Many quantitative assays are available for the detection of ROS. The majority of the methods are based on the identification of the peroxide radical, as it more stable in aqueous solution at neutral pH (33–35). H_2O_2 and other ROS are powerful oxidizing agents; therefore the most common quantification of H_2O_2 has been based on their oxidative reaction with chemiluminescent or fluorescent dyes. The neutralization of the radicals from the H_2O_2 by the dyes results in their gain or loss of fluorescence which is monitored fluorometrically (36,37). Peroxidases are used to remove the H_2O_2 radicals from the reaction mixture, and enzyme activity is monitored by the change in the fluorescence. Dependence upon peroxidases to detect H_2O_2 and lack of absolute specificity for H_2O_2 (38) are some of the limitations of this method. Other methods that are also used for direct measurement of the ROS include the use of a Clark-type oxygen electrode. Here the oxygen released from H_2O_2 in the cell supernatant is measured after the addition of catalase (39,40). Superoxide radicals are measured by electron spin resonance spectroscopy (ESR) (40). $O_2^{\cdot-}$ in solution is indirectly detected by a spin trap method by using common trapping agents such as 5,5-dimethyl-1-pyrroline N-oxide (DMPO) (41). The ESR spectrum pattern obtained from DMPO is specific to $O_2^{\cdot-}$ and therefore enables its accurate detection (41). However, due to a lower rate constant between DMPO and $O_2^{\cdot-}$, a large amount of DMPO should be added to the solution, which increases the cost per assay. Another drawback with this method is the requirement of a relatively expensive ESR instrument (41,42).

26.3 ANTIOXIDANT ASSSAYS

The total antioxidant capacity of cell extract or blood plasma can give us an indication about the functionality of the compound or food of interest (39). A number of antioxidant assays are available to study the antioxidant activity.

26.3.1 Antioxidant Assays Based on Free Radical Neutralization

Many antioxidant assays are based on their ability to neutralize or quench free radicals. The two free radicals that have been most commonly used for assessing antioxidant activity are 1,1-diphenyl-2-picrylhydrazyl (DPPH)(43,44), and 2,2′-azinobis(3-ethyl-benzothiazoline-6-sulfonic acid) (ABTS)(45,46) (Figure 26.3).

The DPPH free radical is a stable radical with one electron delocalized over the molecule (Figure 26.3). This delocalization gives a deep purple color with absorption maxima at 517 nm in an ethanol solution (43,44). When an antioxidant capable of donating a hydrogen reacts with the DPPH radical it gives rise to a nonradical reduced form of DPPH which has a yellow color. The decrease in the absorption is measured spectrophotometrically and is compared with an ethanol control to calculate the DPPH free radical scavenging activity (43,44).

$$\text{DPPH (Purple)} + \text{AO} \rightarrow \text{DPPH (Yellow)} + \text{AO} \qquad (26.1)$$

This method is a very quick and simple method for the measurement of antioxidant activity. The antioxidant capacity in this assay depends on the chemical structure of the antioxidant (43,44). The reduction in the DPPH radical is dependent on the number of hydroxyl groups present in the antioxidant. This method, therefore, gives an indication of the structural dependence of the antioxidant functionality of many biological antioxidants (43,44).

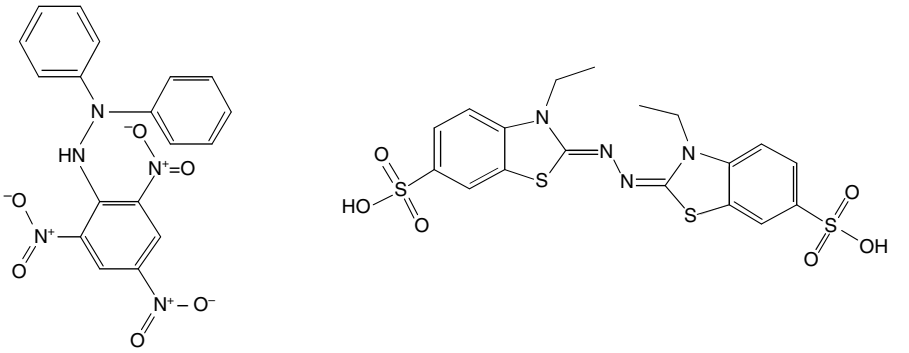

Figure 26.3 DPPH and ABTS — the two most commonly used indicators in antioxidant assays based on free radicals quenching

The absorption maxima of the DPPH radical in ethanol solution at 517 nm is considered as one of the main drawbacks of the assay as it precipitates out most of the proteins and reduces the activity of a majority of single valance phenolic hydroxides (47,48). Dependence on the number of hydroxyl groups also results in the different kinetic rates of reaction between the antioxidant and the DPPH radical and causes fluctuation in the reaction times significantly, suggesting the need for standardization of reaction time and kinetic modeling for different samples (43,44,47,48).

26.3.2 2,2'-Azinobis-(3-ethylbenzthiazoline-6-sulfonic acid)

The antioxidant assay based on the 2,2′-Azinobis-(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS) is similar to the DPPH assay (Figure 26.3). ABTS can react with hydroxyl, peroxyl, alkoxyl and inorganic radicals to form a relatively stable radical cation (ABTS) with absorption maxima at 734 nm (45,46). The antioxidant, added to the reaction mixture prior to the addition of the ROS or the radical, scavenges the free radical and prevents the formation of the ABTS radical cation. This scavenging activity can be spectrophotometrically and quantitated by comparing the antioxidant activity of the sample, extract, or biological fluid with trolox (45,46).

$$\begin{array}{l} \text{ABTS} + \text{ROS} \rightarrow \text{ABTS} \\ \qquad\qquad\quad \vdots \ \textbf{Inhibition} \\ \text{ROS} + \text{AO} \rightarrow \text{R}-\text{H} + \text{AO} \end{array} \qquad (26.2)$$

The ABTS assay can determine the antioxidant contribution from different components in the system as it is capable of reacting with hydroxyl, cysteinyl, and glutathione in biological systems, and therefore has been widely used to study the antioxidant activity of various compounds, both lipophilic and hydrophilic, food products and biological samples (45–48). However, in biological samples the antioxidant enzymes such as peroxidases have been shown to be able to promote the formation of ABTS radical therefore contributing to potential interference resulting in higher absorbance values. Due to the relatively low concentrations of hydrogen peroxide, this assay cannot accurately measure the free radical quenching, as the antioxidants can react with the ABTS radical cation directly instead of the hydrogen peroxide, which can make it look as if there is more antioxidant activity than there really is (45,46). The assay also measures the antioxidant activity of the sample in a fixed time, and does not take into account the time for the completion of the reaction, which may not be suitable as it overlooks the total antioxidant capacity of the sample (47,48).

26.3.3 Ferric Reducing Ability of Plasma (FRAP)

In the ferric reducing ability of plasma (FRAP), plasma or extract is allowed to react with ferric tripyridyltriazine (Fe-III-TPTZ) complex at low pH. Reduction of ferric iron (Fe III) in the complex to ferrous iron (Fe II) results in an intense blue color. This resulting complex can be measured spectrophotometrically at 593 nm, and the intensity of the blue color developed is directly proportional to the antioxidant capacity (49).

$$Fe^{3+}(TPTZ)_2 + AO \rightarrow Fe^{2+}(TPTZ)_2\ (Blue) + AO \qquad (26.3)$$

The main advantages of the assay lie in its relative simplicity, which enables high throughput, and its cheaper cost (48,49). It is a fast assay, and reproducible results can be obtained from plasma and simple antioxidant solutions with minimal sample preparation. However, the reaction is nonspecific, as any compound with a lower redox potential than the standard redox potential of Fe(III) and Fe(II) (0.77 V) can reduce the complex and contribute to high FRAP values. The reaction also assumes that completion of the reduction is spontaneous. However, many biological antioxidants, especially phytochemicals such as caffeic acid and quercetin, continue to reduce the ferric complex even after the completion of reaction time (48,50). The antioxidant activity of any system depends on the pH of the medium in which it is present. The low pH of the reaction in the FRAP assay significantly inhibits one electron transfer from the antioxidant to the ferric ion, resulting in lower values which may not be accurate at physiologically relevant pH (pH 6.8–7.0) (47,48,50).

26.3.4 Oxygen Radical Absorbance Capacity (ORAC) Assay

The ORAC assay is very similar to the direct measurement ROS assay. In this assay, the time dependent decrease in the fluorescence of a fluorescent indicator is monitored at 37°C. The indicator often used is a protein called β-phycoerythrin (beta-PE) (50,51). 2-2′-azobis (2-amidinopropane)dihydrochloride (AAPH) is used to generate peroxyl radicals; oxidative damage of the beta-PE protein results in a decreased fluorescence, which is prevented by the antioxidant (50,51). The total area under the curve determines the antioxidant capacity of the compound or extract. This is a simple, sensitive, and reproducible method of measuring the antioxidant capacity of the natural extracts, biological fluids, and serum against peroxyl radicals (47,48). The method has also been adopted to measure antioxidant capacity against hydroxyl radicals, and the relative simplicity of the assay has resulted in the development of a microplate assay which can be used for screening large number of samples (50,51). Inconsistencies in the purity of the beta-PE protein, coupled with its interaction with many biological antioxidants, especially polyphenols, are one of the drawbacks of this method (48). Recently, fluorescein salt has been used in place of beta-PE to reduce some of the inconsistencies in the analysis (52) (Figure 26.4). One of the main limitations of this method is that it measures the ORAC capacity in comparison to a synthetic antioxidant, trolox, and the ORAC capacity is expressed as trolox equivalents (48). The assay also suggests comparison of the antioxidant activity to a synthetic antioxidant (trolox) which can give misleading information, because the antioxidant capacity of a biological sample depends on many factors such as structure, type of antioxidants, and the synergistic interaction among the constituent antioxidants (53–55). When copper is used as oxidant, trolox cannot be used, because it would act as a prooxidant in the presence of copper (47,56). In biological samples, especially plasma, interference in the scavenging of peroxyl radicals by protein thiol groups may occur; therefore protein needs to be removed from the extract before the assay (57). Nonspecificity in the reaction, especially in biological materials, is introduced by the presence of oxidizable compounds such as citric acid, which can react with the ROS and thus prevent the oxidative damage of the fluorescein and beta-PE protein, which reacts with oxygen radicals more slowly than most biological antioxidants such as

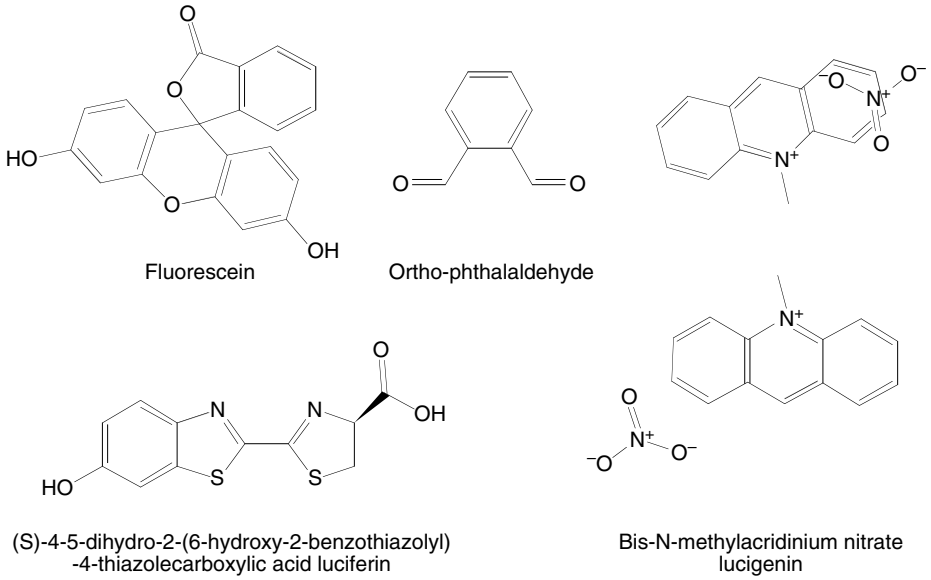

Figure 26.4 Some common fluorescent and chemiluminiscent dyes

thiols, uric acid, and ascorbate (48,52) which can cause a falsely high value for the antioxidant capacity.

26.3.5 β-carotene Oxidation (Bleaching) Assay

The antioxidant protection factor (APF) directly measures the ability of the antioxidant extract to prevent the H_2O_2 catalyzed oxidation of β-carotene. Many antioxidant methodologies based on oxidation of an indicator dye are time consuming, as they depend on the conditions used for the reaction and the oxidizability of the reagent (58–60). However, the β-carotene bleaching assay is a relatively fast method for analysis of antioxidant activity. The reaction is accelerated by carrying out the oxidation at 50°C for 30 min, and free radicals are directly generated using hydrogen peroxide (58,60). Because β-carotene is insoluble in aqueous media, it is introduced into the reaction mixture in the form of an emulsion. Many biological sites of ROS generation and oxidation are at a lipid water interface; therefore, it is believed that an antioxidant that is capable of preventing the bleaching of the β-carotene in the emulsion would be able to act efficiently at the lipid to water interface in biological systems, so the β-carotene bleaching assay will give a measure of the true antioxidant capacity (61,62). This method is sensitive and simple to perform, however, irregularities are introduced in the analysis due to the difficulties in keeping the emulsion particle size constant. The method also suffers for its nonspecificity as it is subject to interference from other naturally occurring oxidizing and reducing agents (60,63).

26.4 LIPID OXIDATION PRODUCTS

In aerobic organisms, reactive oxygen species (ROS) are formed by various endogenous and exogenous processes, such as the mitochondrial electron transport chain, cytochrome P-450 systems, NADPH oxidases, myeloperoxidases and xanthine oxidases, ultraviolet, and ionizing irradiation (11–17,64,65). Excessive formation of ROS, can lead to oxidative stress, which can damage cellular macromolecules including nucleic acids, proteins, and lipids

(11–17,64,65). Biological membranes contain unsaturated fatty acids which are especially prone to oxidation. This oxidation of lipids results in the formation of lipid peroxidation (LPO) products which further propagate free radical reactions. Lipid hydroperoxides (LOOH) are the primary oxidation products (66), and have been shown to oxidize other lipids and cellular proteins (67), and to form cytotoxic and genotoxic compounds (68,69). LPO has been therefore been implicated in the pathogenesis of a number of degenerative diseases, such as cancer (70), atherosclerosis (71–73), and Alzheimer's disease (74,75). It is now believed that primary and secondary lipid oxidation products can serve as good markers for oxidative stress and the functionality of antioxidants (70–75).

26.4.1 Malondialdehyde

Oxidation of lipids in biological systems by reactive oxygen species results in the formation malondialdehyde (MDA) which is a metabolite of lipid hydroperoxides (74–78). MDA is a secondary oxidation product of lipids and serves as a good marker for lipid oxidation and cell membrane injury (78). Recent research has shown that elevated levels of lipid peroxides are associated with cancer, heart disease, stroke, and aging. The MDA concentration in plasma can be determined by its reaction with thiobarbituric acid (TBA) (76). The reaction of TBA with MDA in biological materials can be detected spectrophotometrically at 532–535 nm. This method is simple and easy to perform, but suffers from lack of sensitivity as many compounds, especially the products of the side reactions, also have absorption maxima in the 532–535 nm range (73). Other products of lipid peroxidation, such as hydroperoxides and conjugated aldehydes, can also react with TBA and lower the sensitivity of the method (77). Reducing sugars and aldehydes that have a carbonyl group can also react with TBA to give higher readings (77). MDA in biological samples can also react with proteins and give abnormally low values in an oxidizing system (78). The method has been improved vastly by using diaminonapthalene (DAN) instead of TBA to form a DAN–MDA complex. (78). Unlike TBA, DAN reacts very specifically with MDA; other biological compounds such as sugars, aldehydes, and proteins cannot react with DAN. The DAN-MDA complex can also be easily measured by HPLC and has analytical sensitivity and specificity (78). The HPLC modification of the MDA assay has been extensively used to study lipid peroxidation in *in vivo* studies (78). Other methods of analysis include GC using N-methylhydrazine derivatization (79) and ELISA (80).

26.4.2 LDL Resistance to Oxidation

Lipid hydroperoxides are primary product of free radical oxidation of fatty acids and serve as substrates for the reactions that produce free radicals, which in turn form more lipid hydroperoxides (81). Due to their high reactivity and instability, measurement of LOOH *in vivo* is a very challenging (81). At present, the precise measurement of LOOH in plasma remains a difficult task because of low concentration, instability during extraction, and solvent evaporation, leading to both changes in LOOH composition and production of new hydroperoxides if chain reactions are initiated (82,83). Recent research has shown that peroxidative oxidation of LDL in biological systems is responsible for initiation of plaque formation and enhanced atherogenecity (81). Ability to reduce LDL oxidation by peroxidation is used as an important biomarker for studying the antiatherogenic functionality of antioxidant compounds (82,83). The LDL oxidation is induced by prooxidant metals such as copper, and other free radical generating systems such as 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH) (82,83). The presence and absence of antioxidants, signifying the lag phase before the oxidation of LDL , can be detected by measuring the rate of oxidation and total amount of dienes at 234 nm using the molar extinction coefficient for total lipid

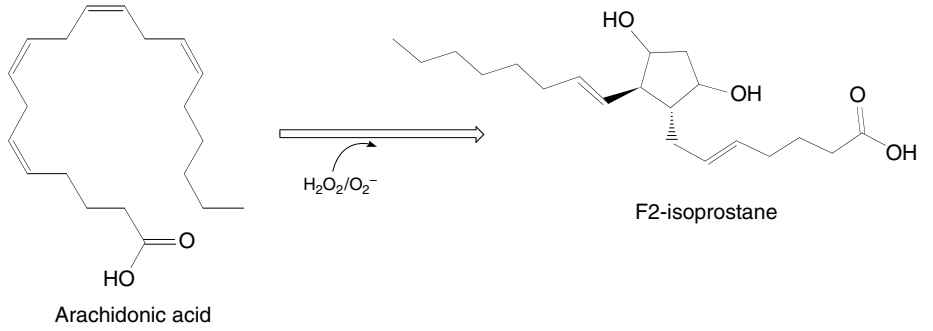

Figure 26.5 Nonenzymatic metabolism of arachidonic acid to F-2 Isoprostanes

hydroperoxides [ε_{234} = 29,500 (mol/L)$^{-1}$ cm^{-1}] (82,83). The total oxidation in the LDL can be measured spectrofluorometrically by extracting the lipid phase and drying it under nitrogen, then resuspending it in chloroform (84–86). This chloroform extract of the lipid phase is subjected to 360 nm excitation and 430 nm emission, and the results are expressed as units of relative fluorescence per milligram of LDL (84–86). The lipid peroxide content can be estimated fluorometrically by the formation of TBARS and expressed as nanomoles of malondialdehyde equivalents per milligram of LDL (84–86).

26.4.3 F2 Isoprostanes

Prostaglandin F2-like compounds (F2-isoprostanes) are formed by nonenzymatic free radical induced peroxidation of arachidonic acid (87) (Figure 26.5). These compounds are formed in phospholipids and then cleaved and released into the circulation before excretion in the urine as free isoprostanes (87). They have been extensively used as novel markers of endogenous lipid peroxidation and potential mediators of oxidant injury (88,89). Elevated levels of F2-isoprostanes have been seen in many diseases including diabetes, myocardial infraction, atherosclerosis, Alzheimer's, and in hepatic toxicity (90–94). Detection and quantification of F2-isoprostanes in biological samples including blood serum and plasma is now used as a tool in assessing oxidative stress status (95). The most common isoprostane formed is 8-isoprostaglandin F_2, which can be detected accurately and easily by using GC/MS or by HPLC/MS (95–97). The longer analysis time required for GC/MS and HPLC/MS has resulted in the development of many immunochemical assays (91,98). However, these immunochemical methods suffer crossreactivity from biological prostaglandins due to their close structural similarity(91).

26.5 DNA OXIDATION PRODUCTS

26.5.1 8-Oxo-7,8-dihydro-2′-deoxyguanosine

Free radicals have been shown to cause damage to lipids, DNA, and proteins. DNA oxidation in biological systems can occur by its interaction with ionic radiation, trace metals, and many carcinogens (11–17,64,65). DNA damage is caused by the oxidation and degeneration of nucleotide bases resulting in the formation of 2-OH-2′deoxyadenosine, 8-Oxo-7,8-dihydro-2′-deoxyguanosine, 5-hydroxymethyl-2′-deoxyuridine (99). However, 8-OHdG , formed from oxidative damage of guanine, is considered a typical marker of DNA damage and repair because guanine is the most fragile nuclear base (99,100). 8-Oxo-7,8-dihydro-2′-deoxyguanosine (8-OHdG), is formed from deoxyguanosine after reaction with a hydroxyl radical or

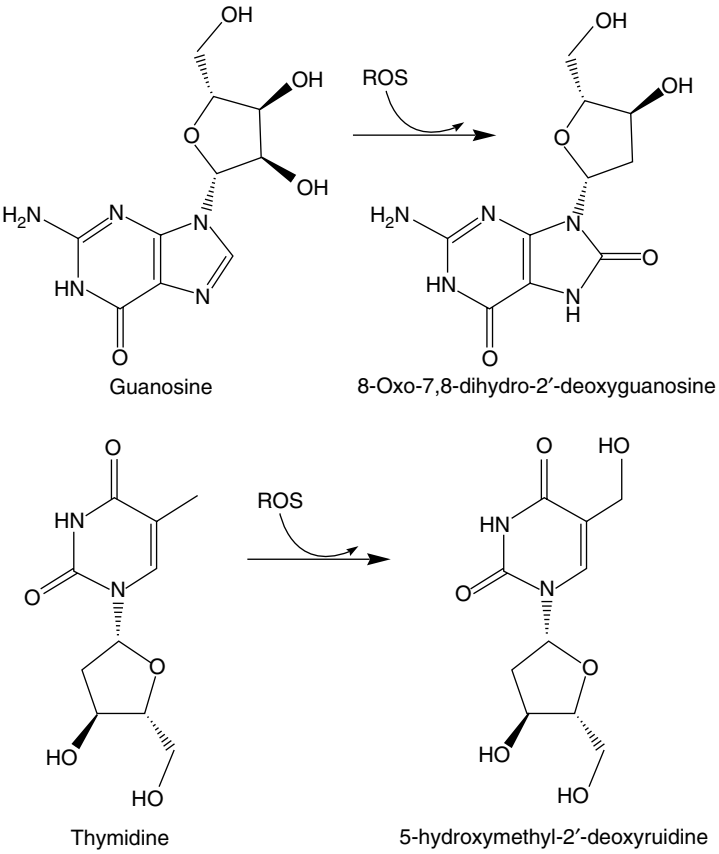

Figure 26.6 DNA oxidation by reactive oxygen species

singlet oxygen (Figure 26.6). 8-OHdG is not metabolized and is quantitatively excreted in urine independent of other metabolic processes, enabling it to be used as a noninvasive marker of oxidative DNA damage by ROS in various physiological and nutritional studies (99,100). Oxidative damage to DNA has now been shown to be responsible for aging, cardiovascular disease, degenerative neurological disease, and various types of cancer (11–17,64,65,99,100). 8-OHdG can be analyzed by many different assays. The most common methodology is high performance liquid chromatography using an electrochemical detector (HPLC-ECD) (99,100). ^{32}P-postlabeling assay using thin layer chromatography (TLC) (101), and gas chromatography (102) are also used in detecting 8-OHdG. Immunodetection using specific antibodies against 8-OHdG. Another possible biomarker, 5-hydroxymethyl-2′-deoxyuridine (HMdU) (103,104), which is a product of thymine oxidation, is gaining popularity because its higher sensitivity, specificity, and stability(105) (Figure 26.6).

26.5.2 Glutathione Reduced (GSH) and Oxidized (GSSG)

Glutathione (GSH, γ-glutamylcysteinylglycine) and its oxidized form (GSSG) (Figure 26. 7) together form the first line of defense against the cellular protection against reactive oxygen species (22,23,106,107). They carry out their protective functions by reducing ROS via their thiol groups, and therefore are involved in a variety of processes in the cellular systems that involve generation of free radicals such as detoxification of xenobiotics, reduction of hydroperoxides, and synthesis of leukotrienes and prostaglandins (106,107). The reducing power

of glutathione is also involved in the maintenance of protein and membrane structure, and regulation of numerous enzyme activities and transcription factors that could be effected by oxidation as a result of reaction with ROS (11,106,107). The thiol groups are capable of participating in a number of chemical reactions including redox transitions, exchange of thiol groups, and radical scavenging (106,107). Recent research has also shown that the redox capability of thiol groups in the GSH/GSSG couple are also involved in gene regulation and intracellular signal transduction by critically regulating the functions of transcription factors and key cellular signaling molecules through oxidation and reduction (106). Because of the many protective functions of glutathione in the body, it is now considered one of the many biomarkers important to an understanding of the oxidative status of the cell (107). Many assays are based on conjugation of GSH with a chromophore or fluorophore, such as *o*-phthaladehyde (OPA) (Figure 26.4). OPA does not fluoresce until it reacts with a thiol group in the presence of a primary amine. The OPA method for the detection of GSH has been limited due to the presence of other fluorogenic thiol and nonthiol components that react with OPA (107,108). Many biological constituents have been shown to quench fluorescence or inhibit the reaction of OPA with GSH, causing the underestimation of GSH levels or the overestimation of GSSG levels (107,108). Recent modifications in the OPA method by using a phosphate buffer at a lower pH, higher concentrations of OPA, and dithionite as the reductant for

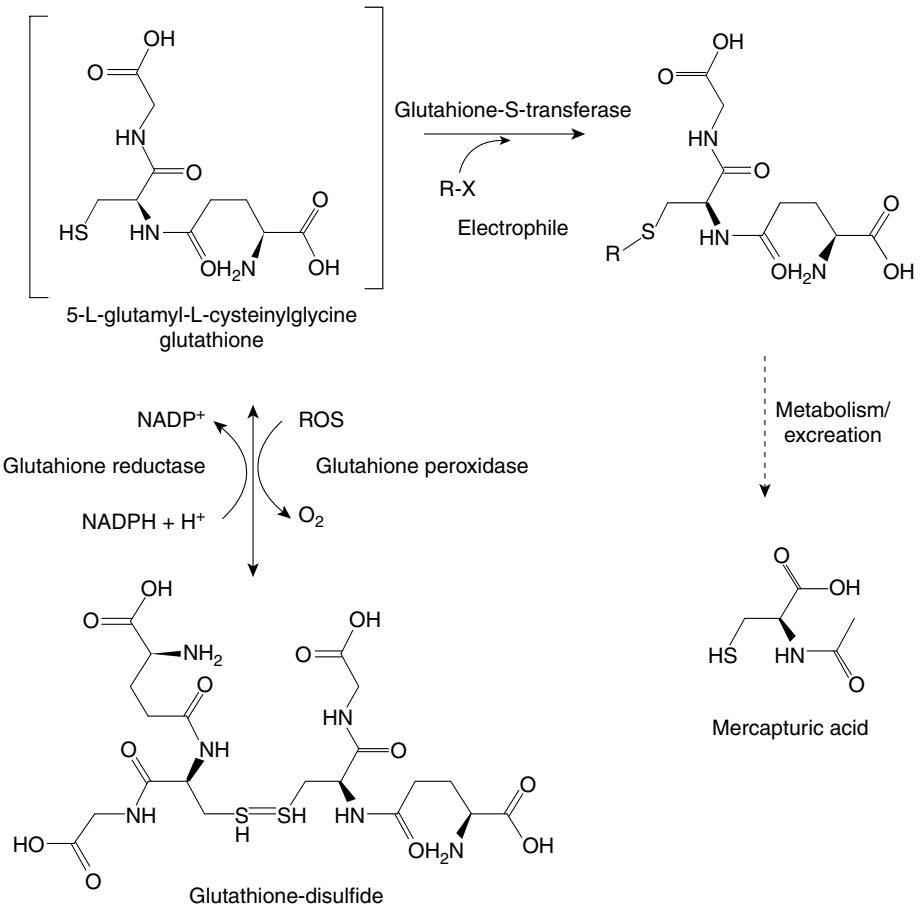

Figure 26.7 Metabolism of glutathione in eukaryotic cell

GSSG have led to rapid analysis, lower cost, and high sensitivity. These revised protocols have been able to estimate GSH and GSSG with accuracy comparable to established HPLC methods (108).

26.5.3 Glutathione Peroxidase

Glutathione peroxidase (GPX)(EC 1.11.1.9) is a selenium containing peroxidase involved in the cellular reduction of hydroperoxides. Two main types of GPX are found in the cells: mitochondrial peroxidase and phospholipid hydroperoxide glutathione peroxidase (22,23). Both types of GPX react directly with fatty acid hydroperoxides and hydrogen peroxide, and reduce them at the expense of glutathione (Figure 26.1, Figure 26.7). Depletion of GPX has now been observed in several forms of cancer, in heart disease, and in hypersensitive pathologies, and therefore is thought to make a good marker for studying the effects of certain types of foods and bioactive compounds on reducing the symptoms of certain types of heart disease, liver disease, and cancer (22,23). The most common assay method for measuring the activity of GPX is by glutathione reductase (GR) coupled assay. The reaction is initiated in the presence of a lipid hydroperoxide or hydrogen peroxide (109,110). The glutathione in the GPX reacts with GSH and oxidizes to GSSG which is reduced by GR back to GSH using $NADPH_2$. The rate of disappearance of $NADPH_2$ is monitored at 340 nm and is used to calculate the enzyme activity (109–111).

26.5.4 Glutathione-S-Transferases

The glutathione-S-transferases (GST) are important phase II detoxification enzymes found mainly in the cytosol, and are involved in the detoxification of drugs and harmful chemicals in the body (112). They are found in very high concentrations in the liver, where they conjugate glutathione to the electrophilic centers of lipophilic compounds and increase their solubility in order to facilitate their excretion (113,114) (Figure 26.7). GST posses a wide range of substrate specificities and can catalyze the reduction of breakdown products of macromolecules formed as a result of oxidative stress including reactive unsaturated carbonyls, oxidized DNA bases, and hydroperoxides, and therefore play a vital role in protecting tissues against oxidative damage and oxidative stress (112–115). As a result of the beneficial functions of GST it serves as an important biomarker for oxidative stress (115). Most of the methods to assay the GST activity involve measuring the conjugation of 1-chloro-2,4-dinitrobenzene (CDNB) with reduced glutathione (114). The conjugation of GSH with CDNB results in an increase in absorbance at 340 nm which is measured spectrophotometrically. The rate of increase is directly proportional to the GST activity in the sample. This assay can also be used to measure GST activity in plasma, cell lysates and tissue homogenates (114).

26.5.5 Superoxide Dismutase

The superoxide radicals are formed by the activity of enzymes like xanthine oxidase and NADPH-oxidase (22,23) (Figure 26.1). They are extremely reactive and have been shown to be able to oxidize biological macromolecules such as DNA, lipids and proteins (11,19,21–23). Superoxide dismutase (SOD) (EC 1.15.1.1) is involved in the dismutation of the superoxide radicals into hydrogen peroxide and molecular oxygen. In humans, there are four forms of SOD: cytosolic Cu, Zn-SOD, mitochondrial Mn-SOD, and extracellular-SOD (EC-SOD) (22,23).

The process of dismutation yields hydrogen peroxide, which is also a reactive oxygen species and causes oxidative damage to cellular systems. Therefore, in the body, activity of SOD is often coupled to another enzyme called “Catalase” (CAT) to remove hydrogen peroxide molecules which are byproducts of the reactions created by SOD (22,23). CAT is

also abundant in the body and is prevents both cell damage and, more importantly, the formation of other, more toxic, free radicals (22,23).

Pathogenesis, mediated by virus and *Helicobacter pylori* (116,117), has been implicated in lowered antioxidant defense and alterations of enzymatic pathways; diabetes mellitus, endothelial, vascular, and neurovascular dysfunction. Neurodegenerative disorders such as Alzheimer's and Parkinson's disease are also now linked to oxidative stress and can be associated with lower responses of enzymes CAT and SOD (118,119). The activity of SOD and CAT is therefore considered as an important biomarker for these diseases (116–119).

The most common SOD detection method is based on spectrophotometric detection. Superoxide, which is a substrate of SOD, is generated by a xanthine to xanthine oxidase, which reacts with either cytochrome C (120) or nitroblue tetrazolium (NBT) (121), and changes color, which can be monitored spectrophotometrically. Detection of O_2^- by the cytochrome C reducing method is based on the color change to generate purple colored dye from reduced cytochrome C. The NBT method is based on the generation of water insoluble blue formazan dye (λmax: 560 nm) by a reaction with O_2^- (120,121). Recent methods developed use chemiluminescence probes such as lucigenin, and luciferin derivative (MCLA) for O_2^- detection (122,123). They react with the superoxide radical and produce a signal which can be used to quantitate SOD activity.

26.5.6 Catalase

Catalase (EC 1.11.1.6) is a ubiquitous oxidoreductase that is present in most aerobic cells. Catalase (CAT) is involved in the detoxification of hydrogen peroxide (H_2O_2), a (ROS), into molecular oxygen and two molecules of water (22,23). CAT can be assayed directly by measuring the rate of appearance of molecular oxygen using a Clark-type electrode (124). Here, the enzyme extract is allowed to react with a known concentration of hydrogen peroxide. The formation of oxygen changes the potential of the Clark-type electrode which is proportional to the enzyme activity (124). Catalase activity has also been determined spectrophotometrically at 240 nm by monitoring the disappearance of hydrogen peroxide at pH 7.0 (125). Catalase also has a peroxidative activity which has been used to assay its activity by reaction with methanol in the presence of an optimal concentration of H_2O_2 (126,127). The formaldehyde produced is measured spectrophotometrically with 4-amino-3-hydrazino-5-mercapto-1,2,4-triazole (Purpald) as the chromogen, in which low molecular weight alcohols can serve as electron donors. Fluorogenic dyes such as amplex red have also been recently used to measure CAT activity. Amplex red reacts with hydrogen peroxide to form a highly fluorescent resorufin which can be measured in a spectrofluoremeter (excitation and emission of 563/587 nm) (126,127).

26.5.7 Xanthine Oxidase and Uric acid

Xanthine oxidoreductase (XOR), a metalloflavoprotein, catalyzes the oxidation of the purine bases hypoxanthine and xanthine to uric acid. XOR is a site for ROS generation in the cell (128) (Figure 26.1). High levels of XOR activity resulting in ROS production has now been shown to play an important role in reperfusion injury; and in congestive heart failure (129). Xanthine oxidase and its reaction product uric acid are therefore now considered to be important biomarkers for oxidative stress and cardiovascular diseases (129,130). Uric acid in urine, serum, and plasma is measured using a spectrophotometric assay based on phosphotungstic acid reagent (131); however, for improved specificity and characterization, HPLC methods have been used recently (132,133). The most popular assay method for xanthine oxidoreductase involves the spectrophotometric measurement of urate production at 292 nm, using xanthine or hypoxanthine as the substrate (134). A spectrofluorometric assay utilizing pterin

as the substrate for XOR, and the formation of fluorescent isoxanthopterin, is quantified for xanthine oxidase activity (135). Chemiluminescence methods are also used alternatively which assess the ROS production by xanthine oxidase which reacts with chemiluminescent dyes such as luminol or lucigenin (Figure 26.4) which are then measured and quantitated as enzyme activity (136).

26.5.8 NADPH Oxidoreductase

NADPH oxidase (NOX) is a membrane bound enzyme present in neutrophils and other phagocytic cells (138). This plasma membrane associated enzyme complex catalyzes the univalent reduction of oxygen using NADPH as an electron donor to produce superoxides, which are involved in the bactericidal activity of the neutrophils (137,138). Though NOX is involved in the generation of ROS for bactericidal activities, recent research has shown that a new family of NADPH oxidases are expressed in various cell types, including the epithelium, smooth muscle cells, and the endothelium (134,135). These enzymes produce superoxide and other ROS, including hydrogen peroxide (Figure 26.1). The activity of this enzyme in vascular cells is a main source of ROS in inflammation and is believed to be a cause for atherosclerosis and hypertension. NOX expression is also found to be high in certain forms of cancer and endocrine disorders as a result of superoxide and other ROS production (137–139). Elevated levels of ROS are also seen in patients with progressive neurological diseases like Alzheimer's, and Parkinson's disease (140). These recent discoveries about the many different functions of the nonphagocytic functions of NOX has made it an attractive target for therapeutic agents and an important biomarker for these diseases in different cell types (139,140). NOX is usually measured in cell free extracts by using them with $NADPH_2$ for superoxide radical generation, which is measured by following the reduction of ferric cytochrome-C at 550 nm (141,142) or by monitoring the inhibition of the formation of formazan blue from NBT at 560 nm (143). Use of a new tetrazolium based assay to study the production of superoxide radicals has also been done, with the NOX and $NADPH_2$ as a source for superoxide radical generation (143). Chemiluminescence assays based on oxidation of a chromophore such as lucigenin are also being used to measure NOX activity (144). In this assay, the chromophore becomes chemiluminescent after reacting with the superoxide radical generated from the NOX reaction. This is then measured and quantitated as NOX activity (145).

26.5.9 Myeloperoxidase

Myeloperoxidase (MPO) is a lysosomal enzyme that is found in white blood cells and neutrophils. In these cells the NADPH oxidase produces superoxide radicals which then dismutates to hydrogen peroxide. Myeloperoxidase uses hydrogen peroxide and chloride to produce another highly reactive ROX called hypochlorous acid (HOCl) (145,146). This potent oxidant then reacts with proteins, DNA, and lipids to cause cellular injury. The primary function of these enzymes is to mediate a defense response against invading pathogens. However, it has been shown recently that, due to the remarkably high oxidant potential of MPOs, they function as mediators of inflammatory pathologies, autoimmune diseases, and rheumatoid arthritis (145,146). The hypochlorous radical and tyrosyl radicals made by MPO have been shown to cause oxidation of LDL leading to atherosclerosis (148) and other cardiovascular diseases (145,146). MPO therefore has evolved into the most promising cardiac marker and a good inflammatory biomarker. The strong oxidant capacity of MPO is often exploited in assaying its activity. MPO is capable of oxidizing many different chromophores such as tyrosine (147) and 3′,5,5′-tetramethylbenzinide (TMB) (148) which are monitored spectrophotometrically or fluorometrically in cell free extracts. Possible interference from other peroxidases and ROS in

the system has led to the development of many enzyme linked immunosorbent assays which are more specific to myeloperoxidases and their isoforms (149–151).

26.6 PLANT PHENOLIC DEPENDENT PEROXIDASES

Phenolic dependent peroxidases catalyze the oxidative coupling of phenolic compounds using hydrogen peroxide to make lignins, phenolic hemicellulose, and phenolic to tyrosine cross links to aid structural development in plant tissues (152,153). These phenolic dependent peroxidases, often referred to as guaiacol, peroxidases have been well characterized in plants and are known to be inducible enzymes, expressed in response to a need for structural growth and development (154,155). Plant peroxidases are induced in response to oxidative stress, exposure to environmental toxins, and high energy radiation (156–160). They protect the plants from these stresses by removing the reactive oxygen species, and by using them to oxidatively couple phenolic phytochemicals to make lignin and other cross-linked phenolics important in plant cell wall protection (154). The oxidative polymerization of phenolics also contributes to the increase in antioxidant activity which is believed to further protect the plant against oxidative stress (54,155). Recently, it has been shown that these peroxidases are also stimulated in response to exogenous phenolic elicitors in germinating fava bean sprouts and that the proxidases contributed to increased antioxidant activity observed during the course of germination (161). It has now been proposed that peroxidases similar to the phenolic dependent guaiacol peroxidase could be stimulated in human cells in response to exogenous phenolics for protection against oxidative stress (162). It is also believed that that these phenolic dependent peroxidases reduce oxidative stress by removing reactive oxygen species by oxidatively polymerizing dietary phenolics without affecting the cellular pools of glutathione, ascorbate, and other antioxidants (162). Stimulation of these peroxidases was recently observed in peroxide stressed porcine muscle models in response to treatment with phenolic extract from oregano (163).

The most common analytical method for assaying the activity of phenolic dependent peroxidases is based on oxidation of a substrate catalyzed by the enzyme in the presence of hydrogen peroxide, which can be followed spectrophotometrically (154,164). The time dependent oxidation of guaiacol to tertraguaiacol ($\varepsilon = 26.6\ mM^{-1}cm^{-1}$) at 470 nm, described by Laloue et al. (165), has been extensively used in characterization of these peroxidases. Other substrates that are used for assaying the activity of peroxidases include *o*-dianisidine, pyrogallol, syringaldazine and 2,2′-azinobis(3-ethylbenzothiazoline-6-sulphonate) (ABTS) (154).

Enzymatic Synthesis of Oligosaccharides: Progress and Recent Trends

V. Maitin and R. A. Rastall

CONTENTS

27.1 OLIGOSACCHARIDES

Carbohydrates play an important role in numerous biological processes. However, until a few decades ago, the chemistry and biology of carbohydrates was a Cinderella field (1), an area with significant activity but lacking the glamor of genomes and proteins. In recent years, concomitant with the rapid establishment of the field of glycobiology based on a range of synthetic and analytical methods, the potential of carbohydrates in the maintenance of health and as therapeutic agents has been realized (2,3). Oligosaccharides consist of two to ten monosaccharide residues linked via glycosidic linkages; these can be liberated by depolymerization (4,5). Oligosaccharides composed of monosaccharides only are termed simple or true oligosaccharides and those linked to nonsaccharides such as peptides and lipids are termed conjugate oligosaccharides.

27.1.1 Biological Importance of Oligosaccharides

According to Varki (6), oligosaccharides either mediate specific recognition events or provide modulation of biological processes. The former activity includes the role of cell surface oligosaccharides and their conjugates as recognition sites for bacteria, viruses, toxins, antibodies, and hormones. The latter activity refers to their functions in cell recognition, cell growth, cell differentiation, cell adhesion, signal transduction, development, regulation, and other intercellular communications. Several workers seem to agree that the major function of oligosaccharides is in molecular recognition (2,3,7). The involvement of oligosaccharides in a wide range of specific recognition mechanisms results from their incredible structural diversity. This diversity arises from the fact that they can be highly branched, and the monomeric units may be connected to one another by many different linkage types.

27.1.2 Oligosaccharides as Drugs and Functional Foods

It has been established that many pathogens use carbohydrate binding proteins, or lectins, to attach to cells and initiate disease (8,9). Specific membrane bound oligosaccharides serve as receptors for the attachment of the pathogen onto the cell. One of the natural defense mechanisms of the body against infection involves decoy oligosaccharides present in the mucosal lining of epithelial cells and in saliva, tears, urine, sweat, and breast milk. This is especially significant in breast milk, where the presence of many oligosaccharides at high concentration (up to millimolar levels) protects infants from many infections (9,10). An invading pathogen binds to these decoy oligosaccharides instead of the host cell and the host is thus protected from infection. This is the basic concept behind use of oligosaccharides as antiinfective agents. Because these oligosaccharides prevent the adhesion of the pathogen to the host cell, the term antiadhesives is used to describe this class of carbohydrate drugs. They also have a possible antiinflammatory application against tumors or virally infected cells. Many pharmaceutical companies are now involved in research and development of carbohydrate drugs (2,11).

Two types of antiinfectives are under investigation: receptor oligosaccharides, for use against respiratory and gastrointestinal disease; and sialic acid analogues for use against influenza (10) and cholera. It is important that the antiadhesives used are safe, nontoxic, and nonimmunogenic. Short chain oligosaccharides, for example, human oligosaccharides about 1kDa in size are promising antiadhesive agents. This is because of their high water solubility, and resistance to heat and pH, making their delivery and administration more effective. Another important factor in their efficacy is the strength of binding to the bacterial lectins. For this reason, polyvalent oligosaccharides have been found to be much more effective than monovalent ones because they form a stable structure by binding

to more than one adhesin (9). Several glycomimetics, such as glycodendrimers (12) and mixed type glycoclusters (13) have emerged as valuable tools in this regard. The concept of antiinfective therapy is an exciting one, considering its potential commercial impact and wide application. However, at present, it is in its developmental stages. There are practical limitations to its widespread use because of factors such as the lack of animal models for clinical trials, availability of appropriate oligosaccharides, and limited knowledge of the host surface glycoconjugates (9,10).

Apart from their role in recognition, there has been recent interest in the use of oligosaccharides as functional food ingredients to promote growth of probiotic or beneficial bacteria in the human gut (14). Oligosaccharides provide a combination of suitable physicochemical and physiological properties, which make them very good candidates for use as food ingredients. The 1991 legislation for Foods for Specified Health Use (FOSHU) of the Japanese government comprised 223 items, of which more than half incorporate oligosaccharides as the functional components (15). Food grade oligosaccharides are manufactured using simple methods, and avoiding expensive purification steps, in order to keep the prices competitive. As a result, they are generally impure products containing residual feedstock carbohydrate and monomer sugars (11). Pharmaceutical applications in most cases require pure compounds of a defined chemical structure, and synthesis of these oligosaccharides is complex and expensive.

The biological importance of oligosaccharides coupled with their potential as prophylactic agents and functional food ingredients has generated considerable research interest in this area about various aspects of their structure, function, and uses. The limiting factors in this research and application of the results are the limited quantity and range of available oligosaccharides, and their very high prices. It is therefore important to develop oligosaccharide synthesis methods that are efficient, cost effective, and easy to scale up, in order to increase the repertoire of oligosaccharides available.

There are two methods of oligosaccharide synthesis: chemical and enzymatic.

27.2 CHEMICAL SYNTHESIS

Traditionally, oligosaccharides are synthesized by chemical methods. Though well developed, chemical methods of synthesis are complicated and involve a number of steps. Because carbohydrates have several hydroxyl groups of similar reactivity, there are numerous protection and deprotection steps required in order to achieve regioselectivity (16). In spite of this, a mixture of isomeric oligosaccharides is often produced. Moreover, the number of steps increases with the size of the oligosaccharide (up to 7 steps needed for disaccharide synthesis and more than ten for a trisaccharide), making the synthesis of even simple oligosaccharides a lengthy process. The method needs expensive chemicals, yields are low, and scale up is difficult. For an overview of chemical oligosaccharide synthesis, the reader is referred to exhaustive reviews by Boons (17) and Davis (18). Several oligosaccharides of biological importance have been synthesized using chemical methods, including oligosaccharides corresponding to the capsular polysaccharide of *Cryptococcus neoformans* and outer cell wall of *Moraxella catarrhalis* (19), a high mannose nonasaccharide corresponding to part of the glycoprotein gp120 of the viral coat of HIV-1(20), myoinositol containing compounds (21), glycopeptide containing tumor associated carbohydrate antigens (22), α-1,2-linked disaccharide derivatives, (23) and recently, mixed type glycocluster oligosaccharide mimetics containing sugar derivatives from different sugar series (galactoside, mannoside and fucoside) (13) with potential as antiadhesives. Chemical methods have also been reported for synthesis of sugar nucleotides needed for enzymatic

synthesis reactions using Leloir-transferases (24). New strategies to improve the chemical synthesis process are being developed and are summarized by Bartolozzi and Seeberger (25). A significant achievement has been that of programmable one pot synthesis. Based on difference in reactivity between glycosyl donors, a database, search engine, and computer program called Optimer was developed (26). The program enables the user to select from a list of the best reagent combinations for the synthesis of an oligosaccharide of interest, along with predicted yields (27). The program has been successfully employed for controlled synthesis of both linear and branched trisaccharides and tetrasaccharides, allowing the possibility of creating a library of oligosaccharides. To facilitate the synthesis of some linkages, which are difficult to synthesize by chemical methods, chemists are now using chemoenzymatic synthesis, wherein an enzyme is used to synthesize part of the oligosaccharide structure, in combination with chemical methods. One such example is the synthesis of β-mannosyl linkage of *N*-glycans; Watt et al. (28) used β -mannosyltransferase for the synthesis of the core of *N*-linked oligosaccharides.

In spite of these advancements, the area of chemical synthesis remains a challenge because of its technical complexity and absence of general procedures applicable to synthesis of a range of oligosaccharides, which makes their adaptation to industrial scale next to impossible. Their application is currently limited to synthesis of some bioactive oligosaccharides for research purposes; large scale manufacture for food and drug use remains impractical.

27.2.1 Enzymatic Synthesis

Because most of the complex heterooligosaccharides in nature are produced by enzymes, it was thought that it must be possible to use the synthetic potential of enzymes *in vitro* to bring about oligosaccharide manufacture (29). In recent years, enzymatic synthesis of oligosaccharides has become the method of choice for most researchers. It helps to overcome two major problems posed by chemical synthesis: selective protection and deprotection is not necessary, and the configuration of the newly formed anomeric centres can be controlled well. As a result, a mixture of isomers is not obtained. Other advantages include lack of byproducts, wider range of reaction conditions and regiospecificity and stereospecificity of the enzymes. Thus enzymes can be used to synthesize oligosaccharides by single step reactions and to synthesize novel oligosaccharides. Production of the enzymes by fermentation and immobilization to enable reuse can reduce the cost of the enzymes, making the process very economical.

Two main types of enzymes are used to catalyze oligosaccharide synthesis: glycosyltransferases (biosynthetic) and glycosidases (hydrolytic).

27.2.2 Glycosyltransferases

Glycosyltransferases are type II membrane bound glycoproteins consisting of a short N-terminal cytoplasmic domain, a transmembrane domain that anchors it to the cell membrane, and the C-terminal catalytic domain (30). They are currently classified into 60 families according to the sequence based classification of Coutinho and Henrissat (31). Glycosyltransferases catalyze the stereospecific and regiospecific transfer of a monosaccharide from a donor substrate (glycosyl nucleotide) to an acceptor substrate. They are classified according to the sugar transferred from the donor to the acceptor and by the acceptor specificity. For example, β 1, 4-galactosyltransferase (GalT) from bovine milk catalyzes the transfer of a galactose (Gal) unit from UDP-Gal to the 4-OH group of terminal N-acetylglucosamine (GlcNAc) β -R acceptors generating Gal β 1-4GlcNAc β -R (N-acetyllactosamine-R) structures. A completely different enzyme, β 1,3-GalT is required for synthesis of isomeric Gal β 1-3 GlcNAc β -R structures from the same substrates (32). The regiospecificity and stereospecificity, the high selectivity for the acceptor

substrate, and the high yields that can be achieved are attractive features of these catalysts (16). The reaction can be represented by the following general equation:

$$\text{Nucleotide sugar} + \text{R-OH} \rightarrow \text{R-O-sugar} + \text{nucleotide} \qquad (27.1)$$

where R is a free saccharide or a saccharide linked to a protein or lipid.

In vivo, the synthesis occurs via three fundamental steps: activation, transfer, and modification (33). In the first stage of the sequence, a monosaccharide is transformed into a sugar-1-phosphate (sugar-1-P) by a kinase enzyme. This then reacts with a nucleoside triphosphate (NTP) in a reaction catalyzed by nucleoside transferase, and forms a chemically activated nucleoside diphosphate sugar (NDP-sugar). The sugar unit is then transferred to a sugar acceptor by glycosyltransferases Each one is specific for a certain donor and acceptor and for the linkage position of the new glycosidic bond (29). Owing to this high specificity, they have been used in synthesis of oligosaccharides *in vitro*. However, such high specificity also means that a wide range of glycosyltransferases is required to enable the synthesis of a variety of desired oligosaccharides *in vitro*. At the moment, not many glycosyltransferases are commercially available [nine, as reported by Bastida et al. (34), of which only β-1,4-galactosyltransferase is available in amounts higher than 1 unit]. They are difficult to isolate and purify from their natural sources because they are usually membrane bound and present in low concentrations. Several glycosyltransferase genes, including those coding for glucosyltransferase (35,36), sialyltransferase (37,38), fucosyltransferase (34,39), mannosyltransferase (40,41), and galactosyltransferase (42–45) have been cloned, but many more need to be cloned and probably modified to make the enzymes more widely available and overcome problems of instability. In practice, the range of routinely used glycosyltransferases at the moment is mainly limited to β-1,4-galactosyltransferase, α-2,3-and α-2,6-sialyltransferases and α-1,3/4-fucosyltransferases (46,47).

Besides the availability of the actual enzyme, the availability of the sugar nucleotide donors was also a problem until recently, as they were very expensive and unstable. Eight sugar nucleotides: UDP-Glc, UDP-Gal, GDP-Fuc, CMP-NeuAc, UDP-glucuronic acid, GDP-Man, UDP-GlcNAc, and UDP-GalNAc act as donor substrates for most mammalian glycosyltransferases. With the exception of UDP-glucuronic acid, they are now commercially available, though still expensive. Because the initial report for regeneration of UDP-Glc and UDP-Gal by Wong et al. (48), numerous regeneration methods have been developed for all of these sugar nucleotides, which not only reduce their cost but also overcome the problem of product inhibition resulting from the released nucleoside monophosphates or diphosphates in the reaction (Figure 27.1). Representative papers include regeneration of UDP-Glu, UDP-Gal, CMP- NeuAc (49), and UDP-Gal, UDP-2-deoxyGal, UDP-Galactosamine (50) using multienzyme systems, regeneration of GDP-Man (40), and a simplified pathway for regeneration of UDP-Gal (51). Gram scale synthesis has been reported for UDP-Gal (52), and yields up to multikilogram levels have been achieved for some oligosaccharides such as SLe^x (32).

It must be realized, however, that the enzymes that are involved in these pathways are not recovered and recycled, which is essential for the process to be feasible at industrial scales. The obvious biotechnological solution was enzyme immobilization (53,54). Nishiguchi et al. (55) carried out the synthesis of a trisaccharide derivative Neu-5Acα(2→6) Galβ(1→4)GlcNAcβ-O-$(CH_2)_6$-NH_2 using recombinant β1,4-galactosyltransferase and α2,6-sialyltransferase immobilized by coupling reactions with activated Sepharose. The oligosaccharide was built up by glycosylation on a water soluble primer having GlcNAc residues and an α–chymotrypsin sensitive linker, for the release of final product by α-chymotrypsin treatment.

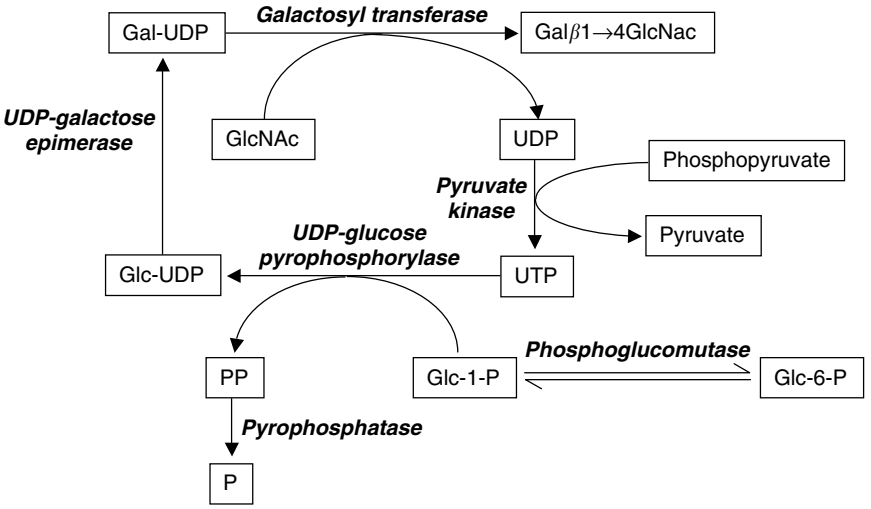

Figure 27.1 Multienzyme synthesis of *N*-acetyllactosamine using galactosyltransferase with cofactor regeneration

Several workers have also investigated the feasibility of using whole cells of recombinant bacteria as catalysts, as this approach obviates the need for enzyme isolation and in many cases tedious purification. Herrmann et al. (56) were able to synthesize disaccharides Manα1, 2Man, Manα1, 2ManOMe, and two dimannosylated glycopeptides using whole recombinant *E. coli* cells expressing cloned α-1,2-mannosyltransferase reported earlier (40). The group of Ozaki has produced a series of papers reporting the use of coupled recombinant or metabolically engineered bacterial strains: *Corynebacterium ammoniagenes* for NTP (re)generation, recombinant *E. coli* with NDP-sugar generation and regeneration cycle expression and recombinant *E. coli* with glycosyltransferase (57) : for large scale production of globotriose (188 g/L) (58), N-acetyllactosamine (107 g/L) (59), 3'-sialyllactose (33 g/L), (60) and sialyl-T_n epitope (45 g/L) (61). Chen et al. (62) have developed a superbug, an engineered *E. coli* strain containing a plasmid harboring an artificial gene cluster containing all the necessary genes for sugar nucleotide generation and regeneration as well as oligosaccharide accumulation for the synthesis of an α-Gal epitope. Another engineered *E. coli* strain ($lacZ^-$) has been used by Priem et al. (63) for the production of human milk oligosaccharides by efficient conversion from lactose. The $lacZ^-$ mutant accumulated lactose when grown on glycerol. The accumulated lactose acted as an acceptor for the heterologous β1,3-N-acetylglucosaminyltransferase enzyme expressed from a *Neisseria meningitidis* gene. The resultant trisaccharide acted as acceptor for the coexpressed *N. meningitidis* β1,4-galactosyltransferase enzyme. This system produced lacto-N-neotetraose and lacto-N-neohexaose at over 5 g/L yield. Similarly, a $nanA^-$ *E. coli* was able to produce sialyllactose.

Another particularly elegant regeneration methodology is sugar nucleotide regeneration beads or superbeads (57,64,65). The superbeads technology involves overexpression of individual enzymes along the sugar nucleotide biosynthetic pathway in a His_6-tagged form followed by their coimmobilization onto nickel nitrilotriacetate agarose beads. The beads can be employed for synthesis of specific oligosaccharide sequences by combination with a variety of glycosyltransferases. UDP-Gal regenerating superbeads were developed as a model system and in combination with β1,4-GalT and/or α 1,3/1,4-GalT, 100 mg-1.03 g scale synthesis of biologically important oligosaccharides was achieved (66). The first

generation superbeads required four enzymes and the reactions were performed in stirred batch mode whereas the second generation superbeads (65) involve seven enzymes and the reactions performed by circulation of the reaction mixture through the superbeads in a packed bed column reactor configuration, proving to be more efficient.

The aforementioned advancements over the last decade have transformed the status of Leloir glycosyltransferases in oligosaccharide synthesis by alleviating the problems associated with them earlier: of low availability of enzymes and sugar nucleotide donors, product inhibition, and high reagent costs. These developments, together with their inherent regioselectivity and stereoselectivity should significantly increase their applicability.

27.2.3 Glycosidases

As the name suggests, the natural function of glycosidases is hydrolytic cleavage of glycosidic bonds. Glycosidases occur widely in nature; in viruses, microorganisms, and plant and animal cells (16), and consequently are more available than glycosyltransferases. They are also more stable, act on easily available substrates, and do not need cofactors.

Their main drawback is that if nonlinkage specific enzymes are used, the regioselectivity tends to be low, which results in the formation of a product which is a mixture of several different linkages (usually 1→6, 1→4, 1→3 and 1→2), posing problems of purification. Linkage specific glycosidases, however, generally produce products with very high regioselectivity. In spite of this, keeping in mind their availability, relative economy of use and simplicity of the reaction, glycosidases have become established as a popular choice for oligosaccharide synthesis. While the high specificity of glycosyltransferases can allow precise sequential construction of desired oligosaccharides, the wide acceptor specificity of glycosidases makes them useful for synthesis of novel oligosaccharides of unknown and potentially exploitable biological activities.

Glycosidases can be divided into two groups: the exoglycosidases, which cleave glycosidic bonds at the nonreducing end of the oligosaccharide, and the endoglycosidases, which cleave internal glycosidic bonds (33). In most instances, synthesis has been carried out using retaining exoglycosidases. According to Coutinho and Henrissat (31), glycosidases are currently classified into 90 families based on sequence similarities. Based on mechanism (67–71), they are classified as retaining or inverting glycosidases depending on whether the hydrolysis proceeds by net retention or inversion of the stereochemistry of the anomeric center. In either case, the reaction is acid base catalyzed through an oxocarbenium ionlike transition state, and involves two carboxylic groups at the active site. Inverting glycosidases operate via direct displacement of the leaving group by water. The two carboxylic groups are suitably positioned at the active site such that one provides base catalytic assistance to the attack of water, while the other provides acid catalytic assistance to cleavage of the glycosidic bond. Retaining glycosidases use a double displacement mechanism involving the formation of a covalent glycosyl enzyme intermediate. Unlike the inverting enzymes, where one residue functions as a general acid and the other as the general base, in retaining enzymes one residue serves both functions, acting as acid catalyst for the glycosylation step and base catalyst for the deglycosylation step. The second carboxylic group acts as a nucleophile and a leaving group. A significant difference between the two enzyme classes is the separation between the carboxylic acid side chains, which is approximately 11 Å in inverting enzymes and 5.5 Å in retaining enzymes.

Detailed studies have been carried out on the mechanism of retaining glycosidases using several strategies, details of which can be found in reviews by Withers (68,71). These include intermediate trapping by (1) modification of the substrate through fluorination of its 2-hydroxyl or 5-hydroxyl group by fluorosugar reagents which has led to the identification of the catalytic nucleophiles of several families of retaining glycosidases; and (2)

mutation of the enzymes to decrease the turnover of the intermediates and enable determination of their three dimensional structure by crystallographic analysis. Crystallographic studies have also been performed on the enzyme itself (72) at various stages of reaction, providing snapshots of the free enzyme, enzyme substrate complex, covalent intermediate, and product complex.

The mechanism of efficient acid base catalysis by a single residue in retaining glycosidases was investigated using *Bacillus circulans* xylanase as a model. This was achieved by measuring the pK_a values of the two relevant carboxylic acid residues in the active site by ^{13}C NMR (73). While the pK_a of the catalytic residue (Glu172) was 6.7 in the first step, it dropped to 4.2 in the intermediate, allowing it to act as the base catalyst in the second step. Mutagenesis studies attribute the higher pK_a of 6.7 to the negative charge on the other residue Glu 78; in the absence of this charge, the pK_a drops to the lower value of 4.2. During the reaction, this shift in pK_a occurs when the charge on the catalytic nucleophile is removed upon ester formation. The carboxylic acid residue in question is thus able to operate as an acid or base catalyst depending on the charge on the second residue. This has been suggested as a general mechanism for retaining glycosidases.

There are two well established approaches for oligosaccharide synthesis using glycosidases: equilibrium controlled synthesis and kinetically controlled synthesis.

27.3 EQUILIBRIUM CONTROLLED SYNTHESIS

The equilibrium approach is based on the reversal of the catabolic role of enzymes in a thermodynamically controlled reaction (74). It involves a simple reversion of the glycoside hydrolysis reaction by combining a free monosaccharide and nucleophile by direct coupling (condensation). This is also referred to as direct glycosylation or reverse hydrolysis. The equilibrium constant of the reaction favors hydrolysis over glycoside formation and the yields therefore are usually low. In order to shift the reaction equilibrium toward product formation, various approaches have been used (33,46,74,75). The most common way is to use high concentrations of the products of the forward reaction (e.g., monosaccharides) and reduced concentrations of the reactants. This is achieved by incubating the enzyme in a highly concentrated solution of monosaccharide, of the order of 70–80% (w/w), that is, in conditions of lowered water activity (74). Second, to accelerate the otherwise low reaction rate, higher reaction temperatures of 50–60°C are used (74). Increased yields result from controlled and selective removal of the product oligosaccharides from the reaction mixture over the course of the reaction using molecular traps such as activated carbon (76,77). This makes reaction yields comparable to those achieved through transglycosylation. The greatest advantage of this method is the simplicity of the reaction procedure. Both homooligosaccharides and heterooligosaccharides can be synthesized using the equilibrium approach.

