Milk contains an indigenous lysozyme, also know as muramidase (EC 3.2.1.17), which causes lysis of certain bacteria by hydrolyzing cell wall polysaccharides. Lysozyme hydrolyses the β(1-4)-linkage between muramic acid and N-acetylglucosamine of mucopolysaccharides of the bacterial cell wall, thereby causing cell lysis. Lysozyme is fairly heat stable in acid conditions, but heat labile at pH 7 or above. Lysozyme is effectively an antibacterial agent and is also used exogenously in cheese making. As levels of indigenous milk lysozyme are so low, it is thought not to have a significant effect on the shelf life of milk (3).

20.2.6 Xanthine Oxidase

Xanthine oxidase (EC 1.2.3.2) is a broad specificity oxido-reductase, concentrated in the MFGM where it is one of the principal proteins. Milk processing treatments can affect its activity, when it is transferred from the fat phase to the aqueous phase. All of the major milk proteins can act as either activators or inhibitors of xanthine oxidase, depending on their concentration, and may have some significance in the activation, inactivation, and reactivation of the enzyme. The pH optimum is about 8.5 and the enzyme requires flavin, adenine, dinucleotide, and other cofactors to work. The presence of xanthine oxidase in milk is associated with oxidative rancidity, as it can excite stable oxygen to from a prooxidant (3). Xanthine oxidase has also been implicated as having bacteriostatic properties, as it is thought to be secondarily involved in generating H_2O_2 for the lactoperoxidase system (17).

20.2.7 γ-Glutamyl Transpeptidase (Transferase)

γ-Glutamyl transpeptidase (EC 2.3.2.2) catalyses the transfer of γ-glutamyl residues from γ-glutamyl-containing peptides. It plays an important role in amino acid transport in the mammary gland. It may have a role in cheese making as γ-glutamyl peptides have been isolated from cheeses which have arisen through the activity of this enzyme (3).

20.2.8 Other Enzymes

A number of other enzymes have been identified in milk, but do not directly influence milk or milk products. For further information see Farkye (1991) (17).

20.3 EXOGENOUS ENZYMES USED IN THE DAIRY INDUSTRY

The use of enzymes in the dairy industry for commercial applications is, in general, fairly limited. Even then, the use of milk-clotting enzymes in the production of cheese and the use of lipases in cheese manufacture are easily the most widely used applications. However, the uses of enzymes in many minor applications in the dairy industry are significant. Most applications use proteinases or lipases because protein and fat are the major milk constituents.

20.3.1 Exogenous Enzymes – Role in Natural Cheese Making

20.3.1.1 Milk Clotting Enzymes (Rennet and Coagulants) – Role in Natural Cheese Making

Milk clotting enzymes for cheese manufacture have been used for thousands of years and go back to the earliest days of cheese making. Initially, unpurified crude preparations extracted from the stomachs of ruminants were used to coagulate milk. These were followed by the use of microbes and plant extracts. It is relatively unimportant in this context to go into any detail regarding the use of these crude preparations in cheese making. Suffice to say that it was probably the first recorded instance of the use of enzymes in the development of foods.

Some confusion has occurred over the years regarding nomenclature of milk clotting enzymes. Initially, milk clotting enzymes which were derived from the fourth stomach of calves were called chymosin, derived from "chyme," which means "gastric liquid" in Greek. In 1890 the word "rennet" was used and found wide acceptance in English speaking countries; however because of confusion with the proteolytic enzyme "renin" the enzyme was renamed chymosin in 1992 by the International Union of Biochemistry and Molecular Biology. However, as all cheeses are not produced using milk clotting enzymes from ruminant sources it was felt that milk clotting enzymes from different sources should be further classified. Therefore it is now generally accepted that the word "rennet" should be reserved for milk clotting enzyme preparations from ruminant stomachs, and that milk clotting enzymes from sources other than ruminant stomachs or genetically modified organisms (GMO) should be named "coagulants." Milk clotting enzymes derived from GMOs have had to be further categorized, and are now called "fermentation-produced chymosin" (FPC) (18).

Commercially available rennet has existed for many years, and a standardized chymosin was first introduced by Chr. Hansen A/S in Denmark in 1874 (18). Commercially available microbial and fermentation produced milk clotting enzymes have become widely available in recent years to meet increased demand. Other sources of milk clotting enzymes are used, but only in specialized cases. The use of plant sources of coagulants is generally limited to sources from dried cardoon flower heads, and is found mainly in Portugal. Other plant sources of coagulants exist but contain other proteinase activities, which impair milk coagulation. Some other nonbovine animal sources of rennet have also been used, but again their modern use is limited to specialized cheese production or used for religious reasons (19).

It is important to understand the molecular aspects of the different milk clotting enzymes to differentiate between them. All of these enzymes are aspartic proteinases (EC 3.4.23) and therefore have identical catalytic mechanisms, containing two aspartic residues in their catalytic site (20). Distinct differences exist between the various sources of milk clotting enzymes and have been well characterized to date. For a detailed review see Harboe and Budtz, (1999) (18).

The action of milk clotting enzymes is the first step in cheese making and results in the splitting of κ-casein which causes the destabilization of casein micelles and subsequently leads to the formation of a coagulum. Milk contains four major types of casein, α_{s1}-, α_{s2}-, β-, and κ-caseins which, along with calcium phosphate, form spherical structures called casein micelles which are colloidal aggregates and are stabilized by κ-casein. It is generally accepted that these micelles are formed by many submicelles held together by colloidal calcium phosphate bridges, hydrophobic interactions, and hydrogen bonding. α- and β-caseins are calcium sensitive and interact to form the core of the micelles through hydrophobic interactions with κ-casein, which binds calcium weakly on the surface of the micelles. κ-casein provides a stabilizing influence though the nature of its peptide sequence and consists of two parts, a hydrophobic part known as para-κ-casein (consisting of amino acids 1–105), and a hydrophilic part known as the glycomacropeptide or caseinomacropeptide (consisting of amino acids 106–169). Para-κ-casein is bound to the core proteins, with the caseinomacropeptide (CMP) projecting out of the micelle surface, which is negatively charged. This negative charge exerts a steric hindrance preventing micelles from coming together. It is at the junction between the para-κ-casein and the CMP that the enzyme chymosin acts, splitting κ-casein into its two components and thereby destabilizing the casein micelle structure by reducing intermicellar repulsive forces. Once approximately 80 to 85 % of κ-casein is hydrolysed, the caseins start to form a coagulum which retains fat and expels most whey proteins and some water, thereby ending the first phase of cheese making (Figure 20.2) (18,21). For a detailed account, see Fox & Grufferty (1991) and Guinee & Wilkinson (1992) (21,22).

20.3.1.1.1 Rennet – Milk Clotting Enzymes Derived from Animal Sources
Bovine rennet consists of two main proteinases, the milk clotting enzyme chymosin and pepsin. The proportion of chymosin to pepsin is age dependent and varies between individual animals. For young calves, abomasum extracts can contain 80–90% chymosin, and adult animals can contain as much as 90% pepsin. Therefore, throughout the world the composition of rennet can vary markedly. Most commercial suppliers offer standardized rennets, which are available in liquid, powder, or paste form, and are stable for a period of months at given temperatures. The rennet is produced from either fresh, dried, or frozen stomachs, which are cut and minced. The rennet is extracted by water, buffer, or salts. The liquid component is separated by filtration or centrifugation and the extract consists of active enzymes and proenzymes. The proenzymes are activated by acid, usually at pH 2, and the pH is subsequently raised to solubilize protein. The proenzymes are then reclarified by centrifugation or filtration (18). Calf rennet is seen as the standard reference product to which all other milk clotting enzymes are compared, and is widely used in many countries. Lamb and kid-goat rennets are also used, but mainly in countries with traditional cheeses made from sheep or goat's milk. Lamb and kid-goat rennets are similar to calf rennet in activity and are produced by maceration and drying of the stomachs filled with milk to produce paste-type products.

Chymosin (EC 3.4.23.4) has a specific milk clotting activity and in calves is found in two allelic forms, A and B. Subtle differences exist between these enzymes, but for cheese making purposes they are all but identical. In adult animals, pepsin A (EC 3.4.23.1) is the predominant proteinase and has a broader specificity and higher pH dependency than

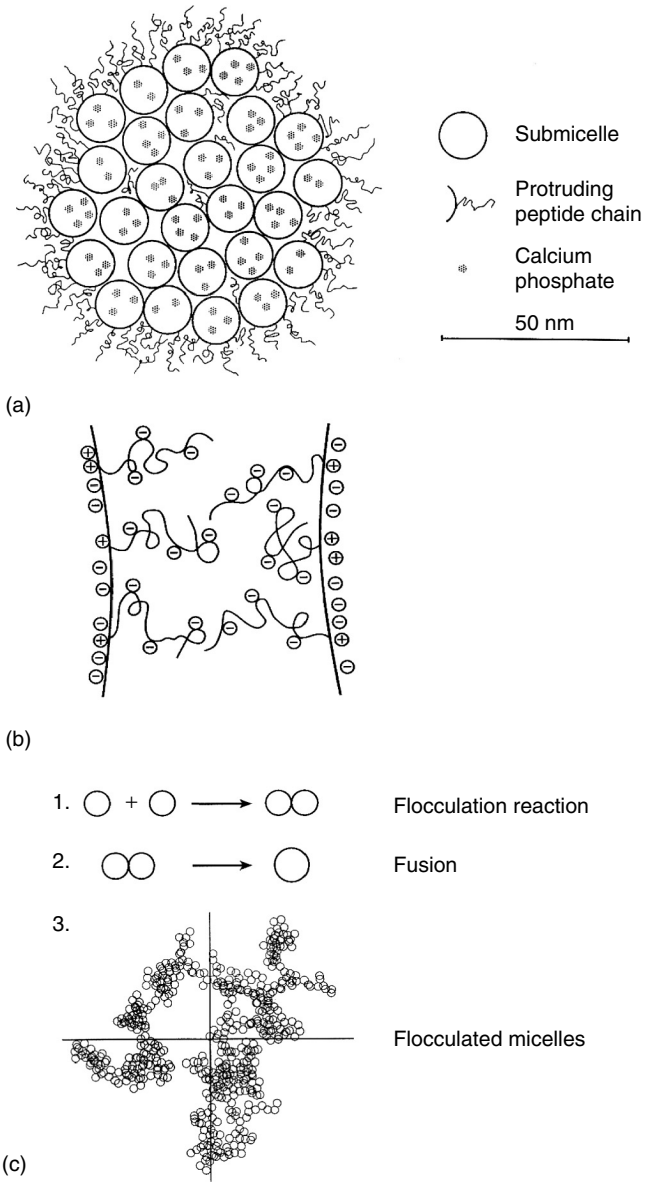

Figure 20.2 (a) Schematic of casein micelle aggregation, (b) Hypothetical diagram of electrostatic charges between two casein micelles, (c) Schematic model of a cross-section of a casein micelle.

chymosin. Two other proteinases exist in rennets and both are found in minor amounts in porcine stomachs: pepsin B (EC 3.4.23.2) and gastricin (EC 3.4.23.3), with the latter also found in adult bovine stomachs.

20.3.1.1.2 Coagulants – Milk Clotting Enzymes Derived From Microbes The declining supply of calves for slaughter and resulting chronic shortages and price increases fuelled the search for alternate sources of milk clotting enzyme (22). Various microorganisms were assayed for their suitability and approval for their use in cheese making was granted in the 1960s. Today three commercially available microbial coagulants exist which are all derived from fungal sources. The predominant coagulant is from

Rhizomucormiehei and exists as three distinct types; the other sources are from *Rhizomucor pusillus* and *Cryphonectria parasitica*. *Rhizomotor miehei* coagulants exist in three different types; the native type L which is heat stable and more proteolytic than calf rennet; the destabilized version type TL which is made by oxidation of the native enzyme and is heat labile and less proteolytic than type L; type XL which is the most heat labile and even less proteolytic. The *R. pusillus* coagulant is similar to the type L *R. miehei* product, with the *C. parasitica* coagulant being the most proteolytic and having a low pH dependency (18).

These coagulants are produced by fermentation where the proenzyme is converted to its active form during production by the slightly acidic environment. Production is typically by submerged batch fermentation, where a mother culture is propagated on selected media and grown to produce sufficient cells to inoculate a large scale culture. Production takes a number of days with process parameters closely controlled. The fungus is removed by filtration or centrifugation and the coagulant concentrated by ultrafiltration and clarified by filtration. The activity of these coagulants is standardized and stabilized to ensure product quality and consistency (19).

20.3.1.1.3 Fermentation Produced Chymosin – Milk Clotting Enzymes Produced Using Genetic Engineering The need for large amounts of standard milk clotting enzymes to meet the needs of the modern dairy industry brought about the development of fermentation produced chymosin (FPC) which is chymosin produced by fermentation brought about by an organism genetically modified with a gene for chymosin. Manufacturers claim that these enzymes give more consistent milk clotting and proteolytic activities and therefore offer a more standardized product. They are widely used in the USA and in some European countries; however some countries have continued to use standard calf rennet, presumably due to fear of affecting market share due to negative consumer feedback from the use of GMO products in foodstuffs. Two of these products are produced commercially containing chymosin from calf abomasum that has been expressed and produced in *Aspergillus niger* or *Kluyveromyces lactis*. A third product, containing calf chymosin produced by *Escherichia coli* is no longer commercially available. Another product commercially available contains the *R. miehei* coagulant proteinase expressed and produced in *Aspergillus oryzae*.

20.3.1.1.4 Effects of Milk Clotting Enzymes on Cheese Making Obviously some differences exist between the actions of different milk clotting enzymes; however in most circumstances they may have little influence on the overall cheese making process. Experiments with Cheddar cheese have shown that there was no advantage in terms of yield or quality of cheese produced with standard calf rennet and FPC (24). No significant differences were noted in yields between Cheddar cheeses made using identical procedures where the pH at whey drainage was 6.15 between standard calf rennet, the coagulants *R. miehei*, *R. pusillus*, and FPC products. (T. Guinee, personal communication). However, this does not support the conclusion that differences in yield or flavor and texture will not exist in cheese making with lower drainage pH or for different cheese varieties. An important aspect of differences between these milk clotting enzymes is their thermostablity, which differs considerably. Thermal stability is important when the whey is to be used in processing, as up to 90% of the enzyme can be lost to the whey during cheese making (18,25). Studies have shown that less than 2% of these enzymes remain in whey after normal low pasteurization at pH 6.0, which is acceptable for all uses of whey and whey products (18). The purity of milk clotting preparations is also an issue as some enzymatic side activities may survive pasteurization and act on whey proteins or in products containing whey proteins, which is particularly the case for starch degrading enzymes. The FPC coagulants do not have this inconvenience, because of their high purity. The cooking and scalding of curds in different cheese manufacturing procedures will also affect the activity

of these enzymes in the curd. This is particularly relevant for Mozzarella and Swiss cheeses and is an issue which should be considered by the cheese maker, because of the range in thermostabilities of the different milk clotting enzymes available.

20.3.2 Lipase – Role in Natural Cheese Making

Lipases and esterases (EC. 3.1.1.3) are enzymes which hydrolyse tri-, di-, and monoglycerides at an oil-in-water interface. Lipases have different selectivity, which is dependent upon a number of factors such as source, concentration, and the environment in which they are active. Lipases can be grouped according to their selectivity: some are substrate specific in that they hydrolyse only monoacylglycerols, mono-and diacylglycerols, or just triacylglycerols. Others are regiospecific, i.e., are Sn-1, Sn-3 regioselective, or Sn-2 regioselective. Some are nonspecific, showing no preference for substrate or acyl position, while others show acyl specificity in that they have a preference for certain fatty acids (5).

Lipases are very important in the formation of aroma and flavor substances in certain cheese varieties, but uncontrolled lipolysis can also lead to major flavor defects and result in downgrading of cheese. The impact of lipolysis can be critical in natural cheese making and needs to be controlled in all cases. A major problem with lipolysis in cheese is because milk fat contains high levels of short chain fatty acids, which when in free form are very volatile and have low flavor thresholds. High levels of short chain FFAs have been implicated with the development of rancidity, while high levels of large chain FFAs have been implicated with soapy off flavors. The extent of lipolysis varies markedly between different cheese varieties as does its significance. Table 20.1 lists typical FFA levels in some well known cheese varieties.

Lipolysis in natural cheese originates traditionally from three sources: raw milk (containing indigenous milk lipases and microbial sources), rennet paste (pregastric esterases), and microorganisms (molds, yeasts, and bacteria).

20.3.2.1 Indigenous Milk Lipases – Role in Cheese Making

Indigenous milk lipase LPL has a role to play in cheese making, particularly in raw milk cheeses and to a much lesser extent in cheese made from pasteurized milk, as most are inactivated by pasteurization.

20.3.2.2 Rennet Paste – Role in Cheese Making

Rennet paste is almost exclusively used in the manufacture of Italian cheese varieties and is a combination of the milk clotting enzyme rennet and pregastric lipases, which contribute to the required flavor and aroma development. Traditional methods of manufacture consisted of feeding calves milk, then slaughtering them, removing the stomachs, drying, and macerating them. These pastes were often used in the manufacture of Italian cheese varieties in the USA, but in 1945 the FDA prohibited the use of imported rennet paste from Italy due food safety concerns. This brought about the development of purified lipases from ruminants, which were derived from salvia glands and pancreatic tissues (pregastric and gastric lipases). Oral or salvia lipase was found to be the lipase of interest in rennet paste and is now widely used, produced in powdered format. It can be used with rennet to provide a safe standardized alternative to traditional rennet pastes. Conversion to pregastric lipase brought about an improvement in the quality of Italian cheese varieties produced from them (19). The advantages of using pregastric lipase instead of rennet paste are improved microbiological quality, improved standardization of the cheese, and the ability of adding the lipase independently of the rennet. Traditional rennet pastes are still used in some regions of Italy today.

Table 20.1
Total Free Fatty Acid Content of Various International Cheeses

Cheese Type	Variety	FFA (mg/kg)
Extra-hard cheeses	Parmesan	4,993[a]
	Romano	6,754[b]
Hard cheeses	Cheddar	1,028[b]
	Cheshire	1,265[c]
	Idiazabal	5,557[a]
	Manchego	32,404[d]
	Roncal	8,178[a]
Semi-hard cheeses	Caephilly	1,253[c]
	Colby	550[b]
	Mahon	8,743[a]
	Majorero	20,794[a]
	Monterey Jack	736[b]
	Port Salut	700[b]
Cheeses with 'eyes'	Edam	356[b]
	Emmenttal	2,206[c]
	Gruyere	1,481[b]
Cheeses with internally ripened moulds	Blue (US)	32,230[b]
	Roqueforti	32,453[b]
Cheeses surfaced-ripened with moulds	Brie	2,678[b]
	Camembert	681[b]
Cheeses surface-ripened with bacteria	Brick	2,150[b]
	Limburger	4,187[b]
	Munster	6,260[e]
Pasta-filata cheeses	Mozzarella	363[b]
	Provolone	2,118[b]

20.3.2.3 Pregastric Esterases (PGE) – Role in Cheese Making

Semipurified sources of PGE are now widely used in making Italian-type cheeses, and are required to provide the sharp piquant flavor associated with Pecorino, Romano, and Provolone cheeses. This piquant flavor is primarily due to short chain FFAs arising from the action of PGE. PGEs are sometimes used in the production of Romano, Caciotta, Feta, and Manchego cheeses, which are typically made from ewe's or goat's milk. However, in shortages of ewe's and goat's milk, cow's milk is often added and the lipases are required to give the desired piquant flavor associated with the use of ewe's and goat's milk. The differences in flavor from ewe's and goat's milk in comparison to cow's milk arise from differences in their fatty acid composition (26). Varieties such as Fontina, Ras, and

Kopanisti, which were traditionally produced from raw milk, now have added lipases to replace indigenous milk lipases destroyed during pasteurization. Lipases can be added at very low levels to varieties such as, Mozzarella, Parmesan, Romi, and Cheddar cheeses to enhance flavor and aroma development (19).

PGEs are regioselective for the Sn1 and Sn3 positions of milk triglycerides and have a particular affinity for short chain fatty acids at the Sn 3 position. This ensures the release of the most volatile free fatty acids, which by their nature have the greatest impact on flavor and aroma. Slight differences exist between the specificity of PGEs from calves, kid-goats, and lambs and therefore give differences in the cheeses made from these sources. For a detailed review of PGE see Nelson, Jenson, and Pitas (1977) (27).

20.3.2.4 Microbial Lipases – Role in Cheese Making

Microbial lipases are lipolytic enzyme preparations, which are derived from yeasts, molds, and bacteria. In terms of natural cheese making, molds play a direct role in flavor and aroma development in some varieties, predominately through the action of lipases. Surface ripened and blue veined cheeses rely on lipases from molds added during their preparation to aid in the development of their characteristic appearance, flavor, and aroma. Extensive lipolysis occurs in many blue veined cheeses and not only does this contribute to flavor by the generation of FFA directly, but these also provide precursors of other flavor compounds, the most important of which are methyl ketones which give Blue cheeses their characteristic flavor. This reaction begins with the release of FFA from tri-acylglycerides by the lipase in the mold, which are oxidized to form β-ketonic acids, and subsequently decarboxylated to produce methyl ketones (28). The lipases originate from the mold *Penicillium roqueforti* used in the manufacture of the cheese, which is generally added to the milk. The cheeses are then pierced using rods, which enables carbon dioxide to be released from the curd and oxygen to penetrate. This together with the correct humidity, salt, and oxygen facilitates germination of the spores. Blue veined cheeses, such as Stilton, Roquefort, Gorganzola, and Danish Blue are cheeses typically made in this manner. The lipase of *P. roqueforti* is Sn-1, Sn-3 regiospecific with acyl specificity for short chain fatty acids (5). Other cheeses utilize surface mold for flavor development, such as Camembert, which uses a different mold, *Penicillium camemberti*. *Penicililum camemberti* lipase is substrate specific for triacylglycerols (5). For further details on the lipases activity of *P. roqueforti* and *P. camemberti* and their role in the development of different cheese varieties, see Kinsella and Hwang (1976) and Gripon (1993) (29,30).

Lactic acid bacteria (LAB) are essential for the manufacture of most cheeses. LAB are often called starter cultures as they initiate the start of the production of lactic acid, their primary role in natural cheese making. However, they also have a secondary role, which is to contribute to the cheese ripening process by the release of cell wall or intracellular enzymes. In the context of this section, the lipolytic activity of these bacteria is very low, but lipase activity has been identified in many LAB (31). Therefore, the role of this source of lipases in natural cheese making should be addressed. This is also the case for nonstarter lactic acid bacteria (NSLAB) which are predominant in the microbiological content of many cheese varieties during ripening and therefore may also have a role in the level of lipolysis in these cheeses (32).

Yeasts are often present on a variety of cheeses and are known to contribute to lipolysis levels in these cheeses. *Geotrichum candidum* is commonly found on some cheese varieties before salting and is very acylspecific for cis-9 unsaturated fatty acids (32). Other yeast species are present in different cheese varieties; however their lipolytic role in cheese has not been fully characterized.

Although many sources of microbial lipases are available commercially, vey few are used in natural cheese making. Some have been used in accelerated cheese ripening and are used in other dairy process applications.

20.3.3 Accelerated Cheese Ripening

One of the major costs of cheese production occurs with the ripening of cheese, which can take up to two years for some varieties. The high costs associated with ripening are involved in controlling the environment in which the cheeses are stored until ready for distribution to retail outlets. Also, money paid out at day zero is not recouped until months later at variable market dependent prices. In some varieties, costs associated with ripening are not a problem as these cheeses have short ripening periods. In others such as Cheddar, where a mature cheese is typically 12 to 18 months old, costs associated with ripening become a major issue. Therefore, the ability to reduce ripening time while maintaining quality has the potential to offer considerable cost savings. This chapter focuses on Cheddar cheese as it is one of the largest volume cheeses in the world. Various techniques described here to accelerate its ripening can also be applied to other varieties. Although the main driving force for accelerating the ripening of Cheddar cheese has and will remain cost reduction, over recent years other factors have also become important. The power of retail outlets to control the cost and type of cheese required has become an important factor for cheese producers, as the acquisition or loss of contracts to supply multinational retail chains can be the making of or the end of producers. Standards applied to the selection of cheeses by retailers have increased markedly over the years and are themselves in direct response to consumer demands. Consumers are not only interested in cost effective cheese but also in characteristic cheeses, which means that consistency of quality is vital. The development of characteristic Cheddar cheeses leads to brand loyalty, whereby the consumer associates a product from a certain manufacturer with a particular consistent flavor profile. Therefore the producer has to be able to produce a Cheddar cheese with characteristics that distinguish it from other brands, and which are acceptable to a wide range of consumers at a cost effective rate throughout the year, from a variable seasonal raw material, milk. This is not an easy task, considering the number of dynamics which come into play during production of Cheddar cheese.

Over the years, a wide variety of options has been used to accelerate ripening, all with various success rates, but none has yet proven to be the perfect solution (Table 20.2). In biochemical terms, cheese ripening is in itself an enzymatic process; therefore the solution to achieving the goals previously outlined involves, at least in part, an enzymatic system, whether involving the use of enzymes directly or indirectly through the use of LAB.

20.3.3.1 Nonenzymatic Methods For Accelerating Cheese Ripening

Nonenzymatic methods exist for accelerating cheese ripening and are mentioned here because they can be used in association with enzymatic methods. The first is elevated temperature ripening, which provides a better environment for the enzymes to work, thereby accelerating ripening. This mechanism has been favored in recent years, mainly because it is the most cost effective. Generally, Cheddar cheeses are ripened at 12 to 15°C using this method (as opposed to 8°C), however care needs to be taken to ensure microbial safety and to prevent textural defects. In commercial practice, cheese may be held at different temperatures throughout its ripening to make flavor development coincide with market demands at particular times of the year.

The second method is high pressure treatment, which still in its infancy, but may have the potential to accelerate cheese ripening. Work to date has shown conflicting

Table 20.2
Method for accelerated cheese ripening

	High Pressure
Enzymatic methods	Exogenous enzymes
	Attenuated starter cultures
	Adjuncts
	Genetic modification

results, with initial work by Yokoyama, Sawamura, and Motobayashi (1992) (33), reporting substantial accelerated ripening for Cheddar and Parmesan cheese. Later studies have not found any major differences between high pressure treatments and controls for other cheese varieties (34,35). However, it is too early to dismiss this as a possible mechanism for accelerating cheese ripening, as it may have a role in combination with other enzymatic technologies. A useful review of the use of high pressure treatment in cheese applications is given by O'Reilly, Kelly, Murphy, and Beresford (2001) (36).

20.3.3.2 Accelerating Cheddar Cheese Ripening Using Enzyme Technology

20.3.3.2.1 Exogenous Enzymes The addition of enzymes in the cheese making process has seen commercial application and has been tried as far back as 1978 (37). The potential of this system is very obvious as it involves adding increased amounts of enzymes during the cheese making process, enabling quicker hydrolysis of the major milk components and thereby reducing its ripening time. Achieving a balanced flavor and texture profile using this technology has proven difficult. Enhancing hydrolysis of the major casein proteins causes bitterness, losses in yield, and weakness in texture. These problems have become less critical with advances in understanding the proteolytic action of various enzymes in cheese flavor and texture development. Initial problems associated with this technology could be traced to uncontrolled protein hydrolysis. It was not until detailed investigations into the mode of action of different proteinases/peptidases were done that the most suitable enzymes were identified. Also, advances in understanding of why bitter peptides accumulate in cheese to cause bitterness, and how this could be alleviated through selection of the right types of peptidase activity, enabled bitterness to become less of an issue associated with this technology. The inclusion of exogenous lipases to accelerate Cheddar cheese ripening has not shown promise, as off flavors develop (38). However, other studies have shown lipolysis to be important in Cheddar cheese flavor development (39). A major difficulty in enhancing lipolytic flavor and aroma in Cheddar cheese is that small increases in the level of lipolysis can have major negative sensory impacts. Therefore the correct dosage level of lipase is critical for success.

Today blends of enzymes or enzyme cocktails are available to accelerate cheese ripening, which contain the necessary enzymes to accelerate ripening without negative effects. However, their use is not wholly widespread as problems can still occur with unbalanced ripening making it difficult to ensure a suitable shelf life of the cheese in the market place. Unbalanced ripening can occur when the enzymes have not been added to the curd uniformly, thereby creating zones in a cheese block where the rate of hydrolysis differs. In fact the point of addition of exogenous enzymes for the accelerating ripening of cheese is a major hurdle in the development of this technology. Differences in production techniques among different factories are also an issue, and manufacturers of these enzyme preparations work closely with individual cheese makers to try to alleviate problems that

may occur due to differences in protocols and equipment. The issue of shelf life is important, as it may be possible to produce a cheese with typical characteristics of a cheese twice its age using exogenous enzymes, but stopping the rate of accelerated ripening, enabling the cheese to have a required shelf life, is also an issue that has not been wholly resolved. It appears that advances are being made in this area, and may involve changes in temperature and pH, and the use of starter culture technology, to control enzyme activity but as yet no detailed information has been published.

As mentioned, the point of addition of exogenous enzymes to the cheese making process has precluded its use in certain cheese manufacturing processes. Simply adding soluble enzymes directly to the milk is not feasible, as most of the enzyme would be lost in the whey, which would also adversely affect downstream applications of this product. Also, proteinases acting at the early stages of cheese making would affect the overall yield, as casein fragments would also be lost to the whey. An ideal system would enable enzymes to be added to the milk. The enzymes would then fully partition with the curd and not negatively affect yield. This system would be advantageous in that it would be easy to use, but also ensure even distribution of the enzyme in the curd. Work carried out by a number of groups in the 1980s and 1990s using liposome technology showed some promise. This involved encapsulating water soluble enzymes in the aqueous phase between phospholipid layers in liposome globules (Figure 20.3). The benefits of this system were even distribution of enzymes in the cheese curd, and early enzyme release during ripening as the liposome capsules break down. A number of problems existed with this technology and mainly revolved around maximizing enzyme encapsulation rates and eliminating high costs due to the expense of using soya lecithin in the production of liposomes. Recent work carried out in this area used a commercial phospholipid mixture (Pro-Lipo® S) from Lucas Meyer, France to encapsulate cell free extracts of LAB. This work has highlighted further limitations precluding the use of commercial phospholipid mixtures, such as increased moisture and changes in rheological characteristics of the cheese (40). It difficult to determine if this technology will find commercial application in the near future due to the limitations described, but also due to the fact that most soya lecithin is derived from genetically modified soya which further limits its use in certain countries.

Currently, adding exogenous enzymes at the salting stage (milling) of the cheese making process offers the best route for Cheddar cheese production, despite problems associated with uneven enzyme distribution in the curd. The enzymes may be preblended with the salt or added independently. Many different types of exogenous enzymes have been added to different cheeses, and most have shown an increase in the indices of ripening, although numerous defects were also reported. Most applications have involved Cheddar cheese and the use of commercial proteinase preparations, although quite a few have also involved the use of cell free extracts of various microbial cultures. For a more detailed description of the addition of exogenous enzymes during cheese making the reader is referred to Wilkinson (1993); Fox, Guinee, Cogan, and McSweeney (2000); Law (2001) (41,42,43).

20.3.3.2.2 Commercial Enzymes for Accelerating Cheese Ripening Very few commercially successful enzyme systems to accelerate cheese ripening exist. One which has survived the marketplace for years is the Accelase system (Rhodia Food). Accelase consists of a range of blends of enzyme systems (proteinase, peptidases, and lipases) tailored to suit different applications. They are purported to accelerate ripening, give particular flavor characteristics, and can be added to the milk or the curd (44). Other commercial systems exist (NaturAge, FlavourAge, DCA50, Enzobact, and ACR), but little information has been published regarding their use. For a more detailed review, see Wilkinson, Van den Berg, and Law (2002) (45).

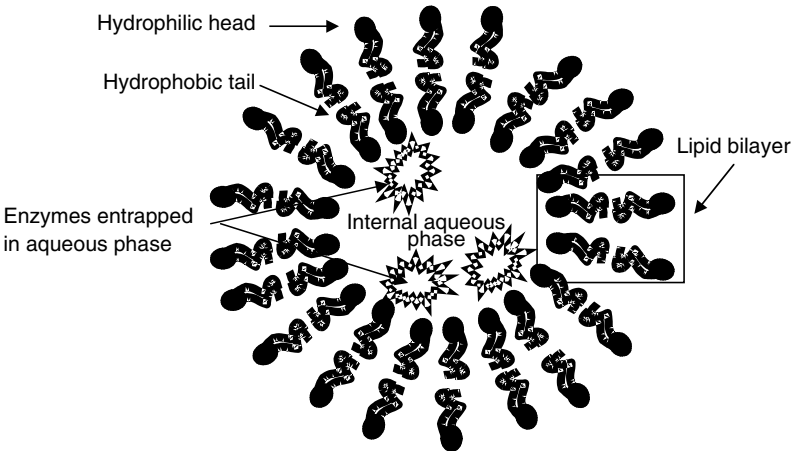

Figure 20.3 Schematic representation of 2-dimensional layer of a liposome with enzymes entrapped in the internal aqueous phase.

20.3.3.2.3 Attenuated Starter Cultures and Adjuncts Due to problems associated with the use of exogenous enzymes to accelerate cheese ripening, research has concentrated on using starter cultures for the same purpose. Starter cultures have been shown to contain the necessary pool of enzymes required to develop characteristic Cheddar flavor, as they have been used in cheese manufacture for years. They can also be added directly to the milk, and distribute evenly in the curd. Essentially, starter cultures are excellent vehicles for distributing enzymes into the curd to accelerate cheese ripening.

In natural Cheddar cheese, as in many other varieties, starter cultures are used to acidify the milk enabling curd formation, and to act as sources of enzymes necessary for the development of characteristic flavors. In commercial reality, starter cultures are selected for their phage resistance and their ability to grow well and produce acid over the temperature profiles used in cheese making. Those strains prone to phage attack, and those which do not produce good quality cheese, have been removed leaving the specific strains which produce good quality flavor (42). Cheese curd has the capacity to retain up to 3 times the level of starter typically used in cheese making, therefore opening the possibility of enabling extra starter culture, containing more enzymes, to be added to the curd to accelerate its ripening (43). To achieve this, the acid producing capability of the extra starter must be attenuated in order to prevent excess acid production, which would adversely affect the cheese making procedure. This can be achieved by using sublethal heat treatments or freeze-thaw treatments, which do not affect the enzyme activity of the starter bacteria. Lactose-negative strains may also be used, as these occur naturally, and because they cannot produce acid they can also be used to accelerate cheese ripening. An important facet of this technology is cell lysis, as many of the enzymes necessary to develop flavor are intracellular and therefore are not released until the cells lyse at death. Therefore the ability of a cell to lyse rapidly in the curd is important to enable the enzymes to work on the substrate as early as possible to accelerate ripening.

Another important aspect of cheese ripening in many varieties is the presence of nonstarter lactic acid bacteria (NSLAB), which predominate during the latter stages of ripening in some cheeses, such as Cheddar. Some of these cultures have been adopted and attenuated for use as adjunct cultures in conjunction with starter cultures in cheese making. They are generally used to impart certain characteristic flavors rather than accelerate ripening, but can be used to accelerate ripening (42).

The advent of genetic modification (GM) has enhanced the possibility of using cultures for the acceleration of cheese ripening. Not only has the taxonomy of cultures been advanced but also their enzyme complement, activities, bacteriophage resistance, and lysis potential. This technology has without doubt the potential to aid our understanding of cheese flavor development and provide a suitable mechanism for the acceleration of cheese ripening. However, the widespread use of this technology in the production of cheese has not occurred, due to consumer and political reservations about the safety of this technology, whether founded or not.

20.3.4 Enzyme Technology in Cheese as an Ingredient

Cheeses have been used as ingredients in foods for years with large volumes used in the retail, food service (catering), and industrial sectors. Natural cheese is widely used as an ingredient, but it also undergoes secondary processing into various products for a wide range of applications. Secondary processing of natural cheese includes shredding, grating, grinding, portioning, cooling, freezing, thawing, heating, or reheating; and cheese is still required to perform various rheological, visual, or sensory functions after such processes. A detailed review of the functionality of cheese as an ingredient is given by Guinee (2002) (46). The use of cheese as an ingredient has seen major growth in recent years, due to the increased demand for processed consumer foods and the demand for ethnic foods that use cheese in their preparation. Natural cheese is an essential ingredient in many products, providing flavor, aroma, color, texture, and functionality, but it can be quite expensive. This aspect has driven suppliers to develop cost effective alternatives to using natural cheese in ingredient formulations.

20.3.4.1 Fast Ripened Cheese

These cheese products have been loosely termed "ingredient-type cheeses" and are defined by their high moisture content and short ripening times, which can be weeks rather than months. They are developed to provide ingredient alternatives to semihard- and hard-type natural cheeses, which can take many months to ripen. Texture is not a factor with such cheeses as they are usually shredded after production and used solely as an ingredient cheese for further processing. The enzymes and starter cultures used in their production are similar to those outlined in the accelerated cheese ripening section and are added at levels higher than that found in natural cheese. These cheeses are high moisture cheeses, which are typically ripened at 15 to 20°C to increase the rate of enzyme reaction and thus hydrolysis. Once an acceptable flavor profile has been reached, the cheeses are typically shredded and stored chilled or frozen until required, and are solely used in the industrial sector. A variation of this type of cheese involves shredding the cheese and adding enzymes, then reblending it in a fashion similar to processed cheese, and ripening it at high temperatures. This cheese can be further processed into slices or grated depending upon the desired application. Virtually no information is published on this process, but it appears to offer potential to give the flavor, visual, and some functional characteristics of cheese to certain processed foods.

20.3.4.2 Enzyme Modified Cheese

Enzyme modified cheeses (EMCs) are defined as concentrated cheese flavors produced enzymatically from cheeses of various ages. They are principally used as a cheese flavor ingredient in processed foods, where they provide a cost effective alternative to natural cheese. Whereas natural cheese is consumed for its flavor, texture, appearance, and functional properties, either on its own or as an ingredient, EMCs are consumed almost exclusively as a flavor ingredient (47). EMCs can be used as the sole source of cheese flavor, to intensify an existing

cheese taste, or to impart a specific cheese character to a blander product (1). The main applications of EMCs are in processed cheese, analogue cheese, cheese spreads, snack foods, soups, sauces, biscuits, dips, and pet foods. The main advantages of EMCs for use as an ingredient are low production costs, high flavor intensity, diverse flavor range, extended shelf life, and low storage costs (48). EMCs are generally perceived as being natural flavor providers as they are produced using the same flavor pathways that occur in natural cheese. The high degree of flavor intensity of EMCs enables them to be added to foods at very low levels (typically 0.1%, w/w) to achieve the desired flavor (47). This low addition level enables EMCs to be used in low fat foods and ensures that they have no adverse physical affect on the final product characteristics, which is particularly useful in frozen foods where they impart a smooth mouth feel. They can also be used cost effectively to replace a percentage of the natural cheese in a product where it is necessary to have some natural cheese for its physical characteristics. EMCs are available in a wide range of cheese flavors, which correspond to most natural cheese varieties. However, many different flavor types are also available for individual cheese types: e.g., Cheddar EMCs are available as a range of Cheddar-type EMC flavors. This highlights the fact that the relationship of EMCs to their corresponding natural cheese is at best unclear. EMC flavor is generated using the same pathways that occur in natural cheese ripening, i.e., proteolysis, lipolysis, and glycolysis. But, as opposed to natural cheese where the influence of each pathway on the flavor depends upon the variety (49), EMC flavor is principally derived through proteolysis and lipolysis with texture not recognized as a factor in its production. EMCs are used to provide the perception of cheese flavor and aroma to a product. The specific flavor and aroma characteristics they are expected to mimic typically resembles the main flavor and aroma character of a natural variety.

The basis of EMC production is the utilization of specific enzymes, under optimum conditions, to produce cheese flavors from dairy substrates, usually cheese curd. This technology has developed from studies by Kristoffersen, Mikolajeik, and Gould (1967) (50) where cheese flavor was produced rapidly using a curd slurry technique. The original process involved mixing fresh curd and a sodium chloride solution to make an emulsion of approximately 40% (w/v) solids. Enzymes and preservatives were added and the slurry was incubated at 30°C for 4–5 days with daily agitation, after which characteristic cheese flavors developed. This work demonstrated the potential of generating a range of intense cheese flavors in a short time from cheese substrates by modification of process parameters.

The fundamental procedure is similar today, where typically mature or immature cheese is incubated with specific exogenous enzymes or microorganisms under controlled conditions. The process is terminated by heat treatment and the final product standardized to a desired flavor intensity and composition. EMCs are generally manufactured by one of three enzymatic processes: an integrated approach, where a single substrate is hydrolysed simultaneously by proteolytic and lipolytic enzymes to the desired final flavor; a two step process where a single substrate is hydrolysed initially by proteolytic enzymes and subsequently by lipolytic enzymes to create the final product; and a component approach, where individual substrates are hydrolyzed independently by either proteinases or lipases and subsequently combined to create the desired flavor profile (Figure 20.4). (47,48,51,52).

Emulsification of the substrate is very important to optimize enzyme activity, as is consistency and quality of the curd substrate. Many EMC products are produced with the inclusion of flavor enhancers or potentiators, often called “top notes” in the industry, to create a greater diversity of products. The most commonly used flavor enhancers are monosodium glutamate, yeast extracts, and organic acids such as acetic acid, butyric acid, propionic acid, lactic acid, and diacetyl. The actual processing conditions used depend upon many factors, and directly relate to the enzymes being used. In general, EMCs are produced in 1–4 days at a temperature range of 25–45°C and with pH of 5–7 (48).

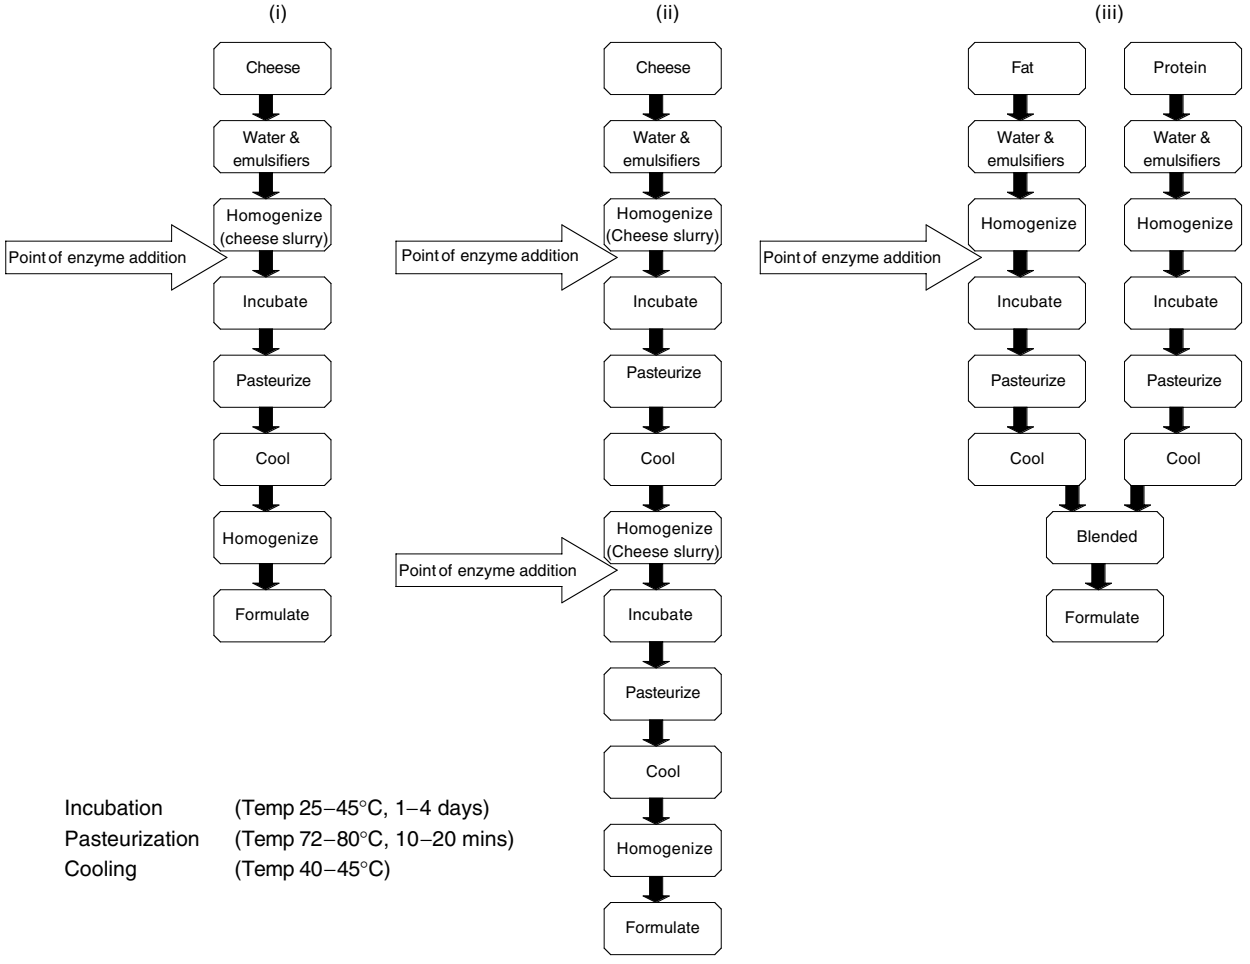

Figure 20.4 Methods of EMC production

The enzymes used in EMC manufacture are those that degrade dairy protein and fat into flavor compounds and precursors of flavor compounds (i.e., proteinases, peptidases, and lipase). A wide range of commercial enzymes are available, derived from plant, animal, or microbial sources. Most of the enzymes used in EMC production are derived from microbial or animal sources. Plant enzymes are not used as they are comparatively impure and are expensive because large volumes of crops are required to produce sufficient amounts of enzyme.