Mannooligosaccharides, both homo- and hetero-, have been obtained in good yields by reversal of the α-mannosidase reaction. There is interest in their synthesis because not only are they present in the high mannose type sugar chains of glycoproteins, but they have potential as antiadhesives. Different linkage isomers show varying degrees of inhibition at varying concentrations (78–80).The exceptionally high solubility of mannose in water has enabled synthesis to be carried out in mannose concentrations up to 85% (w/w) and maximum total yields of up to 70% mannooligosaccharide have been achieved using α-mannosidase from Jack bean (75,81). The same enzyme has been used to synthesize heteromannooligosaccharides by cocondensation with a range of acceptor sugars, in addition to homooligosaccharides (82,83). In general, the yields were higher at 70% total sugar

concentration than at 50%, except in the case of lactulose, where the yield at 50% was more than double than at 70% total sugar. Higher yields were obtained for heteromannooligosaccharides using reverse hydrolysis compared to kinetic syntheses. A range of linkages, α(1→1), α(1→2), α(1→3), α(1→4), and α(1→6), were obtained and the product spectrum showed a predominance of lower oligosaccharides, mainly disaccharides, trisaccharides, and tetrasaccharides in the case of homooligosaccharides. Partially purified α-mannosidases from almond meal and limpets were employed by Singh et al. (84) for synthesis of α(1→2) and α(1→3) linked mannose disaccharides in ratios of 65:35 and 57:43 respectively. Fungal α-mannosidase from *Aspergillus niger* (85) produced α(1→2), α(1→3) and α(1→6) linked disaccharides and trisaccharides, but no α(1→1) or α(1→4) linkages were detected. The yield of individual regioisomers in equilibrium synthesis is correlated with the standard free energy. In the synthesis of oligosaccharides using α-glucosidase, the standard free energy of the α(1→6) disaccharide was the lowest, followed by α(1→2), α(1→3), α(1→4), and α(1→1). The standard free energy was in inverse correlation to the oligosaccharide yields (76). Regioselective synthesis of α(1→2) mannobiose and mannotriose was achieved (86) using specific 1,2-α-mannosidase from *Aspergillus phoenicis*. A novel α-1,6- mannosidase isolated from the same organism (87) resulted in synthesis of α(1→6)-linked mannobiose and mannotriose with absolute regioselectivity.

Other fungal enzymes used in synthesis by this approach include glucoamylase from *Aspergillus niger* (88) and *β*-glucanase from *Penicillium emersonii* (89). While homooligosaccharides were obtained in moderate yields (14–16%), the yields of heterooligosaccharides were rather low compared to the mannosidase enzymes. Using purified *A. niger* glucoamylase (90), a thorough investigation was carried out of its ability to form condensation products from aqueous mixtures of individual carbohydrates (arabinose, fructose, galactose, myoinositol, lyxose, mannose, ribose, and xylose) or their mixtures with glucose. Heterodisaccharides were produced with each of the eight sugars in combination with glucose. Interestingly, the enzyme was able to condense not only glucose but also galactose and mannose individually into disaccharides.

Cellulases (cellobiohydrolase I and endoglucanase I) from recombinant *Trichoderma reesei* (91), α-amylase from *Bacillus licheniformis* (92) and α-glucosidase from *Bacillus stearothermophilus* (93) provide some instances of use of bacterial glycosidases in reverse hydrolysis. Cello bio hydrolase (CBH) I gave yields in the order of 40% in the best case experimental conditions. Homooligosaccharides and heterooligosaccharides from DP 1-10 were obtained using α-amylase; however the products in this case as well in the case of CBH I were not characterized. The *B. stearothermophilus* α-glucosidase was able to produce isomaltose (51%), nigerose (25%), maltose (14%), and kojibiose (10%) in 50% glucose solution, and heterooligosaccharides were obtained both with mannose and xylose, with quantity being dependent on glucose:saccharide acceptor ratios.

Recently (94), a range of glycosidases were screened for their ability to synthesize thioglucosides, which in the context of glycobiology are useful as specific enzyme inhibitors and as glycosyl donors in oligosaccharide synthesis. Of the enzymes tested, *β*-glucosidase from almonds showed the highest activity in the reverse hydrolysis reaction and high yields of 1-propanethioglucoside were obtained (68% and 41%), based on 1-propanethiol and glucose respectively.

27.3.1 Kinetically Controlled Synthesis

This approach, also known as transglycosylation, employs an activated glycoside donor to form an active intermediate in high concentrations. This intermediate is then trapped by a second nucleophile (other than water) to yield a new glycoside (Figure 27.2) (33,46). The donor glycosides include oligosaccharides, substituted aryl glycosides and glycosyl fluorides.

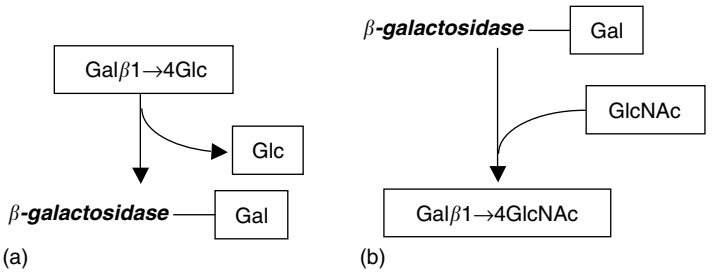

Figure 27.2 Synthesis of *N*-acetyllactosamine using β-galactosidase from *Bacillus circulans* (a) Activation to form a galactosyl-enzyme complex (b) Galactosyl transfer to *N*-acetyl glucosamine acting as an acceptor in competition with water

The reaction is efficiently controlled kinetically as the product is a potential substrate of the glycosidase enzyme (95). As a result, higher product yields using lower enzyme concentration can be obtained. However, the donor glycoside is used up during the reaction in greater than stoichiometric quantities and cannot be reused. This drives up the cost of synthesis.

Table 27.1 summarizes some recent glycosides synthesized using the kinetic approach.

27.4 INFLUENCE OF REACTION COMPONENTS AND CONDITIONS ON YIELD AND SELECTIVITY

27.4.1 Donor:Acceptor Sugar Ratio

In equilibrium controlled heterooligosaccharide synthesis, the proportions can be regulated by the ratio of the individual substrates in the reaction mixture. Usually, heterooligosaccharides are obtained exclusively at higher ratios of the saccharide acceptor to donor, but yields are invariably lower. Using glucoamylase from *A. niger*, heterooligosaccharides were produced exclusively at a fucose:glucose ratio of 85:15, with a yield of 1.6%; highest yield of 3% was at 65:35 ratio but comprised only 42% heterooligosaccharides (88). The same trend was observed in the case of α-glucosidase from *B. stearothermophilus* (93); at a xylose:glucose ratio of 90:10, heterodisaccharides were the major products, but their final concentration was less than half (22mM) of that obtained at a ratio of 50:50 (53mM).

In kinetic synthesis, the donor and acceptor determine the structure of the glycoside synthesized. Although the same glycoside can be synthesized with several different donor and acceptor combinations, the yields vary depending on their nature. For instance (Table 27.1), while α-L-Fuc-(1→3)-α-GlcNAc-OAll and α-L-Fuc-(1→3)-β-GlcNAc-OAll could be synthesized in 34% and 25% yields respectively using α-L-Fuc-O-NP as donor and α/β -GlcNAc-OAll as acceptors, the yield was only 8% for the former when α-L-Fuc-F was the donor instead, and the second glycoside could not be isolated (96). The low yield was attributed to the increased hydrolysis rate of the fluoride donor.

The donor:acceptor ratios need to be optimized for best yields. Equimolar ratios gave higher yields compared to ratios of 1:0.5 and 1:0.2, in a study of galactooligosacharide synthesis using β-galactosidases from three different sources (97); presumably due to higher transglycosylation rates and reduced secondary hydrolysis at 1:1 ratios. The nature of the glycosyl acceptor also influences the regiospecificity of the transfer. For instance, addition of α-Gal-O-p-NO_2Ph to α-Gal-O-Me gives predominantly 1→6 linked product, while the same addition to β-Gal-O-Me gives predominantly the 1→3 linked product (33).

Table 27.1
Synthesis of oligosaccharides using the kinetic approach

Enzyme	Source	Glycosyl Donor	Glycosyl Acceptor	Main Glycoside Product	Yield (%)	Ref.
N-acetylhexosaminidase	*A. oryzae*	p-NP- β-GlcNAc	GalNAc	β-GlcNAc-(1→6)-GalNAc	26	151
		p-NP- β-GalNAc	GalNAc	β-GalNAc-(1→6)-GalNAc	38	151
β -galactosidase	*B. circulans*	p-NP- β-Gal	β-GlcNAc-(1→6)-GalNAc	β-Gal-(1→4)- β-Gal(1→4)-β-GlcNAc-(1→6)-GalNAc	48	151

				α-L-Fuc-(1→3)-Glc (2+7)	34	

27.4.2 Temperature

The equilibrium synthesis reactions are typically carried out at temperatures of 50–60°C and kinetic synthesis reactions at 37°C, although temperatures ranging from room temperature to 45°C have been employed, depending on the enzyme source and thermal stability. The high substrate concentrations used in reverse hydrolysis exert a protective effect on the enzyme, thus allowing use of higher temperatures.

Statistical analysis was performed for effect of temperature (20, 30, 40, and 50°C) on lactose conversion by β-galactosidase from *B. circulans* with the aim of developing a kinetic model which could aid reactor design for the process (98). Reaction rate as well as yield increased at higher temperatures.

A recent study employing dextransucrase has reported surprising results where not only yield but also selectivity improved considerably with decreasing reaction temperature, best results being obtained in reactions in the frozen state (99). The yield of leucrose (0.1M sucrose as substrate) increased from 10% at 25°C to 65% at −4°C. Similarly, in reactions containing sucrose with isomaltulose as acceptor, overall yields (trisaccharide, tetrasaccharide, and pentasaccharide) at −4 to −10°C were 80–86%, double the yield of reactions in the 5–25°C range.

Temperature has been reported to have a bearing on the selectivity of β-glycosidases for donors differing in their glycon parts, as observed from an investigation with β-glucosidases and galactosidases from almond, a mesophilic (*K. fragilis*), and three thermophilic organisms (*C. saccharolyticum, S. solfataricus, P. furiosus*) (100). Selectivity, calculated as the specificity constant (V_{max}/K_m) or V_{max} ratio of glucoside to galactoside donor (p-NP or phenyl-β-glucoside/galactoside), decreased with increasing temperature in case of almond, *K. fragilis* and *C. saccharolyticum,* and remained constant for the other two thermophilic enzymes.

Klepsiella fragilis β-galactosidase became a β-glucosidase when the temperature was raised from 25 to 50°C.

The range of temperatures employed in enzymatic oligosaccharide synthesis combined with the high sugar concentrations has been reported in some instances (101,102) to limit optimum oligosaccharide yields owing to glycation induced enzyme inactivation. We have provided possible evidence for this (103) during synthesis of mannooligosaccharides by reverse hydrolysis. Inhibitors of the Maillard reaction were partially able to alleviate these effects resulting in reduced loss of enzyme activity and increased oligosaccharide yield.

27.4.3 Enzyme Origin

Regioselectivity can vary with different enzymes, and careful selection of the enzyme can effect the formation of desired linkage. A major objective of researchers in this field is to build up a library of glycosidases capable of selectively catalysing the formation of any desired glycosidic bond (47).

Same donors and acceptors lead to a range of glycosides varying in linkage as well as yield (Table 27.1), when β-galactosidases from two different sources were used (porcine liver and *Bacillus circulans*). Only (1→6) linked products were obtained with the former, while the bacterial enzyme gave rise to (1→3) linkages as well (104). β-glucosidases and galactosidases from almond, *K. fragilis*, *C. saccharolyticum, S. solfataricus,* and *P. furiosus* differed in their substrate specificity and donor selectivity and in the extent to which it was influenced by temperature (100). Another study investigated β- galactosidases from *B. circulans, A. oryzae, K. lactis, and K. fragilis* (98). There were obvious differences with respect to the amount, size, and type of oligosaccharides produced by these enzymes. *Bacillus circulans* enzyme produced the highest yield and variety of oligosaccharides, and

also largest saccharides (up to pentasaccharides). The *A. oryzae* enzyme also produced higher oligosaccharides but in smaller quantities. The enzymes from *Kluyveromyces* mainly produced trisaccharides, with negligible amounts of higher saccharides. Novel galactooligosaccharides with distinct spectra were synthesized with β-galactosidase from five different species of *Bifidobacterium* (105). Higher yields (48%) of β-galactooligosaccarides were obtained with thermostable β-galactosidase from *Sulfolobus solfataricus* (97) compared to those from *A. oryzae* (36%) and *E. coli* (32%). Maximum oligosaccharide yields were obtained fastest with the *A. oryzae* enzyme, were highest with the *S. solfataricus* enzyme, and lowest with the *E. coli* enzyme.

Partially purified α-mannosidases from almond meal and limpets ,when incubated with a high concentration of mannose in reverse synthesis reaction, gave rise to the same (1→2)- and (1→3)-mannose disaccharides, but in different ratios of 65:35 and 57:43 respectively (84). Taking advantage of the differences in oligosaccharide yields and specificities of mannosidases from different sources, we have recently devised a simple method of regioselective synthesis of α (1→3)-mannobiose (106). A commercial α-mannosidase from almond was highly efficient in reverse hydrolysis, and oligosaccharide yields of 45–50% were achieved. The products were a mixture of disaccharides (30.75%, w/w), trisaccharides (12.26%, w/w) and tetrasaccharides (1.89%, w/w) with 1→2, 1→3, and 1→6 isomers. α-1,2-linkage specific mannosidase from *P. citrinum* (106) and α-1,6-linkage specific mannosidase from *Aspergillus phoenicis* (87) were used in combination to hydrolyse the respective linkages from the mixture of isomers, resulting in α-(1→3)-mannobiose in 86.4% purity.

27.4.4 Use of Organic Solvents

Many workers have experimented with the use of nonaqueous media and organic cosolvents in enzymatic synthesis. While in reverse hydrolysis the aim is to reduce the water activity of the reaction systems and drive the reaction toward synthesis, in transglycosylation the aim is to reduce the extent of competing hydrolysis.

The feasibility of this approach depends to an extent on the enzyme source (107), as many enzymes undergo inactivation in such conditions and reduced yields or decreased reaction rates are observed. The effect of the solvent on enzyme activity under reaction conditions should be studied, and higher enzyme concentrations are generally required than in buffer. Using o-nitrophenyl galactoside as donor and 3-O-methyl Glc or GlcNAc as acceptor, β-galactosidase from *E. coli* synthesized 3-O-methyl *allo*lactose, Gal β(1→6) Gal and N-acetyl *allo*lactosamine in the presence of different concentrations of diglyme at a much reduced rate (55–144 h reaction time), compared to reaction time of only 6 h in aqueous buffer, and there was no improvement in yields. Conversely, with β-galactosidases from *K. fragilis* and *A. oryzae*, synthesis occurred only in the presence of organic solvents (trimethyl or ethyl phosphate, or tetraglyme in >60% v/v concentration) but the yields were not high. In aqueous buffer, these enzymes hydrolysed the donor and no transfer to acceptor was achieved.

Laroute and Willemot (108) investigated the effect of 66 different organic solvents on glucoamylase from *Rhizopus oryzae* and β-galactosidase from *Aspergillus flavus*. Both enzymes demonstrated similar activities in the range of solvents tested, residual activities after 24 h ranging from 0 (methanol, ethylene glycol, dimethyl sulfoxide, and amines) to 100% (1,4-butanediol, 1,5-pentanediol, water, and tributyl phosphate), being 65–100% for most ethers, alcohols, and esters. The exception was acetates, in which glucoamylase was denatured but β-galactosidase retained 60–70% activity. A protective effect against thermal denaturation was correlated with increasing carbon chain length and lower hydroxyl content. No clear correlation could be established between enzyme stability and hydrophobicity of the medium. In the case of ethers, higher half lives were obtained with water

immiscible solvents. In the context of oligosaccharide synthesis, the study suggests that the study of enzyme stability is not sufficient to determine if a solvent would be suitable in synthesis, as synthesis failed to occur with glucoamylase in reaction mixtures containing tetrahydrofuran and tetrahydrofuranfurfuryl alcohol, though they did not cause enzyme denaturation. Most solvents allowed synthesis to occur and best yields were obtained with diethylene glycol diethyl ether (37%), 1-octanol (33%), and 1-hexanol (31%). Another study with glucoamylases in aqueous ether mixtures (109) showed that although the enzyme was stable, the final oligosaccharide concentration was lower compared to aqueous media due to limited solubility of glucose in organic rich media. Neither the product specificity nor the relative order of initial rates of disaccharide formation by glucoamylase was modified in aqueous ethers. Glucoamylase was considered unsuitable for oligosaccharide synthesis by the authors owing to its broad specificity.

The hydrophobicity of the solvent had a bearing on the size of oligosaccharides synthesized with thermophilic β-glycosidases from *S. solfataricus* and *P. furiosus* (110), synthesis of larger saccharides being favored in presence of a more hydrophobic solvent. Initial reaction rate increased as a function of log P. Toluene and nonane were found to be the best as organic phases, resulting in maximum yields equivalent to the aqueous solution.

Cosolvents DMF and acetone at 50% (v/v) decreased the yields of galactosyl and xylose compared to those in the absence of cosolvents, (111) but the rate of transglycosylation was doubled in the presence of 50% (v/v) acetone.

Improved synthesis of galactooligosaccharides was obtained from lactose by *A. oryzae* β-galactosidase in sodium bis (2-ethylhexyl) sulfosuccinate (AOT) isooctane reverse micelles (112). At 45% (w/v) lactose, a maximum yield of 42.5% (w/w) GOS was obtained in the AOT isooctane solution compared to 31% (w/w) in aqueous solution. The improved yield is a result of inhibition of the hydrolytic activity of the enzyme due to decreased water activity and increased lactose concentration in the core of the micelles.

Attempts to increase oligosaccharide synthesis using α-amylase from *B. licheniformis* in the presence of various organic solvents (ethanol, methanol, N-propanol, propanediol, N-butanol, dioxane, and dimethyl sulfoxide) were unsuccessful (92) and this could not be attributed to the loss of enzyme activity as the enzyme was stable and even stimulated in the presence of low concentrations of some solvents.

27.4.5 Substrate Concentration

As in the case of organic solvents, high substrate concentration drives the equilibrium reactions toward synthesis and decreases the hydrolytic side reaction in transglycosylation. High substrate concentrations also protect the enzyme against thermal denaturation. Substrate concentration is a major determinant of synthesis yields.

In reverse hydrolysis reaction using α-mannosidase from Jack bean, the ratio of initial reaction rate in 83% and 40% mannose was approximately two (81). Maximum yield was obtained at 70% mannose using α-mannosidases from Jack bean and *A. phoenicis* (83); reduced yields were obtained with the Jack bean enzyme at 85% mannose; and synthesis was completely inhibited at 80% mannose in the case of *A. phoenicis*. Synthesis using β-glucanase from *P. emersonii* gave maximum yield of 14–16% at 60% glucose concentration and yield fell sharply at 70% glucose. The initial lactose conversion rate and oligosaccharide production rate were independent of the initial lactose concentration during synthesis of oligosaccharides by thermostable β-glucosidase from *Pyrococcus furiosus* (108). However, the relative oligosaccharide yield increased slightly. Increase in concentration of xylose did not influence the rate of o-nitrophenyl-β-galactose (ONPG) conversion significantly in β-galactosidase catalysed synthesis of galactosyl xylose (106) but yield increased to 21% from 12% with increase in xylose concentration from 0.05M to 2.7M. In a study of oligosaccharide synthesis

using β-galactosidases from four different sources (97), a higher lactose concentration increased yields in all the cases. Similarly, an increase in the maltose concentration (15–50%) led to an increase in the maximum trisaccharide (131– 498 mM) and tetrasaccharide (39–283 mM) concentrations using α-glucosidase from *B. stearothermophilus* and trisaccharide concentration (24–217 mM) for the same enzyme from brewer's yeast (109).

27.4.6 pH

pH of reaction has not been investigated as a variable in many synthesis studies. In most cases, the pH was chosen on the basis of the enzyme,e and variation of pH did not exert a significant influence on yields. In kinetic syntheses, pH can affect the proportion of hydrolysis and transglycosylation.

The influence of pH on the stability of Jack bean alpha mannosidase was studied (81) by measuring its residual activity in 83% mannose solution at pH 4.5, 5.5, and 6.5 after 24 h at 75°C and 80°C. At 75°C, the enzyme was completely stable at all pH values, whereas at 80°C, the residual activities were 35%, 65%, and 71% at pH 4.5, 5.5, and 6.5 respectively. At 75°C, the initial reaction rate at pH 4.5 and 5.5 was 0.42M disaccharides formed per hour and 0.23 M at pH 6.5. At 55°C, however, pH (4.5 or 5.5) did not influence reaction rates.

A pH to temperature correlation was also seen while optimization of galactooligosaccharide production from lactose using β-glycosidases from *S. solfataricus* and *P. furiosus* (110); optimal pH for synthesis differed with temperature. Optimal transglycosylation was obtained at pH 8.0 at 22°C and pH 5.0 at 90°C. This difference could be due to variable influence of pH on protein structure at different temperatures.

No effect of pH was found on the reaction rate between a pH range of 5.0–7.0 using *P. furiosus* β-glucosidase (113), reduced reaction rate was observed at pH 4.0. Relative yield was highest at pH 6.0 in the range tested.

27.4.7 Time

In reverse hydrolysis, the reaction time is the time taken to attain equilibrium, which is usually the point at which no increase in oligosaccharide yield is observed for a period of two or more days and is the point of maximum yield. This is influenced by many factors such as substrate concentration, enzyme source, activity and stability, reaction temperature, and pH. The time scales in equilibrium synthesis are generally in the order of 1–2 weeks although shorter times have been reported for mannooligosaccharide synthesis using Jack bean alpha mannosidase (81) and β-glucanase (89).

The time of reaction is more crucial in the case of transglycosylation than equilibrium synthesis and needs to be carefully monitored to prevent decreased yields due to secondary hydrolysis of products.

Using α-glucosidase from *B. stearothermophilus*, trisaccharides were rapidly synthesized up to a value of 27% on a molar basis from maltose within two days and their concentration declined thereafter (114). Tetrasaccharides reached their maximum concentration in 5 days and did not undergo appreciable hydrolysis. Only trisaccharides were formed by α-glucosidase from yeast, but they were stable over the time period of reaction (10 days). A time dependent modulation of product spectrum was found in the study; with α-(1→4) linked trisaccharides synthesized exclusively by the bacterial enzyme at 2 and 6 h intervals and a low proportion (<5%) of (1→3) and (1→6) linkages appearing after 20 h of reaction. All tetrasaccharides were α-(1→4) linked. The yeast glucosidase also produced mainly α-(1→4) linkages at 6 h, with 12% α-(1→3). The percentage of α-(1→3) linkage increased to 34% after 20 h accompanied by 7% α-(1→6).

27.4.8 Enzyme Immobilization

Synthesis using immobilized glycosidases drives the cost of synthesis down by enabling reuse of the catalyst. The yields are generally lower compared to synthesis using the free enzyme, but were improved in some cases. Immobilization is also able to modulate product spectrum, primarily due to steric effects on the immobilized enzyme. The reactor configuration and mode of operation (batch or continuous) also affects yield and spectrum.

A tetrasaccharide OS-1 (gal/glu 3:1) and a trisaccharide OS-2 (gal/glu 2:1) were synthesized in 32–35% total yield by free and immobilized β-galactosidase from *Thermus aquaticus* YT-1 (115). The enzyme was immobilized by cocrosslinking with bovine serum albumin followed by entrapment in agarose beads of about 2.0 mm diameter. The immobilized enzyme gave significantly higher lactose conversion rates, higher yields, and produced more OS-2 and less OS-1 than the free enzyme.

Using β-galactosidase from *Bullera singularis* immobilized by adsorption onto Chitopearl resin, galactooligosaccharides were produced in 55% yields with a productivity of 4.4 g/L/h from 100 g/L lactose solution in a continuous process in a packed bed reactor (116). In comparison, β-galactosidase from *A. oryzae* when immobilized on glutaraldehyde treated chitosan beads and used in a plug reactor (117) produced only 18% yield from 100 g/L lactose. Although the thermal stability of the immobilized enzyme was higher, yield of enzyme activity and galactooligosaccharides was lower than the free enzyme. High productivities of 80 and 106 g/L/h with corresponding yields of 21 and 26% (w/w) have been reported for the *A. oryzae* β-galactosidase immobilized on cotton cloth and operated in a plug flow reactor (118), from 200 g/L and 400 g/L lactose respectively.

A dramatic rise in yield (573%, oligomers mg/ml.mg of enzyme) was reported (119) for glucooligosaccharide synthesis using immobilized β-glucosidase from almond compared to the free enzyme at 7.5 M (1350 g/L) glucose concentration. Immobilization led to a decrease in hydrolytic activity and increase in the synthetic activity of the enzyme. It has been suggested that this might result from creation of a hydrophobic microenvironment in the region of the active site.

Immobilized α-glucosidase was employed in a column system comprising an immobilized α-glucosidase column and an activated carbon column sequentially (77). The disaccharides formed in the enzyme column were adsorbed in the carbon column preferentially, expelling glucose and making it available for recycling into the enzyme column. In this manner, formation of disaccharides occured by repeated condensation. This system resulted in a higher yield of α-(1$\rightarrow$4) linked disaccharide than α-(1$\rightarrow$6), which was different from the batch system. This was due to lower energy barrier of the α-(1$\rightarrow$4) linked disaccharide enzyme activation intermediate, resulting in its faster formation and immediate adsorption in the activated carbon column.

The method of immobilization influenced the regioselectivity of linkage specific α-mannosidase from *A. phoenicis* (120). The enzyme immobilized by entrapment in alginate beads gave rise predominantly to α-(1$\rightarrow$2) product, as in case of the free enzyme, but the predominant product was Man α-(1$\rightarrow$6) Man in the cases of enzyme immobilized on China clay and DE-52. Additionally, immobilization on China clay gave rise to α-(1$\rightarrow$3) linked disaccharide. The loss of regioselectivity has been correlated with the likely conformational freedom of the immobilized enzyme as the covalently crosslinked enzyme displayed the lowest regioselectivity followed by the noncovalently modified enzyme tightly bound to an ion exchange resin, and then by the enzyme entrapped in alginate beads. Total oligosaccharide yield was over 10% lower than that obtained with the free enzyme. Mannose at 80% concentration was used for synthesis with immobilized enzyme, but was inhibitory in synthesis with free enzyme.

27.5 RECOMBINANT AND ENGINEERED GLYCOSIDASES IN OLIGOSACCHARIDE SYNTHESIS

Recombinant glycosidases

The cloning of an increasing number of glycosidases is improving their availability, and many of these are being investigated for their synthetic potential.

Yield of cloned α-galactosidase from *Bifidobacterium adolescentis* expressed in *E. coli* (121) was 100 times higher than the native enzyme and could be purified by a single anion exchange chromatography step. The enzyme exhibited transglycosylating activity and α-galactooligosaccharides were synthesized from melibiose and stachyose.

Purified recombinant β-glycosidase from *Thermus thermophilus,* overexpressed in *E. coli,* had an optimum temperature of 88°C and performed transglycosylation at high temperature with yields of over 63% in transfucosylation reactions. The enzyme catalysed the hydrolysis of β-D-galactoside, β-D-glucoside, and β-D-fucoside. The enzyme specificity in decreasing order toward different linkages was β (1→3) (100%)> β (1→2) (71%)> β (1→4) (40%)> β (1→6) (10%). Potential application of the glycosidase was suggested in the synthesis of fucosyl adducts and fucosyl sugars.

β-glucosidase II from *Pichia etchellsii* expressed in *E. coli* (122) was able to carry out glucooligosaccharide synthesis both by reverse hydrolysis (glucobiose and triose, at 18 and 6 mmol/L from 167 mmol/L glucose) and transglycosylation (glucotriose and pentose at 4.5 and 2 mmol/L from 79 mmol/L cellobiose). High conversion of 25% was observed in transglycosylation reaction with sophorose. The enzyme exhibited low regioselectivity and β (1→2), β (1→3), and β (1→6)-linked glucobioses were obtained in equilibrium synthesis.

27.5.1 Mutant Glycosidases

27.5.1.1 Glycosynthases

Glycosynthases (123–126) are engineered mutant glycosidases constructed by mutation of the catalytic nucleophile of a retaining glycosidase to a small nonnucleophilic residue. These mutant enzymes are able to efficiently synthesize oligosaccharides, but lack hydrolytic activity due to their inability to form the glycosyl enzyme intermediate. Their hydrolytic inactivity obviates the main problem of secondary hydrolysis in transglycosylation and oligosaccharide synthesis using glycosynthases resulted in high yields of over 95% in some instances. The first reported glycosynthase was a Glu358Ala mutant of *Agrobacterium* species β-glucosidase (Abg) (123). The k_{cat} value was 10^7 times lower than the wild-type enzyme, but was restored 10^5-fold by addition of small anions such as azide or formate (127). In the case of azide, the reaction intermediate was identified as α-glucosyl azide indicating that the reaction proceeded via the direct attack of azide. This implies that the mutant underwent a shift in mechanism from retaining to inverting. The transfer of donor sugar to an acceptor is catalysed only from activated donors with a good leaving group such as fluoride and an opposite anomeric configuration to the normal substrate of the wild-type enzyme. The glycosyl fluoride substrate mimics the glycosyl intermediate and the mechanism of transfer is similar to that occurring during transglycosylation. Formate functions differently (124,128), acting as an assistant nucleophile in the formation of the intermediate from an activated β-substrate, termed as a retaining glycosynthase mechanism. During synthesis using Abg Glu 358 Ala, α-glucosyl fluoride proved to be a better donor, resulting in longer oligosaccharides and higher yields, than α-galactosyl fluoride, which catalysed only a single galactosyl transfer to give disaccharides. Synthesis of

several valuable substrates and inhibitors of cellulases including those unattainable by the wild-type enzyme was achieved using this glycosynthase in gram scales.

The efficiency of the glycosynthase was increased dramatically with a 24-fold improvement in rate constant when serine instead of alanine was used to substitute the catalytic nucleophile, i.e., in an E358S mutant (129). The increased reaction rates resulted in higher yields. Also, the enzyme was able to glycosylate some glycosides like PNP-GlcNAc which were weak acceptors in the case of E358A. A specific stabilizing interaction such as hydrogen bonding between the Ser hydroxyl group and the anomeric fluorine of the α-glycosyl fluoride has been suggested as the reason for the increased glycosylation ability of Abg E358S. From a 20:l culture, 3.5 g of the pure mutant enzyme could be obtained, which affords the possibility of its application in large scale oligosaccharide synthesis.

A β-mannosynthase constructed by Glu519Ser mutation of recombinant β-mannosidase from *Cellulomonas fimi* overexpressed in *E. coli* has been used for synthesis of β-mannosides using the donor α-D-mannosyl fluoride and various acceptors (130). Highest yield of 99% was obtained using PNP β-D-cellobioside as acceptor. The products contained a mixture of β-(1→3) and β-(1→4) linkages. The Glu519Ala mutant was both a poor hydrolase and mannosynthase and only 8% yields of disaccharides and trisaccharides were obtained.

Other glycosynthases include E387G mutant of *Sulfolobus solfataricus* β-glucosidase and those derived from endoglycosidases: E134A mutant of *B. licheniformis* glucanase and E197A mutant of *Humicola insolens* cellulase. The details of these enzymes are tabulated and discussed in reviews by Jakeman and Withers (125) and Williams and Withers (126). The two endoglycosynthases have been used in tandem in a one pot synthesis (131) of hexasaccharide substrates of 1,3/1,4- β-glucanases in 70–80% yields, useful in their kinetic and structural studies.

All of these glycosynthases give rise to β-(1→3) or β-(1→4) linked products. Jakeman and Withers (132) have generated a glycosynthase (Glu537Ser) from *E. coli* β-galactosidase capable of forming Gal- β- (1→6)-linkages. Product yields of 40–63% were obtained by reactions between α-D-galactosyl-fluoride (α-Gal-F) and β-D-glucopyranoside (pNPGlc), pNP β-cellobioside, and phenyl β-D-glucoside. A second mutation generated close to the enzyme's active site resulted in the double mutant Glu537Ser/Gly794Asp which was much more active and resulted in improved product yields of 80–85%. X-ray crystallography studies showed that the introduced Asp lies within the active site and might facilitate transglycosylation by interacting with the acceptor sugar.

A new endoglycosynthase has been generated by E231G, E231S, or E231A mutation of barley (1,3)-β-D-glucan endohydrolase (133). E231G exhibited the highest catalytic efficiency. The mutant enzymes had no activity on laminarin but activity could be restored partially with formate. The glycosynthase was able to bring about autocondensation of α-laminaribiosyl fluoride and heterocondensation of α-laminaribiosyl fluoride and 4'-nitrophenyl β-D-glucopyranoside to form polymeric products: linear (1,3)-β-D-glucans of DP 30−34.

The Abg E358S and E358G mutants of *Agrobacterium* species β-glucosidase have been used for solid phase oligosaccharide synthesis (134). A galactose moiety was transferred by these enzymes from α-Gal-F with >90% efficiency to acceptors linked to PEGA resin via a backbone amide linker (BAL) and the recovery of products was high.

The increasing repertoire of glycosynthases with a broadening donor and acceptor range, combined with their application in methodologies such as solid phase synthesis suitable for large scale use, make them attractive catalysts for oligosaccharide synthesis.

27.5.1.2 Mutant Enzymes other than Glycosynthases

The performance of β-glucosidase CelB from hyperthermophilic *Pyrococcus furiosus* in oligosaccharide synthesis was improved by two active site mutations (135): a phenylalanine to tyrosine (F426Y), and methionine to lysine (M424K). F426Y improved oligosaccharide yield from 40 to 45% compared to the wild type enzyme, and M424K increased the pH optimum of transglycosylation. The improvement in transglycosylation capacity and oligosaccharide yield was especially significant at low lactose concentrations of 10 to 20%. The F426Y/M424K double mutant gave 40% yield at 10% lactose, compared to only 18% for the wild-type enzyme. It also displayed a higher ratio of tetrasaccharides to trisaccharides. The increased yields were due to an increase in the transglycosylation:hydrolysis ratio. The high yields at low lactose concentrations are desirable characteristics for an industrial process.

β-galactosidase BIF3 from *Bifidobacterium bifidum* has a molecular mass of 188kDa and consists of a signal peptide, an N-terminal β-galactosidase region and a C-terminal galactose binding motif. The enzyme was converted from a hydrolytic to an efficient transgalactosylating enzyme by deletion of about 580 amino acid residues from the C-terminal including a putative galactose binding motif by deletion mutagenesis and termed a transgalactosylase (136). The truncated enzyme expressed in *E. coli* displayed a 9:1 ratio of trangalactosylating to hydrolytic activity during galactooligosaccharide synthesis over a range of lactose concentrations from 10 to 40% and yields of 37–44% were obtained.

27.5.1.3 Mutant Glycosidases Created by Directed Evolution

Directed evolution has been revolutionary in its approach to creating enhanced biocatalysts in that no structural information is required for the catalyst whose improvement is sought. The main requirements for successful directed evolution (137) are: the functional expression of the enzyme in a suitable microbial host, the availability of a screen (or selection) sensitive to the desired properties, and identifying a workable evolution strategy.

The techniques generally used for directed evolution were oligonucleotide directed mutagenesis and error prone PCR until the invention of a method called DNA shuffling by Stemmer (138). Since then, this has been the most widely used method for a range of enzymes. The method was further optimized by Zhao and Arnold (139) for improving the fidelity of recombination. Other methods of directed evolution include staggered extension process (140), random elongation mutagenesis (141), a phage display based method (142), cycling mutagenesis (143), and heteroduplex recombination (144).

Some examples of properties of biocatalysts improved by directed evolution can be found in Affholter and Arnold (145). Applications fall into a few major categories: improving function in nonnatural or extreme environments (where activities or stabilities are low), improving activity toward a new substrate, tuning specificity, and increasing functional expression in a heterologous host.

All of these general categories apply in the context of glycosidase catalysed synthesis of oligosaccharides and a few examples are available in recent literature, including improvement of regioselectivity.

Directed evolution of *E. coli* β-galactosidase carried out by DNA shuffling and colony screening in a plate based assay using chromogenic fucose substrates led to a 10- to 20-fold increase in K_{cat}/K_m for fucose substrates relative to the native enzyme (146). Thirteen base changes resulting in six amino acid changes were responsible for the change from galactosidase to fucosidase specificity.

Using staggered extension process, it has been attempted (147) to evolve the minor 1, 3 regioselectivity of α-galactosidase from *Bacillus stearothermophilus,* which is of greater biological and medical significance than the major 1, 6 selectivity. The initial

screening of the mutants was based on their inability to grow on melibiose (1, 6-linked). Just one generation of random mutagenesis and one recombination of the best mutants led to the loss of 1, 6 hydrolytic and synthetic activity to a large extent. The mutant enzymes had preference for 1, 3 linkage ($R_{1,3/1,6}$=6.9, compared to 0.3 for the wild type), however no improvement in yield was obtained and it remained constant at about 5%. The increase in 1, 3 selectivity is thus primarily due to decrease in 1, 6 regioselectivity rather than an improvement in the 1, 3 regioselectivity.

The genes coding for β-glucosidase Cel B from *Pyrococcus furiosus* and β-glycosidase LacS from *Sulfolobus solfataricus* were subjected to evolution (148) by DNA family shuffling. Three rounds of screening led to isolation of two improved hybrids with 1.5-fold–3.5-fold and 3.5-fold–8.6-fold increases in lactose hydrolysis rates respectively. The study is an example of successful DNA shuffling between sequences of enzymes with limited homology.

Devising a suitable and efficient screen is, in fact, the most important step of a directed evolution experiment, and it is the first law of directed evolution that "You get what you screen for" (149). On this principle, a screening method has been developed by Mayer et al. (150) for identification of functional synthetic enzymes for oligosaccharide synthesis, in this case glycosynthases. The method was a plate based coupled enzyme screen employing two plasmids coexpressed in the same cell: one coding for the screening enzyme (releases a chromogenic product only from glycosynthase derived product and not the acceptor) and the other for the glycosynthase. The screen was used to detect glycosynthase activity in a library of random mutants generated by saturation mutagenesis of the catalytic nucleophile in *Agrobacterium* species β-glucosidase (Abg). In addition to the glycosynthases generated from this enzyme in previous studies (123,129), two new glycosynthases, E358G and E358C, were discovered using this assay. The E358G had a K_{cat}/K_m which was more than double than that of the previous best mutant, E358S.

27.6 CONCLUSIONS

It is evident that the use of biotechnology to manufacture oligosaccharides of food and medical importance has developed rapidly. We now have a range of synthetic approaches which can be employed to bring about the synthesis of a wide range of biologically important structures. The development of glycosynthases and the Superbead technology will increase the availability of complex mammalian oligosaccharides and facilitate drug development based on glycoconjugates. The use of glycosidases as synthetic catalysts is also maturing and we can now manufacture multigram quantities of several bioactive oligosaccharides without the need for derivatization. This approach is also a promising route to novel oligosaccharide structures. The application of directed evolution techniques to glycosidases can be expected to increase the range of glycosidases with desired specificities. Genetic engineering techniques can also be seen as a means for scaling up the manufacture of glycosidases from plant and mammalian sources and should, at least in principle, make them more readily available.

Developments in carbohydrate biotechnology are already facilitating efforts to understand the roles of complex carbohydrates in biological systems and they will also enable the exploitation of such knowledge for practical ends.

3.01

Molecular Evolution and Diversity of Food Borne Pathogens

Katy Windham, Kendra Kerr Nightingale, and Martin Wiedmann

CONTENTS

1.1 INTRODUCTION

An understanding of microbial evolution and diversity is critical to our ability to control food borne pathogens throughout the food chain and to reduce human food borne infectious diseases. While different phenotypic methods (such as multilocus enzyme electrophoresis and serotyping) have been used for many years to characterize the diversity of food borne pathogens, the advent of inexpensive, rapid, and increasingly easy to use molecular characterization methods (for example, polymerase chain reaction [PCR] and automated DNA sequencing) has revolutionized our ability to study the molecular diversity and evolution of food borne pathogens. Consequently, an extraordinary amount of information on the molecular diversity and evolution of food borne pathogens is currently available. Various molecular studies have not only provided a better understanding of the basic biological processes underlying the emergence and maintenance of virulence traits and the transmission dynamics of food borne pathogens, but have also yielded widely used tools to differentiate food borne pathogens in order to detect, track, and control outbreaks of food borne disease.

A sound understanding of the evolution of food borne pathogens can also allow for classification of these organisms into clonal groups, which share specific virulence and transmission characteristics. While we already possess a good understanding of the evolution of virulence and virulence associated traits for some food borne pathogens (e.g., *Escherichia coli*), our understanding of the evolution of other food borne pathogens is considerably more limited. Defining evolutionary related groups of food borne pathogens will be critical to allow for improved control of these pathogens throughout the food continuum, and to reduce the incidence of human food borne disease. For example, it can be crucial for the design and implementation of appropriate food processing steps and barriers to understand whether different evolutionary groups of a bacterial pathogen differ in heat or acid resistance. An understanding of clonal groups of a pathogen and their ability to cause disease, and infectious dose between clonal groups of a bacterial pathogen, may also have considerable implications for regulatory policies, intervention strategies, and risk assessments (1).

Food borne pathogens include viruses, protozoans, and bacteria. While some knowledge on the diversity and evolution of protozoan and viral food borne pathogens exists, the

majority of research has been conducted on bacterial food borne pathogens. We will therefore focus our discussions in this chapter on bacterial food borne pathogens. This chapter provides an overview of mechanisms of evolution relevant to bacteria, and methods to infer evolutionary relatedness and other evolutionary processes in these organisms. In addition, this chapter includes an overview of molecular subtyping methods used to study the evolution and diversity of food borne bacterial pathogens, as well as brief summaries on our current knowledge of molecular diversity and evolution of selected food borne pathogens.

1.2 MECHANISMS OF BACTERIAL EVOLUTION

Evolution is the process of change in the genetic makeup of populations (Table 1.1). Bacteria demonstrate an amazing level of diversity in respect to cell structure, metabolism, and general way of life, considering the relatively small variation that is observed between the genome sizes of different bacterial species. More specifically, even within defined taxonomic groups such as enteric bacteria, of which several species are known to share a common ancestry, individual species show distinct affinity for defined ecological niches and ability to infect specific host species (2). The forces involved in the evolution

Table 1.1
Definitions of important terms

Term	Definition
Allele	Alternate forms of a gene at a given locus
Clone	A group of bacteria that descended from a common ancestor and represents a monophyletic branch on a phylogenetic tree
Evolution	The process of change in the genetic make-up of populations
Haplotype	Collective DNA polymorphism combinations based on several loci being studied
Homologous recombination-	Recombination between two DNA sequences that have the same or very similar nucleotide sequences
Horizontal gene transfer	Lateral transfer of genes from one genome to another
Intergenic recombination	Recombinational events between different genes
Intragenic recombination	Recombinational events within a given gene (e.g., between two repeats present within a given gene)
Intergenomic recombination	Recombinational event between two sequences present on a single DNA molecule or genome (e.g., between two rRNA operons of a bacterial chromosome)
Intragenomic recombination	Recombinational event between two sequences originating from two different genomes
Lineage	Evolutionary group that contains the ancestral sequence and its descendants
Linkage disequilibrium	Non-random assortment of alleles indicative of clonal population structure
Linkage equilibrium	Random association of alleles; presence of an allele at one locus is independent of presence or absence of alleles at other loci
Polymorphism	Presence of two or more genetic variants at a defined locus

of microorganisms include mutation, horizontal gene transfer, random genetic drift, migration, and natural selection. Random genetic drift can be defined as the change in allele frequency in a population that occurs by chance alone. Random genetic drift diminishes the genetic variation that is introduced by mutations in a population. The movement of organisms among subpopulations is known as migration. In essence, migration defines the limit of the amount of genetic diversity that can occur within a defined population (3). The two processes that are responsible for the majority of changes in genetic makeup that bacteria experience include mutation and horizontal gene transfer. Although mutations clearly contribute to the generation of prokaryotic diversity, they are more likely to cause subtle changes and gradual evolution; whereas horizontal transfer of genetic information provides a mechanism for rapid introduction of complex genetic traits, including those that can give rise to new pathogenic variants (4).

Bacteria multiply asexually by binary fission, in which two daughter cells are produced from a single mother cell. Because these daughter cells have a chromosome that is essentially identical to their mother cell, variation seen in the bacterial chromosome can be primarily attributed to changes in the genetic makeup of an organism that occur after reproduction. These mutations will then be passed on to descendents and, provided the mutations are successfully accumulated in the bacterial population, new lineages may ultimately emerge (5,6). The main focus of bacterial evolution studies for many years has been on mutations and the vertical transmission of genetic material between mother and daughter cells. Only more recently has it become apparent that the transfer of genetic information between unrelated cells by sexual means (horizontal or lateral transfer) plays an important role in the evolution of many bacterial food borne pathogens (6).

The advent of rapid and increasingly affordable whole genome sequencing strategies (7) has contributed considerably to our increased recognition of the importance and extent of horizontal transfer in bacterial food borne pathogens, as well as the impact this mechanism has on bacterial evolution. Thus, genome and large scale sequence data have challenged previous assumptions that evolution occurs as a treelike process. Recent evidence suggests that the relative contributions of mutations and recombination to microbial diversity and evolution differ considerably between bacterial genera, species, and possibly even genetic lineages (5). Some food borne pathogens (e.g., *Listeria monocytogenes*) appear to represent highly clonal populations, for which mutations have contributed considerably more than horizontal gene transfer to genetic diversity. Other food borne pathogens, such as *Staphylococcus aureus,* appear to have evolved predominantly by horizontal gene transfer, such that analysis of multilocus sequence data have revealed rates of recombination high enough to eliminate any detectable phylogenetic signal from mutations (5).

1.2.1 Mutations

While DNA sequences are normally copied exactly during the process of replication, rare errors in DNA repair and replication give rise to new DNA sequences. These erroneous changes are generally known as mutations, which can further be defined as the heritable unit of genetic change (8). Mutations may be classified into two broad categories by the length of DNA that is affected by these changes as either point mutations, which involve a single nucleotide, or segmental mutations, which affect several adjacent bases. More commonly, mutations are categorized by the type of change caused by the mutational event: nucleotide substitutions, deletions, insertions, inversions, and recombinations (9). Specific aspects of these different types of mutations and their importance for the evolution of bacterial food borne pathogens are discussed below.

1.2.1.1 Substitutions

Substitutions are often also referred to as point mutations. Substitutions involve the replacement ("substitution") of a single nucleotide base for another in a DNA sequence (10). Two types of nucleotide substitutions, transitions and transversions, may occur during the evolution of DNA sequences. Transitions are substitutions where a purine base (A or G) is replaced by another purine base or where a pyrimidine base (C or T) is replaced by another pyrimidine base. Transversions are substitutions where a purine base changes to a pyrimidine base or vice versa. Mutations that occur in coding sequences can also be classified as synonymous (silent), leading to no change in the amino acid sequence encoded, or as nonsynonymous changes, which lead to a change in the amino acid encoded. Nonsynonymous mutations that result in a stop codon, and therefore lead to expression of a truncated protein, are often referred to as "non-sense mutations" (9).

1.2.1.2 Insertions and Deletions

Insertion and deletions refer to the addition or removal of one or more bases in the DNA sequence of an organism. It is impossible to determine whether an actual insertion or deletion event caused an observed difference between sequences of interest. Therefore, when homologous sequences or genomes are compared, the presence or absence of one or more nucleotides compared is often referred to as an "indel". Insertions and deletions can occur by a variety of mechanisms, including unequal crossover, intrastrand deletion, and replication slippage or slipped strand mispairing (8). In coding regions, indels that are not multiples of three nucleotides incur a shift in the reading frame that results in numerous amino acid changes, and new, often premature, stop codons downstream of the indel. Mutations that disrupt the correct reading frame are thereby referred to as frameshift mutations (8).

In many bacteria (including in many food borne pathogens), insertions and deletions ranging from single nucleotides, through short repeats (as short as 3 nucleotides), to chromosomal virulence gene islands exceeding 10 kb in length have been observed. Both gene acquisition and gene loss clearly play an important role in the evolution and emergence of pathogens and bacterial lineages with novel phenotypic characteristics (11). While smaller indels generally involve intragenomic genetic events, insertions of larger sequences (e.g., virulence gene islands, antibiotic resistance genes), typically include horizontal (or lateral) gene transfer (intergenomic genetic events). Interestingly, it is not only the introduction of new genetic material that may cause important phenotypic changes and emergence of a more pathogenic lifestyle. Gene deletions have also been linked to the evolution of pathogenicity in food borne pathogens. For example, in *Shigella*, deletion of *cad*A results in the loss of lysine decarboxylase activity. This deletion has been identified as a pathoadaptive mutation (12) since cadaverine, the product of this lysine decarboxylase activity, acts as an enterotoxin inhibitor and thus decreases virulence of *Shigella* (13).

Duplication and deletion of repeated sequences (ranging from as few as 3 nucleotides to more than 300 nucleotides) represents a considerably more frequent genetic event than substitutions. Thus, detection of indels in repeat sequences has been employed for highly sensitive molecular subtyping of bacterial pathogens in different subtyping techniques, including a technique termed MLVA (multiple locus variable number tandem repeat [VNTR] analysis) (14).

1.2.1.3 Inversions

Inversion of DNA sequences within a chromosome or plasmid can occur by either chromosomal breakage and rejoining or by intrachromosomal crossover between two homologous

segments oriented in opposite directions. While inversions of large chromosomal fragments have been observed in different bacterial species, including different S*almonella* serotypes, the specific evolutionary importance of these inversions is often not clear. It has been hypothesized that large chromosomal inversions restore chromosomal balance after disruptions by other insertions, deletions, and inversions (15,16).

1.2.1.4 Recombination

The term "recombination" is generally used by geneticists to describe the process of exchanging two genetic loci that may be present on a single DNA molecule (intragenomic or intragenic recombination) or on two different DNA molecules (intergenomic recombination). Homologous or generalized recombination involves recombination between homologous sequences and can be classified as either crossing over (reciprocal recombination) or gene conversion (nonreciprocal recombination) (8). Both types of homologous recombination generally are thought to occur through an intermediate called the "Holliday junction". In contrast to homologous recombination, site specific recombination involves the exchange of a usually very short sequence by another typically long sequence that has no similarity to the original sequence (8). Site specific recombination is, for example, responsible for integration of phage genomes into bacterial chromosomes, a mechanism that has been shown to be important in the evolution of many food borne bacterial pathogens (e.g., introduction of shiga toxin encoding genes into certain strains of *E. coli)* (17).

In bacteria, homologous recombination can occur within sequences present in the genome of a given bacterial cell, which can be referred to as intragenomic recombination. For example, recombination between rRNA operons of a given genome has been shown to provide a mechanism for genomic rearrangement in eubacteria (18). Homologous recombination between a chromosomal sequence and a homologous sequence introduced into a recipient bacterial cell, usually from another closely related donor bacterium by horizontal gene transfer, can be referred to as intergenomic homologous recombination. Because relatively short sequence fragments generally participate in this intergenomic homologous recombination, this process differs in its evolutionary implication from the meiotic recombination of eukaryotes (3).

1.2.2 Horizontal Gene Transfer

Horizontal gene transfer in prokaryotes broadly involves the exchange of chromosomal DNA segments between different genomes, therefore introducing variability into the gene pool that may give some organisms an evolutionary advantage. Horizontal gene transfer can occur through three common mechanisms: transformation, conjugation, and transduction. These processes allow for unidirectional genetic exchanges that can introduce large DNA fragments (up to more than 10 kb) into a recipient cell. Conjugation, which usually requires a vector for information transfer, involves the physical transfer of host DNA (usually a plasmid or a transposon) from a donor to a recipient cell. Transformation involves the uptake of DNA from the environment by competent cells. Transduction represents transfer of DNA from one bacterial cell into another bacterial cell via a bacteriophage that packages donor DNA and injects the partial chromosome into a recipient cell.

The term "horizontal gene transfer" is generally used to describe lateral transfer of homologous genes between closely related bacteria (see Figure 1.1A) as well as to describe the transfer of nonhomologous sequences between sometimes highly divergent organisms (see Figure 1.1B). While the magnitude and level of bacterial horizontal gene transfer in natural populations is uncertain, sequence data have shown that these events are quite common in some species (2). While it has been hypothesized that horizontal transfer and

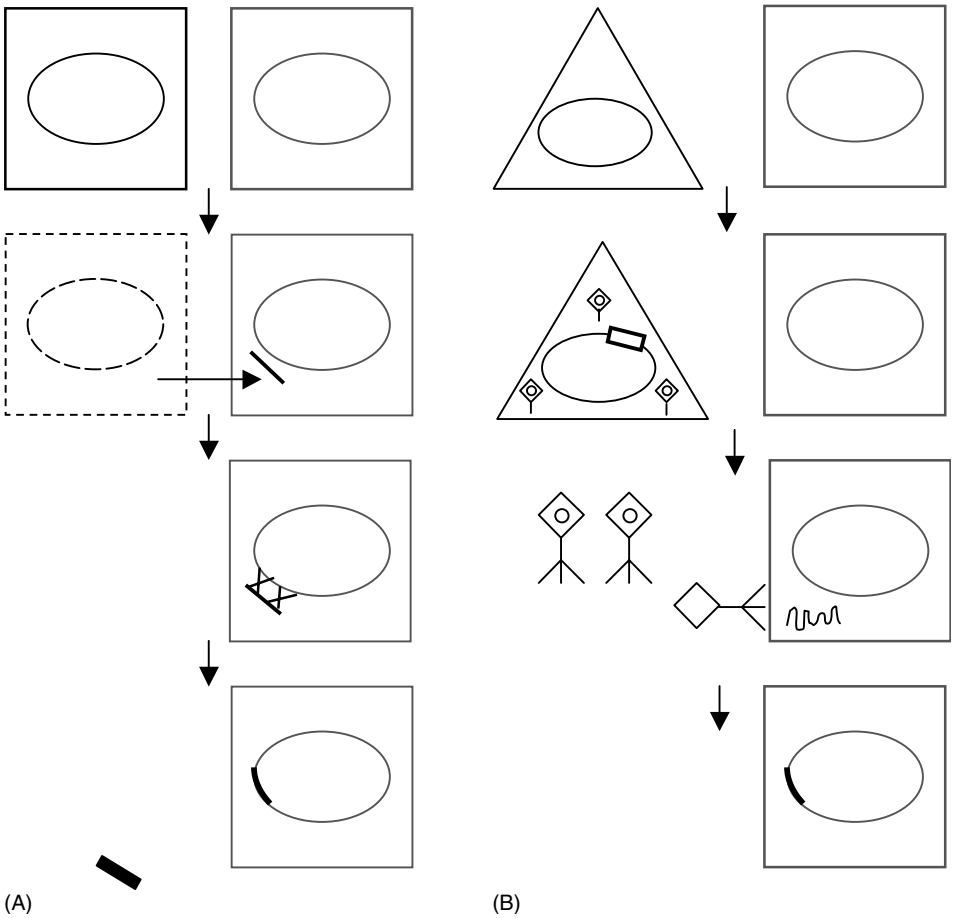

Figure 1.1 Schematic representation of horizontal gene transfer of homologous gene sequences (Figure 1.1A) and horizontal gene transfer of non-homologous gene sequences (Figure 1.1B). Figure 1.1A show uptake of homologous gene sequences by transformation followed by integration into the host genome by homologous recombination. Figure 1.1B shows phage mediated transfer of a non-homologous gene sequence followed by site-specific recombination into the host genome. Donor cells are shown in black and recipient cells are shown in red.

subsequent recombination of homologous sequences plays a negligible role in ecological and phenotypic diversification of bacteria (2), lateral transfer of nonhomologous sequences from highly divergent organisms clearly has played an important role in the evolution of food borne pathogens.

1.2.2.1 Horizontal Gene Transfer of Homologous Gene Sequences

While it has become apparent that horizontal gene transfer of homologous gene sequences occurs commonly in many bacterial species, determining whether and to what extent horizontal gene transfer and recombination have occurred in bacterial isolates collected from natural sources can be challenging. A variety of mathematical and statistical methods have been developed over the years to probe for evidence for the exchange of genetic information (5). Multilocus enzyme electrophoresis (MLEE) data has traditionally been used to asses the presence of linkage equilibrium, which would indicate a considerable rate

of horizontal gene transfer. Similarly, multilocus sequence data can be used to probe for the presence of linkage disequilibrium. However, analysis of linkage disequilibrium represents a highly insensitive method to probe for the presence of horizontal gene transfer, and Maynard Smith et al. (19) estimated that an allele must change at least 20 times more frequently by genetic exchange events than by point mutation to eliminate linkage disequilibrium within a population (5). In addition, other factors, such as sampling bias (5), could also cause an apparent linkage disequilibrium in bacterial populations with significant rates of horizontal gene transfer.

1.2.2.2 Horizontal Gene Transfer of Nonhomologous Gene Sequences

DNA sequence data have been used in different ways to identify lateral gene transfer of nonhomologous sequences. While bacterial species display considerable variation in their overall G+C content and codon usage, the genome of a particular species in general shows a very homogeneous base composition (2). Thus, sequences introduced through horizontal gene transfer from a divergent species can often be recognized by their distinct GC content or codon usage. However, amelioration of horizontally introduced nonhomologous gene sequences over time may make it more difficult to differentiate "foreign DNA" from ancestral genome sequences (20).

Horizontal gene transfer of nonhomologous gene sequences has been shown to critically contribute to the evolution of many food borne pathogens, in particular through transfer of antibiotic resistance genes and through transfer of so called pathogenicity islands. Pathogenicity islands (PAIs) are large genomic regions that range from 10 to 200 kilobases or more and carry genes that encode for one or more virulence factors. Typically, PAIs are found in the genomes of a given pathogenic species or lineage but are absent (or rarely seen) in closely related nonpathogenic organisms. While PAIs are generally found on the chromosome, they may also be part of bacteriophages, plasmids, or conjugative transposons (21). They often have a GC content that differs from the rest of the genome, are often flanked by repetitive DNA sequences, and frequently are associated with tRNA genes, which can act as sites for incorporation of foreign DNA (21). PAIs have been described in a variety of Gram-negative pathogens, but also have been identified in several Gram-positive genera such as *Listeria* and *Staphylococcus*.

Virulence factors such as adhesion molecules, invasion molecules, toxins, and various secretion systems can be encoded on these islands. In particular, type III secretion systems, which can inject bacterial proteins into host cells to facilitate the uptake of several Gram-negative food borne pathogens including *Salmonella, Shigella*, and *E. coli* by nonphagocytic host cells, are commonly associated with PAIs. Although type III secretion systems may be conserved between distantly related pathogens, the proteins that are secreted and injected into host cells differ greatly, resulting in a wide spectrum of observed virulence phenotypes between pathogens (22). Various numbers of PAIs have been identified in different pathogens. While in some organisms, such as *E. coli*, the acquisition of a single PAI appears to be sufficient to confer pathogenic potential; in other species, such as *Salmonella enterica*, as many as five pathogenicity islands have been identified in isolates of specific serotypes (11).

1.2.3 Natural Selection

While mutations and horizontal gene transfer are the mechanisms that are responsible for generating genetic diversity in bacterial populations, it is natural selection that determines whether distinct genotypes will survive and multiply in different environments and hosts. Natural selection is defined as the differential reproduction of divergent genotypes within

a population (8). Fitness is a measure of an individual's ability to survive and multiply in a population. In most cases, new mutations will be deleterious and lower fitness; therefore, these mutations will be removed from a population by negative or purifying selection. Conversely, new mutations that confer an enhanced fitness to an individual are maintained and spread within a population through positive or adaptive selection (10).

Food borne pathogens are exposed to a variety of selective pressures in different environments and foods, as well as in human and often animal hosts. Evolution of food borne pathogens is thus driven by a variety of selective pressures, which need to be balanced to maximize pathogen transmission and multiplication. While external or environmental stressors encountered during food processing and preparation (i.e., pH, temperature, and osmotic pressure) often represent selective pressures different from those encountered in a host, sometimes similar selective pressures (e.g., acidic pH) may be present in certain foods and within a host, raising particular concerns as to whether changes in the food processing methods and environments may also select for pathogens with enhanced human virulence. Changes in selective pressures encountered by food borne pathogens within both human and animal hosts have also considerably impacted the evolution of these pathogens. One of the most obvious selective pressures has been the application of antibiotics in human and animal hosts, which has provided the selective pressure to facilitate the rapid emergence and spread food borne pathogens such as *Salmonella typhimurium* DT104 that are resistant to multiple antibiotics (23).

1.3 MOLECULAR SUBTYPING METHODS TO STUDY EVOLUTION OF FOOD BORNE PATHOGENS

In general, bacterial subtyping methods can be divided into phenotype based and molecular genetic or DNA based methods (24). While phenotype based methods have been used for many years to subtype food borne pathogens, molecular methods have revolutionized our ability to differentiate bacterial subtypes. Key aspects of selected and commonly used subtyping methods are summarized below; for a more comprehensive review the reader is referred to one of the many review articles on bacterial subtyping methods (24–26). Additional review articles and book chapters on the current state of subtyping methods for specific food borne pathogens such as *Campylobacter* (27), *Listeria monocytogenes* (28,29), *E. coli* O157:H7 (30), and *Salmonella* (31) are also available.

1.3.1 Phenotype Based Subtyping Methods

Commonly used phenotype based strain typing (or subtyping) methods for bacterial pathogens include serotyping, biotyping, phage typing, and MLEE. While a variety of shortcomings and concerns may be associated with different phenotype based strain typing methods (24), these methods are still regularly used and have some utility for characterization of bacterial food borne pathogens. Phenotype based methods may often lack discriminatory power and reproducibility (28). Furthermore, a considerable proportion of bacterial isolates may be untypable by some of these methods. To overcome these issues and to provide improved strain differentiation, molecular subtyping methods are increasingly applied for characterization of bacterial isolates, and it is likely that these molecular methods will ultimately replace phenotype based strain typing methods.

Among the phenotypic subtyping methods, phage typing, and particularly MLEE, have been instrumental tools for the development of an initial understanding of bacterial population genetics and evolution. For example, phage typing of *Salmonella* has contributed to the detection and description of the emergence of a multiresistant *Salmonella*

typhimurium strain, which was termed "DT (definitive type) 104", based on its phage type (32,33). In France, routine application of phage typing to *L. monocytogenes* isolates from humans and foods led to the detection of at least one human listeriosis outbreak (34). Multilocus enzyme electrophoresis differentiates bacterial strains by variations in the electrophoretic mobility of different constitutive enzymes. Cell extracts containing soluble enzymes are separated by size in nondenaturing starch gels, and enzyme activities are determined in the gel by using color generating substrates (35). This method usually provides 100% typability, and MLEE has been widely used for studies on the population genetics of many bacterial pathogens (36). For example, MLEE data were critical for the development of an initial understanding of the evolution of *E. coli* O157:H7 (37,38).

1.3.2 DNA Based Subtyping Methods

The widespread development of different DNA based subtyping methods has dramatically improved our ability to differentiate subtypes of bacterial food borne pathogens and to study their evolution and population genetics. Commonly used DNA based subtyping approaches for bacterial isolates include plasmid profiling, Pulsed-Field Gel Electrophoresis (PFGE), ribotyping, Amplified Fragment Length Polymorphism (AFLP),and random amplification of polymorphic DNA (RAPD) as well as other PCR based subtyping methods (24,28). Most of these methods provide DNA banding based data outputs that can be used to classify bacteria into genetically similar subtypes. These methods have contributed considerably to our ability to characterize, often with high discriminatory power, genetically related subtypes within a bacterial species, and to develop a better understanding of the diversity of bacterial food borne pathogens. However, the data generated by these methods are generally not suitable for evolutionary analyses, since it is generally not feasible to infer the primary genetic changes leading to different DNA banding patterns. Methods that rely on DNA sequencing subtyping and characterization, such as multilocus sequence typing (MLST), on the other hand provide data suitable for evolutionary analyses and have provided considerable improved insight into the evolution of food borne pathogens. Even more recently, other DNA sequence based characterization and subtyping methods, such as MLVA and whole genome microarrays as well as comparative whole genome sequencing have further enhanced our ability to study the genome evolution of food borne pathogens.

1.3.2.1 DNA Sequencing Based Subtyping and Characterization Methods

Multilocus sequence typing refers to a molecular subtyping approach that uses DNA sequencing of multiple genes or gene fragments to differentiate bacterial subtypes, determine the genetic relatedness of isolates, and make inferences about population genetics parameters of interest. Sequencing of multiple housekeeping genes is often what MLST refers to (39), but sequencing of multiple virulence genes can also be used as a subtyping method (28). A major advantage of DNA sequencing based subtyping, as compared to other molecular subtyping methods is that sequence data are considerably less ambiguous (39) and easier to interpret than banding pattern based subtype data obtained by many other DNA based subtyping approaches (e.g., PFGE and ribotyping). Data from DNA sequencing also provide an opportunity to reconstruct ancestral relationships among bacterial isolates, allowing further insight into the evolution, epidemiology, and ecology of food borne pathogens.

The development of internet accessible databases for MLST information (such as the MLST database at http://www.mlst.net/) will also facilitate global, large scale surveillance and tracking of bacterial food borne pathogens, as well as large scale evolutionary studies (39). While sequencing of housekeeping genes provides an opportunity to probe the evolutionary relatedness of bacterial organisms without the confounding effects of adaptive

selection, which often occurs among virulence genes, sequencing of virulence genes may provide critical information on the evolution of virulence characteristics among clonal groups of bacterial pathogens. In addition, studying the effects of adaptive selection in specific lineages or strains of food borne pathogens may help explain variations in the ability of these clonal groups to cause disease. As DNA sequencing continues to become cheaper and more broadly accessible and as DNA chip based DNA sequencing methods are developed, the use of DNA sequencing data for bacterial subtyping and evolutionary studies will continue to expand.

1.3.2.2 MLVA

Multiple locus variable number tandem repeat analysis (MLVA) utilizes the detection of length polymorphisms in short repeated nucleotide sequences (caused by insertions or deletions of single or multiple repeat elements) to classify bacterial isolates into subtypes (14). Typically, MLVA involves the use of multiple sets of PCR primers targeting different VNTRs; design of these primers generally requires the availability of a full genome sequence of the target organism to allow identifications of target VNTRs and PCR primers. VNTRs appear to be highly polymorphic (14) and MLVA consequently appears to show a higher discriminatory power than most other DNA based subtyping methods. Due to the apparent rapid evolution of VNTRs, MLVA seems to provide a suitable approach to study the short term evolution of bacterial pathogens, providing a unique tool to study the diversity and evolution of *Bacillus anthracis*, a highly monomorphic bacterial pathogen (14) and other bacterial pathogens, such as *Yersinia pestis*, that show limited diversity and appear to have emerged relatively recently (40).

1.3.2.3 Whole Genome Sequencing and Whole Genome Microarray Based Characterization Methods

As full genome sequences of a variety of bacterial food borne pathogens [e.g., *L. monocytogenes*, *Salmonella typhimurium*, and *E. coli* O157:H7 (41-43)] become available, our ability to study the genome evolution of food borne bacterial pathogens continues to increase. Comparative genomic studies on closely related pathogens and nonpathogens [e.g., *E. coli* O157:H7 (43) and *E. coli* K12 (44); *L. monocytogenes* and *L. innocua* (41)] have already provided some interesting insight in the evolution of virulence in the food borne pathogens *E. coli* O157:H7 and *L. monocytogenes*. While full genome sequencing of multiple strains of different bacterial pathogens may occur for some strains of selected pathogens, whole genome microarrays provide a more cost effective approach to characterize the entire genome content of different bacterial strains and to study genome evolution of bacterial pathogens. For example, Zhang et al. (45), used *L. monocytogenes* serotype 1/2a microarrays to gain further insight into the evolution of different lineages of the food borne pathogen *L. monocytogenes*. Combination of multilocus housekeeping and virulence gene sequencing with whole genome microarrays may currently provide the most cost effective method to probe comprehensively the evolution of food borne bacterial pathogens.

1.4 PHYLOGENETIC AND POPULATION GENETIC METHODS

Methods for analysis of phylogenetic and population genetics data have developed considerably over the past decades, and a variety of outstanding books on these topics are available. For a comprehensive overview of phylogenetic analysis readers are referred to “Inferring

Phylogenies" (46). Phylogeny is the study of evolutionary relationships between organisms. Molecular biology techniques are used to generate data that can then be used to reconstruct a phylogenetic tree that describes the degree of genetic relatedness and elucidates the genealogy among specific organisms of interest (47). The primary goals of phylogenetic analysis are to rebuild an accurate evolutionary relationship between organisms and estimate the time since organisms last shared a common ancestor (9). A general overview of some of the major concepts relevant to reconstruction of phylogenies and estimation of recombination and natural selection from DNA sequence data follows.

1.4.1 Models of DNA Substitution

All methods used to infer phylogeny make assumptions about the DNA substitution process, and phylogenetic analyses thus strongly depends on the model of DNA substitution used for a particular analysis. Therefore, all phylogenetic analyses should first determine which model of DNA substitution best fits a particular set of data (48). Models that are a poor fit for the data being analyzed can easily lead to inaccurate and biased phylogenies (49). Four major models of DNA substitution, including the Jukes and Cantor (JC69), Kimura-2-Parameter (K2P), Hasegawa, Kishino and Yano (HKY85), and General Time Reversible (GTR) models will be briefly discussed.

The JC69 model is the simplest model of DNA evolution and assumes equal base (A, T, G, and C) frequencies and an equal rate of substitution for all bases. The K2P model is similar to the JC69 model, except K2P allows a different rate of substitution for transitions and transversions. While both the JC69 and K2P models are easily computed, they are greatly simplified and do not reflect realistic DNA sequence evolution. The HKY85 model relaxes some of the assumptions of the JC69 and K2P models by allowing base frequencies and rates of substitution for transitions and transversions to be estimated from the actual sequence data. The JC69, K2P and HKY85 models are all reversible, that is, the probabilities of changing from A to T and from T to A are equal. The GTR model is a model in which one unit of time is the time in which we expect to see one substitution per base (46); in this model a different substitution rate for each of the six possible substitutions between the four bases is estimated from the sequence data. The GTR is the most general model of DNA evolution and all other models described above are nested within the GTR.

The likelihood ratio test is widely used to test the goodness of fit of different models of DNA substitution for a given set of DNA sequence data. Maximum likelihood methods to estimate phylogeny (discussed in more detail later) produce a log likelihood estimate for the most likely tree topology determined under a specific model of DNA substitution. The test statistic for the likelihood ratio test is calculated by multiplying by two the difference between the log likelihood estimate of the null model and alternative model. The test statistic is approximated by a chi-square test and the degrees of freedom are determined by the difference in the number of parameters between the nested models. The likelihood ratio test can thus be used to determine which model of DNA substitution best fits a given set of DNA sequence data.

Molecular studies indicate that all sites along a sequence do not change at the same rate and, in fact, a gamma distribution may explain among site substitution rate heterogeneity (50). The addition of a gamma distribution to explain substitution rate heterogeneity along DNA sequences to the most likely model of DNA evolution often significantly improves the ability to describe DNA sequence data for phylogenetic analysis. Furthermore, mutation rate variation may be described by assigning different weights to changes occurring at different positions in the codon; these models can also account for a proportion of invariable sites (51). The likelihood ratio test can also be utilized to evaluate the ability of these additional parameters to explain the heterogeneity of mutation rate along DNA sequences.

Posada and Crandall (48) developed the MODELTEST program, which allows an evaluation of 56 different nested DNA substitution models coupled with various other parameters (i.e., substitution rate heterogeneity). MODELTEST specifically uses log likelihood scores to select the model of DNA evolution and the additional parameters that best explain a given set of sequence data. However, it should be noted that this program uses Neighbor-joining trees to evaluate models of DNA substitution and evolutionary parameters. Therefore, the model and conditions determined by MODELTEST should be validated using the likelihood ratio test and a maximum likelihood tree to ensure the highest accuracy of inferring phylogeny.

1.4.2 Estimating Phylogenetic Trees

A phylogenetic tree consists of nodes and branches; furthermore, branches connect nodes, which are points where two or more branches diverge. While nodes signify taxonomic units, branches describe the descent and ancestry among taxa in the phylogenetic tree (52). Phylogenetic trees are composed of monophyletic groups known as clades, which share a more recent common ancestor than any other taxa on the tree (53). Trees may be presented either with a root (rooted tree) or without a root (unrooted tree), and the tree branching pattern is known as the tree topology. A rooted tree contains a specific node, known as the root, and the distance from the root to any other node on the tree is the same. Rooted trees should only be constructed for data that have been shown to follow a molecular clock, which implies that evolution occurs at a constant rate among lineages within a phylogeny; in these trees the root functions as the common ancestor for all taxa in the phylogeny. Although an unrooted tree describes the relationship between taxa, this phylogenetic presentation fails to define the course of evolution for the taxa being studied (Figures 1.2A, 1.2B). While most phylogenetic data follow a molecular clock, and can therefore be used for construction of rooted trees, phylogenetic tress for taxa that do not follow a molecular clock should be presented as an unrooted tree with an outgroup included. Any organism thought to have diverged earlier than the taxa being studied can be used as an outgroup to root an unrooted tree (9,54). Numerous approaches, including distance based, maximum parsimony, maximum likelihood, and Bayesian inference methods have been used for reconstructing phylogenetic trees, and are briefly described in the following sections.

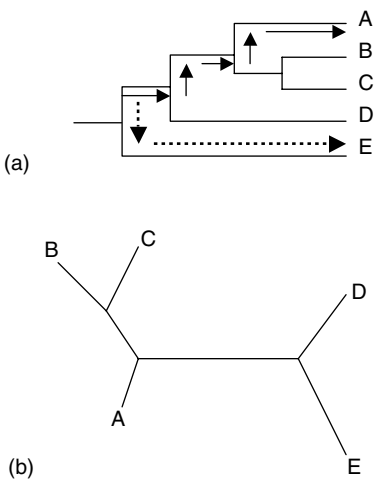

Figure 1.2 Rooted (a) and unrooted (b) five taxa phylogenetic trees. The evolutionary path for each taxa can be traced in the rooted tree as depicted by arrows.

1.4.2.1 Distance Based Methods to Infer Phylogeny

Distance based methods to estimate phylogeny calculate the difference in the number of nucleotide substitutions between all possible pairs of taxa and compress DNA sequence data to a distance matrix to estimate evolutionary distance. The major advantage of distance based methods is that they are very fast, but information is generally lost when DNA sequences are analyzed as a distance matrix, and an accurate estimate of the true phylogeny can be difficult to attain for diverse taxa. Neighbor-joining is the most popular distance based method, and Neighbor-joining trees can be constructed in several phylogenetic analysis programs, including PAUP* (50), PHYLIP (55) and MEGA (56). An unfavorable aspect of using distance based methods to construct phylogenetic trees is that, in some circumstances, these methods may yield two or more equally plausible tree topologies for a given data set. These trees must then be carefully evaluated to determine the reliability of branching patterns in order to prevent making incorrect inferences about the evolution of genes or populations represented by these alternative tree topologies (57). Neighbor-joining trees often serve as the starting point for more computationally intensive approaches to determine phylogeny (58).

1.4.2.2 Parsimony Methods to Infer Phylogeny

Unlike the distance based methods mentioned above, the phylogenetic trees estimated by maximum parsimony and maximum likelihood approaches illustrate the evolutionary relatedness of a group of taxa. Parsimony is a valuable approach for analyzing data without complex underlying model assumptions (59). Maximum parsimony conducts a site by site analysis to reconstruct a phylogenetic tree from sequence data; the number of nucleotide changes is summed over all sites to assign a parsimony score to each possible tree topology. Both the maximum parsimony and maximum likelihood phylogenetic approaches typically utilize what is known as a heuristic search to explore a large number of tree topologies (60). The tree with the least amount of changes is selected as the phylogenetic estimate of the data, and is termed the most parsimonious tree by the maximum parsimony method (61). More specifically, the shortest route or the fewest number of evolutionary changes that leads to the observed state of the sequence data is selected as the correct phylogeny. Maximum parsimony approaches are included in PAUP*, PHYLIP, and MEGA.

1.4.2.3 Maximum Likelihood Methods to Infer Phylogeny

Maximum likelihood selects the most likely phylogeny by assigning a maximum likelihood value to each character state arrangement within the sequences being studied and selects the tree topology with the highest maximum likelihood value. Specifically, phylogenetic trees generated under different models (which can also include additional free evolutionary parameters) are compared. A likelihood value is generated for each phylogenetic tree, and a heuristic search using these values determines the most likely tree topology under each hypothesized model and the parameters to select the most likely tree observed for a given data set (62). One of the main advantages of the maximum likelihood approach is that the likelihood ratio test can be used to define the model of DNA substitution and the additional parameters (e.g., mutation rate variation and molecular clock hypothesis) that best explain the observed DNA sequence data. Simulation studies (63,64) showed that the maximum likelihood approach determined the correct phylogeny more often than other methods including Neighbor-joining and parsimony methods. The most comprehensive and reliable phylogenetic program for utilizing maximum likelihood methods is PAUP*.

1.4.2.4 Measures of Confidence for Traditional Phylogeny Estimation Methods

Bootstrapping is a method to measure how strongly the sequence data actually support the phylogeny that has been inferred by traditional phylogenetic analysis methods. This tool has been widely used to assign a measure of confidence to each clade of a phylogenetic tree (65). The bootstrapping procedure works by randomly resampling (with replacement) the original data to generate replicate data sets, which are used to repeat the selected phylogenetic analysis on each replicate data set. The proportion of times that each clade observed in the original topology is recovered in replicate topologies is the bootstrap value (58). Bootstrap values have been criticized for being too conservative, and determining bootstrap values may be computationally intensive for phylogenies inferred by complex evolutionary models or for data sets with a large number of taxa (65).

1.4.2.5 Bayesian Methods

Bayesian methods are a close relative of maximum likelihood with the major exception being that Bayesian methods incorporate a prior distribution to explain the probability that a given tree topology is correct. Maximum likelihood relies on selecting the tree topology that shows the relationship of the taxa, branch lengths, and phylogenetic model parameter estimates that correspond with maximizing the probability of observing the DNA sequence data; while Bayesian statistics depend on the posterior probability of these characteristics to infer phylogeny (49). The model that maximizes the posterior probability is the most favorable one in the Bayesian perspective. The Bayesian approach relies on the Markov chain Monte Carlo (MCMC) search algorithm to sample the tree space (all possible tree topologies). One of the main advantages of Bayesian phylogenetics is that the primary analysis yields both a phylogenetic tree and a measure of confidence for grouping of taxa on that tree. Additionally, Bayesian methods can be used to estimate divergence times and to identify sites under recombination (58). Bayesian phylogenetic analysis can be performed in the MrBayes program (66).

1.4.3 Measuring Recombination

Due to the increasing availability of DNA sequence data for one or multiple bacterial genes or gene fragments from different isolates (e.g., from MLST analyses), analysis of DNA sequence data is now often used to probe for evidence of recombination among bacterial isolates (67). In recent years, it has become apparent that horizontal gene transfer and recombination of bacterial housekeeping genes occurs more commonly than originally anticipated (68). Traditional methods to infer phylogenetic relationships among organisms assume that recombination is absent. If recombination has occurred within a given DNA sequence data set, conclusions about the genealogy drawn from these sequences may therefore be incorrect. Different nonparametric and parametric methods have consequently been developed to probe for evidence of recombination and to estimate recombination rates based on DNA sequence data.

1.4.3.1 Nonparametric Methods to Detect Recombination

Several nonparametric methods have been developed to detect the presence of recombination in a set of DNA sequences without actually describing the rate at which recombination occurs. These nonparametric methods used to collect evidence of lateral gene transfer events can be divided into two classes: comparative, and phylogenetic dependent approaches. However, these comparative and phylogenetic based nonparametric methods are only useful to detect the presence of recombination in sequence data sets and so are limited due to their inability to estimate the rate of recombination in underlying populations (69).

Estimating the rate of recombination is crucial, though, to determine the validity of phylogenetic inferences and measure the diffusion rate of advantageous mutations and transfer of genetic information (70).

Comparative nonparametric methods attempt to recognize specific genes that appear to be atypical in comparison to the content of the complete genome (71). These methods specifically use multiple sequence alignments to detect regions within a sequence that show more similarity in base composition and codon usage than is expected by chance. These comparative methods have been used to identify evidence of horizontal gene transfer in bacterial species (20,72,73). The application of these methods to compare bacterial genomes to uncover acquisition of pathogenicity via incorporation of foreign genetic material is discussed in greater detail in the section on "Molecular evolution and diversity of selected food borne pathogens".

In addition, phylogenetic based methods can be used to identify uncharacteristic distribution of genetic information between organisms. Conflicting phylogenetic signals within a gene or between genes from the same organism provide evidence for recombination. For example, the split decomposition method for inferring phylogeny (74) does not force sequence data into a treelike structure. Instead, this method allows conflicting phylogenetic information between taxa to be visualized as a meshlike network. Generation of this meshlike network can thus be interpreted as evidence for conflicting phylogenies and may indicate recombination has occurred.

When determining the phylogenetic relationship of a group of taxa, DNA sequence data may be partitioned to give different weights to specific nucleotide changes (i.e., synonymous versus nonsynonymous changes), or sequence data from multiple genes may be combined to improve phylogenetic accuracy. Several parsimony based methods including the Templeton test, incongruent length difference test, and Rodrigo test evaluate the degree of incongruence between partitions in sequence data. These tests may be used to evaluate the accuracy of partitioned and combined data by determining whether the degree of incongruence observed for data partitions significantly affects the phylogenetic signal (75). If a dataset shows significantly different phylogenetic signals for different partitions, one might conclude that recombination occurred.

Several approaches have been utilized to assess the consistency of phylogenetic signal inferred along DNA sequences as a means to detect recombination. One approach implemented in the program called RETICULATE calculates a compatibility matrix based on pairwise comparison of all polymorphic sites in aligned sequences. Two sites are compatible if a phylogeny exists in which all nucleotide changes at the site can be inferred to have occurred only once; incompatible sites require multiple mutation events, indicating that these sites have experienced recombination or repeated mutation (76). The observed compatibility is then compared to the neighborhood similarity value obtained for a high number of randomized matrices (e.g., 10,000). A significant difference between the observed similarity value and the similarity and randomized matrix values may indicate that recombination has not occurred (77). Evaluation of the similarity matrix and a similarity matrix plot can also be used to identify likely regions of recombination, as shown by Reid et al (76).

Other approaches using sliding window analyses to detect evidence of recombination include the Dss (Difference in the sum of squares) method, which has been implemented in TOPAL. In this method, a sliding window is moved along the nucleotide alignment. The window is then split into two halves and a phylogenetic tree is estimated based on the first half of the window. This tree is used to compute the goodness of fit scores for both parts of the window; the Dss value represents the difference between these goodness of fit scores for each window (78). The same calculation is subsequently repeated with sliding windows

moving in the opposite direction. The highest Dss value between the reverse run and the forward run becomes the Dss statistic for that window (78). These calculations yield a Dss value for each sliding window along the sequence alignment. Parametric bootstrapping (Monte Carlo simulation) is then used to simulate a distribution of Dss values under the null hypothesis that no recombination has occurred. The resulting 99% significance point of Dss obtained from the Monte Carlo simulation is used to identify observed Dss values above the threshold (99%) Dss, indicating regions with conflicting phylogenies, which may have been caused by recombination events. RECPARS [as detailed in Hein, 1993 (79)] represents another method that uses a parsimony based approach to probe for evidence of recombination in DNA sequences. This method overcomes the problems associated with using a finite window in a sliding window analysis. In this approach, the best phylogenies for different regions of the aligned sequences are defined; and a recombination event is postulated for sites that correspond to a transition from one tree topology into another topology.

Several methods, including the homoplasy test and the index of association, may be used to detect repeated recombination in a population. These tests recognize stretches of linked nucleotides with unique ancestry as potential recombination events. The homoplasy test implemented in the program HOMOPLASY TEST (80) builds a maximum parsimony tree for a sequence data set and the number of homoplasies (h) is calculated by subtracting the number of polymorphic sites from the number of steps required to build the tree. If the population is clonal then h is expected to equal zero, but if recombination has occurred then h is expected to be larger than 0. Another measure of recombination is the index of association (I_A), which has been used to analyze recombination in MLEE data. In this method, the variance of genetic diversity between pairs of isolates (observed variance) is divided by the variance obtained for a shuffled matrix (expected variance) to yield the I_A; if the I_A is greater than 1, the data is not greatly influenced by recombination (80–81).

Another approach, known as the informative sites test (implemented in PIST), evaluates the underlying assumption of clonality in DNA sequence data sets by analyzing the relationship between substitution rate heterogeneity and recombination. More specifically, the polymorphic site composition is expected to differ in data sets affected by recombination induced rate heterogeneity, while clonal data sets should maintain a more constant rate. The informative sites test compares the number of parsimony informative sites to an expected distribution of this number in clonal data sets generated by Monte Carlo simulation. An excess of parsimony informative sites indicates that null hypothesis of clonality is not valid (82).

1.4.3.2 Parametric Methods to Detect Recombination and Measure Rate of Recombination

Parametric methods rely on describing linkage disequilibrium within the haplotype structure of population genetics data. Specifically, these methods estimate population recombination rates from population genetic data by estimating the likelihoods for theta (effective population size multiplied by mutation rate) and r (per site recombination divided by per site mutation) rates under a coalescent based population genetics model (70,82,83,84). Several methods examine linkage disequilibrium between segregating sites to identify recombination. Linkage disequilibrium based methods offer the ability to make inferences about both the observed data and the underlying population, thus allowing estimates of the actual rate of recombination (69).

Husmeier and Wright (85) formulated an approximate Bayesian approach to discriminate between alternative sequence partitions that may have resulted from exchange of genetic information between taxa within a set of DNA sequence data. This method

performed well when compared to nonparametric sliding windows methods like RECPARS (79) and TOPAL (86), but is limited by the number of taxa that can be analyzed.

The RECOMBINE program (84) uses maximum likelihood estimation under a neutral model of evolution via Metropolis Hastings sampling to search many recombinant genealogy reconstructions that are weighted by the posterior probability of the data and use different parameter values. A distinct advantage of this method is the ability to include other parameters such as population growth estimators [FLUCTUATE, (87)], and migration rate estimators [MIGRATE, (88)] in an analysis. By simultaneously estimating these population genetics parameters in the LAMARC package, the bias that could be introduced by estimating each parameter separately and by ignoring the effects of other important population parameters can be greatly reduced. Although this method is very powerful, it is also is very computationally intensive. Furthermore, the lack of ability to assess the validity of the likelihood estimate and to make statistical inferences represents limitation of this method (89).

In 2001, Hudson (89) suggested an approximate likelihood coalescent based method to estimate the recombination rate parameter in populations under a neutral mutation rate by assessing the level of linkage disequilibrium between sites. In contrast to the full multisite likelihood methods described previously, Hudson (89) used likelihood methods to analyze recombination in all pairwise combinations of segregating sites. Hudson reported that the presence of more than two linked polymorphisms within a given data set would lead to some loss of information in comparison to full likelihood methods. This method is intended to be used on data sets where full likelihood methods are not computationally practical.

McVean et al. (70) extended Hudson's method to accommodate bacterial and viral genomes that are expected to have high nucleotide substitution rates and contain sites that may have experienced multiple mutations. These patterns of genetic variation may be falsely categorized as recombination events, leading to bias in the estimation of the population recombination rate. McVean et al. (70) modified Hudson's method by implementing a finite sites mutation model and also suggested a likelihood permutation test to test the null hypothesis of no recombination. This group reported that both the likelihood permutation test and Hudson's method appeared to work well for data sets that contain recurrent mutations. Moreover, the likelihood permutation method was shown to be more powerful than the formerly described permutation methods and was not sensitive to specification of an incorrect mutation model (70).

1.4.4 Detecting Natural Selection and Models of Population Genetics

The strictly neutral theory of evolution (90) revolves around the concept that all mutations are either neutral or strongly deleterious. All alleles in a population evolving under the strictly neutral model have the same fitness; moreover, the estimation of many population genetic parameters assumes strict neutrality. Neutrality tests including Tajima's *D* test (91) and the HKA test (92) are designed to detect deviation from this strictly neutral model of evolution. Noncoding regions in DNA sequences (e.g., intergenic regions), as well as synonymous changes in coding regions, are assumed to not be influenced by selective constraints. The objective of Tajima's *D* test is to assess this assumption of neutrality by sampling sequences from a population and comparing the number of segregating sites and the average number of nucleotide differences (54). The HKA test is designed to test the hypothesis that the level of DNA variation is correlated both within and between populations, which is expected if the neutral assumption holds true (9). In 1973, Ohta (93) developed the "slightly deleterious model", which included slightly deleterious mutations but continued to disallow positive selection. Kimura (94) modified the strictly neutral model to describe negative mutations as following a gamma distribution and termed this model the

effectively neutral model. In contrast, others (95–96) have suggested models of evolution that include positive selection (97).

1.4.4.1 Estimating Synonymous and Nonsynonymous Substitution Rates

The ability to identify adaptive evolution at the protein level is an important tool in evolutionary biology. Selection at the amino acid level can be detected by measuring the nonsynonymous:synonymous substitution rate ratio ($\omega = d_N/d_S$). Synonymous or silent mutations for the most part do not influence natural selection, while nonsynonymous or amino acid changing mutations may be under strong selective pressure. By evaluating the fixation rate of synonymous and nonsynonymous mutations, valuable insight into the evolution of specific protein coding sequences may be gained. An ω greater than 1 indicates evidence for positive selection; nonsynonymous mutations may thus have a distinct fitness advantage and become fixed in the population more rapidly than synonymous mutations. Values of $\omega = 1$ and $\omega < 1$ indicate neutral and purifying evolution, respectively. Codon substitution models that allow ω to vary among sites can be implemented to identify functionally constrained amino acid sites as well as to recognize specific amino acid sites that may be under positive selection. Analyzing the variation of ω among lineages can be used to determine if adaptive evolution is occurring in specific lineages of interest compared to other lineages in a data set (98–100).

1.4.4.2 Prediction of Amino Acid Sites Under Positive Selection

The ability to detect positive selection at specific amino acid sites has important implications in the biological and medical sciences. Several methods have been introduced for the purpose of assessing variability in selective pressures across amino acid sites. The Suzuki and Gojobori (SG) method is a parsimony based method that reconstructs the ancestral sequence state and counts the number of changes at each site along a tree to identify excessive nonsynonymous substitution events (101). This method is implemented in the ADAPTSITE program to test the null hypothesis of neutrality at each codon (102). Suzuki and Nei (103) conducted computer simulations to compare the SG parsimony method to likelihood methods. The authors indicated that likelihood methods were more prone to yield false positive results and parsimony seemed to be a more conservative method.

Nielsen and Yang developed codon substitution models of heterogeneous d_N/d_S ratios among sites using a maximum likelihood framework implemented in the PAML program (104). This maximum likelihood approach uses the likelihood ratio test to compare nested models, to determine whether or not a gene is undergoing positive selection. If the likelihood ratio test is significant and the null model, which does not allow for sites with $\omega > 1$, is rejected in favor of an alternative model that allows for sites with $\omega > 1$, then that gene is considered to be under positive selection. Once a gene is determined to be experiencing positive selection, an empirical Bayes approach is employed to predict which specific amino acid sites are positively selected for (105,106). More specifically, the posterior probability that a site fits in each ω class within the model given the data observed at that site is calculated, and sites with a high posterior probability of falling into the site class of $\omega > 1$ are considered to be under positive selection (107). In 2002, Yang and Swanson (108) refined these codon substitution models to allow sites to be partitioned into classes when prior information about specific sites indicates that those sites are expected to have different selective pressures. These models can be used to test the hypothesis that sites with an explicit biological function might be under diversifying selection or for combined analysis of several protein coding genes from the same taxa to evaluate substitution patterns.

1.4.4.3 Detecting Adaptive Evolution in Lineages

A lineage that experienced Darwinian selection would be expected to show a d_N/d_S ratio that is greater than one or is different from that of other lineages. Messier and Stewart (109) used both parsimony and likelihood approaches to reconstruct the ancestral state of lysozyme genes from extinct ancestors in a phylogeny. This reconstructed ancestral sequence, and the observed sequences, were used to determine d_N and d_S by making pairwise sequence comparisons along each branch or lineage in the primate phylogenetic tree. In 1998, Yang (110) raised concerns about the reliability of using parsimony methods to reconstruct the ancestral sequence and implemented likelihood methods to infer d_N and d_S from lineages in a phylogeny without using the reconstructed ancestral sequence state. In addition, the likelihood models developed by Yang (110) account for transition or transversion rate and codon usage bias that are not addressed in the pairwise comparison methods implemented by earlier researchers. Yang (110) developed several codon based models that permit ω to vary among lineages; however, these models assume that ω remains constant among sites. In addition, the codon substitution models described above assume that ω is invariable among lineages in the phylogeny. These nested models can then be used to perform the likelihood ratio test to establish whether or not ω is variable among lineages, and ultimately if specific lineages of interest demonstrate a d_N/d_S ratio that is greater than one, which would indicate that those lineages were under adaptive selection.

1.5 MOLECULAR EVOLUTION AND DIVERSITY OF SELECTED FOOD BORNE PATHOGENS

1.5.1 Evolution of *Escherichia coli*

Although most *E. coli* strains represent harmless commensals that are part of the normal flora of the gastrointestinal tract, several pathogenic *E. coli* groups that are associated with diverse human and animal diseases have been described. The acquisition of various sets of virulence genes has been critical in the evolution of these pathogenic *E. coli*. After its divergence from *Salmonella* around 100 million years ago, *E. coli* has undergone significant genetic change, and most of the horizontally transferred genetic material in *E. coli* is thought to have been acquired fairly recently (111). Genome comparisons have shown that about 25% of the genes found in *E. coli* do not appear to have homologs in the *Salmonella enterica* genome (112). Comparison of the complete genome sequences available for both *E. coli* K-12 (44), a nonpathogenic laboratory strain, and *E. coli* O157:H7, a pathogenic strain, (43) have shown that while 4.1 million base pairs represent genomic information conserved between the two genomes, 1.34 million base pairs of the *E. coli* O157:H7 genome were specific to this serotype. This analysis also identified some novel putative virulence genes unique to *E. coli* O157:H7 (113). It has been predicted that almost 18% of the *E. coli* K-12 chromosome was introduced from external sources and that the new genes were acquired in at least 234 separate events. (111). Horizontal gene transfer and loss of DNA are thus thought to have significantly contributed to the phenotypic differentiation of *E. coli* and *S. enterica* (111).

Within *E. coli* there are over 200 recognized O antigen serotypes and around 30 H antigen types (114). There are at least five recognized pathotypes of diarrheagenic *E. coli*, including enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), and enteroaggregative *E. coli* (EAEC). Each of these pathotypes is characterized by specific virulence traits. While strains belonging to EPEC, EHEC, ETEC, and EIEC have all been implicated in water or

food borne outbreaks, it is still uncertain whether EAEC strains should be considered food borne pathogens (114). Enterohemorrhagic *E. coli* (EHEC), which includes *E.coli* O157: H7, have been an important cause of water and food borne outbreaks in various developed countries. First recognized as an emerging human food borne pathogen in the early 1980s, *E. coli* O157:H7 can cause severe hemorrhagic colitis as well as hemolytic uremic syndrome (HUS). The EHEC pathotype represents a subset of the Shiga toxin-producing *E. coli* (STEC), which includes all *E. coli* strains that share the ability to produce shiga toxins (Stx) (113). The ability to produce shiga toxins is one of the main characteristics that distinguishes EHEC from EPEC strains. The two main forms of the shiga toxin, Stx1 and Stx2, are encoded on bacteriophages (115).

Although most *E. coli* pathotypes fall into clonal lineages, EHEC and EPEC strains group into divergent lineages. Based on MLEE data, these two pathotypes have been divided into EPEC 1 and EPEC 2, as well as into EHEC 1 (*E. coli* O157:H7) and EHEC 2; EPEC 2 and EHEC 2 are the most closely related lineages (113). These data are consistent with a model that assumes the EHEC pathotype represents two distinct evolutionary emergence processes. Even though the Stx producing EHEC 2 group is quite divergent from *E. coli* O157:H7 strains, they do possess the same key virulence factors and could possibly become a significant emerging pathogen (113).

One feature that is common to almost all EHEC and EPEC is the presence of an approximately 35-kb pathogenicity island termed the locus of enterocyte effacement (LEE). This LEE island includes virulence genes that encode proteins responsible for bacterial adhesions to epithelial cells and the formation of the "attaching and effacing" (A/E) lesions characteristic for both EHEC and EPEC. One of the genes found in the LEE, *eae*A, encodes intimin, which is expressed in both EHEC and EPEC. Intimin is an outer membrane protein that shows similarity to proteins found in other pathogens (116). Tir, which serves as the host cell receptor for intimin, is also encoded in the LEE; this protein is translocated into host cells via the *E. coli* type III secretion systems. The intimin gene has shown high variability and has at least five antigenic types that usually correspond to particular lineages (117). Although there are some exceptions, α intimin is common to EPEC 1 strains, β intimin is mostly found in EPEC 2 and EHEC 2 strains, and γ intimin is generally associated with EHEC 1 strains (117). The genetic variations that are seen in intimin may be due to selective pressures that are often placed on outer membrane proteins in an effort to escape recognition by host immune responses (116). The LEE island was most likely acquired through horizontal gene transfer, because it is absent from nonpathogenic strains of *E. coli* and has a lower G+C content than the rest of the *E. coli* genome (113). Interestingly, the LEE has been found to be located at more that one chromosomal site; in *E. coli* with α or γ intimin it is inserted into *sel*C, but in strains with β intimin the insertion site is in *phe*U (76). These finding support the hypothesis that lateral acquisition of LEE has occurred at least twice in the evolution of *E. coli.* The *sel*C tRNA locus has also served as an integration site for other PAIs, including SPI-3 in *S. enterica* and SHI-2 in *Shigella flexneri* (2).

Even though O157:H7 falls into the EHEC category, this serotype is most closely related to *E. coli* O55:H7, an EPEC that does not produce shiga toxins but carries the LEE (118). Unlike most other *E. coli* strains, O157:H7 lacks the ability to ferment sorbitol (Sor-) and lacks β-glucuronidase activity (GUD-). However, one nonmotile (H-) *E. coli* O157 strain that was able to ferment sorbitol (Sor+) has been identified in an outbreak of HUS in Germany (113). Based on the various data available on the characteristics of different EPEC and EHEC strains, an evolutionary model of the emergence of *E. coli* O157:H7 has been proposed by Feng (118). An EPEC like *E. coli,* that expressed α-glucuronidase (GUD+) and fermented sorbitol (Sor+), and carried the LEE, served as an ancestor for

E. coli O55:H7. Subsequent phage mediated acquisition of Stx2 resulted in a shiga toxin producing *E. coli* O55:H7 strain, followed by a change in somatic antigens from O55 to O157 and the attainment of one or more EHEC plasmids, which encode various putative virulence factors including a hemolysin operon (113). Two lineages subsequently evolved from this hypothesized ancestor, one lineage lost the motility phenotype (converting to H-), but remained GUD+, Sor+ and Stx2 positive. The second lineage became GUD- and Sor- but acquired the Stx1gene, giving rise to the *E. coli* O157:H7 clone found worldwide today. If this hypothesis is correct, the German *E. coli* O157:H7 clone diverged early in the evolution of EHEC, since it retained some of the ancestral characteristics that are not seen in the *E. coli* O157:H7 isolated today (113).

In addition to the LEE pathogenicity island, the pathogenicity characteristics of EPEC strains are also associated with a plasmid know as the EAF (EPEC adherence factor) plasmid, which is present in most EPEC strains (119). The EAF plasmid includes the gene encoding the bundle forming pilus (Bfp), a specific virulence factor that facilitates bacterial adhesion to epithelial cell surfaces. Unlike EHEC strains, which lack the genes necessary to synthesize Bfp, EPEC strains have a characteristic adherence pattern known as localized adherence (120). Although the localized adherence phenotype typical for EPEC may not be exclusively due to Bfp, recent data has shown that Bfp are necessary for full virulence in EPEC strains (120).

Enteroinvasive *E. coli* strains have also been implicated in food borne disease cases and outbreaks (114), but they do not tend to group with EHEC or EPEC strains in phylogenetic trees (113). These strains are genetically similar to *Shigella* species and their virulence mechanisms are remarkably similar (121). Unlike most other *E. coli*, EIEC strains, as well as *Shigella* species lack lysine decarboxylase activity, which is encoded by *cadA,* which appears to have been lost in EIEC and *Shigella* species together with a large, approximately 90 kb region, of their genome. Loss of *cad*A gene leads to an inability to produce cadaverine, a molecule that acts as an enterotoxin inhibitor. This *cadA* deletion has thus been hypothesized to be responsible for an enhanced virulence of EIEC and *Shigella* species (13).

The ETEC pathotype includes *E. coli* strains that secrete one or both of the following entertoxins, LT, a heat labile toxin and ST, a heat stable toxin (119). The LT can be divided into the LT-I type, a toxin that is structurally and functionally similar to cholera entertoxins, and the LT-II type, a type that does not appear to play any role in human disease pathogenesis (121). The heat stable toxins also fall into two groups, STa and STb, with the genes encoding STa found on plasmids (119).

1.5.2 Evolution and Diversity of *Salmonella*

The genus *Salmonella* includes over 2,100 serovars, which are divided into two divergent species, *Salmonella enterica*, which contains seven subspecies (I, II, IIIa, IIIb, IV, VI, and VII), and *Salmonella bongori,* which was formerly classified as subspecies V (122). It has been estimated that the common ancestor for the genus *Salmonella* arose between 35 and 40 million years ago (123). Subspecies I, which includes *S. enterica typhimurium*, represents strains that are highly specialized to infect mammals and birds, and this subspecies accounts for more than 99% of enteric and systemic *Salmonella* infections in humans (124). Although the number of typhoid fever cases (caused by *Salmonella typhi*) has steadily decreased in the United States, the incidence of nontyphoidal salmonellosis has gradually increased to an estimated 1.4 million cases per year (125), with only a few serovars causing the majority of human cases (126).

While some *S. enterica* serovars have a broad host range (e.g., *typhimurium* and *enteriditis*), other serovars appear to be host adapted (e.g., *typh*i in humans). Based on

MLEE analysis, serovars that can infect a wide range of hosts have much greater genetic variability than serovars that are host specific (122). Although the acquisition of virulence genes may play a role in host adaptation, other factors such as selective pressure and competitive exclusion also play an important role in the evolution and ecology of *Salmonella*. For example, *S. enterica gallinarum*, an avian adapted serotype (O9 antigen, D1 serogroup) was eradicated from poultry in the US and Europe in an attempt to decrease economic losses. As long as *Salmonella gallinarum* was present in poultry flocks, other D1 serogroup strains may have been excluded from circulating in poultry, due to the presence of flock immunity against the O9 antigen. After the eradication of *Salmonella gallinarum* in the 1970s, the loss of flock immunity against the O9 antigen appears to have led to the availability of a new niche that was filled by another D1 serogroup, *S. enterica enteriditis*. The exclusion of *Salmonella gallinarum* from poultry thus may have led to the emergence of a new pathogen that triggered a human salmonellosis epidemic (127). This example clearly shows the complex nature of the evolution and population genetics of food borne pathogens, which is affected not only by pathogen factors, but also by host and environmental factors.

As in *E. coli*, horizontal acquisition of virulence genes and PAIs appears to have played a major role in the evolution of virulence characteristics in *Salmonella*. It has been specifically hypothesized that the fact that *S. enterica* serovar strains have the ability to affect a wide range of hosts and cause a variety of different disease manifestations, even though they appear to have a high genetic relatedness based on sequence data, may be largely due to lateral gene transfer of virulence genes (122). *Salmonella* has at least five known PAIs (termed *Salmonella* pathogenicity islands, SPI-1 through SPI-5) that encode an array of virulence factors ranging from epithelial cell invasion to systemic spread (128). These SPIs have not been found in related enteric species, e.g., *Shigella* or *E. coli*, and thus appear to have been introduced into the *Salmonella* genome rather recently, since *Salmonella*'s divergence from *E. coli* (129). SPI-1, which encodes genes that promote *Salmonella* invasion into human host epithelial cells (the *inv/spa* genes), is found in all *Salmonella* lineages, and is thus thought to be have been acquired early in the evolution of *Salmonella,* probably by an ancestor to all *Salmonella* (130). This 40 kb pathogenicity island (SPI-1) appears to have been acquired through horizontal gene transfer because it has a much lower G+C content (42%) than the rest of the genome. Also, several of the genes on SPI-1 are similar to invasion genes found on the *Shigella* virulence plasmid. Homologs of several of the *inv/spa* genes, which are known to aid in bacterial internalization into host cells, have also been found in various other bacterial pathogens even though their locations in the genome can vary (131). While most PAIs are usually flanked by tRNA genes, which are target sites for DNA integration, SPI-1 is bordered by two housekeeping genes, *fhl*A and *mut*S. The remaining SPIs are located near tRNA loci: SPI-2 is flanked by the *pyk*F gene and the *val*V tRNA gene; SPI-3 is located downstream of the *sel*C tRNA gene; SPI-4 is located downstream from an unspecified tRNA gene; and SPI-5 is located downstream of the *ser*T tRNA gene (128).

The SPI-2 island contains more than 40 genes and is divided into two segments, a 14.5 kb piece and a 25.3 kb piece, which may have been transferred into the genome in two distinct steps (132). SPI-2 was probably horizontally transferred into the *S. enterica* genome after its divergence from *S. bongori,* because several of the genes in SPI-2 are not found in *S. bongori* serotypes. The larger portion of the SPI-2 island, which is only found in *S. enterica,* was probably acquired more recently than the smaller segment of the island, which is found in both *Salmonella* species (132). SPI-2 also has a lower G+C content (41%) than the rest of the *Salmonella* genome, further supporting horizontal acquisition of this PAI. The genes found on SPI-2 appear to be specifically important for the ability of *Salmonella* to cause systemic disease (130).

The SPI-3 island, which has a mosaic structure, possesses several genes that are required for virulence and survival within the macrophage (122). Although SPI-3 is quite small (17 kb), the full island is not present in all *Salmonella* species, suggesting that it was acquired in multiple steps (128). The genes of the two remaining islands, SPI-4 and SPI-5, appear to play less of a role in virulence, with many of the genes functions still unknown (122).

Salmonellae also have various chromosomal fimbrial operons, which encode proteins that appear to be critical for host cell attachment and infection initiation. The specific distribution and expression of fimbrial operons among serovars may also affect the host range of different *Salmonella* strains, similar to what has been proposed for enteropathogenic *E. coli* (133). The *fim*, *lpf* and *agf* fimbrial operons were probably acquired early in the evolution of *Salmonella*, although *lpf* appears to have subsequently been lost from several lineages (133). In contrast, the distribution of the *ser* and *pef* fimbrial operons has been limited, probably due to recent acquisition by the *Salmonella* genome (133).

The acquisition of other mobile elements, such as plasmids, phages, and transposable elements, has also played a major role in the evolution of *Salmonella*. Phage genomes as well as phage remnants are widespread within the *Salmonella* chromosome, with many of them encoding important virulence factors. Most *Salmonella* serovars also carry a putative virulence plasmid bearing the *spv* genes. While these genes were initially thought to be important in the survival of *Salmonella* in the host, several groups could not find any evidence for a role of the *spv* gene products in intracellular survival. Further studies on these genes are thus necessary to clarify their function (132). Horizontal gene transfer of antibiotic resistance has also been of importance in the evolution of food transmitted *Salmonella* strains. For example, one strain of *S. enterica typhimurium*, known as definitive type (DT) 104, has emerged as a worldwide health concern because of its resistance to multiple antibiotics. It is resistant to at least five antibiotics including ampicillin, streptomycin, sulfonamides, tetracycline, and chloramphenicol (32). While the antibiotic resistance genes found in DT104 appear to be located on the chromosome, they are surrounded by plasmid and phagelike genes, supporting acquisition by lateral gene transfer and subsequent site specific recombination (122). Interestingly, although PFGE has been used quite successfully in the typing of *Salmonella* Typhimurium strains, DT104 has tested the discriminatory limits of PFGE with its genetic homogeneity (134). Because it is based on tandem repeats in DNA, VNTR has been shown to have a greater discriminatory power than PFGE for distinguishing among DT104 strains (134). These observations support the idea that DT 104 represents a recently emerged genetically homogeneous subtype, and also illustrate the potential for VNTR based subtyping methods for studies on the evolution and population genetics of genetically homogenous bacterial pathogen clones.

While we clearly already have acquired a considerable understanding of the evolution of *Salmonella*, the increasing availability of complete genome sequences for *Salmonella* serovars, including *S. enterica typhimurium* LT2 and *S. enterica typhi* CT18 (42,135) as well as other closely related organisms like *E. coli*, will provide the ability to further probe the genome evolution of these important human food borne pathogens.

1.5.3 Evolution and Diversity of *Listeria monocytogenes*

Of the different species within the genus *Listeria,* only *L. monocytogenes* is considered a human pathogen. Virulence characteristics of *L. monocytogenes* appear to be primarily associated with the presence of different pathogenicity islands, including the *prfA* virulence gene island and different virulence gene islands carrying genes of the internalin family (136). Recent comparative genomics studies facilitated by the availability of full genome sequences for *L. monocytogenes* and the closely related nonpathogenic species

L. innocua also identified additional virulence genes unique to *L. monocytogenes,* such as *bsh* which encodes a bile salt hydrolase (41). Interestingly, the *prfA* virulence gene island, which encodes most of the major *Listeria* virulence genes, has also been identified in the animal pathogen *L. ivanovii* and in the nonpathogenic species *L. seeligeri*. In *L. seeligeri*, the *prfA* virulence gene cluster appears to be improperly expressed apparently making this species incapable of causing human disease (136).

Classically, *L. monocytogenes* has been differentiated into 13 serotypes, with greater than 90% of human listeriosis cases caused by serotype 1/2a, 1/2b, and 4b strains. While the majority of human clinical infections occur as sporadic cases, human listeriosis can also occur in large epidemics. Most sporadic human listeriosis cases and large human food borne listeriosis epidemics have reportedly been caused by *L. monocytogenes* serotype 4b (28). Serotypes 1/2a and 1/2b are also responsible for significant numbers of sporadic cases of human illness, and a serotype 1/2a strain was responsible for a recent multistate human listeriosis outbreak in the USA (137). Serotyping data collected by the CDC in 1986 showed that serotypes 1/2a (30%), 1/2b (32%), 4b (34%) represented the majority of isolates from 144 human sporadic cases (138). Of 1,363 human isolates collected in the UK, 15% were 1/2a, 10% were 1/2b, and 64% were 4b (139). The remaining ten currently recognized *L. monocytogenes* serotypes have been only rarely linked to human disease. This apparent association between a few specific *L. monocytogenes* strains and most cases of human listeriosis raises the intriguing challenge of identifying unique characteristics enabling these strains to be more effective than others in causing human disease. Two hypotheses could explain the apparent predominance of serotype 4b strains in human epidemic listeriosis, and of 4b, 1/2a, and 1/2b strains in sporadic human cases: humans are more commonly exposed to these subtypes as compared to other *L. monocytogenes* serotypes, i.e., these strains are found in foods more frequently than other serotypes; or these subtypes have a unique pathogenic potential for humans.

Molecular subtyping methods have consistently grouped *L. monocytogenes* into two major lineages. Multilocus enzyme electrophoresis (MLEE), PFGE, ribotyping, and amplified restriction fragment length polymorphism analysis (AFLP) all show that *L. monocytogenes* can be separated into two major genetic groups (28). Allelic analyses of several virulence genes as well as ribotyping revealed a third phylogenetic lineage within *L. monocytogenes.* Specifically, a combination of virulence gene alleles and ribotype patterns allowed separation of *L. monocytogenes* strains into three distinct lineages, designated I, II, and III (28).

Evolutionary analysis of both DNA sequencing (140–141) and microarray data (45) confirmed the existence of two distinct *L. monocytogenes* lineages [previously termed lineages I, and II (140)]. These two lineages correlate with serotype groupings; lineage I comprised serotypes 1/2b, 3b, 3c and 4b; lineage II comprised serotypes 1/2a, and 1/2c (142). Preliminary microarray analyses also identified a considerable number of contigs present in lineage II strains, but absent from lineage I strains (45). Further analysis suggested a model in which the ancestor of the two lineages had the 1/2 somatic serotype, and the regions absent in the lineage I genome arose by loss of ancestral sequences (45). *L. monocytogenes* isolates previously designated as lineage III, which includes the rare *L. monocytogenes* serotypes 4a and 4c, appear to have a mosaic genome structure, based on DNA sequence analyses. Phylogenies based on nonvirulence genes further indicate that lineage III strains may classify into two distinct groups, including at least one group that appears to be closely related to *L. innocua*.

Characterization of a total of 42 human clinical isolates and 502 isolates from ready to eat foods collected in Maryland and California during 2000 and 2001 (143), as well as of 465 additional human clinical isolates collected throughout the USA between 1997 and

2002, was performed to probe associations between specific subtypes and human listeriosis (144). Genotypic analyses of isolates by automated *Eco*RI ribotyping and PCR-RFLP analysis of the *hly* gene (140) allowed assignment of isolates into one of 65 different *Eco*RI ribotypes and into one of three previously described genetic lineages. Statistical analyses showed that, while exclusive associations were rare, the majority of subtypes were significantly associated with isolation from either foods or humans. Using a large isolate set, this study did not only confirm previous data (145,146) that lineage I strains are more significantly associated with human listeriosis cases compared to both animal listeriosis cases and isolation from foods, but also provided specific data on the comparative prevalence of different ribotypes among human clinical and food isolates. Most strikingly, one specific *Eco*RI ribotype (DUP-1062A) was found to represent 30.1% of food isolates, but only 1.8% of human isolates, a highly significant difference in prevalence ($p<0.0001$). Overall these data indicate that the prevalence of certain subtypes among human listeriosis cases is not strictly a reflection of their prevalence in contaminated foods, but might rather reflect virulence differences among *L. monocytogenes* subtypes and clonal groups (28).

Evolutionary analyses of the stress response gene *sigB* and the virulence genes *actA* and *inlA* indicated that while evolution of *sigB* followed a molecular clock model, evolution of *actA* did not follow a clock model, and appeared to be under positive selection ($p<0.005$) as determined by using a likelihood ratio test. Using an empirical Bayes approach, 8 ActA amino acid sites with posterior probabilities $> 95\%$ of being positively selected were identified. Posterior probability plots revealed both highly conserved regions and regions with a significant frequency of positively selected amino acid sites in *actA* (141). These data indicate that active evolution of *actA* may play a role in the development of strain specific virulence characteristics.

In conclusion, currently available data indicate that *L. monocytogenes* is characterized by a predominant clonal population structure (particularly for lineages I and II), although strains previously characterized as lineage III show more diversity and indications for recombination. Both evolution by gene loss and active evolution of specific virulence genes (e.g., *actA*) appear to contribute to evolution of *L. monocytogenes*, including evolution of virulence related characteristics. Recent data (144,146) also support that the previously observed high prevalence of specific *L. monocytogenes* subtypes (e.g., serotype 4b strains) among human listeriosis cases and outbreaks appears to at least partially represent unique virulence characteristics of these subtypes rather then their abundance in contaminated food products.

1.6 CONCLUSIONS

Pathogenesis of food borne pathogens may incorporate complex interactions between the pathogen, diverse environments, and one or more host species. The ability of these pathogens to survive and compete in numerous environments may play an important role in the transmission and pathogenesis of food borne pathogens. Moreover, selective evolutionary pressures exerted by environmental stresses and the host may influence the evolution and emergence of virulence factors that allow specific strains to infect mammalian hosts. Understanding the molecular evolution of food borne pathogens will provide a more complete picture of these organisms' transmission dynamics, and generate essential knowledge required to control these pathogens and prevent their entry into the food system; ultimately reducing the risk of human food borne disease. Furthermore, a thorough understanding of the evolution of food borne pathogens is required to develop reliable subtyping methods for food borne pathogens and to correctly interpret subtyping data, e.g., in food borne disease outbreak investigations.

Genetics and Physiology of Pathogenicity in Food Borne Bacterial Pathogens

Michael Gray and Kathryn J. Boor

CONTENTS

2.1 INTRODUCTION

Food borne diseases are estimated to be responsible for 76 million illnesses, 325,000 hospitalizations, and 5,000 deaths annually in the United States. The pathogens responsible for these illnesses include viruses, eukaryotic parasites, and bacteria. Bacteria are responsible for more than 70% of the deaths attributed to known food borne pathogens (1). Clearly, understanding these bacteria and controlling their presence in foods is a critical element of food safety.

At a physiological level, bacterial pathogens produce characteristic "virulence factors", which are proteins or protein complexes which contribute to the ability of an organism to cause disease in a host. Virulence factors may affect a host directly (e.g., toxins can disable or kill host cells through various mechanisms) or indirectly (e.g., flagella, which are comprised of a long filament and a set of spinning motor proteins, allow bacteria to efficiently move toward and colonize mucosal surfaces). For a pathogen to cause disease, virulence factors need to be produced and active at appropriate times and locations within the host organism. At the genetic level, virulence factors, like all other proteins, are encoded by genes on the bacterial DNA. Regulation of the expression of these genes constitutes the genetics of pathogenicity. In order to fully understand how a given organism causes disease, both the physiology and genetics of its pathogenesis must be deciphered.

Food borne bacterial diseases can be classified into two broad categories based on the virulence factors which are most important in causing the characteristic symptoms of the disease. Intoxications are illnesses with symptoms resulting from the effects of a toxin or toxins. Typically, the toxin alone can cause disease symptoms, even in the absence of live bacteria. Infections, on the other hand, are illnesses with symptoms resulting from growth of the bacteria inside the host. Most food borne pathogens primarily infect the gastrointestinal tract and therefore cause diarrheal symptoms, but some food borne pathogens can penetrate further into the host and colonize other organs. These invasive infections typically have more serious consequences for the host than gastrointestinal infections. In general, the virulence factors necessary for establishing an infection are more varied and complex than the factors involved in intoxications.

The study of the physiology and genetics of virulence has yielded many important insights into the mechanisms by which bacterial pathogens cause food borne illness. In order to obtain an overview of these insights, we will examine three examples of important food borne pathogens and the diseases they cause: *Clostridium botulinum*, which causes botulism, a food borne intoxication, *Escherichia coli* O157:H7, which causes a noninvasive infection, and *Listeria monocytogenes*, which causes listeriosis, an invasive infection. Each of these organisms poses serious human health concerns, and an understanding of how they cause disease is important in efforts to control them as well as to provide insight into the general mechanisms of pathogenesis in other bacteria.

2.2 *CLOSTRIDIUM BOTULINUM*

2.2.1 Introduction and History

Botulism is one of the oldest and deadliest of food borne diseases. One of the earliest reliably recorded outbreaks of what was then known as "sausage poisoning" occurred in Wildbad, Germany in 1793. Thirteen people became sick and six died from eating spoiled blood sausage, but the true cause of the disease was unknown at that time. It was not until a hundred years later, in 1897, that Dutch bacteriologist Emile Pierre Marie van Ermengem was able to isolate a pure culture of a bacterium he called *Bacillus botulinus* (after *botulus,* the Latin word for sausage) and demonstrate the essential facts about the organism responsible for food borne botulism (2).

2.2.1.1 Characteristics of Botulism

Food borne botulism is an intoxication. Ingestion of live bacteria is unnecessary for disease to develop; all that is required is consumption of a toxin produced by the bacteria. This toxin is among the most poisonous substances known, and as little as 0.1 to 1 μg may

be lethal for a human (3), although some other species, such as dogs and chickens, are resistant to its effects (2). The botulism toxin causes paralysis by blocking neurotransmitter release. Paralysis generally starts with the nerves in the face and head, works its way downward, and is fatal if it reaches the heart or lungs (2). Botulism toxin is heat labile, so cooking food thoroughly will inactivate the toxin. Heating to 85°C for 5 minutes is enough to inactivate the most thermostable botulism toxin tested (4).

Before 1950, botulism had a very high mortality rate (approximately 60%), but improvements in supportive care and the availability of antitoxin have reduced the case fatality ratio to 15.5% (5). A vaccine, made from inactivated toxin, is available, but not commonly given to humans. This is mostly due to the expense and risk associated with production of large quantities of botulism toxin. Alternative methods for production of a botulism vaccine are being explored, but none have yet been fully developed (6).

On average, there are 23 reported cases of food borne botulism in the U.S. per year, mostly associated with consumption of improperly home canned or pickled foods, with approximately one death per year. *Clostridium botulinum* can also cause occasional wound infections, particularly associated with the abuse of injected drugs, and infant botulism, which results from the colonization of an infant's intestinal tract by *C. botulinum*, leading to production of toxin inside the child's intestine. Because commercial food processing is very effective at preventing food borne botulism, infant botulism is now the most common form of botulism in the U.S. (5).

2.2.1.2 Characteristics of Clostridium botulinum

Clostridium botulinum is a Gram-positive obligate anaerobic spore-forming bacterium (7). Gram-positive bacteria have a single cytoplasmic membrane with a thick peptidoglycan layer. As an obligate anaerobe, growth of *C. botulinum* is inhibited by oxygen. Spores are a stress tolerant resting state formed by *C. botulinum* and some other Gram-positive bacteria. The spores of *C. botulinum* are resistant to heat: boiling at 100°C for half an hour is only sufficient to reduce their numbers by 90% (a one log reduction, or one D value). Canning processes are designed to produce a 12D reduction in numbers of *C. botulinum* spores at temperatures of 121°C. This 12D process ensures a very low risk of *C. botulinum* survival and outgrowth in the anaerobic interior of a given can. Under most conditions, *C. botulinum* will not produce toxin at a pH below 4.6, so high acid foods (for example, many tomato products) require less stringent heat treatment than foods with a higher pH (2).

Historically, any Gram-positive, spore-forming anaerobe which produces botulism toxin has been classified as *C. botulinum* (3). Modern taxonomy methods, involving comparison of conserved DNA sequences, including the sequences encoding 16S rRNA, have shown that this group of bacteria is extremely diverse. Some researchers have proposed reclassifying *C. botulinum* into as many as 20 different genera and several families (8,9).

2.2.1.3 Classification of C. botulinum

Clostridium botulinum was first classified into different categories according to toxin type. In 1904, only seven years after Van Ermengem's isolation of *C. botulinum*, G. Landmann reported that the organism responsible for a botulism outbreak in Darmstadt, Germany produced a toxin with similar activity to Van Ermengem's strain, but antitoxin prepared against one would not cross protect against the other. These two types were later designated type A and type B. Over the course of the next 70 years, five more toxin types were discovered and given alphabetical designations (C–G) (2). Toxin types A, B, and E are associated with human disease, while types C and D are associated with animal disease (10).

Clostridium botulinum strains are also classified according to their physiological properties into four major Groups. Group I strains produce proteolytic enzymes and their spores are the most heat and acid tolerant. They produce toxins of type A, B, or F. Group II strains are nonproteolytic and much less heat tolerant than strains in the other groups, but they can grow at lower temperatures. For example, some Group II strains can grow at refrigeration temperatures (approximately 4°C). They produce toxins of type B, E, or F. Group III and IV strains are not associated with human disease, so are less well studied, but group III strains, associated with animal disease, are nonproteolytic and produce toxin types C or D. Group IV strains, which produce toxin type G, are not known to be associated with disease in either humans or animals (11).

2.2.1.4 Sources in the Environment

Clostridium botulinum is found in soils and sediments world wide, but different types are commonly found in different types of environments, which affects their prevalence in foods and the patterns of disease they cause. For example, strains producing type A and B toxins are both commonly found in relatively dry soils. In the U.S., type A strains are most common in soil west of the Rocky Mountains, with type B strains more common in the eastern U.S. This parallels the pattern of disease-causing strains in these regions. Similarly, *C. botulinum* in marine sediments commonly produce type E toxin, and botulism outbreaks caused by seafood are most frequently caused by type E strains (2).

2.2.2 Virulence Factors

2.2.2.1 The Botulism Toxin

The most important virulence factor of *C. botulinum* is the botulism toxin. As mentioned, this toxin is one of the deadliest poisons known (3). Because botulism is an intoxication, other properties of the organism are less important in the course of the disease. In fact, some strains of *C. botulinum* are phenotypically indistinguishable from other species of *Clostridium* (such as *C. novyi* or *C. sporogenes*) except for their ability to produce the botulism toxin (7).

Botulism toxin is released from *C. botulinum* by cell autolysis late in the growth cycle (3). The toxin is a zinc endopeptidase, a proteolytic enzyme which requires zinc and specifically cleaves synaptic proteins (VAMP, SNAP, or syntaxin, depending on the toxin type) in mammalian neurons, inhibiting release of the neurotransmitter acetylcholine at motor neuron synapses (10). As little as one toxin molecule can totally destroy function of a neuron (6). The result of this activity is paralysis, as the muscles controlled by the affected neurons become unable to contract. This is termed flaccid paralysis and may be fatal if the lungs or heart become paralyzed (10). As intensive care technology, especially artificial respiration, has advanced, the prognosis for victims of botulism poisoning has improved, although survivors are likely to have lingering neurological symptoms (5).

2.2.2.2 Toxin Structure

Botulism toxins are all similar in molecular structure. They are transcribed as a single polypeptide with a molecular weight of about 150,000 Daltons. This polypeptide has relatively low toxicity. Active toxin is produced by proteolytic cleavage of the polypeptide into a heavy (~100 kDa) and a light (~50 kDa) chain, linked by a single disulfide bond (11). Strains of *C. botulinum* which produce their own extracellular proteases (for example, the Group I strains) are more toxic than nonproteolytic strains, even if similar amounts of toxin protein are produced (2).