In the production of EMC it is necessary to rapidly develop a savory cheese flavor, so broad specificity proteinases are used widely. Quite a number of commercial proteinases are available for EMC production and all are microbial in nature. Most are derived from *Bacillus* or *Aspergillus* species and tend to be neutral or slightly acidic in nature. The choice of proteinase depends upon factors such as desired flavor, substrate, cost, and processing parameters. Peptidases are very important in EMC production, as they play an important role in flavor development but also in reduction of bitterness which can be a problem in EMCs due to the significant degradation of all the major caseins. Bitterness can be masked in EMC production by adding flavor enhancers and mature cheese, and is typically controlled by the use of specific peptidases. The most widely used commercially available peptidases are derived from LAB and *Aspergillus oryzae*. These products may contain a range of peptidase activities and, in some cases, proteinase activities. Commercial proteinase and peptidases for use in EMC production have been reviewed (53,54).

Hydrolysis of milk fat by lipases produces flavor and aroma compounds, which also act as precursors for additional flavor and aroma compounds. Lipolysis is very important in EMC production due to the generation of volatile compounds, which are important in providing cheese flavor to the product to which EMC is added. Lipases are available from two main sources, animal and microbial. The most significant animal lipases are isolated from bovine and porcine pancreatic tissues and the pregastric tissues of kid goat, lamb, and calf (27). Different PGEs produce characteristic flavor profiles. Calf PGE generates a "buttery" and slightly "peppery" flavor, kid PGE generates a sharp "peppery" flavor, often called "picante", whilst lamb PGE generates a "dirty sock" flavor, often called "pecorino" flavor (55). Microbial lipases are enzyme preparations derived from yeasts, molds, or bacteria, e.g., *Rhizomucor miehei*, *Rhizopus arrhizus*, *Aspergillus niger*, *Aspergillus oryzae*, *Geotrichum candidum*, *Penicillium roqueforti*, *Achromobacter lipolyticum*, *Pseudomonas* species, *Staphylococcus* species, and *Candida cylindracea* (56). Microbial lipases are generally cheaper than animal lipases because of lower production costs, and have the added advantage of being suitable for use in vegetarian and Kosher foods; and do not contain amylases which can cause problems in foods into which EMCs are added (57). Commercial lipase preparations for potential use in EMC manufacture have also been reviewed (54).

20.3.4.3 Dehydrated Cheese Products

These products can consist of spray dried natural cheese, dried grated cheeses, or extended cheese powders. The first two consist of natural cheese but the third, extended cheese powders, are produced by spray drying a slurry of cheese. Dried cheese powders are produced with varying low moisture contents for different applications. Some contain anticaking agents to prevent clumping, such as microcrystalline cellulose. Mature cheese is usually used because it has a better flavor profile, but also because it is easier to atomize and dry than young cheese. Young cheese has large amounts of intact casein, which produces viscous slurries making it difficult to dry. Extended cheese powders typically consists of mature cheese and enzyme modified cheese, flavorings, flavor enhancers, and emulsifying salts which are blended together under high shear, and then pasteurized and dried. Color,

extenders (such as whey, skim milk, or milk fat), antioxidants, and carriers (maltodextrins) may be added depending upon the application and the drying procedure (58).

20.3.4.4 Substitute or Imitation Cheese

These are cheese products which, as opposed to natural cheese, are not made directly from milk. Two types of imitation cheese are produced in very high volumes: processed and analogue cheese. Neither imitation cheese uses enzymes directly in its manufacture, but either may contain ingredients produced using enzymes.

Cheese analogues are typically defined as products made by blending individual constituents, including nondairy fats or proteins, to produce a cheese-like product to meet specific requirements. They are cost effective as they employ a high proportion of cheaper nondairy fat and protein. This product is utilized in convenience foods , but is predominantly used as a source of cheese flavor in pizza topping to reduce the costs of using 100% natural cheese on a product. The major disadvantage of this product as a direct replacement to natural cheese is its lack of flavor. However, this has been overcome in certain applications by using enzyme modified cheese in addition to or in association with natural cheese.

Processed cheeses are further classified into different categories depending upon the ingredients used in their preparation. Different guidelines exist on labeling different processed cheese products and are dependent upon the countries where they are produced. Some processed cheese products also contain enzyme modified cheeses to impart characteristic flavors to the final product. For a detailed review of this area, see Fox, Guinee, Cogan, and McSweeney (2000) (59).

20.3.5 Lipolysed Cream and Butter Products

Lipases hydrolyze milk fat and catalyze the conversion of triglycerides to diglycerides, monoglycerides, and FFAs. These FFAs impart characteristic flavors and aromas, so the specificity of the lipase has a major role in determining the flavor of a product (60). Lipases are used to hydrolyze milk triacylglycerols to produce intensely flavored dairy products. As mentioned earlier, EMC technology uses this approach to create intensely flavored cheese for ingredient purposes. Lipolysed milk fats are used mainly in a wide range of confectionery and baking applications, but also find uses in nutritional products. A host of different microbial enzymes are available for these applications and flavors developed are directly related to the specificity of the lipases used in their manufacture. The specificity of commonly used lipases are detailed in Villeneuve and Fogilia, (1997); Balcao & Malcata, (1998) and Gunstone, (1999) (5, 61,62).

Production of lipase modified milk fat ingredients generally follows the following procedure (51):

1. Preparation of condensed milk or butter-oil substrate
2. Standardization of the lipase preparation
3. Contact of lipase and substrate
4. Homogenization to facilitate emulsion formation to enhance enzyme activity
5. Incubation of emulsion to achieve desired conversion of substrate to products
6. Enzyme inactivation in a manner that minimizes the loss of developed flavor volatiles
7. Final product standardization and formulation

Lipases can be used to produce pronounced dairy flavors in milk fat emulsions or in whole milk concentrate substrates. Such flavors are desired for the production of milk

chocolate and account for the unique superiority of some milk chocolate flavors. These are produced in powdered form and are resistant to oxidative rancidity, which is of major advantage over their whole milk counterparts (63). Lipase modified milk fat products include milk chocolate, chocolate syrups, chocolate coatings, chocolate beverages, butter, margarine, butter creams and sauces, coffee whiteners, and creams. Lipolysed milk fat emulsions are also very effective carriers of synthetic fatty acids, diacetyl, butter esters, and lactones (61,64).

A lot of interest has been generated toward the development of structured lipids, which are basically lipids designed to have specific fatty acids attached to given positions on triglycerides. This approach can also be used to develop milk fat, in the formulation of confectionery fats, or to provide milk fat with enhanced nutritional qualities for specific applications. Milk fat can be modified by physical means, such as fractionation, or by chemical means, such as hydrogenation or interesterificiation. Interesterificiation is carried out by enzymes and involves the exchange and redistribution of acyl groups among milk fat triacylglycerols. Therefore, it is possible to enrich milk fat with certain fatty acids which could then be used in various flavor or nutritional applications, as well as imparting distinct physical properties for functional uses in food applications such as margarines (60,61).

20.3.6 Protein Hydrolysis

In the past, large scale generation of flavor during food processing was carried out by chemical or acid treatments and sometimes created unwanted byproducts or required very high energy demands, which has limited their potential uses. Recently natural product use has created a demand for enzyme produced flavors. Enzyme hydrolysis is generally seen as a noninvasive technology, and is an extrapolation of many natural processes.

Two milk proteins, casein and whey, are used in the food industry for specific flavor, functional, or nutritional applications. These proteins are hydrolysed to meet various applications, particularly in baby foods, baby milks, nutritionally fortified drinks, and other dietetic food formulations. A wide variety of commercial enzymes are useful in the preparation of hydrolysates that are very soluble, and stable at low pH and when heated (65). However, a major problem associated with protein hydrolysis, particularly for casein and whey proteins, is the development of bitterness, which is associated with the accumulation of hydrophobic peptides. Bitter peptides contain 3–15 amino acids and are characterized by the presence of the hydrophobic amino acid residues leucine, isoleucine, proline, valine, phenylalanine, tyrosine, and tryptophan. Bitterness can be alleviated by the degradation of these bitter peptides and is an area which has been widely studied over the years (66).

Generally, a number of key peptidase activities are important in bitterness reduction. General aminopeptidase activity, which cleaves single amino acids from the N-terminal of a peptide (Pep N and Pep C activity) is important. The removal of the amino acid proline from a peptide can greatly reduce bitterness, because it alters the peptide's three-dimensional structure, changing its solubility and increasing its susceptibility to hydrolysis (66,67). Key peptidase activities involved in removing proline are proline specific peptidases such as: postprolyl dipeptidyl dipeptidase (Pep X), which releases N-terminal dipeptides from prolyl peptides; proline aminopeptidase (Pep P), which exclusively hydrolyzes the N-terminal amino acid from peptides that have proline in the second position; proline iminopeptidase (Pep I) which removes unsubstituted N-terminal proline residues from tri-, oligo-, and polypeptides; prolinase (Pep R) which cleaves N-terminal Pro-X dipeptides; and prolidase (Pep Q) which hydrolyzes X-Pro dipeptides (68,69).

However it is not necessary to completely convert peptides to free amino acids to eliminate bitterness. In practice, the final level of bitterness will be the result of a tradeoff between the economics of bitterness control, desired functionality, and how tolerant the final application is to bitterness.

20.3.7 Lactose Hydrolysis

Lactose is hydrolysed by the enzyme β-galactosidase (EC 3.2.1.23) or lactase to produce glucose and galactose, and is used in a number of applications in the dairy industry. β-galactosidase is available from a number of animal, plant, or microbial sources and must be purified prior to use in dairy applications. The commonly used preparations are derived from yeasts and fungi and have different pH and temperature optima, so it is important to understand the conditions of a process prior to selecting the most suitable source.

β-galactosidase has found uses in certain dairy applications, particularly in products for people with lactose intolerance. Lactose intolerance is the inability to hydrolyse lactose into galactose and glucose in the small intestine due to a lack of β-galactosidase, and is a problem for a majority of the population (70). Symptoms include various intestinal disorders, including gas and diarrhea (28). As lactose is present in high levels in many dairy products, this is of major concern to processors, particularly in countries where a high proportion of the population are predisposed to lactose intolerance. β-galactosidase can be used to hydrolyse lactose to more digestible byproducts, enabling individuals with lactase intolerance to easily digest dairy products. Most of these products have a slightly sweeter taste as the byproducts of lactose, glucose and galactose, are sweeter than lactose. This technology has also been proposed for yogurt manufacture to make it sweeter without increasing its calorific content. It has also been shown to accelerate acid formation in yogurt (71).

β-galactosidase may stimulate starter and secondary starter activity and is thought to have a possible role in accelerating cheese ripening (22). However, studies were carried out on accelerating cheese ripening using β-galactosidase derived from the yeast *Kluyveromyces lactis*, which contained a proteinase that may have been responsible for the increased ripening rates (70).

Glucose–galactose syrups produced by the hydrolysis of lactose from whey are used for the production of syrups and sweeteners for the food industry. These are sweeter and more soluble than lactose. Such syrups have several applications in food products (71). Lactose can form insoluble crystals on drying and these can cause problems in some food products. Hydrolysis of milk lactose for its use in ice cream to prevent crystallization has been shown to be successful. The treatment of hydrolysed whey for animal feed removes problems associated with crystallization of lactose on drying and makes the whey more useful as a feed component (71).

20.3.8 Lysozymes

Lysozyme is used in some Dutch, Swiss, and Italian cheese varieties to prevent late gas blowing and off flavors caused by the growth of *Clostridium tyrobutyricum*. Most commercial lysozyme is derived from chicken egg white. Nitrate is also used in some countries for the same application. However because of possible nitrosamine production, its use is precluded or permitted levels reduced in other countries (8).

20.3.9 Transglutaminase

Transglutaminase (TGase) is an enzyme which catalyzes an acyl-transfer reaction introducing a covalent cross link between glutamine and lysine residues. TGase has found applications throughout the food sector particularly in improving functional properties of various products. The use of TGase in the dairy industry at present is generally limited to research on improving the gelation properties of yogurts and improving the rheological properties of whey proteins. However, some recent studies suggest that it has a role in masking bitterness in casein hydrolysates and in improving the curd firmness in imitation cheese. Other research has found that TGase has the potential to improve the heat stability of milk (72). It is quite likely that further dairy applications for this enzyme will be found in the future.

Egg Yolk Antibody Farming for Passive Immunotherapy

Jennifer Kovacs-Nolan and Yoshinori Mine

CONTENTS

21.1 INTRODUCTION

Immunoglobulins, or antibodies, are large molecules formed by the immune system, developed by higher organisms to combat the invasion of foreign substances (1). In both humans and animals, the administration of specific antibodies is an attractive approach to establishing protective immunity against viral and bacterial pathogens, and has been prompted by the need to find alternatives to antibiotics in response to the increasing number of antibiotic resistant organisms, as well as organisms that are not responsive to traditional antibiotic treatment (2). There are also individuals who are unable to mount an active immune response against pathogens, including infants, children with congenital or acquired immunodeficiency syndromes, and those rendered immunodeficient by chemotherapy, malnutrition, or aging (3,4), who would benefit significantly from effective passive immunization techniques.

Passive immunization, a technique in which preformed pathogen specific antibodies are administered orally to individuals to prevent, and in some cases treat, infectious diseases, may be one of the most valuable applications of antibodies (5). It is proposed that the antibodies may exert a sort of antimicrobial activity against pathogens, by binding, immobilizing, and consequently reducing or inhibiting the growth, replication, or colony forming abilities of pathogens (5).

Traditionally, polyclonal antibodies have been produced in mammals such as mice, rats, rabbits, and goats. The antibodies are then collected from the serum of the animal (6). However, these antibodies cannot be prepared on the industrial scale that is required for passive immunization techniques, because of the limitation in the amount of blood that can be collected at any one time. Chickens have attracted considerable attention as an alternative source of antibodies for the prevention and treatment of infectious diseases (2,7,8). The serum immunoglobulin of chickens, referred to as immunoglobulin IgY, is transferred in large quantities to the egg yolk in order to give acquired immunity to the developing embryo (9), and can be readily extracted from the egg yolk.

The large scale potential of IgY, as well as its source, a normal dietary component, makes it ideally suited for passive immunization applications. Egg yolk antibodies, therefore, have significant potential for food fortification and nutraceutical applications for the reduction of the morbidity and mortality associated with infection by human and animal pathogens.

The following chapter details the structural and physical characteristics of IgY, the numerous advantages and immunotherapeutic applications of IgY, and future prospects in IgY research.

21.2 AVIAN EGG ANTIBODIES

21.2.1 Avian Immune System

Immunoglobulin production in chickens is significantly different from that of mammals. While the rearrangement of immunoglobulin genes is an ongoing process in mammals, in chickens, it occurs in one single wave during embryogenesis, limiting the possible number of antibodies to the number of B-cell precursors (10,11), estimated to be around $2–3 \times 10^4$ cells (12). In contrast to mammalian systems, gene rearrangement also contributes little to chicken antibody diversity (13). However, despite the fact that chickens have an extremely limited number of immunoglobulin genes compared to mammals, they have developed other methods of producing a wide range of immune responses and diverse antibody molecules (13), enabling their use for the production of specific antibodies.

Three immunoglobulin classes have been shown to exist in the chicken: IgA, IgM, and IgY. The IgA and IgM are similar to mammalian IgA and IgM. Chicken IgY is the

functional equivalent of IgG, the major serum antibody found in mammals, and makes up about 75% of the total antibody population (2). The serum concentrations of IgY, IgA, and IgM have been reported to be 5.0, 1.25, and 0.61 mg/mL, respectively (14). In mammals, the transfer of maternal antibodies can take place after birth, however, in the chicken, the maternal antibodies must be transferred to the developing embryo to give acquired immunity to the chick (5,7). Antibody, specifically IgA and IgM, is incorporated into the egg white during egg formation. Serum IgY is selectively transferred to the yolk via a receptor on the surface of the yolk membrane which is specific for IgY translocation (15,16). Morrison et al. (17) identified the regions within the IgY molecule which are important for its uptake and specific translocation into the yolk. Egg white contains IgA and IgM at concentrations of around 0.15 and 0.7 mg/mL, respectively, whereas the yolk may contain up to 25 mg/mL of IgY (18). Mammalian equivalents of IgE and IgD have not been identified in chickens (13).

21.2.2 Molecular Properties of IgY

21.2.2.1 Structure of IgY

The structure of IgY is significantly different from that of mammalian IgG (7), even though they share a similar function. IgY contains two heavy (H) and two light (L) chains and has a molecular mass of 180 kDa, larger than that of mammalian IgG (159 kDa). IgY also possesses a larger molecular weight H chain (68 kDa) as compared to that in mammals (50 kDa). The H chain of IgG consists of four domains: the variable domain (V_H) and three constant domains (Cγ1, Cγ2 and Cγ3). The Cγ1 domain is separated from Cγ2 by a hinge region, which gives flexibility to the Fab fragments (the portion which contains the antigen binding activity). In contrast, the H chain of IgY does not have a hinge region, and possesses four constant domains (Cν1-Cν4) in addition to the variable domain (Figure 21.1). Sequence comparisons between IgG and IgY have shown that the Cγ2 and Cγ3 domains of IgG are closely related to the Cν3 and Cν4 domains of IgY; while the equivalent of the Cν2 domain is absent in the IgG chain, having been replaced by the hinge region (19). The content of β-sheet structure in the constant domains of IgY has been reported to be lower than that of IgG, and the flexibility between the Cν1 and Cν2 domains, corresponding to the hinge region of IgG, is less than that of IgG (20). Unlike IgG, IgY has two additional Cys residues, Cys331 and Cys 338, in the Cν2-Cν3 junction, which likely participate in the inter-ν chain disulfide linkages (19).

Both IgG and IgY are known to contain Asn linked oligosaccharides. However, the structures of oligosaccharides in IgY differ from those of any mammalian IgG, containing unusual monoglucosylated oligomannose-type oligosaccharides with $Glc_1Man_{7\text{-}9}GlcNAc_2$ structure (21,22).

Furthermore, the isoelectric point of IgY is lower than that of IgG (23), and it has been suggested that IgY is a more hydrophobic molecule than IgG (24). It also does not have the ability to precipitate multivalent antigens, except at high salt concentrations (25), possibly due to the steric hindrance caused by the closely aligned Fab arms. High salt concentrations may serve to release the Fab arms, thereby permitting precipitation (19).

21.2.2.2 Physicochemical Properties of IgY

IgY and IgG display differences in their stability when subjected to pH, heat, and proteolytic enzymes. Although the stability of both immunoglobulins is similar when subjected to alkaline conditions, IgY demonstrated much less stability than rabbit IgG to acid denaturation. Shimizu et al. (20,26) found that the activity of IgY was decreased by incubating at pH 3.5 or lower, and completely lost at pH 3. The rabbit IgG antibodies did not demonstrate

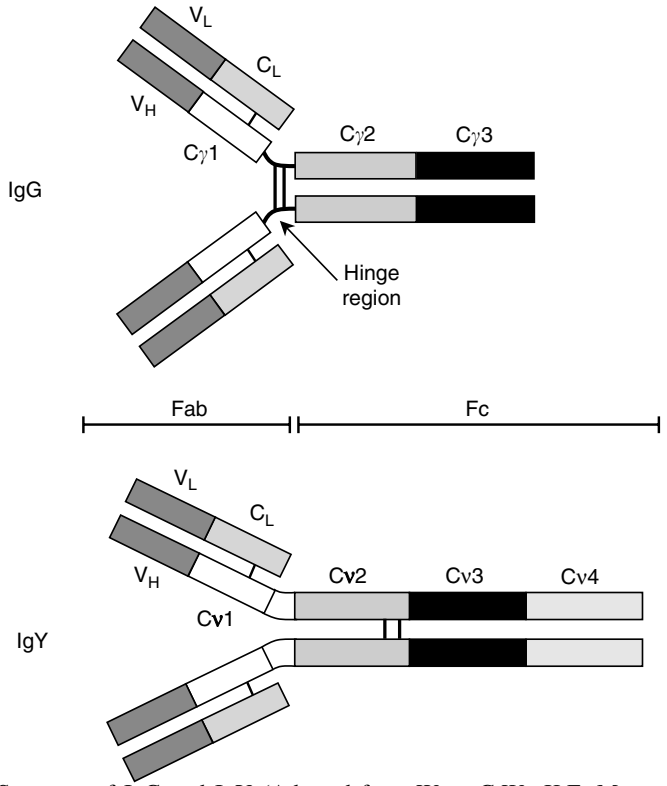

Figure 21.1 Structure of IgG and IgY (Adapted from Warr, G.W., K.E. Magor, D.A. Higgins, *Immunol. Today* 16:392–398, 1995.)

a loss of activity until the pH was decreased to 2, and even then some activity still remained. Similar results were also observed by Hatta et al. (27), using IgY produced against human rotavirus. The denaturing effects of acidic conditions on IgY were also found to be reduced by the addition of sucrose (28) or sorbitol (29). IgY is also more sensitive to heating than the rabbit IgG. Shimizu et al. (20) found that the activity of IgY was decreased by heating for 15 minutes at 70ºC or higher, whereas the activity of the IgG did not decrease until 75–80ºC or higher. The addition of stabilizers, such as sucrose, maltose, or glycerol to IgY preparations has been found to reduce the extent of thermal denaturation when heated at high temperatures (28,30). The addition of sugars may also increase IgY stability under various processing conditions, including high pressure (5000 kg/cm^2) (28) and freeze drying (31). It has also been observed that that IgY is more susceptible to digestion with proteolytic enzymes such as pepsin, trypsin, and chymotrypsin than IgG (32), but this will be discussed in more detail later.

Because immunoglobulins are large, complex molecules, the structural features causing the stability differences of the two immunoglobulins are unknown. Shimizu et al. (20) predicted that the lower content of β-structure in IgY may indicate that the conformation of IgY is more disordered, and therefore less stable, than mammalian IgG. The lack of a hinge region in IgY may be another factor affecting molecular stability. The lower flexibility of the Cv1 and Cv2 domains of IgY, as compared to the hinge region of IgG, may cause the rapid inactivation of the antibody by various treatments, because the flexibility of the hinge region is considered to influence the overall properties of immunoglobulin molecules (33).

21.2.3 Advantages of IgY

The production of polyclonal antibodies in chickens provides many advantages over the traditional method of producing antibodies in mammals (Table 21.1). The method of producing antibodies in hens is much less invasive, involving only the collection of eggs rather than blood, and is therefore less stressful to the animal (34). Animal care costs are also lower for chickens than for mammals such as rabbits (2). In contrast to mammalian serum, egg yolk contains only a single class of antibody, IgY, which can be easily purified from the yolk by precipitation techniques (35). The phylogenetic distance between chickens and mammals allows the production of antibodies in chickens against highly conserved mammalian proteins. This would not be possible in mammals, as demonstrated by Knecht et al. (36), who produced and compared antibodies against human dihydroorotate dehydrogenase in both rabbits and chickens. In contrast with mammalian systems, much less antigen is required to produce an efficient immune response in chickens (37), and sustained high titers reduce the need for frequent injections (35). Chicken antibodies will also recognize different epitopes than mammalian antibodies, giving access to a different antibody repertoire than with mammalian antibodies (7). Hens therefore provide a more hygienic, cost efficient, convenient, and plentiful source of antibodies, as compared to the traditional method of obtaining antibodies from mammalian serum (2,35).

In terms of safety, eggs are normal dietary components, so no risk of side effects from IgY consumption would be expected (2). In contrast to IgG, IgY does not activate mammalian complement or interact with mammalian Fc receptors that could mediate inflammatory response in the gastrointestinal tract (2). Even though IgY has been detected at low levels in the serum of calves and piglets after antibodies were orally administered, no absorption of intact antibodies has been shown in humans (2), so the risk of allergic reaction to purified IgY preparations would be expected to be low.

Nakai et al. (38) estimated that the productivity of antibodies in hens as nearly 18 times greater than that in rabbits based on the weight of antibody produced per head, which means that the use of hens can effect an overall reduction in animal use for the same level of antibody production (2). Because of the high yolk IgY concentrations, over 100 mg of IgY can be obtained from one egg (39). A laying hen produces approximately 20 eggs per month, therefore over 2 g of IgY per month may be obtained from a single chicken (7). Once purified, IgY has been found to be stable for years at 4°C (40). The large scale feeding, and automated collection and separation of eggs is a common practice (41), as is

Table 21.1

Comparison of the production and characteristics of IgG and IgY (Based on Schade, R., C. Pfister, R. Halatsch, P. Henklein. *ATLA* 19:403–419, 1991).

	Mammals (IgG)	**Chicken (IgY)**
Source of antibody	Blood serum	Egg yolk
Antibody sampling	Bleeding (invasive)	Egg collection (noninvasive)
Antibody amount	200 mg/bleed (40 ml blood)	50–100 mg/egg (5–7 eggs/week)
Amount of antibody per year	1400 mg	40 000 mg
Amount of specific antibody	~5%	2–10%
Protein A/G binding	Yes	No
Interference with rheumatoid factors	Yes	No
Activation of mammalian complement	Yes	No

vaccination of chicken flocks to control infections (42), making the large scale production and harvesting of antibodies in chicken eggs for therapeutic purposes quite feasible.

21.3 PASSIVE IMMUNIZATION WITH IGY

21.3.1 Immunotherapeutic Applications of IgY

Antibiotics have been widely used to treat infections. This method of treatment is being threatened by the growing numbers of immunosuppressed individuals, the emergence of new pathogens (including those which do not respond to antibiotics, such as viral pathogens), and the increasing resistance of organisms to antimicrobial drugs (43,44). This has prompted much research into the administration of specific antibodies as an alternative to antibiotics and antimicrobial chemotherapy to treat infections. Passive immunization also offers benefits in applications for which conventional vaccines may be less suitable, including providing immediate protection, controlled duration of activity, as well as selectivity of target organism (45).

The potential applications of IgY for the prevention and treatment of infections caused by pathogenic bacteria and viruses have been studied at length (Table 21.2).

21.3.1.1 Rotavirus

Human rotavirus (HRV) has been identified as the major causative agent of acute infantile gastroenteritis (46), infecting up to 90% of children under the age of three, and resulting in more than 600 000 deaths annually (47). Human rotavirus causes a shortening and atrophy of the villi of the small intestine (46), resulting in decreased water absorption, leading to severe diarrhea and vomiting and eventually death due to dehydration (48,49). Yolken et al. (3) found that orally administered antibodies isolated from the eggs of chickens immunized with three different serotypes of rotavirus (mouse, human, and monkey) were capable of preventing rotavirus induced diarrhea in mice infected with murine rotavirus, whereas IgY isolated from the eggs of unimmunized chickens failed to prevent rotavirus infection. Using an HRV infection model in suckling mice, Hatta et al. (27) reported that antiHRV IgY decreased the incidence of rotavirus induced diarrhea in mice, both when administered before and after HRV challenge, suggesting its use for both therapeutic and prophylactic applications. Similarly, Ebina (50) also observed the prevention of HRV induced symptoms in mice using antiHRV IgY. The production of specific IgY against recombinant HRV coat protein VP8*, a cleavage product of the rotavirus spike protein VP4 has been reported (51). VP4 has been implicated in several important functions, including cell attachment and penetration, hemagglutination, neutralization, and virulence (52–54). VP8 has been found to play a significant role in viral infectivity and neutralization of the virus. Kovacs-Nolan et al. (51) immunized chickens with recombinant VP8*, and found that the resulting antiVP8* IgY exhibited significant neutralizing activity against the Wa strain of HRV *in vitro*, indicating that antiVP8* IgY may be used for the prevention and treatment of HRV infection. The oral administration of antiHRV egg yolk to children infected with HRV resulted in a modest improvement in symptoms, but further studies are required (55).

Neonatal calf diarrhea caused by bovine rotavirus (BRV) is a significant cause of mortality in cattle (56). The passive protection of calves against BRV infection, using antiBRV IgY, has also been demonstrated (57).

21.3.1.2 Escherichia coli

Diarrhea due to enterotoxigenic *Escherichia coli* (ETEC) is a major health problem in humans and animals. ETEC is the most common cause of enteric colibacillosis encountered

Table 21.2
Specific IgY against various bacterial and viral antigens.

Pathogen	Effect of IgY	Ref.
Rotavirus	Prevented murine rotavirus in mice	3
	Prevented HRV-induced gastroenteritis in mice	27, 50
	Prevented HRV infection *in vitro*, using IgY against recombinant subunit protein VP8	51
	Protected calves from BRV-induced diarrhea	57
	Improved HRV-associated symptoms in children	55
Escherichia coli	Prevented K88+, K99+, 987P+ ETEC infection in neonatal piglets	63, 65
	Inhibited adhesion of ETEC K88 to piglet intestinal mucosa, *in vitro*	64
	Inhibited attachment of F18+ *E. coli* to porcine intestinal mucosa *in vitro*, and reduced diarrheal cases in infected piglets	66
	Protected neonatal calves from fatal enteric colibacillosis	67
	Prevented diarrhea in rabbits challenged with ETEC	68
	Inhibited growth of *E. coli* and colonization of cells by EPEC, using IgY against BfpA	69
	Protection of chickens against APEC-associated respiratory disease	70
Salmonella spp.	Inhibited SE and ST growth *in vitro*	72
	Inhibited adhesion of SE to human intestinal cells *in vitro*	73
	Protected mice challenged with SE or ST from experimental salmonellosis, using IgY against OMP, LPS and Fla	75, 81
	Protected mice challenged with SE from experimental salmonellosis, using IgY against SEF14	82
	Prevented fatal salmonellosis in neonatal calves exposed to ST or S. Dublin	83
Pseudomonas aeruginosa	Prevented pathogensis of *P. aeruginosa in vitro*	85
	Inhibited *P. aeruginosa* adhesion to epithelial cells *in vitro*	86
	Prolonged time before *P. aeruginosa* re-colonization, and prevented chronic infection in CF patients	84, 87
	Anti-*P. aeruginosa* IgY stable in saliva for 8 hrs	88
Streptococcus mutans	Reduced caries development in rats	91
	Prevented *S. mutans* adhesion *in vitro*, and *in vivo* in humans	93
	Prevented *S. mutans* accumulation and reduction of caries in rats using IgY against *S. mutans* GBP	94
	Reduced caries incidence in desalivated rats, using IgY against Gtf	89
Helicobacter pylori	Inhibited growth of *H. pylori* and reduced binding to human gastric cells, *in vitro*	97, 98
	Decreased gastric mucosal injury and inflammation in a gerbil model of *H. pylori*-induced gastritis	97, 98
Bovine coronavirus	Protected neonatal calves from BCV-induced diarrhea	101
Yersinia ruckeri	Protected rainbow trout against *Y. ruckeri* infection	103

(*Continued*)

Table 21.2 (*Continued*)

Pathogen	Effect of IgY	Ref.
Edwardsiella tarda	Prevented Edwardsiellosis in Japanese eels infected with *E. tarda*	104
Staphylococcus aureus	Inhibited production of *Staphylococcus aureus* enterotoxin-A	85
IBDV	Protected chicks from infectious bursal disease virus	106
PEDV	Protected piglets against porcine epidemic diarrhea virus	107
Cryptosporidium	Prevented cryptosporidiosis in mice	108

in children in developing countries and travelers to these countries, accounting for one billion diarrheal episodes annually (58). It is also a problem in neonatal calves (59) and piglets (60), causing significant economic losses to the pig industry from both mortality and reduced growth rates, killing 1.5–2.0% of weaned pigs (61).

The strains of ETEC which are associated with intestinal colonization and cause severe diarrhea are the K88, K99, and 987P fimbrial adhesins (62). The production of IgY against these fimbrial antigens has been described and was found to inhibit the binding of *E. coli* K88+, K99+, and 987P+ strains to porcine epithelial cells (63) and to porcine intestinal mucus (64), *in vitro*. The antifimbrial IgY was also found to protect piglets against infection with each of the three strains of *E. coli* in a dose dependent manner in passive immunization trials (63). In another feeding study, 21 day old pigs were challenged with ETEC. AntiK88 IgY was administered to the piglets in milk three times a day for 2 days. Control piglets developed severe diarrhea within 12 hrs and 30% of the pigs died. In contrast, the pigs that were fed IgY exhibited no signs of diarrhea 24 or 48 hrs after treatment (65). Imberechts et al. (66) produced IgY against *E.coli* F18ac fimbriae, and found that the IgY inhibited attachment of F18ac+ *E. coli* to porcine intestinal mucosa *in vitro*, and decreased incidences of diarrhea and death in animals infected with F18ac+ *E. coli*.

The passive protective effect of antiETEC IgY against fatal enteric colibacillosis in neonatal calves has also been examined (67). Calves fed milk containing IgY had only transient diarrhea, 100% survival and good body weight gain. O'Farrelly et al. (68) reported the use of IgY for the prevention of diarrhea in rabbits through the oral administration of antiETEC IgY. The use of IgY against enteropathogenic *E. coli* (EPEC), another major cause of childhood diarrhea, has also been examined. de Almeida et al. (69) produced IgY against a recombinant EPEC protein (BfpA), one of the factors required for EPEC pathogenesis, and found that the antiBfpA antibodies were capable of inhibiting the colonization of cells by EPEC, as well as inhibiting *E. coli* growth *in vitro*. Finally, IgY has also been suggested for the passive protection of chickens against respiratory disease caused by avian pathogenic *E. coli* (APEC) (70).

Because anti*E. coli* IgY has been shown to inhibit binding of *E. coli* both *in vitro* and *in vivo*, the clinical application of IgY for the passive protection against *E. coli* related diarrhea in humans is now being examined.

21.3.1.3 Salmonella species

Salmonella species are a significant cause of food poisoning, and it is estimated that 2 to 4 million cases of salmonellosis occur in the U.S. annually (71). Symptoms include fever, abdominal pain, headache, malaise, lethargy, skin rash, constipation, and changes in mental state. However, infants, the elderly, and immunocompromised individuals may develop more severe symptoms. In these cases, the infection may spread from the intestines to the blood

stream and to other sites in the body, and can cause death. *Salmonella enteritidis* (SE) and *Salmonella typhimurium* (ST), in particular, are the major agents of salmonellosis (71).

Lee et al. (72) found that IgY against SE and ST was capable of inhibiting the growth of SE and ST *in vitro* when added to culture medium. They also suggested that the IgY bound to antigens expressed on the *Salmonella* surface, resulting in structural alterations on the bacterial cell. AntiSE IgY was also found to inhibit the adhesion of SE to human intestinal cells *in vitro* (73).

Salmonella has several surface components which are virulence related, including outer membrane protein (OMP) (74,75), lipopolysaccharides (LPS) (76,77), flagella (Fla), and in some strains fimbrial antigens (78,79). OMP is involved in pathogenicity determination (80), and has been used successfully for vaccine applications in both active and passive immunization studies (74,75). Lipopolysaccharides have also been shown to be highly immunogenic, producing large amounts of LPS specific IgY, and have demonstrated potential application for the inhibition of *Salmonella* adhesion (76,77). The ability of antiOMP, antiLPS or antiflagella (Fla) IgY to passively protect mice against experimental salmonellosis was examined. In mice challenged with SE, administration of specific IgY resulted in a survival rate of 80% (OMP specific IgY), 47% (LPS specific IgY), and 60% (Fla specific IgY), compared to only 20% in control mice. In the case of ST, the survival rate was 40%, 30%, and 20% using OMP, LPS or Fla specific IgY, while none of the control mice survived (81). A novel fimbrial antigen, SEF14, produced primarily by SE and *S. dublin* strains, has been described (82). Mice challenged with SE and treated with antiSEF14 IgY had a survival rate of 77.8%, compared to a 32% survival rate in the control mice.

Salmonella infection in calves is also a worldwide problem, with ST and *S. dublin* accounting for most salmonellosis within the first 2 weeks after birth. The passive protective effect of IgY was investigated by orally inoculating calves with SE or *S. dublin*, and administering IgY against SE or *S. dublin* orally 3 times a day for 7 to 10 days after challenge. All control calves died within 7–10 days. Calves given a low titer dose of IgY displayed 60–70% mortality, and calves treated with a high titer dose of IgY had only fever and diarrhea (83).

21.3.1.4 Pseudomonas aeruginosa

Cystic fibrosis (CF) is the most common fatal genetic disease in Caucasians. Colonization of the airways of CF patients by *Pseudomonas aeruginosa* (PA) is the main cause of morbidity and mortality, and once a chronic infection has been established it is very difficult to eliminate, even with the use of antibiotics (84).

It has been shown that specific IgY is capable of preventing the pathogenesis of PA (85). Carlander et al. (86) found that IgY raised against PA was capable of inhibiting adhesion of PA to epithelial cells *in vitro*, but did not inhibit bacterial growth, suggesting that specific IgY might be capable of interfering with the bacterial infection process and prevent colonization in CF patients.

In vivo studies with CF patients have demonstrated that antiPA IgY, when administered orally to CF patients on a continuous basis in the form of a mouth rinse, is capable of preventing, or prolonging the time before, PA recolonization (84,87). Kollberg et al. (84) found that the antiPA IgY prevented recolonization in 40% of CF patients, compared to only 14% with no recolonization in the control (untreated) group. As well, none of the IgY treated patients became chronically colonized with PA, in contrast to recolonization in 24% of the control patients. These results indicate that antiPA IgY may reduce the need for antibiotic treatment of CF patients.

The stability of antiPA IgY in saliva from healthy individuals, following a mouth rinse with an aqueous IgY solution, was examined (88). Antibody activity in the saliva

remained after 8 hours. After 24 hours, the antibody activity had decreased significantly, but was still detectable in some subjects, suggesting the use of specific IgY for the treatment of various local infections, such as the common cold, and tonsillitis.

21.3.1.5 Streptococcus mutans

The role of *Streptococcus mutans* in the development of dental caries is well recognized (89). The molecular pathogenesis of *S. mutans* associated dental caries involves a series of binding events that eventually lead to the accumulation of sufficient numbers of these cariogenic bacteria to cause disease (90). IgY against *S. mutans* MT8148 or cell associated glucosyltransferases (CA-Gtf), one of the major virulence factors in the pathogenesis of dental caries (89), was prepared and tested against dental caries (91,92). Consumption of a cariogenic diet which contained more than 2% IgY containing yolk powder resulted in significantly lower caries scores (91), and effective passive protection against the colonization of *S. mutans* in the oral cavity, in a rat model of dental caries. It has also been reported that mouth rinse containing IgY specific to *S. mutans* was effective in preventing the dental plaque of humans *in vitro* and *in vivo* (93). Krüger et al. (89) found that the incidence of caries in desalivated rats fed antiCA-Gtf IgY was decreased in severity and number, indicating that IgY may be effective as prophylaxis for high caries risk patients.

Glucan-binding proteins (GBPs) are believed to be involved in *S. mutans* biofilm development, and antibodies against GBP-B appear to have the potential to modulate infection and disease caused by *S. mutans* (94). Smith et al. (94) found that rats treated with antiGBP-B IgY displayed a decrease in *S. mutans* accumulation, as well as a decrease in the overall amount of dental caries, as compared to control rats.

21.3.1.6 Helicobacter pylori

Helicobacter pylori is the most common cause of gastritis and gastric ulcers, and has been implicated in the development of gastric carcinomas. Around 25–50% of the population carry *H. pylori*, and this number is higher in developing countries (95). Antibiotic therapy is often employed to treat *H. pylori* infection, but this therapy is often undesirable due to increasing medical costs, low eradication rate, and the development of antibiotic resistant strains (29,96).

Anti*H. pylori* IgY was shown by Shin et al. (97) to significantly inhibit the growth of *H. pylori, in vitro*, and inhibit urease activity (a critical virulence factor), as well as reduce the binding of *H. pylori* to human gastric cells. The oral administration of specific IgY decreased gastric mucosal injury and inflammation *in vivo*, using a gerbil model of *H. pylori* induced gastritis (97,98), suggesting the use of anti*H. pylori* antibodies for the treatment of *H. pylori* associated gastric diseases.

Immunodominant *H. pylori* proteins were also identified, and used to produce highly specific anti*H. pylori* and antiurease IgY, to address concerns that antibodies produced against whole cell *H. pylori* might cross react with other bacteria, including normal human flora (96,99).

21.3.1.7 Coronavirus

Bovine coronavirus (BCV) is an important cause of neonatal calf diarrhea and acute diarrhea in adult cattle (100). Ikemori et al. (101) examined the protective effect of antiBCV antibodies in egg yolk in calves challenged with BCV. They found that control calves which received no antibodies experienced severe diarrhea and died within 6 days after infection. Calves fed milk containing egg yolk, however, all survived and had positive

weight gain. The results indicate that orally administered egg yolk antibodies are capable of passively protecting calves against BCV infection.

21.3.1.8 Fish Pathogens

Yersinia ruckeri is the causative agent of enteric redmouth disease, a systemic bacterial septicemia, in salmonid fish (102). The persistence of *Y. ruckeri* in carrier fish for long periods and the shedding of bacteria in feces can present a continuing source of infection. The clearance of *Y. ruckeri* from carrier fish by orally administered anti*Y. ruckeri* antibody would provide a cost effective alternative to slaughtering fish which pose a health risk. The passive immunization of rainbow trout (*Oncorhynchus mykiss)* against *Y. ruckeri* infection has been examined (103). Groups of rainbow trout fed anti*Y. ruckeri* IgY prior to being challenged with *Y. ruckeri* had lower mortalities compared with fish receiving normal feed. The group fed IgY also appeared to have a lower number of infected fish, based on organ and intestine culture. The number of IgY fed fish carrying *Y. ruckeri* in intestine samples also appeared to be lower than the normal feed controls, regardless of whether the feeding was given before or after the challenge. The oral administration of specific IgY against fish pathogens could provide an alternative to the use of antibiotics and chemotherapy for prevention of bacterial diseases in fish farms, and would provide a novel approach for the prevention of viral infections in fish, as no medicine has been reported to be effective.

Edwardsiella tarda, another important fish pathogen, is spread by infection through the intestinal mucosa. Edwardsiellosis in Japanese eels is a serious problem for the eel farming industry, and egg yolk antibodies have been investigated for the prevention of this infectious disease, as treatment with antibiotics has been found to promote the growth of bacteria resistant strains (104). Eels were challenged with *E. tarda*, and anti*E. tarda* IgY was orally administered. Infected eels died within 15 days, whereas the eels given IgY survived without any symptoms of *E. tarda* infection (104,105).