Botulism toxin belongs to a class of toxins called AB toxins. The light chain (or A subunit) is the active part of the toxin, and harbors the zinc endopeptidase activity. The heavy chain (or B subunit) is required for the light chain to cross the cell membrane into the host cell and is responsible for specific binding to neurons (10). A number of accessory proteins are also found bound to the botulism toxin protein to form large toxin complexes. These include HA (hemagglutinin) proteins and the large (~150 kDa) NTNH (nontoxic, nonhemolytic) protein. Depending on the specific strain, toxin type, and growth conditions of the culture, the final toxin complex may range in size from ~300 to 900 kDa (3). The accessory proteins are not required for toxicity, but seem to be involved in protection of the neurotoxin from proteolytic attack in the host environment (10).

2.2.3 Sporulation

Without toxin production, *C. botulinum* is avirulent, but the ability of *C. botulinum* to form heat resistant spores can also be considered an important virulence factor. Many harmless bacteria form spores, but in *C. botulinum* the ability to sporulate is important in how the organism causes disease. In order for botulism to occur, four conditions must be met:

1. *Clostridium botulinum* must be present in the food.
2. The bacteria must survive processing. Spores are critical in this stage, as they can survive conditions which kill normal bacterial cells.
3. Conditions must enable germination and outgrowth of spores, along with the associated production of toxin, i.e., anaerobic conditions within the food, a pH above about 4.6, high enough water activity to support growth ($a_w > 0.94$), and a temperature which allows the bacteria to reproduce (20°C − 45°C) (2).
4. The intact toxin must enter the body. If contaminated food is cooked thoroughly before consumption, the toxin will be destroyed (2).

One of the reasons botulism is so dangerous is because the spores can survive common cooking and preservative methods (condition 2). For example, a recent outbreak of botulism in Thailand resulted from consumption of bamboo shoots which had been canned and boiled for an hour. They were then stored at ambient temperature for 3–6 months (12). Without spores able to survive boiling, as well as storage conditions which encouraged the germination and growth of the spores, *C. botulinum* would not have been able to produce toxin in the food and cause disease.

Sporulation of *C. botulinum* begins in late exponential phase of growth (13). Spores develop at one end of the cell and have a complex structure. At the center of the spore is the protoplast which contains the tightly packed DNA. This is surrounded by several protective layers including the cytoplasmic membrane, the cortex (composed of peptidoglycan and diaminopimelic acid), and the inner and outer spore coats (which have a keratin-like structure and are rich in disulfide bonds). The spores are resistant to a number of stresses including heat, drying, radiation, alcohol, and acid (2).

2.2.4 Genetics and Regulation

2.2.4.1 Toxin Genes

The genes encoding botulism toxin and its various accessory proteins are found grouped together in the botulism toxin gene cluster (Figure 2.1). The exact genes in the cluster vary

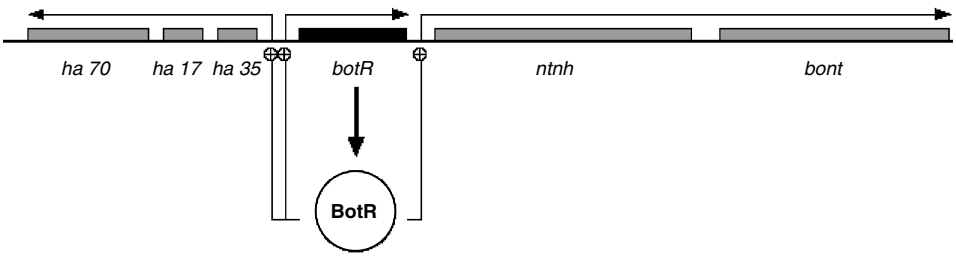

Figure 2.1 Regulation of virulence genes in *Clostridium botulinum*. The botulism toxin gene cluster shown is typical of a toxin type A strain. Gene products are as follows: *ha70*, *ha17*, and *ha35* = hemaglutinin proteins, *botR* = BotR regulatory protein, *ntnh* = nontoxic nonhemolytic protein, *bont* = botulism neurotoxin. BotR is a positive regulator at each of the three promoters indicated by +

among strains of different toxin types, but the toxin gene (*bont*) is always found associated with a gene immediately upstream which codes for nontoxic nonhemolytic protein (NTNH). The island also commonly contains genes for hemagglutinin proteins (*ha17*, *ha35*, and *ha70*) and a regulatory gene (*botR*) which will be discussed in more detail in what follows. Some toxin gene clusters also include other genes which encode proteins of unknown functions (3).

All of the different toxin types have had representative toxin gene clusters fully sequenced, and the degree of relatedness among them has been determined by DNA sequence homology. All of the botulism toxins have significant regions of similarity, suggesting that they are closely related to one another (11). The tetanus toxin of *C. tetani* is also related to the botulism toxins and has a similar structure and mode of action. The tetanus toxin, however, has different specificity and results in a spastic paralysis, in which the muscles affected contract and cannot relax, rather than the flaccid paralysis characteristic of botulism (10).

The genes for the botulism toxin are known to be located on pseudolysogenic bacteriophages for toxin types C and D and on large plasmids for toxin type G. A pseudolysogenic bacteriophage is a viral genome, integrated into the bacterial chromosome, which has lost some of the genes necessary to produce active phage particles. Plasmids are loops of DNA separate from the chromosome in the bacterial cytoplasm. In the absence of evidence for location on a mobile or extrachromosomal element, the genes for the other toxin types (A, B, E, and F) are assumed to be chromosomal. This has been shown to be the case for at least one type A strain of *C. botulinum* (3). The presence of some toxin genes on extrachromosomal elements suggests that it may be possible for these genes to be horizontally transferred from one bacterium to another, conveying the ability to produce botulism toxin to a previously nonpathogenic strain. In fact, strains of *C. butyricum* have been found which produce a type E neurotoxin which is 97% identical to that found in type E *C. botulinum* (11).

2.2.4.2 Regulation of Toxin Production

The genetic regulation of toxin production is still poorly understood, but several important points are known. The botulism toxin gene cluster in most toxin types contains a gene for a regulatory protein called BotR. BotR is required for toxin expression (at least in type A strains), has homology to known transcriptional regulators, such as TetR from *C. tetani* and UviA from *C. perfringens*, and has structural characteristics typical of this type of regulatory protein, including a DNA binding helix-turn-helix motif. BotR has been shown to bind

to the promoter regions of NTNH and *ha35*, and overexpression of BotR results in overproduction of toxin and accessory proteins. BotR is therefore a positive regulator of toxin production. Some evidence has been found suggesting that there may also be negative regulation of toxin production. This might involve a regulatory protein or proteins which decrease expression of toxin genes, but the genes encoding this putative regulator or regulators have not yet been found. It is also unknown what upstream factors might influence the expression of BotR or botulism toxin (3).

2.2.4.3 Sporulation Genes

The regulation of sporulation is slightly better understood than the regulation of toxin production. While relatively few studies have directly examined the sporulation genes in any species of *Clostridium*, much less those of *C. botulinum*, it is clear from what has been observed that there is a fundamental similarity between the genes for sporulation in *Clostridium* and those found in the well studied genus *Bacillus* (13). In *Bacillus*, sporulation involves a complex regulatory network including a multi component phosphorelay chain and multiple alternative sigma factors. The phosphorelay is a signaling system which detects various stimuli and transmits a signal through the cell by transferring phosphate groups from one protein to another, ultimately activating transcriptional regulators. Sigma factors (symbolized by the Greek letter σ) confer specificity to RNA polymerase, and allow the bacterium to regulate transcription of large numbers of genes simultaneously (14).

Homologues of many of the sporulation specific sigma factors from *Bacillus* have been found in various *Clostridium* species. Genes encoding clostridial versions of the sigma factors σ^E, σ^G, and σ^K have all been found in *C. acetylbutylicum*, and the organization of these sporulation genes is very similar to that in *Bacillus*. Many of the phosphorelay genes also have homologues in *Clostridium*, including *spo0A*, *spoIIGA*, and *spoIID*. In addition, the promoter sequences for the clostridial sporulation genes match the expected sequences based on what is known from *Bacillus*. This suggests that the sporulation specific sigma factors also regulate genes involved in sporulation in *Clostridium* (13).

There are, however, distinct differences known in the regulation of sporulation between *Clostridium* and *Bacillus*. Sporulation is initiated by *Bacillus* species in response to starvation conditions, while *Clostridium* species cannot sporulate without an available carbon source. Sporulation in *Clostridium* is triggered by the cessation of growth or by exposure to oxygen. The mechanism and physiological rationale behind this difference are unknown (15), but it demonstrates that knowledge of sporulation in *Bacillus* is not sufficient to fully understand how sporulation is regulated in *Clostridium* species.

2.2.5 Summary

C. botulinum is the cause of botulism, a food borne intoxication. The botulism toxin (encoded by the *bont* gene) is a potent neurotoxin which can cause fatal paralysis. The toxin gene is located on a virulence gene cluster along with genes for several accessory proteins (NTNH, *ha17*, *ha35*, and *ha70*) and a transcriptional regulator called BotR (encoded by *botR*) which is a positive regulator of toxin production. *Clostridium botulinum* produces heat tolerant spores which contribute to pathogenicity by allowing the bacteria to survive some food processing methods. Regulation of sporulation in *C. botulinum* has some parallels with sporulation in *Bacillus*. Modern food processing techniques are very effective at preventing botulism, and this disease is now very rare in developed countries.

2.3 *ESCHERICHIA COLI* O157:H7

2.3.1 Introduction and History

In contrast to the long history of *C. botulinum*, *Escherichia coli* O157:H7 (classified as a strain of EHEC, enterohemorrhagic *E. coli*) has emerged quite recently as an important cause of food borne illness. The first outbreak of *E. coli* O157:H7 infection was described in 1982. Forty-seven people in two states were sick with severe abdominal pain and bloody diarrhea. The Centers for Disease Control and Prevention associated the disease with consumption of hamburgers at a restaurant chain by isolating and identifying *E. coli* O157:H7 from both human clinical cases and from uncooked ground beef patties. Prior to this outbreak, isolation of *E. coli* O157:H7 had been extremely rare (16–18). Pathogens which appear to be new or rapidly increasing in incidence are considered to be "emerging pathogens."

2.3.1.1 Characteristics of Disease

Since 1982, *E. coli* O157:H7 has been identified as the cause of increasing numbers of food borne illness (18). As of 1999, it was estimated to be responsible for approximately 73,000 illnesses and 61 deaths each year in the United States (1). *Escherichia coli* O157:H7 infection has a lower mortality rate than botulism (approximately 1% of cases), but this is still much deadlier than most food borne illnesses. Two to seven percent of infections result in a complication called hemolytic uremic syndrome (HUS). HUS occurs primarily in children under five and in the elderly, and can result in acute kidney failure. People who develop HUS may also suffer various long term complications including abnormal kidney function, high blood pressure, or seizures (17–19). Another rare but dangerous complication of *E. coli* O157:H7 infection is thrombotic thrombocytopenic purpura (TTP), which occurs mostly in adults and results in hemolysis, renal failure, neurological problems, and blood clots in the brain (18,19). TTP has been associated with a deficiency (either genetic or acquired) in an enzyme called von Willebrand factor-cleaving metalloprotease (20).

The majority of *E. coli* O157:H7 outbreaks have been associated with ground beef, but outbreaks have been linked to foods as diverse as Romaine lettuce, milk, apple cider, mayonnaise, coleslaw, and contaminated drinking water (18,21). Some of these foods (e.g., cider, mayonnaise) are unusual vectors for food borne disease due to their high acidity, but *E. coli* O157:H7 may have unusually high acid tolerance.

A major difference between *E. coli* O157:H7 and *C. botulinum* is that *E. coli* O157:H7 causes an infection, not an intoxication. In order for disease to develop, live *E. coli* O157:H7 cells need to be ingested and survive to colonize the host's large intestine and colon. *Escherichia coli* O157:H7 does not seem to penetrate the epithelial cells of the intestine in large numbers, so is considered generally noninvasive (17,22). The infective dose, or number of cells which must be ingested in order for the disease to develop, is remarkably low. Various studies have yielded estimates from 20 to 700 cells (17,18,23). In contrast, related strains of *E. coli* which cause milder forms of diarrheal disease (EPEC, enteropathogenic *E. coli*) require $> 10^8$ cells for an infection to become established (23,24).

2.3.1.2 Characteristics of E. coli O157:H7

Escherichia coli O157:H7, like other *E. coli* strains, is a Gram-negative, facultatively anaerobic bacterium (7). Gram-negative bacteria have a double cell membrane with a thin peptidoglycan layer between the two membranes. A facultative anaerobe can grow either

in the presence or absence of oxygen (25). The designation O157:H7 is an example of a serotype. Serotyping allows differentiation of strains of bacteria based on the immunological properties of their surface proteins. For *E. coli*, there are three commonly typed surface antigens. The O antigen is the lipopolysaccharide (LPS) of the outer membrane, found in all Gram-negative bacteria. The H antigen is flagellar and the K antigen is used for strains which produce a polysaccharide capsule. Each separate antigen is numbered as new types are distinguished (18,26). In addition to serotype O157:H7, a number of other EHEC serotypes, including O111:H-, O26, and O103 have been associated with a similar diarrheal disease (17,19,23).

A relative of *E. coli* O157:H7, the nonpathogenic lab strain *E. coli* K-12, is an extensively studied and well understood model organism. Comparisons between *E. coli* K-12 and *E. coli* O157:H7 have been informative in determining what factors allow *E. coli* O157:H7 to cause severe disease (27). There are metabolic differences between the two strains, notably *E. coli* O157:H7's inability to ferment the sugar sorbitol or produce the enzyme β-glucuronidase, which have been useful for laboratory differentiation of *E. coli* O157:H7 from other *E. coli* strains (18,19,27).

The complete genomic DNA sequences of examples of both *E. coli* K-12 and *E. coli* O157:H7 have recently been determined (27). The two strains share 4.1 megabases (Mb) of very similar sequence, but large sections of each genome are unique to one strain or the other. *Escherichia coli* O157:H7 has 1387 genes (1.34 Mb of DNA) not found in *E. coli* K-12, while *E. coli* K-12 has 528 genes (0.53 Mb) not found in *E. coli* O157:H7 (27). The genes unique to *E. coli* O157:H7 have been examined to determine which of them are likely to contribute to virulence. The unique sequences include several bacteriophages integrated into the chromosome and clusters of genes encoding potential virulence factors such as secretion systems and adhesins. Among these the toxin-carrying bacteriophage Stx1 and Stx2 and a large pathogenicity island called the LEE (locus of enterocyte effacement) have been shown to make significant contributions to virulence. Many other potential virulence factors are as yet relatively uncharacterized (27).

2.3.1.3 Relatives of E. coli O157:H7

Escherichia coli belongs to a group of Gram-negative organisms known as enteric organisms, which are common inhabitants of the gastrointestinal tracts of animals, including humans, and include other species of food borne pathogens, including *Salmonella* and *Shigella* (7). The most important toxin produced by *E. coli* O157:H7 is called Shiga-like toxin, which is almost identical to the toxin produced by *Shigella dysenteriae*, the bacterium which causes dysentery (17,28). *Escherichia coli* which produce Shiga-like toxins (including *E. coli* O157:H7) are often grouped together as Shiga toxin producing *E. coli* (STEC) (17,23) or verocytotoxigenic *E. coli* (VTEC) (26). Not all types of *E. coli* which can produce Shiga-like toxin are implicated in causing human disease (17,23). The presence of other virulence factors, such as adhesins, secretion systems, or other toxins, appears to be necessary for efficient pathogenesis.

Strains of *E. coli* which do not produce Shiga-like toxins include harmless symbiotic bacteria as well as various pathogenic types. Examples of *E. coli* types which cause diarrheal disease are enteropathogenic *E. coli* (EPEC), enteroaggregative *E. coli* (EAggEC), enteroinvasive *E. coli* (EIEC), and enterotoxigenic *E. coli* (ETEC) (29). The diarrhea caused by these strains is more common [responsible for an estimated 160,000 illnesses per year in the U.S. (1)] and typically milder than that caused by *E. coli* O157:H7, although it is a significant cause of infant death in the developing world (25). Some of the virulence associated secretion systems and adherence factors found in these strains (particularly EPEC) are also found in *E. coli* O157:H7 (17,23).

2.3.1.4 Sources in the Environment

Escherichia coli are common commensal organisms found in the intestines of animals. Commonly, STEC are found among the colonic microflora of cattle (17,18). Cattle and other livestock are believed to be important reservoirs of *E. coli* O157:H7 and the presence of the bacteria in food is often associated with contamination by cattle feces. Ground beef is particularly vulnerable to this form of contamination during slaughter and processing, and more outbreaks are associated with foods of bovine origin than with any other source (17,18), but several outbreaks have been traced to the use of improperly treated manure as fertilizer for fruits or vegetables (19,30). About 4% of cattle herds in North America and the UK are positive for *E. coli* O157:H7 at any given time (17,18), but infection of any individual cow appears to be a very transient event (19,31). Cattle do not appear to naturally develop symptoms of STEC infection. The infectious dose in the laboratory for healthy adult cattle is extremely high ($>10^7$ cells), and experimental infections did not result in any diarrhea in cattle except in very young calves (19,31).

2.3.2 Virulence Factors

Escherichia coli O157:H7 has many virulence factors, not all of which have been fully characterized. This is in distinct contrast to botulism where a single, well understood factor (the botulism toxin) dominates the course of disease. In order for *E. coli* O157:H7 to cause its characteristic disease, the bacteria employ a number of adhesins, secretory systems, and toxins. Development of infection occurs in several distinct steps, each of which brings a different set of virulence factors into play.

2.3.2.1 Acid Tolerance and Low Infective Dose

The first step of *E. coli* O157:H7 infection is consumption of contaminated food. As mentioned, the infective dose of *E. coli* O157:H7 appears to be extremely low, and the organism can survive in relatively high acid foods like apple cider and fermented sausages. These characteristics may be related. A high acid tolerance might allow *E. coli* O157:H7 to survive passage through the acidic environment of the stomach. There are at least three known acid tolerance mechanisms in *E. coli*, but *E. coli* O157:H7 is only slightly more acid tolerant than the tested non-O157 *E. coli* strains (17,19,23). Whether acid tolerance contributes to the low infective dose of *E. coli* O157:H7 has not been clearly established.

2.3.2.2 Adhesion to the Intestinal Epithelium

Once *E. coli* O157:H7 reaches the large intestine, it adheres to the intestinal epithelium and produces characteristic lesions called attaching and effacing (A/E) lesions (17,18,24). Adhesion is an important stage of infection because it protects the bacteria from being flushed out of the gastrointestinal tract by peristaltic movements. Attachment of cells to the intestinal wall is well characterized in EPEC and EAggEC, in which specific proteins called adhesins mediate attachment. These adhesins include filamentous structures such as bundle-forming pili and fimbriae, as well as nonfilamentous outer membrane proteins (24,32). However, *E. coli* O157:H7 does not appear, in general, to possess these types of adhesins (17,23). The initial steps of *E. coli* O157:H7 adhesion to the intestines are not yet well understood.

2.3.2.3 A/E Lesions

The formation of the A/E lesion, on the other hand, is quite well characterized. A/E lesion formation has been most extensively studied in EPEC, but the mechanisms appear to be very similar in *E. coli* O157:H7 (17,24). In an A/E lesion, the bacterial cells form a strong, intimate attachment to the surface of the intestinal epithelium. The attached bacteria affect

the host cell in such a way that the actin cytoskeleton of the host cells is extensively reorganized. The microvilli (projections on the surface of intestinal epithelial cells) disappear and are replaced by pedestal structures which support the *E. coli* cells (24). These pedestals can extend up to 10 μm above the surface of the host cell, are rich in host cell cytoskeletal components such as F-actin, α-actinin, and myosin, and move slowly across the surface of the host cell. Beyond their role in the strong attachment of *E. coli* cells to the cells surface, the function of the pedestals is unknown (33).

2.3.2.4 The Locus of Enterocyte Effacement (LEE)

All of the bacterial proteins necessary for the formation of A/E lesions are encoded by genes on the LEE (34). The LEE is a 35.6 kilobase (kb) chromosomal pathogenicity island which contains 5 operons and codes for many different virulence factors. It is found in *E. coli* O157:H7 as well as in some other pathogenic *E. coli*, notably EPEC strains (24). Transfer of the LEE from EPEC into nonpathogenic *E. coli* K-12 is sufficient to allow those bacteria to induce A/E lesions in cultured epithelial cells (35). Exactly how A/E lesions induce diarrhea is unknown, but evidence points toward the disruption of the tight junctions between intestinal cells, alterations in electrolyte transport across host cell membranes, and interactions with the host immune system, all of which could lead to fluid loss in the intestines (24,33).

2.3.2.5 Type III Secretion

Among many other genes, the LEE encodes a type III secretion system which is important in formation of the A/E lesion. Type III secretion systems are common among Gram-negative pathogens, including members of the genera *Yersinia*, *Salmonella*, *Pseudomonas*, and *Chlamydia*, as well as *E. coli*. They mediate contact dependent secretion of virulence factors, and can secrete toxins and other bacterial proteins directly into the host cell cytoplasm (34). The type III secretion apparatus is composed of approximately 10 proteins which form a "needle complex" spanning both the inner and outer membranes. The type III secretion mechanism can translocate proteins across both membranes in a single step (34,36). The needle complex structure appears to be related to the flagellar basal body (36). How the needle complex interacts with and translocates bacterial proteins into host cells is not fully understood (34).

The type III secretion system encoded by the LEE secretes a number of proteins. These include EspA, EspB, EspD, EspF (Esp stands for *E. coli* secreted protein), and Tir (34). All of these are encoded by genes in the LEE, and all except EspF are required for A/E lesion formation. The protein EspA forms filamentous structures on the surface of the bacterial cell and may form a channel between the bacterium and the host cell. Proteins EspB, EspD, and Tir are translocated into host epithelial cells. The exact functions of EspB and EspD are unknown, but they may form a pore in the host cell membrane, and may also act as effectors or toxins. Tir is translocated into the host cell membrane and serves as a receptor for the LEE encoded adhesin intimin. Intimin, a protein found in the *E. coli* outer membrane, binds tightly to Tir in the host cell membrane, and this interaction is required for the tight attachment of EPEC or EHEC to the epithelial cells and for pedestal formation (33,34).

Some differences in A/E lesion formation have been characterized between EPEC and *E. coli* O157:H7. In EPEC, Tir must be phosphorylated at a specific tyrosine residue by the host cell in order to be active. Tir from *E. coli* O157:H7 is not tyrosine phosphorylated (33). The *E. coli* O157:H7 LEE is not sufficient to confer the ability to form A/E lesions on *E. coli* K-12, unlike the LEE from EPEC (37). The reasons for these differences are not known.

2.3.2.6 *Shiga-Like Toxin*

A major difference between *E. coli* O157:H7 and EPEC strains is the presence of Shiga-like toxin, commonly referred to as Shiga toxin or verotoxin. Shiga toxins in *E. coli* O157:H7 are very closely related to the toxins produced by *Shigella dysenteriae*. Shiga toxin causes extensive damage to the intestinal epithelium, leading to bloody diarrhea (23).

Shiga toxins are, like botulism toxin, AB toxins, with an enzymatically active A portion and a B portion involved in binding to host cells. Active Shiga toxin is comprised of five 7.7 kDa B subunits and one 32 kDa A subunit. The A subunit, once internalized by a host cell and cleaved into A_1 and A_2 fragments, inhibits protein synthesis by cleaving an adenine residue from the 28S ribosomal RNA, leading to host cell death and lysis (17,28). The B subunit binds to specific receptors on host cell surfaces. Only host cells with the correct receptor (the cell membrane glycolipid Gb3) will be affected by the toxin. Cells with the correct glycolipid receptors include intestinal epithelial cells and renal endothelial cells (17). This may explain the specificity of Shiga toxins, in particular the severe kidney damage typical of HUS (17,28).

There are two main subtypes of Shiga toxin, called Stx1 and Stx2, which have slightly different properties. Stx2 is 1000 times more toxic to human kidney cells, and is more commonly associated with cases of HUS. Most *E. coli* O157:H7 isolates produce only Stx2, but many STEC produce Stx1, and some produce both types (23). Shiga toxins in *E. coli* strains are associated with bacteriophage sequences, and in *E. coli* O157:H7 both toxin types are encoded on lambdoid lysogenic prophage. Lysogenic prophages have integrated their genomes into the bacterial chromosome. The Stx phages are close relatives of the extensively studied phage lambda (λ). Under certain conditions, these prophages can enter a lytic cycle, where they excise themselves from the chromosome, replicate, and cause cell lysis, releasing phage particles which can infect other *E. coli* (38). The Shiga toxin genes are therefore highly mobile and can in theory be transferred easily among bacteria, for example from *Shigella* to *E. coli* or among *E. coli* strains.

2.3.2.7 *Other Potential Virulence Factors*

Escherichia *coli* O157:H7 has a variety of other genes whose importance to virulence has not been firmly established. Many of these have been identified by comparison of the *E. coli* O157:H7 and *E. coli* K-12 genomes. Genes found only in the *E. coli* O157:H7 genome may encode potential virulence factors (27). One, an extracellular serine protease called EspP, can cleave human coagulation factor V and may affect the blood clotting cascade (23). A hemolysin, a catalase/peroxidase, and a putative type II secretion system are encoded by the large plasmid pO157. This plasmid is almost always found in *E. coli* O157:H7 strains (39). Type II secretion is another system for exporting proteins from the cell to the outside environment which involves a two step translocation across the double cell membrane of Gram-negative bacteria (36). The pO157 plasmid also contains a gene for a protein with significant similarity to one of the cytoskeleton-altering toxins produced by *Clostridium difficile*. However, it is not known whether any of these genes contribute directly to virulence (23).

2.3.3 Genetics and Regulation

The regulation of virulence in *E. coli* O157:H7 is complex, and is accomplished through a combination of virulence factor specific regulatory systems and global regulatory mechanisms, which coordinately regulate expression of large sets of genes throughout the genome. Regulation of *E. coli* O157:H7 virulence genes is still incompletely understood, but regulation of the major virulence factors (the LEE and Shiga toxins) has been extensively studied (See Figure 2.2).

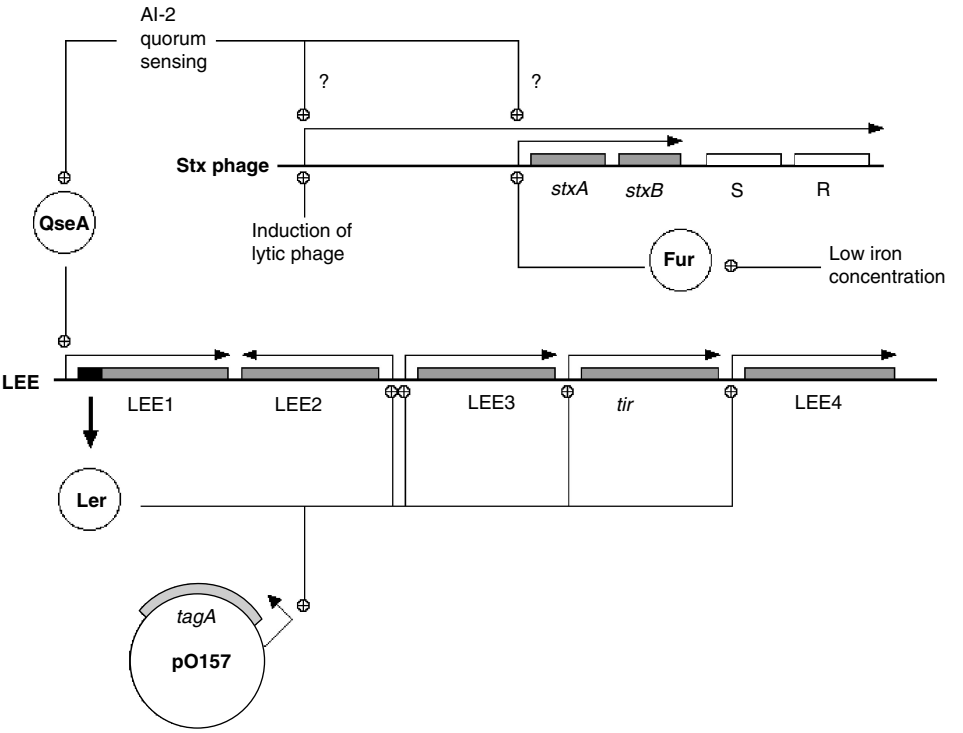

Figure 2.2 Regulation of virulence genes in *Escherichia coli* O157:H7. For simplicity, the multigene operons found in the locus of enterocyte effacement (LEE) are shown as single grey boxes. Gene products are as follows: *stxA* and *stxB* = Shiga toxin subunits, S and R = *Stx* phage late lytic phase proteins, LEE1 = includes *ler* (Ler regulatory protein) and type III secretion system components, LEE2 and LEE3 = type III secretion system components, *tir* = includes *tir* gene (Tir adhesin) and intimin gene, LEE4 = proteins secreted by type III secretion system, *tagA* = TagA protein on pO157 plasmid. The regulatory proteins QseA and Fur are shown without their respective genes, which are encoded at separate chromosomal loci. For each regulatory protein, positive regulation at their respective promoters is indicated by +

2.3.3.1 Structure of the LEE

The LEE is a pathogenicity island 35.6 kilobases in length, and is found in a variety of pathogens which cause A/E lesions. These include EPEC and *E. coli* O157:H7 as well as the animal pathogens *Citrobacter rodentium* and REPEC (rabbit enteropathogenic *E. coli*), among others (40). There are 41 open reading frames (ORFs) in the LEE, organized into 5 operons, termed LEE1, LEE2, LEE3, LEE4, and *tir*. The *tir* operon encodes Tir and intimin (34). The LEE1 operon encodes the regulatory protein Ler and some structural elements of the type III secretion system (*esc* genes – *E. coli* secretion). The rest of the type III secretion system is encoded by LEE2 and LEE3. LEE4 encodes proteins which are secreted by the type III secretion system (*esp* genes). There are several ORFs throughout the LEE which encode proteins of unknown function (40).

2.3.3.2 Regulation of the LEE

Expression of the LEE genes is dependent on several regulatory proteins. These include Ler, a regulatory protein specific to the LEE, as well as global regulatory mechanisms such as quorum sensing and alternative sigma factors.

2.3.3.3 LEE Encoded Regulator (Ler)

The first gene in the LEE1 operon is a gene called *ler* (LEE encoded regulator) (34). Ler protein is a transcriptional regulator whose DNA-binding domain is related to the H-NS/StpA family of DNA-binding proteins (37). Ler binds to the promoters of the other LEE operons (LEE2, LEE3, and *tir*) and activates their transcription (34,41). Activation of transcription of the LEE4 operon appears to be more complex. LEE4 is not expressed in a Δ*ler E. coli* O157:H7 mutant (which has had its *ler* gene deleted), but expression can be restored by addition of a plasmid carrying *ler*. However, when LEE4 is transferred into *E. coli* K-12, it is constitutively expressed at high levels in both the presence and absence of Ler. This suggests that a protein found in *E. coli* O157:H7, but not *E. coli* K-12, acts as a repressor of LEE4 transcription and that Ler acts to derepress LEE4 expression. The identity of this putative repressor is unknown (42). Efficient production of the type III secretion system and other components necessary for formation of A/E lesions (Tir, intimin) requires functional Ler protein in both EPEC and *E. coli* O157:H7 (41,42).

LEE encoded regulator (Ler) also regulates expression of genes outside the LEE in *E. coli* O157:H7. The *tagA* gene, located on the pO157 plasmid, is upregulated in the presence of Ler. The function of TagA is unknown, but it is very similar to TagA from *Vibrio cholerae*, the bacterium which causes cholera, a severe diarrheal disease. TagA in *V. cholerae* is also coregulated with virulence genes and has no known function (42). There is a large protein (110 kDa) which wild-type *E. coli* O157:H7 secretes, but which does not appear in cultures of Δ*ler* mutants. The identity of this protein is unknown. Finally, Δ*ler E. coli* O157:H7 mutants have long slender fimbriae (filamentous structures) which are not seen on the surface of wild-type cells (42).

2.3.3.4 Quorum Sensing

A global regulatory mechanism which affects expression of the LEE is called quorum sensing (34). Quorum sensing is a type of cell to cell communication which bacteria use to coordinate behavior at high cell densities. The bacteria produce a small molecule called an autoinducer. Once the concentration of autoinducer passes a certain threshold, transcription of the regulated genes is activated. Autoinducer concentration is essentially a measurement of bacterial cell density. Quorum sensing is found in both Gram-negative and Gram-positive bacteria, although the biochemical details differ (43).

Gram-negative bacteria may possess two known types of quorum sensing mechanisms. The first was originally discovered in the bioluminescent bacterium *Vibrio fischeri* and involves the genes *luxI* and *luxR*. In these systems, a LuxI type protein synthesizes an acylated homoserine lactone (AHL) autoinducer which diffuses through the cell membrane. Each LuxI type enzyme produces a distinct AHL molecule. The LuxR type protein is a transcriptional regulator which activates transcription of specific promoters when bound to its cognate AHL. LuxI/LuxR systems are widely distributed among Gram-negative bacteria (43).

A second type of quorum sensing in Gram-negative bacteria was discovered more recently. It uses a different type of autoinducer, called AI-2 (autoinducer 2), which is synthesized by an enzyme called LuxS. AI-2 has recently been discovered to be a furanosyl borate diester. Unlike the various LuxI/LuxR systems, which produce different and incompatible AHLs, the LuxS enzymes from a wide variety of species appear to produce the same autoinducer molecule (43). *Escherichia coli* O157:H7 has a *luxS* gene, and uses the AI-2 quorum sensing mechanism to regulate a variety of genes, including virulence genes (34,44,45).

In *E. coli* O157:H7, AI-2 activates expression of *ler*, which in turn activates expression of the rest of the LEE genes (45). Production of Shiga toxin is also upregulated in the

presence of AI-2 (44). In experiments using genomic microarrays, AI-2 appears to regulate as much as 10% of the *E. coli* O157:H7 genome, including genes for cell division, flagella production, and 19 putative transcriptional regulators which could regulate even more genes. One of these, called QseA (quorum-sensing *E. coli* regulator A), has been examined in more detail. A Δ*qseA* mutant can still produce A/E lesions, but secretes significantly reduced amounts of Tir, EspA and EspB. QseA appears to enhance expression of *ler*, but does not have any effect on production of Shiga toxin or other virulence factors (46). The mechanism of Shiga toxin activation by AI-2 is unknown (17,44).

One interesting aspect of the quorum sensing activation of virulence genes in *E. coli* O157:H7 is the fact that identical AI-2 autoinducer is produced by a variety of different bacterial species. This appears to allow for a degree of interspecies communication. Presumably the levels of AI-2 in the large intestine, which has a dense population of bacteria, including *E. coli* and many other Gram-negative organisms, are quite high. One possibility is that *E. coli* O157:H7 detects the high levels of AI-2 in the large intestine and uses this as a signal to initiate infection. In this case, quorum sensing could activate virulence genes even without a dense population of *E. coli* O157:H7. This is consistent with the low infective dose of *E. coli* O157:H7 (17,45).

2.3.3.5 Alternative Sigma Factors

Another global regulatory mechanism used by bacteria involves alternative sigma factors, as discussed, for the regulation of sporulation in Gram-positive organisms. Housekeeping genes in *E. coli* are transcribed by RNA polymerase bound to σ^{70}. Many genes that are transcribed under stressful conditions, including environmental stresses (acid, heat) and entry into stationary phase growth, are transcribed by RNA polymerase bound to σ^{38} (encoded by a gene called *rpoS*) (47).

The promoter sequences for LEE1 and LEE2 are typical σ^{70} promoters, while the LEE3 and *tir* promoters more closely resemble σ^{38} promoters. In a Δ*rpoS* mutant of *E. coli* O157:H7, expression of LEE3 was lower than in the wild-type. It is likely that the genes in LEE3 (including *escV*, *escN*, and *escQ*, which encode genes for structural components of the type III secretion system) and probably *tir* are upregulated under stressful conditions (45). Differences in the *rpoS* genes of *E. coli* O157:H7 and other *E. coli* strains might also explain the slightly higher acid tolerance of *E. coli* O157:H7, but the importance of σ^{38} to virulence in *E. coli* O157:H7 has not yet been established (23). For two other enteric pathogens, *Salmonella enterica* and *Yersinia enterocolitica*, *rpoS* is known to influence the expression of virulence factors (48,49).

2.3.3.6 Regulation of Shiga Toxin Production

In addition to the activation of Shiga toxin production by quorum sensing discussed, there are a number of other factors which influence toxin production and release. As mentioned, Shiga toxins are encoded on integrated bacteriophage (Stx1 and Stx2) which are close relatives of phage λ (17). The regulation of gene expression in λ is one of the best understood systems in genetics, and an understanding of the λ lifecycle is invaluable in understanding expression of Shiga toxins.

2.3.3.7 Bacteriophage Lambda (λ)

Lambdoid phage (those closely related to λ) have both lytic and lysogenic phases to their lifestyle. In the lytic phase, the viral genome is actively replicated in the bacterial cytoplasm

and the proteins which form the phage head are synthesized. Viral genomes are packaged into phage heads, and eventually the bacterium lyses, releasing intact phage particles into the environment. In the lysogenic phase, however, a single copy of the viral genome inserts into a specific site on the bacterial chromosome. An integrated bacteriophage is called a prophage. It is then carried by the bacterium and replicated each time the host cell divides. Although some prophage lose genes necessary for production of phage particles (becoming pseudolysogenic), an intact prophage can excise itself from the chromosome under the right conditions and reenter the lytic phase. In λ and its relatives, this transition is stimulated by the presence of single stranded DNA. In this way the phage can detect damage to the host DNA which may be fatal to the bacterium and produce phage particles, which are more likely to survive in some kinds of damaging environmental conditions than the host cell (47,50).

In many cases, the *stx* (Shiga toxin) genes of *E. coli* O157:H7 reside within fully functional lambdoid prophage. This means that under appropriate conditions, the Stx phage will enter the lytic phase. This has important implications for toxin production (17,38). Not only does it mean that the genes for toxin can be transferred to other bacteria via phage transmission, but production of toxin is coordinated with production of other phage proteins during the phage lifecycle.

2.3.3.8 Regulation of Stx Genes

The *stx* gene is inserted into the Stx phage genome near genes (called S and R) which are involved in the late stages of the lytic phase. It also has its own promoter, called p_{stx1}. The regulation of *stx* expression thus has two distinct aspects.

Expression from the p_{stx1} promoter is dependent on iron concentration. A small amount of toxin is produced under high iron conditions, but 10 times more is transcribed under low iron conditions. Iron dependent regulation of p_{stx1} is dependent on the regulatory protein Fur, which is a global regulator encoded on the *E. coli* chromosome and which is activated by the absence of available iron. Low iron availability is often used as a signal by pathogenic bacteria to determine whether they are in a host, because host environments are typically low in available iron. Under low iron conditions, Shiga toxin accumulates in the cytoplasm of *E. coli* O157:H7, but very little is detected in the surrounding medium (38).

The *stx* gene is also transcribed along with the lytic phase genes of the Stx phage. Any conditions which trigger the transition from lysogenic to lytic growth will also result in greatly enhanced (100-fold) expression of the *stx* gene. Among the known conditions which can induce lytic growth of Stx phage are damage to the bacterial DNA, the presence of some antibiotics, and attack by components of the host immune system (neutrophils). In contrast to the toxin produced by transcription from p_{stx1}, nearly all of the toxin produced under phage inducing conditions is found extracellularly (38).

Shiga toxins cause extensive damage to the intestinal epithelium and are thought to be responsible for the intestinal bleeding associated with *E. coli* O157:H7 infection (17). The induction of toxin production under low iron conditions in the large intestine and subsequent bleeding may allow more efficient growth of *E. coli* O157:H7, because it is able to utilize the iron bound to the hemoglobin in blood (23). Production of toxin under phage inducing conditions may also benefit the bacterium. When *E. coli* O157:H7 is under attack by the immune system, release of toxin from lysed cells may destroy immune cells in the vicinity. This mode of toxin production also helps to explain the observation that antibiotic treatment often results in the worsening of disease symptoms, consistent with more extensive toxin release upon phage induction (18,38).

2.3.4 Summary

Escherichia coli O157:H7 causes a noninvasive food borne infection with serious symptoms, including bloody diarrhea and kidney damage. It has many virulence factors. A large pathogenicity island called the LEE encodes a type III secretion system and other proteins responsible for tight attachment of the bacteria to the intestinal epithelium and formation of A/E lesions. The genes of the LEE are regulated by a specific transcriptional activator (called Ler) as well as by global regulatory mechanisms (which include quorum sensing, and alternative sigma factors). The other primary virulence factor of *E. coli* O157:H7 is the cytolytic Shiga-like toxin, which is encoded by *stx* genes on lysogenic bacteriophage. Production of Shiga-like toxin is also regulated by specific mechanisms (phage induction) and global regulatory mechanisms (quorum sensing and Fur). Both the LEE and the Stx bacteriophage appear to have been transferred more or less intact to *E. coli* O157:H7 from other species of bacteria, transforming a commensal organism into a dangerous pathogen.

2.4 *LISTERIA MONOCYTOGENES*

2.4.1 Introduction and History

Listeria monocytogenes causes a serious invasive disease called listeriosis. It is, like *E. coli* O157:H7, considered an emerging pathogen. However, *L. monocytogenes* is not a newly discovered organism. Murray, Webb, and Swann are generally credited with the first isolation and description of *L. monocytogenes* from the blood of infected rabbits in 1924 (51), but organisms which closely match the modern description of *L. monocytogenes* were isolated from rabbits in 1911, and from human cases of meningitis in 1915 and 1918 (52). The genus *Listeria* was named for the pioneering microbiologist Lord Joseph Lister, who is most famous for his invention of antiseptics for use in surgery (52,53).

During most of the twentieth century listeriosis was not a major human health concern. *Listeria monocytogenes* was known mostly as a pathogen of ruminants, especially sheep, although occasional human cases were seen. Then, in 1982, an outbreak of 41 cases of human listeriosis was linked to consumption of contaminated coleslaw (54). Since that time, recognition of *L. monocytogenes* infections has become more common, and numerous large outbreaks have been observed. *Listeria monocytogenes* is currently estimated to cause approximately 2500 illnesses and 500 deaths per year in the U.S. (1). These cases are usually associated with consumption of contaminated ready to eat foods like deli meats and soft cheeses (55,56). This increase in cases is particularly worrisome, because listeriosis has very serious symptoms unusual for a food borne disease, including central nervous system infection and abortion, and a 20–30% case fatality rate, even with early antibiotic treatment (57).

2.4.1.1 Characteristics of Listeriosis

Listeriosis usually begins with mild, flu-like symptoms, including chills, fatigue, headache, and muscle pain. In nonpregnant adults, this can be followed by increasingly severe symptoms. The symptoms which develop depend on the tissues infected most severely by the bacteria. Meningoencephalitis, which is the infection of the brain tissues and meninges, can cause movement disorders, changes in consciousness, and paralysis of cranial nerves. Systemic infection, or sepsis, has more generalized symptoms, but is equally fatal. In pregnant hosts, the mother is often asymptomatic or only has very mild symptoms, while the fetus becomes severely infected. This may lead to abortion, stillbirth, or sepsis in the newborn. Infected babies who survive birth are very likely to have neurological complications later in

life. For unknown reasons, mothers who contract fetomaternal listeriosis are very rarely affected by meningoencephalitis or systemic infection. Infection by *L. monocytogenes* is much more common among certain high risk groups than in the general population. People at increased risk for listeriosis include the elderly, pregnant women, newborns, AIDS patients, or patients taking immunosuppressive medication (55,57).

Listeria monocytogenes has also been associated with cases of gastroenteritis, with symptoms including fever, vomiting, and diarrhea. These cases have generally been among healthy adults and appear to require extremely high doses of bacteria. Foods associated with outbreaks of *L. monocytogenes* gastroenteritis have contained 10^5 to 10^9 bacteria per gram. The same kinds of ready to eat foods are associated with this form of listeriosis as with invasive listeriosis. Some researchers suggest that many incidences of gastroenteritis with an unknown cause may actually be due to *L. monocytogenes* (58,59).

2.4.1.2 Characteristics of Listeria monocytogenes

Listeria monocytogenes is a Gram-positive, facultatively anaerobic bacterium which is motile at 10 to 25°C (7). The genus *Listeria* includes six species: *L. monocytogenes*, *L. ivanovii*, *L. seeligeri*, *L. innocua*, *L. welshimeri*, and *L. grayi*. Both *L. monocytogenes* and *L. ivanovii* are potential pathogens, but because *L. ivanovii* only rarely causes disease in humans, most research has focused on *L. monocytogenes*. The *Listeria* spp. are related to other Gram-positive organisms in the genera *Bacillus*, *Clostridium*, and *Enterococcus* (52).

Listeria monocytogenes is tolerant to a variety of environmental stresses. It will grow at temperatures from 1–45°C and at a pH between 6 and 9. It is also very salt tolerant, surviving in media containing as much as 20% NaCl. *Listeria monocytogenes* strains grow well in the presence of bile salts, which are lethal to most Gram-positive bacteria (7). High stress tolerance means that *L. monocytogenes* can survive many food processing methods designed to eliminate less resilient bacteria, although it does not form spores. *Listeria monocytogenes*'s ability to grow at refrigeration temperatures (approximately 4°C) is one of the most important factors in its emergence as a food borne pathogen. Shelf life extension of perishable processed foods often involves refrigerated storage for long periods of time before consumption. Extended refrigerated storage can function as a relative enrichment for *L. monocytogenes*, which can reproduce with reduced competition from mesophilic bacteria under those conditions (60).

Complete genome sequences have been published for *L. monocytogenes* and its nonpathogenic relative *L. innocua*. This allows the same kind of comparisons that have been made between *E. coli* O157:H7 and *E. coli* K-12, as discussed. Genes which are present in *L. monocytogenes* but not in *L. innocua* are good candidates for virulence factors. The genomes of the two *Listeria* species are very similar. Each is about 3 Mb in length, with about 3000 protein coding genes. There are 270 genes unique to *L. monocytogenes*, including some potential virulence genes and a 10kb virulence gene cluster, and 149 genes unique to *L. innocua* (61). In general, the genomes of *L. monocytogenes* and *L. innocua* are more similar to each other than are the genomes of *E. coli* O157:H7 and *E. coli* K-12.

2.4.1.3 Classification of Listeria monocytogenes

Many methods have been used to distinguish different strains of *L. monocytogenes* (62,63). Distinguishing between strains of *L. monocytogenes* is important for epidemiology and determination of the source of listeriosis outbreaks, but also has important implications for understanding virulence. Not all strains of *L. monocytogenes* are equally capable of causing disease (55,64), and various subtyping schemes have been developed to try and separate strains of differing virulence. For example, there are 13 serotypes of *L. monocytogenes*,

three of which (1/2a, 1/2b, and 4b) account for 90% of human and animal cases of listeriosis. Serotype 4b alone accounts for 50% of listeriosis cases, and seems to be more frequently associated with fetomaternal disease than with systemic disease (55,63). However, despite the ability to separate *L. monocytogenes* strains into increasingly precise categories, no reliable predictor of virulence has been found.

For more discriminatory subtyping of *L. monocytogenes*, a wide variety of DNA based methods have been developed. One of the most commonly used is called ribotyping, and involves Southern hybridization using probes for the genes encoding ribosomes. Different alleles of these genes will produce different ribotype banding patterns on a gel. This method is standardized and allows researchers to distinguish different strains of *Listeria* (62,63).

Using a classification method based on ribotyping and allelic variation in virulence genes, *L. monocytogenes* can be subdivided into three lineages. Lineage I strains (serotypes 1/2b, 3b, 3c, and 4b) include all the strains responsible for human listeriosis outbreaks, along with human and animal isolates from sporadic cases. Lineage II (serotypes 1/2a, 1/2c, and 3a) contains both human and animal isolates, but no epidemic strains. Lineage III (serotypes 4a and 4c) is rare, but more common among animal isolates than among human isolates. This suggests that lineage I strains may have a greater potential to cause human disease, while lineage III strains may be better adapted to causing disease in animals (65,66). Regardless, almost any strain appears to be capable of causing isolated cases in humans or animals.

Three other common methods used for subtyping of *L. monocytogenes* are random amplified polymorphic DNA (RAPD) analysis, pulsed field gel electrophoresis (PFGE), and multiple enzyme electrophoresis (MEE) (62,67,68). RAPD is a polymerase chain reaction (PCR) based method which involves the use of short (approximately 10 nucleotide) arbitrary primers. PCR of genomic DNA with these primers under low stringency conditions results in banding patterns which vary depending on the genetic content of the bacterial strains (68). RAPD has been shown to be highly discriminatory for different isolates of *L. monocytogenes* from a variety of sources, although differences in methods can make comparison of RAPD types from different laboratories difficult (67–71). PFGE typing is a powerful discriminatory method which involves digesting genomic DNA with restriction enzymes and separating the fragments on a gel. The banding patterns produced by these DNA fragments differ from strain to strain. PFGE and RAPD typing give similar results for classifying and grouping *L. monocytogenes* strains (67,69,71). PFGE types cluster into two major divisions; division I, which correlates to serotypes 1/2a, 1/2c, 3a, and 3c, and division II, which correlates to serotypes 1/2b, 3b, 4b, 4d, and 4e (72). These correlate well with lineages I and II (62). PFGE types can also be correlated with virulence. For example, strains of PFGE type 1, which are commonly found in foods but are relatively rare in human cases, seem to be less invasive *in vitro* than other PFGE types (73). MEE is an older method which involves determining the electrophoretic mobility of 11 different cellular enzymes. Different banding patterns are designated as different electrophoretic types (ETs). Most ETs are in approximate agreement with PFGE types, although some ETs contain multiple PFGE types and vice versa (74). All of these methods allow differentiation among *L. monocytogenes* strains, but, like serotyping, ribotyping, and lineage determination, are of limited value in predicting the virulence of a particular isolate.

2.4.1.4 Sources in the Environment

Listeria spp are found in a wide variety of environmental sources, including soil, water, decaying vegetation, a wide variety of foods, and human and animal feces. Little is known about the life cycle of *L. monocytogenes* outside of an animal host, but it seems to be well

suited to an independent, saprophytic existence. *Listeria* are most common in moist surface soils and decayed vegetation, and are detected in highest numbers in early spring (75). *Listeria monocytogenes* has been isolated from many species of mammals, birds, reptiles, amphibians, and insects, as well as being common in sewage and water (76). Because it is so ubiquitous in the environment, contamination of foods with *L. monocytogenes* can come from a variety of sources, and is therefore difficult to control.

2.4.2 Virulence Factors

In terms of number of virulence factors, *L. monocytogenes* falls between the single dominant virulence factor of *C. botulinum* and the elaborate network of interacting virulence factors in *E. coli* O157:H7. *Listeria monocytogenes* seems to be capable of infecting almost any animal host, and it uses the same relatively small set of virulence genes in all of them. As in *E. coli* O157:H7, at each stage in the course of infection *L. monocytogenes* brings a particular virulence factor to bear, the coordinated combination of which allows the bacterium to cause its characteristic disease. The important virulence factors of *L. monocytogenes* include internalins, membrane-lysing toxins, and an actin-nucleating protein called ActA (55).

2.4.2.1 Internalins

The first step in *L. monocytogenes* infection is attachment to and invasion of a susceptible host cell. The large family of proteins called internalins (Inl) are important in this process. There are two major groups of internalins, the large, membrane associated internalins (including InlA, InlB, InlC2, InlD, InlE, InlF, InlG, and InlH) and the small, secreted internalins (InlC in *L. monocytogenes* and a number of others in *L. ivanovii*) (55). The best studied of these are InlA and InlB, which are required for efficient invasion of host cells and formation of a close association between the bacteria and host cells (77). The internalin InlA binds to E-cadherin, a eukaryotic membrane protein found in epithelial cells, including intestinal cells, liver cells, dendritic cells, and placental epithelium; cell types which are particularly susceptible to invasion by *L. monocytogenes*. The internalin InlB has different specificity, and binds to several different host membrane proteins, including Met and gC1q-R, but not to E-cadherin (55,77). The receptors for the other internalins have not been determined. Binding of InlA or InlB to a host cell induces uptake of the *L. monocytogenes* cell. They do this by different molecular mechanisms, but the end result is the same: rearrangement of the host cell cytoskeleton and internalization of the bacteria within a vacuole by phagocytosis. Either InlA or InlB is sufficient for uptake into a cell with the appropriate receptor molecule, as demonstrated by experiments which observed internalization by host cells of latex beads that had been coated with the purified proteins (55,77). Different internalins are probably important for efficient invasion of different types of host cell, and may work synergistically to increase overall invasion efficiency (78).

2.4.2.2 Listeriolysin O (LLO)

Once *L. monocytogenes* has been internalized by a host cell, it must escape from the phagocytic vacuole into the cytoplasm. Any *L. monocytogenes* which fail to escape the vacuole are likely to be killed by acid and powerful oxidants. *Listeria monocytogenes* has several proteins involved in escape from the vacuole. The most important is listeriolysin O (LLO), also known as hemolysin, encoded by the *hly* gene. Pathogenic species of *Listeria* all produce LLO, while the nonpathogenic species do not (55). LLO is a cholesterol dependent secreted cytolysin, a member of a family of toxins produced by many Gram-positive pathogens, which act by forming pores in cholesterol containing cell membranes (79). Because bacterial membranes do not contain cholesterol, these toxins only affect host cell

membranes. Most cholesterol dependent secreted cytolysins attack the cytoplasmic membrane of host cells and kill them, but LLO has very low activity at neutral pH, and is only active in the low pH environment of the phagocytic vacuole, where it lyses the vacuolar membrane and allows *L. monocytogenes* to escape into the cytoplasm without killing the host cell (79). Addition of the *hly* gene to nonpathogenic bacteria, such as *Bacillus subtilis*, is sufficient to allow those bacteria to escape from phagocytic vacuoles (80). *Listeria monocytogenes* reproduces readily in the eukaryotic cytoplasm, where it is protected from attack by the host's immune system.

2.4.2.3 Phospholipases

Listeria monocytogenes produces two enzymes with phospholipase activity which are also important for efficient escape from the phagocytic vacuole. They are called PI-PLC and PC-PLC, and even in the absence of LLO, their presence allows *L. monocytogenes* to escape from phagocytic vacuoles in some types of host cells (79). Deletion of the genes *plcA* (which encodes PI-PLC) and *plcB* (which encodes PC-PLC) individually have minor effects on virulence, but a double deletion decreases virulence markedly. *In vivo*, presumably LLO and the phospholipases work in concert to efficiently lyse vacuolar membranes (55).

Enzyme PI-PLC specifically cleaves phosphatidylinositol, a phospholipid which is found mostly on the inner side of eukaryotic membranes. Enzyme PC-PLC is less specific, and cleaves a number of other phospholipid components of eukaryotic membranes. Enzyme PI-PLC is most active at acidic pH, suggesting that, like LLO, it is active in phagocytic vacuoles (55). Enzyme PI-PLC seems to be more important in escaping the primary vacuole formed when *L. monocytogenes* is first taken up by a host cell, while PC-PLC seems to be more important for escaping the double membraned secondary vacuole formed when the bacteria are spreading from one host cell to another (55,79). The presence of three different membrane-lysing toxins with different specificities in *L. monocytogenes* reflects the importance of vacuolar escape to its pathogenic lifestyle, and may also be an adaptation to the variety of membrane structures it might encounter in different host species (55,79).

2.4.2.4 ActA and Actin Based Motility

Once *L. monocytogenes* escapes the phagocytic vacuole, it becomes mobile within the host cell cytoplasm (55,64,79). Outside of a host cell, *L. monocytogenes* use flagella for motility, but the cytoplasm is too viscous for flagella to be effective. Instead, *L. monocytogenes* stimulates polymerization of actin, a major protein of the eukaryotic cytoskeleton, into a tail like structure which pushes the bacterium through the cytoplasm (81,82). Using this rocket like mechanism, *L. monocytogenes* can attain speed of 0.3 μm/s inside a host cell (55). The main advantage of this form of intracellular motility is that it allows *Listeria* to spread from cell to cell. When an actin propelled bacterium reaches the host cell membrane it forms a long finger like protrusion into the adjacent host cell. Phagocytosis of this protrusion encases the *L. monocytogenes* in a double layered vacuole (81), which is lysed by LLO and the phospholipases, releasing the bacterium into a new host cell (55,79). *Listeria monocytogenes* can thereby spread through a tissue without being exposed to the host's immune system.

The process of actin based motility is mediated by a single bacterial protein, called ActA (82). Deletions of the *actA* gene result in *L. monocytogenes* which escape from vacuoles but cannot spread from cell to cell. ActA is a membrane bound protein which is localized at one pole of the rod shaped *L. monocytogenes* cell. It recruits host cell cytoskeletal proteins, including Ena/VASP proteins and the Arp2/3 complex, with the ultimate effect of causing actin to polymerize at that pole of the bacterium, forming the tail (55,79).

Insertion of the *actA* gene into *L. innocua* or *Streptococcus pneumoniae* is sufficient to give these bacteria the ability to form actin tails and spread intracellularly (55).

2.4.2.5 Other Virulence Factors

In addition to the virulence factors discussed, there are other genes which are important for virulence in *L. monocytogenes*. These include some housekeeping and stress response genes, as well as genes which seem to be more specialized for virulence functions.

Any food borne pathogen is exposed to attack by bile salts as it passes through the intestine of its host. *Listeria monocytogenes* is also commonly found growing in the livers of infected animals, where they are also exposed to bile. Gram-positive organisms are not ordinarily resistant to bile, but *L. monocytogenes* has a bile salt hydrolase enzyme (encoded by the *bsh* gene). The virulence of Δ*bsh* mutants is decreased in mouse and guinea pigs, and *bsh* is only found in pathogenic species of *Listeria* (*L. monocytogenes* and *L. ivanovii*), suggesting that bile salt hydrolase is a specific virulence factor and not a housekeeping gene (83).

Another recently discovered virulence gene in *L. monocytogenes* is *hpt*, which encodes a hexose phosphate transporter. Hexose phosphates (such as glucose-1-phosphate) are common in the cytoplasm of animal cells and appear to be an important carbon source for intracellular *L. monocytogenes*. Hpt is required for utilization of hexose phosphates and Δ*hpt* mutants grow much slower inside mammalian cells than wild-type bacteria. They are also attenuated for virulence in mice (84).

Evidence also points toward stress response genes having a role in virulence. The host environment, both in the intestine before invasion and inside the phagocytic vacuole, is a hostile one for *L. monocytogenes*, and the bacteria are exposed to a variety of stresses in that environment. These include exposure to acid, reactive oxygen species, and iron limitation, among others (55). General stress response is controlled in *L. monocytogenes* by an alternative sigma factor, σ^B, which regulates transcription of many stress response proteins (85,86). Mutants lacking σ^B are deficient in virulence, although the effects are relatively minor. Some evidence, however, suggests that regulation of stress response through σ^B may have a connection to regulation of some of the major virulence factors (85,87,88).

2.4.3 Genetics and Regulation

2.4.3.1 Organization of Virulence Genes

The genes for LLO (*hly*), both phospholipases (*plcAB*), and ActA (*actA*), along with a gene for a metalloprotease required for activation of PC-PLC (*mpl*) are all encoded on a 10 kb gene cluster (55). This cluster is only found in the two pathogenic species of *Listeria*, *L. monocytogenes* and *L. ivanovii*. *Listeria seeligeri* has the cluster, but with an insertion that blocks production of the virulence genes (89). The internalins are encoded separately, in a number of different loci. InlA and InlB are encoded together in the *inlAB* operon. Internalin InlC (the small secreted internalin of *L. monocytogenes*) and InlF are encoded as monocistronic genes, *inlC* and *inlF*, respectively. A fourth internalin locus in *L. monocytogenes* contains three genes, which may be *inlGHE* or *inlC2DE*, depending on the strain. These two operons are homologous, but not identical (55). The *hpt* and *bsh* genes are also encoded at separate loci on the *L. monocytogenes* chromosome (83,84) (Figure 2.3).

2.4.3.2 PrfA

The virulence gene cluster also contains the *prfA* (positive regulatory factor A) gene, which encodes a regulatory protein called PrfA. The protein PrfA is the master regulator of virulence genes in *L. monocytogenes*. Mutants lacking *prfA* are completely avirulent (90,91).

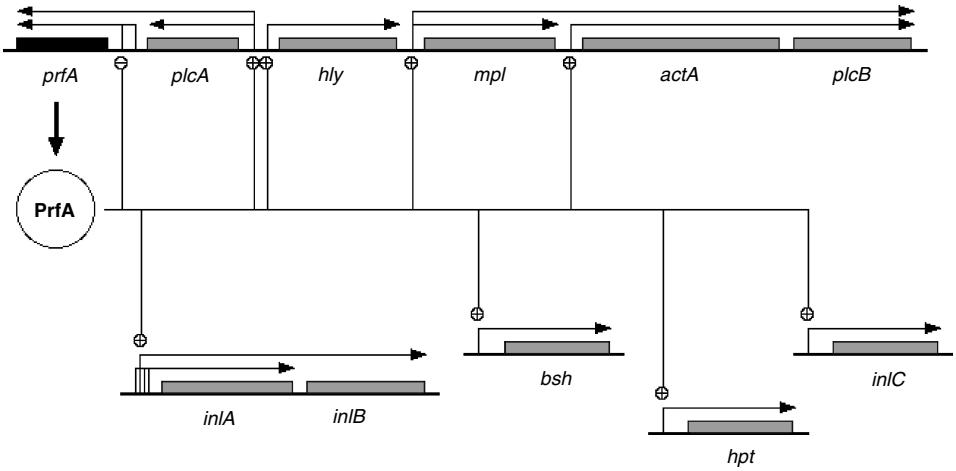

Figure 2.3 Regulation of virulence genes in *Listeria monocytogenes*. Gene products are as follows: *prfA* = PrfA regulatory protein, *plcA* = PI-PLC phospholipase, *hly* = listeriolysin O (LLO), *mpl* = metalloprotease, *actA* = ActA actin nucleating protein, *plcB* = PC-PLC phospholipase, *inlA* = internalin A, *inlB* = internalin B, *bsh* = Bsh bile salt hydrolase, *hpt* = Hpt hexose phosphate transporter, *inlC* = internalin C. PrfA is a positive regulator of promoters indicated by + and a negative regulator of the promoter indicated by −

Regulatory protein PrfA activates transcription of all the major virulence genes, including *hly*, *actA*, *plcAB*, *mpl*, and *prfA* itself. It also positively regulates expression of *bsh*, *hpt*, and the internalin genes *inlAB* and *inlC*. Interestingly, the other internalins (InlC2, D, E, F, G, and H), whose role in virulence appears to be relatively minor, are not regulated by PrfA (89).

Protein PrfA is related to a family of bacterial regulatory proteins called the Crp/Fnr family (92). The proteins Crp and Fnr are well studied regulatory proteins from *E. coli*; Crp is a regulator of catabolite repression, and responds to cyclic AMP (cAMP) levels, while Fnr regulates anaerobic growth factors. Although related, PrfA lacks several residues required in Crp for cAMP binding, and cAMP has no effect on PrfA activity. However, mutations in PrfA suggest that a domain homologous to the cAMP binding domain of Crp affects whether PrfA is in an active or an inactive conformation. Whether or not PrfA activity is affected by a small molecule cofactor is unknown (89). Two domains exist in PrfA that do not occur in other Crp/Fnr family regulators, a putative N-terminal helix-turn-helix domain and a putative C-terminal leucine zipper domain. Both are required for PrfA activity, but the exact roles of these domains are unknown (89,92).

2.4.3.3 Regulation of PrfA Expression

Because expression of virulence is dependent on activation by PrfA, regulation of expression of PrfA is of central importance in controlling pathogenicity in *L. monocytogenes*. Expression of PrfA is from three different promoters: P*plcA*, which produces a bicistronic transcript encoding both PI-PLC and PrfA, and two PrfA-specific promoters, P1 and P2, which produce monocistronic PrfA transcripts (93,94). The strong promoter P*plcA,* is dependent on PrfA, which can therefore upregulate its own expression. Expression from P1 is constitutive, but relatively weak, and translation of the P1 transcript is thermoregulated to prevent production of PrfA protein at temperatures below 37°C (95). Expression from P2 is also weak, and is dependent on the general stress sigma factor σ^B (87). The precise mechanisms and signals which *L. monocytogenes* uses to activate PrfA are not well

understood, but conditions inside a host organism (high temperatures, low iron availability, acid stress) are believed to stimulate production of PrfA protein from P1 and P2, which in turn activates transcription from P*plcA*. This leads to an increase in the amount of PrfA in the bacterium (89). High concentrations of PrfA negatively regulate PrfA expression, ensuring that the autoregulatory loop does not overproduce PrfA, although this negative regulation does not appear to be required for virulence (94,96).

2.4.3.4 Regulation of Virulence Genes

As PrfA levels increase, transcription of virulence factors is activated. At low levels of PrfA, the virulence factors most important for escape from the phagocytic vacuole, LLO and PI-PLC, are produced (94). As the *L. monocytogenes* continue the infective process, beginning to spread from cell to cell, PrfA levels increase, and the other virulence factors important in this phase of infection are transcribed. These include ActA and PC-PLC, as well as Hpt and Bsh (83,84,97,98). The differential regulation of these genes depends on differences in their promoters. Promoters dependent on PrfA contain a sequence called the PrfA-box. As PrfA binds to the PrfA-box it activates transcription from these promoters. The more similar a PrfA-box is to the consensus PrfA-box sequence, the lower the concentration of PrfA protein is required to activate transcription. The promoters for PI-PLC and LLO have perfect PrfA-boxes, while the other virulence gene promoters have one or two mismatched bases in their PrfA-boxes, ensuring that they will not be transcribed until higher levels of PrfA protein have accumulated (83,84,89,92).

Regulation of internalin expression is more complex. Internalins A and B are required for invasion of most host cell types, but not for escape from a vacuole or cell to cell spread (55,77). The *inlAB* operon has four promoters (99). Expression of internalin is higher outside of host cells than when *L. monocytogenes* is growing intracellularly (100), but one of the *inlAB* promoters has a PrfA-box with two mismatches, suggesting that this promoter is activated during cell to cell spread (99). What appears to happen is that internalins are expressed at high levels outside of a host from the other three promoters, one of which is σ^B-dependent, and therefore activated by growth under stress (101). When *L. monocytogenes* is growing intracellularly, expression from these promoters is repressed by unknown mechanisms and relatively low levels of internalins are produced from the PrfA-dependent promoter. More work needs to be done to clarify the regulation of the internalins. The small secreted internalin InlC appears to be PrfA-dependent and expressed primarily intracellularly, suggesting it may have a role in cell to cell spread, but the function of this protein has not been established (102).

It appears that PrfA is also involved in negatively regulating a variety of genes in *L. monocytogenes*. These include *prfA* itself, some stress response genes, and genes for flagellar synthesis (94,96,103,104). In the case of the flagellar genes, this explains the loss of flagella by invading *L. monocytogenes* cells, which then become motile by means of actin polymerization. The rationale behind PrfA repression of some stress response genes is not clear.

2.4.4 Summary

Listeria monocytogenes causes an invasive food borne infection, which can cause sepsis, meningoencephalitis, abortion, and death. It primarily affects the immunocompromised. Major *L. monocytogenes* virulence factors include internalins, which stimulate phagocytosis and entry into host cells, membrane lysing toxins (LLO and phospholipases), which mediate escape from the phagocytic vacuole, and ActA, which allows intracellular motility and cell to cell spread. In addition, *L. monocytogenes* produces Hpt, which allows the

use of hexose phosphates in intracellular growth, and Bsh, a bile salt hydrolase which is important for survival in the intestine and in liver cells. All of these virulence factors are regulated by the transcription factor PrfA. Regulation of virulence is also related to regulation of stress response. Regulation of virulence in *L. monocytogenes* is relatively well understood, but many details about how this bacterium senses changes in its environment and coordinates the multiple factors required for infection are still unknown. Why certain strains appear to be more pathogenic than others and whether it is possible to predict the virulence of an isolate remains unclear.

2.5 CONCLUSIONS

2.5.1 Common Themes in Bacterial Pathogenesis

Examining the regulation of virulence in three important food borne pathogens reveals that, while each organism has a different mode of pathogenesis depending on its particular complement of virulence factors, there are common themes which link all three. An important goal of the study of bacterial pathogens is to discover these common themes and general principles which govern the process of pathogenesis in all bacteria. In all three example organisms, pathogenesis requires coordination of virulence factors, which may include toxins, adhesins, secretion systems, or motility mechanisms. The regulation of virulence involves a complex interaction between the effect of virulence specific regulators (e.g., BotR, Ler, or PrfA) and the effects of more general global regulatory mechanisms (e.g., regulation of sporulation, quorum sensing, or general stress response) which regulate genes for both virulence factors and housekeeping proteins.

2.5.2 Pathogenicity Islands, Horizontal Gene Transfer, and the Evolution of Pathogens

Another common theme among bacterial pathogens is that virulence genes are generally found grouped together in virulence gene clusters. These virulence gene clusters include the botulism toxin gene cluster in *C. botulinum*, the LEE, and Stx phages in *E. coli* O157:H7, and the PrfA-dependent virulence gene cluster in *L. monocytogenes*. A region of DNA carrying several related virulence genes in close proximity is called a "pathogenicity island". Pathogenicity islands range in size from relatively small, like the *L. monocytogenes* PrfA-dependent virulence gene cluster (~10 kb, sometimes referred to as a pathogenicity "islet") through medium sized islands like the LEE from *E. coli* O157:H7 and EPEC (~36 kb) to very large islands (~200 kb) like those associated with virulence in uropathogenic *E. coli* (not a food borne pathogen) (105).

An important feature of pathogenicity islands is that they often contain sequences which indicate that they have or once had the ability to be mobilized, i.e., pathogenicity islands can be horizontally transferred from the genome of one bacterium into another. This is particularly clear in the case of *E. coli* O157:H7, which appears to have acquired the ability to cause disease by incorporating two pathogenicity islands, the LEE and the Stx phage (29). The LEE is widespread among Gram-negative enteric pathogens, especially among strains of *E. coli*, and, although the structure of the LEE remains consistent between strains, it is often found incorporated at different positions on the chromosome (106), which supports the idea that the LEE is mobile and can be spread from one strain to another. Stx phage are functional viruses capable of transducing the genes for Shiga-like toxin into any phage susceptible strain of bacteria. The Shiga-like toxin produced by *E. coli* O157:H7 is essentially

identical to that produced by *Shigella dysenteriae*, but the *Shigella* toxin is encoded on the chromosome rather than on a bacteriophage. Stx phage may have acquired the toxin gene from *Shigella* and transferred it to *E. coli* (106). The botulism toxin gene cluster also shows evidence of horizontal transfer. Distantly related strains of *Clostridium* have similar gene clusters, and many are located on potentially mobile genetic elements like plasmids or prophage (107). There are no obvious mobilizing elements associated with the PrfA-dependent virulence gene cluster in *L. monocytogenes*, which has led to the suggestion that this pathogenicity islet may be very old. This hypothesis suggests that the PrfA-dependent gene cluster was once mobile, but lost that ability so long ago that evolution has completely eliminated any trace of the vestigial mobilizing elements (108).

Pathogenicity islands make it possible for previously innocuous bacteria to quickly acquire whole sets of virulence genes in a single step, which has enormous implications for the evolution and appearance of emerging pathogens. Current knowledge cannot fully explain how horizontally acquired genes become integrated into the global regulatory mechanisms of bacteria so that virulence genes can be correctly coordinated during infection.

2.5.3 Emerging Pathogens and Human Food Practices

The interaction between a pathogen and its host is only one factor in how a bacterium causes disease. The interaction between the bacteria and their environment is equally important, and for food borne pathogens, environmental factors are dependent on food processing and storage technology. Historically, one of the main goals of food processing is preservation or extension of shelf life. Most food processing technologies are intended to kill or slow the growth of the bacteria which are most likely to be a spoilage concern in that food product. Common preservative techniques include canning, pasteurization (with heat or electromagnetic radiation), drying, addition of salt, and refrigeration. However, sublethal applications of these treatments can select for organisms which can survive treatment, and produce an environment in which the survivors can multiply with minimal competition. If a new preservative technique provides an environment in which a potential pathogen can thrive, those organisms would then generally be considered emerging pathogens, because they were not a health hazard before the new technology gave them new opportunities to infect humans (109).

For example, fresh foods generally are not considered a botulism hazard. *Clostridium botulinum* typically only causes disease upon consumption of foods which contain anaerobic zones and have been stored for periods of time sufficient for outgrowth and toxin production. Food processing techniques, such as sausage making or canning, if improperly conducted could lead to these conditions and make botulism possible. Both sausage making and canning are intended to allow food to be stored for long periods of time by controlling or killing spoilage organisms, most of which are considerably less robust than *C. botulinum* spores. Food processing methods can be adjusted to minimize the risk of *C. botulinum* toxin production, by addition of nitrate in the case of sausage or through heat treatments designed to kill 12 logs of *C. botulinum* spores in the case of canning, which accounts for the relative rarity of botulism today. Most modern cases of food borne botulism are accounted for by inadequate home processing using methods that do not kill *C. botulinum* spores, but, instead, create the necessary conditions for bacterial growth and toxin production (2).

A somewhat more recent example of how food storage technology affects bacterial pathogens is the emergence of *L. monocytogenes* as an important food borne pathogen. Because *L. monocytogenes* can grow at refrigeration temperatures, which inhibit the growth of most spoilage bacteria, *L. monocytogenes* can grow with relatively little competition in food stored for long periods in a refrigerator. The increased demand for long shelf life, ready to eat food products has created a niche for these bacteria that probably has greatly

increased human exposure to *L. monocytogenes*. More or less simultaneously, a growing population of immunocompromised and elderly persons supported by modern health care methods has appeared. These people are more susceptible to infection by *L. monocytogenes*. The combination of environmental and host factors accounts for how a once rarely encountered pathogen of sheep and rabbits has become, in the last 20 years, one of the deadliest food borne pathogens in the developed world (110).

How human food practices may have affected the development of *E. coli* O157:H7 is less clear. Unlike *C. botulinum* and *L. monocytogenes*, *E. coli* O157:H7 appears to have evolved relatively recently, by acquisition of the LEE and Stx phage, in contrast to being an "old" organism that is simply taking advantage of a newly available niche (111). However, the continued emergence of other Shiga-toxin producing serotypes of *E. coli* with similar properties and virulence suggests that some factor in the modern environment allows enterohemorrhagic *E. coli* to thrive and spread. What that factor or factors might be is unknown, but some possibilities present themselves. Food products are now often shipped to distant locations from a single processor. A single meat packing plant may supply ground beef to fast food restaurants across the country, which would allow a single isolated incidence of contamination to be spread widely. Another possible contributing factor is the development of very intensive, high density cattle farming, which might contribute to the carriage of *E. coli* O157:H7 among beef cattle (18,30).

For a bacterium to cause disease, several conditions must be met. The pathogen must possess genes for virulence factors which allow it to infect a host organism and the host must be susceptible to attack by that pathogen and its particular combination of virulence factors. In addition, the environment must allow exposure of the host to the pathogen, and for food borne pathogens, the most important environmental factors are dependent on how the food is produced, processed, stored, prepared, and consumed. Through development of new processing strategies and food handling systems, we have selected for many of the pathogens which potentially contaminate our foods.

2.5.4 Applications of Genetic and Molecular Understanding of Pathogenesis

Research into the genetic and physiological basis of virulence is critical in improving our ability to detect dangerous pathogens and prevent disease. When the genes for a particular pathogen's virulence factors are known, DNA based methods can be developed to quickly detect and identify that pathogen, to distinguish between virulent and avirulent strains of closely related bacteria, and to help develop vaccines specific to those virulence factors. Currently, DNA based methods have been most useful for diagnosis of infections caused by pathogens which are particularly difficult to culture (such as *Mycobacterium tuberculosis*, which causes tuberculosis, *Bordetella pertussis*, the cause of whooping cough, and a variety of viral diseases), but as automation and less expensive methods become more widely available, DNA based molecular diagnostics are expected to become increasingly valuable tools in identifying a wide range of pathogens (112).

Another important application of understanding the molecular mechanisms of pathogenesis is the development of DNA based subtyping methods. These methods allow rapid strain "fingerprinting" for epidemiological studies to assist in disease management and control. If an outbreak of disease is caused by a specific strain of a pathogen, and foods containing that specific strain can be found, it will allow epidemiologists to very precisely identify the source of the outbreak. Molecular subtyping has been an important tool used

in tracking recent outbreaks of *L. monocytogenes* and *E. coli* O157:H7, as well as for a wide variety of other pathogens (26,62,112).

Finally, researchers hope that understanding the molecular mechanisms of pathogenesis will allow them to design new treatments or antibiotics which specifically attack those mechanisms. The better pathogens are understood at a molecular level, the better we are able to confront them at a clinical level. The continued emergence of new food borne pathogens and antibiotic resistant strains of known pathogens means that we will require innovative strategies to combat these bacteria and preserve the safety of the food supply. Studies of the genetic and molecular mechanisms of pathogenesis provide an important part of the information necessary to formulate these strategies.

3.03

Biofilm Production by *Listeria monocytogenes*

William K. Shaw, Jr. and Lynne McLandsborough

CONTENTS

3.1 INTRODUCTION

In their natural environments, bacteria do not exist as isolated cells but grow and survive in organized communities (1). Simplistically, biofilms are microorganisms growing on a solid surface. In practice, however, biofilms are generally defined as matrix enclosed bacterial populations adhered to a surface or to each other, producing a dynamic environment in which the component microbial cells appear to reach homeostasis, optimally organized to make use of all available nutrients (2–6). Once colonizing the surface, microorganisms form a monolayer or multilayer of cells at the interfaces between solids and liquids, or air and liquids (1,5). Biofilms are formed by almost every type of microorganism under suitable conditions, including spoilage microorganisms such as *Pseudomonas* and pathogens

of great concern to the food industry including the genera of *Bacillus, Vibrio, Listeria*, or *Salmonella*, (5,7,8). Throughout natural ecosystems, biofilms can be found on almost any surface exposed to water (9). In addition, biofilms are of great concern to the medical community, because biofilms play an important role in persistent human infections (4,10). In summation, biofilms can be found on almost any surface exposed to water (9) and, once established, are well documented to have a greater resistance to antimicrobial agents than free growing (planktonic) organisms (11–19). This chapter will discuss the basics of biofilm formation with an emphasis on *Listeria monocytogenes*.

3.2 BIOFILM FORMATION AND STRUCTURE

There are several steps in the formation of bacterial biofilms: transport, initial adhesion, substrate attachment, and microcolony formation or cell to cell adhesion (Figure 3.1). The first step in biofilm formation is transport of the organism to a solid surface. This can be via motility of the organism, diffusion of the organism through the environment, or convection of the system. Biofilm forming bacteria may use all of these mechanisms at one time or another. It is well documented that flagella mutants often have lower biofilm production under static conditions indicating that under these conditions flagella are involved in active cellular transport to surfaces. Under fluid flow greater deposition of bacteria has been observed when compared to static conditions (20), and it is speculated that turbulent flow may thrust bacterial cells onto the surface, enhancing adhesion and biofilm formation (17).

Once the organisms approach the surface, physicochemical forces are thought to influence the initial adhesion of the organisms. Physiochemical forces that can take place are: van der Waals interactions (>50 nm from the surface), repulsive electrostatic interactions (10–20 nm from the surface), a combination of repulsive and attractive electrostatic interactions (2–10 nm from the surface), and hydrophobic interactions (0.5–2 nm from the surface) (21). Van der Waals forces are brief dipole interactions between atoms in each body and are generally considered to be attractive forces (22). Electrostatic forces are due to the charge around each interacting body. Bacteria, as well as most natural solid surfaces,

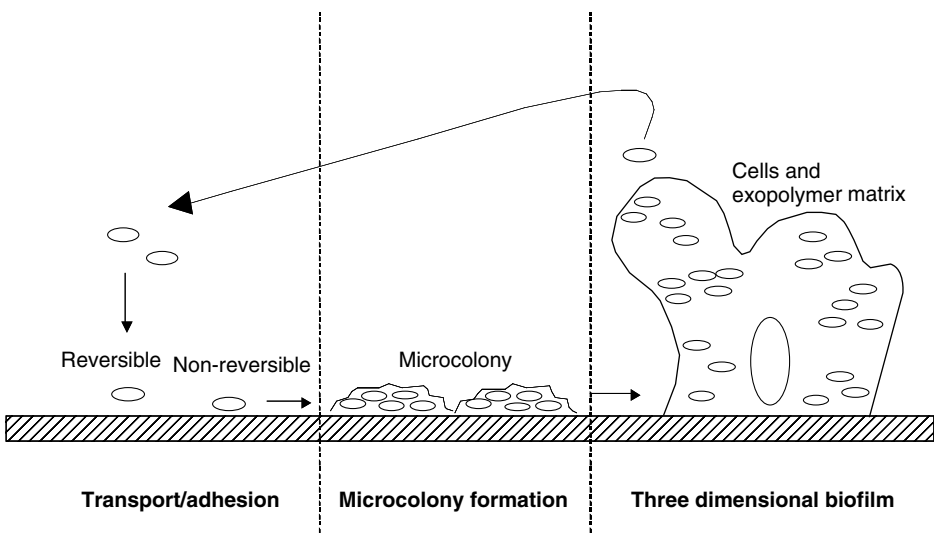

Figure 3.1 Schematic of steps involved in biofilm formation.

have an overall gross negative charge (23). Surface charge on biological materials and bacterial cells is due to ionization of surface groups, such as amino, carboxyl, phosphate, and less commonly, sulfate groups and capsular macromolecules. When immersed in an aqueous media, each surface becomes surrounded by oppositely charged ions, some of which are strongly attached to the surface, whereas the rest are distributed in a diffuse layer. The thickness of this diffuse layer depends on the ionic strength of the solution and the valences of the counter ions. The electrical interactions between particles (including bacteria) in solution are governed by the extension of the diffuse layer; when two particles are charged alike there is a repulsion between the two interacting bodies (23,24).

The Derjaguin, Landau, Verwey and Overbeek (DLVO) theory assumes that the interaction of the bacteria and the solid surface is the sum of the attractive van der Waals forces and electrostatic repulsive interactions (24,25). This interaction is dependent upon the distance of separation. Initially, van der Waals attractions are thought to predominate and pull the two surfaces closer together. As bacterial cells move closer to surfaces, the repulsive electrostatic force creates an energy barrier that must be overcome before the two interacting bodies can move closer together (25). At this point, the adhesion is considered reversible or in a secondary minimum (25,26). Hydrophobic or biological interactions are thought to be important in irreversible bacterial adhesion or primary minimum (22,27–30). Since the hydrophobic interactions in water are much stronger than van der Waals attraction at small separations (22), it has been suggested that hydrophobic interactions between the cell surface and the solid substratum may be one mechanism for overcoming the repulsive electrostatic force described by the DVLO theory, excluding water between the two surfaces and causing the bacterial to adhere irreversibly (31,32). Due to the complex nature of the bacterial cell surface, adherence may not always follow DVLO theory, because a single bacterial strain can adhere to a variety of surfaces with differing surface energies (21).

After initial adhesion occurs, bacteria form strong attachments to surfaces by synthesis of extracellular polymeric substances (EPS), facilitating irreversible bacterial attachment to a surface and maintaining the microcolony and biofilm structure (3,4,6,33,34). EPS has been shown to also enhance nutrient capture and resistance to environmental stress and antimicrobial agents (1,4–6,10,35). When mature, biofilms exist as a structured matrix with vertical and horizontal channels to allow liquid flow and dispersion of nutrients and waste. Within a microbial biofilm, the matrix consists of microbial cells (2–5%), polysaccharides (1–2%), and water (up to 97%), along with excreted cellular products (1–2%) (6). Although made up of these components, the actual structure of the biofilm matrix will vary depending on the types microbial cells present, their physiological status, the nutrients available, and the physical conditions present (6).

When growing in a biofilm, bacteria are known to have different growth rate, morphology, and physiology than their planktonic counterparts, and may exhibit varied physiological responses to nutrient conditions (9,36–38). Data show that biofilm bacteria receive less oxygen and fewer nutrients than cells in suspension, resulting in advantages in growth, altered physiology, and increased resistance to toxic agents compared with their planktonic forms (6,39,40). Sutherland proposes that these alterations dictate the placement of different organisms within the biofilm in order to take full advantage, matching environment to microorganism (6).

3.3 *LISTERIA MONOCYTOGENES*

Listeria monocytogenes is ubiquitous in the environment and resistant to diverse environmental conditions. It is associated with plant material (alive or dead), water, and soil.

Although exposure to *Listeria* is probably very common due to the wide environmental distribution on green plant material (some of which is consumed as food), listeriosis is a rare foodborne disease (41). It is the severity of the nonenteric disease (meningitis, septicemia, and abortion) in susceptible individuals (such as immunocompromised or pregnant woman) that warrants the alarm concerning this organism (41).

The very high mortality of listeriosis victims (20–30%) (41) has prompted the United States Department of Agriculture (USDA) to adopt a zero tolerance policy in processed foods. *Listeria monocytogenes* was the most frequent microbial agent associated with FDA food product recalls in the years 1994–1998 (61% of all food product recalls and 88% of all Class I food product recalls), with the next most frequent recall being due to *Salmonella* (11%) (42). Almost three fourths of the *Listeria* related recalls by the FDA occurred in dairy products, pastries, salads, or sandwiches (42). Other food products associated with outbreaks include hot dogs and ready to eat meats (43).

It is generally thought that biofilms within food processing environments are a major source of *L. monocytogenes* (5,44,45). The recent FSIS rule, which required that all establishments producing ready to eat meat and poultry products reformulate products to prevent growth of, and conduct environmental testing of food contact surfaces for the presence of *Listeria* species (43), acknowledges that transfer from the food processing environment is critical in the journey of this organism into processed foods after a lethal heat treatment. In processing plans, common sites of post processing *L. monocytogenes* contamination are filling or packaging equipment, conveyors, collators used for assembling product for packaging, racks for transporting product, hand tools, gloves, and freezers (5,44). One recall from a baking company involved 128 different products after it was discovered that the machine used to slice the items was contaminated with *L. monocytogenes* (42). The presence and persistence of this organism within the food processing environment continues to be a major challenge for the food industry (46).

3.3.1 Biofilm Formation by *Listeria monocytogenes*

3.3.1.1 Attachment and Biofilm Formation of L. monocytogenes to Surfaces

Research into the attachment by pure cultures of *L. monocytogenes* has focused on the influence of environmental conditions such as growth temperature, pH, and media composition (9,47–51); physiochemical forces of adhesion (51–53); and the influence of absorbed food components (or "conditioning layer") in *listerial* adhesion (54,55). In general, *L. monocytogenes* attaches better when grown in minimal or diluted rich media (48,56). Increased production of flagella and extracellular matrix components were observed at lower incubation temperatures (20°C or 4°C), although this may be due to increased incubation times required at lower temperatures (47,57). Neutral pH (7.0) appears to foster greater attachment than basic or acidic media (47,51).

Several different researchers have studied the involvement of physiochemical forces in adhesion. *Listeria monocytogenes* has been shown to attach tofood processing surfaces such as stainless steel, glass, polypropylene, and rubber with varying surface free energies (47,50,57). The surface charge of *L. monocytogenes* cells has been observed to be dependent upon growth temperature; as growth temperature decreased to 8°C, the electrophoretic condition of the cells became less negative (52). In addition, as the ionic strength of the suspending media decreased, the numbers of adherent *L. monocytogenes* cells increased, indicating that electrical interactions and Lewis acid base interactions are involved in adhesion to stainless steel (52). Others have measured cell surface hydrophobicity and calculated interfacial free energy of adhesion to stainless steel and rubber, and found these parameters alone did not explain the attachment capabilities of *L. monocytogenes* (50,53), suggesting another mechanism such as production of exopolymer or protein may

be important for adhesion (50,53). This is further supported by the observation that the presence of the proteinase trypsin could reduce *listerial* adhesion to rubber and stainless steel by 99.9% (50). The presence of adsorbed proteins on surfaces generally reduced the adhesion of *L. monocytogenes* regardless of the surface composition or free energy (54,55,58,59). Flagella mutants of *L. monocytogenes* have been observed to attach to stainless steel at levels tenfold lower than wild-type cells under short incubation times (4 h) (40). With longer incubation periods, cell coverage by flagella negative mutants reach close to the same level as flagellated cells, indicating that the flagella are important for initial attachment (40).

3.3.1.2 Genetics and Proteomics of Biofilm Formation

Researchers have been investigating the genes needed for *L. monocytogenes* surface growth using both genetic and proteomic approaches. Using a transposon mutagenesis approach, *L. monocytogenes* mutants that were deficient in attached surface growth were isolated. The genes encoding (p)ppGpp synthase (*relA*), and a gene in the purine salvage pathway (hpt) were identified as responsible for the reduction in surface growth, and mutants were unable to accumulate (p)ppGpp and induce a stringent response (60). In addition, these researchers showed that the *relA* gene was induced after bacterial adhesion, suggesting that adhesive bacteria adapt physiologically to the early stages of biofilm formation (60). Others have used a proteomic approach to compare the proteins produced within a single strain growth in broth and within a biofilm, and have identified 31 proteins at variable levels between the two growth conditions (61). Twenty two proteins were up regulated while nine others were down regulated. Of the seven proteins identified and compared to the *L. monocytogenes* genome, the majority (5) were unknown in *Listeria*. Levels of superoxide dismutase and 30S ribosomal protein S2 were increased in biofilms and the level of flagellin protein decreased when compared to protein levels isolated from planktonically grown cells (61). In addition, Cabanes et al. (62) pointed out that *L. monocytogenes* has a gene homologue to Esp that was shown to be important in biofilm formation of *Enterococcus faecalis* (63).

Some have questioned whether *Listeria monocytogenes* has the ability to produce extensive growth as a biofilm (17,49,64). Hood and Zottola did not observe large increases in cell numbers after initial adhesion (49), and Kalmokoff et al. argue that because only one strain out of 36 tested produced a basic biofilm under high nutrient conditions, this organism may adhere to other organisms in the environment rather than produce an independent biofilm (64). Dolan questioned whether this organism could grow within a biofilm due to its fastidious growth requirements and inability to compete with other microflora (17).

The question remains: Does *Listeria monocytogenes* produce biofilms? In pure laboratory systems, *L. monocytogenes* has been observed to produce fibrils and extracellular materials when attached to a variety of surfaces (47,57,64,65). This growth has been shown to have a distinct three dimensional structure form: a honeycomb, or groups of aggregates surrounded by voids (56,65,66). The thickness of the biofilm varies, with higher cell density layers attached to the substratum and at the edge of the biofilm, and lower cell levels in the center (67). In addition, the growth rate in biofilms was slower that planktonic cells (67), the biofilm grown cells required a greater level of phosphate (9), and a stringent response was induced upon surface growth, which appears to be necessary for biofilm formation (60). This indicates that in laboratory systems *L. monocytogenes* has exhibited the three benchmark biofilm characteristics: extracellular material, three dimensional structure, and altered cellular physiology.

3.3.1.3 Influence of Lineages on Biofilm Formation

Many researchers have studied the variation in the ability of different strains to adhere and form biofilms on processing surfaces. This is because, simplistically, the strains that have the ability to produce persistent biofilms in the food processing environment would be more likely get into foods during processing and cause foodborne disease. However, the relationship between biofilms and postprocessing contamination may be more complex. Researchers have suggested that different isolates of *L. monocytogenes* may have different levels of pathogenicity (68,69). Theoretically, strains with differing levels of pathogenicity may also vary in their ability to form biofilms. Virulent strains that cannot form biofilms may be less likely to cause outbreaks in processed foods, because such organisms will not persist in the processing environment. On the other hand, a biofilm forming, but less virulent, strain of *L. monocytogenes* may also be less likely to cause foodborne outbreaks, due to differences in pathogenicity rather than ecological survival. Following in the same logic, the virulent strains that can form persistent biofilms would be most the likely to cause foodborne listeriosis, because of their ability to persist in the processing plant and their ability to cause human disease.

This potential relationship between pathogenesis and persistence has spurred a number of investigations into adhesion of biofilms produced by different strains of *L. monocytogenes*. Lunden et al. (70) observed that persistent strains had higher levels of adhesion to stainless steel than nonpersistent strains after two hours contact time, but this difference was not observed after increased incubation time (70). My lab adapted a commonly used rapid microtiter plate assay that utilizes crystal violet staining, as an indication of level of surface growth (56). We obtained thirty strains that have been characterized into three genetic lineages (69,71) from both clinical and food processing environments. The strains arrived were coded to remove any researcher bias. After testing using the biofilm microtiter plate assay, it was found that lineage 1 strains (predominately serotype 4b), which were generally associated with human disease, exhibited higher level of biofilm formation than the other two lineages. No correlation was found between environmental persistence and biofilm staining intensity. However, Boruchi et al. recently used this assay to compare a larger sample size (eighty isolates), and found that Division II strains (serotypes 1/2a and 1/2c) predominantly formed greater amounts of crystal violet stained films (72) than division I strains (serotypes 4b and 1/2b). They also compared a number of the same strains from the study by Djordjevic et al. (56) and found similar test results, indicating that differences between the two were not due to technique, but instead were related to sample sizes, and to the specific strains used in each study. This was confirmed by electron micrographs of highly stained biofilms' dense, multidimensional growth, while less stained strains showed loosely distributed cells adherent on a surface; once again indicating that strains of *L. monocytogenes* can vary widely in their biofilm production under laboratory test conditions (72). In addition, Boruchi et al. observed a statistical correlation between persistent strains from a dairy processing plant and greater biofilm formation (72).

A large variation in ability of pure cultures of *L. monocytogenes* to adhere and grow on surfaces under laboratory conditions has been shown (56,64,70,72,73). However, it is still unclear whether laboratory tests accurately evaluate the reasons behind strain persistence in the food processing environment. Recently Moretro and Langsrund proposed that the differences in persistence might be due to the ability of strains to adapt to the complex diversity of biofilms present in food processing environments (46) and if this is the case, monospecies evaluations may not be the best approach to give the answers behind ecological persistence.

3.3.2 *Listeria* in the Processing Environment

Jenkinson and Lappin-Scott describe a biofilm as a dynamic entity: cells continually enter or leave the community, promoting diversification or dispersal, and protozoal grazing and shear forces in flow systems lead to remodeling of the biofilm structure (1). Within the food processing environment, *Listeria monocytogenes* biofilms do not exist in pure culture, but as members of a diverse bacterial community. This commensal and mutual community allows *L. monocytogenes* to survive low nutrient and decreased temperature conditions on food processing surfaces, not as a pure culture but rather in conjunction with other microbes (1,9,74).

Several researchers have studied the interactions of *L. monocytogenes* with other bacteria. In one study by Sasahara and Zottola, *Listeria monocytogenes* levels in biofilms were greater when grown in mixed culture with *Pseudomonas fragi* (75). Other researchers have also observed enhanced biofilm formation with exopolysaccharide producing *Pseudomonas putida* (76). Jeong and Frank showed that *L. monocytogenes* grew with *Flavobacterium* sp. and *Pseudomonas* sp. in multispecies biofilms on stainless steel (77). There is some indirect evidence that *Listeria* may have favorable interaction with fungi and bacteria: because it can grow in the presence of trehalose and cellobiose, two carbohydrate sources commonly found and fungi (78) and enhanced biofilm formation has been observed with trahalose as the only carbon source (48) although this may be strain dependent (56). In addition, *Listeria* can utilize amino sugars glucosamine, N-acetylglucosamine, and N-acetylmuramic acid that are components of both bacterial and fungal cells walls.

In a recent project, in my laboratory in collaboration with R.E. Levin (University of Massachusetts) set out to evaluate levels of *L. monocytogenes* present in food processing biofilms using an enrichment most probable number (MPN) with polymerase chain reaction (PCR) confirmation. Floor drains in a seafood processing plant were sampled bimonthly over a course of 7 months, and two locations consistently were confirmed to harbor *L. monocytogenes*. The MPN had a detection limit of 0.03 MPN/cm^2 and when detected, the levels of *L. monocytogenes* varied between 9×10^{-1} and greater than 1×10^4 MPN/cm^2. The plate counts for heterotrophic bacteria for the same areas where consistently between 7×10^5 and 3×10^8 CFU/cm^2. This indicates that the population of *L. monocytogenes* within the biofilm was a vast minority of the population within a complex floor drain ecosystem (manuscript in preparation). It is important to point out that this data does not define how *Listeria* is interacting within the biofilm population. It may be randomly becoming entrapped and growing within the EPS of the diverse biofilm, specifically coaggregating with some members of the population, or possibly forming "microcolonies" or three dimensional compartments of *Listeria* within the biofilm. To date, limited knowledge is available with regard to the other organisms that are present in the processing environment, and the interaction of *Listeria* with these organisms.

The majority of biofilm research has been performed on single species biofilms under laboratory conditions. However, biofilms often exist as multispecies communities in the environment. One of the best studied areas of multispecies biofilms has been in the area of plaque formation in dental microbiology. In plaque, some species of bacterial cells are thought to be primary or early colonizers, adhering to the teeth and forming microcolonies and EPS. Secondary colonizing bacteria then adhere to the developing biofilm through a mechanism called coaggregation (79). In coaggregation, single cells or aggregated clumps of cells adhere to the primary colonizing cells through the presence of surface adhesions and receptors, thus developing a biofilm with a diverse bacterial population (79). Coaggregation has also been observed between bacterial species isolated from fresh water biofilms (80,81), and has been associated with lectin to polysaccharide interactions

between species that were depending upon the growth phase of the cultures (81). Since *L. monocytogenes* appear to persist within floor drains in processing plants, it is a possibility that this organism may be interacting with fresh water biofilms.

3.3.3 Resistance of *L. monocytogenes* Biofilms to Sanitizing Agents

These dynamic communities pose great difficulties to food processors who attempt to remove them, because once the organisms attach to the surface, they become more resistant to chlorine, iodine, acid anionic, and quaternary ammonium sanitizers (74,82). *Listeria monocytogenes* has been reported to produce sanitizer resistant biofilms while attaching to glass, stainless steel, and buna-N rubber (14,83,84). Research has also determined that the processing surface used, concentration of sanitizer, and age of the biofilm affect the ease of removal (7). On stainless steel, for example, adherent cells in biofilms demonstrated significant resistance to conventional chemical sanitizers, germicides, and heat (9,14,57,83,85). With respect to age, entrapped cells grow and reproduce, producing multilayers within the biofilm and increasing resistance to chlorine with age (8,86).

An example of increased resistance of biofilms is shown in Figure 3.2. Colony biofilms were grown on filters placed on agar plates and exposed to sanitizer using a modification of the method of Anderl et al. (87). Colony biofilms growing at a solid to air interface exhibit a three dimensional structure similar to a biofilm grown at a liquid to solid interface [Figure 3.2 (a)]. The advantage of using colony biofilms is that they are easy to grow and easy to remove from the surface substrate. When grown on high nutrient media tryptic soy both (TSB) or minimal defined media (modified welshimers both (MWB) + 1.5% agar) (78), both colonies had similar growth patterns, reaching stationary phase within 20 hours and a final cell number of approximately 6×10^8 CFU/colony at 48h. When exposed to hypochlorine (200 ppm HOCl for six consecutive, ten minute exposures), cells grown under low nutrient conditions were more resistant (1.6 log reduction) than cells grown under high nutrient conditions (3.3 log reduction) [Figure 3.2 (b)]. However, when colonies are removed from the filter and then exposed to 200 ppm HOCl in suspension, the cells from both growth conditions exhibit a similar sensitivity, with a greater than 4 log reduction within 30 seconds. This is the same log reduction as seen with 48h stationary phase planktonically grown cells. This illustrates that the increased resistance of the biofilm is related to the spatial layout, because when the spatial layout is removed, the cells become sensitive to the sanitizer. However, the mechanism behind the increase in resistance to sanitizer when growing in biofilms is still somewhat ambiguous. In the case presented here, it is likely that the cellular components neutralized the HOCl solution as it diffused into the biofilm mass. Differences in high versus low nutrient conditions may be due to differences in cellular physiology or production of extracellular material.

It is likely the increased resistance of biofilms is due to a variety of factors that are either related to the structural form of the biofilm, or due to physiological differences in biofilm growing cells. Theories that support biofilm structure contributes to increased resistance suggest that it is due to reduced diffusion of chemicals through the biofilm mass, or chemical neutralization of sanitizers by the outer layers of biofilm, which would protect the inner cells (1,88). On the other hand, reduced growth rates and cellular physiology may also contribute to this resistance. Reduced growth rates in the biofilm reduce the susceptibility to select agents such as antibiotics that require active cellular component synthesis (such as protein translation or cell wall synthesis) (88). In addition, cell to cell communication may be more likely due to the close proximity of cells within a biofilm. Researchers have observed increased resistance to oxidative stress in biofilms due to quorum sensing in *Pseudomonoas aeruginosa* (89). Also in the *P. aeruginosa* system, others have hypothesized that the presence of a small population of "persister" cells with a higher resistance to antimicrobials were responsible for the increased resistance to antimicrobials in both biofilm and stationary phase cultures (90).

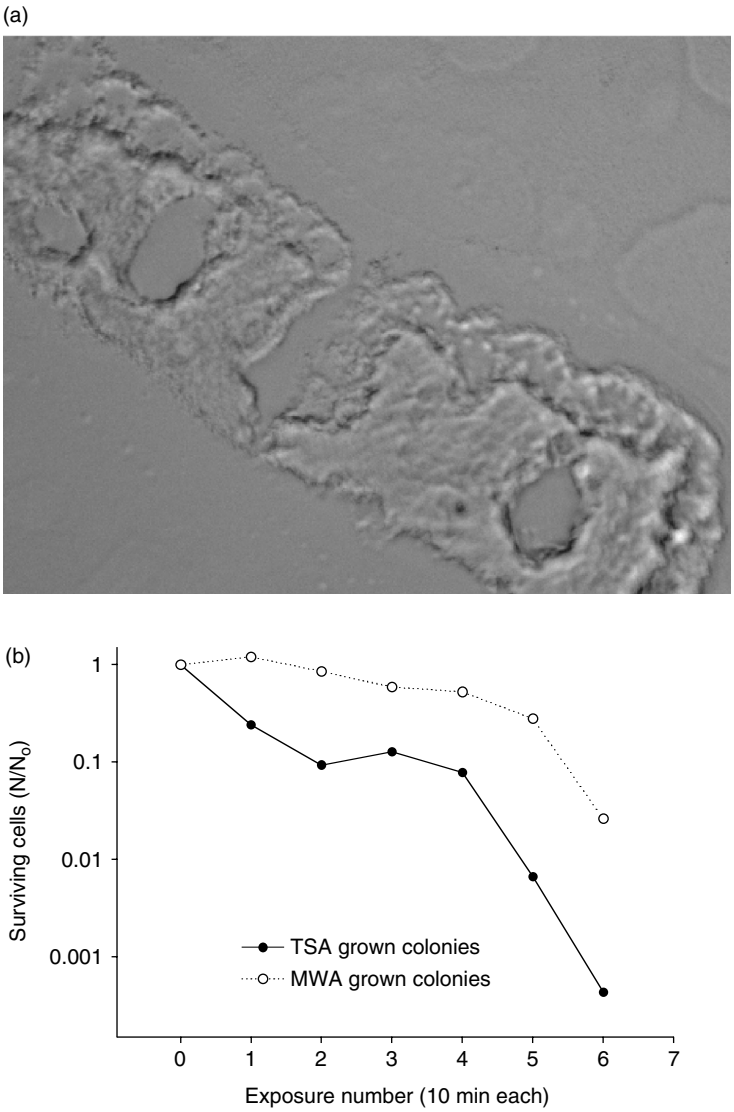

Figure 3.2 Colony biofilms were grown on 0.22 μm polycarbonate filters placed on solid 1.5% agar media with either high nutrients (tryptic soy broth) or low nutrients (modified Welshimers broth with 1.5% agar). Colonies were transferred to fresh agar plates every 24 h. (a) A cryosection of a 48 h colony grown on tryptic soy agar. (b) Colony biofilms were grown for 48 h at 32°C prior to consecutive 10 min exposures of 200 ppm HOCl solution pH 7.0. Every 10 min, surviving cell numbers were evaluated by removal from the filter in neutralization buffer and plated.

3.4 FUTURE DIRECTIONS

There are still many questions with regard to the ability of *L. monocytogenes* to grow and persist on food processing surfaces. Some genetic determinants needed for biofilm formation have been identified, and with the publication of the genome (91) it is likely that the genetic nature of monoculture biofilms will be unraveled in the future. At this time, it is unclear why certain strains of this organism persist within a processing environment and

how it interacts and survives within a multispecies biofilm. Utilization of the published genome data along with the study of the microbial diversity of the food processing environment may be a start in answering these questions.

ACKNOWLEDGMENTS

Colony biofilm work was performed in the laboratory of Philip Stewart at the Center for Biofilm Engineering at Montana State University-Bozeman, Bozeman Montana with the assistance of Betsey Pitts. This material is based upon work supported by the Cooperative State Research Extension Education Service, U.S. Department of Agriculture, Massachusetts Agricultural Experiment Station and the Department of Food Science Under Project number MAS 00837 and Seafood Safety Special Research Grants 2000-34423-9131 and 2001-34423-1031.

Application of Microbial Molecular Techniques to Food Systems

Robert E. Levin

CONTENTS

4.1 THE POLYMERASE CHAIN REACTION (PCR)

4.1.1 Introduction

The Polymerase Chain Reaction (PCR) is one of the most powerful analytical techniques ever developed. It allows segments of minute amounts of double stranded DNA to be amplified several millionfold in several hours. Its most notable application to foods is for the detection of low numbers of food borne pathogenic and toxigenic bacteria in a wide variety of food products in addition to confirming the identification of such organisms isolated from food.

4.1.2 Requirements for the PCR

The polymerase chain reaction uses repeated temperature cycling involving template denaturation, primer annealing, and the activity of DNA polymerase for extension of the annealed primers from the 3′ ends of both DNA strands (Figure 4.1). This results in exponential amplification of the specific target DNA sequence. The availability of the thermostable *Taq* DNA polymerase, from the extreme thermophile *Thermus aquaticus* greatly facilitates repeated thermal cycling at ~95°C for template denaturation, without having to repeatedly add a less thermally stable DNA polymerase after each cycle. The notably high optimum temperature for *Taq* polymerase activity (75–80°C) allows high extension temperatures (72–75°C) which when coupled with a high annealing temperature (50–65°C) and denaturation at 95°C increases specificity, yield, and sensitivity of the PCR reaction (1). Polymerase chain reactions are usually performed in 0.5 mL or 0.2 mL thin walled polyethylene PCR tubes containing 50 µl total reaction volume. The availability of second generation thermal cyclers with heated lids has eliminated the previous need for overlaying the reaction volumes with 50 µl of mineral oil to prevent evaporation. The four deoxynucleotide triphophosphates (Table 4.1) are presently available commercially premixed. Variables that require optimization include components 5, 6, 7, 8, and 9 in Table 4.1. The concentration of $MgCl_2$ is particularly critical. Innis and Gelfand (2) have discussed the optimization of PCR in detail. Most thermal cycling of PCR encompasses 35 cycles; rarely are more than 35 cycles of benefit.

A typical thermal cycling protocol is given in Table 4.2. After an initial denaturation step at 95°C, steps 2, 3, and 4 are then sequentially performed for 35 cycles, followed by step 5 at 72°C to ensure that the final round of strand synthesis at high substrate concentration is completed. The 6th step, involving reduction of the temperature to 4°C, is used to terminate all reactions for convenient holding until agarose gel electrophoresis is performed. The time required to traverse from one temperature to another is referred to as the

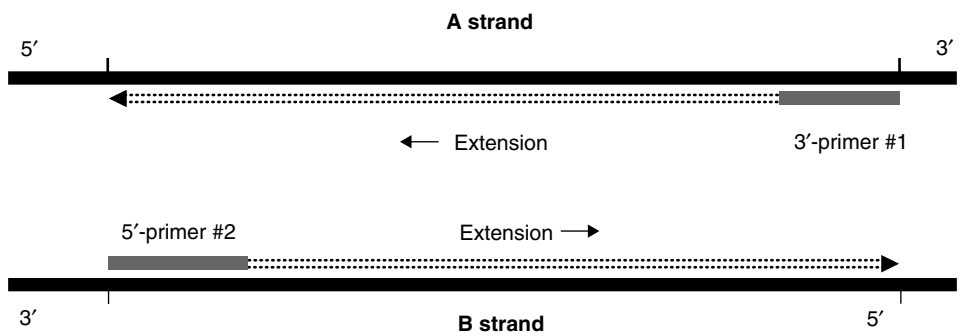

Figure 4.1 Amplification of a known target sequence with a set of two primers.

Table 4.1
Typical PCR reaction components.

1.	Template DNA	1-10 µl
2.	Tris-HCl (pH 8.3 @ 20°C)	20 mM
3.	KCl	25 mM
4.	Triton X-100	0.1%
5.	dNTP's (dATP, dCTP, dGTP, dTTP)	50 mM each
6.	*Taq* polymerase	1.0 unit
7.	$MgCl_2$	1.5 mM
8.	Primers	10 pmoles each

Table 4.2
Typical PCR thermal cycling protocol

Step#	Process	Temperature	Time
1	Initial denaturation	95°C	3 min
2	Denaturation	95°C	1 min
3	Annealing	60°C	1 min
4	Extension	72°C	1 min
5	Final extension step	72°C	4–7 min
6	Terminate reactions and hold	4°C	1–16 min

ramp time, and usually contributes significantly to the total thermal cycling time. Most 35 cycle amplification protocols for PCR are usually completed within 3 to 4 hrs. The total cycling time can often be significantly reduced to less than 90 min by lowering each holding time to 10–20 sec.

4.1.3 Sample Preparation Without Enrichment

A variety of components in foods and various tissues are capable of inhibiting PCR. Sample preparation is therefore one of the more critical steps that can adversely affect PCR. Meat and cheese products are particularly challenging. With ground beef, a 10 g sample is stomached with 90 mL of 0.01 M phosphate buffered saline (PBS, pH 6.0) in a Wirl-pak™ stomacher bag with a mesh insert and homogenized at normal speed for 60 s. A majority of the homogenate (~80 mL) is then centrifuged at low speed (160 g, or 1000 rpm) for 3 min at 4°C to pellet tissue debriss. Most of the supernatant (~75 mL) is then centrifuged at high speed (16,000 g or 10,000 rpm) for 10 min at 4°C to pellet bacterial cells. The supernatant is discarded and the pellet is resuspended in 1 mL of saline solution.

4.1.4 Lysing of Cells and Isolation of Bacterial DNA

Lysing solution (1 mL) (3) at 2X concentration (5.0 mg/ml of sodium azide and 4.0% Triton X-100 in 0.2 M Tris-HCl buffer, pH 8.0) containing proteinase K (0.4 mg/mL) is then added to the resuspended pellet from above. After incubation for 30 min at 37°C the sample is heated at 100°C for 10 min to inactivate the proteinase K and to lyse the target cells. The lysate is then centrifuged at 10,000 g for 10 min to remove cellular debriss.

Bacterial DNA is then isolated from the lysate with the "Wizard" DNA cleanup system (Promega Co, Madison, Wisconsin, USA) by mixing 0.45 mL of the lysate with 1.0 mL of the DNA cleanup resin. The mixture is then passed through a "Wizard" micro

column, washed with 2.0 mL of 80% isopropanol, and dried by centrifugation (2 min at 10,000 g). DNA is then eluted from the column with 0.45 µl of sterile Milli-Q water. The eluate is then mixed with 1 µl of pellet paint (Novogen Co., Madison, Wisconsin, USA), which is a visible fluorescent dye labeled carrier to facilitate visualization of the ultimate DNA pellet, followed by the addition of 5 µl of 3M sodium acetate and 102 µl of ice cold 100% ethanol. The preparation is then stored at 4°C for 30 min and then centrifuged at 14,000 g at 4°C for 10 min. The supernatant is removed, the pellet air dried, and dissolved in 20 µl of sterile Milli-Q water, and the entire preparation incorporated into the PCR reaction.

4.1.5 PCR for Identification of Pure Cultures

Confirmation of the identity of pure cultures using PCR is most readily achieved by picking up a small visible amount of cells from an agar culture on the end of a needle and suspending the cells in 20 µl of Milli-Q water. Gene releaser (20 µl, Bioventure, inc., Murfreesboro, TN) is then added and the heating protocol of the manufacturer is used to lyse the cells. 1.0 µl of the resulting cell lysate is then added directly to the PCR reaction mixture.

4.1.6 Quantitative PCR

The author has found that the following methodology is ideally suited for quantitative assessment of target DNA incorporating an internal standard with the use of a conventional thermal cycler.

The operational assumption is that PCR yields an exponential rate of increase of the initial number of target DNA molecules. This is described by the following equation:

$$P = T\,(2^n) \tag{4.1}$$

where P is the number of PCR product molecules formed, T is the number of input target sequences, and n is the number of amplification cycles.

This exponential equation does not, however, apply to the entire amplification process. During the first few cycles, when the number of initial target molecules is very low, the rate of amplification can be anticipated to be low (4). During the last few cycles, when the ratio of PCR product molecules to unreacted primer and *Taq* polymerase molecules has greatly increased, the overall amplification rate can be expected to decrease significantly from an exponential rate. This is illustrated in Figure 4.2. It is only along the linear portion of the plot that a reliable quantitative relationship between the number of input molecules and final accumulated products can be derived. A direct approach to determine when amplification enters the plateau phase is to increase the number of input target molecules and measure the number of product molecules after cycling (Figure 4.2). With quantitative PCR assays, it is important that the initial number of target DNA molecules be low, because the linear range of amplification is represented by no more than about a two log increase in DNA. This will often result in a working range of input target colony forming units (CFU) of about $1.5 \times 10^2 - 1.5 \times 10^4$ (5). If an enrichment step (usually 4.5–6.0 hrs.) is used, then an appropriate dilution of the resulting CFU should be used for the PCR to ensure that the number of input target molecules falls within the linear PCR amplification range. There are several advantages to the use of nonselective enrichment cultivation of food samples: only viable CFU are increased, detection of the initial viable CFU is lowered to 0.5 to 1.0 CFU/g of sample, and dilution of PCR inhibitors in the food sample.

It is important to keep in mind that a 10% reduction in the efficiency of amplification will result in a reduction of PCR product accumulation by more than 95% (4). The inclusion of an internal standard involving an identical set of primers and a similar target can be used to eliminate variations in amplification efficiency, allowing reliable PCR quantitation.

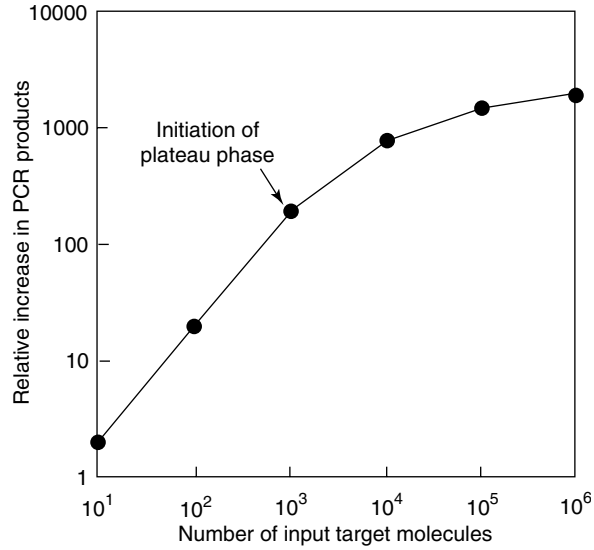

Figure 4.2 Dependence of PCR product accumulation on number of input targets from 35 amplification cycles.

4.1.7 Use of an Internal Standard for Quantitative PCR

The application of an internal standard is based on the coamplification of the target sequence and an internal DNA standard, which is amplified with the same efficiency as the target sequence by using the same primer pair. The internal standard contains the same primer binding sites as the target, and the two DNA pieces compete for reaction reagents to produce PCR products of different sizes, which can be separated in an agarose gel. The log ratio of intensities of amplified target DNA to internal standard is determined by the following equation given by Zarchar et al. (7):

$$-\text{Log}\,(N_{n1}/N_{n2}) = \log\,(N_{01}/N_{02}) + n\log\,(\text{eff}_1/\text{eff}_2) \tag{4.2}$$

Where N_{n1} is the number of resulting target molecules after amplification, N_{n2} is the number of resulting internal standard molecules after amplification, N_{01} is the number of initial target molecules, N_{02} is the number of initial internal standard molecules, n is a given cycle, eff_1 is the efficiency of amplification of target molecules, and eff_2 is the efficiency of amplification of internal standard molecules.

If the efficiencies of amplification ($\text{eff}_1/\text{eff}_2$) are equal, the ratio of amplified products (N_{n1}/N_{n2}) is dependant on the log ratio of starting reactants (N_{01}/N_{02}). Even if the efficiencies of the two reactions are not equal, the values for N_{n1}/N_{n2} still hold, assuming that $\text{eff}_1/\text{eff}_2$ is constant and amplification is in the exponential phase (7). With this technique, varying amounts of target DNA are coamplified with a constant amount of internal standard. The resulting log ratio of intensities of PCR products are plotted against the log of target CFU for construction of a standard curve which is used for determining the number of CFU per gram of food product.

4.1.8 Construction of an Internal Standard for Quantitative PCR

The ideal internal standard should consist of a nucleotide sequence derived from the target sequence, and should utilize the same two primers and primer binding sites so that when the internal standard is added to the PCR mix, amplification occurs in a competitive mode. An internal DNA standard can be synthesized by PCR using a hybrid primer and the

reverse primer (8). The hybrid primer contains two components: a 5′-portion consisting of the original forward primer, and a 3′-portion consisting of a small DNA fragment derived from the target sequence. A 20 nucleotide sequence, about 200 to 300 nucleotides in from the 5′ terminal of the target sequence, is identified and a hybrid primer is synthesized (Figure 4.3) for use in the construction of an internal DNA standard. Complete details are given by Guan and Levin (6).

4.1.9 Construction of a Calibration Curve for Quantitative PCR

Varying amounts target DNA from a pure culture are coamplified with a constant amount of the internal standard (IS). The amplified co-PCR products are separated by electrophoresis in a 1.5% agarose gel (Figure 4.4). The gel images are then captured by an Electronic Archival System (Spectroline Model EAS-1000 Spectronics Corp., Westbury, New York, U.S.A.) and analyzed with NIH Image 1.61 software. To correct differences in the intensity of fluorescence of ethidium bromide stained PCR fragments of different sizes, the intensity of the internal standard is multiplied by the ratio of the number of nucleotides in the target sequence to that of the internal standard. The log of the ratio of fluorescence intensity of the amplified target sequence to that of the internal standard is then plotted against the log of CFU to establish a standard curve, using a constant amount of internal standard and varying the number of CFU (Figure 4.5). It is important to note that the calibration curve is operational over little more than a one log cycle of input target sequences (CFU).

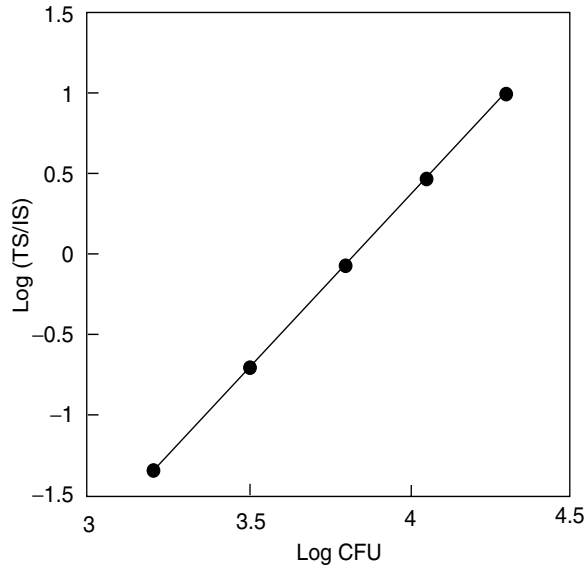

Figure 4.5 Standard curve for quantitative PCR.

4.1.10 The Use of Immunomagnetic Beads in Conjunction with PCR

The use of immunomagnetic beads coupled with PCR for the detection of specific pathogens in foods affords an additional element of selectivity if required (6). *Escherichia coli* O157:H7 produces two shigalike toxins, designated SLT-1 and SLT-2. Both of these toxins are also produced by other serotypes of *E. coli,* and by *Shigella shiga.* If DNA sequences derived from the genes coding for these toxins are used as the targets for amplification to detect this pathogen, the possibility exists that organisms other than *E. coli* O157:H7 may be mistaken for the target organism. The use of immunomagnetic beads coated with *E. coli* O157 specific antibody allows the specific target organism to be physically captured before PCR is undertaken. Immunomagnetic separation (IMS) of the target organism also allows its physical separation from PCR inhibitors in the food product or culture medium. Immunomagnetic separation is presently recognized as an efficient method to increase specificity and to concentrate a target organism from a food product.

A wide size range of immunomagnetic beads (IMB) is available. Generally, beads with a nominal mean diameter of 4.5 μ are used to capture bacterial cells. The magnetic beads are manufactured by precipitating microscopic grains of superparamagnetic iron oxide onto a monodispersion of polymer particles such as polystyrene. The particles may then be coated with a polymeric material such as polystyrene to facilitate subsequent surface binding of immunoglobulins. Alternatively, porous borosilicate glass particles are embedded with superparamagnetic iron oxide. Affinity purified immunoglobulin is covalently bound to the surface of the beads. Magnetic beads are also

available for adsorption coating of immunoglobulins. The term paramagnetic refers to the ability of the beads to exhibit magnetic properties when placed in a magnetic field, without retaining residual magnetism when removed from the magnetic field. Superparamagnetic beads exhibit magnetic properties on all sides or throughout their surface. The beads may be irregular in shape or highly uniform spheres. The author has found that if the beads are not coated with polystyrene and they are added directly to a PCR reaction tube, they will inhibit the PCR, presumably due to leakage of Fe_2O_3 out of the beads. Paramagnetic beads are now commercially available, coated with sheep anti-rabbit IgG antibodies, to facilitate coating with any secondary IgG of rabbit origin. Beads are also available coated with sheep antimouse Ig to facilitate coating with any secondary monoclonal antibody. IgG coated beads for capture of *Listeria* species, *Salmonella* species, *E. coli* O157, and *Cryptosporidium parvum* are available at a concentration of at least 4×10^8 beads/mL.

The direct use of magnetic beads on a homogenized food, however, is encumbered by fibrous food products such as meats. With such products, a 4.5–6.0 hr nonselective enrichment is useful in that it allows subsequent dilution of the enrichment broth to eliminate interference of magnetic separation of the beads from tissue debris. Alternatively, without enrichment, differential centrifugation can be used with meat products involving the stomaching of 10 g of product with 90 mL of diluent such as PBS (pH 7.4), followed by initial low speed centrifugation for 3 min at 1,000 rpm (164 g) at 4°C to sediment tissue debris. The supernatant is then removed and subjected to high speed centrifugation at 10,000 rpm (16,300 g) for 10 min at 4°C to pellet the cells. The cell pellet is then suspended in 1.0 mL of PBS followed by the addition of 0.02 mL of IMB (2×10^6 total beads). The beads will capture the target organisms when the sample is subjected to slow intermittent agitation and usually requires 60 min for maximum binding of cells to the beads (6). Any magnet can be used to magnetically attract and pellet the beads with bound cells. We have found however, that the larger the magnet and its magnetic power, the more rapidly are the beads concentrated. We routinely use rectangular bar magnets (Harbor Freight Tools, Cammarillo, CA) with a lifting capacity of 150 lbs ($6'' \times 1'' \times 1.75''$) that magnetically pellet the beads within 2 min. The pelleted beads can be readily washed and resuspended several times with intermittent magnetic pelleting before the captured cells are lysed for PCR.

4.1.11 Nested PCR

The use of a pair of "nested primers" flanking a DNA sequence internal to the sequence encompassed by the external pair of primers allows a greater level of amplification than is normally achieved with a single set of primers. A target sequence is initially amplified by an external pair of primers for 20–40 cycles. A small aliquot of this reaction is then amplified a second time, for another 20–40 cycles using the internal or nested primer set (Figure 4.6). The inner pair of primers anneal to complementary sequences internal to the initially amplified product. This has been shown to result in greater amplification than reamplifying with the same initial pair of primers (9). The number of nucleotides flanked by the internally nested primers determines the final product size.