21.3.1.9 Others

In addition, specific IgY has been shown to be effective at preventing and treating several other pathogens. Sugita-Konishi et al. (85) found that specific IgY was capable of inhibiting the production of *Staphylococcus aureus* enterotoxin-A *in vitro*. Its use has also been suggested for the passive protection of chicks against infectious bursal disease virus (IBDV) (106), for the protection against porcine epidemic virus (PEDV) in piglets (107), and for the prevention of cryptosporidiosis due to *Cryptosporidium* infection (108). Finally, IgY against *Bordetella bronchiseptica*, *Pasteurella multocida*, and *Actinobacillus pleuropneumoniae*, causative agents of swine respiratory diseases, has been proposed as an alternative method to control infectious respiratory diseases in pigs (109,110).

21.4 ANTIBODY STABILITY

21.4.1 Physiology of the Gastrointestinal Tract

The human gastrointestinal tract consists of the stomach, small intestine (which is divided into the duodenum, jejunum, and ileum), and the large intestine (111). Ingested proteins are subjected to denaturation by the acidic pH of the stomach, as well as to degradation by the proteolytic enzymes present in the stomach and small intestine (112).

The pH of the stomach ranges from 1 to 3.5 due to secretion of hydrochloric acid by the parietal cells (112–114). In neonates, however, the gastric fluid has a pH near neutral, which rapidly decreases to a pH below 3 within the first few days after birth (2). In both

infants and adults, the pH of the gastric fluid will rapidly rise to about 4 or 5 soon after food reaches the stomach (111), but will return to low pH, occurring much more slowly in infants than in adults (115). It is in the stomach that proteins are subjected to digestion by pepsin, which is secreted by chief cells (116). Pepsin is optimally active at pH 1.8 to 3.5 (111), but will start to lose activity around pH 4 and is completely inactivated in alkaline conditions (111,117). The digestive activity of pepsin is terminated when the gastric contents are mixed with alkaline pancreatic juice in the small intestine (116). The extent of gastric protein digestion is determined by the physical state of the ingested protein, the activity of the pepsin in the gastric juice, and the length of time it stays in the stomach (111). The transit time in the stomach has been found to vary considerably, and has been reported to range from 0.5 to 4.5 (112,118), with a median time of 1 to 1.5 hours (114,118).

Trypsin and chymotrypsin continue digestion in the small intestine, where the pH ranges from around pH 6 to 7.4 (113,114). Transit through the small intestine has been reported to take from 1 to 4 hours (119), but may be as high as 7.5 hours (114). The pH rises to around 7.5 to 8 in the large intestine, where the transit time can be as long as 17 hours (112,114).

Along with the duration of exposure in each of the segments of the gastrointestinal tract, the ratio of enzyme to protein will also determine to what extent a protein is degraded (112).

21.4.2 Degradation and Stability of IgY

Several investigations have been carried out *in vitro* to study the effects of gastrointestinal enzymes and pH on the structure and activity of IgY, in order to predict its fate when administered orally (112). Antibodies were tested with pepsin at pH 2 to 4, and trypsin and chymotrypsin at a pH around neutral, simulating passage through the stomach and small intestine.

IgY has been found to be relatively resistant to trypsin and chymotrypsin digestion, but sensitive to pepsin digestion (120). It has, however, been found to be more susceptible to pepsin, trypsin, and chymotrypsin digestion than IgG (26,32). Using IgY raised against HRV, Hatta et al. (27) demonstrated that almost all of the IgY activity was lost following digestion with pepsin, but activity remained even after 8 hours incubation with trypsin or chymotrypsin. They found that digestion of IgY with pepsin at pH 2 resulted in complete hydrolysis of the antibody molecule, leaving only small peptides, however IgY digested with pepsin at pH 4 retained some of its activity, with heavy (H) and light (L) chains still present, along with smaller peptides. Shimizu et al. (120) also obtained similar results following the digestion of IgY against *Escherichia coli* with gastrointestinal enzymes.

In vivo results have also yielded similar results. Ikemori et al. (121) described the feeding of anti*E.coli* IgY to calves, and found that the activity of the antibodies was decreased significantly following passage through the stomach. Similarly, the feeding of specific IgY, also against *E. coli*, was carried out by Yokoyama et al. (122) using pigs. The morphology and physiology of the gastrointestinal tract of pigs has been found to be similar to that of humans, and therefore pigs represent a good animal model to study digestion in humans (123). Using piglets of varying ages, from 10 hours (neonatal) to 28 days old, it was observed that the IgY was degraded upon passage through the gastrointestinal tract, with some intact IgY detected in the intestine of neonatal pigs but to a lesser extent in the older pigs, possibly reflecting the increasing gastrointestinal maturity of the pigs.

Methods of encapsulating IgY, to provide resistance to the proteolytic and denaturing conditions of the stomach have been examined. Shimizu et al. (124) encapsulated IgY using lecithin or cholesterol liposomes, and found that the stability of the antibodies to *in vitro* gastric conditions was increased. Encapsulation of IgY in a water in oil in water (W/O/W) emulsion was examined by Shimizu and Nakane (125), who found that the antibody activity

was significantly reduced by encapsulation alone, suggesting that denaturation of the IgY was occurring at the oil to water interface. Ikemori et al. (121) treated anti*E. coli* IgY with hydroxypropyl methylcellulose phthalate, an enteric coating substance used for drugs, and examined its activity following passage through the gastrointestinal tract of calves. They found that although the activity of the encapsulated IgY was decreased, it was not decreased to the same extent as the nonencapsulated antibodies. This research would indicate that the successful encapsulation of IgY would be an effective means for protecting IgY under gastric conditions.

21.5 BIOTECHNOLOGY OF AVIAN EGG ANTIBODIES

As demonstrated, the chicken is a useful animal for the production of specific antibodies for immunotherapeutic purposes. The many advantageous characteristics of IgY also make it ideal for use in diagnostic applications, where monoclonal antibodies have traditionally been used. Hybridomas can be cloned and grown in large quantity for indefinite periods of time, secreting high concentrations of monoclonal antibodies. The production of monoclonal IgY has also been examined, generated through the fusion of spleen cells from immunized chickens with chicken B cells, to produce monoclonal IgY-secreting hybridomas (126–131). These cells are capable of providing a consistent supply of antibody with a single and known specificity and homogeneous structure (1). Several researchers have described the production of single chain fragment variable region (scFv) monoclonal IgY via recombinant DNA technology (132–134), in order to improve upon the low levels of antibodies produced in the chicken hybridoma systems (133). Using RNA extracted from chicken hybridoma cells, Kim et al. (134) were able to express recombinant monoclonal IgY in *E. coli* and reported the production of 5–6 mg of IgY per litre of culture, suggesting that the production of monoclonal IgY on a large scale may be possible. Lillehoj and Sasaki (128) and Kim et al. (134) produced monoclonal IgY against *Eimeria* species, an intracellular parasite responsible for avian coccidiosis, in order to study the avian immune response to this parasite and to aid in vaccine development, as it was thought that monoclonal antibodies from mice would not adequately reflect the avian immune response due to the differences in antibody repertoire. Given that it is possible to produce antibodies against a vast array of antigens and epitopes using chickens, antibodies against any number of bacterial, viral, or biological antigens could be produced, suggesting the significant potential of avian antibodies for further use in immunodiagnostics and identification of disease markers, immunotherapy, and the treatment and prevention of disease, as well as affinity purification methods. Research is being continued to develop potential methods of production and application of egg yolk antibodies. Romito et al. (135) suggested the immunization of chickens with naked DNA, to elicit antigen specific IgY. Using DNA rather than a protein antigen could eliminate the protein expression and purification steps, and would allow the production of antibodies against pathogenic or toxic antigens. Not only are chickens useful for the production of specific IgY, but Mohammed et al. (136) demonstrated the deposition of recombinant human antibodies into the egg yolk of transgenic chickens, suggesting an extension of the production of specific IgY in eggs.

Application of Transgenic Fish Technology in Sea Food Production

Pinwen Peter Chiou, Jenny Khoo, and Thomas T. Chen

CONTENTS

22.1 INTRODUCTION

Fish into which a foreign gene or noncoding DNA fragment is artificially introduced and integrated into their genomes are called *transgenic fish*. Since 1985, a wide range of transgenic fish species have been produced mainly by microinjecting or electroporating homologous or heterologous transgenes into newly fertilized or unfertilized eggs, and sometimes sperm (11,21,27). To produce a desired transgenic fish, several factors should be considered. First, an appropriate fish species must be chosen. This decision would depend on the

nature of each study and the availability of the fish holding facility. Second, a specific gene construct must be designed based on the special requirements of each study. For example, the gene construct may contain an open reading frame encoding a gene product of interest, and regulatory elements that regulate the expression of the gene in a temporal, spatial, or developmental manner, or some combination of the three. Third, the gene construct has to be introduced into sperm or embryos in order for the transgene to be integrated stably into the genome of the embryonic cells. Fourth, because not all instances of gene transfer are efficient, a screening method must be adopted for identifying transgenic individuals.

Since the development of the first transgenic fish in the mid 1980s, techniques to produce transgenic fish have improved tremendously, resulting in the production of many genetically modified (GM) fish species. In recent years, transgenic fish have been established as valuable models for different disciplines in biological research as well as human disease modeling. In addition, the application of transgenic fish technology to produce fish with beneficial traits, such as enhanced somatic growth and disease resistance, is also rising. In this chapter, we will review the progress of transgenic fish technology and its biotechnological applications.

22.2 METHODS OF TRANSGENIC FISH PRODUCTION

22.2.1 Types of Transgene Constructs

A transgene is a piece of nonself origin gene or DNA fragment that is introduced into fish for the production of transgenic fish. Transgenes are usually constructed in plasmids that contain appropriate promoter or enhancer elements for proper expression of transgenes in fish. A variety of promoters from nonfish species have been employed to control the expression of transgenes in fish (Table 22.1). Additionally, increasing number of fish promoters (Table 22.1) are available for the purpose of generating "all fish" expression cas-

Table 22.1
Examples of Promoters Used in Production of Transgenic Fish

	Origin Species	Promoter
Non-fish Origin:		
	Rat	GAP43[a] (Udvadia et al., 2001)
	Chicken	β-actin (Lu et al., 1992)
	Xenopus	elongation factor 1α (Amsterdam et al., 1995)
	Cytomegalovirus	CMV intermediate-early (Sarmasik et al., 2002)
	Moloney murine leukemia virus	MoMLV LTR (Lu et al., 1994)
Fish Origin:		
	Carp	β-actin (Lu et al., 2002)
	Goldfish	α1 tubulin[a] (Goldman et al., 2001)
	Medaka	elongation factor 1α (Wakamatsu et al. 2001a), β-actin (Hsiao et al., 2001)
	Zebrafish	H2A.F/Z (Pauls et al., 2001), α-actin[a] (Higashijima et al., 1997), heat shock protein 70[b] (Halloran et al., 2000)

[a]tissue-specific promoters- GAP43: nervous system; α1 tubulin: nervous system; α-actin: muscle (see Table 22.3 for more examples)
[b]Inducible promoters; LTR: long terminal repeat; H2A.F/Z: histone H2A.F/Z

settes, among which is the carp β-actin promoter, which has been shown to drive strong expression of transgenes in various fish cell types. Tissue specific promoters and inducible promoters such as zebra fish *heat shock protein 70* (*hsp70*) have also been used successfully to control the expression of transgenes in the intended tissue at the desired time. For example, activation of an *hsp70*-controlled transgene can be achieved by heat shock ;and, intriguingly, by focusing a sublethal laser microbeam onto individual cells that carry the transgene (28). The targeted cells appear normal after the treatment.

Depending on the purpose of the gene transfer studies, transgenes can be grouped into three major types: gain-of-function, reporter-function, and loss-of-function. The basic organization and the function of these transgenes are discussed below.

Gain-of-function transgenes are designed to add new functions to the transgenic individuals or to facilitate the identification of the transgenic individuals if the genes are expressed properly. The coding regions of the transgenes are usually homologous or heterologous genomic or cDNA sequences which encode polypeptide products (Figure 22.1A). The expression of the transgenes is usually driven by promoter or enhancer sequences of homologous or heterologous sources. If the transgenes contain functional signal peptide sequences, the gene products will be secreted out of the cells once they are synthesized. Transgenes containing the structural gene of mammalian or fish growth hormones (GH), or the respective cDNA fused to a functional promoter or enhancer of chicken or fish β-actin gene are examples of the gain-of-function transgene constructs. Expression of such transgenes in transgenic individuals has been shown to result in growth enhancement (12,16,52,84). Winter flounder antifreeze protein gene and chicken δ-crystalline gene, with their own promoter or enhancer sequences, are other commonly used gain-of-function transgenes used in various gene transfer studies (59,70).

Genes such as bacterial chloramphenicol acetyltransferase (CAT), β-galactosidase (β-gal), neomycin phosphotransferase II (neo^R), luciferase, and green fluorescent protein (GFP), are frequently used to produce gene construct with reporter-functions. These reporter genes serve as a convenient marker for indicating the success of gene transfer into the target cells, because the translational products of these genes can be easily monitored. Furthermore, because these gene products can be measured quantitatively, they are also routinely adopted for identifying the sequence of an undefined promoter or enhancer or measuring the relative activity of a promoter or enhancer element in question. A less frequently used reporter type is the one with target specificity. One such example is cameleon, a fluorescent calcium sensor, which was originally used to detect calcium transients in culture cells and pharyngeal muscle of *Caenorhabditis elegans*. Recently, cameleon and several other indicator genes have been used to establish transgenic zebra fish for monitoring neuronal activity (32). The prototypes of a reporter-function transgene are shown in Figure 22.1B.

Among the commonly used reporters, the jellyfish (*Aequorea victoria*) GFP and its variants have become the choice markers for transgenic fish because the detection of GFP signal is direct and easy, requiring no exogenous substrate (2). There are numerous GFP variants available, including those producing green, blue, and yellow fluorescence light. Together with the red fluorescence protein (RFP), these reporters can be easily detected in live transgenic fish such as zebra fish and medaka, whose embryos and body are transparent, without the need to sacrifice the fish (2,30). Additionally, these reporters can be used to study multiple transgenes simultaneously in the same fish. Since the first GFP transgenic fish in 1995 (2), GFP tagged transgenic embryos and fish have become the most convenient and widely used tools in basic biological research, particularly in the regulation of gene expression and morphogenetic movements during embryonic development. In many cases, similar applications can be achieved with the other reporter genes mentioned above. However, the detection of these reporters is indirect and involves in additional steps

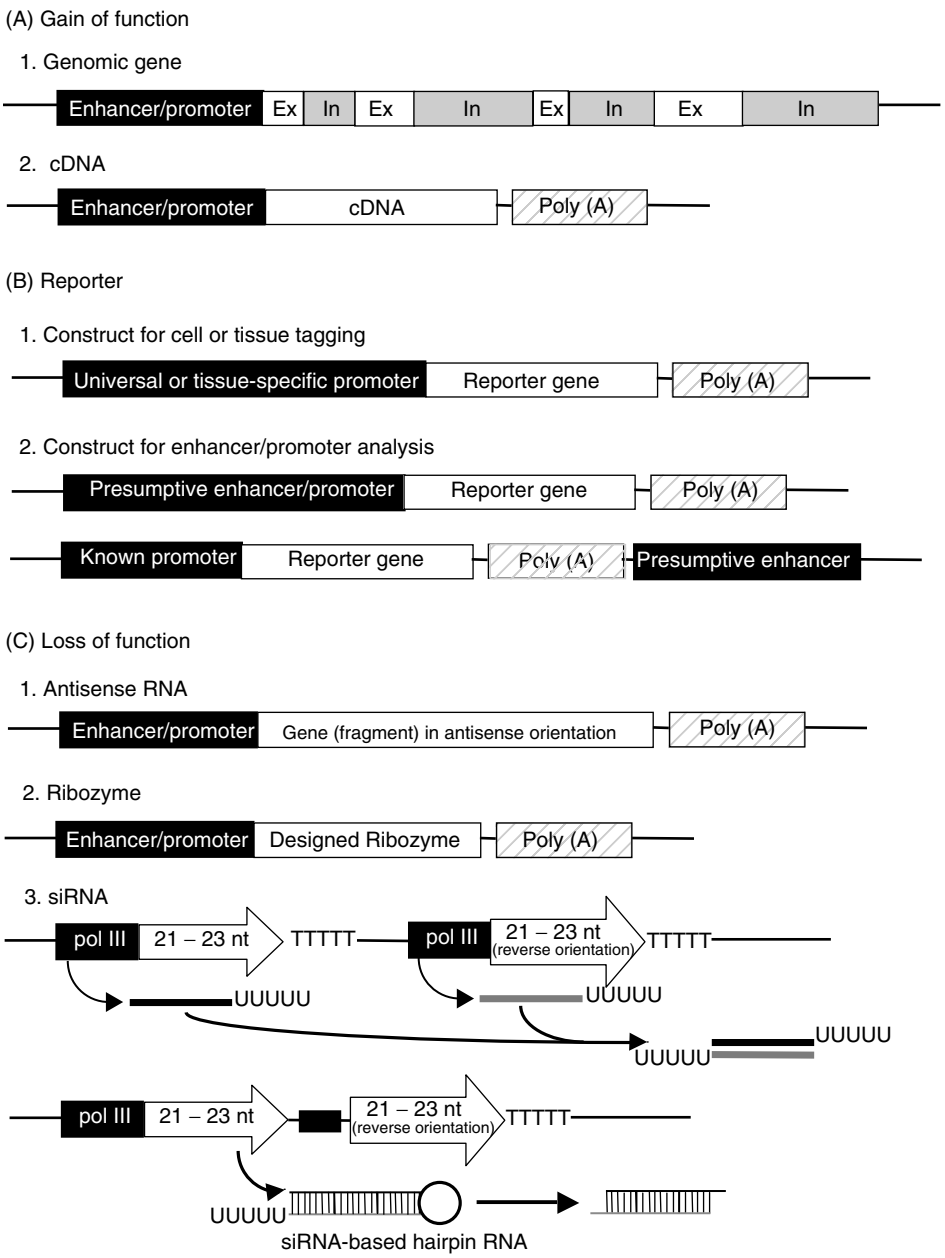

Figure 22.1 Prototypes of transgenes for fish transgenesis. Depending on the experimental purpose, the promoter used in the transgene construct can be either constitutive or inducible one. Ex: exon; In: intron; pol III: RNA polymerase III promoters.

such as enzymatic reaction with substrate and immunohistochemical staining with specific antibody to the reporter.

The loss-of-function transgenes are constructed for interfering with the expression of host genes at the transcriptional or translational level. Mechanistically, there are at least three groups of loss-of-function transgenes. The transgenes might encode antisense RNA or oligonucleotides that selectively hybridize to a target endogenous mRNA, resulting in

degradation of the mRNA by RNase H, or interference with translation of the mRNAs via preventing the binding of ribosomes to mRNA. A variation of the antisense RNA approach is to introduce a group of chemically modified oligonucleotides known as morpholino phosphorodiamidate oligonucleotides (MOs) into fish embryos. In contrast to ordinary antisense molecules, MOs exhibit long term stability with less toxicity to living cells, and appear to function through translation blockage only. The second group of loss-of-function transgenes is catalytic RNA (ribozymes) that can cleave specific target mRNA at a specific site and thereby "knock down" the normal gene expression (14). The most recent development of the loss-of-function transgenes is to introduce a group of small RNAs known as small (short) interfering RNAs (siRNA) into cells. siRNA will guide a ribonuclease known as RISC (the RNA-induced silencing complex) to recognize mRNA containing a sequence homologous to the siRNA, resulting in degradation of the mRNA by the ribonuclease (19). The prototype of loss-of-function transgenes is shown in Figure 22.1C. Although there is currently no report of stable lines of transgenic fish carrying this type of transgenes, the feasibility of this approach in silencing genes has been demonstrated in numerous fish cell lines *in vitro*. Moreover, many recent studies also prove that MOs and siRNA molecules can silence their targets specifically and effectively when introduced into fish embryos, such as zebra fish, medaka, and rainbow trout (4,5,53).

22.2.2 Selection of Fish Species

Gene transfer studies have been conducted in several different fish species such as salmon, rainbow trout, common carp, goldfish, loach, channel catfish, tilapia, northern pike, walleye, zebra fish, and Japanese medaka (11,21,27). Depending on the purpose of the transgenic fish studies, the embryos of some fish species prove to be more suitable than others. In selecting a fish species for gene transfer studies, a series of parameters are considered. These parameters are: (1) length of the life cycle; (2) year round supply of eggs and sperm; (3) culture conditions; (4) size of the adult at maturity; and (5) availability of background information on genetics, physiology, and endocrinology of the fish species.

Japanese medaka (*Oryzias latipes*) and zebra fish (*Danio rerio*) are regarded as ideal fish species for conducting gene transfer studies. Both fish species have short life cycles (3 months from eggs to mature adults), produce hundreds of eggs on a regular basis without exhibiting a seasonal breeding cycle, and can be maintained easily in the laboratory for two to three years. Their eggs are relatively large, 1.0–1.5 mm in diameter, and possess very thin and semitransparent chorions. These features allow easy microinjection of DNA into the eggs if appropriate glass needles are used. Furthermore, inbred lines and various morphological mutants of both fish species are available. These fish species are suitable candidates for producing transgenic fish for: (1) studying developmental regulation of gene expression and gene action; (2) identifying regulatory elements that regulate the expression of a gene; (3) measuring the activities of promoters; and (4) producing transgenic models for human diseases and environmental toxicology. However, a major drawback of these two fish species is that their small body size makes them unsuitable for endocrinological or biochemical analysis.

The handicap of using small body size fish species such as medaka or zebra fish in gene transfer studies can be easily overcome by the use of fish species such as loach, killifish (*Fundulus*), goldfish, and tilapia. The body sizes of these fish species are big enough so that sufficient amounts of tissues can be isolated from individual fish for biochemical and endocrinological studies. Another important attribute of these fish species is their shorter maturation time compared to rainbow trout or salmon. In particular, tilapia is a very appropriate medium size fish species for gene transfer studies because it only requires about three months to complete its entire life cycle. It is possible to produce three

generations of transgenic tilapia in one year. Unfortunately, the lack of a well defined genetic background and asynchronous reproductive behavior of these fish species present some problems for conducting gene transfer studies.

Rainbow trout, salmon, channel catfish, and common carp are commonly used large body size model fish species for transgenic fish studies. Since the knowledge of endocrinology, reproductive biology, and physiology of these fish species has been well worked out, they are well suited for studies on comparative endocrinology as well as aquaculture application. However, the maturation time for each of these fish species is relatively long. For example, rainbow trout and salmon require two to three years to reach reproductive maturity, and common carp or channel catfish about one to two years. Thus it will prolong inheritance studies. In addition, because these fish species have a single spawning cycle per year, the number of gene transfer attempts that can be conducted per year is restricted.

22.2.3 Methods of Gene Transfer

Techniques such as calcium phosphate precipitation, direct microinjection, retrovirus infection, electroporation, and particle gun bombardment have been widely used to introduce foreign DNA into animal cells, plant cells, and germ lines of mammals and other vertebrates. Among these methods, direct microinjection and electroporation of DNA into newly fertilized eggs have proven to be the most reliable methods of gene transfer in fish systems.

Microinjection of foreign DNA into newly fertilized eggs was first developed for the production of transgenic mice in the early 1980s (60). Since then, the technique of microinjection has been adopted for introducing transgenes into Atlantic salmon, common carp, catfish, goldfish, loach, medaka, rainbow trout, tilapia, and zebra fish (10,21). The gene constructs that were used in these studies include human or rat growth hormone (GH) gene, rainbow trout or salmon GH cDNA, chicken δ-crystalline protein gene, winter flounder antifreeze protein gene, *E. coli* β-galactosidase gene, and *E. coli* hygomycin resistance gene (11,21). In general, gene transfer in fish by direct microinjection is conducted as follows: Eggs and sperm are collected in separate, dry containers. Fertilization is initiated by mixing sperm and eggs, then adding water, with gentle stirring to enhance fertilization. Eggs are microinjected within the first few hours after fertilization. The injection apparatus consists of a dissecting stereo microscope and two micromanipulators, one with a glass micro needle for injection and the other with a micropipette for holding fish embryos in place. Routinely, about 10^6–10^8 molecules of a linearized transgene are injected into the egg cytoplasm. Following injection, the embryos are incubated in water until they hatch. Since natural spawning in zebra fish or medaka can be induced by adjusting photo period and water temperature, precisely staged newly fertilized eggs can be collected from the aquaria for gene transfer. If the medaka eggs are maintained at 4°C immediately after fertilization, the micropyle on the fertilized eggs will remain visible for two hours. The DNA solution can be delivered into the embryos by injecting through this opening during this time period. The parameters for microinjection are summarized in Table 22.2.

Depending on the species, the survival rate of injected fish embryos ranges from 35% to 80% while the rate of DNA integration ranges from 10% to 70% in the survivors (11,21). The tough chorions of the fertilized eggs in some fish species; e.g., rainbow trout and Atlantic salmon, can make insertion of glass needles difficult. This difficulty has been overcome by any one of the following methods: inserting the injection needles through the micropyle, making an opening on the egg chorions by microsurgery, removing the chorion by mechanical or enzymatic means, preventing chorion hardening by initiating fertilization in a solution containing 1 mM glutathione, or injecting the unfertilized eggs directly.

Electroporation is a successful method for transferring foreign DNA into bacteria, yeast, and plant and animal cells in culture (58,63,71). This method has become popular for

Table 22.2
Parameters of Fish Transgenesis by Microinjection and Electroporation

Parameters	Gene Transfer Method	
	Microinjection	**Electroporation**
Developmental stage	1 to 2 cells	1 to 2 cells
DNA size	<10 Kb	<10 Kb
DNA concentration	10^{6-7} molecules/embryo	100 µg/ml
DNA topology	linear	linear
Chorion barrier	dechorionated/micropyle	intact chorion
Electrical field strength	N/A[a]	500 to 3,000 v
Pulse shape	N/A[a]	exponential/square
Pulse duration	N/A[a]	mS[c] to S
Temperature	RT[b]	RT[b]
Medium	PBS/saline	PBS/saline

[a]N/A, not applicable; [b]RT, room temperature (25°C); [c]mS, millisecond

transferring foreign genes into fish embryos or sperm in the past few years (52,64,72). Electroporation utilizes a series of short electrical pulses to permeate cell membranes, permitting the entry of DNA molecules into embryos or sperm. The patterns of electrical pulses can be emitted in a single pulse of exponential decay form (exponential decay generator) or high frequency multiple peaks of square waves (square wave generator). The basic parameters are summarized in Table 22.2. Studies conducted in our laboratory (52,64) and those of others (7) have shown that the rate of DNA integration in electroporated embryos is on the order of 20% or higher in the survivors. Although the overall rate of DNA integration in transgenic fish produced by electroporation was equal to or slightly higher than that of microinjection, the actual amount of time required for handling a large number of embryos by electroporation is orders of magnitude less than that required for microinjection. Several reports have also appeared in the literature describing successful transfer of transgenes into fish by electroporating sperm instead of embryos (72,75,78). With the success seen in electroporating sperm, electroporation can therefore be considered as an efficient and versatile mass gene transfer technology.

By microinjection or electroporation, plasmid encoded transgenes can be introduced at a satisfactory efficiency into many fish species to produce transgenic offspring. However, the resulting P_1 transgenic individuals are almost always mosaics as a result of delayed transgene integration. Furthermore, neither method is efficient or applicable in transferring foreign DNA into embryos of live bearing fish, marine fish, and invertebrates due to the restrictions imposed by the unique spawning behavior or anatomical structure of these species. Modification of transgenes has been adopted to increase the efficiency of gene transfer by microinjection or electroporation. Hsiao et al. (35) and Thermes et al. (76) have taken the following approaches: using the inverted terminal repeat DNA from adenoassociated virus to increase the stability of transgene integration; and employing *I-SceI* meganuclease to mediate high transportation efficiency of the transgene into the nucleus. Despite the improvement, these modified approaches can not be applied to the mentioned species whose transgenic offspring can not be produced by either microinjection or electroporation. Instead, transformation of mature or immature germ cells by infection with transgene encoded retroviral vectors may be an effective approach for transgenesis in these fish.

A replication defective pantropic retroviral vector containing the long terminal repeat (LTR) sequence of Moloney murine leukemia virus (MoMLV) and transgenes in a

viral envelope with the G-protein of vesicular stomatitis virus (VSV), was developed by Burns et al. (8). Since entry of VSV into host cells is mediated by interaction of the VSV-G protein with a phospholipid component of the host cell membrane, this pseudotyped retroviral vector has a very broad host range and is able to transfer transgene into many different cell types. Using the pantropic pseudotyped defective retrovirus as a gene transfer vector, transgenes containing neo^R or β-galactosidase were transferred into zebra fish (48), medaka (50), and dwarf surf clams (51). More recently, Sarmasik et al. (66) and Chen et al. (unpublished results) also used the pantropic retroviral vector to transfer genes into the immature gonads of crayfish, desert guppy, and shrimp, respectively. They found that by using the pantropic retroviral vector as a gene transfer vector, the problem of transgene mosaicism in P_1 transgenic fish is eliminated, as the transgenes are introduced into immature male gonads by the pantropic retroviral vector.

Nuclear transplantation is a key technique in animal cloning. This method involves the transfer of nuclei from donor cells to enucleated eggs, stimulating eggs into cleavage and early phase embryonic development, and, in the case of mammals, the developing embryos are transferred into pseudopregnant females to complete the final stages of development. The first successful cloning of animals by nuclear transplantation was established for Northern Leopard Frog (*Rana pipiens*) by Briggs and King in 1952 (15). However, Dolly, the lamb, is the first mammal successfully cloned by the nuclear transplantation technique (83), and since then, many laboratories throughout the world have adopted this technique to clone other mammals (15). To date, production of diploid and fertile fish by the nuclear transplantation technique has been achieved in two small laboratory fish species, medaka and zebra fish (40,47,80). Three types of donor cells have been used for nuclear transfer: sperm, long term cultured somatic cells, and embryonic cells.

In the study reported by Wakamatsu et al. (80), embryonic cells from two transgenic medaka lines were used as donor cells to generate transgenic medaka. Blastoderm cells from the donor embryos in the mid-blastula stage were collected and dissociated into single cells. These were subsequently transplanted into the cytoplasm of the recipient enucleated eggs at the animal pole through the micropyle. In this study, 1 out of 588 eggs transplanted with the first donor and 5 out of 298 eggs transplanted with the second donor developed successfully to adulthood. The transgene of the donor nuclei was also transmitted to the F_1 and F_2 offspring in a Mendelian fashion.

Two versions of nuclear transfer technique have been established for zebra fish recently. Jesuthasan and Subburaju (40) reported the use of sperm nuclei as donor for nuclear transfer. Sperm collected from mature males were demembranated by treatment with lysolecithin, digitonin, or by freeze thawing. The demembranated sperm were then incubated with transgene DNA at room temperature prior to microinjection into the animal pole region of the unfertilized egg. This method could produce nonmosaic expression of transgene in all cells of the embryos if incubation of the demembranated sperm with DNA was prolonged to 20 minutes. Few of the treated eggs, however, developed into fertile adults and the transgene was shown to be transmitted through the germ line. In the report by Lee et al. (47), embryonic fibroblast cells from disaggregated embryos were used as donor cells. These cells were first modified by retroviral insertions expressing GFP as a reporter, and were cultured for at least 12 weeks before their nuclei were transplanted into enucleated, unfertilized eggs. The method resulted in 2% of the transplants developing into fertile, diploid offspring. This study clearly demonstrated that nuclei from slowly dividing cultured fish somatic cells could be reprogrammed to support rapid embryonic development and used as donor cells for nuclear transfer in fish. Moreover, the promising use of modified somatic cells provides an alternative choice of vehicle for gene targeting and fish cloning because fish ES cells are still unavailable. Overall, these studies have demonstrated the

feasibility of using germinal and somatic cells from fish as donors for conducting nuclear transfer studies in different important fish species for both basic research and application purposes. In addition, the problem of transgene mosaicism in P_1 transgenic fish can be overcome by the nuclear transplantation method.

22.2.4 Characterization of Transgenic Fish

Identification of transgenic individuals is the most time consuming step in the production of transgenic fish. Traditionally, dot blot and Southern blot hybridization of genomic DNA were common methods used to determine the presence of transgenes in the presumptive transgenic individuals. These methods involve isolation of genomic DNA from tissues of presumptive transgenic individuals, digestion of DNA samples with restriction enzymes, and Southern blot hybridization of the digested DNA products. Although this method is expensive, laborious, and insensitive, it offers a definitive answer as to whether or not a transgene has been integrated into the host genome. Furthermore, it also reveals the pattern of transgene integration if appropriate restriction enzymes are employed in the Southern blot hybridization analysis. In order to handle a large number of samples efficiently and economically, a polymerase chain reaction (PCR) based assay has been adopted (12,52). The strategy of the assay involves the isolation of genomic DNA from a very small piece of fin tissue, PCR amplification of the transgene sequence, and Southern blot analysis of the amplified products. Although this method does not differentiate whether the transgene is integrated in the host genome or exists as an extrachromosomal unit, it serves as a rapid and sensitive screening method for identifying individuals that contain the transgene at the time of analysis. This method has been used in our laboratory as a routine preliminary screen for the presence of transgenes in thousands of presumptive transgenic fish.

Studies conducted in many fish species have shown that following injection of linear or circular transgene constructs into fish embryos, the transgenes are maintained as an extrachromosomal unit through many rounds of DNA replication in the early phase of the embryonic development. At a later stage of embryonic development, some of the transgenes are randomly integrated into the host genome while others are degraded, resulting in the production of mosaic transgenic fish (27). To determine the pattern of transgene integration, genomic DNA from PCR positive fish is digested with a series of restriction endonucleases, and the resulting products resolved in agarose gels for Southern blot analysis. In many fish species studied to date, it is found that multiple copies of transgenes are integrated in a head-to-head, head-to-tail, or tail-to-tail form, except in transgenic common carp and channel catfish where a single copy of the transgene was integrated at multiple sites on the host chromosomes (27,84).

Stable integration of transgenes is an absolute requirement for continuous vertical transmission to subsequent generations and establishment of a transgenic fish line. To determine whether the transgene is transmitted to subsequent generations, P_1 transgenic individuals are mated to nontransgenic individuals and the progeny are assayed for the presence of transgene by the PCR assay method described earlier (11,12,52,70). Although it has been shown that the transgene may persist in the F_1 generation of transgenic zebra fish as extrachromosomal DNA (73), detailed analysis of the rate of transmission of transgenes to F_1 and F_2 generations in many transgenic fish species indicates true and stable incorporation of gene constructs into the host genome (11,27). If the entire germ line of the P_1 transgenic fish is transformed, with at least one copy of the transgene per haploid genome, at least 50% of the F_1 transgenic progeny would be expected in a backcross involving a P_1 transgenic with a nontransgenic control. In many such crosses, only about 20% of the progeny are transgenic (12,52,70,73,74,84). However, when the F_1 transgenic is backcrossed with a nontransgenic control, at least 50% of the F_2 progeny are transgenics. These results clearly

suggest that the germlines of the P_1 transgenic fish are mosaic as a result of delayed transgene integration during embryonic development.

An important aspect of gene transfer studies is the detection of transgene expression. Depending on the levels of transgene products in the transgenic individuals, the following methods are commonly used to detect transgene expression: RNA northern or dot blot hybridization; RNase protection assay; reverse transcription polymerase chain reaction (RT-PCR); immunoblotting assay; and other biochemical assays for determining the presence of the transgene protein products. Among these assays, RT-PCR is the most sensitive method and requires only a small amount of sample. The strategy of this assay is summarized in Figure 22.2. Briefly, it involves the isolation of total RNA from a small piece of tissue, synthesis of single stranded cDNA by reverse transcription, and PCR amplification of the transgene cDNA by employing a pair of oligonucleotides specific to the transgene product as amplification primers. The resulting products are resolved on agarose gels and analyzed by Southern blot hybridization using a radiolabeled transgene as a hybridization probe. Transgene expression can also be quantified by a quantitative RT-PCR method (3), or a quantitative real time RT-PCR (21).

22.3 BIOTECHNOLOGICAL APPLICATION OF THE TRANSGENIC FISH TECHNOLOGY

As techniques of producing various species of transgenic fish have become available in the last two decades, there has been a rapid boom in applying transgenic fish technology to different disciplines of basic research and biotechnological applications. Teleost fishes serve as extremely valuable models for basic research in vertebrate biology as they are functionally similar to mammalian species; and because they are sufficiently evolutionarily distant to mammals, they are well suited for comparative genomics. Since transgenic fish can be easily and economically produced and reared in large quantities, they are a better choice than transgenic micel, especially in studies requiring a large number of animals. In recent years, transgenic fish technology has made major contributions in studying vertebrate development, analyzing promoter or enhancer elements of genes, dissecting signal transduction pathways, and developing human disease models.

Transgenic fish technology research has also been driven toward biotechnological applications in recent years, with a hope to produce high economic returns for humans. Some of the advances will be reviewed below.

22.3.1 Growth Hormone Transgenic Fish

The initial drive of transgenic fish research came from attempts to increase production of economically important fish for human consumption. The worldwide supply of fishery products has traditionally depended upon commercial harvest of finfish, shellfish, and crustaceans from freshwater and marine sources. In recent years, while the world wide commercial catch of fish experienced a sharp reduction, the world wide demand for fish products has risen steeply. In order to cope with the demand for fish products, many countries have turned to aquaculture. Although aquaculture has the potential to meet the world demand for fish products, innovative strategies are required to improve its efficiency.

There are three aspects of fish growth characteristics that could be improved for aquaculture: increasing the initial growth rate of fry for an early head start; enhancing somatic growth rate in adults to provide larger market body size; and improving feed conversion efficiency of to achieve effective utilization of feeds. Among these three, enhanced somatic growth rates via manipulation of the GH gene show considerable promise. Studies conducted

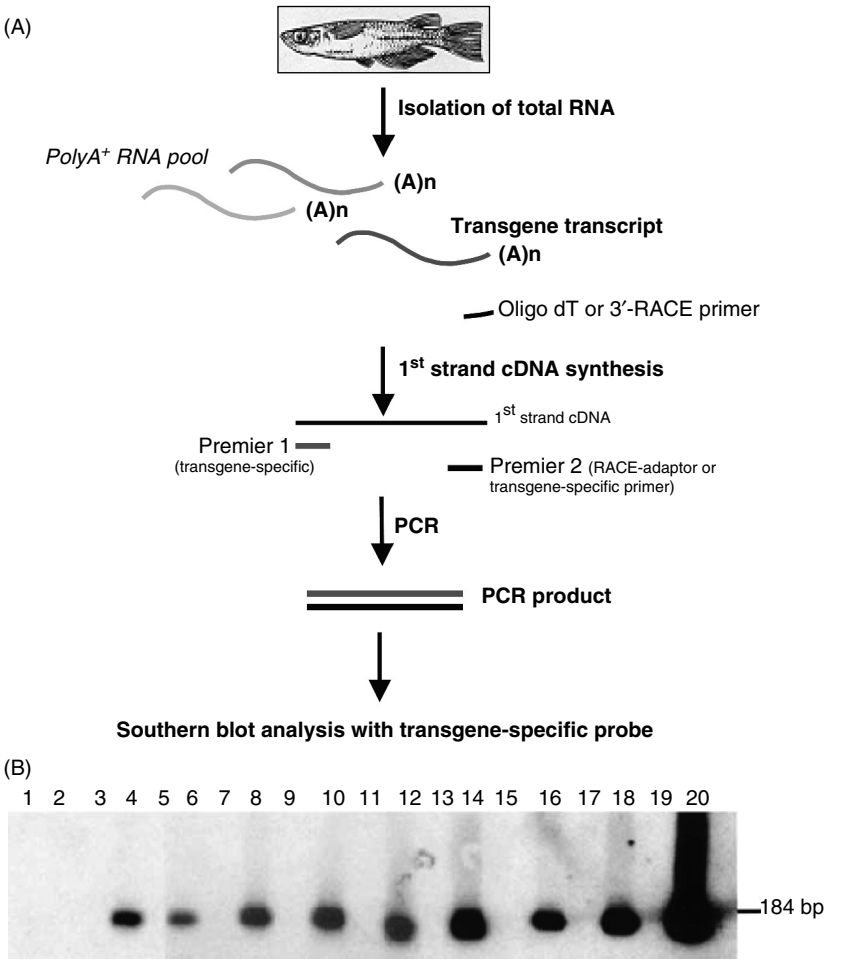

Figure 22.2 Determination of transgene expression by RT-PCR or RACE-PCR. (A) Strategy of RT-PCR and RACE-PCR. (B) An example of detecting cecropin transgene in transgenic medaka. Total RNA was isolated from fin tissues of F_2 transgenic medaka. Expression of cecropin transgene was detected by reverse transcribing poly A^+ RNA into complementary cDNA and PCR amplification of the cecropin cDNA by using cecropin-specific primers. The amplified product was further confirmed by Southern hybridization using a cecropin-specific probe. RT-PCR was conducted with mRNA from transgenic fish without prior reverse transcription (lanes 5, 7, 9, 11, 13, 15, 17, 19) or with 1st cDNA transcribed from mRNA isolated from the transgenic fish (lanes 4, 6, 8, 10, 12, 14, 16, 18). Lane 1: RT-PCR with no mRNA input; lane 2: RT-PCR with mRNA from negative control fish (c-mRNA); lane 3: PCR with c-mRNA without prior reverse transcription; lane 20: PCR with control plasmid containing cecropin gene. [From Sarmasik et al., 2002, with permission]

by Agellon et al. (1) and Paynter et al. (62) showed that treatment of yearling rainbow trout and oysters with recombinant rainbow trout growth hormone (GH) resulted in significant growth enhancement. Similar results of growth enhancement in fish treated with recombinant GH have been reported by many investigators (23,57,69). These results point to the possibility of improving the somatic growth rate fish by manipulating fish GH or its gene.

Zhu et al. (85) reported the first successful transfer of a human GH gene fused to a mouse metallothionein (MT) gene promoter into goldfish and loach. The F_1 offspring of

these transgenic fish grew twice as large as their nontransgenic siblings. Since then, similar enhanced growth effect has been observed in the GH-transgenic fish of many other species, such as tilapia, carp, catfish, sea bream, and salmon (16,17,52,53,54,65,84). These studies have shown that the expression of a foreign human or fish GH gene could result in significant growth enhancement in the P_1, F_1 and F_2 transgenic fish. Additionally, Dunham et al. (18) demonstrated that transgenic common carp carrying rainbow trout GH transgene consistently display, in two consecutive generations, a favorable body shape, better dressout yield, and better quality of flesh compared with controls. These studies have demonstrated that the production of GH transgenic fish could be beneficial to worldwide aquaculture, and could help to alleviate starvation in many economically poor countries by providing more efficient, cheaper, and yet high quality protein sources.

22.3.2 Transgenic Fish with Enhanced Resistance to Pathogen Infection

Disease is one of the most severe bottlenecks in aquaculture. For the past few decades, efforts to control infectious diseases in commercially important teleosts have primarily focused on the development of suitable vaccines for fish and selection of fish strains with robust resistance to infectious pathogens. Although effective vaccines have been developed for several important fish pathogens, the current vaccination practice is expensive, laborious, and time consuming. Genetic selection based on traditional crossbreeding techniques is time consuming, and the outcome is frequently unpredictable (and sometimes unachievable due to the lack of desired genetic traits). More effective approaches for controlling fish disease in aquaculture are highly desirable.