Nested PCR is of particular value with foods in the absence of enrichment cultivation, where inhibitors present from the food may significantly reduce the efficiency of amplification. In addition, the nested primers serve as a control for the specificity of the amplified external sequence and can therefore improve both sensitivity and specificity of DNA amplification (10). Nested PCR, however, introduces an additional risk of amplification of contaminating DNA when used routinely. This problem can be circumvented by using a "one tube nested PCR" involving the use of two primer pairs of

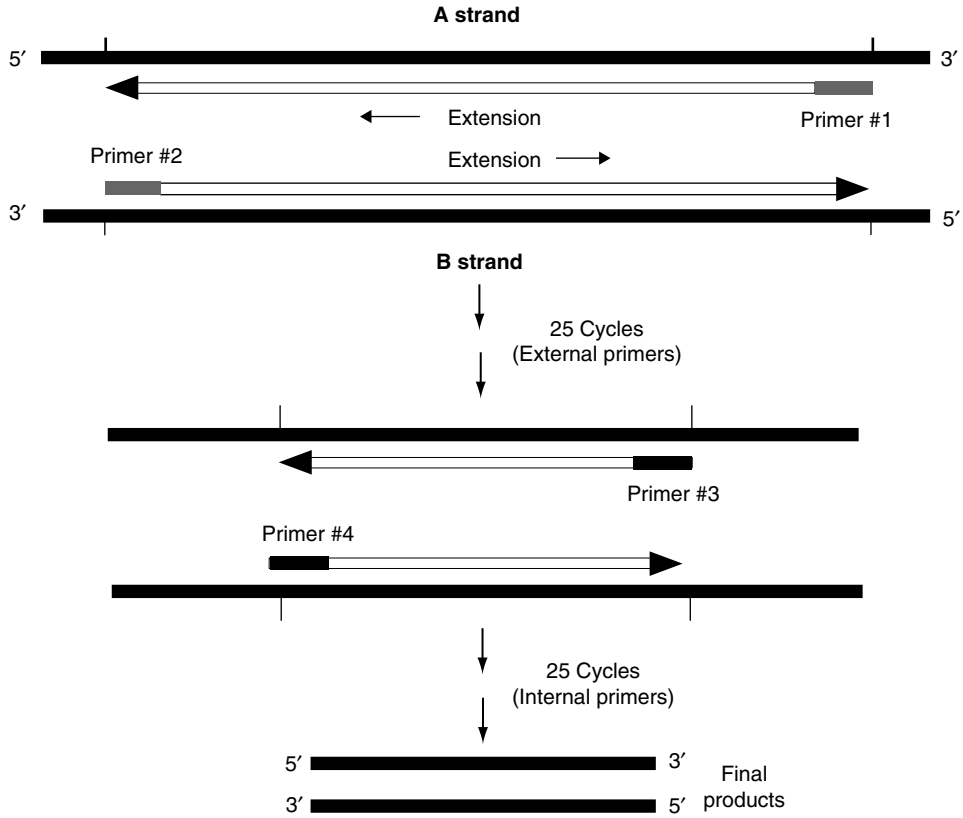

Figure 4.6 Two tube nested PCR. Amplification with external primers for 25 cycles followed by amplification of an aliquot for 25 cycles using internal nested primers.

different melting points (Tm values) in a single reaction mixture. Annealing of the nested primers during the first set of cycles is prevented by their lower Tm. The larger external fragment should ideally have a higher G + C content so that it will denature at a slightly higher temperature than the nested fragment. This difference in Tm values for the two amplified products has to be critically determined for both the larger and the nested fragment. A number of mathematical approaches have been developed for calculating the Tm based on either the G + C content of the fragments or slightly more accurate values based on nearest neighbor thermodynamics (11–13). Other calculations of Tm values for primers are based on formulas developed for nucleotides over 100 bp in length (14). The equation of Suggs et al. (15),

$$\text{Tm} = 2°\text{C} \times (\text{A} + \text{T}) + 4°\text{C} \times (\text{G} + \text{C}) \tag{4.3}$$

is widely used for its convenience and approximate determination of Tm values of primers. In addition, the GCG software program "Prime" will readily determine Tm values for primers.

Nested PCR has been applied to the detection of a variety of pathogens in a number of foods (16–20). The use of immunomagnetic capture of target cells prior to nested PCR has been found to increase the sensitivity of detection of *E. coli* O157:H7 from ground beef without enrichment cultivation from 110 CFU/10 g to 24 CFU/10 g (21) presumably due to magnetic separation of captured cells from PCR inhibitors.

4.2 RANDOM AMPLIFICATION OF POLYMORPHIC DNA

4.2.1 Introduction

Random Amplification of Polymorphic DNA (RAPD) has been found to be a rapid and valuable technique for distinguishing different strains of the same species (22) with a high level of strain discrimination (23). It is a particularly useful technique for genetic typing of human pathogens from foods, processing plants, and foodborne outbreaks. In addition, it has been found to be a powerful method can advantageously replace other more cumbersome typing methods such as serotyping, ribotyping, multilocus enzyme electrophoresis, restriction enzyme analysis, and phage typing, and has been found to be very efficient in differentiating strains while still allowing the clear recognition of clusters (24). Random Amplification of Polymorphic DNA has been found capable of distinguishing strains of a given species with identical 16s rDNA sequences (25). This high level of discrimination should allow RAPD to be used in establishing the persistence of a specific strain in foods and in processing plants and its distinction from transient strains of the same species.

4.2.2 Mechanism of RAPD

In conventional PCR, a known DNA sequence is amplified by using two primers, one that anneals to the 3′ end of the sequence on the A strand and is extended inward with *Taq* polymerase from the 3′ end of the primer. The second primer anneals to the 3′ of the B strand and is also extended inward from the 3′ end (Figure 4.1). After the first cycle and denaturation, four target sequences are then available for duplication. The sequence is usually highly specific for the target gene and occurs only once (monomorphic) in the genomic DNA of the organism.

With (RAPD) a single random primer of about 10 nucleotides is used, with no known target sequence being required, and the first round of amplification results in single strands having palindromatic termini (Figure 4.7). The single randomly chosen primer targets specific but unknown sites in the genomic DNA, which are polymorphic (repeating) with respect to the terminal sequences that the single primer anneals to. During subsequent cycles a number of different target sequences are amplified, many of which will be of differing base pair length so as to generate a variety of DNA agarose bands, resulting in a specific DNA banding pattern for each culture (Figure 4.8).

The ratio of primer to template in the RAPD reaction is critical. Template DNA concentration should be carefully titered against a standard concentration of primer so as to reveal the most reproducible amplified products (26). A hazy smear obscuring the amplified bands on the agarose gel is usually caused by failure to saturate the DNA template with primer. This is easily corrected by adjusting the ratio of primer to template DNA (26). Meuner and Grimont (27) expressed concern about the reproducibility of RAPD profiles, but concluded that reproducibility was excellent with standardized methodology. They found that reproducibility of banding patterns was dependant on the make of thermal cycler, with variations in patterns occurring with less rigid temperature control. Reproducibility of RAPD with whole cells is critically dependant on all strains being in the same stage of growth (24). Mazurier and Wernars (28) obtained reproducibility in RAPD profiling of strains of *L. monocytogenes* by using suspensions of washed whole cells grown overnight in broth that were adjusted to an absorbance at 600 nm of 1.5 yielding 7.5×10^6 CFU/ml. 5 µl of the cell suspension were then incorporated directly into a 50 µl PCR reaction volume without a prior cell lysis step. Establishing the same cell density among isolates being subjected to RAPD comparison is particularly important for reproducibility of faint bands.

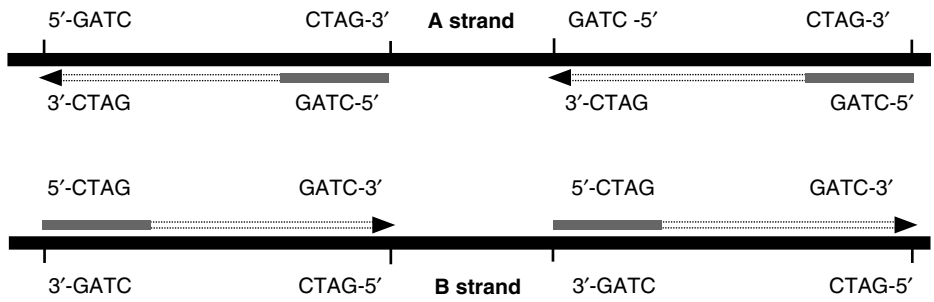

Figure 4.7 Random amplification of polymorphic sequences with a single random primer.

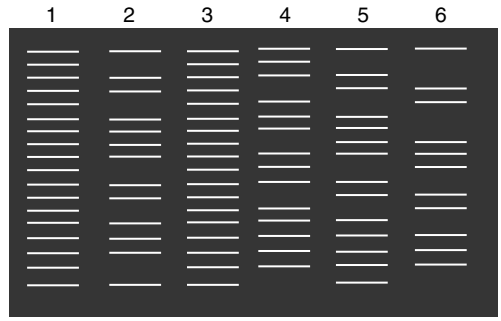

Figure 4.8 RAPD banding profiles of 6 bacterial isolates of the same species. Isolates corresponding to lanes 1 and 3 have identical DNA banding patterns and are therefore considered of identical clonal origin. Isolates corresponding to lanes 2, 4, 5, and 6 are distinguishable from each of the other 5 isolates on the basis of differences in the DNA banding patterns.

4.3 PULSED FIELD GEL ELECTROPHORESIS

4.3.1 Introduction

Pulsed Field Gel Electrophoresis (PFGE) is presently considered the method of choice for discriminating genetic differences and lineage among strains of the same bacterial pathogen. The method is particularly useful in epidemiology, and has also been applied to the detection of clonal strains of pathogens that have been found to persist in food manufacturing facilities (29–31).

4.3.2 Mechanism of PFGE

Pulsed Field Gel Electrophoresis is based on the use of low frequency restriction nucleases to generate a family of high molecular weight fragments derived from genomic DNA, and their subsequent resolution based on size using changes in the direction of the electric field during agarose electrophoresis. Large fragments stretch out linearly in the direction of the electric field. When the direction of the field changes, the fragments undergo an initial relaxation in conformation and then form multiple undulations or kinks in the direction of the new field, followed by linearization (32). The most widely adapted system presently is the contour clamped homogeneous electric field (CHEF) apparatus, involving a hexagonal distribution of electrodes that undergo periodic alternate uniform

electric fields with an angle of 120° (Figure 4.9). Clamped homogeneous electric field instruments are available from Bio-Rad, Pharmacia, and BRL. A longer pulse time increases the size of the fragment that can be separated, but results in a decrease in resolution of fragments of similar size. Progressive increases in pulse time (pulse time ramping) can significantly increase resolution. A ramp from 5 s to 40 s will allow optimal separation of DNA fragments from 50 kb to 600 kb, while increasing the pulse time to 75 s will extend the separation to 1 Mb (33). Pulsed field gel electrophoresis is usually performed at 12–15°C for enhanced band resolution, and to prevent the development of temperature gradients in the gel. Agarose of high gel strength and low elecroendosmosis (EEO) is used. Fragments of DNA from 50 kb to 1 Mb are usually separated with 1.0% agarose. Reducing the agarose concentration will increase the pore size and allow separation of larger fragments. Higher concentrations of agarose (1.2–1.6%) reduces pore size, and will increase resolution and sharpness of bands, but reduces separation of larger fragments and results in longer running times (33). Birren et al. (34) have reported on optimized conditions for PFGE and the effects of a variety of variables on the resolution of DNA fragments.

The restriction nucleases used with PFGE are selected on the basis of the rarity of their recognition sequence in the target genome. Struelens et al. (33) and Tenover et al. (36) have listed restriction nucleases useful for PFGE analysis of a number of bacterial genera and species.

The usual methodology for DNA extraction is unsuitable for PFGE because the large size of genomic bacterial DNA (~5×10^9 Da) results in rapid shearing during pipeting to ~1×10^7 Da. To prevent such rupture of large DNA molecules, intact cells are embedded in an equal volume of 2.0% nuclease free, low melting temperature agarose plugs. The cells are then lysed *in situ* immersing the plugs first in lysozyme, and then proteinase, K, or other suitably lytic enzymes for the specific organism involved. To save time, lysozyme can be added to the agarose and cell mixture before solidification The agarose plugs are then placed in wells for PFGE. Uniform cell densities of $1 - 5 \times 10^9$ cells/mL are critical for valid comparison of resolved bands. Adjusting cell suspensions to a uniform A_{600} value is reliably effective and convenient, provided each culture is of the same age. To ensure adequate alignment and normalization of banding patterns, and accurate fragment size estimates, appropriate DNA ladders should be included in at least every fifth lane (33).

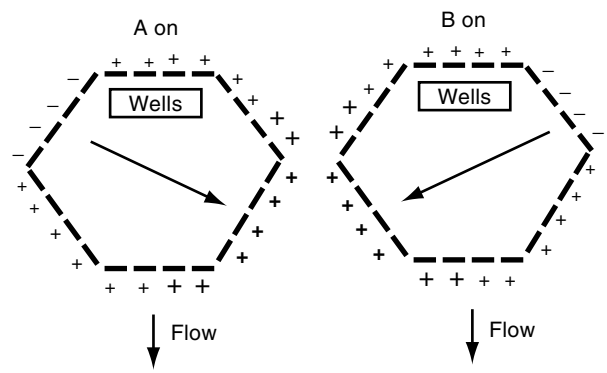

Figure 4.9 Voltage clamping by the CHEF-DR-II system. (a) Relative electrode potentials when +60° held vector is activated. (b) Relative electrode potentials when the −60° held vector is activated.

4.3.3 Interpretation of PFGE Banding Patterns

Distinctions in banding patterns are based on the size and shape of resolved bands. The problem of how minor differences in banding patterns should be interpreted has been dealt with in detail by Tenover et al. (36), with the establishment of well reasoned criteria based on the resolution of at least 10 distinct fragments derived from each culture being compared. The utility of strain typing using PFGE is based on the assumption that isolates derived from the same reference strain are of recent lineage from the original strain. A limitation occasionally arises when unrelated isolates may have similar or indistinguishable genotypes, especially if there is limited genetic diversity within a species or subtype (37). It should also be assumed that random genetic events, including end point mutations and deletions and insertions of nucleotides, will alter PFGE patterns of DNA from progeny derived from an original reference strain. An isolate is interpreted to be closely related to a reference strain if its PFGE pattern differs from the reference strain by changes reflecting a single genetic event, i.e., a point mutation or a frame shift mutation involving the insertion or deletion of one or more sequential nucleotides. Such changes usually result in two to three band differences. For example, a single spontaneous mutation that creates a new genomic restriction site will split one restriction fragment into two smaller ones. The loss of the original large fragment plus the appearance of two new smaller fragments will result in a three band difference between the reference strain and its direct progeny that has undergone such a single mutational event (36). In addition, variations of two to three bands have been reported in strains repeatedly cultured or isolated multiple times from the same patient (38, 39). Patterns that are distinctly different from an outbreak or reference strain by only two or three fragments should therefore be considered subtypes of the same clonal lineage. An isolate is considered to be possibly related to a reference strain if there are four to six different band differences. An isolate should be considered unrelated to a reference strain if its PFGE pattern differs by seven or more bands, reflecting three or more independent genetic events.

4.4 SUMMARY

The PCR is a powerful analytical method that can be used to rapidly identify microorganisms of public health significance. The method has been advanced to the state where it can be effectively used at present to detect and quantitate the presence of low numbers (~1 CFU/g) of specific organisms in foods and on processing equipment in near real time without the necessity for overnight cultivation, isolation, and subsequent immunological and time consuming metabolic identification. Those aspects of the food industry presently encountering massive and costly recalls are in critical need of near real time assays such as the PCR prior to shipment of product. When the PCR is coupled to immunomagnetic capture a high level of specificity can be achieved. The application of RAPD and PFGE for assessing clonal similarities and distinctions among strains of the same species derived from food processing equipment, foods, and foodborne outbreaks, is encountering widespread use and acceptance.

Control of Food Borne Bacterial Pathogens in Animals and Animal Products through Microbial Antagonism

Mindy M. Brashears, Alejandro Amezquita, and Divya Jaroni

CONTENTS

5.1 MICROBIAL ANTAGONISM

The concept of microbial antagonism or microbial interference has been known for a long time, even before other common food preservation methods (i.e., canning or refrigeration) were established. Microbial antagonism is the inhibition of undesired or pathogenic microorganisms caused by competition for nutrients, and by the production of antimicrobial metabolites (68,77,79,82,85,163). Pure cultures of lactic acid bacteria (LAB) have been used since the beginning of the twentieth century as starter cultures in fermented food products. Metabolism of these cultures may contribute in a number of different ways to the control of pathogens and the extension of the shelf life as well as modification of the sensory attributes of the food product (68,77,82,85). Antagonism between two different species or genera of microorganisms takes place when they compete for a common niche, or when one of the microorganisms produces an antagonistic extracellular agent or modifies the environment such that the other is inhibited (79,107,172).

The use of LAB as protective cultures rather than starter cultures has gained importance during recent years. Biopreservation is the extended storage life and enhanced safety of food products using their natural or controlled microflora and their antibacterial products (68,77,85,163). Additionally, the protective effects can inhibit food borne pathogens in a live animal prior to slaughter.

5.1.1 Lactic Acid Bacteria

The lactic acid bacteria constitute a group of Gram-positive bacteria that share similar morphologic, metabolic, and physiologic characteristics. They are nonsporeforming rods and cocci that ferment carbohydrates, forming lactic acid as the major end product (5), hence the denomination lactic acid bacteria. Depending on the metabolic pathways used to ferment carbohydrates and the resulting end products, lactic acid bacteria are divided into two major groups, homofermentative or heterofermentative. They are generally catalase negative, anaerobic, and nonmotile, and do not reduce nitrate (145). Lactic acid bacteria have complex nutritional requirements such as carbohydrates, amino acids, peptides, nucleic acid derivatives, fatty acids, salts, and vitamins for their growth (72). They are generally acid tolerant with different species having adapted to grow under widely different environmental conditions. They are widespread in nature, found wherever high concentrations of soluble carbohydrates, protein breakdown products, vitamins, and a low oxygen tension occur (146). Consequently they are common in milk and dairy products, fermented foods, intact and rotting vegetable material, silage, and the intestinal tracts and mucous membranes of humans and animals.

Phylogenetically, the lactic acid bacteria belong to the clostridial branch of the Gram-positive bacteria, which also includes genera such as *Clostridium, Bacillus, Listeria* and *Staphylococcu*s, and is characterized by a low G + C DNA content (5). However, the term lactic acid bacteria has become commonly associated with the genera *Lactobacillus,*

Lactococcus, Leuconostoc, Pediococcus, *Enterococcus,* and *Streptococcus*. Members of this bacterial group are known to provide considerable benefits to humankind, some as natural inhabitants of the intestinal tract and others as fermentative bacteria that impart flavor and texture to a multitude of fermented foods. For many years there has also been widespread interest in the use of lactic acid bacteria in the biological preservation of foods. These organisms are particularly suitable as antagonistic microorganisms in food because of their ability to inhibit other food borne bacteria by a variety of means, including production of organic acids, hydrogen peroxide, or bacteriocins. In recent years their use as direct fed microbials for humans and animals has received increased attention (54,89). Their favorable effect on growth and health is thought to be due to the modulation of other bacterial growth through one or more of these antagonistic factors.

5.2 REDUCTION OF FOOD BORNE PATHOGENS IN FOODS OF ANIMAL ORIGIN

Biopreservation of foods in food and meat systems can be achieved by different mechanisms: (1) adding a pure culture of a bacteriocin-producing strain of LAB to favor *in situ* production of the bacteriocin, (2) adding only the bacteriocin, either as a crude preparation or as a purified compound to have more predictable results, or (3) adding strains of LAB that do not grow at refrigeration temperatures to serve as indicators of temperature abuse and to protect the products from the growth of pathogens under temperature abuse conditions (50,80,107,162).

Many strains and species of lactic acid bacteria are generally considered as food grade microorganisms, and are considered GRAS (Generally Regarded as Safe) because they have had a history of safe, widespread use in the manufacture of food prior to the 1958 Food Additives Amendment. The use of LAB cells in numerous food fermentations is a common practice. Cells of food grade LAB are added to foods mainly for three reasons: to produce safe, shelf stable, and desirable fermented foods; to serve as indicators of product abuse, especially temperature abuse of some refrigerated foods; and to control the growth of spoilage and pathogenic bacteria in refrigerated foods. The first two applications require the growth of LAB cells, whereas for the last application, the mere presence of cells is effective, and growth is undesirable (86,162).

5.2.1 Antimicrobial Substances Produced by Lactic Acid Bacteria During *In Vitro* Application

Reduction of pH and removal of large amounts of carbohydrates by fermentation are the primary preserving actions that LAB provide, mainly in fermented foods. However, it has also been recognized that LAB are capable of producing inhibitory substances other than organic acids, with inhibitory activity to different microorganisms. Additionally, these substances may be produced at refrigeration temperatures with no growth (8). These substances include hydrogen peroxide (38,89,137,141,175,180), diacetyl (85,128), reuterin (9,48), bacteriocins (27,32,91,127,163,164), and other low molecular weight metabolites (122).

5.2.1.1 Hydrogen Peroxide

Many fermentative bacteria, including LAB, produce hydrogen peroxide (H_2O_2) as a mechanism for protecting themselves against oxygen toxicity. Lactic acid producing bacteria, lack heme and thus do not utilize the cytochrome system (which reduces oxygen

to water in respiratory metabolism) for terminal oxidation. Lactic acid producing bacteria utilize flavoproteins, which generally convert oxygen to H_2O_2. This mechanism, together with the absence of the heme protein catalase, generally results in the formation of H_2O_2 in amounts that are in excess of the capacity of the organism to degrade it. The H_2O_2 formed may inhibit or kill other members of the microbiota. Hydrogen peroxide is an effective antimicrobial due to its strong oxidizing effect on the bacterial cell; sulfhydril groups of cell proteins and membrane lipids can be oxidized (34,90,92,107,175,180). The formation and accumulation of H_2O_2 in growth media with a subsequent antagonistic effect was shown with *Staphylococcus aureus* (38) and *Pseudomonas* species (137). Hydrogen peroxide can react with other components to form inhibitory substances. In raw milk, for instance, hydrogen peroxide generated by LAB can react with endogenous thiocyanate that is catalyzed by lactoperoxidase to form intermediary oxidation products inhibitory to microorganisms. This mechanism, also known as the lactoperoxidase antibacterial system (LP system or LPS), has been well documented (34,98,135). Rodríguez et al. (141) studied the combined effect of the LP system and bacteriocin producing strains of LAB in milk at 4°C and 8°C to inhibit the growth of *Listeria monocytogenes*. These authors failed to demonstrate synergism between these two antimicrobial systems, given that the increment in the reduction levels of the pathogen was only 0.19 $\log_{10}$ cycles after 4 days at 8°C when the combined treatment was applied. The authors suggested that rather than synergism, the production of nisin by the evaluated strain of *Lactococcus lactis* subspecies *lactis* (strain ESI 515) was enhanced in activated in LP system milk.

5.2.1.2 Weak Organic Acids

Lactic acid bacteria are nonrespiring microorganisms, principally generating ATP by fermentation of carbohydrates coupled to substrate level phosphorylation. The two major pathways for the metabolism of hexoses are homofermentative or glycolysis (Embden-Meyerhof pathway), in which lactic acid is virtually the only end product; and heterofermentative (phosphoketolase pathway), in which other end products such as acetic acid, CO_2, and ethanol are produced in addition to lactic acid (9,93,184).

Weak organic acids are known to have strong antimicrobial activity. In solution, these acids exist in a pH dependent equilibrium between the undissociated and dissociated state. Their effectiveness as antimicrobials is greater at low pH because this favors the uncharged, undissociated state of the molecule, which is freely permeable across the cell membrane, because it is lipid soluble (36). Subsequently, upon encountering the higher pH inside the cell, the molecule will dissociate, resulting in the release and accumulation of charged anions and protons, which cannot cross the cell membrane (20,45,128).

Of the two major weak organic acids produced by lactic acid bacteria, acetic and lactic acid, the former is the strongest inhibitor due to its higher dissociation constant (pK_a=4.75) as compared to lactic acid (pK_a=3.08) at a given molar concentration and pH (45,77,128).

Ahamad and Marth (6) found that 0.2% (approximately 22 mM) lactic acid inhibited the growth of *Listeria monocytogenes* strains V7 and CA in tryptose broth at 7°C, but that a minimum of 0.3% (approximately 33 mM) was required for lethal effect.

5.2.1.3 Reuterin

Reuterin is a neutral, broad spectrum antimicrobial substance formed during anaerobic growth of *Lactobacillus reuteri* in the presence of glycerol (9). Reuterin is an equilibrium mixture of

monomeric, hydrated monomeric, and cyclic dimeric forms of β-hydroxypropionaldehyde. The inhibitory effect of reuterin has been associated with its action on DNA synthesis by acting as an inhibitor of the substrate binding subunit of ribonucleotide reductase.

El-Ziney et al. (48) reported the antimicrobial activity of reuterin against *E. coli* O157:H7 and *Listeria monocytogenes* on the surface of cooked pork at 7°C. The initial levels of each pathogen on the surface of the product were approximately $\log_{10}$ 5 CFU/cm^2. After 15 seconds of application of reuterin (500 AU/ml), the numbers decreased by 0.45 and 0.3 $\log_{10}$ CFU/cm^2 for *E. coli* O157:H7 and *L. monocytogenes*, respectively. After 24 h of exposure to reuterin, the numbers decreased by 2.7 $\log_{10}$ CFU/cm^2 for *E. coli* O157:H7 and 0.63 $\log_{10}$ CFU/cm^2 for *L. monocytogenes*.

5.2.1.4 Diacetyl

Diacetyl is the compound responsible for the characteristic aroma and flavor of butter. It is produced by species of the genera *Lactobacillus*, *Leuconostoc*, *Pediococcus*, and *Lactococcus* (85). Diacetyl is formed from the metabolism of citrate via pyruvate (9,107). Jay (85) reported that this compound was more effective when the pH was lower than 7.0, but it was progressively ineffective at pH values higher than 7.0. This study was particularly extensive because it evaluated the antimicrobial effects of diacetyl against 40 different cultures, including 10 of LAB, 12 of Gram-positive non-LAB, 14 of Gram-negative bacteria, and 4 of yeasts. Diacetyl was found to be more active against Gram-negative bacteria, yeasts, and molds than against Gram-positive bacteria.

5.2.1.5 Bacteriocins

The biosynthesis, classification, mode of action and characterization of bacteriocins has been well reviewed and published (11,84,94,95,116,119,120,135,143,163,172,183). Bacteriocins are low molecular weight, heat stable, ribosomally synthesized and cationic proteinaceous compounds, produced by Gram-positive organisms, with antibiotic like functionality against closely related species, mainly Gram-positive bacteria, by adsorption to receptors on the target cells (84,95,96). Klaenhammer (95) proposed that bacteriocins be classified into four major groups, based on their biochemical properties. Class I or lantibiotics are small peptides ($<$ 5 kDa) and membrane active bacteriocins, containing the unusual dehydroamino acids and thioetheramino acids lanthionin and 3-methyllanthionine, respectively. Nisin, produced by *Lactococcus lactis* subspecies *lactis*, is the most widely studied Class I bacteriocin. Class II bacteriocins are subdivided into three subclasses, and in general are small, nonlanthionine containing and heat stable, membrane active peptides. Further subdivisions of Class II bacteriocins include class IIa or Listeria active bacteriocins; class IIb, poration complexes requiring two peptides; and class IIc, thiol activated peptides requiring cysteine residues. Examples of Class II bacteriocins are pediocin JD (IIa) produced by *Pediococcus acidilactici*, lactacin F (IIb) produced by *Lactobacillus johnsonii*, and lactococcin B (IIc) produced by *Lactococcus lactis* subspecies *cremoris*. Class III bacteriocins are large, heat labile proteins. Class IV includes complex bacteriocins, in which lipids and carbohydrates appear to be necessary for activity (95,128). In cases where the mode of action has been investigated, the cell membrane appears to be the site of action. There is enough evidence to conclude that bacteriocins produced by lactic acid bacteria act by the common mechanism of depleting proton motive force (PMF) (27).

Nisin is the best characterized LAB bacteriocin. The structure of nisin was first elucidated by Gross and Morell (70). Nisin dissipates the membrane potential ($\Delta\psi$) in cells of sensitive organisms (142), and causes PMF depletion of whole cells of *L. monocytogenes* (27)

and *Clostridium sporogenes* (127). Other LAB bacteriocins such as lactococcin A, lactococcin B (174), and pediocin JD (32), share this common mechanism of action, which is the dissipation of the PMF in sensitive cells.

5.2.1.6 Low Molecular Weight Metabolites

Some species of LAB have been reported to produce some metabolites of low molecular weight, such as benzoic acid, mevalonolactone, and methylhydantoin, which exhibit inhibitory activity toward Gram-negative bacteria as well as some fungi (122). Niku-Paavola et al. (122) reported the production of compounds with a molecular weight lower than 700 Da that inhibited the growth of the Gram-negative *Pantoea agglomerans* when these substances were used in combination at a level of 10 ppm. Addition of 1% lactic acid produced a synergistic effect, inhibiting the growth of *P. agglomerans* by 100%.

5.2.2 Lactic Acid Bacteria and Inhibition of Food Borne Pathogens in Meat Products

Because much of the inhibitory activity of the lactobacilli is related to like species, much of the work has been focused on the Gram-negative pathogen, Listeria monocytogenes. The inhibition of Listeria monocytogenes in different types of meat products as well as in laboratory media by bacteriocin producing strains of LAB has been reported (8,16,25,28,29,39,41,43,79,87,121,123,135,138,149,150,177,181).

Different genera and species of LAB have been studied for antilisterial properties under different conditions. *Carnobacterium piscicola,* for instance, has been widely studied (28,29,43,123,135,150). In 1995, Pilet et al. (135) reported that two strains out of a total of 22 LAB isolates from fish products were selected for their antilisterial properties and identified as *Carnobacterium piscicola* and *Carnobacterium divergens*. These two isolates turned out to be bacteriocin producing strains, and their bacteriocins were heat resistant and sensitive to pronase E, proteinase K and trypsin. These bacteriocins, named piscicocin V1 and divercin V41, exhibited a bactericidal and nonbacteriolytic mode of action toward *L. monocytogenes*. When the pathogen was grown in the presence of cell free supernatants containing the bacteriocins, the numbers were reduced by approximately 2 $\log_{10}$ cycles after 120 hours of incubation at 30ºC. A similar study reported by Duffes et al. (43) demonstrated that after screening 160 fish isolates of LAB, 23 were selected for antagonism toward *L. monocytogenes*, and 22 of this 23 belonged to the genera *Carnobacteria*. *Carnobacterium divergens* V41, *C. piscicola* V1 and *C. piscicola* SF668 were found to be the most inhibitory strains reducing the numbers of the pathogen from 10^3 to <10 CFU/mL after 11 days of storage at 4ºC in the case of *C. divergens* V41, in a simulated cold smoked fish system (pH = 6.2, 4% NaCl). The mechanism of inhibition was strictly attributed to production of bacteriocin and not to nutritional competition between strains or to the production of other inhibitory substances such as acid or hydrogen peroxide.

Conversely, Buchanan and Bagi (28) reported that two bacteriocin producing strains of *Carnobacterium piscicola* inhibited the growth of *Listeria monocytogenes* in associative cultures in brain heart infusion mainly due to nutrient depletion rather than to the production of bacteriocins. These researchers suggested that *C. piscicola* is a microorganism of rapid growth and in associative cultures with *L. monocytogenes* may produce an insufficiency of a limiting nutrient for this pathogen. This was evident when coculturing the pathogen with *C. piscicola* in 1X, 3X and 6X brain heart infusion slightly increased the numbers of the pathogen after incubation at 12ºC for over 10 days. This mechanism of

inhibition was supported by another study that demonstrated that the reduction in the numbers of *L. monocytogenes* in cocultures with *C. piscicola* LK5 was not a function of acid production, or the accumulation of any other inhibitory extracellular substance. Instead, increasing levels of nutrients favored the growth of the pathogen, suggesting a mechanism involving nutrient depletion.

Nilsson et al. (123) added cells of *C. piscicola* to control the growth of *L. monocytogenes* on cold smoked salmon. These researchers found that out of 4 strains of *C. piscicola*, two of them produced bacteriocins that inhibited the pathogen in laboratory media, whereas the other two strains showed antilisterial activity that was independent of bacteriocin production. The bacteriocin producing strains of *C. piscicola* caused a long lag phase and reduced the number of *L. monocytogenes* from 10^3 to <10 CFU/mL after 32 days of storage at 5°C. Additionally, even the strains of *C. piscicola* that did not produce bacteriocins inhibited the growth of *L. monocytogenes*, suggesting that some other inhibitory compounds were produced during refrigerated storage. This study failed to demonstrate nutrient depletion as a mechanism of inhibition. These researchers selected for strains of *C. piscicola* with fast growth rates, because their objective was to enhance the production of bacteriocins at refrigeration temperatures, but did not take into account the increasing numbers of the LAB.

In a separate study, Schöbitz et al. (150) inoculated beef steaks with a partially purified bacteriocin like substance produced by *C. piscicola* L103, together with cells of *L. monocytogenes*, and evaluated the inhibitory activity at 4°C under vacuum package conditions. Numbers of *L. monocytogenes* decreased by 3 $\log_{10}$ cycles until complete inhibition of the pathogen after 14 days of storage when the substance was initially inoculated at a level of 100 AU/ml, whereas the numbers of the pathogen in the control treatment increased by 1 $\log_{10}$ cycle during the same time. The bacteriocin did not show any inhibitory effect toward natural LAB background flora.

Use of bacteriocin producing strains of *Pediococcus acidilactici* has also been studied to control the growth of *Listeria monocytogenes* in different meat products. Berry et al. (16) reported the use of bacteriocin producing *P. acidilactici* JD1-23 and its plasmid cured derivative JD-M for the control of *L. monocytogenes* in frankfurters at 4°C. The two strains of *P. acidilactici* exhibited a bacteriostatic activity toward the pathogen after 60 days of refrigerated storage under vacuum package conditions when the initial level of inoculation of the LAB was high (10^7 CFU/g). With low levels of *Pediococcus* organisms (10^3–10^4 CFU/g), *L. monocytogenes* grew, although the lag phase was increased. This study also reported the effect of package atmosphere on the growth of the pathogen in the presence of either strain of *Pediococcus*. Under aerobic conditions, *L. monocytogenes* was able to grow at 4°C in frankfurters inoculated with strain JD-M, whereas JD1-23 inhibited the growth for up to 30 days. Under temperature abuse conditions (storage at 15°C), the pathogen grew in the presence of either strain of *Pediococcus* under aerobic conditions, whereas the growth was inhibited under anaerobic conditions for up to 15 days.

Nielsen et al. (121) utilized a bacteriocin produced by a strain of *Pediococcus acidilactici* found in a commercial starter culture to inhibit the growth of *L. monocytogenes* in fresh meat. This study reported a strong antilisterial activity from this bacteriocin at concentrations ranging from 500 AU/mL to 5,000 AU/mL during the first 10 minutes of inoculation, reducing the levels of the pathogen by 1 to 2 $\log_{10}$ cycles depending upon the concentration of the bacteriocin. Bacteriocin production was reported to be stable after 28 days of refrigerated storage. However, when meat was treated with the bacteriocin and stored at 5°C for 28 days, only a 0.5 $\log_{10}$ reduction occurred after 7 days of storage; the numbers of *L. monocytogenes* actually increased in a similar fashion to the untreated control after 21 days of storage. These researchers suggested that the bacteriocin effect might have been diluted in

the dripping fluid or exudate as a consequence of storage of meat for a long period of time. A study by Pucci et al. (138) also reported the use of bacteriocin PA-1 produced by *P. acidilactici* PAC 1.0 to inhibit the growth of *L. monocytogenes* in laboratory media and in different food systems including cottage cheese, half and half cream, and cheese sauce. The minimum inhibition concentration (MIC) for the inhibition of *L. monocytogenes* in a broth system was reported to be 54.7 AU/ml. Significant inhibition was detected at both 4°C and 32°C when the pH of the medium ranged from 5.5 to 7.0, and the initial inoculum of the pathogen was 1.2×10^2 CFU/ml. When the bacteriocin was applied to food systems, it reduced the numbers of *L. monocytogenes* during the first 7 days of storage at 4°C in non-acidic foods, but the pathogen was able to grow effectively after the first 7 days, indicating loss of activity. In acidic food systems, the combination of bacteriocin PA-1 and lactic acid present in the foods showed a synergistic effect controlling the growth of the pathogen for up to 14 days. Again, the effect of high pH values in the food systems favored the growth of *L. monocytogenes*, even in the presence of bacteriocins.

Several lactobacilli have also been reported to exhibit inhibitory activity toward *Listeria monocytogenes*. Juven et al. (1998) reported the use of the psychrotrophic strain FloraCarn L-2 of *Lactobacillus alimentarius* and its antibiotic resistant (streptomycin and rifampicin resistant) mutant SRL-2 to inhibit the growth of *L. monocytogenes* in ground beef (pH=5.4) at 4°C during a total storage time of 9 weeks. Both strains produced a 2-$\log_{10}$ reduction in the numbers of the pathogen during the storage period. The pH value in the samples inoculated with *L. alimentarius* L-2 decreased from 5.37 to 4.71, and the concentration of lactic acid increased from 90 to 142 mM after 9 weeks of storage at 4°C. The numbers of inoculated L-2 increased rapidly from 7 to 9.6 $\log_{10}$ CFU/g in the absence of *L. monocytogenes* and from 7 to 8.4 $\log_{10}$ CFU/mL in the presence of *L. monocytogenes* within 4 weeks of storage; progressive growth of strain SRL-2 was also detected during refrigerated storage. Inhibition of *L. monocytogenes* in this study was reported to be due to production of lactic acid and did not appear to be due to a bacteriocin. The concentrations of lactic acid produced by the two strains of *L. alimentarius* used in this study (approximately 50 mM) appeared to be high enough to explain the antilisterial effect.

Different strains of *Lactobacillus sake* have also been identified to have significant antilisterial properties. Bredholt et al. (25) isolated 5 strains of LAB from servelat sausage and ham for their antilisterial activity at temperatures below 8°C and their ability to grow at 3°C, in pH ranging from 5.8 to 6.2 with 3% NaCl added. The strains were identified as being *Lactobacillus sake*. Even if the five strains exhibited bacteriostatic activity toward *L. monocytogenes* in coinoculated ham samples at 8°C for 28 days of storage, the numbers of the LAB increased rapidly during the first three days of storage, from levels of 10^4-10^6 to levels of 10^8-10^9 CFU/g. Indigenous LAB background flora were also reported to increase from <100 CFU/g to 10^8-10^9 CFU/g in 4 weeks. Even with these increasing numbers of both inoculated LAB and indigenous flora, the authors reported nonsignificant sensory changes in the samples. Only 1 of the 5 strains produced bacteriocin. Nevertheless, all five strains exhibited the same level of inhibition toward *L. monocytogenes*, suggesting that mechanisms other than bacteriocin production were responsible; most likely it was competition for nutrients as the LAB strains were selected for their fast growth rates.

De Martinis and Franco (39) isolated a bacteriocin producing strain of *L. sake* from lingüiça, a Brazilian sausage, with antilisterial activity. In this study, the isolated strain was coinoculated in lingüiça with *L. monocytogenes* at a final concentration of 10^4 and 10^3 CFU/g respectively. The *L. sake* strain exhibited a bacteriostatic action over the pathogen during 4 weeks of storage of the sausage at 8°C. The counts of *L. monocytogenes* in the coinoculated treatment were 6 $\log_{10}$ cycles lower than the control treatment (*L. monocytogenes* only) after 4 weeks of storage, demonstrating effective diffusion of the bacteriocin in this particular

food matrix. Conversely, Winkowski et al. (181) studied the inhibition of *L. monocytogenes* in beef cubes at 4°C and 10°C by using *Lactobacillus bavaricus* MN, a meat isolate which produces the bacteriocin bavaricin MN. The inhibition occurred only during the first week of storage at 10°C, but by the end of the fourth week of storage there were no differences among the coinoculated samples and the controls. However, when the beef cubes were held at the same temperature but immersed in gravy containing glucose, the numbers of *L. monocytogenes* cells were 5 $\log_{10}$ cycles lower than the controls at the end of a four week storage period. Inhibition of the pathogen in this study was not due to decrease in pH because the antilisterial effect was observed at pH values close to 6.1. Schillinger et al. (149) reported the production of sakacin A by *Lactobacillus sake* Lb 706, a bacteriocin with antilisterial properties. In MRS broth, the presence of sakacin A decreased the numbers of *L. monocytogenes* from 6×10^5 / mL to 4×10^3 /mL in 24 hours at 15°C. However, in minced beef stored at 8°C the viable numbers of *L. monocytogenes* cells remained unchanged for the first week, increasing by 1 $\log_{10}$ cycle after 9 days of storage, demonstrating that the bacteriocin effect was inactivated after 1 week.

Hugas et al. (80) reported another study in which a strain of *L. sake* was utilized to inhibit the growth of *L. monocytogenes* in meat products. These researchers utilized *L. sake* CTC494, which produces the bacteriocin sakacin K, to inhibit the growth of *Listeria* spp. on poultry breasts, cooked pork and raw minced pork samples under different conditions of packaging (oxygen permeable films, vacuum package, and modified atmosphere using 20% CO_2 and 80% O_2) at 7°C for 8 days. *Listeria innocua* and not *L. monocytogenes* was utilized as the target pathogen for this study because these two microorganisms show a similar behavior in meat packaged under modified atmospheres, and the former had shown to be more resistant to sakacin K in previous studies from the same research group. Inoculation of *L. sake* CTC494 or its bacteriocin sakacin K exhibited a bacteriostatic effect over *L. innocua* after 8 days of storage at 7°C in all of the studied samples. The greatest inhibition was observed in the vacuum packaged samples of poultry breasts and cooked pork, and in the modified atmosphere packaged samples of raw minced pork, suggesting that the type of meat and the levels of indigenous flora are important to sustain the growth of LAB.

The initial level of inoculation of protective cultures as it relates to the initial number of the pathogen present in the food matrix is important to ensure inhibitory activity. Buncic et al. (31) selected two LAB strains of a total of 210 isolates from chilled meat products due to their ability to produce antilisterial bacteriocins. The two selected strains were identified as *L. sake* 265 and *Lactobacillus casei* 52. Even if bacteriocin activity toward *L. monocytogenes* was detected in agar well diffusion tests, the authors failed to show inhibition of the pathogen in coinoculated experiments on vacuum packaged sausages at 4°C after 23 days of storage. The inability of these bacteriocin producing strains to inhibit the growth of the pathogen at refrigeration temperatures was attributed to the relatively low initial numbers of the selected strains (approximately 10^3 CFU/g). The authors suggested that when low initial numbers of LAB are applied on chilled meats there might be extensive inactivation of bacteriocins by binding to meat compounds and bacterial cells, and that depletion of the bacteriocin during storage may occur. Consequently, the concentrations of active bacteriocins present on the samples were too low to affect the growth of *L. monocytogenes*. The most effective strain reported in this study (*L. sake* 706) exhibited better inhibitory properties due to its ability to grow rapidly in the meat systems (from 10^3 /g to $10^8 - 10^9$ /g within 3 weeks at 4°C). However, this rapidly increasing number of LAB produced undesirable sensory changes in the product. Similar results were obtained by Beumer et al. (17), who studied the interaction of two strains of lactic acid bacteria in coinoculated samples of sliced meat products (ham, chicken breast, and luncheon meats)

with *L. monocytogenes*, and reported insufficient ability to inhibit the growth of the pathogen within 35 days of storage at 7°C due to a low initial inoculum level. The strains studied were *Lactobacillus curvatus* and nisin producing *L. lactis*. The initial level of the pathogen in the samples was approximately 10^1 CFU/g, and the initial numbers of lactic acid bacteria were in the order of 10^2 CFU/g.

Other genera and species of lactic acid bacteria have been reported to exhibit antagonistic activity toward *L. monocytogenes*. Harris et al. (73) used 14 different strains of LAB known to be bacteriocin producing microorganisms to inhibit the growth of *L. monocytogenes* in laboratory media. The 14 strains covered a wide range of genera including *Lactobacillus*, *Leuconostoc*, *Pediococcus* and *Lactococcus*. Out of the 14 strains studied, 7 of them showed inhibition toward the pathogen in agar spot tests (deferred antagonism), but only the supernatant of 3 of these strains exhibited antagonistic activity toward *L. monocytogenes* in well diffusion agar tests. The inhibitory strains were reported to be *Lactobacillus* UAL11, *Leuconostoc* UAL14 and *P. acidilactici* PAC 1.0. Dimitrijevic et al. (41) identified 5 different bacteriocin producing strains of LAB belonging to different genera and species, which were then evaluated for their antilisterial activity at 37°C for 24 h and at 4°C for 12 days in laboratory media. The strains evaluated were *Lactococcus* UW, *Lactobacillus sake* 148, *L. sake* 265, *Pediococcus* 347 and *Lactobacillus sake* 706. This study was particularly extensive because 98 strains of *L. monocytogenes* were evaluated, 50 human isolates and 48 strains of animal and food origin. By using well diffusion agar tests, these researchers reported that bacteriocins produced by *L. sake* 265, *L. sake* 706 and *Pediococcus* 347 exhibited antilisterial activity on almost every analyzed strain of the pathogen, with bacteriocins from *L. sake* 265 showing the greatest inhibition.

A study by Vignolo et al. (177) reported the use of *L. casei* CRL 705, and the bacteriocin produced by this microorganism, named lactocin 705, to control the growth of *L. monocytogenes* in a meat slurry. The effect of this bacteriocin producing microorganism was evaluated in sterile and nonsterile samples of ground beef at 20°C. Two different initial levels of *L. monocytogenes* (10^4 cells/mL and 10^7 cells/mL) and three different levels of bacteriocin (4200, 8400 and 16800 AU/ml) were studied. In all cases in which lactocin 705 was added, a bacteriostatic effect on the pathogen was observed and lasted over 24 hours of incubation; actually at the highest bacteriocin concentration there was a 2 $\log_{10}$ reduction in the numbers of the pathogen in autoclaved beef that was inoculated with approximately 10^4 cells of *L. monocytogenes*/mL. The use of cells of *L. casei* CRL 705 to produce the bacteriocin *in situ* had a bacteriostatic effect toward the pathogen over a period of 24 hours of incubation at 20°C. Numbers of *L. casei* CRL 705 utilized in this study as well as the change of these numbers during the incubation period were not reported.

Jeppesen and Huss (87) utilized one strain of *Leuconostoc* (V 6) and one strain of *L. plantarum* (LKE 5) to control the growth of *L. monocytogenes* in a shrimp model system (pH=6.0) at 5°C. Both lactic acid bacteria decreased the growth rate of the pathogen. After 15 days of storage, the maximum cell number was reduced from approximately 10^8 CFU/mL to approximately 10^6 CFU/mL when the coinoculated treatments were compared to the control treatment with no LAB. The greatest inhibitory effect was obtained with *Leuconostoc* (V 6) when the initial numbers of *L. monocytogenes* were approximately 10^2 CFU/mL and NaCl was added to the system at a level of 3% w/v; the effect observed was bacteriostatic because the numbers of the pathogen did not change significantly over 25 days of storage. However, there was a reduction of more than 3 $\log_{10}$ cycles compared to the control. The mechanism of inhibition was not clearly identified, although the authors suggested that hydrogen peroxide might have been involved in the antagonistic effect of *Leuconostoc*, and a proteinaceous substance might have been responsible for the inhibition exhibited by *L. plantarum*.

Schillinger et al. (149) utilized two bacteriocin producing strains, *L. sake* Lb 706, which produces sakacin A, and *Enterococcus faecium* BFE 900, which produces enterocin B, to control the regrowth of nisin resistant mutants of *L. monocytogenes*. In order to achieve this goal, these researchers selected for nisin resistant mutants of both LAB, which showed initially high sensitivity to low concentrations of nisin. The resulting mutants were able to grow at a concentration of 500 IU of nisin/mL and were still able to produce their respective bacteriocin. In the presence of 100 IU of nisin/mL, *L. monocytogenes* Li3 (nisin resistant) grew rapidly after a short lag phase to a high cell density at 30°C. In associative cultures with *L. sake* Lb 706-1a (nisin resistant), at the same temperature, almost no increase in viable counts of *L. monocytogenes* Li3 was observed after 24 h and the numbers decreased more than 2 $\log_{10}$ cycles after 48 h. *Enterococcus faecium* BFE 900-6a (nisin resistant) was less effective than *L. sake*, and the numbers of *L. monocytogenes* Li3 viable cells actually increased by almost 2 $\log_{10}$ cycles within 24 h. Both strains of LAB significantly decreased the numbers of a nisin sensitive strain of *L. monocytogenes* Scott A in a separate study. Hence, the authors demonstrated that a combination of nisin and a starter or protective culture producing a non-nisin bacteriocin might be effective in preventing the emergence of spontaneous nisin resistant subpopulations of *Listeria monocytogenes*.

Wessels and Huss (179) reported the use of the nisin producing strain *L. lactis* subspecies *lactis* ATCC 11454 to inhibit the growth of *L. monocytogenes* in laboratory media and in a cold smoked salmon infusion simulating conditions of light preservation. At 5°C in M17 broth, the *L. lactis* grew well and produced nisin. In associative cultures in brain heart infusion, this strain reduced the levels of *L. monocytogenes* by 5 $\log_{10}$ cycles at 30°C within 31 h. However, in the cold smoked salmon infusion at the same temperature, the microorganism did not grow. Also, at a level of NaCl of 4%, *L. lactis* grew well and produced nisin efficiently, while 5% NaCl resulted in very slow growth and no detectable nisin. Samples of sliced cold smoked salmon were coinoculated with an initial number of 10^4 CFU/g of *L. monocytogenes* and 10^6 CFU/g of *L. lactis*. The presence of the *L. lactis* cells led only to a decline in the pathogen count within the first 5 days of incubation at 10°C. After that period of time, the *Listeria* growth rate was only slightly depressed relative to the control (with no *L. lactis* inoculum). This study showed that under adverse conditions (5°C and high levels of salt), the use of nisin producing *L. lactis* ATCC 11454 does not prevent the growth of *L. monocytogenes* in cold smoked salmon; however, under temperature abuse conditions (10°C), this culture may be effective as a supplement to other preservative agents.

Amezquita and Brashears (8) isolated several species of LAB from refrigerated deli meats and hot dogs. They screened the isolates for their ability to inhibit *L. monocytogenes* during refrigeration without growing. Several isolates were obtained and one species of the LAB completely eliminated the growth of *L. monocytogenes* during refrigerated storage. Additionally, there were no increases in the number of LAB during the refrigerated storage. Sensory studies were conducted and there were no detectable differences in the products that contained the LAB compared to the controls.

While much of the research in meat products has focused on the inhibition of *Listeria monocytogenes*, other food borne pathogens can be inhibited in meat products during refrigerated storage. Brashears and Durre (23) reported that *L. lactis* completely eliminated the growth of *Salmonella* species and *E. coli* O157:H7 during growth and refrigerated storage. Brashears et al. (22) conducted a study to determine if four strains of lactic acid bacteria (LAB) inhibited *E. coli* O157:H7 and *Salmonella* species in ground beef at 5°C. In raw ground beef the cocktail combination of 4 LAB strains reduced *Salmonella* and *E. coli* O157 by 3−4 log cycles after 12 days of refrigerated storage. Similarly, Brashears et al. (24) reported that *E. coli* O157:H7 was significantly inhibited on raw chicken breasts during

refrigerated storage when inoculated with *Lactobacillus* species. They reported that more than a 1 log cycle reduction occurred during a 7 day storage period.

5.3 USE OF LACTIC ACID BACTERIA FOR *IN VIVO* REDUCTION OF FOOD BORNE PATHOGENS

5.3.1 Definition of Probiotic and Direct Fed Microbial

The word probiotic, which means "for life," is derived from the Greek language and has been given several definitions over the years (59). It was first used in 1965 by Lilly and Stillwell (108) to mean substances produced by one protozoan that stimulated the growth of another. In 1974, Parker (130) defined it as "organisms and substances that have a beneficial effect on the host animal which contribute to intestinal microbial balance." However, this general definition was not precise enough, because the word substances includes chemical supplements such as antibiotics. In 1989, Fuller (58) revised the definition to "a live microbial feed supplement which beneficially affects the host animal by improving its intestinal microbial balance." This definition was less confusing, as it emphasized the importance of live cells as an essential component of an effective probiotic. The definition of probiotic has since been expanded to include treatments with live bacteria that are not administered by mouth and that do not exert their effect through the intestinal microflora. In 1991 Huis in't Veld and Havenaar (81) broadened the definition to "a mono- or mixed culture of live microorganisms which, applied to man or animal (e.g., as dried cells or as a fermented product), affects beneficially the host by improving the properties of the indigenous microflora."

Kmet et al. (99) defined ruminal probiotics as "live cultures of microorganisms that are deliberately introduced into the rumen with the aim of improving animal health or nutrition." Based on the various definitions, probiotic could possibly refer not only to microbial cultures, but also extracts and enzyme preparations. The Office of Regulatory Affairs of the Food and Drug Administration, as well as the Association of American Feed Control Officials, have recommended the term direct fed microbials (DFM) be used to describe feed products that contain a source of live, naturally occurring microorganisms. The term DFM will be used in the remainder of this text to describe live cultures of that are fed to animals to reduce food borne pathogens.

5.3.2 Use of Direct Fed Microbials in Farm Animals

5.3.2.1 Concept of Direct Fed Microbials

The gastrointestinal microflora, which are established immediately after birth, are considered very important for the performance of farm animals (58,124). The fetus *in utero* is sterile, but on passage through the reproductive tract during birth acquires microorganisms which are rapidly added to the gut (58). The gut microflora are also obtained from the immediate environment, which is heavily contaminated with bacteria from the mother (26,139). The final indigenous microflora that stabilize the gut are characteristic of the host species and forms a complex system of interrelationships between different microorganisms and between microorganisms and the host (58). This stable flora helps the animal to resist infections by creating a defense barrier against invading microorganisms or toxic substances in the diet (52,110). It also aids in digestion, especially in ruminants, where the metabolism of fibrous components in the diet is dependent on the fermentative action of bacteria in the rumen (147,148).

Although the protective flora in the gut are very stable, they can be influenced by dietary and environmental factors. Modern methods of animal rearing often restrict the access that the animal has to the mother, preventing it from acquiring the full complement of characteristic microbes (58). This in turn makes farm animals very susceptible to an imbalance in normal microflora, leading to inefficient utilization of feed and poor growth performance (124). Stress is another factor that affects gut flora, and can be induced by severe changes in the physical or emotional environment (165). Antibiotics have been used over the years as feed supplements to overcome these problems and promote the growth of the animal. However, there is growing concern that use of antibiotics is resulting in the development of resistant populations of harmful bacteria, which can make the use of antibiotic therapy difficult (75,109). Use of antibiotics also induces intestinal infections resulting in enteritis and diarrhea. In a study by Smith and Tucker (153), inclusion of subtherapeutic levels of antimicrobial growth promoters in the feed prolonged the excretion of *Salmonella* in the feces of chickens (52). A similar effect was obtained in mice dosed experimentally with antibiotics (52). Considering the effects produced by antibiotics, the Swann Committee in 1969 restricted the use of antibiotics as animal feed supplements to only those which were not used in the treatment of disease (58). On the other hand, the antiadditive lobby saw antibiotics as foreign substances that should not be present in the food chain (58). These conditions stimulated an interest in the use of more natural feed additives: Direct Fed Microbials.

Direct Fed Microbials that have been included in food for many years without any adverse effects are, according to the Food and Drug Administration (60), Generally Regarded As Safe (GRAS) and have been shown to have beneficial effects in the animal (58,89,105). The concept of direct fed microbials is now universally accepted, and a substantial amount of research is being directed towards formulation of mixtures of direct fed microbial strains that would have beneficial effects in the animal.

5.3.2.2 Microorganisms Used in Direct Fed Microbials

Intestinal strains of lactic acid bacteria and *Bifidobacteria* are most widely used as direct fed microbials, although yeasts such as *Saccharomyces, Aspergillus*, and *Torulopsis,* and microorganisms such as *Bacillus* and *Clostridium* have also been used (60,112,166,167). Among the lactic acid bacteria, strains of *Lactobacillus* species are most commonly used, and include *L. acidophilus, L. bulgaricus, L. helveticus, L. casei, L. lactis, L. plantarum, L. rhamnosus, L. reuteri, L. fermentum, L. brevis,* and *L. salivarius* (58,60,112). Other strains of lactic acid bacteria include *Enterococcus faecalis, E. faecium, Streptococcus salivarius thermophilus, S. lactis,* and *Pediococcus pentosaceus*. Most frequently used strains of *Bifidobacterium* include *B. bifidum, B. breve, B. thermophilus*, and *B. pseudolongum* (58,112). The composition of DFM preparations may vary from those containing a single strain of microorganisms to those containing multiple strains (58,60). There is, however, more interest in multiple strain preparations, as it is assumed that they are active against a wider range of conditions, including microbial infections and antibiotic relieved growth depression, and in a wider range of animal species (58,60).

5.3.2.3 Direct Fed Microbials and Microbial Angogonism in Animals

Since the first scientific explanation of the favorable effects of soured milk products in humans by Metchnikoff at the beginning of twentieth century (114), the most beneficial part of the intestinal flora has been considered to be lactic acid bacteria. Lactic acid bacteria are also the most common organisms used for commercial DFM preparations (8,170). The emphasis on the lactic acid bacteria stems from the fact that there is evidence that lactic acid bacteria occupy a central role in the gut flora that enables them to influence the composition

of the flora to the benefits of the host. The stomachs of neonatal pigs are known to be colonized by *Lactobacillus* and *Streptococci* within 48 hours after birth (44). Similarly, in newborn calves one of the first groups of microorganisms in the rumen is lactic acid bacteria (24). Studies show that when the gut flora develop after birth, as the lactobacilli increase other components of the flora decrease (152). The claims made for probiotic effects of lactic acid bacteria in farm animals are many and varied, and are summarized in Table 5.1 (60).

The potential benefits of probiotic lactic acid bacteria can be placed into three broad categories: reduction of food borne pathogens, improved animal performance, and stimulation of immune response.

5.3.2.4 Pathogen Reduction

The most commonly identified beneficial effect of lactic acid bacteria as live feed supplements is their role in resistance to infection, particularly in the gastrointestinal tract. It has been proposed that these organisms can prevent infection through competitive exclusion (CE) or other mechanisms against pathogenic bacteria in the animal intestine (10,136). According to Bailey (10), competitive exclusion implies the prevention of entry of one entity into a given environment because that space is already occupied, the competing entity is better suited to establish and maintain itself in that environment, or the competing entity is producing a product hostile (toxic) to its competition. The phenomenon of CE was first described by Nurmi and Rantala (125) when they demonstrated that *Salmonella* colonization in the gut of a newly hatched chicken could be prevented by dosing it with a suspension prepared from gut contents of healthy adult chickens. The efficacy of the CE concept has since been demonstrated in several laboratories around the world (13,136,156).

5.3.2.4.1 Poultry Much of the work involving competitive exclusion by lactic acid bacteria has been done in poultry and has focused on the reduction of *Salmonella*. The most commonly studied organisms are strains of *Lactobacillus*, especially *L. acidophilus*. However, the results obtained from the studies to demonstrate the efficacy of DFM have been controversial. The original work by Nurmi and Rantala (125) to explain the concept was done with *Salmonella enteritidis*, and subsequent studies have shown that DFM can work against other strains of *Salmonella* such as *S. typhimurium, S. pullorum, S. salivarius*, and *S. blockley*. Jin et al. (88) demonstrated that a combination of *Lactobacillus* strains isolated from chicken intestine were able to inhibit growth of five strains of *Salmonella*: *S. enteritidis* 94/448, *S. typhimurium, S. pullorum, S. blockley,* and *S. enteritidis* 935/79, and three serotypes of *E. coli*: O1:K1, O2:K1 and O78:K88. Fuller (56) examined the effects of *Lactobacillus* on *E. coli* in the chicken crop and in associative cultures and observed that *E. coli* growth was suppressed both *in vitro* and *in vivo*. In a study by Gilliland and Speck (63), *Lactobacillus acidophilus* exerted antagonistic actions on growth of *S. typhimurium*, enteropathogenic *E. coli*, *Staphylococcus aureus,* and *Clostridium perfringens* when grown with each in associative cultures. Similar studies involving the

Table 5.1
Probiotic effects of lactic acid bacteria in farm animals

Effect	Ref.
Resistance to infectious diseases	(14) (61) (88)
Improved growth performance	(1) (37)
Improved feed efficiency	(12) (182)
Increased milk or egg production and quality	(115)

effect of lactic acid bacteria on *Salmonella, E. coli, S. aureus,* and *C. perfringens* have shown the inhibition of pathogens by lactic acid bacteria (14,178).

On the other hand, there are studies that have raised questions regarding the efficacy of DFM microorganisms in reducing colonization of pathogenic bacteria. In experiments conducted by Hinton and Mead (76), results showed that DFM products containing strains of *Lactobacillus* or *Enterococcus*, administered to day old chicks in feed or drinking water or by spraying on bird's feathers, did not reduce *Salmonella* in the ceca. Similarly, Adler and Da Massa (4) found no protection by *Lactobacillus* against *Salmonella* or *E. coli* colonization in the ceca of newly hatched chicks.

The controversy regarding the effectiveness of the DFM microorganisms can be explained partially by the use of defined and undefined cultures and also by using various strains and species to get the desired effects. Defined product comprises a known mixture of pure bacterial cultures derived from fecal and cecal contents of the bird, whereas undefined product consists of a homogenous mixture of known aerobic microorganisms and unknown, mainly anaerobic, microorganisms derived from the ceca of the bird (118). According to a review by Mulder et al. (118), results from studies on the effect of microflora consisting of 50 different pure cultures were less promising than those obtained after the administration of undefined microflora. Similarly, in a study by Stavric et al. (160), results with mixtures of pure cultures of *Lactobacillus* showed that the preparations were ineffective in reducing *Salmonella* carriage in chicks. On the other hand, undefined anaerobic culture prepared from feces of adult birds showed a significant reduction in the number of *Salmonella typhimurium* in chicks.

Even more important are the selection criteria used to obtain cultures to be used as DFM cultures. These criteria are discussed later in this chapter.

5.3.2.4.2 Pigs The work associated with the use of DFM in pigs is very limited, but the use of lactic acid bacteria has been growing in the past few decades. The most commonly tested lactic acid bacteria are the strains of *Lactobacillus* and *Enterococcus*, and the majority of the studies involve starter pigs, based on the assumption that adult pigs are more resistant to intestinal disorders. It has been demonstrated in several feeding trials that selected strains of lactic acid bacteria can be beneficial in reducing pathogenic bacterial count (14,40,129). A study by Barrow et al. (14) demonstrated that when two day old piglets, weaned to a sow's milk substitute diet, were given *L. fermentum* alone or in combination with *S. salivarius* in their milk, there was a significant decrease in the *E. coli* counts in the stomach and duodenum. Similarly, fecal coliform counts and hemolytic *E. coli* 0141:K85ab were reduced in piglets when treated with *E. faecalis* and *E. faecium* respectively (40,129). Underdahl et al. (171) also demonstrated that *E. faecium* reduced the number of pathogenic *E. coli* and the severity of illness associated with it in gnotobiotic piglets. However, contrasting results have also been reported by some researchers regarding the efficacy of DFM lactic acid bacteria in pigs. One such study involving the interaction between *Lactobacillus* species and *E. coli* K88 in gnotobiotic pigs showed that *Lactobacillus* was unable to prevent the adherence of *E. coli* to the intestinal mucosa (19). In spite of some negative results, the use of lactic acid bacteria in pigs holds considerable potential. The selection criteria for probiotic microorganisms are a big factor influencing the efficacy of a particular strain or mixture of strains, combined with the need for appropriate *in vitro* and animal models, sensitive and reproducible techniques, and repeated experimentation to validate the efficiency of probiotic lactic acid bacteria.

5.3.2.4.3 Cattle Since the recognition of cattle as the principal reservoir of *E. coli* O157:H7, the CE approach to reduce the carriage of pathogen in the animal has received tremendous attention. Unfortunately, the literature on the use of lactic acid bacteria as CE microorganisms in cattle is limited, because the probiotic products fed to cattle are primarily

fungal cultures (78). Many of the studies examining the effects of probiotic lactic acid bacteria have been limited to calves (124). However, the number of studies done in feedlot animals is growing. As with other species, there is inconsistency in the results obtained from studies involving use of direct fed microbials in cattle. Nonetheless, use of DFM microorganisms in cattle is on an increase, and several studies have been conducted to understand the specific role of lactic acid bacteria in reducing the carriage of pathogenic bacteria in cattle.

One of the earlier studies, done by Ellinger et al. (46), reported a decrease in fecal coliforms when the liquid diet of newborn calves was supplemented with *Lactobacillus* cultures. In a similar study, Gilliland et al. (65) demonstrated that *Lactobacillus* strains isolated from cow were more effective than those isolated from pigs, suggesting the importance of host specificity of the probiotic strains. Ozawa and coworkers (129) tested the effect of *E. faecalis* BIO4R on intestinal flora of calves and found that the strain had an antagonistic effect on *Salmonella.*

Studies by Brashears et al. (21) indicate that *E. coli* O157:H7 can be reduced in feedlot age cattle. The use of Direct Fed Microbials (DFM) has been effective in significantly reducing the amount of *E. coli* O157:H7 detected in the feces and on the hides of beef feedlot cattle in two separate large scale studies conducted at Texas Tech University. In the first study, 180 beef feedlot cattle were separated into 3 treatment groups. One group received NP 51, one received NP 35, and one received a carrier of the DFM and served as a control. NP 51 and NP 35 contained two separate strains of *Lactobacillus acidophilus* as the DFM. The cultures were fed at a level of 1×10^9 cells/head/day for the last 60 days of the feeding period. Overall the reduction in shedding was 50% for the animals fed NP 51 compared to the control group (Figure 5.1). There were no significant reductions in those fed NP 35. At slaughter, the prevalence of *E. coli* on the hides was reduced from 20% in the controls to 3% and 0% in NP 51 and NP 35, respectively. In a follow up study conducted the following summer, the treated animals were fed NP 51 and a combination of other commercially available DFM cultures for the entire duration of the feeding period. At 7 days prior to slaughter and at slaughter, 27% of the fecal samples in the control animals tested positive for *E. coli* O157:H7 while the treated animals contained significantly fewer detectable numbers with only 13% being positive (Figure 5.2). Again there were significant reductions in the number of animals testing positive for *E. coli* O157:H7 on the hides with 14% of the control samples testing positive and only 5% of the treated samples testing positive. In all studies there was a trend toward improved performance characteristics.

5.3.2.5 Improved Animal Performance

Over the years, numerous claims have been made about the beneficial effects of lactic acid bacteria involving improved animal performance. Some of the potential benefits of feeding lactic acid bacteria as probiotic supplements, as suggested by Fuller (60), include increased growth rate, improved feed conversion, improved digestion and better absorption of nutrients, increased milk or egg production, and increased milk or egg quality. Several studies have shown that administration of lactic acid bacteria improved birth weight gain and mortality in piglets and calves (1,37) and also growth rate and egg production in chickens (42,115). An increase in daily weight gain and improvement in feed conversion was obtained by Baird (12) in separate experiments with feeder and growing finishing pigs using *Lactobacillus* supplements. In two studies reported by Wren (182) and Lee and Botts (103), higher feed intakes and weight gains were obtained in newborn claves when *Lactobacillus* species were supplemented with milk replacer diets. Dilworth and Day (42) evaluated the effects of adding *Lactobacillus* cultures to broiler diets and found a significant improvement in growth rate and efficiency. Miles et al. (115) reported significant increase in egg production when

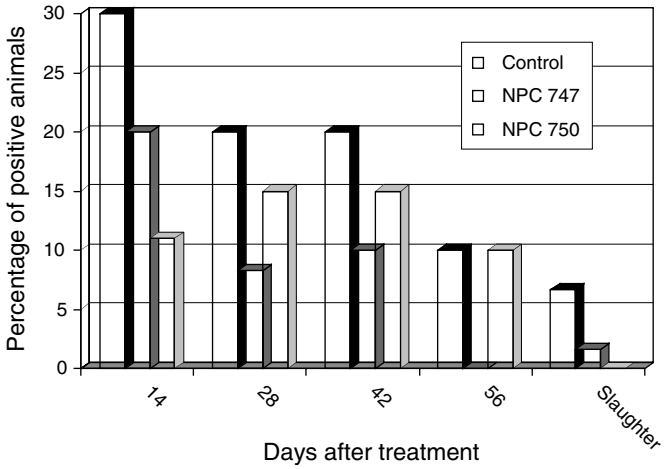

Figure 5.1 Prevalence of *E. coli* O157:H7 in 180 Cattle After Treatment with Direct Fed Microbials During the Last 60 Days of the Feeding Period

L. acidophilus cultures were fed to commercial layers. Although the statistical effects on growth, egg production, feed conversion, and daily weight gain have been reported, there is a lack of good, controlled field experiments and most of the positive results are obtained in studies involving young animals. There is therefore need for more research involving large scale field trials involving both young and mature animals.

5.3.2.6 Effect on Immune Response

The effect of probiotic lactic acid bacteria on the host immune response has been studied to some extent, and it is postulated that both mucosal and systemic immune responses can be affected by direct fed microbials. Bealmer et al. (15) demonstrated that conventional animals with complete gut flora have higher immunoglobulin levels and phagocytic activity than germ free animals. Roach and Tannock (140) suggested that a systemic effect was exerted by *E. faecium* that was established as a monoassociate in germ free mice, reducing *S. typhimurium* counts in the spleen. Similarly, *L. casei* was involved in the stimulation of phagocytic activity when administered perorally to mice in a study by Perdigon et al. (131). In order for a microorganism to affect systemic immunity it may be necessary for it to enter the systemic circulation. Bloksma et al. (18) showed that *Lactobacillus* species were able to survive in the spleen, liver, and lungs for several days. Saito and coworkers (144) showed that *L. casei*, given parenterally, stimulated phagocytic activity in mice. Serum IgA and IgG levels have been shown to be increased with administration of *Lactobacillus* in piglets and mice (106,132). These findings suggest that direct fed microbials have the potential to modulate immunity, and that their effect on systemic immune response can be used to overcome infections that occur in tissues away from the intestinal tract, caused by pathogens such as *Salmonella*.

5.3.3 Selection Criteria for Lactic Acid Bacteria to be Used as Direct Fed Microbials

Although lactic acid bacteria used as direct fed microbials are generally shown to have a positive effect *in vitro* and *in vivo*, the responses attained with the studies have been variable. One of the reasons for controversial results is the selection of strains for DFM use. There are

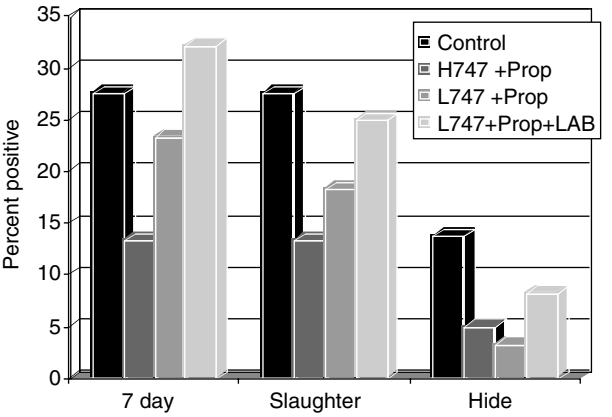

Figure 5.2 Prevalence of *E. coli* O157:H7 in 240 Cattle After Treatment with Direct Fed Microbials During the Entire Feedlot Feeding Period

certain attributes that an organism must possess in order to be functional or desirable as a probiotic microorganism. Following is a discussion of the selection criteria that are considered to produce suitable direct fed microbial bacteria.

5.3.3.1 Survival in the Gastrointestinal Tract

In order for a DFM to produce desirable effects, it must be able to survive and metabolize in the intestine. This means that the strain must be resistant to gastric juices, low pH, enzymes, organic acids, and bile and pancreatic secretions.

Most bacteria do not survive well at low pH values, and the severe acidic condition of the intestinal tract has an adverse effect on most microorganisms. It is therefore suggested that microbial cultures to be used as probiotic products should be screened for their resistance to acidity. In a study by Conway et al. (35) on the survival of lactic acid bacteria in the human stomach, strains showed variable survival at different pH conditions, demonstrating the importance of screening the strains for acid tolerance. Similarly resistance of lactic acid bacteria to bile is an important characteristic that enables them to survive and grow in the intestinal tract (64,66). Bile entering the duodenal section of the small intestine has been found to reduce survival of bacteria probably due to the fact that all bacteria have cell membranes consisting of lipids and fatty acids, which are very susceptible to destruction by bile salts. Gilliland et al. (1984) reported that when a diet supplemented with a more bile resistant strain of *L. acidophilus* was fed to newborn dairy calves, greater numbers of facultative lactobacilli were detected in the upper part of small intestine (jejunum) than when a strain with lower bile resistance was used. It was also suggested that the ability of *L. acidophilus* to cause significant increase in numbers of *Lactobacillus* in the intestinal tract may be critical for controlling growth of intestinal pathogens. Hence the success of probiotics also depends on the selected strain possessing bile resistant qualities.

5.3.3.2 Adhesion to Intestinal Epithelium

The adhesion properties of specific bacterial strains to intestinal cells enhance colonization and have become standard criteria for selecting new DFM strains (145). It is speculated that by attachment to the gut wall, the probiotic strain will occupy colonization sites and make

them unavailable to other microorganisms, especially pathogens, thereby demonstrating competitive exclusion. The role of adhering bacteria in protection against enteric pathogens was recognized by Fuller (54), who suggested treating newly hatched chicks with pure cultures of adhering lactobacilli. Adhesion is also considered necessary for the microorganism to resist being washed away by contents of the stomach and intestine, and by peristalsis (60). In order for the probiotic organism to manifest its effect, ability to remain in the gut for a maximum amount of time is a crucial property (58) which can be attained by attachment. Another reason to use adhesion property as a selection criterion for strains is the variability obtained between strains of the same species. Mayra-Makinen et al. (113) reported that the degree of adherence varied greatly between the 13 strains of *Lactobacillus* that showed adherence to columnar epithelium of pigs and calves.

5.3.3.3 Host Specificity

In selecting strains for use as DFM supplements, the source of the organism is important because most of these organisms exhibit host specificity. For example, *Lactobacillus* isolated from a specific site of a specific animal source can only colonize epithelium of the same kind. Host specificity of bacterial strains is well recognized and documented (14,55). Barrow et al. (14) tested the attachment of lactic acid bacteria to gastric epithelium of pigs *in vitro* and found that with the exception of two strains of *Lactobacillus* isolated from the chicken gut, no isolates from animals other than domestic pigs and the closely related wild boar were able to adhere to pig squamous epithelium. Similarly, Fuller (54) demonstrated that *Lactobacillus* obtained from fowl crop only adhered to squamous epithelial cells of chicken intestine and not mouse, rat, or pigs.

5.3.3.4 Production of Antimicrobial Compounds

Lactic acid bacteria produce a wide variety of antimicrobial compounds such as bacteriocins, organic acids, hydrogen peroxide, and other low molecular weight metabolites. Production of these substances may give them a competitive advantage over pathogenic strains in the gastrointestinal tract and promote their colonization. However, production of antibacterial substances may not be an important criterion for selection, because several probiotic strains of lactic acid bacteria have been shown to exert beneficial effects in the intestinal tract without possessing this property.

5.3.3.5 Antibiotic Susceptibility

Antibiotic resistance in probiotic bacteria is an area of growing concern. According to a recent report, the FDA blocked the introduction of two DFM products for use in chickens on grounds that some of the microorganisms in the products were possibly antibiotic resistant, which could lead to humans contracting diseases not treatable by drugs (134). It is speculated that antimicrobial drugs used in food animals can promote emergence of resistant bacteria that may not necessarily be pathogenic to the animal, but may cause severe infections in humans (134). The use of antibiotics in food animals can also cause nonpathogenic bacteria to become resistant, which may directly or indirectly cause infections in humans.

In the past few years, the lactic acid bacteria most commonly associated with antibiotic resistance have been strains of the genera *Enterococcus*, especially *E. faecalis* and *E. faecium* (51). *Enterococcus* species have been used as direct fed microbials to maintain intestinal microbial balance and also as a treatment for gastroenteritis in humans and animals. However, the fact that these bacteria have acquired resistance toward most clinically

used antibiotics, including the glycopeptide antibiotics vancomycin and teicoplanin, increases their threat as opportunistic pathogens (51). Resistance is acquired by gene transfer systems such as conjugative or nonconjugative plasmids, or transposons (133,168). Several antibiotic resistance plasmids from *Lactobacillus* species have also been detected. Ishiwa and Iwata (83) indicated plasmid linkage of tetracycline and erythromycin resistance in human isolates of *L. fermentum*. Morelli et al. (117) observed plasmid linked resistance for chloramhpenicol in *L. acidophilus* and *L. reuteri* isolated from poultry.

Plasmid associated antibiotic resistance is of special concern because of the possibility of resistance spreading to other, more harmful species and genera. Resistance can be transferred from nonpathogenic bacteria to pathogenic bacteria and from bacteria that are normally present in the intestinal tract of animals to those that cause infections in humans. *In vitro* studies have demonstrated that vancomycin resistance is transferable to other Gram-positive bacteria including *Listeria monocytogenes* and *S. aureus* (101). A chloramphenicol resistance plasmid from an *L. plantarum* strain isolated from raw ground pork (7) was shown to be transferred to other Gram-positive bacteria by the help of a wide host range (33). Of other concern is the potential risk of transfer of antibiotic resistance and associated virulence traits to other lactic acid bacteria in foods that could eventually lead to emergence of opportunistic pathogens, especially in immunocompromised individuals. Although *Streptococcus* and *Enterococcus* are the predominating lactic acid bacteria associated with human infections, other lactic acid bacteria have also been implicated in human infections despite their traditional GRAS status (61). New species and more specific strains of probiotic bacteria are constantly being sought, and these may not share the same historical safety of traditional strains. It therefore becomes important to carefully assess antibiotic resistance in new strains prior to incorporating them into probiotic or CE products.

5.3.3.6 Technological Properties

It was not until recently that technological properties were established as a selection criteria for DFM strains because they largely dictate the successful production and delivery of direct fed microbials. Direct fed microbials are fed to the animals directly or through their food in the form of pellets, capsules, paste, powder, or granules. Therefore, at the industrial level, DFM strains that are produced in large quantities have to undergo several processing steps before their use as feed supplements. The processing steps may involve separation by centrifugation or filtration, fermentation in cultured products, and freeze drying or lyophilization (97,124). Direct fed microbial bacteria should therefore be able to withstand stresses such as freezing, high pressure, and temperatures (60−80ºC for 5−10 minutes during pelleting); and should have a high growth rate and achievable cell mass. They should also be able to retain their viability under storage conditions. However, the stability of probiotic strains in continuous industrial culturing is a challenge for the industry (105). According to Nousiainen and Setala (124), most *Lactobacillus* strains do not tolerate pelletizing in an economically feasible way. Crowell et al. (97) showed a dramatic decrease in the viability of *L. acidophilus* in dried pellets held under refrigeration or at room temperature over a period of 12 months. Stability during culture propagation and storage may have an impact on the *in vivo* response toward the probiotic. It is therefore important, during the selection of a probiotic culture, to consider these production and stability criteria.

These selection criteria were used to select specific strains of lactic acid bacteria from cattle feces as potential candidates as direct fed microbials to reduce *E. coli* O157:H7 in the live animal (22). A total of 686 LAB were selected and screened for

inhibition of *E. coli* O157:H7. One half of the 686 inhibited the pathogen. Further screening for acid and bile tolerance resulted in identification of 75 candidates. Well identified strains were subjected to inhibition studies in rumen fluid and manure during which only 2 LAB were identified as potential candidates. These candidates were used in *in vivo* trials and successfully reduced *E. coli* O157:H7 in the animal (22).

5.3.3.7 Possible In Vivo Mechanisms of Action

One of the reasons for the beneficial effects exhibited by lactic acid bacteria is a direct antagonistic action against harmful microorganisms. However, the exact mechanisms by which lactic acid bacteria affect the microflora of the intestinal tract are not clearly understood. Modes of action that have been proposed for competitive exclusion are production of antimicrobial metabolites, competition for nutrients and competition for adhesion sites on the gut epithelial surface.

Lactic acid bacteria are known to produce several antibacterial agents and primary metabolites, such as organic acids, hydrogen peroxide, enzymes, low molecular weight metabolites, and bacteriocins. Among the organic acids, lactic acid and acetic acid are the two major end products of carbohydrate fermentation by homofermentative and heterofermentative lactic acid bacteria respectively. The inhibition of pathogenic bacteria *in vitro* by production of organic acids is well documented, but the evidence for *in vivo* inhibition is not very convincing. In a study by Jin et al. (88) inhibition shown by *Lactobacillus* strains against pathogenic strains of *Salmonella* and *E. coli* was suggested to be due to the production of organic acids by *Lactobacillus* isolates. It is assumed that the primary reason for antagonism by lactic acid production is the reduction in pH, which inhibits the growth of many bacteria including Gram-negative pathogenic organisms (30,157). Although pH is the main factor in antagonism, it has also been demonstrated that lower pH values govern the activity of organic acids, because the undissociated forms are most bactericidal (2,157). The undissociated acid is easily diffused through the bacterial cell wall, thereby reducing the intracellular pH and slowing down metabolic activities of the bacteria (77). *Escherichia coli* is shown to be inhibited by lactic acid at a pH of 5.1 (71). Tramer (169) also showed that the inhibition of *E. coli* by *L. acidophilus* was due to the strong bactericidal effect of lactic acid at low pH. However, acetic acid, due to its higher dissociation constant, shows stronger inhibition than lactic acid at a given molar concentration and pH (77). These volatile acids are especially antimicrobial at low oxidation reduction potentials (144), which lactic acid bacteria help maintain in the intestine.

Hydrogen peroxide, which is produced in the presence of molecular oxygen together with lactate, pyruvate, and NADH by flavin enzymes (34,62,69,93), is one of the primary metabolites of lactic acid bacteria that may contribute to antagonism. It inhibits the growth of pathogens through its cytotoxic effect on the bacterial cells by generating highly reactive and toxic oxygen species, such as the hydroxyl radical that initiates oxidation of biomolecules (90). The antimicrobial activity of hydrogen peroxide is well recognized and documented. The formation and accumulation of hydrogen peroxide by *Lactobacillus* in growth media with a subsequent bactericidal effect on *S. aureus* has been reported by Dahiya and Speck (38). Gilliland and Speck (63) showed that *L. acidophilus* exhibited antagonistic activity against intestinal and food borne pathogens in associative cultures. In addition, hydrogen peroxide may also activate the lactoperoxidase system, indigenous to milk, causing the formation of hypothiocyanite and other antimicrobial products that may inhibit enteric.

Bacteriocin production by lactic acid bacteria is also recognized as one of the mechanisms used for antagonism against other microorganisms. Bacteriocins are defined

as potent antimicrobial peptides or proteins produced by bacteria, which have a bactericidal action against other bacteria . The inhibitory spectrum of bacteriocins is restricted to closely related organisms, which implies that bacteriocins produced by lactic acid bacteria may not be active against Gram-negative pathogens and spoilage bacteria. A number of Gram-positive toxinogenic and pathogenic bacteria have been found to be inhibited by bacteriocins of certain lactic acid bacteria. For example, a strain of *Pediococcus acidilactici* was found to produce a bacteriocin (pediocin AcH) that inhibited several pathogenic bacteria associated with food including *Bacillus cereus, Clostridium perfringens, Listeria monocytogenes* and *S. aureus*. A bacteriocin like substance (lactocidin) produced by intestinal strains of *Lactobacillus* isolated from humans and several laboratory animals was found to be inhibitory against numerous genera including *Salmonella* species, *E. coli*, and *Staphylococcus* species.

Competition for adhesion sites on the intestinal epithelium, which prevents colonization of pathogens, is another mechanism involved in CE by lactic acid bacteria. A prerequisite for invasion by enteropathogens, including *E. coli*, is for the pathogen to have access to receptors on the host tissue (100,155). It is therefore believed that occupation of the receptor or attachment site by the native or protective intestinal flora is part of their protective role. The ability to adhere to mucosal surfaces has been suggested to be an important property of the bacterial strains used in probiotic products (111). Lactic acid bacteria, particularly *Lactobacillus* and *Streptococcus*, are known to be intimately associated with the nonsecretory squamous epithelial cells of pig stomach (14,57) and chicken crop (53). Mayra-Makinen et al. (113) demonstrated the adhesive capacity of *Lactobacillus* strains to columnar epithelial cells of calves and pigs *in vitro*. The role of adhering lactic acid bacteria in protection against enteric pathogens has been studied to some extent with mixed results. Barrow et al. (14) reported a statistically significant reduction in the numbers of *E. coli* in the stomach when strains of *Lactobacillus* and *Streptococci* were fed, alone or in combination, to artificially reared pigs. Stavric et al. (160) demonstrated that the microflora that remained attached to the cecal wall of chickens after four successive washes in buffered saline had a protective effect against *Salmonella*. On the other hand, in a trial by Spencer and Chesson (159) strongly adherent strains of *Lactobacillus* did not have any effect on the attachment of enterotoxigenic *E. coli* to porcine enterocytes under conditions of exclusion (*Lactobacillus* added to enterocytes before *E. coli*), competition (simultaneous addition of *Lactobacillus* and *E. coli*), or displacement (*E. coli* added before *Lactobacillus*). The inconsistencies in the results reported so far have made the mechanism of CE difficult to understand, because too many generalizations have been made about CE being able to work regardless of attention to individual pathogens' mechanism of adherence to host cells. Some researchers believe that the principle of exclusion by occupation of receptor sites is only applicable when both the lactic acid bacteria and the pathogens involved have the same attachment sites. It will not work with Gram-negative pathogens, because the mechanisms of attachment by lactic acid bacteria and Gram-negative bacteria are different. For example, adhesion of *E. coli* usually takes place by an interaction between the glycan component of host glycolipids and glycoproteins, which act as receptors for bacterial proteinaceous projections (fimbrial lectins) (126). The adherence of lactic acid bacteria, on the other hand, is a process mediated by extracellular components including carbohydrate, protein, or lipoteichoic acid polymers (173). However, another pool of scientists believe that adherent strains can mask pathogen and toxin receptors without necessarily binding to the same epitope, and thus limit the ability of a pathogen to colonize and infect (159). In view of the controversy associated with the exact mechanism that makes an adhering strain effective, it becomes necessary that the importance of adhesion in CE be evaluated thoroughly.

Bacteriocins: Antimicrobial Activity and Applications

A. Satyanarayan Naidu, Ragip Unal and Joseph Tulpinski

CONTENTS

6.1 INTRODUCTION

Bacteriocins (including colicins) are defined as antimicrobial proteins characterized by lethal biosynthesis, a very narrow range of activity, and adsorption to specific cell envelope receptors (1). The established association of bacteriocin biosynthesis with plasmids has been added to this definition, and it has been further modified to include the properties of bacteriocins produced by Gram-positive bacteria (2). To avoid confusion with therapeutic drugs, bacteriocins are not called "antibiotics." (3). These antimicrobial agents are polypeptide molecules with a narrow specificity of action against strains of the same or closely related species.

Bacteriocins from Gram-positive bacteria do not bind to specific receptors for adsorption, are generally of lower molecular weight (than colicins), and demonstrate a broader spectrum of antimicrobial activity (4). These antimicrobial agents also demonstrate different modes of release and cell transport, and possess leader sequences that cleave during maturation (5–7). These ribosomally synthesized polypeptides possess bactericidal properties and are rapidly hydrolyzed by proteases in the human digestive tract (8).

Lactic acid bacteria (LAB) produce a wide range of antagonistic factors that include metabolic products, antibiotic-like substances and bacteriocins (9,10). Several specific species of LAB are commonly used as starter cultures in the manufacturing of dairy, meat, vegetable and bakery products. In addition to health and nutritional benefits, LAB also

contribute to the safety of fermented foods. Accordingly, these bacteria produce organic acids, diacetyl, hydrogen peroxide, and bacteriocins during fermentation (11–13). These compounds contribute to the desirable effect on food flavor and texture, but also inhibit undesirable microflora as well as extend product shelf life (14,15). Food applications of bacteriocins are limited, as efficacy and cost remain issues impeding the broad use of these antimicrobial compounds as biopreservatives. Hence, there is a continuous search for new and more effective bacteriocins as well as research and development activities ongoing for optimization of existing bacteriocins to overcome efficacy and economic limitations.

LAB produce bacteriocins either spontaneously or by induction. The genetic determinants for most bacteriocins are located on plasmids, with a few exceptions of chromosomally encoded ones (16). Secretion of bacteriocins into the milieu requires expression and activity of bacteriocin release proteins and the presence of detergent resistant phospholipase-A in the bacterial outer membrane of LAB (17,18). These antimicrobial agents are species specific and exert their lethal activity through adsorption to specific receptors located on the external surface of sensitive bacteria, followed by metabolic, biological, and morphological changes resulting in the killing of such bacteria. There is increasing evidence that bacteriocins from many bacterial genera share similar characteristics.

Currently, the term bacteriocins refers to a wide range of antimicrobial peptides or proteins produced by various bacteria. Molecular hydrolysis by proteolytic enzymes such as trypsin, α-chymotrypsin, and pepsin is a standard procedure to confirm the proteinaceous nature in the characterization of any new bacteriocin. Furthermore, any evaluation of bacteriocin for possible application as a food additive also requires consideration of protein stability at elevated temperatures given the widespread use of thermal processing in food production. Over the years, several publications have reviewed colicins and bacteriocins and their possible applications in foods, animal health, and medicine (3,5,19–25).

6.2 BIOSYNTHESIS AND FUNCTION

6.2.1 Genetics

Genes encoding bacteriocin production and immunity are linear ribosomally synthesized peptides generally organized in operon clusters (16–18,26). These peptides are post-translationally modified and contain unusual amino acid (dehydrate and lanthionine) residues. These are produced on the ribosome as a prepeptide and undergo extensive post-tranlational modification to form a bioactive peptide with a characteristic N-terminal leader (18,20,21,26). Synthesis of linear unmodified bacteriocins including plantaricins, carnobacteriocins, and sakacins is stimulated by specific inducing peptides or peptide pheromones located on the same gene cluster (27–29).

The best known and most characterized bacteriocin is nisin (18). There are 11 genes making the nisin cluster that code for nisin production, immunity, and externalization. The gene *nisA* encodes the nisin precursor molecule and is part of the gene cluster. Nisin A production and immunity genes are found on a 70 kb conjugative transposon (30). The transposons of nisin also encode *sacA*, *sacB* and *sacC* which are sucrose utilization genes. Nisin contains 34 amino acids arranged in a pentacyclic structure (16).

Bacteriocin gene clusters are located on the chromosome (i.e., subtilin and mersacidin); on plasmids (i.e., divergicin A, sakacin A); or on transposons (i.e., nisin, lacticin 481) (31–35). The operons for lantibiotic biosynthesis generally contain genes coding for the prepeptide (LanA - the abbreviation *lan* refers to homologous genes of different

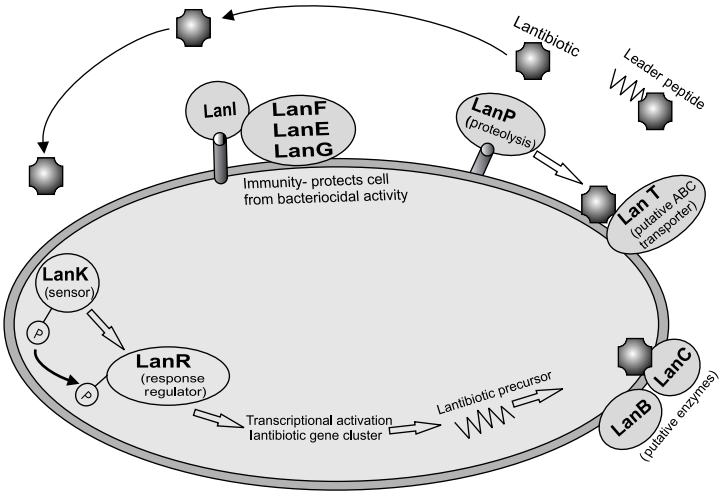

Figure 6.1 General scheme of lantibiotic biosynthesis consisting of pre-peptide formation, modification reactions, proteolytic cleavage of leader peptide, and translocation of modified pre-peptide or mature pro-peptide across cytoplasmic membrane.

lantibiotic gene clusters); enzymes for modification reactions (LanB,C/LanM); processing proteases for removal of the leader peptide (LanP), the ABC (ATP binding cassette), superfamily transport proteins involved in peptide translocation (LanT), regulatory proteins (LanR, K), and proteins involved in producer self protection (immunity) (LanI, FEG). These regulatory pathways have been established based on genetic analysis and biosynthesis of several lantibiotics including epidermin, nisin, subtilin, lacticin 481, and mersacidin (20,31,32,36–42).

Genetic regulation of class II bacteriocins, lactococcins A, B, and M; pediocin PA-1/AcH (pediocin PA-1 and AcH are the same molecule; the term pediocin PA-1 is more commonly used); and plantaricin A have been studied (43–50). Genes encoding the biosynthesis of these bacteriocins share many similarities in their organization. They consist of a structural gene that encodes a prepeptide containing a leader sequence with two glycine residues, followed immediately by a dedicated immunity gene and genes for an ABC transporter and an accessory protein, which are required for the externalization of the bacteriocins. In certain cases, regulatory genes have been identified. Furthermore, accessory proteins are essential for the export of class II bacteriocins, and such counterparts of these accessory proteins in lantibiotics are not reported (24,51).

6.2.2 Regulation

Most bacteriocins are synthesized as inactive prepeptides with an N-terminal leader sequence attached to the C-terminal propeptide. For lantibiotics, the serine, threonine, and cysteine residues in the propeptide region undergo extensive post-translational modification to form Lan/MeLan. The biosynthetic pathway of lantibiotics follows a general scheme with steps consisting of prepeptide formation, modification reactions, proteolytic cleavage of leader peptide, and translocation of modified prepeptide or mature propeptide across cytoplasmic membrane (Figure 6.1). Cleavage of the leader peptide could occur prior, during, or after export from the microbial cell. Based on the biosynthetic pathway, two categories of genetic organization of lantibiotics, Groups I and II, have been identified (16,26,52). During the synthesis of Group I lantibiotics (nisin, epidermin, subtilin, and Pep5), the dehydration reaction is presumably catalyzed by the LanB enzyme, while LanC

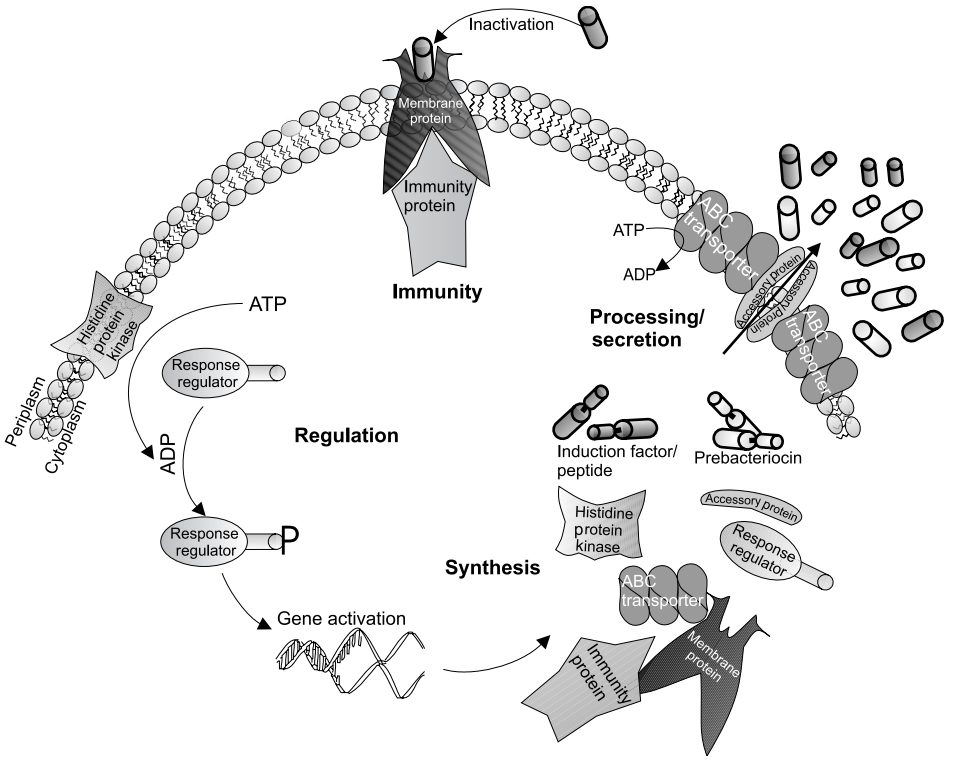

Figure 6.2 Pathways of class IIa bacteriocin biosynthesis. N-terminal leader peptide serves as a recognition site to direct the pre-peptide for maturation and transport proteins, self-immunity of producer strain and ensures conformational changes.

is involved in the thioether formation. The modified prepeptide is processed by a serine protease LanP and translocated through the ABC transporter LanT. In contrast, the Group II lantibiotics (cytolysin, lacticin 481, and mersacidin), are very likely modified by a single LanM enzyme and processing takes place concomitantly with transport by LanT(P) (16,53). Lactocin S is an exception to this group, because a single LanM enzyme modifies this bacteriocin and processing occurs prior to export (54).

Class II bacteriocins are synthesized as a prepeptide containing a conserved N-terminal leader and a characteristic double glycine proteolytic processing site, with the exception of class IIc bacteriocins, which are produced with a typical N-terminal signal sequence of the *sec*-type and processed and secreted through the general secretory pathway (33,55). Unlike the lantibiotics, class II bacteriocins do not undergo extensive post-translational modification. After formation, the prepeptide is processed to remove the leader peptide concomitant with export from the cell through a dedicated ABC transporter and its accessory protein (24,56).

The biosynthetic pathway of class II bacteriocins is shown in Figure 6.2. Several functions of the leader peptides have been proposed that may serve as a recognition site to direct the prepeptide toward maturation and transport proteins, protect the producer strain by keeping the bacteriocin in an inactive state while it is inside the producer, and interact with the propeptide domain to ensure a suitable conformation essential for enzyme to substrate interaction (16,51,57,58).

A three component system consisting of a histidine protein kinase, response regulatory, and induction factors has been shown to be responsible for most regulated Class IIa

bacteriocins (56). An induction factor (IF) is required as a signal to induce the transcription of target genes (56,59). The IFs are small, heat stable, hydrophobic, cationic peptides that are produced as prepeptides with a double glycine leader sequence (24).

Regulation of lantibiotics responds to the extracellular bacteriocin with a two component regulatory system. This system is made up of two signal producing proteins, the membrane bound histidine kinase sensor protein NisK, and the cytoplasmic response regulator NisR. These regulatory systems as a class consist of two signal producing proteins, a membrane bound histidine protein kinase (HPK), and a response regulator (RR) (17,60,61). In the signal transduction pathway HPK autophosphorylates the conserved histidine residue in its intracellular domain when it senses a certain concentration of bacteriocin in the milieu. The phosphoryl group is subsequently transferred to the conserved aspartic acid residue on the RR receiver domain and the resulting intramolecular change triggers the response regulator to activate the transcription of the regulated genes, leading to the expression of the genes involved in immunity, synthesis, and post-translational modifications (62). These regulated genes include the structural gene, the export genes, the immunity genes, and in some cases, the regulatory genes themselves (59).

For nisin and subtilin, the bacteriocin molecule itself acts as an external signal to autoregulate its own biosynthesis via signal transduction (52,62). In contrast, most class II bacteriocins produce a bacteriocin-like peptide with no antimicrobial activity and use it as an induction factor (IF) to activate the transcription of the regulated genes. The IF is a small, heat stable, cationic, hydrophobic peptide that is first synthesized as a prepeptide with a double glycine leader sequence. A dedicated ABC transporter specifically cleaves the leader peptide of IF concomitant with export of the mature peptide from the cell. The secreted IF acts as an external signal that triggers transcription of the genes involved in bacteriocin production (24,56).

Other concepts for the bacteriocin-like peptides in the non-lantibiotic antimicrobial peptides is the peptide pheromone concept regulation of biosynthesis. This concept has been shown to be valid by several groups (27,63,64). Research has shown this concept valid for several bacteriocins including carnocin, plantaricin and sakacin.

6.2.3 Post-translational Events

A two step post-translational modification reaction of a pre-lantibiotic leading to formation of Lan/MeLan was first proposed by Ingram (65,66). The post-translational events begin with the dehydration of hydroxyl amino acids, serine and threonine, to yield 2,3-didehydroalanine and 2,3-didehydrobutyrine, respectively. Some of the dehydrated amino acids do not contain cysteine residues and are consistent in the mature peptide. Other dehydrated amino acids undergo an intramolecular addition reaction involving thiol groups of the neighboring cysteine residues and double bonds of the didehydroamino acids to form thioether bridges. The modified pre-lantibiotics undergo proteolytic processing to release the leader peptide for lantibiotic activation. For Group I lantibiotics, the leader peptide is removed by a serine protease, LanP. This event could occur before or after the peptide is exported from the producing cell via a dedicated ABC transporter, LanT, depending on the location of the protease LanP. For example, the proteases LanP of epicidin 280 and Pep5 are located intracellularly for proteolytic processing, however, the proteases of nisin and epidermin are extracellularly located, and lantibiotics are activated only after export by the ABC transporter (26,37,67). The ABC transporter contains 500 to 600 amino acids and is characterized by two membrane associated domains. The N-terminal domain consists of six membrane spanning helices that could recognize the substrate and form pathways across the membrane, while the cytoplasmic C-terminal domain contains two ATP binding domains with the conserved ATP binding or Walker motif. Hydrolysis of ATP, which likely occurs at the ATP

binding domains, provides energy for the export process (16,68). The LanB and LanC enzymes, together with the LanT transporter, probably form a multimeric membrane associated complex (69,70). For Group II lantibiotics, which possess a conserved double glycine cleavage site, proteolytic processing takes place concomitantly with export through a hybrid ABC transporter. This unique ABC transporter possesses an N-terminal protease domain of ~150 amino acid residues that cleaves the double glycine leader (24,51).

Substantial similarities exist between the leader peptides of Class IIa and IIb and those of Group II lantibiotics. Both contain a characteristic double glycine cleavage site (24,56). Conservation of the cleavage site strongly suggests that the mechanism of processing and translocation of Class IIa and IIb bacteriocins is similar to Group II lantibiotics. Class IIc bacteriocins are processed by a signal peptidase during translocation across the cytoplasmic membrane.

6.2.4 Immunity and Resistance

Two systems of lantibiotic immunity in the producing microbial cell have been identified. Protection could be mediated by immunity proteins, LanI, and dedicated ABC transport proteins, LanFEG encoded on multiple open reading frames (16,71–74). These two immunity systems work synergistically to protect the producing microbial cells from their self bacteriocin (75,76). LanI, also known as PepI encoded by the *Pep5* operon, is a 69 amino acid protein containing a hydrophobic N-terminal domain and a hydrophobic C-terminal part. This suggests that the PepI protein is membrane associated and probably confers immunity to the producer microbial cells by antagonizing the pore formation by the bacteriocin (71). *LanF* codes the intracellular ATP binding domain whereas LanE and LanG represents the membrane spanning subunits. The collective LanFEG apparently acts by transporting bacteriocin molecules that have inserted into the membrane back to the surrounding medium, and thus keeping bacteriocin concentration below a critical level in the membrane.

For Class II bacteriocins, the immunity gene usually codes for a dedicated protein loosely associated with the cytoplasmic membrane. A major part of the immunity protein CbiB2 of carnobacteriocin B2 is found in the cytoplasm and a smaller proportion is associated with the membrane (77). Most of the immunity protein MesI of mesentericin Y105 is in the cytoplasm, with only a small proportion detected in the membrane (78). The immunity protein, which is cationic and ranges in size from 51 to 254 amino acids, provides total immunity against the bacteriocin. Interaction of immunity protein with the membrane could protect the producer against the self bacteriocin (79–81).

The presence of an antibacterial substance in a given milieu would eventually select for varieties of bacteria resistant to the antagonistic component. As found with therapeutic antibiotics in the environment, bacteriocin resistant mutants have been reported. Gravesen et al. (82) tested the responses of a number of strains of *L. monocytogenes* to pediocin PA-1 and nisin, and found a wide range of resistance to both bacteriocins. Influence of environmental stress (reduced pH, low temperature, and reduced salt) is bacteriocin specific; thus the frequency of nisin resistance is significantly reduced, whereas pediocin PA-1 is unaffected. Furthermore, stability of the phenotype of nisin resistance varies substantially, while resistance to pediocin is stable with continuous proliferation of *Listeria monocytogenes*.

6.3 ISOLATION AND CHARACTERIZATION

6.3.1 Purification Methods

Isolation and purification of bacteriocins from complex fermentation broth media is primarily based on the cationic and hydrophobic properties of these antimicrobial compounds (83).

Purification steps usually include an ammonium sulfate precipitation, followed by various combinations of ion-exchange and hydrophobic-interaction chromatography (HIC), with a final Reverse Phase (RP)-HPLC process. It is possible to replace chromatography with preparative isoelectric focusing (84). A rapid single step purification of nisin A using immunoaffinity chromatography has also been described (85). These procedures are not suitable for large commercial scale bacteriocin recovery and separation; however, these methods provide excellent yield and purity (86).

Several processes based on adsorption and desorption or on phase partitioning have been developed for large scale recovery and purification of bacteriocins. Bacteriocins could be recovered by adsorption on producer cells at pH 6.0–6.5, followed by cell separation and desorption at pH 2.0 with 0.1M NaCl. This method is effective for the separation of pediocin AcH, nisin, sakacin A, and leuconocin Lcm1, however, recovery could be limited for other strain and bacteriocin combinations (87,88). Vortex flow filtration systems could replace centrifugation and may be more amenable for large scale recovery of cells (89). However, when bacteriocin concentration is high, the ability of cells to adsorb nisin could be exceeded and result in partial recovery of bacteriocin from the cell fraction. The lantibiotics nisin and carnocin UI49 have been purified to homogeneity using a simple two-step protocol based on adsorption to HIC and cation exchange resins (90). Recovery is high (attributed to removal of interferences in the bioassay due to isolation procedures) and purification was 245- and 60-fold for carnocin and nisin, respectively. SepPak® C8 cartridges are excellent adsorbent materials for nisin Z. SepPak C8 cartridges have been used in an integrated fermentation system with a batch process coupled to microfiltration; permeate is circulated on the cartridge and returned to the fermenter (91). This process has resulted in an improved growth of the producer strain and a high yield of nisin.

Ingestible porous silica compounds such as Micro-Cel E® have also been used to separate bacteriocins (nisin, pediocin PO2, brevicin 286, and piscicolin 126) from fermentation broths (92). Adsorbed bacteriocins are eluted with 0.1% SDS and the final removal of SDS (by cold precipitation) from the eluting mixture was only partial (60–70%) (93). Bacteriocins isolated from this process are 110- to130-fold homogenous and showed an optimum inhibitory activity against target organisms.

A simple two-step purification system based on phase partitioning using the detergent Triton® 114, followed by an adsorption and desorption process on a cation exchange resin has been developed (94). Addition of 2% detergent to culture supernatants resulted in accumulation of divercin V41 in the detergent phase. Divercin V41 was recovered up to 95% purity after adsorption on a cation exchange resin followed by an elution with 0.7 M sodium chloride. This method is effective for the recovery of mesenterocin Y105 and nisin.

6.3.2 Quantitative Assays

A number of methods for detection and measurement of bacteriocin activity have been described (95–97). A common technique for screening bacteriocin activity in producing strains is the spot on lawn approach, which involves an agar overlay. In this method, the producing and indicator cultures are incubated concurrently before examination for zones of inhibition around the growth of producing strains (2,98).

In another procedure, the producing and indicator strains each are grown on different optimal media. The producing culture is spot inoculated on a spread plate; after growth, the agar mass is aseptically dislodged with a spatula from the petri dish bottom and transferred to the lid. A soft agar overlay seeded with the indicator is poured over the inverted agar. Following reincubation, bacteriocin positive cultures display a halo of lawn clearance around the original button of growth. This assay minimizes the effects of acids and bacteriophage, because the producing and indicator strains are physically separated by an agar layer (99).

Media composition is an important factor in plate assays; however, the limitation of these assays includes nutritional requirements of the producing and target organisms. The gelling agents used in solid media may interfere with bacteriocin diffusion and compromise the sensitivity of these screening methods (100). Other compounds could also interfere with or impede the results. For example, β-glycerol phosphate (a buffering agent) in M17 agar during the soft agar overlay of the Kekessy-Piguet methods could interfere with zones of inhibition by *Pediococcus acidilactici* PO2 compared to other agar media and buffering agents (101).

A matrix assisted laser desorption and ionization time of flight mass spectroscopy (MALDI-TOF MS) has been developed for rapid detection of pediocin, nisin, brochocins A and B, and enterocins A and B from culture supernatants (102). In this method, the interfering compounds in the supernatant are removed with a 30 s water wash. However, this washing step requires further improvement to eliminate other contaminants in foods that could potentially interfere with identification of bacteriocins.

Polymerase chain reaction (PCR) methods have been used to detect genes responsible for bacteriocin production and regulation in bacterial cultures. Rodriguez et al. (103) demonstrated the amplification of a 75-bp gene fragment of the lactocin S structural gene in seven bacteriocin positive strains of lactobacilli isolated from fermented sausages. Garde et al. (104) detected the genes necessary for synthesis of lacticin 481 and nisin using PCR techniques with specific probes in an isolate of *Lactococcus lactis* ssp. *lactis* from raw milk cheese.

Enterocin AS-48 from *Enterococcus faecium* isolates from milk and dairy products has been detected using dot blot and colony hybridization (105). Genes encoding for synthesis of AS-48 have been sequenced and a PCR technique has been developed for rapid detection of these genes in field isolates (106,107).

A rapid and sensitive flow cell method for detection of bacteriocins in fermentation broth has been described (108). Low concentrations of potassium ions released from bacteriocin sensitive indicator strains are directly measured and correlated to the concentrations of crude bacteriocin present in fermentation broth. This method demonstrated a high degree of correlation with conventional agar well diffusion assays.

6.4 CLASSIFICATION

Most bacteriocins produced by LAB are cationic, hydrophobic, or amphiphilic molecules composed of 20 to 60 amino acid residues (81). These bacteriocins are commonly classified into four groups that also include bacteriocins from other Gram-positive bacteria (19,24).

6.4.1 Class I: Lantibiotics

Lantibiotics are a group of ribosomally synthesized, post-translationally modified peptides containing unusual amino acids, such as lanthionine (Lan), α-methyllanthionine (MeLan), dehydroalanine, and dehydrobutyrine residues. The lantibiotics (from lanthionine containing antibiotic) are unique in that they are produced on the ribosome as a prepeptide which undergoes extensive posttranslational modification to form a bioactive peptide (20,21,26).

These bacteriocins are a heterogenous group of compounds with respect to molecular mass, structure, and mode of action. Based on chemical structure and antimicrobial mechanism, class I bacteriocins are further subdivided into types A and B lantibiotics (Table 6.1) (52,53,109).

Table 6.1

6.4.1.1 Type A

These lantibiotics are elongated, flexible peptides with a net positive charge that could elicit bactericidal activity by pore formation in bacterial membranes. The most prominent member of this group is nisin, which is elaborated in Section 5.1.

6.4.1.2 *Type B*

These lantibiotics are small globular peptides due to their head to tail cross linkage. These peptides form a group of natural variants that carry a negative or no net charge. Their antimicrobial mechanism is by inhibition of specific enzyme functions. Bacteriocins such as ancovenin, duramycin A, B, C, and cinnamycin are members of this group.

6.4.2 Class II: Small Heat Stable Peptides (Non-lantibiotics)

These bacteriocins are ribosomally synthesized as inactive prepeptides. They are modified by post-translational cleavage of the N-terminal leader peptide, generally at a double glycine to release mature amphiphatic and thermostable cationic peptides (110). Potent anti-listerial activity is a common characteristic of this class of bacteriocins.

Classification of bacteriocins of this group is challenging. One of the criteria is based on the presence of a YGNGVXC amino acid motif near the N-terminus of the active peptide, and the presence of cysteine residues resulting in disulfide bridges. Bacteriocins consisting of the YGNGVXC motif frequently are referred to as pediocin-like or listeria-active. The function of this sequence, if any, is not known and both descriptions are misleading. The non-lantibiotic class II bacteriocins in this chapter are subdivided as class IIa to IIe (typical) and IIf (atypical) according to the scheme proposed by van Belkum and Stiles (110). The typical classes IIa to IId bacteriocins are listed in Table 6.2.

6.4.2.1 *Class IIa*

These are cystibiotics containing four cysteine residues that form two S-S bridges, one in the N-terminal half and the other in the C-terminal half of the molecule. Only three well characterized bacteriocins, pediocin PA-1/AcH, enterocin A, and divercin V41 fit this group. Reaction of pediocin PA-1 with dithiothreitol to maintain cysteine residues in the thiol form markedly decreases its activity (112). Pediocin from this subclass is described in Section 6.1.

6.4.2.2 *Class IIb*

These are the largest group of this class; cystibiotics containing one S-S bridge in the N-terminal half of the molecule. Many of these bacteriocins, including sakacins, contain a high degree of sequence homology in the N-terminal amino acid residues, whereas the C-terminal amino acids are relatively diverse (113). Sakacin from this subclass is described in Section 6.2.

6.4.2.3 *Class IIc*

These are cystibiotics which lack the YGNGVXC motif of class IIa and IIb, and the S-S bridge spans the N- and C-sections of the molecule. Carnobacteriocin A and enterocin B are included in this group. Their genetic arrangement is unusual and their structural and immunity genes are encoded on opposite strands of the DNA in the opposite orientation to one another.

6.4.2.4 *Class IId*

This is a small group of bacteriocins that do not contain the YGNGVXC motif and consists of only one or no cysteine residues. Lactococcins A and B are included in this group but lactococcin B is the only bacteriocin that has been characterized as a thiolbiotic (45).

6.4.2.5 *Class IIe*

These are characterized by their antimicrobial activity, which is dependant on the functional combination of two peptides (Table 6.3). These two separate peptides are either type E (enhancing) in which one of the peptides has antibacterial activity that is enhanced by the other; i.e., thermophilin 13, lactacin F, and plantaracin S; or type S (synergistic) in which the peptides have little or no activity alone; i.e., lactococcin G, plantaricin A, and brochocin-C (110,114–116). Lactococcin G was the first two peptide bacteriocin described (117). This class also includes lactococcin M and plantaricins EF and JK (29). They do not contain cysteine residues and the antibacterial spectra are even more limited than the thiobiotics (5).

6.4.2.6 *Class IIf – Atypical Class II Bacteriocins*

These are cyclic and leaderless peptides; i.e., bacteriocin AS-48 which is better classified as a bacteriocin than a peptide antibiotic, widespread among *Enterococcus faecalis* and *E. faecium* strains (118). Some investigators even consider cyclic peptide bacteriocins as separate from the class II.

6.4.3 Class III: Large Heat Labile Proteins

This class of bacteriocins is not well characterized. This group consists of large (>30 kDa) heat labile proteins that are of limited interest to food scientists. This group includes Helvetin J produced by *Lactobacillus helveticus* and enterolysin produced by *E. faecium* (119,120).

6.4.4 Class IV: Complex Proteins

This group consists of either glycoproteins (lactocin 27) or lipoproteins (lacstrepcins) that require nonprotein moieties for antimicrobial activity (124,121). Plantaricin S also belongs to the group IV bacteriocins (19). Bacteriocins in this class have not been characterized adequately at the biochemical level, to the extent that the definition of this class requires additional descriptive information (16,122).

6.5 CLASS I: LANTIBIOTICS

Most of the class I bacteriocins have a fairly broad inhibitory spectrum. They not only inhibit closely related bacteria, such as species from the genera *Enterococcus*, *Lactobacillus*, *Lactococcus*, *Leuconostoc*, *Pediococcus*, and *Streptococcus*, but also inhibit several less closely related Gram-positive bacteria, such as *L. monocytogenes*, *Staphylococcus aureus*, *Bacillus cereus*, and *Clostridium botulinum*. Several bacteriocins in this class, such as nisin and thermophilin 13, prevent germination and proliferation of spores of *B. cereus* and *C. botulinum*. Interestingly, acidocin J1132 has a very narrow inhibitory spectrum and sensitive strains are limited to members of the genus *Lactobacillus*, while at the other extreme, plantaricin LP84 (produced by *Lb. plantarum* NCIM 2084) has a potent inhibitory activity against *Escherichia coli* (123).

6.5.1 *Type A:* Nisin

Nisin is a small, heat stable, antimicrobial peptide described as a class I type A bacteriocin, a group that comprises lantibiotics (123). In 1947, Mattick and Hirsch (124) first isolated nisin from culture broths of *Lactococcus lactis* ssp. *lactis*. Nisin is the first compound of this class type to be used in the food industry on a broad scale. Its discovery prompted the search for other antimicrobial peptide products from LAB, but nisin is still the only purified bacteriocin commercially available, and is unique in its acceptance worldwide as a food preservative. In 1953, the first industrial production of nisin (Nisaplin®) was launched by Aplin and Barrett, Ltd., UK.

*-Molecular mass estimated by peptide sequence fragmentation modeling.

6.5.1.1 *Mechanism of Action*

The cytoplasmic membrane is the primary target site for both nisin A and nisin Z, where the activity results in pore formation, membrane perturbation and voltage dependent polarization of lipid bilayers (125,126). The flexible nature and amphiphilic properties of the nisin molecule are important for this mode of action.

The ability of nisin to inhibit N-acetylglucosamine synthesis in *B. subtilis*, and DNA, RNA and protein synthesis in *Micrococcus luteus* has prompted speculation that this bacteriocin interacts with the phospholipid components of the cytoplasmic membrane. Studies have indicated that isolated cytoplasmic membranes and phospholipid components of membranes show an antagonistic effect on nisin inhibition (127). Due to its cationic nature, nisin interacts with charged groups membrane phospholipids via ionic forces. The C-terminal region of the nisin molecule is responsible for the initial electrostatic interaction (128–131). Nisin could also bind to non-energized liposomes with a high affinity via the negatively charged phospholipids.

The nisin induced pore formation across the cytoplasmic membrane is non-selective and transient in nature with varying pore sizes. This suggests that nisin molecules could associate and dissociate with the pore in a dynamic process (5). The energy for formation and opening of the pores is accessed from the trans-membrane potential of the target organism (132,133). The lethal outcome with nisin is optimum against proliferating cells with actively energized membranes (133,134). However, nisin activity could be induced in the absence of a trans-membrane electric potential ($\Delta\Psi$) with high pH gradient across the membrane (ΔpH) (135).

Based on several lines of experimental evidence, a barrel stave mechanism of pore formation has been proposed for nisin lantibiotic mediated antimicrobial activity (Figure 6.3). According to this model, nisin monomers (the staves) bind to the membrane, insert into the membrane (dependent on the electric potential) and aggregate within the membrane to form a water filled pore (the barrel) (117,136). The nisin molecule orients perpendicularly into the membrane with its hydrophobic sides facing the membrane and its hydrophilic regions oriented into the lumen of the pore, forming the sides. If the membrane is sufficiently energized,

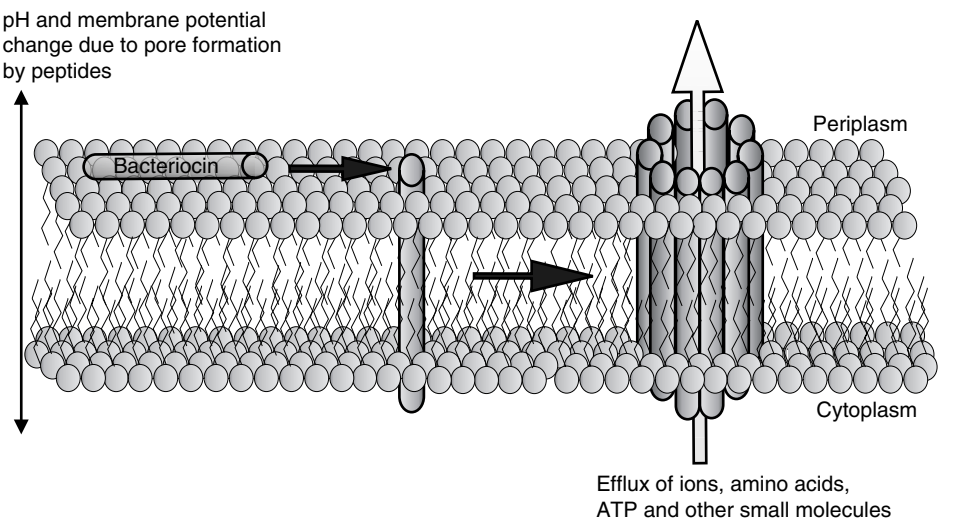

Figure 6.3 'Barrel-stave' model of pore formation by nisin. Nisin monomers ('staves') bind, insert and aggregate within the membrane to form a water-filled pore (the 'barrel').

nisin molecules travel through the membrane, bind to the surface, and penetrate across phospholipids. Binding of several nisin molecules at the same site results in the formation of a transient pore.

In another proposed wedge model, nisin molecules bind to anionic membrane surface by electrostatic interactions and disturb the lipid dynamics (130). This further leads to localized damage of the membrane that ultimately forces the nisin into the target cell membrane. This model suggests that multimeric nisin molecules form wedge-like pores and the electric potential propels the insertion of phospholipid surface bound nisin molecules into the cell membrane. Subsequently, the positively charged carboxyl terminal residues are drawn across the membrane in response to the electric potential, causing a structural defect in the phospholipid bilayer.

Nisin interaction and perturbation of membrane is dependent on an array of molecular properties such its amphipathic character, flexibility of its central segment, and overall negative surface charge of the membrane (128,131,137). Pore formation leads to leakage of small molecules such as K^+ ions, solutes, and metabolites such as ATP and amino acids. This phenomenon rapidly depletes the proton motive force, causing cellular energy deprivation and inhibition of vital biosynthetic processes (Figure 6.4) (26,125).

Other mechanisms of nisin activity against vegetative cells have been suggested (138). Interference of nisin with the murein biosynthesis of *B. subtilis* cell wall has been reported (127). Adsorption of nisin to teichoic acids in cell wall and activation of autolytic enzymatic degradation has also been suggested (139). These two mechanisms could be slower in effect than pore formation, but may contribute to an overall bactericidal effect.

6.5.1.2 Antimicrobial Spectrum

Nisin is a potent inhibitor of several species of Gram-positive bacteria, including the heat resistant endospore formers. The susceptibility of Gram-negative bacteria to nisin activity is limited due to their lantibiotic impermeable outer cell membrane. However, the cell wall deficient spheroplasts of *E. coli* and *Salmonella typhimurium* are susceptible to nisin (140). Furthermore, treatments that alter the outer membrane barrier functions could

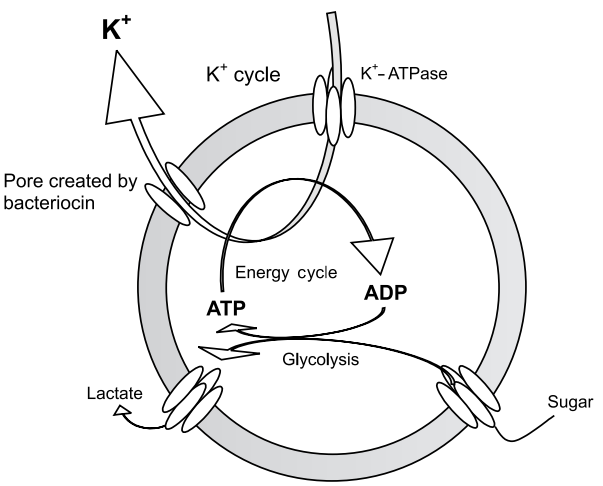

Figure 6.4 Cellular mechanism of pore-forming bacteriocin activity. Pore formation leads to depletion of proton motive force by causing cellular energy deprivation and inhibition of vital biosynthesis functions.

potentiate nisin activity in Gram-negative bacteria. Such treatments include hydrostatic pressure, heat, freezing and thawing and chelating agents such as EDTA or ethyl maltol (141–146). Yeasts, like the Gram-negative bacteria, are also insensitive to nisin, and any removal of their cell wall allows the bacteriocin access that leads to yeast cell lysis (147). However, the insensitivity of yeast to nisin has been exploited in fermentation applications with yeast based starter cultures and fermented products.

Nisin sensitivity could vary among strains even of the same species (148,149). About 10–100 times more nisin is needed to prevent the outgrowth of spores of *C. botulinum*, compared to *C. butyricum* (150). Spores and vegetative cells of thermophilic species such as *B. stearothermophilus* and *C. thermosaccharolyticum* are more sensitive to nisin than mesophilic spore forming species (151).

Comparative studies with nisin A, nisin Z, and pediocin showed that LAB, *Clostridium* and *Bacillus* (spores and cells) are more effectively inhibited by the nisin variants compared to pediocin (149). Antilisterial inhibition studies indicated that Nisin A is more efficacious than nisin Z, however, the effective dosages showed marked variations. Accordingly, nisin concentration required for complete inhibition of *L. monocytogenes* varies from 10 to 2500 μg/mL, depending on the culture medium and the target strain (152). The dosage limitation could be overcome in foods by using nisin in combination with a starter culture producing a nonlantibiotic antilisterial bacteriocin (153). In practice, however, varied listerial sensitivities are overcome by standard hurdle technology, where nisin acts in combination with other control measures in the food matrix, such as reduced water activity.

Spontaneous resistance to nisin has been reported in strains of *C. butyricum, L. lactis* ssp. *cremoris*, *L. monocytogenes* and *S. agalactiae* (154,155). Resistance has been linked to the production of an anionic phosphate polysaccharide with subunits of rhamnose and galactose (156).

The functional efficacy of nisin in a food matrix is affected by several factors including: changes in nisin solubility and charge, binding of nisin to food components (i.e., meat phospholipids), inactivation of nisin (by proteases or food ingredients), and changes in the cell envelope of the target organisms in response to environmental factors (157). The activity of nisin produced *in situ* may also be affected by food components.

6.5.1.3 Applications

Nisin is suitable for use in a wide range of foods: liquid or solid, canned or packaged, chilled or warm ambient storage (elaborated in Section 6.7). Based on target organisms, its usage falls into three broad categories: to prevent spoilage by Gram-positive endospore formers (particularly in heat processed food), to prevent spoilage by LAB and similar organisms such as *Brocothrix thermosphacta*, to kill or inhibit Gram-positive pathogens; i.e., *L. monocytogenes*, *B. cereus*, and *C. botulinum*.

Nisin provides advantages as an antimicrobial food additive in extending shelf life of both chilled and ambient storage temperatures (such as canned products in warm climates). Nisin also protect products, particularly chilled foods, from storage temperature abuse. Addition of nisin may contribute to the general preservation of a food so that thermal processing could be reduced. This has the double advantage of improving product quality (which may be impaired by harsh heat treatment) and reducing manufacturing costs, because both the time and temperature of thermal treatment could be diminished.