Transgenic fish technology can facilitate the genetic selection process by directly modifying the undesirable genetic traits that confer vulnerability to pathogens or introducing specific genes that are related to disease resistance into fish. The introduced transgenes can be fish originated genes or genes from other species. We have recently demonstrated the feasibility of introducing the antimicrobial peptide genes, cecropin B and cecropin P1, into fish to enhance disease resistance. Cecropins, first identified in the *Cecropia* moth, are members of the antimicrobial peptide family that are evolutionarily conserved in species from insects to mammals (6). These peptides possess activities against a broad range of microorganisms, including bacteria, yeasts, and even viruses (6). *In vitro* studies conducted by Sarmasik et al. (67) showed that recombinant cecropin B inhibited the propagation of common fish pathogens such as *Pseudomonas fluorescens, Aeromonas hydrophila, and Vibrio anguillarum*. Furthermore, Chiou et al. (13) showed that cecropin and a designed analogue, CF-17 peptide, effectively inhibited the replication of fish viruses such as infectious hematopoietic necrosis virus (IHNV), viral hemorrhagic septicemia virus (VHSV), snakehead rhabdovirus (SHRV), and infectious pancreatic necrosis virus (IPNV) (Figure 22.3). More recently, our laboratory has shown that synthetic peptide CF-17 is also effective in inhibiting the propagation of insect baculovirus (Khoo et al. unpublished result). Additionally, Jia et al. (41) demonstrated the enhanced resistance to bacterial infection in fish which were continuously transfused with a cecropin–melittin hybrid peptide, CEME, and pleurocidin amide, a C-terminally amidated form of the natural flounder peptide. These results led to the hypothesis that production of disease resistant fish strains may be achieved by introducing into fish known antimicrobial peptide genes through transgenic fish technology.

To test this hypothesis, we introduced gene constructs containing prepro–cecropin, procecropin, mature cecropin B, and cecropin P1 into medaka embryos by electroporation (67). The resulting F_2 transgenic medaka were subjected to bacterial challenges at a LD_{50} dose with *Pseudomonas fluorescens* and *Vibrio anguillarum*, respectively (67). The resulting relative percent survival (RPS) of the tested transgenic F_2 fish ranged from 72 to 100%

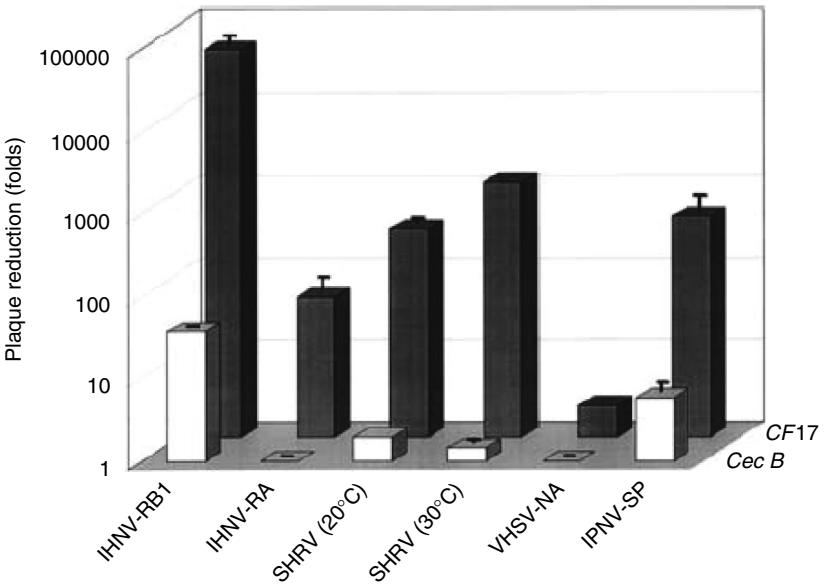

Figure 22.3 Effect of peptides cecropin and CF-17 on inhibition of fish virus propagation in vitro. The antiviral activity of the peptides cecropin B (Cec B) and CF17 was evaluated against one non-enveloped birnavirus, the SP isolate of infectious pancreatic necrosis virus (IPNV), and three enveloped rhabdoviruses: the RB1 (type2) and RA (type 1) isolates of infectious hematopoietic necrosis virus (IHNV), snakehead rhabdovirus (SHRV), and an avirulent North America isolate (NA) of viral hemorrhagic septicemia virus (VHSV). Viral infection was carried out in EPC cells for SHRV, and CHSE-214 cells for the rest viruses. [From Chiou et al., 2002, with permission]

against *P. fluorescens* and 25 to 75% against *V. anguillarum* (Table 22.4). These results clearly demonstrate the potential application of transgenic fish technology in producing fish with more robust resistance to infectious pathogens.

22.3.3 Transgenic Fish with Different Body Color

There are two main motives in producing fish with altered body color: to generate novel varieties of ornamental fish with rare colors for the purpose of rearing as pets, and to use the change of body color as indicators of environmental changes. GFP and several GFP variants are the most used genes for such purposes. Additionally, melanin-concentrating hormone (MCH) isolated from chum salmon has also been exploited to generate transgenic medaka fish with altered body color (43). So far, researchers have successfully produced several colorful transgenic zebra fish displaying whole body green, red, yellow, or orange fluorescent colors under daylight, dim light, or UV light (33,82). Some of these fish have been sterilized to avoid contaminating the wild population if they should accidentally be released from aquariums to the environments (33). For research purpose, mutant zebra fish and medaka with less interfering pigmentation for optical observation have also been developed. One such example is a line of see-through transgenic medaka that are transparent throughout their entire lives, thus allowing clear visualization of GFP that is introduced into the fish as a reporter (81).

22.3.4 Transgenic Fish as Environmental Biomonitors

Fish have long been used as models in environmental toxicology studies. Prompted by concerns of human health, tissues of wild caught fish have been monitored as indicators

for the presence of dangerous pollutants such as polycyclic hydrocarbons, oxidants, and heavy metals in the waters or in the fish itself (9,68). Different assays have been employed to measure biological parameters that are impacted by toxic pollutants, including DNA damage, defense enzymes (e.g., glutathione peroxidase and superoxide dismutase), genes inducible by toxic chemicals (e.g., cytochrome P450 1A1 and 1A2), and factors that regulate redox potential (e.g., glutathione and ascorbic acid) (9). Although these assays are very sensitive, they require specialized techniques and equipment, and thus cannot be performed in the field when the samples are collected. In addition, the obtained data from wild caught fish samples give no indication of the exact time when those fish were exposed to the toxicants.

Transgenic fish can potentially serve as sensitive sentinels for aquatic pollution, with the benefit of avoiding the inconveniences mentioned above. The principle of such biomonitor fish is to introduce into the fish reporters that are easy to observe and are under the control of promoter or enhancer elements responsive to pollutants. GFP and its variants are thus the best reporters of choice for easy optical observation, whereas luciferase is best for applications where extreme sensitivity is needed. So far, researchers have made significant progress in establishing transgenic zebra fish carrying luciferase or GFP reporter under control of the aromatic hydrocarbon response elements (AHREs), electrophile response elements (EPREs), or metal response elements (MREs) (9). The specificity of each type of response elements is as follows: AHREs respond to numerous polycyclic hydrocarbons and halogenated coplanar molecules such as 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) and polychlorinated biphenyls; EPREs respond to quinones and numerous other potent electrophilic oxidants; MREs respond to heavy metal cations such as mercury, copper, nickel, cadmium, and zinc. In the zebra fish cell lineZEM2S, these three types of

elements can drive the expression of luciferase reporter in a dose dependent, chemical class specific manner in response to more than 20 environmental pollutants (9). The expression of GFP transgenes can be detected in the F_1 and sometimes the F_2 generations; however, the transgenes are eventually lost following that. There are still technical obstacles in generating transgenic biomonitor fish (9), but the problems can be possibly overcome in the near future.

22.3.5 Other Examples of Transgenic Fish

Other applications include the use of transgenic fish as a model for studying mechanisms of seawater adaptation (38) and generating cold resistant fish carrying antifreeze proteins (AFPs). AFPs are found in many cold water fish species, such as the winter flounder, ocean pout, and sea raven. Expression of *afp* genes permit these fish to survive in freezing seawater as low as -1.8°C (70). However, AFP transgenic Atlantic salmon does not demonstrate a measurable increase of cold tolerance (70).

Transgenic fish can potentially serve as bioreactors for producing therapeutic proteins beneficial to human health (26). The advantages of fish as bioreactors include: (1) relatively low cost as compared to mammals such as cows, (2) easy maintenance, (3) producing large quantity of progeny, and (4) most important, no known viruses or prions have been reported to infect both human and fish. Successful expression of bioactive human proteins such as coagulation factor VII in fish embryos (37) demonstrate this application of transgenic fish to produce therapeutic chemicals for humans in the future.

22.4 CONCERNS AND FUTURE PERSPECTIVES

The application of transgenic fish technology to produce fish with beneficial traits, such as environmental biomonitors and genetically modified (GM) food, is on the rise. There have been ground breaking discoveries made in the past few years based on transgenic fish models, and such applications are expected to grow in the future. The technique to produce transgenic fish has improved tremendously in the last two decades; nonetheless, there are still concerns about low efficiency, mosaic expression, nonfish components of the transgenes, and the long generation time for certain fish species. The following advances would thus be essential in developing the next generation transgenic fish: developing more efficient mass gene transfer technologies; developing targeted gene transfer technology such as embryonic stem cell gene transfer method; identifying more suitable fish origin promoters to direct the expression of transgenes at optimal levels and desired time; and developing methods to shorten the time required to generate homozygous offspring.

Despite the promising future of applying transgenic fish technology in food fish production, there are great concerns about the environmental impacts of such applications of transgenic fish technology to produce GM food or hobby pets. Based on mathematical modeling, a "Trojan Gene Effect" has been demonstrated in the male transgenic medaka carrying salmon growth hormone gene. Release of such fish into the environments could ultimately lead to the extinction of the wild type population, owing to their advantage in mating with the wild type female (34). The study provides a sound analysis of the potential impact of the accidental release of transgenic fish into the environment, reminding us of the delicate interaction between a newly introduced species and the native population and environment. However, we would reason that the potential environmental impact of transgenic fish is controllable and even avoidable. First of all, the Trojan Gene Effect might not necessarily exist for other types of transgenes or in other fish species. In practice, transgenic fish can be maintained in confined areas to avoid the escape of fish into the nearby waters. Moreover, as the desirable genetic traits can be introduced into fish, the undesirable behavior traits could be possibly removed from the transgenic population by screening the behavior pattern of each transgenic individual. Ultimately, establishment of sterile transgenic populations, such as a sterile triploid all female strain, could be applied to avoid the spreading of transgenes into the wild population. Ideally, such sterility should be reversible; otherwise it would mean the loss of the goose that lays golden eggs. Finally, from a historical perspective, the concerns about the environmental impacts in the early days of recombinant DNA technology have not been realized, and many lessons can be learned from this experience.

Acceptance of GM fish as food by society is a key factor for the development of transgenic fish as a new source of cheaper, high quality food. Largely, the concern is due to the public perception that GM food is unsafe for humans. Safety is the ultimate goal of GM fish development and relies on thorough characterization of the transgenes and safety assessment of the GM fish, resembling the development of new drugs. Unfortunately, it is a fact that there is always a subpopulation of people who are allergic, to different degrees, to many existing natural food sources, such as peanuts and shellfish. Therefore, the challenge is great in developing GM fish with absolutely no adverse effect on every single individual in the human population. A thorough evaluation process to fully analyze any health risk of GM fish to humans should be established; and the information should be clearly delivered to the public and well marked on the food product. Development of gene-inactivated transgenic fish may be more acceptable by people who are concerned of the safety of the "new" genes that are introduced into fish. One candidate of such GM fish is transgenic fish strains in which the myostatin gene has been inactivated. Inactivation of myostatin gene causes double muscling in animals, resulting in significant increase in mass

of skeletal muscle. Natural mutation of myostatin gene has been found in the meaty Belgian Blue and Piedmontes cattle breeds; and the double muscling effect has been observed in mice whose myostatin gene is artificially inactivated (42,55). Such a gene-inactivation approach would be very valuable in producing transgenic fish with more flesh and higher food conversion rates, particularly for the economically important aquaculture species.

In summary, the development of transgenic fish has resulted in many valuable discoveries in basic biological science, any one of which could lead to the next breakthrough for new cures for human diseases. On the other hand, the potential of GM fish as bioreactors, or as new food sources, should not be deterred by the environmental and safety concerns. Instead, the concerns should be addressed with more research efforts to develop new GM species with beneficial traits that are also safe to human health and cause no harm to the environment.

ACKNOWLEDGMENT

2.23

The Production, Properties, and Utilization of Fish Protein Hydrolysates

Hordur G. Kristinsson

CONTENTS

23.1 INTRODUCTION

The situation of the world oceans is believed by many to be very close to experiencing major collapses in important fish stocks (1). Recent data on the world harvest estimates wild fish capture at close to 100 million metric tons, the estimated sustainable limit; if aquaculture is included, the value exceeds 120 million metric tons (2). This situation

should encourage harvesters and processors to change their practices, leading to better utilization of the current harvest and directing efforts into developing new means to utilize underutilized species. Currently substantial amounts of protein rich material derived from aquatic animals are discarded or not utilized optimally. These materials are typically byproducts from seafood processing plants, such as frames, cut offs, and by catch from fisheries, such as shrimp fisheries (3). For example, it has been reported that possibly more than 60% of fish tissue remaining after processing is considered to be processing waste and not used as human food (4). This material is high in quality protein ($\geq$10%) and other valuable compounds which could be utilized for human consumption. These values naturally can vary between species and the raw material in question. Furthermore, many species rich in quality protein and lipids are not harvested or utilized due to processing and stability problems of the final product (5). In many parts of the world, discarding byproducts is bound by strict regulations and comes at a high cost. Within the materials here listed are highly functional components (proteins, lipids, antioxidants, minerals) which could be converted into valuable products, provided the proper economic method exist and a market exists for the end products.

In the latter half of the last century there were great research efforts to find means to utilize the vast amount of fish byproducts and underutilized species. Despite this effort we have not come very far, in part due to economic obstacles of processing and generally low acceptance of the final products (3). These materials are typically rich in prooxidants, oxidative susceptible lipids, scales, skin, bones, connective tissue, and viscera. For this reason they have found very limited utilization. The great majority of utilizable byproducts, by catch, and underutilized species is transformed into fishmeal for animal feed and to some extent fertilizer, using harsh processing conditions that may adversely affect the function of the key components of the material. It has been estimated that about 30% of the world's catch is transformed into fishmeal for animal feed (6), and possibly more than 15% of the fish biomass harvested will not find any utilization (7).

There is an obvious need to better utilize processing byproducts, by catch, and underutilized species in light of the world fishing situation and the growing need for quality protein and lipids, both for humans and animals. Some exciting developments in the science and technology of fish utilization have developed recently which move us closer to this goal. To name one of the most important developments, a newly developed process utilizing highly alkaline or acidic conditions now allows for the effective recovery of stable functional proteins from underutilized and previously unutilized materials (8). The proteins are effectively separated from undesirable components in the raw material and can successfully be utilized for their gel forming ability (i.e., forming products similar to surimi) and other functional properties. The relatively pure proteins can also be further processed to modify their functionality for different applications. Another exciting process, enzymatic hydrolysis, although not new has, in the last few years, become more sophisticated and shown to be an excellent method to both recover protein from underutilized raw material and induce many desirable properties in the proteins. It has been shown by a number of researchers that, by applying controlled enzyme technology to recover and modify fish proteins present in byproducts and in underutilized species, it is possible to produce a broad spectrum of protein ingredients with a wide range of applications in the food, pharmaceutical, and specialized feed and fertilizer industries (3,7,9–14). These ingredients are collectively called fish protein hydrolysates (FPH), which can be defined as proteins that to a greater or lesser degree are chemically or enzymatically broken down into peptides of varying sizes (15). This promising approach could make significantly more use of fish proteins, increasing the margin of profit for the fishing industry as well as making it more environmentally friendly. Historically, the practice of fish protein hydrolysis extends back many decades. Much work

on the hydrolysis of fish proteins was conducted in the 1960s and 1970s (16), and was directed into production of cheap, nutritious protein sources for rapidly growing developing countries, or toward animal feed production, primarily through production of fish protein concentrates (FPC), which employs chemical hydrolysis sometimes coupled with enzymatic hydrolysis. Most of these efforts were not successful due to a variety of reasons. In the past 20 years or so only scattered reports have emerged in the literature on FPH, but the past 3–5 years have seen a surge in publications, new developments, and novel uses of FPH. In this chapter we will give an overview of the production of FPH including their various properties, current uses, and future potential as functional ingredients in food, pharmaceutical, and feed and fertilizer products.

23.2 THE ENZYMATIC HYDROLYSIS PROCESS

Different techniques exist for extracting and or hydrolyzing protein from fish. These include using aqueous and organic solvents to extract proteins and concentrated acid or alkali to extract and hydrolyze proteins at elevated temperatures. These methods normally adversely affect the functional and organoleptic properties of FPH and may produce toxic byproducts (3). Biological processes using endogenous or exogenous enzymes are now far more frequently employed in industrial practices to make FPH, because enzyme hydrolysis is usually a mild process that results in products of high functionality, good organoleptic properties, and excellent nutritional value without the formation of toxic byproducts (3,17). Many different aquatic sources have been enzymatically processed into FPH as summarized by Kristinsson and Rasco (3,7). Commercial production of fish protein hydrolysates is growing, and has reached a sizable level in a few countries including Denmark, France, Iceland, Mexico, Norway, Japan, USA, Canada, and several Southeast Asian countries. Although enzymatic hydrolysis is preferred over chemical hydrolysis, it has some drawbacks such as: the potentially high cost of using large quantities of added commercial enzymes, which are not reusable; occasional difficulty in controlling the extent of the reaction (especially in mixed protease preparations), which can result in heterogeneous products consisting of fractions of varying molecular weight; lower protein recovery (depends on extent of hydrolysis); and the need to inactivate enzymes by high or low pH or heat treatment at the end of the reaction, which adds to the processing costs and may adversely affect some functional properties (3,18).

The process of protein hydrolysis is relatively simple, but many variations exist. Figure 23.1 outlines a fairly typical protein hydrolysis process as reported for Atlantic salmon muscle proteins (13). Going into the hydrolysis, the raw material has to be well homogenized and (ideally) diluted with water. The amount of water added can be an important variable in the hydrolysis process. Less water may not only slow down the hydrolysis due to insufficient access of the enzyme to the substrates, but also the high viscosity of the system may lead to less recovery of hydrolyzed protein. Slizyte and coworkers (19) reported that water addition was more important than enzyme type in the recovery and functionality of hydrolyzed proteins from cod byproducts. This was likely due to differences in the extent of hydrolysis and thus the properties of the peptides in the recovered fractions. Prior to hydrolysis, the starting material has to be thoroughly homogenized and diluted, so that the enzyme can have easy access to proteins. The protein substrate is then adjusted to a pH and temperature representing the optimal reaction conditions of the particular enzyme. The enzyme preparation of choice is then mixed into the material, and ideal pH and temperature are maintained. Initially, where a large number of peptide bonds are broken, hydrolysis is fast; followed by a slower rate due in part to enzyme inactivation or substrate limitation

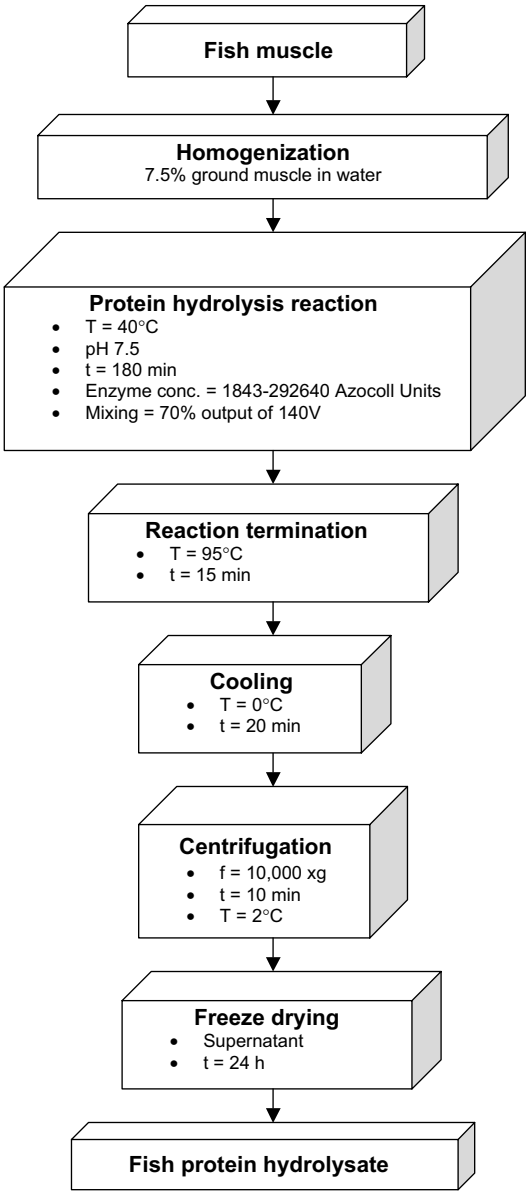

Figure 23.1 An example of a process to make fish protein hydrolysates from Atlantic salmon (adapted from Kristinsson and Rasco, *Proc. Biochem.* 36:131–139, 2000).

(6,10,13,20). Eventually the hydrolysis reaches a stationary phase. Because the extent of hydrolysis highly influences the recovery and the functionality of the proteins, it is imperative to control the hydrolysis if the goal is to produce a product with consistent specified molecular profile and functional properties. Many methods exist for monitoring and calculating the extent of hydrolysis, as summarized by Kristinsson and Rasco (3). The best and simplest method to monitor the degree of hydrolysis directly during the process is the pH-stat method (21), which is based upon maintaining constant pH during the reaction and recording the volume and molarity of base or acid used to maintain the pH. This method

and other methods are discussed in detail by Kristinsson and Rasco (3). Unfortunately, control over the hydrolysis process is often lacking in the literature, and researchers often fail to specify the final degree of hydrolysis (%DH) of their FPH preparations, which makes it hard to compare properties of FPH from different studies. When hydrolysis has reached its desired end point in the process, it is terminated by inactivating the enzymes with high temperatures, or reducing or increasing pH, or a combination of both. The hydrolyzed proteins are then recovered by centrifugation or filtration, to separate them from insolubles; e.g., fat, scales, bones, connective tissue, and unhydrolyzed protein. A substantial amount of utilizable material, most notably proteins and lipids, could be recovered from the insoluble "sludge" fraction after hydrolysis and used for different applications than the FPH. If necessary the soluble fraction containing the hydrolyzed protein can be further treated by passing it through charcoal to deodorize and decolorize it. For long term storage and transportation, the hydrolysates can be stabilized with antimicrobial or antioxidant compounds and kept in liquid form (common for fertilizers), or dried by either freeze or spray drying depending on the use and value of the final product.

23.2.1 Importance of Raw Material Source

Although the process of protein hydrolysis is relatively simple, there are a number of factors that need careful consideration before, during, and after hydrolysis. The nature and quality of the raw material can have a great impact on the hydrolysis process and the quality and functionality of the final product. For example, it is important to distinguish between lean and fatty species, because the latter can lead to serious lipid oxidation problems in the final product, creating unpleasant flavors and odors (4,22). Furthermore, there are bound to be serious oxidative and color problems during the processing and in the final product, such as raw materials high in blood and dark muscle (common with pelagic species) due to high levels of membrane lipids and potent prooxidants (primarily heme proteins and to some extent transition metals). For materials rich in lipids, blood and dark muscle an alkaline processing pH would significantly reduce the development of oxidative and color problems (23), but could cause more microbial spoilage. Incorporating antioxidants and antimicrobial agents early in the processing could partially alleviate the problem, if the starting material is of decent quality. Other components of fish such as bones, skin, and connective tissue can also interfere with the hydrolysis process and contaminate the final product; and have adverse effects on its quality and function. The ideal scenario would be to start out with a "clean" and simple starting material, such as a skinned fillet. However, this is highly uneconomical. Recently a process was developed which aims at economically producing functional and essentially pure protein isolates from underutilized sources of fish, such as pelagic species and processing byproducts (5,24). Because both neutral and membrane lipids have been removed, along with some prooxidants, these proteins are of excellent quality. This revolutionary process would allow one to start out with a relatively clean protein product in the hydrolysis process, yielding a higher quality and more functional protein hydrolysate. This could also result in more protein recovery in the process as centrifugation and filtering methods would not be necessary at the end of hydrolysis.

23.2.2 The Choice of Enzyme and pH Conditions

The choice of enzyme is another very important factor in the hydrolysis process because different enzymes have different specificity, and therefore produce products of different molecular makeup and functional properties. The ratio of enzyme to substrate ratio has been investigated by several workers and an increase in this ratio (i.e., more enzyme) leads to a more rapid reaction and also more recovery of protein (25). However, excessive use of enzymes is costly and generally not necessary for an efficient hydrolysis process. The

choice of enzyme, and its concentration, is usually based on a combination of the enzymes' effectiveness and cost as well as their substrate specificity (26–27). Proteolytic enzymes have either an endopeptidase or exopeptidase activity, or both, which has a dramatic impact on their speed of hydrolysis and the properties of the peptides formed. Endopeptidase enzymes are often very specific and cleave peptide bonds inside of the protein, usually leading to relatively small peptides but only small amounts of free amino acids. Generally, the less specific the enzyme is, the smaller the peptides are. The endopeptidases, on the other hand, cleave amino acids from the ends of the protein polypeptide chain resulting in mixtures of free amino acids and larger peptide fractions (depending on when the reaction is stopped). It is imperative to have a good understanding of the specificity and activity properties of the enzymes available for protein hydrolysis in order to control the extend of hydrolysis and properties of the end products. Commonly a combination of endo- and exopeptidase activities is favored in hydrolysis applications. With the above in mind, it becomes clear that using commercial or purified enzymes instead of endogenous enzyme mixtures (i.e., enzymes naturally present in the material being hydrolyzed) offers many advantages, because it allows good control of the hydrolysis and thereby the properties of the resultant products (10,13). According to the literature, a number of different commercial and purified enzymes have been used to hydrolyze fish protein. Table 23.1 lists some enzymes used for the hydrolysis of fish proteins (28). In early studies pepsin was found to be very efficient (29,30) but given that it is only active at acidic pH levels, it can adversely affect functional properties of the final product (31), as well as its oxidative quality and color, because at low pH lipid oxidation proceeds quickly (32). In part this is because heme proteins are rapidly denatured and become more active prooxidants (23). However, processing at low pH limits microbial growth, which positively contributes to the products' microbial stability. Enzymes active in the range of pH 6–8 have been more commonly employed in the past 20 years or so. One of the more popular enzymes, Alcalase (made by Novozymes, USA), an alkaline enzyme with both high endo- and exopeptidase activity, has repeatedly been reported to be one of the best enzymes used to produce functional FPH (13,33–36). Alcalase has also shown to give good protein recovery; between 70% and 88%, for a variety of species tested (10,12,13,33,36). Other enzymes have resulted in high recovery and protein content. The protease P "Amano" 3 gave ~87% recovery of proteins when used to produce hydrolysates from *Aristichtys noblis* (37). Kristinsson and Rasco (13) compared five different enzyme preparations (Alcalase 2.4L, Corolase PN-L, Corolase 7089, Flavourzyme 1000L, and a salmon visceral pyloric caeca extract) for their ability to produce protein hydrolysates from Atlantic salmon mince. All gave good protein recoveries and high protein contents of the final product (13) (Table 23.2, Table 23.3). Although Alcalase gave the highest protein content (>88%), Flavourzyme gave the highest protein recovery, with Alcalase and Corolase 7089 closely following. The protein recoveries were found to be highly dependent on the degree of hydrolysis (Table 23.3). The higher the %DH the more the protein recovery, while final protein content in the hydrolysate is less affected by %DH (13). This is very possibly due to the formation of more soluble peptides at higher degrees of hydrolysis which would stay suspended during the last centrifugation step.

It is also possible to perform the hydrolysis process using endogenous proteases to hydrolyze fish muscle proteins. This process depends on the action of endogenous digestive enzymes present primarily in the fish viscera (mainly trypsin and chymotrypsin from pyloric caeca and pepsin from stomach), and to some extent muscle tissues (lysosomal proteases). The end product is generally a fairly viscous liquid, rich in free amino acids and small peptides. Using visceral material to hydrolyze fish protein has an advantage over using commercial enzyme preparations in that processing costs can be reduced. However, a major drawback is that the viscera are a complex mixture of enzymes with different

Table 23.1
Some examples of enzymes used to hydrolyze fish proteins (adapted in part from Gilmartin and Jervis, *J. Agric. Food. Chem*. 50:5417–5423, 2002.)

Enzyme	pH Range	Temp. (°C) Range	Specificity	Source	Supplier
Alcalase 2.4L	6.5–8.5	55–70	Endo	*Bacillus licheniformis*	Novozymes

activity requirements, and the concentration of desirable enzymes can fluctuate greatly from season to season, as well as within and between species. This makes it very hard to control the hydrolytic process from one batch to another, resulting in hydrolysates with varying peptide and polypeptide molecular weights and varying functional properties. However, if the goal is extensive hydrolysis, variations in enzyme activity are not a major concern. For this reason extensive hydrolysis using endogenous proteases is widely used to produce hydrolyzed liquid products for human consumption, specifically fish sauces, fertilizers, and animal feeds.

Fish sauce is the major endogenously hydrolyzed fish product presently consumed in the world, with a reported annual production in Southeast Asia of about 250,000 metric tons (23). The raw material is typically small pelagic fishes, such as anchovies, that are mixed with concentrated (20–40%) salt solution at ambient temperatures (25–45°C). Hydrolytic breakdown via endogenous proteases proceeds under anaerobic conditions for 6–12 months. This slow but extensive breakdown results in a liquefied fish sauce composed predominantly of free amino acids. The goal of the process is not to improve the nutritive value of the protein per se, but to extend the shelf life of the protein along with improving its organoleptic characteristics (38). Microorganisms can also be used to produce liquefied fish products, via proteolysis and fermentation. For these processes, bacterial fermentation is typically initiated by mixing minced or chopped fish with a fermentable sugar. The fermentable sugar encourages the growth of lactic acid bacteria, which is advantageous because it produces acid and antibiotics that together limit the growth of competing spoilage bacteria (39).

Few research reports have been published on the utilization of endogenous enzymes to produce functional fish protein hydrolysates, especially for human food applications. Fish sauce is almost the only endogenously hydrolyzed fish product on the market in the USA and Europe. In order to produce a functional protein hydrolysate with specific properties, a good

knowledge of the enzymes involved is crucial. The major limitation in being able to produce a functional hydrolysate with consistent properties (other than fish sauce) using endogenous enzymes is the lack of control over enzyme activity and specificity. Shahidi et al. (10) hydrolyzed ground capelin (*Mallotus villosus*) using endogenous enzymes, which yielded far less protein recovery (22.9%) than FPH produced with Alcalase (70.6%), a commercial enzyme mixture. Earlier Hale (10) reported a similar lower recovery of proteins from red hake muscle when it was hydrolyzed with fish viscera compared to Alcalase. Kristinsson and Rasco (13,14,27) however, reported high protein recovery and excellent functional properties using a preparation of endogenous visceral serine proteases to hydrolyze ground salmon muscle fillets and frames. Protein recovery was close to 70% at 15% degrees of hydrolysis (%DH), comparable to the recoveries obtained from using four commercial enzyme preparations (13). An added benefit of the endogenous mixture was that it had significantly higher proteolytic activities at ambient temperatures (20–22°C) compared to the commercial preparations, in addition to being less expensive (14,27). The salmon FPH produced with the endogenous enzymes also had better emulsifying properties than soy protein concentrate or FPH made from four commercially available enzymes (13). One of the reasons that the serine protease mixture gave significantly better results than were previously achieved using endogenous enzymes is very likely due to the fact that the mixture was a partially purified form of visceral enzymes with uniform enzyme properties, whereas other studies used ground visceral material, probably of highly variable enzymatic activities. This underlines how important it is to have a characterized enzyme preparation to be able to produce FPH with good and consistent functional properties.

23.3 PROPERTIES, APPLICATIONS, AND POTENTIAL USES OF FISH PROTEIN HYDROLYSATES

23.3.1 Food Functionality

Good functional properties of FPH are very important in order to successfully utilize it as a food ingredient. The size and chemical properties of the hydrolyzed proteins has a dramatic impact on their functionality, and thus control of enzyme specificity and %DH is critical if the goal is to produce hydrolysates with improved or different properties suitable for a wide array of products (13,41).

23.3.2 Solubility and Water-Binding Properties

Many functional properties of proteins are positively affected by increased solubility. Intact fish myofibrillar proteins have limited solubility at concentrations between ~0.3 mM and ~300 mM NaCl and in the pH range of most foods and therefore would find limited use as added ingredients in food products under normal conditions. Solubility of myofibrillar proteins is increased by enzymatic hydrolysis, as it leads to smaller peptides and newly exposed amino and carboxyl groups that enable more interactions with water (42,43). Sugiyama and coworkers (34) reported that solubility of sardine meal was greatly enhanced after treatment with enzymes. Quaglia and Orban (33,44) reported over 90% solubility for sardine hydrolysates produced with either Alcalase or papain. A recent study on salmon FPH made with Alcalase showed that it had between 96 and 100% solubility in 100 mM NaCl from pH 2 to 11. In the pH range ~4–8 (common to most food) intact myofibrillar proteins would have been largely insoluble in 100 mM NaCl. FPH thus has the advantage of being highly soluble over a wide range of pH and ionic strength (10,11,13) which could extend its use in many food systems. For example, FPH produced from Atlantic salmon

with Alcalase exhibited 96–100% solubility in 100 mM NaCl from pH 2 to 11 (13). The good solubility and nutritive value of enzymatically hydrolyzed fish proteins has made them a feasible choice to produce milk replacers for weanling animals (6,45), which is presently being pursued in Japan and France (22). The good solubility of FPH could also make it a promising ingredient in nutritional drink formulas, provided that flavor is not adversely affected.

Due to good solubility over a wide range of pH, FPH is easily injected into muscle products for a variety of purposes, one of them being to aid in water uptake and retention. A number of commercially available hydrolyzed food proteins are used to control the water balance of food systems, to improve quality and increase yield and profits. The most common are soy and milk proteins. There is an advantage to using a muscle protein in a muscle product, in large part because of labeling issues. Limited research has been conducted on the potential of using FPH (or any muscle protein hydrolysate) as a water binder. In one of the earlier studies it was found that a significant increase in cooking yield was observed for a sardine hydrolysate when it was added to hamburgers (46). Shahidi et al. (10) reported that capelin protein hydrolysates incorporated into minced pork muscle increased its water holding capacity upon cooking. Similar findings were reported for shark protein hydrolysates mixed with comminuted pork, where cooking yield was increased in proportion to increased FPH addition (12). Kristinsson and Rasco (13) reported that salmon FPH incorporated into salmon mince patties prevented drip loss significantly better than egg albumin and soy proteins. In this study the type of enzyme used to make the hydrolysates was found to be more important than the %DH. Recent studies in the author's laboratory, injecting hydrolyzed fish protein isolates into fish fillets under certain conditions of pH and ionic concentration, have demonstrated a better overall performance in terms of water holding than by using salts and phosphates (Kristinsson, unpublished data). In the near future, therefore, hydrolysates could replace or in part substitute for phosphates, which are looked on unfavorably in several countries and by some consumers. Because the hydrolysates are a natural product, using them would help in creating a cleaner label for the food product. Fish protein hydrolysates could therefore be a great opportunity for the seafood industry to control the water balance of seafood products.

It is not well understood how FPH aids in the water retention characteristics of a food. The increase of terminal carboxyl and amino groups upon hydrolysis could increase the amount of water that can be bound compared to an intact protein, in part explaining the increased solubility. Free, small FPH peptides in the water phase of the mince or muscle could increase its osmotic character and thus slow water loss, explaining the decrease in drip loss. It is also possible that the peptides may aid in the gel forming mechanisms of the muscle proteins upon cooking. Recent studies report that fish hydrolysates may partially protect other proteins with which they are in contact. Khan et al. (47) found that FPH from five different species provided some stabilization of lizard fish myofibrillar proteins during drying, because more ATPase activity was retained. The FPH treated myofibrillar proteins also had a higher amount of bound unfrozen water, suggesting increased water binding to the myofibrils. The same study also reported similar effects of squid and krill protein hydrolysates on lizard fish myofibrillar proteins (48,49) and shrimp muscle proteins (48). These studies indicate that FPH could be a beneficial processing aid during drying of fish muscle or fish proteins to help retain more of the native protein conformation and function. Cryoprotective effects have also been reported for FPH (47,50). Khan and coworkers (47) reported that high gel forming ability and Ca-ATPase activity was retained after mixing FPH (5% w/w) into lizard fish surimi followed by freezing at -25°C. FPH added to products such as surimi could therefore be in part substituted for common ingredients like sucrose and sorbitol, and potentially give similar gel qualities. The mechanisms by which

FPH stabilizes proteins at freezing temperatures has not been well studied. Netto et al. (51) reported that FPH had similar effectiveness in lowering glass transition temperatures, and its effectiveness increased with lower molecular size. More research is needed in this area to understand the mechanisms of water retention, so that peptides can be tailor made to exhibit maximum water holding properties and be effective in protecting muscle proteins from denaturation.

23.3.3 Interfacial and Surface Properties

Fish protein hydrolysates with good interfacial and surface properties may find use as ingredients to aid in the formation and stabilization of oil in water or water in oil emulsions (e.g., margarine, dressing, and meat batters) and foams (e.g., mousse, whipped cream, and meringues).

Initial limited hydrolysis may expose more hydrophobic groups, thus increasing the surface and interfacial active properties of proteins. However, as the hydrolysis progresses, a decrease in surface and interfacial activity is observed (13). Even though small peptides may rapidly adsorb at the interface due to their high solubility, they are less able to produce good and stable emulsions as they become smaller (i.e., as the %DH becomes higher) (13). The specificity of the enzymes used is important here, because it can greatly influence the molecular size, topology, and hydrophobicity of the resulting polypeptides, all which influence the interfacial and surface properties of the FPH. Using enzymes with more narrow specificity and lower degree of hydrolysis is generally recommended, because larger and more amphiphatic peptides result. For good interfacial and surface properties, it has been suggested that peptides should not be smaller than 20 amino acid residues (52).

Results by Kristinsson and Rasco (13) showed that emulsifying capacity and stability of salmon FPH were greatly dependent upon the enzyme used. Using a serine protease mixture from salmon pyloric caeca produced FPH with the best emulsifying properties, and was found to be connected to the narrow specificity of the extract, which gave larger polypeptides than the other enzymes used (13). The salmon FPH had superior emulsifying capacity and stability compared to soy protein concentrates, but performed significantly more poorly than egg albumin. All salmon FPH demonstrated a decrease in emulsifying properties with an increase in %DH in agreement with previous finding about sardine hydrolysates (53). Sathivel and coworkers (54) reported a rather poor emulsifying capacity and stability for FPH made from different herring byproducts, when compared to egg albumin and soy protein concentrate. Liceaga-Gesualdo and Li-Chan (55) however, reported an increase in emulsifier formation and stability when herring muscle was hydrolyzed to 36% DH with Alcalase compared to unhydrolyzed herring muscle. Spinelli and coworkers (56,57) had reported similar findings earlier, that FPH from rockfish had improved emulsifying capacity compared to unhydrolyzed myofibrillar proteins. However, the same fish hydrolyzed with bromelain produced FPH with poor emulsifying capacity and stability (58). Jeon et al (59) studied the emulsifying activity and stability of cod protein hydrolysates, and reported that both were highly dependent on molecular size. Hydrolysates ultrafiltrated through a 10K Da membrane exhibited optimal emulsifying ability. Vieira and coworkers (11) reported poor emulsifying properties for lobster waste hydrolysates. Relatively poor emulsifying capacity and stability was also reported for capelin (10) and shark protein hydrolysates (12). The problem with many of the above studies is that the %DH of the FPH was not reported, which makes interpretations of the results impossible. Another complication with all of the above studies and other functional properties are that different methods are used to study them, making it very difficult to compare them.

Only a few studies have been conducted on the foaming properties of FPH. Shahidi and coworkers reported reasonably good whippability and foam stability for shark protein

hydrolysates and capelin hydrolysates (10,12). However, compared to whey protein hydrolysates (60) and egg white proteins (61), the shark and capelin hydrolysates had significantly poorer foaming properties. Studies with herring FPH demonstrated that they had good foam forming properties but poor foam stability due to rapid breakdown, while unhydrolyzed proteins exhibited slightly lower foam forming properties, but far better stability (55). The decrease in peptide molecular weight as a result of hydrolysis leads to a decrease in foaming ability, because the small peptides do not have the ability to stabilize the air cells of the foam (55). Therefore low %DH is necessary to produce FPH with good foaming properties. This was demonstrated by Jeon et al. (59) for cod protein hydrolysates, where ultrafiltered samples had improved foaming characteristics in direct correlation with their particle sizes: 30KDa, $>$ 10KDa $>$ 5 KDa $>$ 3KDa. Interestingly, the unfiltered hydrolysate had lower foamability and foam stability than the 30K, 10K and 5K filtrates, demonstrating the importance of molecular weight. Good foamability can, however, be a problem when it comes to other functional properties of FPH, especially if they are to be used as soluble and injectable protein ingredients. It is crucial to be able to produce a favorable balance of water solubility and good interfacial and surface properties for different applications, which is accomplished by proper selection of enzymes and processing conditions.

23.3.4 Lipid Binding

Many food products rich in lipids, e.g., meat batters (sausages) and confectionaries, require physical stabilization of the lipids. Although in part related to the ability of FPH to emulsify lipids, only a handful of studies have investigated directly the oil and fat binding property of FPH. Shahidi and coworkers (10,12) demonstrated the capacity of capelin and shark protein hydrolysates to bind oil, although no units were reported to express the amount of oil binding. Kristinsson and Rasco (13) reported that salmon FPH had significantly better oil binding than two common food protein ingredients, egg albumin and soy protein concentrate. This study revealed that oil binding was influenced by the enzyme used for the hydrolysis, with increased %DH leading to less oil binding regardless of enzyme used. At 5%DH oil binding varied from 4.48 to 7.07%; at 10% DH from 3.22 to 5.12%; and at 15% DH from 2.86 to 3.86%. In this study egg albumin and soy protein concentrate had oil binding of 2.36% and 2.90%. Sathivel and coworkers (54) also reported higher oil binding with different FPH from herring byproducts, although no %DH was specified.

23.3.5 Flavor Properties

One of the reasons behind the slow penetration of FPH into the food ingredient market is bitterness which often develops on hydrolysis. Bitterness in FPH is also of great importance for animal feed application utilizing FPH as a efficient protein source, because consumption of FPH can lead to increased fishy off flavors (62). There is a sensitive and complex balance between extent of hydrolysis, peptide profile, and bitterness development. Generally, limited hydrolysis eventually leads to the development of bitterness, because hydrophobicity of the peptides formed is increased over the parent protein. Hydrophobic peptides have found to play a major role in the bitterness sensation of protein peptides (63). From work reported by Yu and Fazidah (37) it could be seen that limited hydrolysis of *Aristichtys noblis* up to approximately 15%DH led to only limited bitterness, but between 15 and 20%DH bitterness developed rapidly. On the other hand, extensive hydrolysis yielding very small peptides or free amino acids generally leads to less bitterness. Sugiyama and coworkers (34) reported that sardine FPH with smaller peptides had significantly less bitterness than FPH with larger peptides. However, small basic tripeptides containing asparagine and lysine as the second and C-terminal residues, respectively, and with the N-terminal residue leucine or glycine, have been found to be responsible for

bitter taste in fish protein hydrolysates (64). The relationship between peptide length and properties is therefore a complex one. Extensive hydrolysis of proteins from aquatic organisms may in some cases lead to a flavor enhancement effect, and the use of FPH as a seafood flavor or flavor enhancer is possibly one of its most promising applications. In an early study Fujimaki and coworkers (65) reported that fish protein concentrate treated with Pronase to make FPH had flavor enhancement effect similar to monosodium glutamate (MSG), but accompanied with some increased bitterness. The peptides responsible for this MSG-like flavor were found to be three dipeptides and five tripeptides (66). Vieira and coworkers (11) reported that extensive hydrolysis of lobster processing waste gave a product of superior quality and no bitterness. This is possibly due to large amounts of free amino acids and flavor enhancing nucleotides which lobster is rich in. Imm and Lee (57) prepared hydrolysates from several different species using enzymes specifically developed for maximizing flavor and minimizing bitterness (Flavourzyme and Savorase) and reported that increased levels of free amino acids led to a flavor enhancement effect (called the umami effect). These authors found that optimal flavor was obtained with a 6 hour hydrolysis. ChiaLing et al. (68) also reported an umami effect of hydrolysates made from proteins in tuna cooking juice. The authors concluded that the flavor and quality of these hydrolysates could make them successful as a condiment in the marketplace. There are several different seafood flavors or extracts produced commercially, and most of these are in fact hydrolyzed fish and shellfish proteins. There are multiple uses for these products such as sauces, seasonings, soups, bisques, frozen seafoods, fresh and prepared seafoods, appetizers, snacks, and imitation seafood products (e.g., crabsticks) (69).

To control bitterness when producing FPH, enzyme choice appears to be very important. Enzyme preparations with high exopeptidase activity and high preference for cleaving off hydrophobic amino acids in bitter peptides have been recommended (21,70). Several studies have also pointed out that a proper balance of endoprotease and exopeptidase activity produces less bitterness when compared to using each separately. Several enzyme preparations are now commercially available, with the goal of limiting the development of bitterness while at the same time obtaining good functional properties. Only a handful of studies have compared protease preparations for their effect on bitterness. Lalasidis and coworkers (71) hydrolyzed cod filleting offal which gave a product of bitter taste. Sugiyama and coworkers (34) reported that sardine FPH made with alkaline proteases were significantly less bitter than those prepared with neutral or acid proteases. Hoyle and Merritt (16) reported that herring FPH made with papain had more bitterness than FPH made with Alcalase. The papain samples were at a lower %DH than the Alcalase samples in that study. When the same substrate was defatted and then used to make FPH, much less bitterness developed. This suggests that lipid oxidation products may be a major source of much of the bitterness reported with FPH. This suggestion is strengthened by a recent study on autolytic hydrolysis of frigate mackerel byproducts which showed a good correlation of lipid oxidation and bitterness development during hydrolysis (72). This underlines the importance of substrate selection and quality of the starting material for FPH processes.

Several postprocessing techniques can be used to mask or reduce the bitterness of hydrolysates. Treating FPH with activated carbon may partly remove bitter peptides (10). It has also been reported that treating FPH with synthetic adsorbents led to a significant reduction in bitterness (34). Treating FPH with peptidases may also lower the bitterness of the product, as discussed above. Lalasidis and coworkers (71) found that when cod offal FPH was further treated with pancreatine, which is rich in exopeptidase activity, bitterness was essentially eliminated. Sugiyama and coworkers (34) also reported that bitterness was significantly reduced upon treating sardine FPH with different peptidases. Bitter peptides may also be extracted with solvents (71) and FPH may be debittered using ethyl alcohol

(73), both which may have a negative impact on the food functionality of the FPH. A milder and innovative approach to lower bitterness was described by Sugiyama et al (74). These workers found that when aldehydes were removed from FPH by yeast or acetic acid bacteria at low pH, bitterness was also reduced. Another unique approach to reduce bitterness is to rejoin the hydrolyzed peptide using certain proteases, with a process called the plastein reaction (22,75). These rejoined peptides have reduced exposed hydrophobic residues, i.e., less bitterness (22). Bitterness may also be masked by added ingredients. For example, Imm and Lee (67) reported that addition of 1.5% NaCl and 0.4% sodium tripolyphosphate masked some bitterness and off flavors that developed on hydrolysis of several fish species. A Japanese patent by Suzuki and coworkers (76) describes adding cyclodextrin to hydrolyzed proteins to eliminate bitter taste.

23.3.6 Antioxidant Properties

The potential of peptides to serve as antioxidants to limit lipid oxidation in food systems has recently received increased attention. Lipid oxidation is one of the major causes of quality deterioration in seafood products, especially those rich in lipids and potent prooxidants (77). Fish protein hydrolysates, which are rich in different types of peptides, have shown potential to be used to minimize oxidation. In an early study on the antioxidative potential of FPH, it was found that FPH prepared from sardine myofibrils showed some antioxidant activity which was substantially increased when it was combined with different commercial antioxidants, likely due to a synergistic effect (78). Shahidi and coworkers (10) reported that addition of capelin FPH at 0.5–3.0% level in minced pork reduced formation of thiobarbituric reactive substances (TBARS) by 17.7–60.4%. The authors proposed that this antioxidative property was likely due to chelation. Later work on capelin FPH showed that after fractionation with gel chromatography both prooxidative and antioxidative fractions could be identified (79,80). Presence of transition metals, heme, and heme proteins in the hydrolysates could contribute to the prooxidative effects of FPH. Chuang and coworkers (81) reported that mackerel FPH showed good antioxidant effect, because it decreased both lipoxygenase and hemoglobin mediated linoleic acid oxidation. The hydrolysate was, however, not as effective as the well known antioxidant ascorbic acid. The authors proposed that the antioxidant mechanism was likely due to histidine related dipeptides such as anserine and carnosine, which reportedly scavenge free radicals (81). Jeon and coworkers (59) also reported a good inhibition of cod FPH fractions below 5KDa in a linoleic acid model system. The antioxidative activity was reported to be equal to tocopherol. These antioxidative properties of FPH are likely highly dependent upon the amino acid composition and molecular size of the FPH peptides, as studies have shown that antioxidant activities of hydrolysates are highly dependent on the type of enzyme used (82). An elaborate study by Saito and coworkers (83) on synthesized tripeptides reported that the amino acid composition and sequence in a peptide greatly influences the level and type of antioxidative activity. More studies on molecular basis behind FPH potential to prevent oxidation and their antioxidative function in complex food systems is highly recommended.

23.4 NUTRITIONAL AND PHYSIOLOGICAL PROPERTIES

23.4.1 Animal Feed

It has been know for many centuries, if not thousands of years, that living organisms respond very positively to hydrolyzed fish material, although the reason for this was at that time unknown. A large amount of research in the past 50 years or so has shown that hydrolysates

are excellent sources of protein due in part to their excellent amino acid balance, good digestibility, and rapid uptake. Hydrolyzed fish material (mostly in the form of silage, i.e., autolytically hydrolyzed fish) is widely used as feed for weaning pigs, minks, pigs, and poultry (3,22,84). Hydrolyzed fish products are also being increasingly used as pellets for pet food and in aquaculture feed formulations. The main problem with FPH in these applications has been bitterness, which can make the feed unpalatable for animals. Due to the excellent balance of essential amino acids, FPH have been suggested as a partial replacement for cereal proteins to improve the protein quality of cereal products (45,85). Enrichment of FPH with legume products has also been reported (85). Common Mexican dishes were prepared with cereals and legumes enriched with FPH, and were accepted by 70% of taste panelists even when FPH made up 35% of all protein (85). Fish protein hydrolysates have also been suggested as ingredients in bakery products (6). A French patent describes the use of dried skim milk (15%) and fish protein hydrolysate (14%) in a biscuit formulation designed as an energy food (86). Yu and Tan (87) reported that fried crackers made with tilapia protein hydrolysates were "highly acceptable" up to a 10% FPH addition level.

The protein quality and digestibility of FPH has been investigated by many. Bechtel and coworkers (88) recently reported that FPH from salmon heads and viscera had a calculated protein efficiency ratio (PER) of 2.6 and 2.8, respectively, and both FPH had over 94% protein digestibility. Both products were reported to be especially rich in lysine. Sugiyama and coworkers (34) reported an amino acid score of 100 for FPH from defatted sardine meal. This FPH was also found to have a PER of 3.2, a net protein ratio (NPR) of 5.2 and a biological value (BV) of 86 in rats. Digestibility and net protein utilization was 99% and 85%, respectively. This suggests that FPH would be an excellent protein source for feed and food applications. Good nutritional properties (both tested and predicted) of FPH have also been found for FPH made from tilapia (89,90), dogfish (35) and Atlantic cod (91). Rat trials have demonstrated that FPH inclusion in the diet led to more rapid growth and higher body weight than control proteins such as casein (89,92,93). Fish protein hydrolysates were compared to fish meal on their effect on the growth of rainbow trout (94). FPH diets had better feed conversion ratios than most of the fishmeal feeds and nitrogen retention was better for FPH feeds compared to fishmeal. Lian and Lee (95) reported that squid protein hydrolysates increased the survival rate of trout fingerlings and Atlantic salmon juveniles. The same hydrolysate was also found to serve as a feed attractant. Other studies have reported no or little benefit of using hydrolysates in feed formulations. Wilson and coworkers (96) found that catfish offal FPH was less effective than menhaden fish meal in catfish fingerling growth, feed, and protein efficiency, likely due to the deficiency of important amino acids in the FPH. Oliva-Teles and coworkers (97) reported that partially replacing fish meal with FPH, even at high levels, did not have a positive effect on growth or feed utilization of turbot juveniles. The size of the peptides, i.e., degree of hydrolysis, can play a major role in the effectiveness of FPH in feed formulations. Cordova-Murueta and Garcia-Carreno (98) reported that adding FPH to feed led to lower growth in shrimp than did adding krill protein hydrolysates (KPH). This was thought to be due to the large amount of low molecular weight peptides ($<$14 kDa) in the FPH compared to KPH, which can led to an imbalance of amino acid adsorption, i.e., lack of uptake of essential amino acids. This study suggested that properly controlling %DH and minimizing free amino acids in the feed is important for a successful application of FPH in animal feeds.

Some very interesting and novel developments have recently occurred in the use of FPH in aquaculture operations. FPH has been found to be a good supplemental protein source for juvenile fish (99). According to Gildberg (99) studies performed *in vitro* and *in vivo* suggest that low molecular weight fractions of cod stomach FPH (i.e., silage) makes fish more disease resistant and stimulates nonspecific immune response reactions.

Bogwald et al (100) reported that Atlantic cod FPH injected into Atlantic salmon led to a stimulation of salmon head kidney cells in a dose dependent manner. Gildberg and coworkers (101) reported that selected fractions (500–3000 Da) of cod stomach FPH could be used as an adjuvant in fish vaccine and as an immune stimulant for aquacultured fish. Fish protein hydrolysates could therefore not only be used to increase growth of fish, but also have a positive physiological impact on the animal.

23.4.2 Plant Growth

It is well known that using FPH as a fertilizer or a component of fertilizer positively affects crop growth and yield (3). Several commercial liquid FPH products are sold for this purpose. When sprayed directly on cranberry and cherry trees, FPH significantly increase crop yield (George Pigott, personal communication, 1997). Fish protein hydrolysates have been very successful as fertilizers on golf courses (Stephen D. Kelleher, personal communication, 1999). Novel applications taking advantage of this effect of FPH have been used to stimulate development of commercially important plant varieties. Eguchi and coworkers (102) compared FPH with proline, a known stimulator, to stimulate somatic embryogenesis in Anise (*Pimpinella anisum*) with good success. It has been proposed that FPH has the potential of becoming a proline and amino acid substitute in plant tissue culture applications and may find use in value added applications in the plant propagation industry (103). Research has shown that FPH has the potential to increase the production of valuable bioactive compounds in plant. Andarwulan and Shetty (104) found that mackerel FPH led to more production of rosemaric acid and phenolics in oregano when used as a component of the growth media. In a later study Andarwulan and Shetty (105) reported that mackerel FPH stimulated the growth of Epoxy-pseudoisoeugenol-(2-methylbutyrate) (EPB) in anise root cultures. This phenolic compound has the potential to regulate nutraceutical phytochemicals in plants. Fish protein hydrolysates were also found to increase the level of water extractable phenolics in cranberry pomace when added as a nitrogen source into the culture media (106). Fish protein hydrolysates contain a good amount of glutamic acid and proline, both which can be used to stimulate the pentose phosphate pathway and phenolic synthesis in plants (104). Using FPH can therefore stimulate expression of many commercially valuable phytochemicals which could find use as nutraceuticals in various food products or as antioxidants to extend shelf life of products, which is a new, and possibly very valuable arena for FPH applications.

23.4.3 Bioactivity

Several studies have reported various physiological functions of FPH. Oxidative processes result in various diseases, and the antioxidant potential of FPH has been reported, as previously discussed. Lipoxygenases have been implicated in low density lipoprotein oxidation, which is connected to hypertension and arteriosclerosis, and FPH has been shown to inhibit the activity of this enzyme (81). Angiotensin II is another compound connected to hypertension and it is produced from angiotensin I by the angiotensin I converting enzyme (ACE) (59). Fish protein hydrolysates from a variety of species have been found to have inhibitory effects on this enzyme and thus could possibly lead to less hypertension if consumed (107–110). This inhibition appears to be highly dependent on the peptide size of the hydrolysate, with smaller peptides generally being more inhibitory. Jeon and coworkers (59) found that the effectiveness of fractionated cod FPH to reduce the activity of ACE was in the following order 3kDa $>$ 5kDa $>$ 10 kDa $>$ 30 kDa. Bordenave and coworkers (111) reported that sardine hydrolysate and cod head hydrolysate inhibited close to 30% of ACE activity while a shrimp hydrolysate inhibited 57% of ACE activity.

A commercial cod and mackerel hydrolysate (PC60 and its derivative, Stabilium 200) was found to reduce anxiety in humans (112) and improve learning performance and

memory in humans (113) and rats (114). Furthermore Bernet and coworkers (115) reported the ability of the PC60 hydrolysates to reduce stress in laboratory rats, in a similar manner as the known drug diazepam (valium) does. Fish protein hydrolysates have also been found to enhance flow of red blood cells (81), and therefore could enhance blood flow *in vivo*. A stimulation of proliferation of white blood cells in humans was seen with peptides found in fish sauce, which is one form of FPH (116). In light of the popularity of functional foods FPH may find a niche in this market as a nutritional supplement or nutraceutical due to its positive effects *in vivo.*

23.4.4 Microbial Media

The rapid growth of the biotechnology industry has developed a great need for a variety of different growth media for microorganisms. There may be a niche market here for FPH because extensively hydrolyzed FPH are reportedly an excellent growth media for a variety of microorganisms (99,117,118). Fish peptone has performed better than commercial peptones for many microorganisms and has been successful in cultivating fish pathogens (99). FPH may also find use as growth factors for microorganisms in the food fermentation industry. Yugushi (119) found that FPH stimulated the growth of lactic acid bacteria in skim milk. The FPH was also found to lead to a decrease in curd tension during and after milk fermentation. FPH may also find increasing use as an alternative peptone source to beef peptone due to the advent of Mad Cow disease.

Human Gut Microflora in Health and Disease: Focus on Prebiotics

Tamara Casci, Robert A. Rastall, and Glenn R. Gibson

CONTENTS

24.1 INTRODUCTION TO HUMAN GUT MICROFLORA AND FERMENTATION PROPERTIES

In humans, the colon receives dietary material, which has already been digested in the upper gut, from the ileum, and the contents are then mixed and retained for 6–12 hours in the cecum and right colon. Thereafter, digesta are ejected and pass through the transverse to the left colon for storage, absorption of water, and eventual excretion (1). The typical retention time for the colon is about 60 h in U.K. subjects (2). Thus, the large gut is a tubular system, with nutrients flowing into the cecum, and bacteria, their metabolic products, and undigested food being excreted in feces. The major end products of fermentation in humans are the SCFA (short chain fatty acids), acetate, propionate, and butyrate (3); gases H_2 and CO_2 (4,5); ammonia (6); amines (7); phenols (8,9); and energy, which bacteria use for growth and maintenance of cellular function. Only about 5% of total SFCA are excreted in feces. *In vivo*, SCFA contribute about 10% of the daily energy requirements of the host. Most SCFA produced by gut bacteria are absorbed and metabolized in the body (10).

A range of substrates, of dietary origin or produced by the host, is available for fermentation by the colonic microflora. From the diet, resistant starch is the most quantitatively important (2) and is readily fermented by gut bacteria including *Bacteroides*, *Bifidobacterium* spp., and *Fusobacterium* spp. (11). Nonstarch polysaccharides form the next largest contribution to the fermentable substrates and include plant derived substrates like pectin, cellulose, hemicelluloses, and chemically related substances (2). Oligosaccharides like lactose, lactulose, raffinose, stachyose, and fructooligosaccharides also escape absorption by the small intestine and are fermented in the colon. Mucin glycoproteins, which are produced by goblet cells in the colonic epithelium, are predominant endogenous substances fermented in the colon (2) and can be metabolized by a range of microorganisms, most importantly *Bifidobacterium*, *Ruminococcus* spp., and some *Bacteroides* (12–14). Proteins and peptides originating in the diet, in pancreatic secretions or produced by bacteria, are available in the colon (2,6), although to a lesser extent than are carbohydrates.

The principal polysaccharide degrading bacteria are thought to be the Gram-negative anaerobes belonging to the genus *Bacteroides* (15). They are able to synthesize a wide range of cell associated polysaccharide depolymerases and glycosidases that allows them to grow upon various polysaccharides (15,16). The breakdown of highly polymerized materials in the gut is a cooperative activity, with enzymes from many different species participating in the process (2).

Gibson and Roberfroid (17) defined prebiotics as "nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or the activity of one or a limited number of bacteria normally resident in the colon, and thus attempt to improve host health."

Prebiotic substances, such as lactulose, fructooligosaccharides (including inulin), and galactooligosaccharides, selectively stimulate the growth of *Bifidobacterium* spp. in the colon (18). Isomaltooligosaccharides, glucooligosaccharides, lactitol, xylitol, and xylooligosaccharides (XOS) are candidate prebiotics, but the specific enzymes for the degradation of these molecules have not yet been fully evaluated, so the full explanatory mechanism for any purported prebiotic effect is not yet evident (19).

Fermentation of prebiotic oligosaccharides by probiotic bacteria in the gastrointestinal tract has been shown to have a number of possible health implications including alleviation of lactose maldigestion, increased resistance to gut invasion by pathogenic bacteria, stimulation of the immune system, protection against cancer, effect on mineral bioavailability, and lowering of lipid levels. Potential health benefits may include reduction of the risk of intestinal infectious diseases, cardiovascular disease, noninsulin dependent diabetes, obesity, osteoporosis, and cancer (18).

Zubillaga et al. (18) reported on the link between probiotics and certain health conditions including ulceration, diarrhea, *H. pylori* infection, lactose intolerance, cancer, and immune system function. It was demonstrated that *L. acidophilus* and *B. bifidum* can act as an "ecological" therapy for gastritis and duodenitis, and that high intakes of fermented milk products were associated with reduced risk of ulceration.

In the context of diarrhea, it has been found that a fermented product containing *L. acidophilus* could inhibit growth of *S. dysenteriae*, *S. typhosa,* and *E. coli*. The beneficial effect has been attributed to antimicrobial substances produced by *L. acidophilus*, *in vivo*, which neutralize the enterotoxins of *E. coli* (20).

Helicobacter pylori infection was found to be associated with the deficiency of *Lactobacillus* species in the stomach (18). Moreover, more than one *in vitro* study has shown the ability of *L. salivarius* to inhibit growth of *H. pylori* (21–23).

Lactobacillus acidophilus is associated with an improvement of *in vitro* lactose fermentation (24). However, this is also known to be true for conventional yogurts. *Lactobacillus delbruekii bulgaricus, S. thermophilus, L. acidophilus,* and *Bifidobacterium* are thought to be antimutagenic and anticarcinogenic (25), and are potentially useful for inhibiting cancer. However, the evidence is still unclear and contradictory (18).

Spanhaak et al. (26) showed that consumption of milk fermented with *L. casei* strain Shirota could modulate the composition and metabolic activities of the intestinal flora. This agrees with the findings of Schiffrin et al. (27) who showed that *L. acidophilus* La1 and *B. bifidus* Bb 12 did not modify lymphocyte subsets in humans.

The gut microflora exert a considerable influence on host biochemistry including : enzymatic activity of intestinal contents, SCFA production in the lumen, oxidation reduction potential of luminal contents, host physiology, host immunology, and modification of host synthesized molecules (28). The SCFA and, to a lesser extent, gases primarily provide a source of energy and growth substrates to other gut microorganisms, salvage dietary energy (60–70% of epithelial cell energy is derived from butyrate), affect colonic mucosal cell proliferation and differentiation, control luminal pH, improve mineral ion absorption, and regulate metabolic pathways (29).

In vitro and *in vivo* studies show that the intermediate and end products of fermentation formed by colonic bacteria depend partly upon the chemical composition of the polysaccharide substrate. For example, starch fermentation yields high levels of butyrate, whereas with a more oxidized substrate such as pectin, more acetate is produced (30,31). Cummings and Macfarlane (2) suggested that this may be explained by the fact that different bacteria take part in fermenting different polysaccharides. The relative rate of depolymerization of complex carbohydrates in the colon may influence the types of fermentation product that are generated (2). A contribution is also given by the physiology and anatomical architecture of the gut (32,33). Transit time of digesta through the colon strongly influences the activities of the gut microflora (2) and fecal ammonia concentrations (34). Best estimates indicate that the amount of NSP (nonstarch polysaccharides) available for fermentation from the U.K. diet is in the range of 8–18 g/d (2,35). In persons consuming western type diets, the amount of fermented carbohydrate, other than starch and NSP, is unlikely to be more than 10 g/d (2). Principal sugars escaping absorption in the small intestine are lactose, raffinose, and stachyose (2).

In humans, acetate, propionate, and butyrate account for approximately 85–95% of total SCFA in all regions of the colon. Other acidic products of fermentation are found in the large gut, such as the branched chain fatty acids, isobutyrate, 2-methylbutyrate, and isovalerate, which are products of amino acid fermentation; while other organic acids, including the electron sink products lactate and succinate, accumulate to a lesser degree (36). Further acidic, neutral, or basic products of the hind gut fermentation include phenols, indoles, amines, and ammonia (7), which are generated during the catabolism of amino acids.

The precise mechanisms whereby SCFA are absorbed in humans are not known with certainty; however, the process is concentration dependent, and SCFA transport is associated with the appearance of bicarbonate ions and stimulation of sodium absorption, and is independent of bulk water flow (3,37,38).

24.2 GUT MICROFLORA IN HEALTH AND DISEASE

24.2.1 Acute Infections and Inflammatory Reactions

Disturbances in the normal intestinal microbial community structure can result in a proliferation of pathogens. Acute inflammatory reactions cause diarrhea and sometimes vomiting, and can be associated with a number of bacteria and viruses including *E. coli*, *Campylobacter* species, *Vibrio cholerae*, *S. aureus*, *B. cereus*, *Clostridium perfringens*, *Salmonella* species , *Shigella* species, *Yersinia* species, and protozoa, especially *Giardia lamblia*, *Entamoeba histolytica,* and *Cryptosporidium parvum* (39,40). Bacteria can also be linked to more chronic diseases in the colon. For example, *C. difficile* has been targeted as the primary causative agent of pseudomembranous colitis.

The GI tract functions as a barrier against antigens from microorganisms and food (41). Among the possible mechanisms of probiotic therapy is promotion of a nonimmunological gut defense barrier, which includes the normalization of increased intestinal permeability and altered gut microecology. Another possible mechanism is improvement of the intestinal immunological barrier; particularly through immunoglobulin A responses and alleviation of gut inflammatory responses, which produce a stabilising effect. Many probiotic effects are mediated through immune regulation, particularly from the balance control of proinflammatory and antiinflammatory cytokines (41).

Research has shown that *Bifidobacterium* spp. can exert powerful antagonistic effects toward *E. coli* and other pathogens like *Campylobacter* and *Salmonella*. The inhibitory effect was variable in species of *Bifidobacterium* spp., with *B. infantis* and *B. longum* exerting the greatest effect (42).

Several open studies suggest a beneficial role of *L. rhamnosus* GG, *S. boulardii,* and *L. plantarum* LP299v during *C. difficile* related infections (43–50). Some studies have shown promising effects of probiotics on inflammatory bowel disease in animals. Intracolonic administration of *L. reuteri* R2LC to rats decreased the disease, whereas *L. reuteri* HLC was ineffective (51).

While there is likely to be a more chronic component to Crohn's disease, *Eubacterium, Peptostreptococcus, Pseudomonas, Bacteroides vulgatus,* mycobacteria, and *C. difficile* have all been associated with its onset (52). In an open study, a 10 day administration of *L. rhamnosus* GG to 14 children with active or inactive Crohn's disease resulted in an increase in immunoglobulin A secreting cells to β-lactoglobulin and casein, which indicated an interaction between the probiotic and the local immune system (53). Various epidemiological and animal studies, from numerous groups, have agreed that ulcerative colitis has a microbial etiology. In particular, sulphate reducing bacteria are also thought to play an important role (54).

Studies have shown a probiotic preparation to be as effective as mesalazine in reducing and preventing relapse in ulcerative colitis (55,56). *Helicobacter pylori* survives in the mucosal layer of the gastric epithelium, and is thought to be involved in the etiology of ulcers, type B gastritis, and stomach cancer. It secretes ammonia as part of its normal metabolism, thereby allowing it to survive at the acidic pH in the stomach (57). Attempts to eradicate *H. pylori, in vivo* with a probiotic have mainly failed (58).

24.2.2 Antibiotic Associated Diarrhea (AAD)

Diarrhea occurs in about 20% of patients who receive antibiotics. Antibiotic associated diarrhea (AAD) results from microbial imbalance that leads to a decrease in the fermentation capacity of the colon. Invasion with *C. difficile*, *Klebsiella oxytoca,* and *C. septicum* are causes of AAD (39,59).

Studies have shown that oral administration of *S. boulardii* can decrease the risk of AAD (50,59). Other studies have shown the efficacy of *S. boulardii* (60), *Enterococcus faecium* SF68, and *L. rhamnosus* GG in shortening the duration of AAD (59).

Several trials have suggested a preventive effect of some fermented products on the risk of diarrhea in children (61,62). Saavedra et al. (63) showed that feeding *B. bifidum* and *S. thermophilus* to infants significantly reduced the risk of diarrhea and the shedding of rotavirus.

24.2.3 Immune Stimulation

In a human trial, administration of probiotic yogurt gave an increase in the production of γ-interferon (64). In animal models, probiotics have been shown to stimulate the production of antibodies (local and systemic), enhance the activity of macrophages, increase γ-interferon levels, and increase the concentration of natural killer cells (65).

An enhancement in the circulating IgA antibody secreting cell response was observed in infants supplemented with a strain of *L. casei*, and this correlated with shortened duration of diarrhea in the study group when compared to a placebo group (66). Other studies have reported an enhancement in the nonspecific immune phagocytic activity of granulocyte populations in the blood of human volunteers after consumption of *L. acidophilus* and *B. bifidum* (67–69). It is possible that stimulation of intestinal IgA antibody responses induced by lactic acid bacteria (LAB) may be explained partly by an effect on phagocyte cell functions. Ingestion of yogurt has been reported to stimulate cytokine production, including γ-interferon, in human blood mononuclear cells (70).

It has been shown in experimental animals that the postnatal maturation of small intestinal brush border membranes was associated with increased food protein binding capacity (71). The capacity of antigens to bind to epithelial cells is related to the rate and route of antigen transfer and shown to influence the intensity of mucosal immune responses (72). Oral introduction of *Lactobacillus* species can enhance nonspecific host resistance to microbial pathogens, thereby facilitating the exclusion of pathogens in the gut (73,74). Several strains of live lactic acid bacteria have been shown *in vitro* to induce the release of the proinflammatory cytokines tumor necrosis factor α, and interleukin 6, reflecting stimulation of nonspecific immunity (75).

Oral introduction of *L. casei* and *L. bulgaricus* activates the production of macrophages (73) and administration of *L. casei* and *L. acidophilus* activates phagocytosis in mice (74). Enhanced phagocytosis by *L. acidophilus* Lal was also reported in humans (67).

Probiotic bacteria have been shown to modulate phagocytosis differently in healthy and allergic subjects: in healthy persons there was an immunostimulatory effect, whereas in allergic persons, down regulation of the inflammatory response was detected (76).

Consumption of the adhesive strains *L. johnsonii* Lj1 and *B. lactis* Bb12 has been shown to increase the phagocytosis of *E. coli, in vitro* (67). A combination of both strains, together with *S. thermophilus*, has also been shown to possess adjuvant activity when consumed in combination with an attenuated *Salmonella typhimurium*. The preparation caused a significant increase in a specific serum IgA to the *Salmonella* (77).

In order to influence the immune system, a probiotic microorganism must activate the lymphoid cells of the gut associated lymphoid tissue, which are diffusely distributed amongst epithelial cells and populate the lamina propria and submucosa (78). Some probiotic strains are clearly antagonistic against *Helicobacter pylori, in vitro* although as mentioned earlier, experiments have not been so successful *in vivo* (59). A significant reduction of urease activity *in vivo* (which reflects the activity of *H. pylori*) has been reported in patients treated with a supernatant of *L. johnsonii* La1 (79).

Lactic acid bacteria have been observed to produce antimicrobial substances. The most widely produced antimicrobial substances are organic acids, especially lactic and acetic acids. Hydrogen peroxide and carbon dioxide are also widely produced by LAB. If probiotic LAB are metabolically active during their passage throughout the intestinal tract, it is very likely that some of these substances will be produced. A reduction in fecal pH confirms this. The production of other antimicrobial components, diacetyl, reuterin, pyroglutamic acid, and especially bacteriocins, is not certain under *in vivo* conditions. To date, no studies have been performed to investigate the production or efficacy of bacteriocins in the intestine. Evidence exists that they are produced and active in the oral cavity (80). Mechanisms implicated in the protective effects of probiotics may therefore include the production of acids, hydrogen peroxide, or antimicrobial substances; competition for nutrients or adhesion receptors; antitoxin actions; and stimulation of the immune system (59).

24.2.4 Lactose Intolerance

Lactose intolerance is a problem for approximately 70% of the world's population and is linked to a low intestinal β-galactosidase activity. Inadequate hydrolysis of dietary lactose leads to abdominal discomfort (81). Some lactic acid bacteria, including *L. acidophilus* and *B. bifidum,* produce β-D-galactosidase, the action of which increases tolerance to dairy products (81). There is good evidence for the alleviation of symptoms of lactose intolerance by specific probiotics and, recently, immune changes related to milk hypersensitivity have been shown to be down regulated (76).

It is well established that persons with lactose intolerance experience improved digestion and tolerance of the lactose contained in yogurt than of that contained in milk (82). At least two mechanisms have been reported to explain this: digestion of lactose in the gut lumen by lactase contained in the yogurt bacteria, and slower intestinal delivery or transit time of yogurt compared to milk (82–85). Kim and Gilliland (81) suggested that improved lactose digestion was not caused by lactose hydrolysis prior to consumption, but rather by the action of the enzyme in the digestive tract.

24.2.5 Colon Cancer

Bacterial links to colonic cancer are also evident. The colon is the second most common site of tumor formation in humans, and several bacterial products are carcinogenic (86). Development of colon cancer consists of a sequence of events that, although incompletely understood, occurs in definable steps. First is an initiating step, in which a carcinogen, produced by metabolic activation of a precursor, produces an alteration in DNA. At present, it is believed that several mutations must occur for a tumor to develop. The postinitiation steps are much less clear, but usually involve changes in signal transduction pathways. The next clear step is an overgrowth in colonic crypts, which can be seen morphologically

in an aberrant crypt. Aberrant crypts, which are considered preneoplastic structures, are enlarged and elevated relative to normal crypts, and have a serpentine growth pattern. Aberrant crypts may occur singly or as groups of aberrant crypts within a single focus. A certain small but unknown fraction of these aberrant crypts will progress to polyps and eventually to tumors (87).

The carcinogenic effect of endogenous toxic and genotoxic compounds is probably influenced through the activity of the bacterial enzymes NAD(P)H dehydrogenase, nitroreductase, β-glucuronidase, β-glucosidase, and 7-α-dehydroxylase. Harmful and beneficial bacteria commonly found in the intestine differ in their enzyme activities (88). *Bifidobacterium* spp. and lactobacilli have negligible activities of xenobiotic metabolising enzymes, unlike bacteroides, clostridia, and enterobacteriaceae.

Ingestion of viable probiotics and prebiotics is associated with anticarcinogenic effects, one mechanism of which is the detoxification of genotoxins in the gut (89). Because of the complexity of cancer initiation, progression, and exposure in the gut, many types of interactions may be envisaged. It has been shown (89) that short lived metabolite mixtures isolated from milk that was fermented with strains of *L. bulgaricus* and *S. thermophilus,* were more effective in deactivating aetiological risk factors of colon carcinogenesis than cellular components of microorganisms. The underlying mechanisms are not known. After ingestion of resistant starch, the gut flora induces the chemopreventive enzyme glutathione transferase π (EC 2.5.1.18) in the colon. Together, these factors lead to a reduced load of genotoxic agents in the gut and increased production of agents that deactivate toxic components. Butyrate is one such protective agent and is associated with a lowering of cancer risk (89). The role of butyrate in modulation of nucleic acid metabolism is of particular interest, especially its effects upon regulation of gene expression and cell growth. Butyrate can reversibly alter the *in vitro* properties of human colorectal cancer cell lines by prolonging doubling time and slowing down growth rates (90). Low concentrations of this SCFA reduce DNA synthesis and suppress proliferation in a variety of cell types (91–93).

Ammonia is mainly formed through the deamination of amino acids (6,94). It is rapidly absorbed from the gut and detoxified by urea formation in the liver. Low concentrations can alter the morphology and intermediate metabolism of colonic epithelial cells (95,96), affect DNA synthesis, and reduce their lifespan. Thus, a high ammonia concentration in the colonic lumen may select for neoplastic growth.

Phenols and indoles do not appear to be carcinogenic alone, but act as cocarcinogens (97). Increased production of these metabolites has been found to occur in a variety of disease states (9,98,99). Phenolic and indolic compounds are produced by deamination of the aromatic amino acids, tyrosine, phenylalanine, and tryptophan. Phenols are not found in urine of germ free animals (8).

In colon cancer, the evidence of probiotic efficacy is still not certain. In animal models it was shown that a dietary intake of *B. longum* significantly suppressed development of azoxymethane (AOM) induced aberrant cryptic foci formation in the colon (100). This study was also confirmed by another using *B. longum* and inulin (101). Kinouchi et al. (102) showed that *L. acidophilus* and *B. adolescentis* suppressed ileal ulcer formation in animal models. *Lactobacilus acidophilus* fed to healthy volunteers significantly decreased β-glucuronidase, nitroreductase, and axoreductase activities (103).

Oral administration of *L. casei* strain Shirota has been shown to have inhibitory properties upon chemically induced tumors in rats (104). Also, it may prolong survival during specific cancer treatments (105). The beneficial effect of probiotic based cancer therapy has been associated with their antimutagenic properties and ability to modulate immune parameters including T-cell, natural killer (NK) cell, and macrophage activities,

which are important in hindering tumor development (27,76,104). Some, but not all, epidemiological studies suggest that consumption of fermented dairy products may have certain protective effects against large colon adenomas or cancer (106).

Dietary administration of lyophilized cultures of *B. longum* strongly suppressed AOM induced colon tumor development. The inhibition of colon carcinogenesis was associated with a decrease in colonic mucosal cell proliferation and colonic mucosal and tumor ODC (ornithine decarboxylase) and *ras*-p21 oncoprotein activities (107). *Ras* activation represents one of the earliest and most frequently occurring genetic alterations associated with human cancers, especially that of the colon (108). Elevated levels of *ras*-p21 have been correlated with increased cell proliferation, histological grade, nuclear anaplasia, and degree of undifferentiation (109). The major conclusion from animal data is that there appears to be a synergistic effect of consumption of probiotics and prebiotics on the attenuation of development of colon cancer. The effect is often not large, but it is possible that it could be beneficial, in combination with other methods to reduce risk (87).

24.2.6 Cholesterol Lowering Effect and Lipid Metabolism

Prebiotics in the form of fermented milk are thought to have cholesterol lowering properties in humans. However, studies have given equivocal findings. Even recent studies fail to provide convincing evidence that "live" fermented milk products have any cholesterol lowering efficacy in humans (110).

In animals, dietary FOS caused a suppression of hepatic triglyceride and VLDL (very low density lipoprotein) synthesis, resulting in marked reductions in triglycerides, and to a lesser extent cholesterol, levels (110). Evidence for similar effects in humans is sparse and more studies are needed, particularly with respect to effects on postprandial triglyceride concentrations (110).

Propionate metabolism has also been studied in ruminants, where it is a major gluconeogenic precursor (111). In rats, it has been shown to lower cholesterol (112,113) either by inhibition of hepatic cholesterol synthesis or by redistribution of cholesterol from plasma to the liver (113). In humans, however, no change was seen in total cholesterol levels, although HDL (high density lipoprotein) cholesterol increased when a group of females were fed sodium propionate (114).

In CHD (coronary heart disease) there are variable data and no firm conclusions can be drawn (65). Schaafsma et al. (115) found that daily feeding of 125 mL of a test probiotic milk significantly lowered LDL (low density lipoprotein) cholesterol levels and total serum cholesterol.

24.3 STRUCTURE TO FUNCTION RELATIONSHIPS IN PREBIOTIC OLIGOSACCHARIDES

Eight NDOs have been licensed as having FOSHU (Foods for Specified Health Use) status by the Ministry of Health and Welfare in Japan: GOS (galactooligosaccharides), FOS (fructooligosaccharides), lactulose, XOS (xylooligosaccharides), soybean oligosaccharides, raffinose, lactosucrose, and isomaltooligosaccharides (116). The efficacy of prebiotics toward promoting human health is strongly related to their chemical structure. This section of the review therefore elucidates the interactions between oligosaccharide structure and prebiotic effects.

24.3.1 Fructooligosaccharides

"Fructooligosaccharides" (FOS) is a common name for fructose oligomers that are mainly composed of 1-kestose (GF_2), nystose (GF_3), and 1^F- fructofuranosyl nystose (GF_4) in which fructosyl units (F) are bound at the β-2,1 position of sucrose (GF) (117). FOS are produced from sucrose through the transfructosylating action of either β-fructofuranosidases (β-FFase, EC 3.2.1.26) or β-D-fructosyltransferases (β-FTase, EC 2.4.1.9) (119).

24.3.1.1 Fermentability of FOS

In vitro experiments (anaerobic batch culture fermenters inoculated with human fecal bacteria and a carbohydrate substrate) on the comparative fermentation of chicory inulin and FOS showed that both inulin and FOS were rapidly and completely metabolized by the microbial flora in the fermenters. The relative rate of fermentation was similar for both substrates. A more detailed analysis however, revealed that the rate of degradation of oligomers with a degree of polymerization (DP < 10) was approximately twice that of molecules with a higher DP. Also, GF_n type and F_m type components of inulin hydrolysates disappeared from the culture medium at a similar rate, and the two types are known to have similar bifidogenic effects (119). There is no difference between FOS obtained by partial enzymatic hydrolysis (containing fructan chains ending with a glucose moiety as well as fructan chains ending with a fructose moiety) and FOS obtained by enzymatic synthesis from sucrose (120).

The efficiency of FOS over sucrose and other sugars as substrates for most strains of *Bifidobacterium* spp. is due to the intracellular 2,1 β-D fructan-fructanhydrolase (E.C 3.2.1.7) activity (119,121), which liberates monomeric fructose molecules that are then transported into the bacterial cell (122). The fructose moiety is then metabolized in the specific "bifidus" pathway (19). The enzyme also gives the genus a competitive advantage in the human gut (121). The β(2-1) bond linking the fructose moieties in the FOS chains is central in the nondigestibility as well as the bifidogenic properties of FOS (123).

Lactobacillus plantarum and *Lactobacillus rhamnosus* were found to be capable of metabolising only tri- and tetrasaccharide fractions, not pentasaccharides (124). This suggests that there may be specific transport systems in these organisms for trisaccharides and tetrasaccharides (125). In general, feeding of FOS increases *Bifidobacterium* spp. and *Lactobacillus* species, increases SCFA concentrations, and decreases *Clostridium* spp., *Fusobacterium* spp., *Bacteroides*, and pH (29,126–128). The intake doses of FOS that elicit a bifidogenic effect in human studies has ranged from 4 to 15 g/d (128,129). That *Bifidobacterium* species selectively ferment the fructans in preference to other carbohydrate sources such as starch, fructose, pectin, and polydextrose was confirmed in a volunteer trial using fructooligosaccharides (127) and by other human studies (130,131).

Using continuous chemostat cultures inoculated with fecal slurries, Gibson and Wang (132) showed that after six turnovers, chicory derived FOS, but not glucose, were able to selectively stimulate *Bifidobacterium* spp. growth; the number of these bacteria was almost three orders of magnitude higher than *Bacteroides*. With glucose as the substrate, *Bacteroides* were two orders of magnitude higher than *Bifidobacterium* spp. (119). *In vitro* studies showed that the majority of *Bifidobacterium* species utilized FOS and low polymerized inulins, although twelve out of the thirty strains tested were not stimulated. Incorporation of FOS into the diet stimulated the proliferation of fecal *Bifidobacterium* spp. by 1.6 log cfu/g under *in vivo* conditions, whereas *B. animalis* KSp4 was not effective (133).

Administration of *Bifidobacterium* spp. together with the prebiotic improved the bifidogenic effect by around 1.4 log cfu/g of feces. Supplementation had almost no effect upon some groups of gut microflora (133). This indicates that utilization of inulin by

Bifidobacterium spp. depends on the degree of polymerization (DP) of fructooligomer chains and purity of the preparations. Among FOS, low DP inulin and high DP inulin, FOS was the most fermentable substrate and inulin the least.

It has also been suggested that fructans with higher DP are less rapidly fermented by *Bifidobacterium* (133). The results of this study indicate that the ability of *Bifidobacterium* spp. to metabolize FOS is a species dependent feature, and only to a small extent strain dependent. Muramatsu et al. (121) showed that the β-fructofuranosidase from *B. adolescentis* G1 has a unique substrate specificity to fructooligomers of DP 2-8 than to inulin and sucrose. All *L. acidophilus* strains tested fermented FOS, a result consistent with that recently reported by Sghir et al. (134). Such strains were: 33200 (ATCC), 837 (ATCC), DDS-1 (NC), and NCFM (NCSU), the latter two being widely promoted as probiotics. Three other commercial probiotic strains, *L. plantarum* MR240, *L. casei* MR191, and *L. casei* 685, also fermented FOS, whereas *Lactobacillus* strain GG was found to be a nonfermenter (despite being a well studied probiotic strain). Interestingly, most of the *L. bulgaricus* and *S. thermophilus* strains (the bacteria traditionally used in yogurt manufacture) were not FOS fermenters (124).

Perrin et al. (122) compared the physiological behavior of *B. infantis* ATCC 15697 growing on synthetic FOS or its components. The studies were carried out in batch cultures on semisynthetic media. Glucose, fructose, sucrose, and FOS as carbohydrate sources were compared. Glucose was the preferred substrate for growth and biomass production. Fructose was the best for lactate and acetate production. With FOS more metabolites were produced than with fructose. In a mixture of FOS, the shorter saccharides were used first [this has also been observed with other strains (135)] and fructose was released in the medium. Fructofuranosidase was inducible by fructose. The conclusion was that the glucose contained in FOS and sucrose might sustain growth and cell production while fructose may enable the production of major metabolites (122).

As a consequence of the metabolism of the FOS by fermentative bacteria, SCFA and lactic acid are produced. Both lead to a drop in the pH of the large intestine. This is beneficial for the organism as it constitutes an ideal medium for the development of the bifidogenic flora and, at the same time, limits the development of bacteria which are considered pathogens. The content of the metabolites produced by putrefactive bacteria decrease following the ingestion of FOS (136).

The addition of *L. acidophilus* 74-2 with FOS gave rise to an increase of *Bifidobacterium* spp. Major positive changes occurred in the production of organic acids: a strong upward trend was observed especially in the case of butyric and propionic acids. A noticeable increase of β-galactosidase activity was monitored while the activity of β-glucuronidase, generally considered undesirable, declined (137).

A variety of fermentation products influence the anatomy, physiology, and immunology of the host; and conversely the general constitution of the host affects the microbial community in the intestine (137). Gibson and Wang (132) have shown that *in vitro*, when *Bifidobacterium* spp. are given FOS as a substrate they secrete a peptide that is inhibitory to most of the common organisms causing acute diarrhea. In human healthy volunteer studies, oral dosing with 15 g of FOS daily led to *Bifidobacterium* spp. becoming the dominant species in the large bowel (127).

It was found that neither FOS nor inulin was, to a significant extent, fermented by *B. bifidum* (138). Bacteria other than the *Bifidobacterium* spp. can ferment FOS. These include *K. pneumoniae*, *S. aureus* and *epidermidis*, *E. faecalis* and *faecium*, *Bacteroides vulgatus*, *thetaiotamicron*, *ovatus* and *fragilis*, *L. acidophilus,* and *Clostridium* species, mainly *butyricum* (119). However, their ability to do so in mixed culture is repressed by *Bifidobacterium* spp. competition.

24.3.1.2 FOS Interactions with Lipid Metabolism

Evidence suggests that FOS acts as a soluble fiber and can be useful in increasing intestinal motility and transport, and in the reduction of high levels of plasma cholesterol (136). FOS can decrease triaglycerol in VLDL when given to rats. The triaglycerol lowering action of FOS is due to a reduction of *de novo* fatty acid synthesis in the liver through inhibition of all lipogenic enzymes (139).

Postprandial insulin and glucose concentrations are low in the serum of FOS fed animals and this could explain, at least partially, the metabolic effects of FOS. Some events occurring in the gastrointestinal tract after oligofructose feeding could be involved in the antilipogenic effects of this fructan: the production of propionate through fermentation, a modulation of the intestinal production of incretins, or modification of the availability of digestible carbohydrates. Recent studies have shown that the hypotriglyceridemic effect of fructans also occurs in humans (139).

The effects of inulin-type fructans on glycemia and insulinemia are not yet fully understood, and available data are often contradictory. Other nondigestible carbohydrates are known to modify the kinetics of absorption of carbohydrates, thus decreasing the incidence of glycemia and insulinemia (140,141).

24.3.1.3 FOS Interactions with Mineral Absorption

The production of a high concentration of short chain carboxylic acids in the colonic fermentation of nondigestible carbohydrates facilitates the absorption of minerals, Ca^{2+} and Mg^{2+} in particular (142). Roberfroid (143) argued that inulin-type fructans may improve mineral absorption and balance by an osmotic effect that transfers water into the large bowel, thus increasing the volume of fluid in which these minerals can dissolve. Also, acidification of the colon (as a consequence of carbohydrate fermentation) raises the concentration of ionized minerals, which favors passive diffusion. *In vivo* human studies have confirmed the positive effect of inulin and FOS upon absorption of calcium, but not of iron, magnesium, or zinc (144,145).

It has been observed that the effect of FOS on metabolic calcium balance, calcium content of bone, and prevention of ovariectomy induced loss of trabecular structure became more prominent when dietary calcium was high (146,147). It has been discussed that at least part of the stimulating effect of FOS on mineral absorption might be attributed to SCFA production (148).

24.3.1.4 FOS Interactions with Cancer

Prebiotics, in particular the chicory derived β(2-1) fructans, have been shown to exert cancer protective effects in animal models (149). A study was carried out to determine the effects of two chicory fructans: FOS (Raftilose P95, average DP 4) and long chain inulin (Raftiline HP, average DP 25) on apoptosis and bacterial metabolism in rats (149). Both substrates were shown to exert protective effects at an early stage in the onset of cancer.

It has been shown that inulin at dietary concentrations of 5–10% suppressed ACF (foci) in the rat colon (101,123,150).

NDOs may exert cancer protective effects at the cellular level following SCFA formation during fermentative bacterial metabolism. Butyrate, acetate, and propionate regulate colonic epithelial turnover and butyrate induces apoptosis in colon adenoma and cancer lines (151,152).

Rao et al. (150) and Rowland et al. (101) have reported protective effects of inulin at a postinitiation stage in the form of suppression of early preneoplastic lesions following

treatment with a carcinogen. In this study, there was a trend toward increased colonic β-glucosidase activity and decreased ammonia concentration in the rats fed oligofructose or inulin. This was a positive response as ammonia is a known tumor promoter (96), so suppression of ammonia formation in the gut can be considered beneficial. β-glucuronidase is involved in DMH (1,2-dimethylhydrazine) and AOM metabolism, causing the release of MAM (methylazoxymethanol) from its biliary conjugate in the colon. Therefore, a decrease in β-glucuronidase may be protective (149). Large concentrations of butyrate can be produced as products of colonic fermentation by gut bacteria. Young (153) proposed that butyrate possessed antitumor properties, indicating the potential of probiotic strains such as *Lactobacillus* for preventing cancer. This study has shown a strong increase of β-galactosidase activity during administration of *L. acidophilus* 74-2 with FOS. After addition had stopped, the β-galactosidase activity again declined suggesting a causal link between the intake of a prebiotic product and increase of β-galactosidase activity, whereas β-glucuronidase activity declined (137).

24.3.2 Galactooligosaccharides

6' Transgalactosylated oligosaccharides (GOS, 154) are oligosaccharides produced by transgalactosylation of lactose using a β-galactosidase (β-Gal) (155). *In vitro,* GOS increased ATP, SCFA, and acetate concentrations, decreased pH and were 95% degraded from the fourth day of intake onward. They lead toward an increase in *Bifidobacterium* spp. species, while breath hydrogen excretion was reduced. However, methane excretion and levels of *Enterobacter* species are not affected (156).

GOS can be fermented by a number of intestinal bacteria including *Bifidobacterium* spp., *Bacteroides*, *Enterobacteria,* and *Lactobacillus* species (154,157,158).

A few human feeding studies investigating the prebiotic potential of GOS suggest that they may have bifidogenic potential (156,159). The bifidogenic nature of GOS has been related to a linkage specificity of the *Bifidobacterium* β-galactosidase, which cleaves β1-3 and β1-6 linkages, instead of β1-4 linkages (160).

Two probiotic strains, *Bifidobacterium lactis* DR10 and *Lactobacillus rhamnosus* DR20, were tested for their ability to utilize and grow upon GOS present in a commercial hydrolysed lactose milk powder (161). The results demonstrated that *B. lactis* DR10 preferentially utilized tri- and tetrasaccharides whereas *L. rhamnosus* DR20 preferred sugars with a lower degree of polymerization (di- and monosaccharides). Surprisingly, monosaccharides including glucose were the final sugars to be utilized by *B. lactis* DR10 (161). According to Rastall and Maitin (125) this suggests that *B. lactis* has a specific transport system for GOS that is not present in *L. rhamnosus*. A β-galactosidase that displays hydrolytic activity toward GOS but not lactose has been described in *B. adolescentis* (162). It has a preferential activity toward GOS with DP 2-3.

Fifty-four strains of lactic acid bacteria were studied for their ability to ferment lactose derived oligosaccharides. A good correlation was seen between the ability of a strain to utilize oligosaccharide and the presence of the lactose hydrolysing enzyme β-galactosidase (161). It has been suggested that GOS can be used more readily and selectively *in vitro* by *Bifidobacterium* spp. than other oligosaccharides such as lactulose and raffinose (163). However, the mechanism of utilization of this oligosaccharide by this group of bacteria is poorly understood. It is known that even though most *Bifidobacterium* spp. strains of human gut origin can readily use GOS, only a few strains from other genera, including *Lactobacillus* species, possess this ability (158,163). 4'-Galactosyllactose is selectively utilized by all the *Bifidobacterium* strains tested (157,158,164) compared with lactulose and raffinose whose specificity is less marked. Other studies also show that some strains of *Lactobacillus, Bacteroides* and *Clostridium* ferment GOS, and TD (transgalactosylated

disaccharides) might even be better substrates for these bacteria (157,158). The bacterial species that ferment 4'- and 6'-GOS overlap, although some differences are found (116).

Physiological effects of GOS fermentation in the gut are:

1. Improvement of defecation. Deguchi et al. (165) showed that ingestion of 5g of GOS daily improved defecation frequency in a group of women.
2. Elimination of ammonia. In a human study, the ingestion of 4'-GOS at a dose of 3 g/d reduced the fecal ammonia concentration (166). The fact that other putrefactive products such as phenol, p-cresol, and indole were also decreased indicates that there was a dramatic change in metabolism upon ingestion of 4'-GOS.
3. Colon cancer prevention.
4. Stimulation of calcium absorption. Chonan et al. (167) found a stimulatory effect of GOS on calcium absorption and calcium content in femur and tibia with 0.5% calcium supplementation but not with 0.05%.

In a human volunteer trial, it was found that GOS increased *Bifidobacterium* spp. and *Lactobacillus* numbers while decreasing *Bacteroides* species and *Candida* species (159).

At a dose of 10 g/d, GOS given in the diet for 21 days decreased breath H_2 excretion and increased fecal *Bifidobacteria* without affecting *Enterobacteria* species or fecal pH (147). Similar results were found with inulin and lactose.

Van Laere et al. (162) reported on the effects of both reducing and nonreducing GOS comprising 2 to 8 residues on the growth of *B. adolescentis* DSM20083 and on the production of a novel β-galactosidase (β-GalII). In cells grown on GOS, in addition to the lactose degrading β-Gal (β-Gal I), another β-Gal (β-Gal II) was detected and it showed activity toward GOS but not toward lactose (162). During fermentation of GOS the di- and trisaccharides were first metabolized. β-Gal II was active toward β-galactosyl residues that were 1-4, 1-6, 1-3, and 1-1 linked, indicating its role in the metabolism of GOS by *B. adolescentis*, one of the predominant human fecal bacteria (162). This enzyme might allow *B. adolescentis* to utilize the oligosaccharides more efficiently than other microorganisms. Therefore, this GOS mixture, containing mainly higher molecular weight materials, might be an interesting prebiotic substrate. During the growth of *B. adolescentis* on GOS a large number of glycosidases are produced, including two arabinofuranohydrolases, which are involved in the degradation of arabinoxylooligosaccharides. This may offer an additional competitive advantage, since it allows the organism to scavenge the environment for a range of substrates and use the degradation products for growth (162). No endoglycanase activity could be detected in the cell extract, suggesting that *B. adolescentis* adopted a strategy aimed at utilizing polysaccharide degradation products generated by other microorganisms instead of taking part in the initial depolymerization stage of polysaccharides (162).

These results indicate that certain *Bifidobacterium* spp. together with prebiotics may be used for prophylaxis against opportunistic intestinal infections with antibiotic resistant pathogens (168).

24.3.3 Isomaltooligosaccharides

Isomaltooligosaccharides (IMO) are composed of glucose monomers linked by α1-6 glucosidic linkages. Isomalto-900, a commercial product, is produced by incubating α-amylase, pullulanase, and α-glucosidase with cornstarch. The major oligosaccharides in this mixture are isomaltose, isomaltotriose, and panose. IMO occur naturally in various fermented foods and sugars such as soybean sauce and honey (169).

IMO have been shown to be fermented by *Bifidobacterium* spp. and *Bacteroides fragilis*, but not by *E. coli* and other bacterial populations (169). IMO are efficient prebiotics in that they stimulate a lactic microflora as well as allow elevated production of butyrate, which is thought to be a desirable metabolite in the gut (65). Furthermore, the IMO mixture consisting of a high degree of branched oligosaccharides (due to α-GTase) is expected to be particularly effective at promoting *Bifidobacterium* spp. growth in the human intestine as growth of *Bifidobacterium* spp. is known to be enhanced in proportion to the degree of glucosidic polymerization of the IMO components (170). Kaneko et al. (171) reported that the IMO mixture containing trisaccharides and tetrasaccharides was more effective in enhancing the microflora than the IMO mixture of disaccharides.

Olano-Martin et al. (172) looked into the fermentability of dextran and novel oligodextrans (I, II, and III) by gut bacteria. In anaerobic batch culture, dextran and oligodextrans increased the number of *Bifidobacterium* spp. and butyrate concentration. Using a three stage continuous culture cascade system, it was shown that a low molecular weight oligodextran (IV) was the best substrate for *Bifidobacterium* spp. and lactobacilli. Moreover, dextran and oligodextrans stimulated butyrate production, which suggests that oligodextrans indeed have potential as modulatory agents for the gut microflora.

24.3.4 Lactulose

Lactulose (Galβ1,4 Fru) is formed by heating lactose syrup to caramelization (173). It was discovered by Montgomery and Hudson in 1930 (174) and its growth promoting effect for *Bifidobacterium* species was determined by Petuely (175).

It is difficult to crystallize in water solution, however, a new crystal form of lactulose was recently reported (173,176). It has an energy value of 2.2 and 2.0 kcal/g for miniature pigs and rats, respectively (177). The medical applications of lactulose include the treatment of hyperammonemia, hepatic encephalopathy, and chronic constipation. Lactulose is also thought to prevent renal (178) and liver failures, is expected to lower incidence of colorectal cancer, shows a therapeutic effect in salmonella carrier state, has an antiendoxin effect, and contributes toward a decreased response in diabetics (179). Lactulose prevents postsurgery complications of obstructive jaundice, activates the immune system, prevents contracting infections, including urinary tract infection and respiratory tract infections, and prevents the recurrence of colorectal adenomas (179). In a human study, total bacterial counts were not changed by administration of lactulose (180); however, the *Bifidobacterium* count increased significantly, and lectinase positive *Clostridium* spp., including *C. perfringens*, and *Bacteroides,* decreased significantly. As a result, the ratio of *Bifidobacterium* in total bacterial counts increased from 8.3% before intake to 47.4% after intake. Indole and phenol, metabolites of intestinal bacteria, decreased significantly during intake, as did ammonia. Enzymatic activities of β-glucuronidase, nitroreductase, and azoreductase in wet feces decreased during intake. Fecal pH decreased and fecal moisture content increased significantly during intake (179). Lactulose promoted the growth of a range of lactic acid bacteria, although their growth was more rapid on lactose, particularly for *B. bifidum* (181). When lactulose was incubated with various intestinally derived strains, *B. bifidum*, *L. casei,* and *Lactobacillus* species utilized the disaccharide well with no gas production, while *C. perfringens* metabolized lactulose with a large amount of gas production (182).

Lactulose has been known to exert an antiendotoxin effect. Liehr and Heine (183) reported that endotoxin mediated galactosamine hepatitis in rats, as induced by intravenous injection of galactosamine, developed necrosis of the hepatocytes, and the inflammatory reaction of the liver tissue was virtually prevented by oral (184) and intravenous (184) administration of lactulose beforehand. Iwasaki et al. (185) reported that when

lactulose was administered to hepatic cirrhosis and hepatic cancer patients, improvement of endotoxemia was observed in 50% of the patients.

Chronic portal systemic encephalopathy is a metabolic disorder of the central nervous system and is characterized by psychiatric and neurological disturbances that may progress from mild mental aberration to coma. It is manifest when ammonia, which is produced in the intestine as a metabolite by intestinal putrefactive bacteria, escapes detoxication by hepatic function and is transported to the brain where it acts as a toxin. Lactulose reduces the ammonia level in blood and alleviates symptoms, because lactulose regulates intestinal activity, stimulates the growth of *Bifidobacterium* spp., and suppresses intestinal pH and therefore ammonia production. This lowers ammonia absorption in the intestine.

Organic acids and SCFA produced in the colon migrate to the blood and are metabolized in the liver. In one study, the production of C_4 and C_6 fatty acids was completely inhibited by lactulose in an *in vitro* incubation system. It was suggested that lactulose thus detoxified the profile of SCFA produced in the presence of proteins (186). Genovese et al. (187) observed that lactulose improved blood glucose response to an oral glucose test in noninsulin dependent diabetic patients by preadministration of lactulose. Also, lactulose activated the cell mediated immune system depressed during liver cirrhosis (188). A significant reduction in the number of patients contracting urinary infections and respiratory infections using lactulose therapy has been found (189).

Onishi et al. (190) studied the effect of lactulose on ammonia metabolism during dynamic exercise. Increases in blood ammonia in graded exercise were suppressed, and oxygen intake at moderate exercise was increased significantly through preadministration of lactulose. It was thus suggested that lactulose has some benefits when used in combination with exercise.

24.3.4.1 Colon cancer

In the context of colon carcinoma, lactulose administration to healthy volunteers lowered fecal concentrations of secondary bile salts (191,192). However Rooney et al. (193) did not confirm this observation. Roncucci et al. (194) reported that lactulose decreased the recurrence rate of colon adenomas. Lactulose suppressed DNA damage in the colon mucosa of rats treated with DMH (1,2 dimethylhydrazine)(195). Roncucci et al. (194) evaluated the effect of lactulose on the recurrence rate of adenomatous polyps. It was found that administration of lactulose reduced the recurrence rate of adenomas in the large bowel.

24.3.4.2 Mineral absorption

Lactulose significantly increased calcium absorption but only if the diet contained >0.3% Ca (196). Magnesium absorption from the cecum was affected by inulin but not by the background amount of dietary calcium (197). Suzuki et al. (198) observed that, in rats, lactulose intake promoted the absorption or retention in the body of Ca, Mg, Zn, Cu, and Fe. Igarashi and Ezawa (199) studied the effect of lactulose on bone strength. The results suggested that lactulose promoted calcium absorption in osteoporosis and increased the strength of bones in rats suffering osteoporosis.

24.3.4.3 Constipation

Lactulose has gained popularity in the treatment of constipation and chronic hepatic encephalopathy (147,200–203). Lactulose prevents constipation through its hyperosmotic effects, mainly based on unabsorbed SCFA and cations associated with it (204). Its effects

are manifest through activation of intestinal peristaltic movement and intestinal acidification and osmotic reaction. However, this could be true of all prebiotics and may have more to do with all NDO structures than lactulose specifically (205).

24.3.5 Soya products

The primary oligosaccharides contained in soybeans are raffinose (Galα1,6Gluα1,2βFru) and stachyose (Galα1,6Galα1,6Gluα1,2βFru). They are growth promoters of *B. infantis, B. longum*, and *B. adolescentis* but do not stimulate *E. coli*, *E. faecalis*, or *L. acidophilus* (173,206). Also, raffinose effects a relatively short generation time of *B. infantis*, independent of the substrate upon which the organism has been previously cultured. In a study by Fooks et al. (65), all *Bifidobacterium* species tested fermented this carbohydrate with the exception of *B. bifidum,* while *L. salivarius*, *B. fragilis,* and *Mitsuokella multiacida* metabolized the substrate to a lesser degree. In another study, it was found that addition of a low concentration [0.1% (w/v)] of SOR (refined soybean oligosaccharides) to a two stage continuous culture of fecal bacteria (207) resulted in a threefold increase in the number of bacteria in the total bacterial count.

De Boever et al. (208) examined the survival of *L. reuteri* when challenged with glycodeoxycholic acid (GDCA), deoxycholic acid (DCA), and soygerm powder. Moreover the impact of *L. reuteri* on the bioavailability of isoflavones present in soygerm powder was examined. When 4 g/l soygerm powder was added, the *Lactobacillus* strain survived the bile salt burden better and the membrane damage in the haemolysis test decreased. The *Lactobacillus* strain cleaved β-glycosidic isoflavones during fermentation of milk supplemented with soygerm powder. Interactions between the bacteria and soygerm powder suggest that combining both in fermented milk could exhibit advantageous synbiotic effects. De Boever et al. (209) have shown that consumption of a soygerm powder may beneficially modulate the colonic fermentation. The soygerm powder contained constituents with putative health benefits such as β-glycosidic isoflavones. They can play an important role in the health benefits from soya food, such as lower incidence of estrogen related cancers, cardiovascular diseases, and osteoporosis (210). Saponins are also present in soygerm powder and these compounds may be responsible for the lowering of the serum cholesterol (211). In this study, soygerm powder and a *Lactobacillus reuteri* strain were combined. Because viability is essential for *L. reuteri* to exert its probiotic effects, the ability of soygerm powder to enhance the survival of *L. reuteri* when the latter was exposed to bile salts was investigated. Free isoflavones are only released from soygerm powder in the colon. A second objective was therefore to determine whether *L. reuteri* deconjugated β-glycosidic isoflavones during the fermentation of milk supplemented with soygerm powder, thereby increasing their bioavailability. Soygerm powder contains putative health promoting estrogenic isoflavones. These molecules occur as biologically inactive β-glycosides, which are poorly resorbed by humans. Isoflavones can only be absorbed in a biologically active form after cleavage of their β-glycosidic linkage. It is generally accepted that this does not occur until the compounds reach the colonic microbiota, which produce β-glycosidase (EC 3.2.1.21) (212). Day et al. (213), found that lactase phlorizin hydrolase (EC 3.2.1.108), a β-glycosidase present in the brush border of the mammalian small intestine, was capable of hydrolysing isoflavone glycosides thereby making the free isoflavones available for resorption. Nevertheless, a substantial loss of isoflavone glycosides into the large intestine can be expected because of a limited residence of food compounds in the small intestine and a possible decrease of lactase phlorizin hydrolase levels in adulthood (214). To take advantage of the putative beneficial isoflavones, Izumi et al. (215) suggested that a constant plasma concentration of isoflavones was needed. Therefore one should try to maximize the resorption of free isoflavones by consuming soya foods

already containing free isoflavones or by releasing free isoflavones in the small intestine. The enzyme profile of the fermentations indicated that the presence of high levels of β-galactosidase released the isoflavones from the soygerm powder.

De Boever et al. (209) used the *in vitro* model SHIME (simulation of the human intestinal microbial ecosystem) to study the effect of a soygerm powder rich in β-glycosidic phytoestrogenic isoflavones on the fermentation pattern of the colon microbiota and to determine to what extent the latter metabolized the conjugated phytoestrogens. The addition resulted in an overall increase in bacterial marker populations (*Enterobacteriaceae*, coliforms, *Lactobacillus* species, *Staphylococcus* species and *Clostridium* species), with a significant increase in the *Lactobacillus* population. The SCFA concentration increased about 30% during the supplementation period; this was due mainly to a significant increase of acetic and propionic acids. Gas analyses revealed that the methane concentration increased significantly. Ammonia and sulphide concentrations were not influenced by soygerm supplementation. Use of an electronic nose apparatus indicated that odor concentrations decreased significantly during the treatment period. The β-glycosidic bonds of the phytoestrogenic isoflavones were cleaved under the conditions prevailing in the large intestine. The increased bacterial fermentation after addition of the soygerm powder was paralleled by substantial metabolism of the free isoflavones resulting in recovery of only 12–17% of the supplemented isoflavones (209).

Isoflavones have been shown to compete effectively with endogenous mammalian estrogens in binding to the estrogen receptor of mammalian cells preventing estrogen stimulated growth of cancerous cells (216,217). Microbiota play an important role in the generation of biologically active isoflavones, but also inactivate these bioactive compounds after further bacterial fermentation, resulting in a loss of their purported beneficial effects.

Much of the research concerning the health promoting effects of soya products has focused on the putative role of one dietary ingredient, the isoflavones. Soya is an important source of many other nutrients, however, including dietary fibre, oligosaccharides (which could classify as prebiotics), proteins, trace minerals, and vitamins, which could influence the host wellbeing (218). Soya products typically contain high concentrations of the α-glycosidic GOS, raffinose, and stachyose. These sugars are not absorbed in the upper part of the gastrointestinal tract or hydrolysed by human digestive enzymes (219). Upon delivery to the colon, the sugars are fermented by the colonic microbiota possessing α-galactosidase activity. Administration of soybean oligosaccharides to an *in vitro* culture of human gut microbiota has been reported to be bifidogenic (220). Therefore, Gibson and Roberfroid (17) suggested a potential prebiotic role for soybean oligosaccharides. Studies fully addressing this hypothesis have not been published.

Soygerm powder is marketed mainly because it contains a large amount of isoflavones, through which the product could relieve menopausal problems, reduce osteoporosis, improve blood cholesterol levels, and lower the risk of certain types of cancer (221,222). The oligosaccharides present in the soygerm powder consist mainly of indigestible raffinose (13 g/kg) and stachyose (87 g/kg), oligosaccharides which, therefore, serve as substrates for bacterial fermentation (219). During the treatment period, the concentration of all bacterial groups increased and the greatest increase was observed for *Lactobacillus* species. An increase in lactic acid bacteria is often driven by a decrease in luminal pH because the capacity to thrive in low pH environments gives these bacteria a selective advantage over other species (134). The pH reduction in a microniche could select for lactic acid producing bacteria in this environment, possibly excluding long term colonization by invasive pathogens (132). During the supplementation period, the fermentative capacity of the microbial community was increased, and this led to a general rise in SCFA. The largest

increase was observed in vessel 3, indicating a high level of carbohydrate fermentation. A rise in SCFA concentration is a positive property because these acids, especially butyric acid, are the main energy source for colonocytes and influence colonic function by stimulating water and sodium absorption and modulating motility (223). Furthermore, butyric acid induces differentiation, stimulates apoptosis of cancerous cells *in vitro,* and thus arrests the development of cancer (224). During supplementation of soygerm powder, no effect on ammonia and hydrogen sulphide concentration was observed. Ammonia can alter the morphology and intermediary metabolism of intestinal cells, increase DNA synthesis, and promote tumorigenesis (225). Hydrogen sulphide selectively inhibits butyric acid oxidation in colonocytes and this may play a pathogenic role in inflammatory bowel diseases such as colitis. Hence, increases in the concentration of these compounds are considered to be potentially harmful to the host. Quantitative gas analyses revealed that methane concentration increased significantly in the last two colonic compartments during the supplementation period. Production of methane by the colonic microbiota is important because it permits a more complete fermentation, in that the removal of H_2 is energetically more favorable (226).

Phenolic and indolic compounds have been linked to a variety of disease states in humans, including initiation of cancer, malabsorption, and anaemia (227). Data revealed that during addition of the soygerm powder, the amount of odor significantly decreased. It is the first study in which the odor produced by the gut microbiota was monitored (209). This indicates that consumption of soygerm powder may influence the gut microbiota in a beneficial manner.

24.3.6 Lactosucrose

Lactosucrose is produced from a mixture of lactose and sucrose using the enzyme β-fructosidase. The fructosyl residue is transferred from the sucrose to the 1-position of the glucose moiety in the lactose, producing a nonreducing oligosaccharide (116) according to the following reaction (228):

$$\text{Gal}\beta1 \rightarrow 4\text{Glc} + \text{Glc}\alpha1 \leftrightarrow 2\beta\text{Fru} \rightarrow \text{Gal}\beta1 \rightarrow 4\text{Glc}\alpha1 \leftrightarrow 2\beta\text{Fru} + \text{Glc}$$

β-fructosidase is an artificial oligosugar that is indigestible and therefore low in calories. It enhances the growth of intestinal *Bifidobacteria*. Lactosucrose plays a major role in the refinement of sugars in the food industry (229).

In one study, lactosucrose was used by *B. infantis, B. longum,* and *B. adolescentis*, but not by *L. acidophilus, E. coli* or *E. faecalis* (206). *Bifidobacteria* species grew at a higher rate on lactosucrose than on raffinose (Galα-1,6Gluα-1,2βFru), and the former was utilized by a smaller number of *Enterobacteriaceae* strains than glucose, lactose or raffinose. Fujita et al. (230) found lactosucrose to be similar to FOS in its effects on intestinal bacteria in that it promoted *Bifidobacterium* spp. but few of the other organisms tested.

24.3.7 Xylooligosaccharides

Xylooligosaccharides (XOS) are chains of xylose molecules linked by β-1,4 bonds and mainly consist of xylobiose, xylotriose, and xylotetraose (231), and are found naturally in bamboo shoots, fruits, vegetables, milk, and honey (232). Xylose containing oligosaccharides can be XOS or WBO (wheat bran oligosaccharides). They are produced enzymatically by hydrolysis of xylan from birch wood (233), oats (234), or corncobs (235) by a xylanase from *Trichoderma* (233). WBO are prepared from wheat bran hemicellulose, consisting mainly of branched xylose containing and arabinose containing oligosaccharides such as arabinosylxylobiose, arabinosylxylotriose, arabinosylxylotetraose, and diarabinosylxylotetraose (236). XOS are poorly utilized by *Bifidobacterium* strains, but

xylobiose was reported to be bifidogenic (231,237). Only a few *Bifidobacterium* spp. can ferment xylan (238,239). Few studies have been conducted on XOS. Okazaki et al. (237) carried out a small trial in which five male subjects were fed 1 g/d and five were fed 2 g/day XOS for three weeks. It was found that a dose of 1 g/d XOS was sufficient to elicit a bifidogenic response. In a study by Yamada et al. (236), although WBO could not stimulate all the *Bifidobacterium* strains tested, the substrate was concluded to be more selective than FOS or SOE (soybean oligosaccharide extract). A pure culture study by Jaskari et al. (234) concluded raffinose to be superior to xylooligomers and FOS in increasing *Bifidobacterium* populations without increasing potential pathogens. Van Laere et al. (240) concluded that FOS promoted *Lactobacillus* and other intestinal bacteria more than XOS. Hopkins et al. (231) concluded that overall GOS, Oligomate, and FOS were better bifidogenic substrates than XOS, inulin, and pyrodextrins.

24.4 STRUCTURE TO FUNCTION RELATIONSHIPS IN OTHER OLIGOSACCHARIDES

24.4.1 Lactitol

Lactitol (4-0-[β-galactopyranosyl]-D-glucitol) is a sweet tasting sugar alcohol derived from lactose by reduction of the glucose part of the disaccharide (241).

The fermentation of lactitol encourages the growth of saccharolytic bacteria and decreases the amount of proteolytic bacteria, which are responsible for the production of ammonia, carcinogenic compounds, and endotoxins (241). Most ingested lactitol reaches the colon because a suitable β-galactosidase is missing in the small intestine. Cell free extracts of *L. acidophilus* and *B. longum* showed high fermentation activity for both lactulose and lactitol. However, cell free extracts of *E. coli* and *B. fragilis* showed low activity with lactulose and lactitol indicating that they can aid the growth of saccharolytic bacteria in the colon (241). A 10% addition of lactitol to bacterial cultures reduces pH and gas formation (241). Growth of *Bifidobacterium* and *Lactobacillus* species was induced by lactitol (241). The addition of lactitol at 1, 2, 5, or 10% concentration caused inhibition of proteolytic, toxin producing strains and increased saccharolytic bacterial levels to an extent proportional to the lactitol concentration (241). It also caused a decline in pH and inhibition of NH_3 production (241). Lactitol is mainly fermented by anaerobic organisms (241). Scevola et al. (242) also described a reduction in growth of *E. coli* with lactitol. One possible explanation for this effect may be blockage of the receptor sites of the lectins by which the bacteria adhere to cell walls (241). Patients ingesting lactitol had a higher SCFA concentration, which resulted in a pH reduction. This resulted in increased solubility of minerals in the colon (241). Lactitol is used in the treatment of hepatic encephalopathy and other liver diseases because it aids the growth of saccharolytic bacteria such as *Bifidobacterium* and *Lactobacillus* species. Changing the microbial balance in favor of saccharolytic bacteria inhibits production of endotoxins in the colon and thereby lowers the amount absorbed in blood plasma (241). A marked decrease in the fecal cholesterol concentration and in the concentration of its metabolites, and in total fecal bile acid concentrations of humans has been observed upon lactitol addition to a normal diet (241). These results indicate that saccharolytic microflora were stimulated by lactitol, which has a positive effect on cholesterol.

24.4.2 Laevan Type Prebiotics

Laevan type exopolysaccharide (EPS) from *Lactobacillus sanfranciscensis*, laevan, inulin, and FOS were studied for their prebiotic properties (243). An enrichment of *Bifidobacterium*

species was found for EPS and inulin but not for laevan or FOS. The bifidogenic effect of EPS was confirmed using a selective growth medium. The use of EPS and FOS resulted in enhanced growth of *Eubacterium biforme* and *Clostridium perfringens,* respectively (243). Numbers of *Bifidobacterium* spp. increased exclusively with EPS whereas those of *Lactobacillus* decreased concomitantly. With EPS, the coliform counts increased to a reduced extent in comparison to a control without added carbohydrate. Growth of *Clostridium* was stimulated not only by the two EPS but also by laevan (243). In another study, Korakli et al. (238) investigated the metabolism by *Bifidobacterium* spp. of EPS produced by *L. sanfranciscensis*. The prebiotic properties of bread, and metabolism by *Bifidobacterium* spp. of water soluble polysaccharides (WSP) from wheat and rye were also investigated (238). Cereal products are the most important staple food throughout the world. Cereal grains are predominantly composed of starch; nonstarch polysaccharides composed of glucose (β-glucan), fructose (polyfructan), xylose, and arabinose (arabinoglycan) are present (244). Some of these polysaccharides, like starch, are partially digested, and others are believed to be dietary fibre, such as arabinoxylan. In addition to polyfructan, wheat and rye flours contain kestose, nystose, and other FOS of the inulin type (233). Comparison of an intestinal microflora incubated in media with EPS and without a carbohydrate source showed that EPS favored the growth of *Bifidobacterium* spp. by more than two log values and the growth of *Clostridia* by less than one log (243). EPS of *L. sanfranciscensis* TMW1.392 is composed predominantly of fructans and is therefore probably not degraded under the conditions prevailing in the stomach or small intestine. Thus, EPS meets some requirements for its use as a prebiotic (239). Polysaccharides composed of glucose in WSP isolated from rye sourdough fermented with *L. sanfranciscensis* and from control rye dough could not be fermented by *B. adolescentis*. This can probably be attributed to the enzymatic degradation of a starch fraction during dough fermentation. Furthermore, polyfructan in flour was completely degraded by cereal enzymes (238).

In conclusion, EPS produced by *L. sanfranciscensis* TMW1.392 during sourdough fermentation was metabolized by *Bifidobacterium* spp. species. The WSP in wheat and rye were also degraded by *Bifidobacterium* spp. However, polyfructan and the starch fraction, which possess a bifidogenic effect, were degraded by cereal enzymes during dough fermentation while the EPS was retained. The stability of EPS should enable it to withstand the baking process. This suggests that EPS will improve the nutritional properties of sourdough fermented products (238).

24.4.3 Gentiooligosaccharides

Gentiooligosaccharides (GeOS) are glucose polymers of the form Gluβ1-6[Gluβ1-6]$_n$ where n=1-5. These are not hydrolyzed in the stomach or small intestine and should therefore reach the colon intact (235). Rycroft et al. (245) investigated the fermentation properties of GeOS as compared to FOS and maltodextrin in mixed fecal culture. Gentiooligosaccharides gave the largest significant increases in *Bifidobacterium*, *Lactobacillus,* and total bacterial numbers during *in vitro* batch culture incubations. However, FOS appeared to be a more selective prebiotic as it did not significantly stimulate growth of bacterial groups which were not probiotic in nature. Gentiooligosaccharides and maltodextrin produced the highest levels of SCFA. Lowest gas production was seen with GeOS and highest with FOS (245). Gentiooligosaccharides possessed bifidogenic activity *in vitro,* which was maintained over the 24-hour fermentation period (245). Large amounts of lactate were produced from GeOS and maltodextrin metabolism (21.60±7.26 mmol/L and 21.86± 10.58 mmol/L respectively compared to 11.44±3.21 mmol/L in FOS). Berggren et al. (246) had previously observed that barley β-glucans generated greater SCFA than FOS when fed to rats. This was also the case in this study, where GeOS were

studied, not β-glucans. Highest butyrate production was recorded on FOS in accordance with previous batch fermentation studies (247,248), human trials (127), and rat studies (249,250). FOS also produced the lowest levels of propionate in the fermenters. Lowest gas production in the fermentations was detected with GeOS, whereas FOS produced the highest volume. This is an undesirable characteristic in a prebiotic (245).

24.4.4 Glucose Based Oligosaccharides

Glucose based oligosaccharides include cellooligosaccharides (β1,4), maltooligosaccharides (α1,4), gentiooligosaccharides (β1,6), isomaltooligosaccharides (α1,6) oligosaccharides, and those with mixed linkages such as glucooligosaccharides (α1,2, α1,4 and α1,6 linked), maltodextrin based oligosaccharides, and oligolaminarans.

Yazawa et al. (251) found that oligosaccharides of DP 3-5 from dextran hydrolysate promoted *B. infantis* but not *E. coli*, *E. faecalis* or *L. acidophilus*. Kohmoto et al. (169) observed that panose, isomaltose, isomaltotriose, and IMO900P were utilized as well as raffinose by all the *Bifidobacterium* spp. tested except *B. Bifidum,* which gave no growth on any of the substrates. *Bacteroides* species utilized all the sugars tested, but fewer *Clostridium* species grew on the IMO than the raffinose. Overall IMO900P appeared at least as selective, if not more so, for *Bifidobacterium* spp. than raffinose. IMO (NC) mixtures of different molecular weight distributions were incubated with fecal bacteria in batch cultures and complex gut models (172). The lower molecular weight products showed similar prebiotic activity to FOS with respect to increases in *Bifidobacterium* spp., decreases in *Bacteroides* and *Clostridium* spp., and the production of lactate and acetate. The higher molecular weight products generated higher butyrate concentrations. In the gut model, a validated three stage compound continuous culture system that represents the conditions typical of the human gastrointestinal tract (252), high molecular weight products stimulated *Bifidobacterium* spp. and *Lactobacillus* strains, while stimulating butyrate production, which persisted throughout the model and was greatest in vessel 3 (representing the distal colon). Once again this suggests that DP affected the prebiotic activity and fermentation of a molecule. In this case, a molecule with a low DP seemed to be more bifidogenic *in vitro*. IMO900P clearly had prebiotic potential *in vivo* and the minimum effective dose was 13–15 g/d IMO900 (253). The IMO3 fraction (trisaccharide) had a greater prebiotic effect than IMO2 (171). This may have been due to the greater hydrolysis of IMO2 than IMO3 by isomaltase in the jejunum so more substrate was available for the colonic microflora when IMO3 was administered.

In a limited pure culture study (254), while most *Bacteroides* strains, particularly *B. thetaiomicron*, degraded α-GOS, eight *Bifidobacterium* strains did not do so to the same extent, and three could not degrade it at all. Two *C. butyricum* strains degraded around 50% whereas most *Lactobacillus* strains hydrolysed less than 10% α-GOS, which appears not to have a prebiotic effect. IMO appeared to be prebiotic. Differences among glucooligosaccharides were due to the DP or linkage types of the molecules, suggesting that a low DP and α- rather than β- linkages favor fermentation and prebiotic activity.

24.5 CONCLUSIONS

Increasing consumer awareness for health and nutritional issues makes the market for prebiotics very promising; however, because of the high product costs and the still fragmented scientific backup of some of the health claims, this is still a disorganized area. Structure to function relationship studies, together with the development of cheaper manufacturing techniques, and more understanding of the physiological mechanism by which

prebiotics bring about improved health, provide one answer to establishing the functional oligosaccharide market.

This chapter has reviewed research and conclusions on the complex effects of oligosaccharide structure and size on the human microflora. A large comparative study, as reported by Djouzi and Andrieux (250), involved feeding 4% (w/w) FOS, TOS (transgalactooligosaccharides), and α-GOS diets to rats for four weeks. TOS and FOS led to desirable changes in microflora composition but had little effect on enzyme activities. α-GOS did not affect microflora composition but favorably altered the metabolism. The desirable changes with α-GOS were reduced gas production and increased glycosidase activity. GOS was superior to FOS in the greater *Bifidobacterium* population and the increased β-galactosidase activity when GOS was administered. Galactooligosaccharides, however, gave higher hydrogen and methane excretions. Inulin had a similar effect to FOS although higher doses of the former were needed (127,131). This suggests that a lower molecular weight gives a higher prebiotic activity, in accordance with pure culture studies (251). Transgalactosylated disaccharides were not as effective prebiotics as TOS and Oligomate, as the former needed a higher dose (157,255,256). Therefore, longer chain GOS were more effective than their disaccharide counterparts. Although these findings are contradictory, they suggest that neither disaccharides nor polysaccharides are the most effective prebiotics, and that oligosaccharides of DP>3 would be most likely prebiotic candidates.

In human trials with soybean oligosaccharides (257,258) less SOE than raffinose was needed to gain a prebiotic effect, and since 3 times as much stachyose (tetrasaccharide) than raffinose is present in SOE, it is likely that stachyose has the best prebiotic activity of the two (220). In the case of IMO, a low DP was more bifidogenic *in vitro* fermentation studies (172). α-galactooligosacchride showed some prebiotic activity, MDO (maltodextrin based oligosaccharide) behaved like a polysaccharide, and IMO behaved like a prebiotic. So a low DP and α- rather than β- linkages favor fermentation and prebiotic activity (172,247,248,254). The complexity of structure to function studies is also due to population variation which accounts for many inconsistencies between studies, and the observation that very often the bifidogenic effect is dependent on the original level of the *Bifidobacterium* strains present (259). For this reason, there is a great need for an extensive comparative *in vitro* study of all prebiotics available, involving the same parameters and in the same controlled conditions, so as to allow a comparison of the same amounts. This will help to better inform the most efficacious prebiotics.

Immunomodulating Effects of Lactic Acid Bacteria

Hanne Risager Christensen and Hanne Frøkiær

CONTENTS

25.1 INTRODUCTION

For decades, it has been believed that consumption of fermented dairy products is beneficial for health. In 1907, Eli Metchnikoff, the Nobel Prize winner and director of the Pasteur Institute, postulated in his book *The Prolongation of Life* that eating yogurt would extend the life span due to the health-improving influence of the lactic acid bacteria (LAB) involved in yogurt fermentation on the gut flora. Since that time, many studies have been conducted on gut-associated microorganisms, of which LAB are important members (1–3). These studies have led to the growing recognition today that the microflora colonizing the gastrointestinal tract of man and animal indeed play an important and essential role for the health of the host.

The gut flora comprises a highly evolved and extremely complex microbial ecosystem of hundreds of different microbial species. This metabolically highly active society is in close proximity with the gut epithelia through which it provides an array of signals and products that affect homeostasis of various physiologic processes of the body. Of these processes, the immune function constitutes a very important part; stimulating signals from the gut bacteria are critical for the development and maintenance of the mucosal and systemic immune compartments (4,5). A corollary, which has collected increasing evidence of support, is that the panel of stimulating signals bestowed by the gut flora is dynamically affected by the microbial composition, with some strains exerting stronger bioactivities than others (6–8). The gut flora are composed of a group of resident (autochthonous) bacterial species, and a variable group of transient (allochthonous) species that temporarily fills in functional gaps of the flora. In view of these facts, the concept of manipulating the composition of the gut flora in attempt to improve health of the host has emerged. That is, an increase in numbers but also potency of specific bacterial groups possessing particular health-promoting properties is desirable. One approach much investigated for this purpose is oral supplementation; e.g., via functional food products, with so called "probiotic" microorganisms that supply the gut flora with niches of beneficial functionality. The word probiotic is derived from the Greek meaning "for life." The definition of probiotics has changed over time; in 1989, Fuller defined probiotics as, "a live microbial food supplement which beneficially affects the host by improving the intestinal microbial balance" (9). However, to acknowledge emerging scientific data on proven effects, a broadening of the definition was recently proposed: "Probiotics are microbial cell preparations or components of microbial cells that have a beneficial effect on the health and well-being of the host" (10). In addition to the original concept of probiotics as acting solely via improvements of imbalances of the gut flora as a whole, this newly proposed definition embraces the bioactive effects of microbial compounds, not necessarily within the viable cell, but which are active also as nonviable whole cell or even as fractionated preparations. This broader concept gains ground in the recognition that supplementation of microbial preparations apart from viable cultures in some instances exerts a health promoting effect. Moreover, probiotic effects, e.g., on immune parameters, are not necessarily mediated via a preceding intervention with the gut flora balance (6,11,12).

The probiotic microorganisms currently used are predominantly, though not exclusively, lactic acid bacteria (LAB) such as lactobacilli or bifidobacteria (13). LAB are major components of the gut flora (1–3). Research has revealed these bacteria are far from just

inert commensals, but may constitute one of the most significant microbial populations providing immunoregulatory signals (7,14–16).

In this chapter, we will discuss the current knowledge of how the gut flora as a whole affects the immune system, and then focus on the immunomodulating effects of LAB present either as a natural part of the gut flora or supplemented as probiotics. However, to provide a basis for understanding the functional influence conferred by the gut flora on the immune system, we will begin by giving a view of the organization and function of the intestinal immune system and its affiliation to the peripheral immune system.

25.2 THE GUT MUCOSA – A UNIQUE COMPARTMENT OF THE IMMUNE SYSTEM

The gut mucosal membranes form the interface between the highly controlled internal microenvironment of the body (basolateral side) and the external environment (gut lumen, apical side). To allow efficient absorption of nutrients, the surface area of the mucosal membranes is enormous, reaching around 400 m^2, which exceeds by far that of the skin (~2 m^2) (17). Along this huge area, the gut mucosa continually experiences a massive exposure to both pathogenic and harmless agents derived from the ingested food as well as the gut flora.

The immune compartment present in the gut mucosa — the gut associated lymphoid tissue (GALT) — is recognized as the largest immune organ of the body and plays a crucial role for keeping the body healthy. GALT constitutes a major part in the gut barrier function against pathogens and other harmful antigens entering the body through the gut. Equally important but oppositely directed, GALT is important in down regulating responses toward ingested harmless food antigens to permit entrance of nutritional food antigens into the body – a mechanism designated oral tolerance (18). In keeping with all this, GALT is not only responsible for local immune responses but also for systemic responses via primed immune cells that exit GALT and enter into peripheral circulation. As already touched on, appropriate development and balance maintenance of these rather distinct functions of GALT is affected by the microenvironment of the gut, most importantly the gut flora, including LAB, which is the core subject of the present chapter.

25.2.1 Organization of GALT

GALT is compartmentalized into inductive sites and effector sites; i.e., sites where priming and dissemination, respectively, of an immune response primarily takes place (17). This division is far from absolute, but is, however, very useful in understanding GALT functioning. GALT comprises the highly organized structures of the Peyer's patches and the mesenteric lymph nodes, and the more diffuse tissues consisting of a large number of lymphoid cells scattered throughout the lamina propria and intestinal epithelium (intraepithelial lymphocytes) (Figure 25.1).

Peyer's patches and the mesenteric lymph nodes are thought to be the main inductive sites and are found in all mammals. Peyer's patches are located primarily on the antimesenteric side of the small intestine. They contain a number of B cell rich zones with germinal centers called follicles, and, adjacent to these in the parafollicular areas, there are T cell rich zones. The subepithelial dome area overlying the follicles contains many antigen presenting cells, primarily dendritic cells. This area is extremely important for antigen processing and presentation for the initiation of an immune response such as IgA production. The dome area is covered by a follicle associated epithelium facing the gut lumen. In addition to conventional enterocytes, the follicle associated epithelium contains the very

specialized microfold (M) cells. M cells lack microvilli, exhibit reduced enzymatic activity, and are adept at uptake and transport of intact luminal antigens (such as soluble food antigens, microorganisms, and viruses) into the Peyer's patch for further immunologic processing. M cells are particularly efficient in taking up particulate material such as microorganisms; in fact, particulate material seems to be almost exclusively taken up by M cells, making these cells the only portal for such antigens. Lymphoid structures similar to Peyer's patches are present also in the large intestine, particularly in the appendix and cecum. They consist only of isolated lymphoid follicles but are believed to function in a manner similar to Peyer's patches.

The mesenteric lymph nodes serve as secondary lymph nodes (Figure 25.1). Located in the center of the mesenteric tissue, they assemble all of the lymphatic vessels draining the gut mucosa as afferent (ingoing) lymphatic vessels into the nodes. Their efferent (outgoing) lymphatic vessels lead the lymph fluid to peripheral circulation via the thoracic duct. The mesenteric lymph nodes, therefore, seem to act as a crossover point between the peripheral and mucosal immune response.

The main effector site of intestinal immune responses is the lamina propria, which is the inner part of the intestinal villi (Figure 25.1). The lamina propria contains a large and heterogeneous group of scattered immune cells, including antigen presenting cells (dendritic cells and macrophages) and T and B cells highly differentiated into mature effector

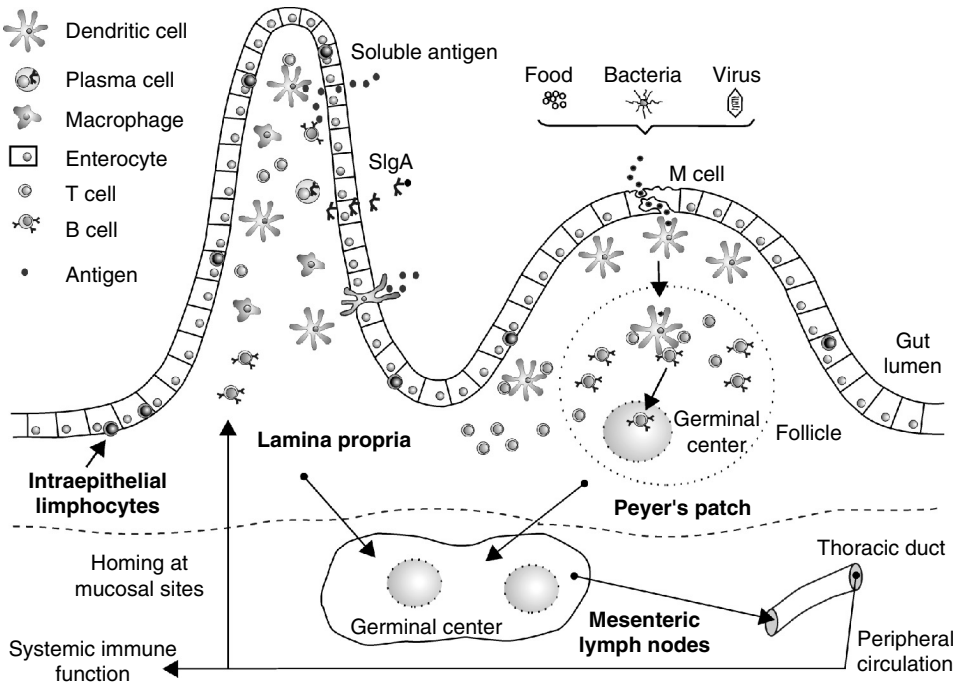

Figure 25.1 Schematic depiction of the gut-associated lymphoid tissue (GALT). The Peyer's patches and mesenteric lymph nodes are organized lymphoid tissues, while scattered immune cells are abundant in lamina propria and inside the epithelium (intraepithelial lymphocytes). Luminal antigen can enter either via M cells (primarily particulate antigen) overlying the Peyer's patch, through the enterocytes (soluble antigen) or potentially via capture by traversing dendritic cells. Immune cells travel from Peyer's patches and lamina propria to mesenteric lymph nodes from where they can enter the blood stream via the thoracic duct. Upon peripheral circulation, some immune cells, particularly IgA^+ B cells, home at effector sites primarily lamina propria.

cells, as will be discussed later. Many of the cells are primed in the Peyer's patches from where they migrate out and traffic through peripheral circulation to the lamina propria to exert immune responses. The most predominant type of response of the lamina propria is IgA production by plasma cells (differentiated B cells). Despite being a major effector site, certain immune responses may be induced in the lamina propria as well. Likewise, certain effector functions may disseminate in the Peyer's patches and mesenteric lymph nodes.

The important compartment of the intraepithelial lymphocytes can neither be grouped exclusively into an inductive or an effector site. The intraepithelial lymphocytes represent one of the largest lymphoid populations in the body and consist mainly of $CD8^+$ (cytotoxic) and $CD4^+$ (helper) T cells with different T cell receptor (TCR) phenotypes ($\alpha\beta$ TCR or $\gamma\delta$ TCR). The proximity of the intraepithelial lymphocytes to the enterocytes and the gut lumen makes them one of the first cellular mucosal immune components to respond to luminal antigens. They perform an effector function by exerting cytolytic activity, playing a role in the barrier function against pathogens; and an inductive function, as they seem to play a role in the induction of oral tolerance toward food antigens. Moreover, they appear very important in regulation of immune homeostasis including regulation of IgA production in the lamina propria.

As a second point of entry besides M cells, antigens can enter GALT through a population of intraepithelial dendritic cells (Figure 25.1) (19). Dendritic cells can take up and process antigens, and *in vitro* models suggest that dendritic cells can extend their dendrites between the enterocytes and into the lumen without disrupting the tight junctions that bind the enterocytes together (20).

Finally, it is important for the overview of GALT to mention the enterocytes. Besides their principal role as cells absorbing degraded luminal nutrients, enterocytes are also capable of transporting soluble intact antigens and thus make up a third point of antigen entry (21). Also, an increasing amount of data shows that these cells participate significantly in the initiation and regulation of immune responses via interaction with GALT, especially the intraepithelial cells (22). Enterocytes moreover, serve to transport IgA into the gut lumen.

25.2.2 Immune Responses of GALT and Peripheral Immune System

In GALT, the various immunocompetent cells such as epithelial cells, dendritic cells, T cells, B cells, and macrophages form a unique homeostatic immune network. During initiation of an immune response, the functionally distinct cells of GALT act coordinately to provide stimuli and share common regulatory elements. These processes are characterized by the production of a highly controlled set of molecules like cytokines, chemokines, and costimulatory molecules that alert the host to breach in the mucosal barrier and focus the immune response at the site of infection. Cytokines are soluble intercellular signaling molecules of principal importance for immune cell communication. They act to stimulate or suppress cell functions; and the chemokines, which constitute a cytokine subgroup, act specifically to attract immune cells.

The gastrointestinal surfaces, like the rest of the body, are protected against pathogens by both antigen nonspecific and specific mechanisms. The specific mechanisms implement immune cells committed specifically to act against a given antigen. The nonspecific mechanisms act without proceeding antigen specific commitment and include both nonimmune mechanisms as well as mechanisms exerted by immune cells. Thus, the nonspecific protective mechanisms are constantly in place to take action instantaneously, and therefore serve as the first line of defense. In contrast, the specific immune response takes time to establish, but afterward exerts a much more precisely targeted and effective response, especially toward reencountered antigens.

The gut flora and probiotic LAB affect both nonspecific and specific immune mechanisms. However, up till now most of the knowledge about the immune modulating effects of LAB was limited to only a few components of these immune mechanisms. To understand the relevance of such effects, an outline of the pertinent mechanisms of the nonspecific and specific immune system, particularly in the gut, is given in what follows.

25.2.2.1 Nonspecific Response Mechanisms

Most macromolecules are prevented from direct contact with the epithelial surface by mechanisms belonging to the nonimmune part of the nonspecific defense. The enterocytes have a folded apical surface of rigid structures (microvilli) that are coated with a thick layer of membrane anchored, negatively charged, mucin-like glycoproteins called glycocalyx. This layer forms a diffusion barrier and a highly degradative microenvironment. Bactericidal compounds such as lactoferrin, peroxidase, lysozyme, and defensins are produced by Paneth cells also situated in the epithelium. Another important nonimmune defense mechanism is the capability of the gut flora to compete with pathogens for nutrients and adhesion receptors and, moreover, to produce antimicrobial substances and acids that inhibit pathogenic colonization (23). These mechanisms are collectively called colonization resistance.

Interaction of microorganisms, such as pathogens, with epithelial cells, including enterocytes, triggers the epithelial cells to secrete factors, like cytokines and growth factors, that activate nonspecific mechanisms of the immune defense. The production of chemokines such as interleukin-8 (IL-8), monocyte chemoattractant protein-1 (MCP-1) and proinflammatory cytokines like IL-1β and tumor necrosis factor-α (TNF-α) by epithelial cells, stimulates activation and migration of phagocytic cells such as macrophages and neutrophils to the site of contact (infection) (24). Phagocytic cells bind and internalize antigens (a process called phagocytosis) through a repertoire of receptors, e.g., the antibody receptors (FcγRI, FcγRII, FcγRIII, FcαR and FcεRI), complement receptors (CR1 and CR3), and mannose receptor (MR). When phagocytosed, the microorganisms are killed by bactericidal compounds such as lysozyme or reactive oxygen species (ROS) — a process called the oxidative burst. Motile dendritic cells in Peyer's patches, lamina propria or within the epithelium are also capable of phagocytosing antigen, although much less efficiently. Upon stimulation by most pathogens, secretion of the cytokine IL-12 by macrophages and dendritic cells enhances cytotoxicity of natural killer (NK) cells. NK cells are another important part of the nonspecific immune system.

In addition to the importance for the initiation of the nonspecific immune defense, dendritic cells are of particular importance for the induction of a specific immune response. In this way, dendritic cells create a link between the nonspecific and the specific immune systems (25).

25.2.2.2 Specific Response Mechanisms – Immunity vs. Tolerance

An impressive feature of the protective mechanisms of GALT is the capacity to discriminate between harmless antigens of the diet or resident microflora, and antigens from potential pathogens. The outcome of exposure to foreign antigens can involve three types of antigen-specific mechanisms: mucosally induced tolerance, also termed oral tolerance; induction of mucosal IgA response; and induction of systemic response (18). It is essential for normal life that the intestinal immune system be exquisitely regulated to mobilize the right type of response to any encountered antigen; i.e., induction of tolerance versus immunity.

The mechanisms regulating the distinction between these responses in the intestine are far from completely understood. It is clear, however, that they depend on establishment

and maintenance of homeostasis among the immunocompetent cells. It is increasingly believed that under well established homeostasis, antigenic molecules such as pure soluble antigens encountered by GALT are not intrinsically immunogenic but rather induce tolerance as the default response. In contrast to such "naked" antigens, antigens that are endowed with "danger" signals, such as microorganisms bearing pathogenic structures, drive the immune response away from the default response and instead induce active immunity (26). During imbalances in immune homeostasis, the immune system may, however, become either hyporesponsive to such danger signals and hence increase the propensity for development of infections or cancer; or it may become hyperresponsive, resulting in misinterpretations of weak signals from harmless antigens as being danger signals, which is the case for organ specific autoimmune diseases (reactions against "self" antigens) and hypersensitivity reactions such as allergy (e.g., reactions against food antigens).

When GALT, or other lymphoid tissues, encounter foreign antigens, via transport through M cells or enterocytes, the antigen is processed by professional antigen-presenting cells (macrophages or dendritic cells) (24). By binding to surface major histocompatibily molecules (MHC), antigen fractions are presented to T cells. T cells, primarily Thelper (Th) cells, that by chance have a receptor (TCR) specific to the antigen, bind to the antigen-presenting cells. During the subsequent intimate cell–cell interaction involving the MHC-antigen-TCR complex, costimulatory molecules, and cytokines, the T cells become activated and polarized to exert specific effector functions.

Activation and polarization of naïve Th cells are crucial for the type of immune response generated. Dendritic cells are the principal stimulators of naïve Th cells and, thus, the gatekeepers of an immune response (27). They perceive stimulating signals from microorganisms (pathogens and gut flora) through a panel of surface receptors (pattern recognition receptors) such as Toll-like receptors that recognize conserved structural patterns on the microorganisms; including lipopolysaccharide on Gram-negative bacteria, peptidoglycans on Gram-positive bacteria, and specific immunostimulatory DNA sequences (e.g., unmethylated CpG), carbohydrates, and glycolipids, occurring in many microbes (28). The dendritic cells, moreover, perceive signals such as cytokines coming from the epithelium and resident effector cells. Depending on the specific combination and timing of perceived signals, the dendritic cells mature and respond differentially whereby they control the type of immune response to be initiated (29–31). Dendritic cells accomplish this by driving differential polarization of naïve Th cells into active mature effector cells, producing different sets of cytokines that direct different types of immune responses as depicted in Figure 25.2. Three functionally discrete groups of T cells characterized by different cytokine profiles exist. Type 1 Th cells (Th1 cells) are characterized by secretion of IL-2 and IFN-γ, support cell-mediated immunity (cytotoxic T lymphocyte activation) and are immunopathologically associated with autoimmune diseases. In the gut, diseases like Crohn's disease are associated with a deleterious Th1 cell-driven response toward certain species of the gut flora. Th1 cells are induced in response to IL-12 produced by dendritic cells.

Type 2 Th cells (Th2 cells) produce IL-4, IL-5, IL-9, and IL-13 and support antibody production, and are immunopathologically associated with allergy such as food allergy, where a humoral IgE response is generated. A primary factor produced by dendritic cells for the initiation of Th2 cells is not identified, but absence of IL-12 and early presence of IL-4 (not produced by the dendritic cells) is important (32).

In contrast to Th1 and Th2 cells, mediating immunity, the third subpopulation of T cells, termed regulatory T (T_R) cells, are specialized in down regulating (suppressing) immune responses. T_R cells include two subtypes: Th3 and Tr1 cells, both of which are important effector cells in down regulating Th1 and Th2 cell activity and therefore play a central role in tolerance mechanisms and maintenance of immunologic homeostasis (33,34).

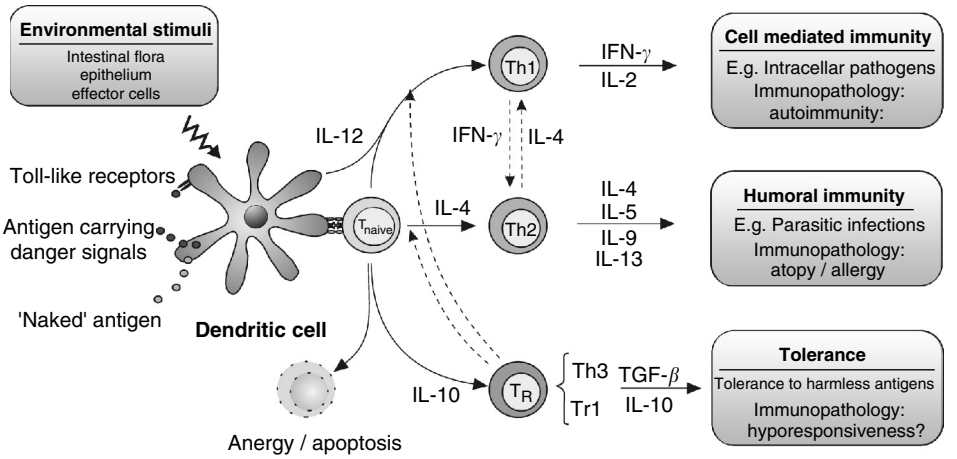

Figure 25.2 Schematic representation of polarized patterns of cytokine production and effector functions of differentiated T helper (Th) cells upon activation by dendritic cells. See text for further explanation.

T_R cells exert their immunoregulatory effect through expression of inhibitory cell surface molecules, or by secretion of immunoregulatory cytokines, most importantly TGF-β and IL-10, or both. Another response suppressive mechanism of the immune system is elimination of potential reactive (i.e., antigen specific) T cells either by "paralyzing" them (anergy) or by inducing apoptosis (deletion).

Many mechanistic details in the regulation of priming (Th1 or Th2) versus tolerance (T_R) are still incompletely understood. Induction of T_R cells or specific T cell anergy or deletion are the major mechanisms involved in the induction of oral tolerance, which depends on the dose of ingested antigen (35). An important prerequisite for tolerance induction is a preserved integrity of the mucosal barrier to avoid excessive antigen leakage into the mucosa (36). Even so, uptake and processing of intact soluble antigen by enterocytes are increasingly believed to play a major role in the induction of oral tolerance. This includes both presentation by the enterocytes themselves (MHC or CD1d molecules) to intraepithelial or lamina propria lymphocytes as well as basolateral releases of exosomes containing MHC-antigen complexes to be taken up by other cells, such as dendritic cells, present locally or at distant sites. Shortly after intake of antigen, antigen-loaded dendritic cells appear in Peyer's patches, lamina propria, and mesenteric lymph nodes, and whether tolerance or priming is the eventual outcome, antigen-specific activation of T cells takes place both in GALT and in the periphery soon after ingestion of antigen (37). Therefore, dissemination of activating or activated immune cells, or antigen bound to MHC or not, from inductive sites of GALT into peripheral tissues as well as into mucosal effector sites, creates an important link between GALT and the peripheral immune system.

It has become evident that enterocytes are not only capable of processing antigens, but, in fact, although they are not immune cells, they can respond actively to contact with luminal antigens, particular luminal bacteria such as LAB or pathogens (38). Enterocytes, like immune cells, express Toll-like receptors, through which they are stimulated by the gut flora and pathogens. The enterocytes respond by secreting a wide range of factors that affect intestinal immune cells, including macrophages, dendritic cells, and intraepithelial lymphocytes, which in turn influence the enterocytes by altering their functionality (39,40). In this way, the enterocytes, representing a predominant cell population, are intimately involved in the immunologic homeostasis and defense against pathogens, and also

regulation of IgA production (41). As discussed later, several recent studies have focused on how the gut flora and LAB affect cellular interactions of enterocytes and intraepithelial cells and the resultant signal generation, important for regulation of tolerance vs. immunity. Impact on these interactions might be a key gate for the immunomodulating effect of LAB.

A last important hallmark of mucosal immunity is the secretory IgA (SIgA) response, which is neither a Th1, Th2, nor a T_R response. IgA is overwhelmingly the most important immunoglobulin in the intestine and other mucosal surfaces. Peyer's patches and mesenteric lymph nodes are important inductive sites for B cells to be committed for IgA production (Figure 25.1) (42). Antigen-loaded dendritic cells in Peyer's patches stimulate activation of B cells both through direct interaction with the B cells and via Th cell activation (IL-4-producing Th2 cells and TGF-β-producing Th3 cells). T cells colocalize with germinal center B cells, which are subsequently undergoing isotype switching from IgM to IgA. This occurs either in the Peyer's patch follicles or via cell migration to follicles of the mesenteric lymph nodes. Antigen-specific activated T and B cells then leave the inductive sites and migrate via the thoracic duct into peripheral circulation. Migrating cells finally home to mucosal effector sites, e.g., intestinal lamina propria or other mucosal membranes, where B cells, upon antigenic restimulation, complete their differentiation into IgA secreting plasma cells.

Production of IgA in lamina propria depends on the presence of IL-5, IL-6, IL-10 and TGF-β produced by effector T cells (43). Plasma cells synthesize IgA as a dimer of two IgA molecules interconnected by a J chain (44). Dimeric IgA is a ligand for the polymeric Ig receptor located on the basolateral surface of enterocytes. Here, bound IgA is taken up and transported across the cytoplasm to be released into the gut lumen by cleavage of the poly-Ig receptor molecule, leaving a so called secretory piece still bound to the IgA molecule. Due to the secretory piece, SIgA is resistant to the highly proteolytic environment in the gut.

The presence of SIgA in the gut lumen prevents infection of epithelial cells by coating pathogenic microorganism or virus and so forestalls binding to the cell surface. SIgA can likewise prevent absorption of antigen. By mediating transport of antigen across the

Table 25.1
Characteristics for Classical Immune Responses

Type of Response		Characteristics
Nonspecific responses		
Nonimmune:	Glycocalyx layer	Diffusion barrier
	Bactericidal compounds	Lysozyme, lactoferrin, defensins
	Gut flora	Competition/antimicrobial
Immune:	Phagocytosis	Neutrophils, macrophages, dendritic cells, IL-8[†], ROS
Specific responses		
Cell-mediated response		Th1, cytotoxic T cells, IL-1, IL-2, IL-12, IFN-γ, TNF-α, ROS
Systemic antibody response		Th2 and B cells, IgG, IgE, IL-4, IL-5, IL-9, IL-13
Tolerance		T_R (Th3, Tr1) cells suppressing Th1/Th2 cells, IL-10, TGF-β
Mucosal IgA response		(Th2), Th3 and B cells, IgA, TGF-β, IL-5, IL-6

[†] Abbreviations: IL: interleukin, IFN: interferon, TNF: tumor necrosis factor, ROS: reactive oxygen species, TGF: transforming growth factor

epithelium, SIgA can also neutralize, and carry back into the lumen, antigen that has leaked through the epithelial barrier. In this way, SIgA prevents pathogenic antigens from coming into contact with the body – a mechanism called immune exclusion. Due to the huge area of the gastrointestinal tract, great amounts of SIgA are necessary in performing its task. In man, approximately 3 grams of SIgA are delivered each day into the intestinal lumen; and 80–90% of all immunoglobulin-producing B cells (plasma cells) of the body, in fact, reside in the mucosa and exocrine glands (42,44).

Essential characteristics for these various immune responses, which are often subjects for measurement in evaluating immune modulation, are summarized in Table 25.1.

25.3 INFLUENCE OF THE GUT FLORA ON THE IMMUNE FUNCTION

It is well documented that the intestinal ecosystem features dynamic and reciprocal interactions among its microflora, the epithelium, and the immune system. Because LAB are a part of the gut flora, either naturally or by supplementation, an understanding of the mechanisms whereby LAB compel their immune modulating effects on the host requires an outline of what position LAB occupy in the gut flora and how the gut flora as a whole interact with the immune system of its host.

25.3.1 The Gut Flora

In man, greater than 75% of the fecal output is composed of bacterial cells derived from more than 400 different strains, totaling approximately 10^{14} viable bacteria, of which only about 40% are culturable (2). This enormous number of bacterial cells exceeds by a factor of 10 the number of eukaryotic cells constituting the human body. The diversity and numerical importance of the bacteria of the gastrointestinal tract vary in the different gut sections, and the

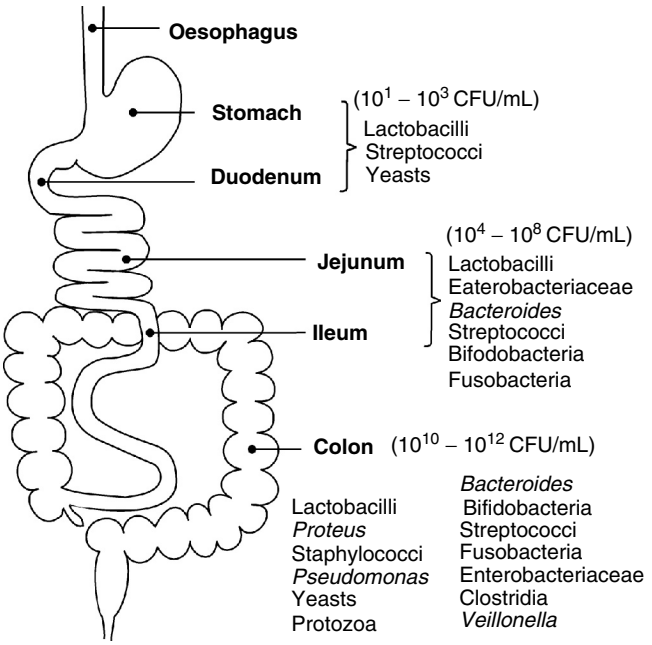

Figure 25.3 Microbial colonization of the human gut (175).

resident LAB are no exception (Figure 25.3). In adults, species of lactobacilli and streptococci as well as some other Gram-positive bacteria vastly dominate the flora of the sparsely populated stomach and duodenum. This is due to their ability to adhere to the epithelium and to resist acid, bile salts, and pancreatic secretions (45). At the distal part of the small intestine (jejunum and ileum), the microbial concentration and diversity increases, and here bifidobacteria species also enter the scene. In the colon which harbors a very diverse population of mostly strict anaerobic species, the levels of bifidobacteria reach 10^{10}–10^{11} cells/g whereas lactobacilli and enterococi species number only 10^{7}–10^{8} cells/g (46). In total, the population of bifidobacteria and lactobacilli in the gut of adults represent no more than 1–5% and <1%, respectively, of the fecal flora when analyzed by molecular analyses.

The predominant flora of adults is remarkably stable, whereas in children it is less stable, and in infancy highly unstable (46). In infancy, vast changes occur during development of the flora. Immediately after birth, the sterile gut of the fetus is rapidly colonized, and levels up to 10^{9} bacteria/g feces are reached within less than 48 hours. The composition of this initial flora represents a span of microbes originating from the environment, e.g., from the mother, but gives no indications of those likely to be retained in the tract (47). Subsequently, a selection of bacterial strains develops consistently along with maturation of the intestinal mucosa and under strong influence of both the microbial exposure and diet. Bifidobacteria constitute a major part of the flora of infants, ranging from 60 to 90%, whereas the values for Lactobacilli resemble those of adults (46). However, the flora varies greatly with neonatal feeding. In breast-fed infants, Bifidobacteria become dominant and the minor flora consist mainly of lactobacilli and streptococci. In contrast, formula-fed infants have similar amounts of bifidobacteria and bacteroides (~40%) and a minor flora frequently containing staphylococci, *Escherichia coli*, and clostridia (47). Upon weaning, the microbial profile becomes adult-like for both breast-fed and formula-fed with a significant increase of bacteroides.

Pioneer bacteria entering the gut in infancy can favor their own growth and inhibit growth of later introduced bacteria by inducing specific and lasting glycosylation of the glycocalyx as well as by modulating enterocyte gene expression. The initial colonization, therefore, widely shapes the final composition of the stable gut flora in adult life. As will be discussed later, increasing evidence shows that the development and maintenance of immunologic homeostasis is influenced by the composition of the gut flora, particularly the content of LAB. For example, distinct differences in the gut flora regarding bifidobacteria persist between atopic and nonatopic 2-year-olds (48). Thus, intake from birth or early infancy of probiotics may induce long term and enhanced efficacy of immune functions as well as other physiological conditions due to colonization as an integral part of the stable gut flora (autochthonous flora); contrasting probiotics ingested by older children and adults getting access only transiently (allochthonous flora) if at all, and thus demanding chronic administration of high concentrations.

In the gut flora of adults, the composition of the bifidobacteria population tends to be generally stable, while the composition of the lactobacilli tends to fluctuate more with only some persisting strains (46,49). Therefore, at least for the lactobacilli population, there seems to be a bacterial niche prone to alterations at a higher level than just bacteria in transit, e.g., through dietary changes or bacterial supplementation with probiotic lactobacilli.

Newly introduced harmless bacteria such as LAB stimulate the immune system including tolerance mechanisms and production of IgA. The produced IgA mediates immune exclusion whereby further contact between the bacteria and the immune system is attenuated as discussed in a previous section (50). Therefore, it has been suggested that for the allochthonous part of the flora, a high turnover of different strains of bacteria through the diet may participate in the continuous stimulation of GALT as a part of maintaining homeostasis.

25.3.2 Interactions Between the Gut Flora and the Host Immune System

In the elucidation of the impact of the gut flora on the immune system, germ-free (gnotobiotic) animals (pigs, mice, or rats) are very useful. Germ-free animals are obtained by delivering the pups through Caesarian section and hand-rearing them in sterile isolators. By comparing germ-free and conventional animals (animals with normal gut flora), or by deliberately colonizing the intestine of germ-free animals with defined microorganisms, it is possible to study the interaction between the gut flora, or gut flora components, and the host immune system. With this approach, species of LAB have often been investigated (51–53). A general observation from such studies is, however, that colonization with a single or a few gut flora-derived microbes is less effective in modifying GALT than complete conventionalization of the animals, revealing the importance of diverse bacterial stimuli.

The immune system of newborn conventional animals and humans matures along with colonization of the intestine. Such maturation does not occur in germ-free animals, leaving GALT development rudimentary and characterized by underdeveloped Peyer's patches and mesenteric lymph nodes lacking follicular germinal centers, reduced epithelial cell turnover, and low densities of immune cells both in gut mucosa and in peripheral lymph nodes (54). Upon microbial colonization, GALT and the systemic immune compartment undergo marked changes, of which the chief structural and functional effects on the immune system are listed in Table 25.2.

IgA production is one function highly influenced by the presence of intestinal microbes. Gut colonization instigates maturation of Peyer's patches, and consequently the numbers of IgA-producing plasma cells in the lamina propria increases (50,55). Within the compartment of intraepithelial lymphocytes, the number and cytolytic potential of $\alpha\beta$ T cells increases after microbial stimulation while the population of $\gamma\delta$ T cells is unaffected by the gut flora (56). As mentioned earlier, gut flora microbes can mediate phenotypic alterations of enterocytes affecting bacterial adhesion (expression of glycoconjugates) but

Table 25.2
Effect of Gut Flora on Structure and Function of the Immune System Observed in Studies of Germ-Free vs. Conventional Animals.

Compartment	Structural or Functional Change
Gut mucosa	Development of Peyer's patches
	Expansion of IgA-producing cells in lamina propria
	Expansion of intraepithelial T cells ($\alpha\beta$ TCR†)
	Acquisition of cytotoxicity of T cells ($\alpha\beta$ TCR)
	Induction of MHC molecules on enterocytes
	Induction of glycoconjugates in enterocytes
	Enhanced cytokine production
Systemic	Increased number of immune cells in lymph nodes
	Enhanced cell-mediated immune response
	Enhanced cytokine production capacity of peritoneal cells
	Enhanced oxidative burst of macrophages and neutrophils
	Development of the capability to induce and maintain oral tolerance in antibody response

† Abbreviations: TCR: T cell receptor, MHC: major histocompatibility complex
Source: References 176 and 177.

also immune regulation; upon bacterial colonization, the expression of MHC class II molecules on enterocytes is provoked gradually (57). Thus, in contrast to the dietary antigens (ingested also by the germ-free mice), bacterial compounds are capable of stimulating the MHC class II expression, important for immunologic presentation of exogenous antigens. MHC class II expression is regulated by cytokines, and intestinal bacteria also greatly affect cytokine production in gut cells, which, in turn, conceivably affects the MHC class II expression (12).

The functional impact of diverse cellular changes may affect different immune functions. Besides enhancing the IgA production as previously mentioned, a major function of the gut flora is the impact on the host's capability to induce oral tolerance. Intake of dietary antigens by germ-free animals elicits an IgE antibody response along with increased levels of IL-4. This aberrant Th2 response, not induced in conventional mice, can, however, be corrected by reconstituting the gut flora of germ-free animals with *Bifidobacterium infantis* (a predominant gut bacteria of infants) at the neonatal stage, but not at a later age, signifying the importance of gut flora including LAB in the maturation of the neonatal immune system (51).

The neonate immune system of humans is immature with a poorly developed GALT. Intraepithelial lymphocytes are not expanded, and germinal centers are not formed, until sometime after birth, again reflecting the dependency of microbial stimuli (4,58). Newborns are generally Th2-skewed and have a reduced capability to induce Th1-mediated responses, and have poor IgA and IgG production capacity. The gut flora is believed to be a major Th2-counterbalancing (Th1/T_R-driving) force in the postnatal establishment of immune homeostasis (4). Many observations support the notion that most mucosal immune cells are competent even before birth, but need to undergo an activation process initiated by environmental signals, most significantly originating from the gut flora. Studies in animals (59) and in humans (60) have identified deficient antigen-presenting cell function as the chief explanation for immunologic immaturity; in neonates dendritic cells and macrophages are unable to deliver adequate costimulatory signals to activate naïve T cells. Thus, the effect of the gut flora, in particular the LAB dominating the flora of infants, may exert an effect on antigen-presenting cells, such as dendritic cells, either directly, or indirectly through interactions with other cells, e.g., enterocytes and intraepithelial lymphocytes, which, in turn, affect the antigen-presenting cells. As will be discussed in far more detail later, many LAB possess Th1- and T_R-inducing capacities and, indeed, interact with the gut epithelium (61,62). Such mechanisms of LAB may be crucial for the establishment and maintenance of immunologic homeostasis, and currently these phenomena have led to focused research into the immunomodulatory mechanisms of LAB as described in what follows.

25.4 IMMUNOMODULATORY MECHANISMS OF LAB

Numerous immunomodulating effects of LAB are observed in cellular mechanistic *in vitro* studies. Common to most of them is the absence of a mechanistic link to the immunomodulating effects observed *in vivo* and, one step further, to the observed "end point" effects on diseases or their prevention. This fact, in addition to the observation that a great deal of variation occurs among the different LAB even at the strain level, has caused probiotic research to be extremely multifarious and sometimes confusing. However, as more and more data accumulate some common characteristics come to light. In this section, we will go over some of the most prevailing immune mechanistic effects found for LAB as evident from either *in vitro* cell studies or *in vivo* studies in experimental animal models

Table 25.3
Summary of Immune Mechanistic Modulatory Effects of LAB[†]

Effect	Characteristics
Increased barrier integrity (Reduced permeability)	Reduced bacterial translocation and Ag leakage
Enhanced colonization resistance	Competitive LAB (adhesion sites, nutrients)
	Altered intestinal surface glycosylation (altered adhesion)
	LAB metabolites (antimicrobial substances, lactate)
Improved phagocytic cell function	Enhanced phagocytic and bactericidal capacity
	Reduced pathogen-induced apoptosis
Improved NK cell activity	Increased tumoricidal activity
Cytokine regulation	Enhanced production of pro-type 1 response cytokines
	Enhanced homeostasis (Th1/Th2/T_R cell balance)
Epithelial interaction	Counter-balance proinflammatory signals from G^- bacteria
	Stimulation of TGF-β production in enterocytes
Lymphocyte proliferation	Altered mitogen-induced T and B cell proliferation
Adjuvant capacity	Increased systemic and secretory Ag-specific Ab response
Secretory response	Nonspecific increase of IgA (incl. IgA^+ B cells in the gut)
	Enhanced Ag-specific IgA (e.g., against rotavirus)

[†] Abbreviations: LAB: lactic acid bacteria, Ag: antigen, Ab: antibody, G^-: Gram-negative

Table 25.4
Commonly Used Methods for Studying the Effects of Probiotic Bacteria on the Immune System

Method
Phagocytic capacity
Tumoricidal activity (NK cells)

Isotype profile (mice: Th1: IgG2a, Th2: IgG1+IgE)

or humans. These mechanisms are summarized in Table 25.3. In the subsequent section we will go into the effect of LAB on diseases and the impact of viable vs. nonviable bacteria and effective dose.

25.4.1 Methods Used for Assessing Immunomodulatory Effect of LAB

Several methods have been employed for studying immune mechanisms as well as for evaluating clinical studies of immunomodulating effects of LAB, ranging from classical immune methods to sophisticated protocols for examining more unique parameters.

Table 25.4 summarizes the most commonly used immune methods, which will be discussed in brief in what follows.

Many different types of cells or cell mixtures are being investigated. When human cells are used for evaluating immune functions, whole blood or blood cell subgroups, such as peripheral blood mononuclear cells (PBMC) or polymorphonuclear cells are routinely used. Carcinoma cell lines of human enterocytes (Caco-2 and HT-29) are often used to study gut epithelial functions, sometimes in combination with PBMC to reflect the interaction between immune cells of GALT and enterocytes. With mice and rats, which are by far the most frequently used experimental animals to study immune functions, cells from the spleen, peritoneum, Peyer's patches, mesenteric lymph nodes, and lamina propria are widely used. Also, tissue samples for histological studies as well as secondary cultures (e.g., dendritic cells derived from bone marrow) and cell lines (macrophages, T, and B cells) are frequently used.

For the evaluation of nonspecific immune functions, cellular phagocytosis and NK cell activity are often determined, as these functions are important in combating microbial infection and growth of neoplastic cells. Phagocytosis is typically measured by cellular *in vitro* uptake of pathogenic bacteria like *E. coli* or *Staphylococcus aureus* following coculture of cell samples containing phagocytic cells such as whole blood, PBMC, or peritoneal lavages, and pathogens. Enumeration is either done by direct microscopic count or by flow cytometric analysis using fluorescence labeled bacteria. In humans, NK cell activity is normally measured as killing of dye-labeled or ^{51}Cr-labeled human tumor cells following coculture with PBMC. Phagocytic capacity and NK cell activity have been used to evaluate human clinical intervention studies.

Lymphocyte proliferation is a common method for measuring cellular response capacity toward *in vitro* stimulation either with antigen using *in vivo*-primed cells (immunization and vaccination), or nonspecifically with polyclonal mitogens. The most common mitogens applied to test lymphocyte proliferation are the T cell mitogens concanavalin A and phytohemagglutinin, and the B cell mitogens lipopolysaccharide and pokeweed mitogen. Although a commonly used method, the biological significance of mitogen stimulation is often questioned because of the broad nonspecific nature of the stimulation. Detection of cellular incorporation of [^{3}H]thymidine into DNA is commonly used for estimating changes in cell number.

Production of cytokines and other immune regulatory compounds are also methods frequently used in the assessment of immune mechanistic effects. Cytokines can be measured in supernatants of cell cultures or in whole blood samples with or without preceding stimulation with antigen or mitogen. Because many cytokines function at a focal level, e.g., in the synapse of interacting cells, and are often present only briefly and in low amounts, their detection is hampered and the biological significance of assessing their level in many *in vitro* experimental settings remains to be established. Cytokines are typically measured by enzyme-linked immunosorbent assay (ELISA) but can also be measured at the mRNA level.

Other measurements have been used to determine the effects of probiotics on immune status. For example, the number and type of immune cells such as blood or intestinal B and T cells can be determined by the use of fluorescence labeled antibodies directed against cell surface markers using flow cytometric analysis. Moreover, qualitative and quantitative determination of antibody production with or without preceding priming is used. Specific antibody responses to vaccination antigens or to bacterial antigens are used as an index for the adjuvant capacity of LAB; i.e., their capacity to potentiate a response to an antigen. The profile of the types of antibody produced indicates the type of response initiated, e.g., IgE in an allergic response.

25.4.2 Effects of LAB on Nonimmunologic Mucosa Barrier Functions

Many effects of LAB are very likely to be mediated through epithelial cell functions. For the nonimmunologic part, the intestinal epithelium provides a physical protective barrier, whose integrity is differentially influenced by various microbial signals. The integrity of the epithelial barrier is dependent on a tight cellular structure of enterocytes joined together by tight junctions. Defects in the barrier function can occur during invasion by pathogens, food intolerance reactions, or exposure to chemicals or radiation. Leakage through tight junctions or direct cell disruption results in increased permeability and consequently translocation of microbes and dietary antigens, which deteriorate the condition and further compromise barrier function (63). Factors such as proinflammatory cytokines, secreted by enterocytes and intraepithelial lymphocytes during contact with certain pathogenic bacteria, affect the integrity of the tight junctions and thus intestinal permeability, resulting in elevated transport of fluid and electrolytes eventually leading to diarrhea. Due to the same molecular mechanisms, beneficial microorganisms of the gut flora, including certain LAB, seem instead to enhance the integrity of the enterocytes tight junctions. For example, administration of the probiotic bacteria *L. rhamnosus* GG or *L. plantarum* 299v has been found to reverse increased intestinal permeability caused by cow's milk in suckling rats, or by *E. coli* infection in rats, respectively (64,65). Likewise, the probiotic product mixture VSL#3, which contains *B. longum*, *B. infantis*, *B. breve*, *L. acidophilus*, *L. casei*, *L. delbruekii* ssp. *bulgaricus*, *L. plantarum*, and *S. salivarius* ssp. *thermophilus*, was found to normalize colonic barrier integrity in parallel with a reduction of the proinflammatory cytokines TNF-α and IFN-γ in a colitis mouse model, where the permeability was otherwise increased by conventional gut colonization compared to germ-free animals (66).

Besides down regulation of proinflammatory factors, epithelial integrity could also be improved by LAB enhancing enterocyte proliferation and, thus increasing cellular turnover of injured and dysfunctional enterocytes. Such an effect has been seen in rats supplemented with *L. casei* (67). Alternatively or in addition, improved permeability could be mediated by LAB through pathogen exclusion due to enhanced resistance to pathogen colonization, which is another nonimmune defense mechanism promoted by certain LAB. Intestinal LAB such as strains of *Lactobacillus* are known to possess antimicrobial activities against pathogenic bacteria such as production of bactericidal peptides (68), and have been found to inhibit adhesion of pathogens to enterocytes *in vitro* (69). Bifidobacteria and some *Lactobacillus* strains, including many probiotics, adhere to enterocytes and are in this way believed to compete with pathogens for adhesion sites (70). The ability of certain bacteria to regulate surface expression of glycosylated compounds that mediate attachment of pathogens to the epithelial surface is another possible explanation for the improving effects of LAB on resistance to pathogen colonization (71). The capability of LAB to up regulate mucin production may also improve colonization resistance. *L. plantarum* 299v has been found *in vitro* to inhibit adhesion of *E. coli* to enterocytes and to up regulate mucin mRNA expression in the cells (72). Mucin up regulation may aid clearance of pathogens while also increasing attachment of LAB, as certain probiotic LAB are known to adhere to intestinal mucus (70). Much still needs to be confirmed and further clarified about the effect of LAB and the gut flora on the nonimmune related defense mechanisms.

25.4.3 Effects on Phagocytic Cells

Probiotic LAB possess the capability to enhance nonspecific immune functions of phagocytic cells (neutrophils and monocytes or macrophages). Although the exact mechanisms involved are largely unknown, the effect seems evident both from *in vitro* and *in vivo* studies, showing, however, a great variation among strains.

Increased phagocytic capacity is one important effect found for certain probiotic LAB: Ingestion of strains such as *L. johnsonii* La1, *L. rhamnosus* HN001, *B. lactis* Bb-12, and *B. lactis* HN019 significantly increases the phagocytic capacity of blood leukocytes or peritoneal cells (mice only), as shown in mice (73) and humans, including the elderly (6,74–77). In humans, this effect was shown to be stronger in individuals with poor phagocytic capacity prior to treatment (78). In contrast, ingestion of *L. casei* Shirota by humans was found not to influence the phagocytic capacity (79). Enhanced phagocytic capacity might be mediated through LAB-induced up regulation of phagocytic receptors, as observed for *L. rhamnosus* GG given to healthy humans, who showed an increased expression of CR1, CR3, FcγRI, and FcαR in neutrophils (80).

Increased phagocytic capacity mediated by probiotics is one mechanism that potentially accounts for enhanced resistance against pathogen infections. For example, mice challenged with pathogens like *Salmonella typhimurium* or *E. coli* 0157:H7 showed increased resistance to infection in conjunction with enhanced phagocytic capacity when fed probiotic LAB (*L. rhamnosus* HN001 or *B. lactis* HN019) (81,82).

Certain LAB are known to affect components involved in bactericidal activity of phagocytes, which is another mechanism potentially explaining increased resistance to infection. LAB enhance macrophage enzymatic activity when fed to mice (*L. casei* and *L. acidophilus*) (83) and have been found to enhance the oxidative burst (production of ROS) of phagocytic cells in humans (*L. johnsonii* La1) (14). Moreover, when exposed *in vitro* to macrophages, many strains of LAB readily induce production of nitric oxide and hydrogen peroxide, although the physiological relevance of such an *in vitro* effect remains unclear (84).

Pathogens such as *Salmonella typhimurium* have developed mechanisms to disseminate into deep tissues like the intestinal mucosa by inducing apoptosis (programmed cell death) of phagocytic and other immune cells. Recently, LAB strains (*L. delbruekii* ssp. *bulgaricus* and *S. thermophilus*) were found to inhibit such apoptosis induction and in so doing possibly enhance the capability of the phagocytic cells to kill the pathogen (85). This effect might, however, be mediated indirectly by an increased bactericidal capacity of the phagocytes that instigate killing of the pathogen before apoptosis is induced. Inhibition of pathogen-induced apoptosis of immune cells is yet another mechanism through which LAB might improve resistance to infection.

25.4.4 Effects on NK Cell Activity

NK cells are another group of cells playing an important role in the nonspecific immune defense against tumor cells, and viral and bacterial infections. A vast majority of NK cells reside in the liver, but they are also found at mucosal sites (86). Many studies, involving both animals and humans, have indicated that ingestion of certain LAB significantly enhances NK cell activity of PBMC observed as an increased tumoricidal activity (77,78,87,88). In some studies, a concomitant increase in the relative proportion of NK cells (cells expressing the CD56 surface molecule) among the isolated PBMC was observed, which could at least partly account for the observed increased tumoricidal activity. The increase in NK cell activity has been found to be positively correlated with age, and thus to benefit particularly elderly people of whom a high proportion have decreased NK cell activity (78). However, a direct link between LAB-induced increased NK cell activity and human health has yet to be documented.

NK cells are activated as an early event in an immune response by IL-12 produced by monocytes, macrophages, and dendritic cells. Activated NK cells produce IFN-γ that functions in the nonspecific immune response to further activate nonspecific immune mechanisms such as phagocytosis. NK cells themselves are also activated by IFN-γ.

Moreover, IFN-γ, like IL-12, is important in the promotion of specific Th1-polarized immune responses. The population of NK cells contained in PBMC is activated indirectly by LAB to produce IFN-γ through the effect of LAB on monocytes, which involves induction of IL-12 and costimulatory molecules (89). As will be discussed in what follows, many LAB induce IL-12 production in monocytes, macrophages, and dendritic cells (90–92), which potentially mediates the enhancing effect of LAB on NK cell activity.

25.4.5 Interactions Between LAB and Intestinal Epithelial Cells

Intestinal epithelial cells are endowed with several important immunoregulatory functions, as we have discussed, including antigen presentation and production of inflammatory and regulatory cytokines. Contact with pathogenic microorganisms such as *Salmonella typhimurium*, *E. coli* or *Helicobacter pylori*, activates enterocytes to secrete cytokines that induce migration of inflammatory cells like neutrophils into the mucosa. Such cytokines include the neutrophil attractant IL-8, and the proinflammatory cytokines IL-1β and TNF-α. Gram-positive versus Gram-negative bacteria appear to exert rather different effects on enterocytes (93). Gram-negative bacteria like *E. coli,* or *E. coli*-derived lipopolysaccharides, activate enterocytes to produce IL-8 and TNF-α through binding to the pattern recognition receptor CD14 (a cofactor for binding of several bacterial components to a Toll-like receptor). In contrast, Gram-positive bacteria including *L. johnsonii* La1 and *L. acidophilus* La10, as well as the cell wall glycolipid lipoteichoic acid derived thereof, inhibit the proinflammatory effect of *E. coli* (94). In line with this, *L. plantarum* 299v has been shown to inhibit *E. coli*-induced neutrophil transepithelial migration (95).

Migration of intraepithelial lymphocytes into the epithelial compartment depends on expression of adhesion molecules (αEβ7 integrin) on their surface, and these molecules are up regulated by TGF-β (96). In contrast to Gram-negative bacteria inducing inflammatory cytokines in epithelial cells, the probiotic *L. johnsonii* La1 was shown to induce TGF-β, potentially affecting the number of intraepithelial lymphocytes, and immunologic homeostasis, through the suppressive effect of TGF-β (61).

These observations suggest that LAB and other Gram-positive bacteria of the gut flora posses a capability to counterbalance the proinflammatory response of Gram-negative bacteria of the flora and so participate in the maintenance of immunologic homeostasis. The interaction of bacteria with enterocytes was found to be dependent on the presence of other immune cells, predominantly Th cells, and, in turn, to affect the activity of the immune cells, such as inducing immunosuppressive antigen-presenting cells (40,97). This provides evidence that luminal bacterial signaling is transduced to the host by a network of cross-talking immune cells in the gut, in which the gut epithelial cells participate considerably.

25.4.6 Effects on Cytokine Production

A large number of studies has clearly shown that LAB can influence cytokine production in immunocompetent cells of animals and humans. From *in vitro* studies with different types of immune cells such as human PBMC, murine spleen cells, dendritic cells or macrophage cell lines, a pattern for the type of cytokines typically induced following exposure to LAB has emerged: many lactobacilli, as well as other Gram-positive bacteria, are often capable of inducing Th1 response-related cytokines; IL-12, IL-18, IFN-γ, and TNF-α, and furthermore often induce IL-6 and IL-10 (87,90–92,98–100). In contrast to this, Gram-negative bacteria, e.g., nonpathogenic *E. coli*, are weak type 1 cytokine inducers but preferentially induce IL-10 (98,101,102). IFN-γ production by T cell or NK cells is induced through induction of the early response cytokine IL-12 in antigen presenting cells (monocytes, macrophages, or dendritic cells) (99,101,103). A large variation in the capacities to induce IL-12 occurs amongst species

and strains of LAB; *L. casei* and *L. paracasei*, have, for instance, been repeatedly reported to include some of the strongest IL-12 inducing strains (91,92,99,104). IL-10 is, like IL-12, induced at different levels by different LAB, and strong IL-12-inducers appear often also to be strong IL-10 inducers. Induction of cytokines occurs in a dose dependent manner. In addition, the ratio between the induced cytokine levels varies not only with the strain of LAB but also with the concentration and duration of exposure, which adds further complexity to the phenomenon of bacterial signaling *in vivo* (92,102).

In addition to the capability of many LAB to be Th1-response potentiators *in vitro*, it has recently been found for a strain of *L. paracasei* (NCC2461), that, in addition to being a strong IL-10 and IL-12-inducer, this strain induced the development of a T_R-like Th cell population producing TGF-β and IL-10 in an *in vitro* system (104). Extension of such effect to *in vivo* conditions could explain some of the effects observed for LAB. In support of this, a recent *in vivo* study in mice showed that T_R cells with specificity toward the gut flora appeared to be dominant in the immune homeostasis of GALT (105).

In vivo cytokine production upon ingestion of LAB has been studied in both humans and animals. The results of these studies vary greatly and seem to depend on the LAB used and the experimental setting. As with the *in vitro* studies, animal feeding studies tend to show that some LAB strains favor Th1 responses. For example, *L. casei* CRL431 and *L. casei* Shirota fed to allergy-primed mice increased serum levels of IFN-γ and reduced IL-4 (106,107). However, in a study with healthy mice fed different LAB, no changes were observed for IFN-γ, TNF-α, or IL-6 (108). In another study, feeding yogurt to mice reduced cytokine expression, especially TNF-α (109). Moreover, in a study based on counting local cytokine-producing cells in the gut villi of healthy mice fed a range of lactobacilli, no changes were observed for IFN-γ, IL-4, or IL-10 (12). Yet in this study, significant induction of TNF-α and IL-2 was observed for some strains (*L. reuteri* and *L. brevis*), clearly showing a great variation between species and strains of LAB in their capacity to modulate the immune function at the site of delivery. Such local responses, however, may not necessarily be reflected systemically.

In human studies, administration of *L. rhamnosus* in combination with *L. reuteri* to patients with atopic disease did not alter IL-2, IL-4, IL-10, or IFN-γ production by PBMC, despite convalescence (110). However, in a similar study with atopic individuals ingesting *L. rhamnosus* GG, a transient up regulation of IL-10 was evident (111). Likewise, in patients suffering from intestinal inflammation, probiotics were shown to up regulate the tissue levels of IL-10 (112). In healthy individuals, intake of *L. brevis* ssp. *coagulans* was shown to increase a virus-induced IFN-α (an important cytokine in nonspecific cell mediated immunity) response. This effect followed a dose dependent pattern, with those subjects with initially lowest levels displaying the greatest increase (113). To date no studies have shown results on the effect of LAB on IL-12 production in humans. IL-12 and as other cytokines function focally between adjacent cells, which hampers factual *in vivo* assessment of changes of these cytokines.

On the whole, probiotic LAB are potentially capable of either improving homeostasis by inducing antiinflammatory cytokines like IL-10, or supporting Th1 responses by enhancing cytokines like IL-12. The pattern of LAB-induced modulation of cytokine production *in vivo* is likely to depend on the condition of the host; i.e., reflecting either immunologic imbalance due to disease or allergy, or proper immunologic balance when healthy.

25.4.7 Effects on Lymphocyte Proliferation

Lymphocyte proliferation responses to mitogens are used to examine T and B cell function upon treatment with immunosuppressive or immunoenhancing agents. The immunomodulating effect of ingested LAB on T and B cell proliferative capacity depends upon the species

and strain of LAB involved. In some studies, ingestion of LAB such as *L. rhamnosus* HN001, *L. acidophilus* HN017, and *B. lactis* HN019 by mice was found to augment T and B cell function as evidenced by elevated proliferation response to concanavalin A, phytohemagglutinin, or lipopolysaccharide stimulation (73,114). However, in similar settings, strains of *L. casei*, *L. gasseri,* and *L. rhamnosus* inhibited mitogen-induced T and B cell proliferation, while *L. acidophilus* was without influence (115). Ingestion of LAB has, in some instances, been found to alter the proportion of T and B cells in lymphoid tissues, which may indirectly affect the proliferation response. Nevertheless, in cases with unchanged relative T cell populations, LAB were still found to alter the proliferation response (116). Cells from spleen, mesenteric lymph nodes and Peyer's patches have all exhibited altered proliferation response, showing, as for other analyses, that LAB exert immunomodulatory effects both at sites remote from and adjacent to the point of delivery. No explicit physiologic interpretation of altered proliferation response tested *in vitro* can be made. LAB inhibiting lymphocyte proliferation might be useful in the management of immune hyperresponsive diseases like allergy, autoimmunity, or intestinal inflammation, whereas LAB that enhance proliferation may be of general benefit to healthy individuals to improve the immune defense.

25.4.8 Effects on Specific Immune Responses – Adjuvant Capacity of LAB

A primary mechanism by which probiotic LAB mediate immune enhancement is through an adjuvant effect. An adjuvant is a compound that enhances the immune response toward a specific antigen when administered along with the antigen. Some examples of adjuvant capacity of certain LAB include studies where *L. rhamnosus*, *L. acidophilus*, *L. fermentum,* or *B. lactis* fed to healthy mice, significantly enhanced the formation of serum antibodies toward oral or parenterally administered antigens like cholera toxin, tetanus toxoid, or ovalbumin (12,73,117). Moreover, some LAB have been found to potentiate the antibody response against *E. coli* when cocolonized in germ-free animals (52,118). However, in this setting it was found that a large proportion of the antibody induced toward the LAB themselves cross reacted with the *E. coli*, which at least could partly account for the apparent adjuvant effect of LAB on the immune response against pathogens.

The LAB adjuvant effect has also been seen at the cytokine level. The *in vitro* antigen stimulated production of cytokines such as IFN-γ (Th1), IL-4, and IL-5 (Th2) in spleen and peritoneal cells of animals primed with ovalbumin and the Th2-driving adjuvant $Al(OH)_3$, was enhanced in animals fed *L. rhamnosus*, which indicates an adjuvant effect on both Th1 and Th2 cytokines (119). Feeding *L. casei* Shirota likewise enhanced Th1 cytokine production, but reduced Th2 cytokine production and, moreover, reduced the formation of ovalbumin-specific IgE (106). Hence, in addition to exhibiting an adjuvant capacity, different LAB strains seem to modulate cytokine regulation differentially, possibly resulting in the polarization of the response. Accordingly, a study in mice showed that intake of *L. acidophilus*, *L. delbruekii* ssp. *bulgaricus,* and *L. casei* all enhanced the IgG1 response (Th2-associated isotype) toward parenterally injected ovalbumin, whereas *L. acidophilus* was the only strain that also enhanced the IgG2a response (Th1-associated isotype), and was also the only strain inducing detectable IL-12-producing cells in lamina propria (117).

Whether such modulations of Th1 and Th2 cytokine production during an antigen-specific reaction are beneficial to the host still remains to be established. It is, however, hypothesized that mechanisms of LAB mediating suppression of Th2 responses, either by favoring Th1 responses or by enhancing tolerance induction mechanisms (in general improving Th1/Th2/T_R-homeostasis), may be effective in the antiallergy effect observed for certain probiotic LAB (62).

Adjuvant effects of LAB are also observed in human studies. For example, enhanced specific antibody responses to rotavirus are reported when patients who are infected with, or vaccinated against, rotavirus, ingest *L. rhamnosus* GG (120,121). However, in a study with subjects receiving attenuated *Salmonella typhi* as an oral vaccine, ingestion of *L. rhamnosus* GG did not enhance antibody formation, indicating significant variations between different experimental settings (122).

In many vaccination regimes and in the defense against pathogenic infections, a secretory IgA response is important. Like systemic antibody responses already discussed, certain LAB enhance secretory IgA responses, which is discussed in what follows.

25.4.9 Enhancement of IgA Production

Augmentation of IgA production following ingestion of LAB is one of the better documented effects of probiotic LAB. LAB enhance IgA production in both a specific and a nonspecific manner. From studies in mice, oral administration of a wide range of lactobacilli and bifidobacteria species are found to increase the number of IgA^+ B cells in the gut mucosa as well as total IgA production (16,53,123,124). Likewise, in humans, ingestion of LAB, such as *L. rhamnosus* GG or *L. johnsonii* La1, is found to increase the total IgA level in blood and feces (15,120,125).

On an antigen-specific level, many species of LAB also promote secretory IgA production as observed both in mice and humans. In mice, several studies show that along with an increased protection against pathogens, probiotic LAB increases pathogen-specific IgA (114,126). Moreover, oral administration of LAB is shown to enhance IgA against dietary antigens like the milk protein β-lactoglobulin or toxins (16,123,127). Such effects are also found in humans, showing that ingestion of *L. johnsonii* La1, bifidobacteria or *L. rhamnosus* GG increases the specific IgA formation to attenuated *Salmonella typhi* (125), poliovirus vaccinations (15), and dietary proteins (in patients with gut inflammation) (128), respectively. Increased rotavirus-specific IgA response in rotavirus patients given probiotic LAB such as *L. rhamnosus* GG has been demonstrated in several studies and is believed to be a contributing mechanism in the observed protection against reinfection with rotavirus (120,129,130).

The cytokine IL-6 is important for the maintenance of an IgA response; Th2 cytokines (IL-4 and IL-5) are more important during response induction (131). Thus, the ability of many LAB to induce IL-6 but not Th2 cytokines, as discussed in a previous section, may be linked to the capability of LAB to act as an adjuvant for IgA production.

25.5 EFFECTS OF LAB ON DISEASES

Scientific evidence is now being accumulated to support both therapeutic and prophylactic properties of probiotic LAB and fermented products. Many beneficial health effects have been claimed for probiotics, especially concerning their potential to prevent or ameliorate intestinal diseases. There are, however, fundamental differences between various LAB, and the clinical effects vary greatly, with only a few probiotic strains showing efficacy in randomized placebo-controlled clinical studies. The probiotic organism that has received by far the most clinical attention to date is *L. rhamnosus* GG. Several other organisms have, however, also been thoroughly studied, of which the most important and their effects are listed in Table 25.5. Most clinical studies have been performed using viable bacteria. However, in some instances, nonviable bacterial preparations have been shown also to be effective, which will be discussed at the end of this section.

Table 25.5
Examples of Probiotics with Reported Immunomodulating Effects in Humans

Bacteria	Effects	Ref.
L. rhamnosus GG	Prevention and treatment of diarrhea, vaccine adjuvant, antiallergy, increased IgA	120,121,128,135,161,162
L. johnsonii La1	Vaccine adjuvant, enhanced phagocytosis, antiinfection (*Helicobacter*), increased IgA	6,14,125,178
L. plantarum 299v	Antiinflammatory bowel disease	145
L. rhamnosus HN001	Enhanced phagocytosis and NK cell activity, antiinfection	77,81,82,179
B. lactis HN019	Enhanced phagocytosis and NK cell activity, antiinfection	76,114,132,180
L. reuteri DSM12246	Treatment of diarrhea, antiallergy	110,136
VSL#3 (mixture of LAB)	Antiinflammatory bowel disease, prevention of diarrhea	148,181,182
L. casei Shirota	Treatment of diarrhea, anticancer, antiallergy, antiinfection, enhanced NK cell activity	88,104,106,168,183,184
L. casei CRL431	Treatment of diarrhea, antiinfection, increased IgA	185–188
B. lactis Bb-12	Antiallergy, prevention of diarrhea vaccine adjuvant, increased IgA, enhanced phagocytosis	6,15,134,161

25.5.1 Effects of LAB on Intestinal Infections

Some LAB have proved effective in preventing gastrointestinal infections and in the recovery from infectious diarrhea due to miscellaneous causes including traveler's diarrhea and rotavirus.

Acute diarrhea caused by gastrointestinal infections is common throughout the world, especially among children. One aspect of the effect of LAB against infectious diseases in the gut is due to enhanced resistance to colonization, e.g., by production of antibacterial metabolites, and, thus, to a lesser extend related to a direct effect on the immune system. However, combating pathogenic infections has also been shown to be due to stimulation of the immune defense, particularly by increasing phagocytic capacity and the secretory antibody (IgA) response, as discussed previously. Studies in mice have demonstrated that in parallel with such immune stimulating effects, dietary supplementation with *L. rhamnosus* HN001 or *B. lactis* HN019 reduces the severity of infections with the pathogens *E. coli* O157:H7 and *Salmonella typhimurium* (81,82,114,132). In contrast, in a clinical study with healthy volunteers challenged with enterotoxigenic *E. coli*, administration of *L. acidophilus* and *L. bulgaricus* did not reduce the attack rate, incubation period, or duration of diarrhea (133).

Nevertheless, in studies concerning children with acute infectious diarrhea (viral or bacterial), probiotics such as *L. reuteri* DSM 12249, *L. rhamnosus* GG, or *B. bifidum* effectively ameliorated the diarrhea in both hospitalized and nonhospitalized patients (134–136). Probiotics have been found to be particularly effective against rotaviral infections. The effect of *L. rhamnosus* GG in the treatment of rotavirus diarrhea in infants and children is one of

the best documented probiotic effects in human subjects (137). Mechanisms including normalization of gut flora and gut permeability, as well as enhancement of mucosal immune response, have been reported in several studies; e.g., clearance of virus after primary infection and subsequent protection against reinfection (seen for at least 1 year) correlates well with the production of mucosal and serum IgA, which are enhanced by probiotics (44).

Antibiotic-associated diarrhea is another form of acute diarrhea that occurs frequently. It is caused by a disruption of the ecosystem of the gut flora resulting in decreased colonization resistance and altered fermentation capacity (microbial imbalance). Under these conditions *Clostridium difficile* or *Klebsiella oxytoca* may colonize the gut and induce colitis. *L. rhamnosus* GG has shown to be effective in preventing antibiotic-associated diarrhea in children while being ineffective in adult patients. The probiotic microorganisms *Enterococcus faecium* SF68 and the yeast *Saccharomyces boulardii*, have also shown prophylactic effects in antibiotic-associated diarrhea (138).

Traveler's diarrhea is another common form of acute diarrhea. In several studies, probiotic LAB demonstrated no effect in preventing traveler's diarrhea, and data to support a prophylactic effect is limited. In one study, however, the incidence of diarrhea in tourists going to Egypt was reduced considerably in subjects given capsules of *S. thermophilus*, *L. bulgaricus*, *L. acidophilus,* and *B. bifidum*, indicating that the effect of probiotics in traveler's diarrhea not only depends upon the probiotic strain or strains, but also on the specific conditions, such as the type of microbial exposure, which can vary at different destinations (139).

Colonization of the gastric mucosa with *Helicobacter pylori* is associated with gastritis, ulcers, and some malignancies. Several probiotic LAB have demonstrated anti-*Helicobacter* activity in *in vitro* studies. *In vivo*, LAB strains including *L. johnsonii* La1 have also been found to exhibit anti-*Helicobacter pylori* activity by suppressing this organism, but do not appear to eradicate it (140).

In summary, probiotic LAB seem to possess the potential to be used in the management of several infectious diseases. In particular, probiotic bacteriotherapy of children and infants, to reduce the incidence and shorten the duration of acute infectious diarrhea, might be effective. This fact may be related to the ability of the bifidobacteria predominating in the flora of breast-fed infants to promote protection against pathogenic infections (141).

25.5.2 Effects on Inflammatory Bowel Disease

Inflammatory bowel disease (IBD), including ulcerative colitis, Crohn's disease, and pouchitis (inflammation of the ileal pouch arising after surgical resection of colon), refers to intestinal disorders of unknown cause that are characterized by chronic or recurrent intestinal inflammation (142). It appears that IBD, particularly Crohn's disease, develops due to genetically influenced dysregulation of mucosal immunity against components of the intestinal flora. Cytokine imbalance due to dysregulated Th cells appears to play an important role in the pathogenesis: Crohn's disease is mediated predominantly by Th1 response, whereas ulcerative colitis is usually associated with a Th2 response.

Some probiotics seem to be very efficient in the treatment of IBD. As discussed earlier in this chapter, IL-10 is a key regulatory cytokine for tolerance to luminal antigens, including the gut flora. IL-10 gene-deficient mice respond to their gut flora by developing spontaneous colitis resembling Crohn's disease and are, therefore, an effective experimental model for IBD (143). A gut flora deficient in LAB is a characteristic of IL-10 gene-deficient mice, and administration of probiotic LAB, such as *L. reuteri* and *L. plantarum* 299v, has been shown to be an effective treatment of these mice (144,145). As also mentioned earlier, bacterial immunostimulatory DNA sequences, especially unmethylated CpG motifs, are known to activate epithelial cells through interaction with Toll-like receptors (28). In different IBD mouse models, treatment with immunostimulatory DNA inhibited induction of colonic

proinflammatory cytokines and chemokines (146). Likewise, genomic unmethylated DNA from the probiotic mixture VSL#3 ameliorated colitis in a similar model, whereas methylated DNA was ineffective, clearly demonstrating the importance of immunostimulatory DNA in probiotics effective against IBD and perhaps against other diseases involving an immune imbalance as well (147).

In humans, a number of clinical studies have now demonstrated an efficacy of probiotics against ulcerative colitis, Crohn's disease, or pouchitis. The VSL#3 product (*B. longum*, *B. infantis*, *B. breve*, *L. acidophilus*, *L. casei*, *L. delbruekii* ssp. *bulgaricus*, *L. plantarum*, and *S. salivarius* ssp. *thermophilus*) has proved very efficient in prophylaxis and reduction of recurrence of chronic relapsing pouchitis (148–150). Significantly, in IBD patients treated with VSL#3, the tissue levels of IL-10 were increased revealing an immunomodulatory mechanism elicited by the probiotics (112).

Other nonLAB microorganisms such as *E. coli* Nissle 1917 and *Saccharomyces boulardii* have also proved efficient in the treatment of IBD (151). Intense research is ongoing to elucidate further the efficacy of probiotic LAB in the treatment and prevention of IBD.

25.5.3 Antiallergy Properties of LAB

The prevalence of allergic diseases has progressively increased in Western industrialized countries (152). Allergy and atopy, featuring IgE production, are closely associated with a Th2 cell-driven response. Atopic eczema due to food allergy represents the earliest manifestations of allergic disease, starting from infancy.

A so called "hygiene hypothesis" was originally formulated by Strachan in 1989 (153), stating a possible explanation for the increasing prevalence of allergy. In essence, this hypothesis stated that the lower microbial exposure of the immune system due to increased hygiene causes an underdeveloped Th1 polarization (newborns are Th2-skewed) and, thus, an imbalance in the Th1/Th2 homeostasis, favoring the Th2-driven allergic responses. While this original hypothesis mainly implied the consequence of increased hygiene to be a reduction in the number of Th1-driving infections known to reduce allergic disorders, a revised hygiene hypothesis was proposed by Wold in 1998 (154), saying that the overly hygienic lifestyle in modern Western countries, rather than limiting pathogenic infections, has altered the normal intestinal colonization pattern in infancy leading to a failure to induce and maintain oral tolerance of innocuous antigens.

Indeed, there is data accumulating showing a clear tendency of atopic subjects to have an aberrant composition of the gut flora in comparison with nonatopic subjects: infants in whom atopy develops tend to have fewer bifidobacteria and more clostridia (8,155,156). Recent findings have, moreover, indicated a correlation between allergic disease and the composition of the intestinal bifidobacteria population, pointing toward allergic infants having a more adult-like bifidobacteria flora with high levels of *B. adolescentis* whereas healthy infants have high levels of *B. bifidum* (157,158). Interestingly, the adhesion capacity to human intestinal cells of the isolated fecal bifidobacteria from healthy infants has been found to be significantly higher than for allergic infants. Furthermore, when testing the capacity to induce cytokines in a macrophage cell line, bifidobacteria from allergic infants vs. healthy infants were found to induce more proinflammatory cytokines such as IL-1β, IL-12, and TNF-α, whilst inducing much less IL-10 with many strains not inducing IL-10 at all. This provides preliminary indications that although bifidobacteria are Th1 cytokine inducers and putatively counteract Th2 responses, the incapability of inducing the response suppressive IL-10 in combination with the TNF-α-inducing capacity (TNF-α is increased during allergic inflammation in the gut) of the gut flora derived bifidobacteria of allergic infants possibly plays a decisive role in allergic disease etiology (159).

A corollary of the documented immunologic repercussions to aberrant gut flora, as well as the general finding of LAB to improve immune homeostasis, is the investigation of the effect of supplementing LAB on allergy. As mentioned earlier, oral administration of *L. casei* Shirota to mice prior to Th2 response priming reduced IgE and IL-4 levels while increasing the Th1 cytokines IL-2 and IFN-γ (106). Likewise, in a mouse model of atopy, administration of *L. casei* CRL431 was shown to down regulate IgE and IL-4 synthesis by increasing IFN-γ. This was, however, only effective when administered before sensitization, indicating the impact of timing (107).

In humans, a number of studies have indicated the efficacy of *Lactobacillus* administration in the treatment and prevention of atopic eczema. In this regard, *L. rhamnosus* GG is the most investigated probiotic LAB strain and has proved efficient in several settings. In studies of infants with atopic eczema, supplementation with *L. rhamnosus* GG has been found to improve clinical symptoms, alleviate intestinal inflammation and enhance IL-10 production significantly (111,160,161). One of these studies also included *B. lactis* Bb-12, which demonstrated this strain to be equally efficient in reducing the severity of eczema (161). In a study involving older children (1–13 years) with chronic atopic eczema, oral treatment with a combination of *L. rhamnosus* 19070-2 and *L. reuteri* DSM12246, decreased the severity of eczema in more than half of the treated subjects (110). These studies substantiate the efficacy of some probiotics in the treatment of manifested allergy.

Clinical research has also aimed at the efficacy of probiotics to prevent development of allergy. The efficiency of *L. rhamnosus* GG to prevent the occurrence of atopic eczema in infants from atopic families has been studied (162). The bacteria were given to mothers during pregnancy, and mothers who were breast feeding continued to take the bacteria after delivery; otherwise the children were given bacteria for 6 months. At 2 years of age, the frequency of atopic eczema in the probiotic group was reduced by half (from 46% to 23%), demonstrating a potential of this probiotic LAB in prophylaxis of allergy. In line with this, administration of *L. rhamnosus* GG to the pregnant and lactating mothers increased the level of TGF-β in breast milk and reduced the risk of the children developing atopic eczema during the first two years of life (163).

There are indications that using probiotics in the management of allergy is most if not solely effective in allergies occurring in infancy or early childhood. For example, *L. rhamnosus* GG failed to prevent both birch pollen allergy and apple allergy in young adults (164). Supplementation of infants via formulas fortified with probiotics or supplementation of mothers during pregnancy and lactation are definite future perspectives for the applicability of probiotics. Research is ongoing, working to identify new probiotics and their mechanisms of action and optimal protocol of administration, especially regarding timing.

25.5.4 Antitumor Effect of LAB

Colorectal cancer is one of the most important causes of death from cancer in Western countries. Epidemiological studies show a diet associated risk, in particular of the low fiber "Western diet;" and many studies confirm the involvement of intestinal microflora in the onset of colon cancer. In animals, several studies have shown that bacteria of the bacteroides and clostridia genera increase the incidence and growth of colonic tumors, whereas other genera such as lactobacilli and bifidobacteria prevent tumorigenesis (165). Likewise, in a human study, high risk of colon cancer was found to be associated with presence of species of *Bacteroides*, whereas low risk was associated with presence of species of *Lactobacillus* (166). Thus, much attention has focused on decreasing cancer through diet alterations, in particular increasing intake of fiber and probiotics both intervening with the gut flora.

No direct experimental evidence has, yet, been established that consumption of LAB suppresses cancer in man; however, a vast amount of indirect evidence exists from laboratory experiments using experimental animal models (167). From such studies, several nonimmunologic mechanisms of LAB have been suggested, such as decrease of fecal enzymes that may be involved in carcinogen formation, elimination of carcinogens, and production of antitumorigenic compounds. However, antitumor effects of LAB in experimental animals seem also to be mediated through immunologic mechanisms. As discussed in the previous section, LAB increase specific and nonspecific immune mechanisms, potentially protecting against tumor development. In different models of tumor bearing mice, injection of heat-killed *L. casei* Shirota (termed LC9018) to the site of tumor growth showed a potent inhibition of tumor growth and increased survival (106,168). This antitumor effect was mediated through production of the tumor-suppressing type 1 cytokines IL-12, IFN-γ, and most importantly TNF-α, as injection of neutralizing anticytokine antibodies abolished the antitumor effect of the bacteria. Studies on the effect of yogurt (*L. delbruekii* ssp. *bulgaricus* and *S. thermophilus*) showed that consumption of yogurt by mice inhibited chemically induced colorectal cancer in conjunction with an increase in IgA^+ B cells in the colon, and with IFN-γ and TNF-α production (169). In summary, these and other studies suggest that certain LAB impart an antitumor effect through modulation of the host's immune system, specifically cell-mediated immunity. However, such antitumor effects of LAB in humans remain to be determined.

25.5.5 Impact of Viability and Dose on the Effects of LAB

Besides strain-related primary selection criteria (adhesion, acid, and bile tolerance, not discussed in this chapter), some practical aspects have an impact on the immunomodulating effects of probiotics; most importantly the consequences of viable vs. nonviable bacterial preparations, and effective doses. Probiotics, as defined in the introduction, include also nonviable bacteria and bacterial components. However, research has shown that some effects demand the bacteria be alive whereas other effects are independent of viability. Effects exerted via prolonged epithelial adherence or (transient) colonization logically require live bacteria although there are indications that nonviable bacteria can, in fact, adhere to epithelial cells (170). A variety of immunomodulating activities, seem to be attributable to specific cell wall or intracellular bacterial components, and are exhibited by nonviable bacteria and even by the isolated components of the cell (100,147).

Only a few studies have focused specifically on testing the effects of viable vs. nonviable bacteria. Viable and heat-killed LAB were equally efficient in enhancing phagocytic capacity in mice, whereas only the viable bacteria enhanced IgA production (171,172). Likewise, only viable *L. rhamnosus* GG enhanced IgA production in patients with acute rotavirus diarrhea, while both viable and nonviable probiotics shortened the diarrhea (130). In an attempt to assess the efficacy of viable vs. heat-killed *L. rhamnosus* GG on atopic disease, the heat-killed preparation induced diarrhea and the study could not be completed, opening the question of safety of ingestion of large amounts of heat-killed bacteria (173). These and other studies clearly indicate that the importance of viable vs. nonviable bacteria depends on the effect in question, although viable probiotics tend to have more health effects than nonviable (113,174). The method of inactivation, e.g., inactivation by natural exhaustion in stored fermented products, which introduces cellular changes; inactivation by heat killing experimentally or due to pasteurization, which highly denatures cellular compounds; or inactivation by UV or gamma irradiation, which spares protein denaturation but affects DNA, may also play a role.

Another important factor involving the effects of probiotic LAB is effective dose. Typically, probiotic LAB are only effective if the dosage is sufficiently high. Accordingly,

the minimum daily dose of viable *L. johnsonii* La1, which significantly increases phagocytic capacity and oxidative burst in humans, is 10^9 bacteria (14). In a study in mice, the minimum daily dose for a significant increase in blood cell phagocytic capacity was 10^7 with a clear dose-response effect up to 10^{11} bacteria per day (172). Most clinical studies apply doses at 10^9–10^{11} viable bacteria/day.

25.6 CONCLUDING REMARKS AND FUTURE PERSPECTIVES

Probiotics are just one aspect of the emerging field of functional foods, and have recently received renewed enthusiasm and far more rigorous scientific pursuit. Well documented beneficial effects on gastrointestinal disturbances are mediated by probiotics. The research worldwide is now focusing on the development of target specific probiotic products with well characterized microorganisms selected for their specific health enhancing properties. For this purpose, more research into the intestinal flora and its interaction with the host immune function is a prerequisite to enhance the scientific soundness of identifying novel probiotics. Currently, many questions remain to be answered as to how probiotic LAB exert their ostensibly wide spectrum of immunomodulating effects. It appears reasonable to assume that the multifactorial effects of LAB stem from merely one or a few primary effects, yet targeted at some early stages of the immune response and thus causing alterations in a variety of mechanisms along the response cascade. Accordingly, increasing amounts of data indicate that LAB greatly affect epithelial cells and antigen-presenting cells such as the dendritic cells important for the initiation and polarization of an immune response. Effects on these cells disseminate like ripples in a pond, potentially modulating multiple immune functions regulated by these cells. Equally important, such primary effects of probiotics can also evoke diversified outcomes depending on the immune status of the host; i.e., healthy, malfunctioning, or diseased.

Like many other areas of biology, regulation of the immune system is extremely complex. Metaphorically, the phenomenon of immune regulation could frankly be compared with jumping in a waterbed: when jumping down the bed, other parts of the bed inevitably go up, with some areas of the bed moving more vigorously than others; until stabilization, many areas move alternately up and down at different amplitudes and in an almost unpredictable pattern very closely linked to even small disparities in factors related to both the "jumper" and the bed — the "jumper" being the probiotic and the bed being the consumer.

ACKNOWLEDGMENT

The authors wish to thank Dr. Charlotte Madsen for critically reading through the manuscript.

Biochemical Markers for Antioxidant Functionality

Dhiraj A. Vattem and Kalidas Shetty

CONTENTS

26.1 INTRODUCTION

An imbalance of prooxidants and antioxidants, which leads to oxidative stress, is now believed to be a key contributing factor in the manifestation of chronic diseases such as cardiovascular disease, hypertension, diabetes mellitus, and some forms of cancer. (1,2). Recent research has shown that populations consuming diets rich in fruits and vegetables have lower incidences of many chronic diseases (3–6), which has encouraged the use of diet as a complementary strategy for the management of these oxidative diseases (7–10). Fruits and vegetables are rich sources of phytochemicals and highly antioxidant vitamins, which are now believed to be responsible for these beneficial effects. The function of antioxidants from fruits and vegetables has been categorized into two types depending on their mode of action. First, oxidation of biological macromolecules such as nucleic acids, proteins, and lipids as a result of free radical damage (oxidative stress) has now been strongly associated with development of many physiological conditions which can manifest as disease (11–17). The protective effect of antioxidants from fruits and vegetables, therefore, is believed to be due to their direct involvement in neutralizing free radicals in biological systems and preventing oxidative damage to cellular systems (18).

Second, reactive oxygen species (ROS) are naturally formed in the body as a result of many metabolic processes. Low levels of ROS therefore, have been implicated in many cellular processes, including intracellular signaling responsible for cell division (11,19,20), immune response (67–69), and via the activation and repression of many genes (11). However, excess formation of ROS can cause damage and therefore disturb cellular homeostasis, so cells have evolved several antioxidant enzyme coupled metabolic systems which can which can quickly remove the excess ROS from cellular systems (22,23). These antioxidant systems involved in the protection against ROS consist of many antioxidant factors including glutathione (GSH) and other tissue thiols, heme proteins, coenzyme Q, bilirubin and urates, and several antioxidant enzymes such as superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPX), and glutathione-S-transferase (GST) (Figure 26.1). Dietary antioxidants from fruits and vegetables and other functional foods are believed to modulate cellular physiology and participate in induction/repression of gene expression or activation/deactivation of proteins, enzymes, and transcription factors of key metabolic pathways (11,21–23) leading to activation of these biological antioxidant systems in the cell.

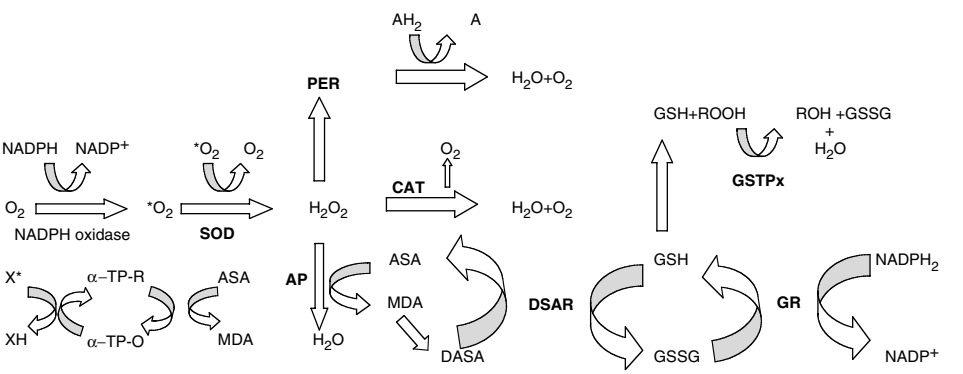

Figure 26.1 The antioxidant defense response of the cell carried out by enzymatic as well as the nonenzymatic antioxidants

The ability of fruits and vegetables to manage oxidation linked diseases has resulted in a strong interest in the development functional foods and other dietary strategies for management of oxidation diseases (3–10). These developments have led to the need for good biomarkers and analytical methodologies to determine how these diets work. Evaluation of the functional antioxidant efficacy of new phytochemicals or functional food products requires a wide range of specific, accurate, and sensitive biomarkers appropriately associated with oxidative stress and related diseases. The biomarkers help to characterize food and food products with respect to their antioxidant activity and associated functional properties; in *in vitro* and *in vivo* models as well as in clinical studies. Some well established biochemical biomarkers currently used for studying antioxidant function in the management of oxidative stress are described here.

26.2 DIRECT MEASUREMENT OF REACTIVE OXYGEN SPECIES

Molecular oxygen in biological system is relatively unreactive and plays an important role in the proper functioning of many biological processes (11). However, metabolic pathways in the cell can reduce oxygen incompletely to produce reactive oxygen species (ROS), which are unstable compared to molecular oxygen, and can react with a number of biological macromolecules and disturb the cellular homeostasis (11–17). ROS are constantly produced in aerobic organisms both enzymatically and nonenzymatically (Figure 26.2). One electron reduction of molecular oxygen in biological systems results in the formation of the superoxide anion which is the precursor of most ROS (24). Biological dismutation of the superoxide anion produces the peroxide radical, which can undergo a complete reduction to form water, or an incomplete reduction to form the highly reactive hydroxyl radical (24) (Figure 26.2). Mitochondrial leakage of electrons or direct transfer of electrons to oxygen via the electron transport chain is another important source of ROS in cellular systems (25,26). Many other sources for the formation of ROS have been identified in cellular systems of living organisms (25,26). Superoxide is also formed upon one electron reduction of oxygen mediated by enzymes such as NADPH oxidase located on the cell membrane of polymorphonuclear cells, macrophages, and endothelial cells; from xanthine oxidase or from the respiratory chain (27–30). Superoxide radicals can also be formed from the electron cycling carried out by the

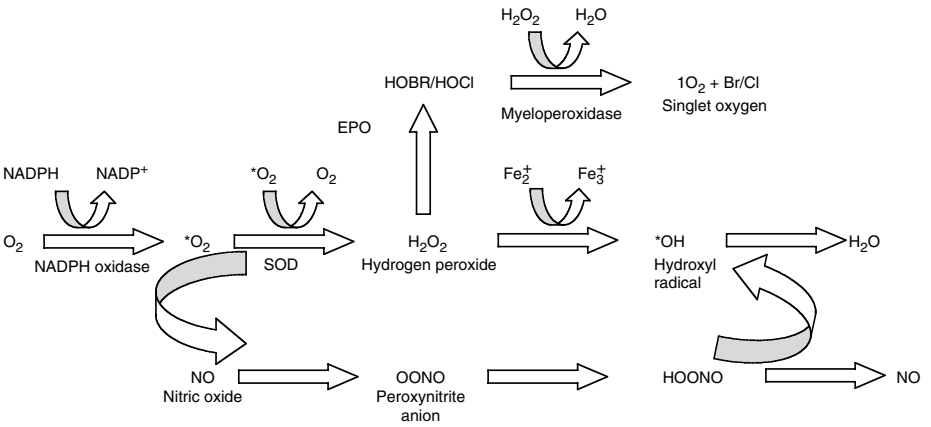

Figure 26.2 Biological mechanisms for ROS formation

cytochrome P450-dependent enzymes in detoxification reactions (31,32). Oxidation of biological molecules has been linked to manifestation of many diseases and therefore the presence of reactive oxygen species in biological systems is often considered as a marker for oxidative stress.