Nisin is best added as an aqueous solution, usually to the liquid portion of a product during processing. For instance, in canned foods nisin could be combined with a small quantity of canning brine followed by a thorough mixing into the bulk product. In dairy desserts and milks, nisin could be added to a small quantity of milk, followed by mixing into the bulk

milk, then filled and processed (158). Nisin could also be added as a powder, provided a uniform dispersal throughout the food matrix is ensured. Nisin could also be used at higher concentrations as a spray or dip (processing aid) for surface decontamination.

The dosage and application of nisin depends on the food type, processing (heat, pH, or salts) and storage conditions as well as the shelf life expectations (Table 6.4). Nisin is often used in acidic foods, but is effective in products across a wide range of pH values (3.5–8.0). Nisin also seems to be an effective preservative in liquid egg, which generally has a pH of 7.3 to 7.8.

Several reports have indicated an effective application of nisin in packaging films and edible casings. Coatings of nisin on silicon surfaces and polyvinyl chloride films have been shown to demonstrate antimicrobial activity (92,159). Biodegradable films containing lysozyme, nisin and EDTA made from soy protein and corn zein prepared by heat

Table 6.4
Nisin applications as bio-preservative for various types of food products

Food Type	Nisin (μg/g)	Application
A) Dairy Foods		
1. Processed cheese	5 – 15	Inhibition of endospores from Bacillus spp. and Clostridium spp.
2. Cottage cheese	5 – 50	Inhibition of *L. monocytogenes* contaminants
3. Soft white fresh cheese	5	Preservation of minimal processed cheeses i.e., ricotta, panir and Latin-American cheeses queso blanco and queso fresco.
4. Natural cheese	5 – 20	Shelf life extension of Camembert and Feta cheeses.
5. Dairy desserts	1.25 – 25	Quality enhancement of crème caramel and cholcolates; anti-listerial protection of ice creams.
6. Yoghurts	0.5 – 1.25	Reduction of over-acidity in fermented milk products.
7. Milk and milk products	0.25 – 1.25	Extension of shelf life of pasteurised milk in developing countries
B) Beverages		
1. Fruit juice (pasteurized)	0.13 – 0.25	Alicyclobacillus acidoterrestris
2. Vegetable protein milks		Reduction in heat processing time and shelf life extension
3. Wine		Suppression of unwanted malolactic acid fermentation
4. Fruit brandy		Selective inhibition of lactic acid bacteria
5. Beer:		Inhibition of unwanted lactic acid bacteria i.e.,
• pitching yeast wash	25 – 37.5	Lactobacillus spp., Pediococcus spp. without
• reduced pasteurization	0.25 – 1.25	affecting yeast
• during fermentation	0.63 – 2.5	
• post fermentation	0.25 – 1.25	
C) Other Foods		
1. Canned food	2.5 – 5	Destruction of clostridial and bacillary spores.
2. Dressings and sauces	1.25 – 5	Inhibition of bacterial, yeast and mold contaminants.
3. Liquid egg	1.25 – 5	Elimination of salmonella and endospore destruction
4. Fresh soups		Control of spoilage flora and shelf life extension
5. Crumpets	3.75 – 6.25	Inhibition of toxigenic *B. cereus* food poisonings.

Adapted from Thomas et al. (159)

press and casting methods exhibit a potent antimicrobial activity against *L. plantarum* and *E. coli* (160).

6.6 CLASS II: SMALL HEAT STABLE PEPTIDES

Compared to class I bacteriocins, most class IIa bacteriocins have a narrow spectrum of activity and inhibit closely related Gram-positive bacteria. In general, members of the genera *Enterococcus*, *Lactobacillus*, and *Pediococcus* are sensitive to Class IIa bacteriocins, and members of the genus *Lactococcus* are resistant. For example, pediocin PA-1 was found active against different species of *Enterococcus*, *Lactobacillus*, and *Pediococcus*; however, only 1 out of 11 *Lactococcus* strains tested (*Lactococcus lactis* LMG 2070) was sensitive to the bacteriocin (63). Certain class IIa bacteriocins, such as pediocin PA-1, demonstrate broad inhibitory spectra and could inhibit certain less closely related Gram-positive bacteria, such as *S. aureus* and vegetative cells of *Clostridium* species and *Bacillus* species. Other class IIa bacteriocins, such as mundticin from *Enterococcus mundtii*, even prevent the germination of spores of *C. botulinum*. Class IIa bacteriocins are generally active against *Listeria*. Different strains of *Listeria* including *L. monocytogenes*, *L. innocua*, and *L. ivanovii* were highly sensitive to four different class II bacteriocins (pediocin PA-1, enterocin A, sakacin P, and curvacin A) (63). The minimal inhibitory concentrations against *L. monocytogenes* for the four bacteriocins varied from 0.1 to 8 ng/mL; however, *L. monocytogenes* V7 and *L. innocua* LB1, have been found resistant to class II bacteriocins (enterocin A, mesentericin Y105, divercin V41, and pediocin AcH) (161).

6.6.1 *Class IIa:* Pediocins

Pediocin A, from *Pediococcus pentosaceus* is a 80 kDa bacteriocin and the pediocins of *P. acidilactici* strains are about 4.6 kDa peptides containing 44 amino acids as pediocin PA-1/AcH. Two *P. parvulus* strains and one *Lb. plantarum* strain also reportedly produce pediocin PA-1/AcH. In general, the bactericidal property of pediocins is relatively resistant to heat, storage conditions, pH, organic solvents, and hydrostatic pressure, but is destroyed by proteolytic enzymes and neutralized by certain anions. Pediocin PA-1/AcH by *P. acidilactici* strains is produced in large amounts in a non-buffered nutritional medium, especially at a low terminal pH. Studies have shown that pediocin PA-1/AcH, or the producer strains, could be effectively used in food systems to control *L. monocytogenes*. Under optimum processing conditions pediocins could also control Gram-positive and Gram-negative spoilage bacteria in foods.

6.6.1.1 Mechanism of Action

Early studies indicated that the antibacterial mechanism of pediocin PA-1/AcH against Gram-positive bacteria is a bactericidal and not a bacteriostatic effect (162). Subsequent studies showed that pediocin induced cell death by impairment of bacterial cytoplasmic membrane, which results in the leakage of cellular ions, small molecules, and UV absorbing materials (163). Furthermore, cationic pediocin molecule binds in a pH dependent manner to anionic lipoteichoic acids in the Gram-positive bacterial cell wall. In Gram-negative cells, due to the lack of teichoic acids, pediocin molecules are not absorbed (or adsorbed at very low concentrations, probably due to lipopolysaccharides which have a barrier function) and the inner membrane remains unaffected. However, Gram-negative bacteria, when stressed or injured, lose the barrier function of their outer membrane, and pediocin could then elicit a bactericidal effect (164).

The mechanism of bactericidal action of pediocin PA-1/AcH is unclear. Based on several lines of evidence, a hypothesis for the mechanism of action is elucidated (Figure 6.5) as follows:

1. The N-terminal half of the molecule adopts a β-sheet conformation, probably after membrane binding, which is stabilized by a disulfide bond between *Cys-9* and *Cys-14*.
2. Cationic amino acids (*Lys-11* and *His-12*) bind to the anionic phospholipids in the membrane through electrostatic interactions.
3. Protein receptors in the membrane are not essential for the binding of pediocin, but such a receptor, if present, could enhance the activity.
4. The C-terminal half also might have a random conformation in aqueous environment, but disulfide bridging between *Cys-24* and *Cys-44*, and β-sheet may help transform it into a defined α-helical amphiphilic structure following any contact with the lipid bilayer.
5. Pediocin molecules subsequently could assemble in the membrane, cause pore formation and lead to dissipation of proton motive force due to the collapse of pH gradient and membrane potential in a voltage independent manner.
6. Susceptible cells lose intracellular ions, UV absorbing materials, ATP, and could no longer transport amino acids or glucose.
7. These cellular events finally lead to cell death (165,166).

6.6.1.2 Antimicrobial spectrum

Compared to other bacteriocins in the class IIa family and to some lantibiotics, pediocin A of *P. pentosaceus* FBB61 and pediocins from *P. acidilactici* strains have a relatively wider bactericidal spectrum against Gram-positive bacteria. Pediocin A inhibits several strains of *P. pentosaceus, P. acidilactici, S. aureus, L. lactis, Lactobacillus* spp., *C. botulinum, C. perfringens* and *C. sporogenes* (167). Pediocin A has also been reported to inhibit six out of eight strains of *L. monocytogenes* (101).

Bhunia et al. (163) demonstrated that a partially purified fraction of pediocin PA-1/AcH effectively inhibited *B. cereus, C. perfringens, S. aureus* and several species and strains of *Lactobacillus* and *Leuconostoc*. In later studies, higher purity preparations of pediocin PA-1/AcH showed growth inhibition against strains of *L. monocytogenes, B. cereus, C. perfringens, C. botulinum, C. laramie*, and several *Lactobacillus, Leuconostoc, Enterococcus, Pediococcus* and *Lactococcus* species (168–170). Although bacterial spores are not sensitive to pediocin PA-1/AcH and other bacteriocins, no growth was observed following inoculation of spores of *C. laramie, C. perfringens* and *C. botulinum* in appropriate growth media containing pediocin. A later study showed that pediocin produced a bactericidal effect on the germinated and outgrowing spores. Studies have also indicated that resistant but stressed Gram-positive bacterial strains of *S. aureus*, *L. lactis* and Gram-negative bacterial strains of *Salmonella* sp., *E. coli* O157:H7, *Serratia liquefaciens* and *Pseudomonas* species turned susceptible to pediocin PA-1/AcH (142,143,171–173).

6.6.1.3 Applications

Pediocin A from *P. pentosaceus* FBB61 and pediocin PA-1/AcH from *P. acidilactici* strains as well as from *P. parvulus* strains and *L. plantarum* WHE92 are potent bactericidal agents against many normal as well as injured foodborne spoilage and pathogenic bacteria. Accordingly, these pediocins could be used as effective food biopreservatives (174).

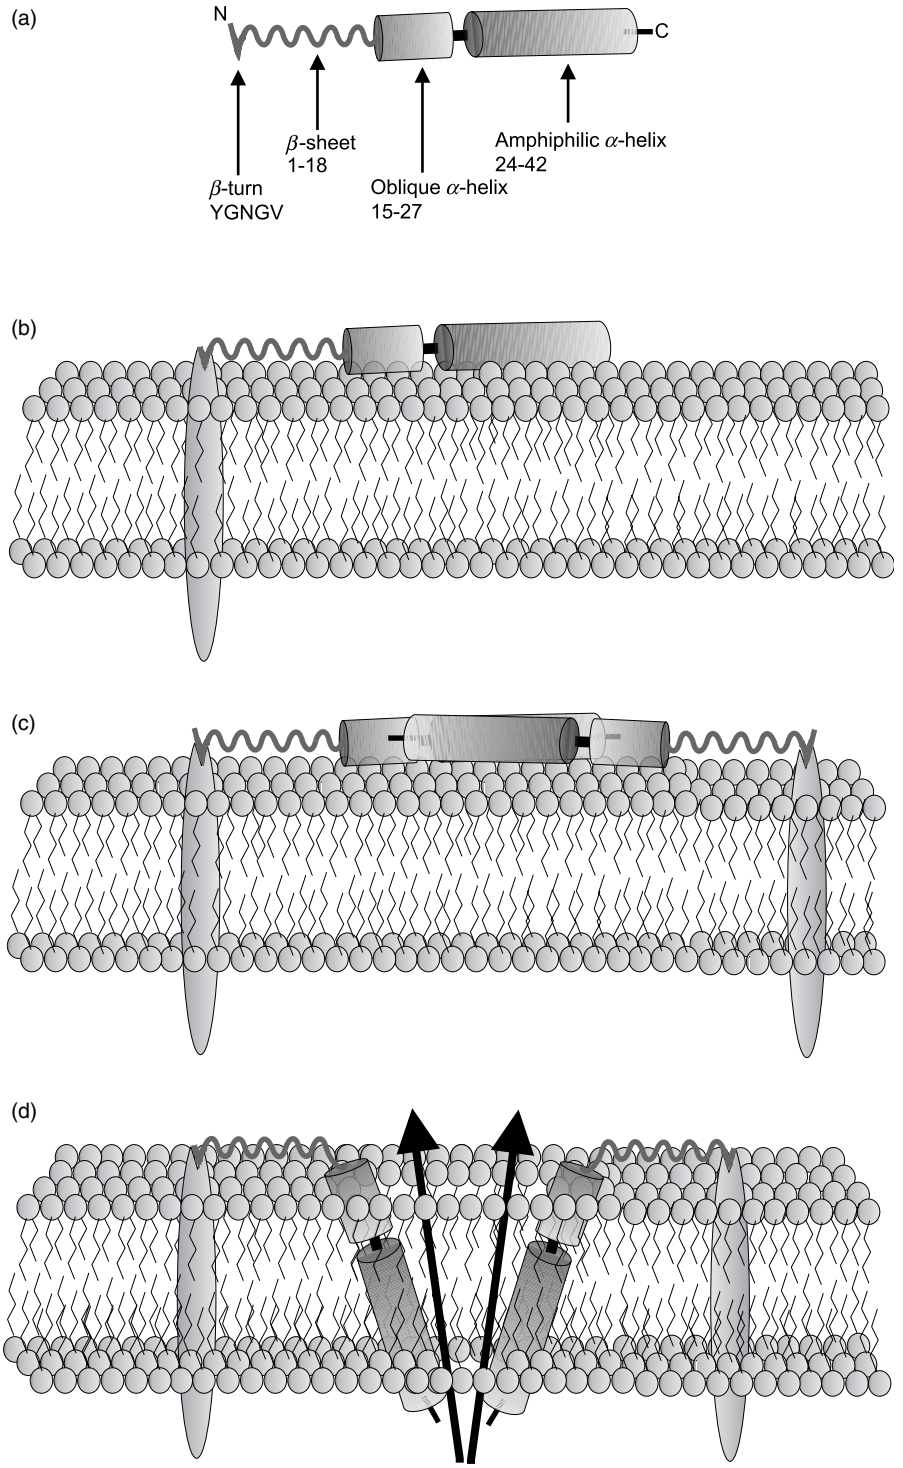

Figure 6.5 Membrane interaction model for class IIa bacteriocin with target cells. (a) Structure of the predicted domain of the bacteriocin. (b) Bacteriocin positioning by receptor (putative) recognition, electrostatic and hydrophobic interactions. (c) Avid binding of bacteriocin with the target site. (d) Bacteriocin aggregation and hydrophobic pore formation.

Other studies have suggested that pediocin A producing *P. pentosaceus* could reduce proteolysis and ammonia formation in caecal fermentation without interfering with the activity of normal caecal microflora (175). Furthermore, this strain could be used as a probiotic bacterium to maintain intestinal health. Pediocin producing *Pediococcus* strains could also control undesirable fermentation during silage fermentation (164).

6.6.2 *Class IIb:* Sakacins

Sakacins are class IIb bacteriocins produced by certain strains of *L. sake*. These small, cationic, hydrophobic peptides contain an N-terminal leader sequence of the double glycine type, and possess a strong antilisterial activity. Sakacin A was the first sakacin reported from *L. sake* Lb706, an isolate from raw meat (176). Subsequent sakacins discovered include sakacin M produced by *L. sake* 148, sakacin P by *L. sake* LTH673, sakacin 674 by *L. sake* Lb674 and *L. sake* Lb16, sakacin B by *L. sake* 251 and sakacin K by *L. sake* CTC 494 (177–182). All known sakacin producers of lactobacilli were predominantly isolated from meat sources.

6.6.2.1 Mechanism of Action

Bacterial cytoplasmic membrane is the primary target site for the antimicrobial activity of sakacins. The lethal action results from sakacin induced hydrophilic pore formation and membrane perturbation with a consequent leakage of vital cellular components as well as a depletion of proton motive force (5,23,183). Bactericidal effect is the antimicrobial outcome for sakacin types A, B, P and K, but only bacteriostatic for sakacin M (176–182). These antibacterial effects are influenced by several factors, including sakacin concentration and purity; testing buffer or broth; sensitivity of the indicator strain; and cell density of the target organism.

6.6.2.2 Antimicrobial Spectrum

Sakacins, as is common for class II bacteriocins, are highly inhibitory against *Listeria* species. (176–179,182,185,186). Furthermore, sakacins are characterized by a narrow inhibitory spectrum, being active against various strains of LAB, especially *Lactobacillus* species. (Table 6.5). The potent antilisterial activity and limited inhibitory spectrum toward LAB makes sakacin P, a promising bacteriocin to combat *Listeria* contamination of foods. Because sakacins do not inhibit the growth of meat starter cultures and certain strains of *Micrococci* and *S. carnosus*, they are suitable for practical use in the production of fermented meat products and to control meatborne pathogens *L. monocytogenes, E. faecalis* and *S. aureus* (176,177,179).

Table 6.5
Class-IIb Sakacin-types and their antimicrobial spectrum

Type	Susceptible Organism	Ref.
Sakacin-A	*L. monocytogenes, Lactobacillus* spp., *Pediococcus* spp., *Car. piscicola*, *Leu. paramesenteroides, Ent. faecium* and *Ent. faecalis*	(185)
Sakacin-B	*Lactobacillus* spp.and *Leuconostoc* spp.	(181)
Sakacin-K	*L. monocytogenes* and *L. innocua*	(182)
Sakacin-M	*L. monocytogenes, Staph. aureus, Lactobacillus* spp., *Leuconostoc* spp., *Carnobacterium* spp.	(177)
Sakacin-P	*L. monocytogenes, Leuconostoc*, *Carnobacterium*, *Ent. faecalis,* and *Br. thermosphacta*	(179)

6.6.2.3 *Applications*

The use of sakacin or sakacin producing LAB in foods, meat products in particular, has been under extensive evaluation (187–191). Besides the control of foodborne pathogens, incorporation of sakacins in foods could also inhibit spoilage bacteria such as the rope inducing, gas producing or flavor disturbing heterofermentative LAB. This characteristic could contribute to the overall sensory and organoleptic qualities of the food, when preserved with sakacins.

In meat technology, sakacin could be used as (partially) purified bacteriocin preparation or through *in situ* production by inoculating with sakacin producing strains. The latter application with nonfermented meat or meat products could result in suppression of growth of spoilage organisms or food pathogens (use as protective culture, for instance in fresh meat, high pH meat products, or minimally processed meat products like vacuum packed or modified atmosphere packaged meat). Furthermore, these sakacin producers may be used as starter cultures or cocultures in fermented meat products to control the fermentation process by inhibiting the growth of competing flora, including foodborne pathogens.

Applications of purified sakacin as food additive are currently not in practice due to the lack of approvals from regulatory agencies. Therefore, *in situ* applications as a food grade starter culture may be more suitable, because labeling is not necessary for sakacin producing LAB (192). Furthermore, it is likely that the starter flora of several fermented meat products already contain sakacin producers. Accordingly, there are several patents for the specific use of sakacin producing LAB as commercial starter cultures for meat fermentations (193,194).

6.7 FOOD APPLICATIONS

Biopreservation is defined as the use of antagonistic microorganisms and their metabolic products to inhibit or destroy undesired microorganisms in foods to enhance food safety and prolong shelf life. Bacteriocins of LAB are considered natural antimicrobial agents or biopreservatives that meet this definition. Biopreservation of foods with bacteriocins could be accomplished in three different ways: by inoculation of food with bacteriocin producing LAB; by direct addition of purified or semipurified bacteriocins to food; and by use of a product previously fermented with a bacteriocin producing LAB as an ingredient in another food.

6.7.1 Dairy Products

Nisin is the most commonly used bacteriocin in cheese manufacturing to inhibit the growth of both spoilage and pathogenic microorganisms, particularly *L. monocytogenes.* Addition of 2000 IU/g of nisin into cottage cheese increases the inactivation rate of *L. monocytogenes* by more than 3-log in 3 days (195). The growth of *L. monocytogenes* in ricotta-type cheeses is also significantly inhibited by addition of 100 IU/mL of nisin over 70 days or more at 6 to 8°C depending on the type of cheese (196). Shelf life of nisin containing pasteurized process cheese (301 and 387 IU nisin/g of cheese) is markedly enhanced over control cheese spreads (197). Nisin (100 and 300 IU/g) could decrease populations of *L. monocytogenes*, *S. aureus*, and *C. sporogenes* spores in cold processed and packed cheese spreads. Butyric acid fermentation by *Clostridium* species is one of the problems in cheese manufacturing; nisin could effectively control such spore forming *C. tyrobutyricum* (198).

Lacticin 3147 produced by *L. lactis* ssp. *lactis* DPC 3147 has a broad spectrum of antimicrobial activity for dairy applications. Ross et al. (199) described the control of cheddar cheese quality attributes by decreasing the population of nonstarter LAB at least 2-log after 6 months ripening with lacticin 3147 producing starter cultures. Nonstarter LAB failed to proliferate even after 6 months of ripening. Cottage cheese manufactured with *Lactobacillus lactis* DPC4275 reduced the population of *L. monocytogenes* by 3-log over a one week ripening period. Lacticin 3147 producing starter culture is an effective biopreservative for reducing listerial population on mold ripened cheese surfaces by 3-log (199). Nisin and lacticin 3147 are both produced by food grade LAB. However, the regulatory approval of the latter bacteriocin is still pending.

Dried preparation of pediocin PA-1/AcH from *P. acidilactici* PAC1.0 could effectively control *L. monocytogenes* growth in cottage cheese, half and half, and cheese sauce at 4°C for 14 d storage (200). Spraying of a pediocin PA-1/AcH producing cell suspension of *L. plantarum* WHE92 on Munster cheese prevented proliferation of *L. monocytogenes* during ripening for 21 d (201).

6.7.2 Meat Products

Naturally occurring microorganisms and their bacteriocins are widely used for enhancing food safety and shelf life of several meat products. Preservation of cooked ready to eat (RTE) foods and minimally processed refrigerated foods (MPRF) are the foremost candidates for such biopreservation.

Nisin (400 and 800 IU/mL) treatments alone and in combination with 2% NaCl were shown to inhibit growth of *L. monocytogenes* in minced raw buffalo meat (202). The inhibitory action of nisin was less pronounced when the storage temperature was increased to 37°C; however, the combination of 2% NaCl with nisin enhanced the bacteriocin efficacy.

Nisin has been used for sanitization of red meat carcass surfaces inoculated with *B. thermosphacta*, *C. divergens*, or *L. innocua* (203). Spray treatments with nisin (5000 IU/mL) decreased the populations 1.8 to 3.5 log CFU/cm^2 at day 0 and by 2.0 to 3.6-log CFU/cm^2 after one day storage at 4°C.

Combination of nisin (1000 or 10000 IU/ml) with modified atmosphere packaging (MAP) (100% CO_2, 80% CO_2 + 20% air) could effectively inhibit growth of *L. monocytogenes* and *Pseudomonas fragi* in cooked tenderloin pork (204). MAP/nisin combination was more effective at 4°C than at 20°C. The antilisterial activity of nisin A and pediocin AcH in fresh ground pork stored aerobically at 5°C has also been reported (205).

Nitrites are commonly used for stabilizing red meat color; inhibiting food spoilage and poisoning organisms, such as *C. botulinum*. However, nitrites and their derivatives the secondary amines, react with meats to form carcinogenic nitrosamines. Bacteriocins, as alternative additives, could reduce levels of nitrite for such meat applications. Combination of nisin (3000 IU/g) and nitrite (40 ppm) could totally inhibit growth of *C. botulinum* spores in meat slurries at 37°C for 56 days (206). Nisin (8000 IU/g) in combination with nitrite (60 ppm) also inhibits germination of clostridial spores in pork slurries at pH 5.5. Nisin (4000 IU/g) and nitrite (120 ppm) combination could delay toxin formation by *Clostridium* species in chicken frankfurter emulsions for 5 weeks (207).

Pediocin PA-1/AcH (1,350 AU/g or mL) could kill >99% of meat spoilage psychrotrophic *Leuconostoc mesenteroides* in ground beef, sausage mix, milk, and ice cream mix (208). Pediocin (3,000 AU/g) could also reduce the populations of *C. laramie, Lactobacillus* species and *Leuconostoc* species during storage at 4°C for 12 weeks (171,209). Incorporation of pediocin (from *P. acidilactici* PO_2) reduced the population and controlled growth of *L. cervatus* in a meat paste during 15 d storage at refrigerated temperature (170). The effectiveness of pediocin in controlling spoilage of salad dressing

and salad caused by *L. Bifermentum,* and also in extending the shelf life of coleslaw, macaroni salad, and potato salad has been reported (210). A possible application of pediocin producing *P. parvatus* strains to control spoilage and pathogenic bacteria in fresh RTE vegetables has been suggested (211).

Efficacy of pediocin from *P. acidilactici* strains to control *L. monocytogenes* in processed meat products has been widely reported (208). In ground beef and sausage mix, pediocin could reduce populations of several strains of *L. monocytogenes* in a dose dependent manner. At a level of 1,350 AU/g the populations were reduced by 3.5 log cycles for strain $Ohio_2$, 3 log cycles for strain Scott A and 1.5 log cycles for strain CA. However, the resistant survivors multiplied during refrigerated storage. Pediocin application could also reduce populations of *L. monocytogenes* in fresh beef and beef byproducts (171,212). Pediocin (5,000 AU/g) could effectively reduce *S. aureus, L. monocytogenes, S. typhimurium* and *E. coli* O157:H7 in roast beef, Cotto salami, and summer sausage (172). Combination of this bacteriocin with hydrostatic pressure at 345 MPa at 50°C for 5 min further reduced the population compared to pressure treated products without pediocin (173,213).

Studies with pediocin producing strains of *P. acidilactici* strain JD 1-23 and PAC1.0 as starter cultures to produce dry fermented sausage showed potent antilisterial activity (214,215). Also, the pediocin PA-1/AcH producing *P. acidilactici* starter cultures when introduced in frankfurter packages along with *L. monocytogenes* cells and stored at 4°C for 60 days or more, caused marked reduction of this pathogen (216,217).

Sakacin K produced by *L. sake* CTC494 has been shown to inhibit *L. innocua* in vacuum packaged poultry breasts, cooked pork, and raw minced pork under MAP conditions (218). A bacteriocin-like substance produced by *C. piscicola* L103 completely inhibited the growth of *L. monocytogenes* in vacuum packaged meat after 14 days at 4°C (219). Lactocin 705 produced by *L. casei* CRL 705 inhibited the growth of *L. monocytogenes* in ground beef (220).

Other bacteriocins produced by LAB have also been examined to control the growth of *L. monocytogenes*. Enterocin CCM 4231 in dry fermented Hornád salami could decrease *L. monocytogenes* counts from 8 to 6.3-log immediately after addition of the bacteriocin (221).

6.7.3 Seafood Products

Several biopreservative applications for bacteriocins to protect various seafood products have been documented. Inhibitory effects of nisin and sakacin P against *L. monocytogenes* in vacuum packed cold smoked salmon stored at 10°C for 4 weeks has been reported (222). During a four week storage, addition of sakacin P-producing *L. sake* culture elicited a bacteriostatic effect against *L. monocytogenes.* However, a combination of purified sakacin P with the *L. sake* culture resulted in a potent listeriocidal outcome.

Efficacy of bacteriocin solutions (nisin and Microgard™) to reduce microbial counts, inhibit *L. monocytogenes*, and extend shelf life of cold smoked salmon was evaluated (223). Total aerobic counts on fresh chilled salmon were reduced by 2-log and the shelf life at 6°C was increased by 3 to 4 days with the combination of nisin and Microgard. This antimicrobial cocktail also reduced the growth of *L. monocytogenes* in frozen thawed salmon and increased the product shelf life (without affecting pH or color) from 5 to 10 days at 6°C.

Survival of *L. monocytogenes* in cold smoked salmon in the presence of nisin (500 or 1000 IU/g), CO_2 and low temperature was reduced by 1–2 logs (224). Antilisterial effect

of a bacteriocin producing strain of *C. piscicola* A9b (bac^+) in model fish system and in vacuum packed cold smoked salmon has also been reported (120). The inhibition of *L. monocytogenes* seems due to deprivation of nutrients resulting from competitive growth of *C. piscicola* in the seafood product.

Efficacy of nisin Z and a preparation of crude bavaricin to prolong the shelf life of brined shrimp was reported (225). This bacteriocin combination has extended the seafood shelf life by 16 and 31 days. The addition of benzoate and sorbate solutions to the bacteriocins has further extended the shelf life of brined shrimp by 59 days.

The inhibition of *L. monocytogenes* and mesophilic aerobic bacteria in cold smoked rainbow trout by nisin (4000–6000 IU/mL) and sodium lactate (60%), alone or in combination has also been reported (226). Listerial counts in nisin and sodium lactate injected smoked trout samples decreased from 3.7 to 1.8 log CFU/g over 16 days at 8°C. Furthermore, the sensory characteristics of cold smoked rainbow trout remained unaffected by these treatments.

6.7.4 Canned Foods

Nisin is the only bacteriocin allowed in canned foods as a preservative. Nisin incorporation could shorten the heat processing time without compromising food safety and quality. Nisin has been used in canned potatoes, peas, mushrooms, soups, tomatoes, and cereal puddings. Amounts of nisin added to canned foods vary based on regulations of individual countries. In Europe, there is no specific limit for the amount of nisin for use in canned vegetables. In the United States, the amount of nisin in foods should not exceed 250 ppm (10000 IU/g). Because nisin is a relatively heat stable bacteriocin, it could be added to canned foods at levels of 100–200 IU/g to control thermophilic spore formers such as *B. stearothermophilus* and *C. tyrobutyricum* (227). For the control of acid tolerant spoilage microorganisms (i.e., *B. macerans* and *C. pasteurianum*), the enhanced activity of nisin at acidic pH makes it an ideal preservative in low pH foods such as canned tomatoes.

6.7.5 Beverages

Gram-negative bacteria, yeasts, and molds are insensitive to bacteriocins of LAB (228). Therefore, nisin could be advantageous in alcohol fermentations to control spoilage LAB without affecting growth and fermentative performance of brewing yeasts or compromising sensory characteristics of the product. Nisin has similar applications in wine making, except for those that require desirable malolactic fermentation. Malolactic fermentation by *Oenococcus oeni*, and various *Lactobacillus* and *Pediococcus* species converts L-malic acid to less sour L-lactic acid with CO_2 production. Nisin resistant strains of *O. oeni* with nisin could be used to control the progress of malolactic fermentation in wine making. Nisin is also used to reduce sulfite levels used in wine making to control spoilage bacteria (159).

6.8 "MULTIPLE HURDLE" APPLICATIONS

The hurdle concept comprises a combination of different preservation methods to inhibit or control microbial growth. In order to achieve the most effective combined treatments without adversely affecting the sensory and nutritional quality of food products, hurdle to hurdle interactions and careful integration of hurdles must be considered to avoid antagonism. Bacteriocins have been used as effective hurdles in combination with several food processing methods to improve the food safety (Table 6.6).

Table 6.6
Combination and synergistic application of nisin with other "hurdle" intervention systems

Combination System	Nisin	Effect	Ref.
Thermal processing			
55°C for 10 and 15 min exposure	100 IU/mL	Treatment for 6-h eliminated *E.coli* O157:H7	(229)
60°C for 5 min / 65°C for 2 min	25 mg/kg	Reduction of *L. monocytogenes* challenge by 3 to 5-logs in lobsters	(230)
55°C for 10 and 15 min exposure	500-2500 IU/mL	Enhanced inactivation of *Salmonella* Enteritidis PT4	(231)
Non-thermal processing			
High-pressure (155-400 MPa)	100 IU/mL	Enhanced bactericidal activity against selected foodborne pathogens	(232)
PEF (50 kV/cm; 32 pulse/2 µS)	10-100 IU/mL	Synergistic inhibition of *L. inocua* strains.	(233)
PEF (16.7 kV/cm; 50 pulse/2 µS)	0.06 µg/mL	Enhanced the inactivation of *Bacillus cereus*	(234)
Metal chelators			
EDTA (500 mg/kg)	500 mg/kg	Inhibited *E.coli O157:H7* and *Br. thermosphacta* in ham / bologna	(235)
20 mM EDTA at 37°C for 1-h	50 µg/mL	Reduction of salmonellae by 3.2 to 6.9-log with combination only.	(141)
EDTA/Citrate/Lactate	2000 IU/mL	Effective under MAP against *E.coli* O157:H7 and *S.* Typhimurium	(236)
Chemical interventions			
2% (w/w) Na-lactate or Na-citrate	500 IU/mL	Treatment for 15 min reduced *Arcobacter butzleri* from poultry skin	(237)
Monolaurin (250 µg/mL)	100 IU/mL	Inhibited *Bacillus cereus* growth in milk at 37°C for 5 days	(238)
5% Ethanol	10 IU/mL	Reduced *L. monocytogenes* by 3-logs at 5 to 37°C temp. ranges	(239)
Lactoperoxidase (LPO) and lysozyme			
LPO (10 enzyme units)	100 IU/mL	Effectively inhibited resident microflora in sardines	(240)
LPO (35 enzyme units)	100-200 IU/mL	Enhanced inhibitory activity against *L. monocytogenes*	(241)
LPO (0.2-0.8 ABTS units/mL)	10-100 IU/mL	Synergistic inhibition of *L. monocytogens* in UHT-processed milk	(242)
Lysozyme (25-125 µg/mL)	30 µg/mL	Synergistic inhibition of *E.coli O157:H* and *L. monocytogenes*	(243)
Plant extracts and essential oils			
0.1% carvacrol,/thymol/ eugenol	0.25 µg/mL	Synergistic inhibition of *L. monocytogens*	(244)
Bearberry ethanol extract (5 mg/mL)	500 µg/mL	Retarded the growth of *Brochothrix thermosphacta*	(245)
Garlic aqueous extract (0.5 mg/mL)	3 IU/mL	Synergistic inhibition of six *L. monocytogens* strains	(246)

6.8.1 Thermal Processing

Other preservative hurdles, such as heat treatments, low water activity, modified atmosphere, and low temperature could enhance the antimicrobial effects of nisin. Thermal synergism of nisin activity against *Lactobacillus* after exposure to a sequential treatment of mild heat (48–56°C) and then nisin (0.5 μg/mL) at 30°C has been observed (247). Combinations of low pH and high sodium chloride concentration have been shown to enhance nisin activity against *L. sake*, *S. aureus* and *L. monocytogenes* (248).

Duration of thermal inactivation time for bacteria could be reduced with bacteriocin combination resulting in improved food quality. The injury and inactivation kinetics of *S. enteritidis* PT4 in the presence of nisin (500 to 2500 IU/ml) in the media, liquid whole egg, or egg white could be reduced from the required pasteurization time by up to 35% (231). Nisin did not enhance the lethality of thermal processes and microbial cell injury was more severe in the egg white containing nisin, presumably as a result of bacteriocin interaction with antimicrobial factors in the egg white. Addition of nisin in cold pack lobster meat reduced the heat resistance of *L. monocytogenes* and significantly shortened the treatment time compared with thermal processing alone (230).

6.8.2 Nonthermal Food Processing

Food preservation with nonthermal food processing technologies, such as high pressure (HP) processing, ionizing radiation, pulsed electric field (PEF), and ultraviolet radiation is rapidly expanding with various product applications. Combination of these emerging food processing technologies with bacteriocins appears to be a promising antimicrobial hurdle mechanism. HP and PEF treatments induce sublethal injury to bacterial cells and enhance the activity of bacteriocins against *E. coli* O157:H7 and *S. typhimurium* (143). Furthermore, the HP inactivation of spores of *B. coagulans, B. subtilis*, and *C. sporogenes* is markedly enhanced with nisin treatment (249,250).

PEF has been successfully used with nisin for various food safety applications (234). Combination of low doses of nisin (0.06 mg/mL) and mild PEF (16.7 kV/cm, 50 pulses each of 2 mS duration) strongly reduced the numbers of *B. cereus* vegetative cells by more than the sum of reductions obtained with single treatments.

HP processing kills or injures microorganisms mainly by damaging the cell membrane, and such effect could potentiate the biopreservative activity of nisin that targets microbial membranes. A four dimensional process consisting of *Pressure x Time x Temperature x Antimicrobial* (such as nisin) has been suggested. Inclusion of nisin would allow lower pressure application with less impairment to food quality while maintaining a high kill level of food borne pathogens (164). *Listeria monocytogenes, E. coli,* and *S. typhimurium* when injured by these treatments turn more sensitive to nisin (143). Ultra HP inactivation of *E. coli* and *L. innocua* inoculated in liquid whole egg was even more effective by adding 1.25 and 5 mg/L nisin to the process (251). Hauben et al. (145) suggested that HP treated *E. coli* turned nisin sensitive due to pressure induced disruption of the bacterial outer membrane permeability. Evidence suggests that cells are least sensitive to HP between the temperature ranges of 20–30°C, however, bacteria turn highly sensitive at temperatures greater than 35°C due to phase transitions of membrane lipids (252–254). Increased cell death by HP processing (345 Mpa, 25 °C for 10 min) with combination of nisin and pediocin PA-1/ACH has been reported. Accordingly, *L. monocytogenes, S. aureus, E. coli* O157:H7 and *S. typhimurium* in the presence of such combined processing showed a total loss in viability ranging from 5–8 log cycles (255).

Combined effects of ultra HP treatment, heat, acidity, and nisin on *B. coagulans* spores has been reported (249). Nisin (0.8 IU/mL) in combination with 400 Mpa pressure in pH 4.0 buffer with a mild heat treatment (70 ºC for 30 min) elicited ~6-log spore reduction.

6.8.3 Metal Chelators and Detergents

Resistance of Gram-negative bacteria to bacteriocins is largely due to the outer membrane as a permeability barrier. Combinations of two or more preservative systems, or hurdles, are better at preventing the emergence of less sensitive organisms, and reduce the extent of a single extreme system or preservative (256).

Nisin is effective against Gram-negative bacteria, if passed through the nisin impermeable outer membrane barrier, gaining access to its cytoplasmic targets. This could be achieved by disrupting the outer membrane with chelating agents (e.g., EDTA), organic acids, or treatments such as sublethal heat or freezing (141,142,144). Chelating agents remove divalent cations, such as Ca^{2+} and Mg^{2+}, from the Gram-negative cell walls, releasing phospholipids and lipoproteins and increasing cell wall permeability. Stevens et al. (257) found effective treatments that comprised 12–25µg nisin/g with 20 mM EDTA or citric monohydrate at 30–42ºC. However, chelating agents are much less effective due to their preferential binding to free divalent ions present in the food matrix. Biochelators such as lactoferrin are milk antimicrobials that potentiate the activity of antimicrobials across outer membranes of Gram-negative bacteria (258).

A potent antimicrobial synergism between EDTA or lactoferrin with nisin against *L. monocytogenes, E. coli, S. enteritidis,* and *P. fluorescens* has been reported (243). Lactoferrin and EDTA enhanced the activity of nisin against two enterohemorrhagic *E. coli* strains. Combinations of nisin, lysozyme, and monolaurin with EDTA resulted in the killing of certain Gram-negative bacteria, whereas none of the antimicrobials alone demonstrated such bactericidal effect. Lactoferrin alone (2 mg/mL) did not inhibit any of the bacterial strains, but did enhance the nisin activity against *L. monocytogenes*.

A synergism between monolaurin and nisin against milk-borne *B. licheniformis* has been reported (238). A combination of nisin (0.75 µg/mL) and monolaurin (100 µg/mL) at pH 6.0 caused inhibition of spores and vegetative cells at 37ºC for 7 days. A synergism between sucrose fatty acid esters (i.e., palmitate, stearate) and nisin was observed (259). Nisin activity could be stimulated by other neutral emulsifiers such as monolaurin, monooleate and Tween-80 (260).

6.8.4 Lactoperoxidase (LPO) System

Nisin synergism with the LPO system in the inactivation of *L. monocytogenes* was reported (242). Addition of nisin (10 or 100 IU/mL) to ultra high temperature (UHT) processed skim milk showed no effect on listerial counts after 24 h at 30°C. However, addition of LPO to this system resulted in 3-log reduction compared to control. Nisin combination with LPO elicited potent inhibition of *L. monocytogenes* by 5.6-log than the control. Such enhanced inactivation was also observed with Gram-negative bacteria, which otherwise are insensitive to nisin.

A novel method of using nisin against both Gram-negative and Gram-positive bacteria involves a treatment combining a solution of low concentration alkali metal orthophosphate (e.g., trisodium orthophosphate) with osmotic shock and lysozyme and nisin (261). Another synergistic combination, resulting in an antimicrobial effect against *Salmonella* species, has been described between nisin, LPO, thiocyanate, and hydrogen peroxide applied at 30–40ºC at pH 3–5 has been described (262). The LPO thiocyanate hydrogen peroxide system occurs naturally in milk, and its antimicrobial effect is due to the generation of transient products of

oxidation of thiocyanate by hydrogen peroxide catalyzed by LPO (263). Synergistic activity of LPO and nisin against *L. monocytogenes* in UHT skim milk has been reported to elicit a 5.6-log reduction of the pathogen compared to control (242).

6.8.5 Acid Interventions

Several commonly used acid preservatives have been reported to show synergism with nisin. Scannell et al. (264) found that 2% sodium lactate could potentiate nisin activity against *Salmonella kentucky* and *Staphylococcus aureus* in fresh pork sausages. In another study, an agar diffusion method was used to show that a combination of lactic acid and whey permeate fermented by a nisin producing *L. lactis* strain had a synergistic effect against fish isolates of *Micrococcus luteus*, *P. aeruginosa*, *P. fluorescens*, and *S. hominis* (265). Combinations of organic acids (citric acid, lactic acid, glucono delta lactone, or acetic acid) with nisin enhance inhibition of thermally stressed *Bacillus* spores, particularly under less acidic conditions and ambient storage (266). The combined treatment of a sorbate nisin mixture greatly reduced initial *L. monocytogenes* counts on vacuum packed and carbon dioxide packaged beef, and prevented growth during 4 weeks of refrigerated storage (267).

Synergistic effects between sodium diacetate and pediocin against *L. monocytogenes* in meat slurries have been reported (268). Listerial population increased from 4.5 to 8-log CFU/mL within 1 day at 25°C and within 14 days at 4°C in the control samples. A listeriocidal effect (~7-log CFU/mL difference compared to the control) was achieved in treatments containing pediocin (5000 AU/mL) with 0.5% diacetate at 25°C and pediocin with 0.3% diacetate at 4°C.

6.8.6 Plant Extracts and Essential Oils

Antibacterial activity of plant essential oils and their components has been recognized for a long time. Several applications have been developed using essential oils as natural food preservatives to control food spoilage organisms and pathogens (269). Combinations of nisin (0.25 μg/mL) and the essential oils of carvacrol, thymol, and eugenol (0.1%) have been shown to elicit a potent antimicrobial synergism to inhibit *L. monocytogenes* (244).

An antioxidant ethanolic extract of bearberry (*Arctostaphylos uva-ursi*) leaves when mixed with nisin demonstrated a strong inhibitory activity against 25 food related bacteria (245). This combination treatment with nisin (500 μg/mL) and bearberry extract (5 mg/mL) most notably has retareded the growth of *B. thermosphacta*, as compared to nisin alone.

Synergistic inhibition of six *L. monocytogenes* strains by nisin and aqueous extracts of garlic has also been reported (246). The synergistic interaction between nisin (3 IU/mL) and garlic extract (0.5 mg/mL) resulted in a strong bacteriostatic effect against *L. monocytogenes* in broth media, however, a potent bactericidal effect was observed at 4°C.

6.8.7 Bacteriocin Cocktails

Several mixtures of bacteriocins have also been tested in combination hurdles and found to enhance the biopreservation (270,271). The combined effects of nisin and leucocin F10 produced by *Leuconostoc carnosum* F10 against *L. monocytogenes* showed a potent inhibitory effect, and the addition of leucocin F10 seemed necessary to prevent the revival of *L. monocytogenes*.

Certain mixtures of antibiotics and nisin had an enhanced antibacterial effect in cheddar cheese (272). Nisin (12.5 μg/g curd), penicillin G (12 U/g curd), and streptomycin (12 mg/g curd) reduced nonstarter LAB by 4–5 log cycles compared with untreated control after 100–160 days.

6.9 FOOD PACKAGING APPLICATIONS

Incorporation of antimicrobial agents into food packaging systems is an innovative concept aptly undertaken in response to current consumer demands and market trends. Two methods are commonly used in the preparation of packaging films with bacteriocins: by direct incorporation into the polymer materials; and by coating the packaging films (273).

In the first method, nisin is incorporated into a polyethylene based plastic film commonly used in the vacuum packaging of beef carcasses. Nisin has retained its antimicrobial activity against *L. helveticus* and *B. thermosphacta* inoculated in carcass surface tissue sections (274). The population of *B. thermosphacta* was initially reduced by 2-log with nisin impregnated packaged beef within the first 2 days of storage at 4°C. *Brocothrix thermosphacta* populations from nisin impregnated plastic wrapped samples were significantly less than control after 20 days of refrigerated storage at 4 or 12°C.

Nisin was also incorporated into film forming edible hydroxypropylmethyl cellulose solution to inhibit the growth of *L. innocua* and *S. aureus* (275). However, stearic acid significantly reduced the inhibitory activity of nisin in this application due to the water vapor barrier properties of stearic acid. Further optimization is required to desorb nisin from the film and effectively diffuse the bacteriocin into the packaged food.

The second method for incorporation of bacteriocins into packaging films is to coat or adsorb bacteriocins onto polymer surfaces. Examples include methylcellulose coatings with nisin for poultry, and spray adsorption of nisin on various packaging materials such as polyethylene, ethylene vinyl acetate, polypropylene, polyamide, polyester, acrylics, and polyvinyl chloride was also reported (273).

Nisin coated onto silica surfaces seem to inhibit the growth of *L. monocytogenes* (276). Antimicrobial efficacy of cellulose based bioactive inserts and antimicrobial polyethylene and polyamide pouches incorporated with lacticin 3147 and nisin against *L. innocua* and *S. aureus* (along with *L. lactis* sp. *lactis*) has also been demonstrated (277). Nisin bound avidly to plastic film, and this bioactive film was stable for 3 months with or without refrigeration, and effective in reducing ~2-log bacteria in vacuum packed cheese in combination with MAP at refrigeration temperatures. Nisin incorporated cellulose based bioactive inserts, when placed between sliced products of cheese and ham under MAP, reduced growth of *L. innocua* by >3-log in cheese after 5 days at 4°C, and by ~1.5-log in sliced ham after 12 days; while *S. aureus* was reduced by 1.5- and 2.8-log in cheese and ham, respectively. The growth of *L. monocytogenes* in meats and poultry was completely inhibited by coating of pediocin onto cellulose casings and plastic bags during 12 weeks of storage at 4°C (278).

Nisin coated polymeric films such as PVC, linear low density polyethylene, and nylon inhibit proliferation of *S. typhimurium* on fresh broiler drumstick skin (279). Coating of solutions containing nisin, citric acid, EDTA, and Tween-80 on PVC, linear low density polyethylene, and nylon films reduced the counts of *S. typhimurium* in fresh broiler drumstick skin by 0.4 to 2.1-log after 24 h incubation at 4°C.

6.10 REGULATORY STATUS

Use of bacteriocin producing starter cultures as ingredients may not require special consideration in the USA if the microorganism is considered generally recognized as safe (GRAS) based on history of safe use prior to the 1958 Food Additives Amendment (190). For use of purified bacteriocin as a food preservative, the substance could be self affirmed as GRAS by the company according to the Code of Federal Regulations (U.S. Government

Printing Office, 1990), However, the US Food and Drug Administration (FDA) might require justification to such affirmation.

In 1969, based on the safety, tolerance, and efficacy data on nisin, the Food and Agriculture Organisation/World Health Organization (FAO/WHO) Expert Committee acknowledged that a level of 3.3×10^6 units/kg body weight had no adverse effect, and permitted an unconditional acceptable daily intake (ADI) to be set at 3.3×10^4 units/kg body weight (280). In 1988, The US FDA affirmed nisin as GRAS for use as a direct ingredient in human food. In the European Union, nisin is listed as E234, and may also be labeled as nisin preservative or natural preservative.

Pediocin PA-1, after nisin, is the most studied bacteriocin of LAB (174,281). Several scientific groups worldwide have recognized its potential as a biopreservative, especially for use in certain specific foods. However, pediocins have not yet been legally approved by the regulatory agencies in the USA, Europe, and other countries.

Several authors have outlined issues involved in the approval of new bacteriocins for food use, and the US FDA has published guidelines for the safety assessment of a new preservative (282). For approval to be granted, the bacteriocin must be chemically identified and characterized, and its use and efficacy must be proven. The manufacturing process must be described, and assays used for quantification and standardization of the peptide must be established. Finally, the toxicity data (safety and tolerance) and physiological turnover of the molecule after ingestion should be verified.

6.11 CONCLUSIONS

Several studies have advanced our knowledge on bacteriocins and their molecular properties, biosynthesis, isolation purification and mechanisms of antimicrobial activity. Genetic engineering or chemical modifications of bacteriocins to improve their functional properties have been the focus in the recent years, which has led to remarkable developments in bacteriocin technology. Accordingly, the solubility and stability of nisin Z has been improved by replacing *Asn-27* or *His-31* with lysine (283); the stability of pediocin PA-1 at 4ºC and room temperature has been improved by replacing *Met-31* with alanine, isoleucine or leucine (284); and the development of a chimeric protein mutant of pediocin PA-1 displayed ~2.8-fold higher activity against an indicator strain, *L. plantarum* (166).

Despite isolation and characterization of a number of bacteriocins, only a few have demonstrated commercial potential in food application, and currently nisin is the only purified bacteriocin approved for food use in the USA. The use of pediocin PA-1 for food biopreservation has been commercially exploited and is covered by several US and European patents (56). A fermentate containing pediocin PA-1 (Alta™), is commercially available for use as a food preservative to inhibit pathogens, especially *L. monocytogenes*, in RTE meats (285). Lacticin 3147, which is active over a wider pH range than nisin, is another promising bacteriocin that might find applications in non-acid foods (199).

Because bacteriocins demonstrate relatively narrow spectrum of antimicrobial activity with limited effect against Gram-negative bacteria, these agents are now paving their way into hurdle concept technologies for food preservation. The simultaneous application of bacteriocins and non-thermal processing technologies, such as HP and PEF, to enhance food protection is highly attractive because products from these non-thermal interventions usually have better sensory and nutritional qualities. Because LAB and their metabolites have been consumed in high quantities by humans for centuries in cultured foods with no adverse effects, LAB continue to be the preferred source for food use bacteriocins, either in the form of purified compounds or as growth extracts. The potential application

of bacteriocins from LAB, in particular, as natural food antimicrobial systems in minimally processed foods is steadily increasing with a high level consumer acceptance.

Genetic Characterization of Antimicrobial Peptides

Haijing Hu, Matthew M. Moake, and Randy W. Worobo

CONTENTS

7.1 INTRODUCTION

To survive in the natural environment and compete with other microorganisms for resources, bacteria produce antimicrobial compounds to inhibit or kill other competing strains. It is assumed that all bacteria produce some type(s) of antimicrobial compound(s), and that we need only find the right indicator strains and growth conditions to identify these compounds (1). The antimicrobial peptides represent just one of the many classes of antimicrobial compounds. These proteinaceous molecules often contain novel amino acid configurations and modifications when compared to normal ribosomally synthesized polypeptides (2). These compounds are typically broken up into two groups, the bacteriocins, and the peptide antibiotics, based upon their biosynthetic mechanisms.

Bacteriocins are ribosomally synthesized compounds produced by bacteria that are active against closely related bacteria (3). Most bacteriocins consist of 20–60 amino acids that may or may not undergo post translational modifications. As hydrophobic or amphiphilic compounds, most bacteriocins target cell membranes, while some also inhibit the biosynthesis of biopolymers (e.g., some colicins), or enzyme activities (e.g., duramycin).

The peptide antibiotics are nonribosomally synthesized and instead are formed through complex, stepwise condensation reactions that utilize large, nonribosomal peptide synthetases (NRPS) (4,5). These compounds often have nonprotein amino acids, including D-amino acids, hydroxy acids, or other unusual constituents and demonstrate a broad range of inhibition mechanisms and spectrums of activity (6).

Here, we will organize our coverage of the antimicrobial peptides into a slightly different scheme according to their applicability to the food industry, placing emphasis on those classes of compounds which are either applicable in foods or whose knowledge base provides insights into food applicable compounds. We will then review some of the current industrial applications of the antimicrobial peptides, and provide some insights into the exciting future prospectus of the field.

7.2 GRAM-POSITIVE BACTERIOCINS

Due to their natural occurrence in many types of foods, numerous Gram-positive bacteria species are considered to have food grade, or Generally Regarded as Safe (GRAS), status. Gram-positive bacteria produce a variety of bacteriocins, many of which have been biochemically and genetically characterized. Bacteriocins as a whole are generally sensitive to human intestinal proteases, which makes them promising resources for food preservation. The bacteriocins from two types of food grade bacteria, lactic acid bacteria (LAB) and *Propionibacteria*, have been intensely studied due to their potential applications in the food industry (7).

Bacteriocins produced by LAB are divided into four classes according to their structure and biochemical characteristics (8). This definition can also be applied to bacteriocins produced by other bacteria.

(1) Lantibiotics: small, membrane active peptides containing the unusual amino acid lanthionine.
(2) Small, heat stable, non-lanthionine-containing membrane active peptides characterized by a Gly-Gly-Xaa processing site in the precursor. This class can be further divided into three subclasses. 2(a) are *Listeria* active peptides with an N-terminal consensus sequence of –Tyr-Gly-Asn-Gly-Val-Xaa-Cys-. 2(b) are pore-forming complexes that require two peptides for activity. 2(c) are thiol activated peptides requiring reduced cysteine residues for activity.

(3) Large heat labile proteins (>30 KDa).
(4) Complex bacteriocins composed of protein plus one or more chemical moieties required for activity.

7.2.1 Class I Bacteriocins: Lantibiotics

Lantibiotics are a group of bacteriocins that, as their name suggests, contain the unique amino acid lanthionine. These bacteriocins also have other nonprotein amino acids, such as dehydroalanine and dehydrobutyrine, all of which are formed by post translational modifications. Based on their structural features and functional properties, lantibiotics can be grouped into three categories (9). Type A lantibiotics, also known as nisin-like or linear lantibiotics, like nisin and Pep5, have a linear structure consisting of around 34 amino acids with overall cationic character and some sequence homology. Their primary target is the cell membrane. Duramycins, which belong to type B, or duramycin-like lantibiotics, are smaller, consisting of 19 amino acids arranged in a globular conformation. The C-terminal residues of type B lantibiotics are involved in bridge formation within the globule. Type B lantibiotics inhibit phospholipases. Type C lantibiotics, like mersacidin, have structural features between those of types A and B and target the biosynthesis of the bacterial cell wall. Table 7.1 lists many of the naturally occurring lantibiotics, and Figure 7.1 shows several of their structures.

7.2.1.1 Nisin

Among the bacteriocins currently identified, nisin is the most intensely studied, and was the first one approved for use in the food industry on a commercial scale. It was discovered in 1928; the same year Fleming discovered penicillin (10,11). Five years later, Whitehead isolated nisin and identified its proteinaceous nature (12). Since then, many studies have been conducted on this antimicrobial compound and its producer strains. It has been previously shown that all the producer strains belong to serological group N of lactic streptococci. Nisin is named after its producer as "Group N Inhibitory Substance" (13). According to modern taxonomy, the producer strains are grouped to *Lactococcus lactis*.

7.2.1.1.1 Structure Nisin has two natural variants, nisin A and nisin Z. Both variants have 34 amino acids and similar sequences, except that nisin A has His27 while nisin

Ancovenin	Type B	*Streptomyces spp.*	1959	[185]
Cinnamycin	Type B	*Streptomyces cinnamoneus*	2041	[184]
Mersacidin	Type C	*Bacillus subtilis*	1825	[186]
Actagardine	Type C	*Actinoplanes sp.*	1890	[187]

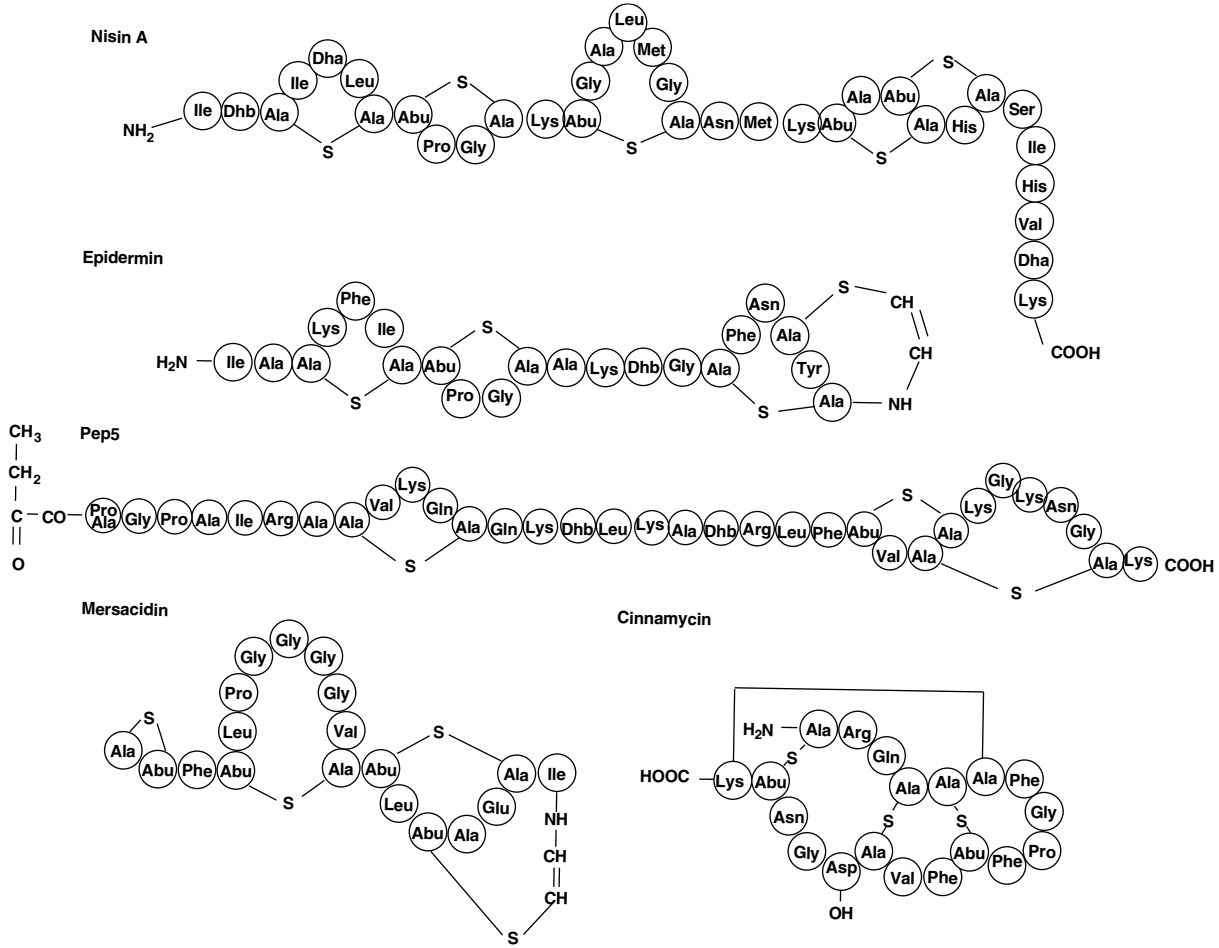

Figure 7.1 Structures of several lantibiotics. Dha: dehydroalanine; Dhb: dehydrobutyrine; A-S-A: lanthionine; Abu-S-A: 3-methyllanthionine.

Z has Gln27. Among these 34 amino acids exist several unusual dehydro amino acid residues including thioether bridged lanthionines. The primary structure of nisin A was proposed in 1971 (14). Figure 7.1 shows that nisin has a linear structure of 5 half rings. NMR spectra of nisin in aqueous solution and a membrane-mimicking environment confirmed and refined this structure (15,16). NMR data indicate that the nisin molecule has two amphipathic domains. The first three half rings on the N-terminal region (residues 3–19) form the first domain while the C-terminal domain (residues 22–28) consists of half rings D and E. The amino acid residues flanking these two structural domains have more variability. This is a typical membrane-acting structure.

7.2.1.1.2 Mode of Action Nisin is a membrane active bacteriocin (17,18) which destabilizes the phospholipid bilayer of the target cell, resulting in the rapid efflux of small molecules from the cytoplasm and loss of membrane potential. The most recent model for nisin interaction with the cell membrane includes three steps. First, the cationic nisin molecule binds to the cell membrane through electrostatic interactions with anionic membrane

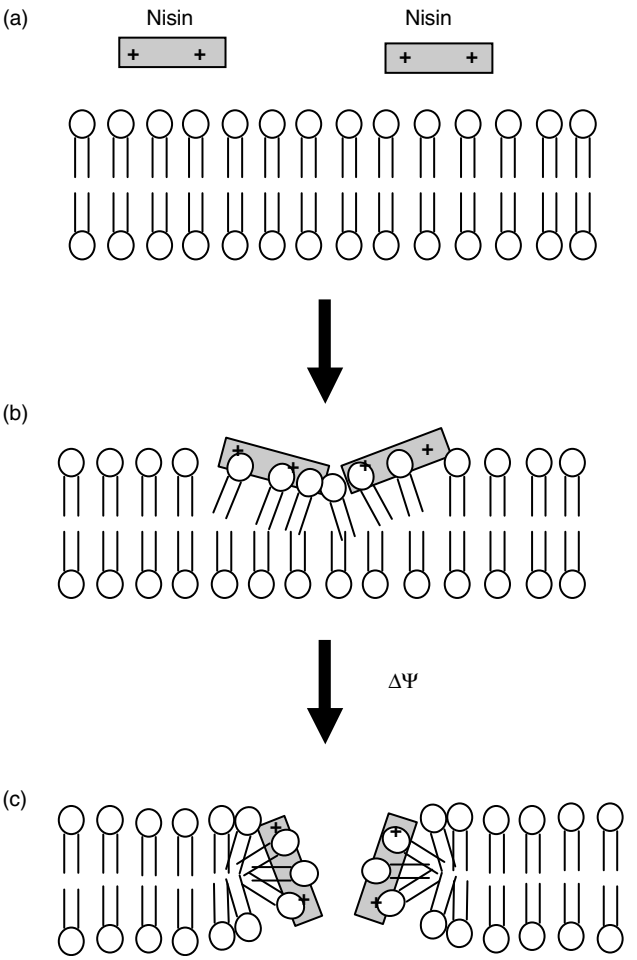

Figure 7.2 Nisin's pore-forming mode of action. (a) The cationic nisin molecule binds to the cell membrane through electrostatic interactions with anionic membrane lipids. (b) Nisin inserts into the cell membrane where its N-terminus penetrates into the outer leaflet of the membrane. (c) The C-termini of nisin molecules translocate across the membrane and form a transmembrane pore.

lipids. Nisin then inserts into the cell membrane where the N-terminus penetrates into the outer leaflet of the membrane. During the last step, the C-terminus of nisin translocates across the membrane (19). Several transmembrane molecules form a short lived transmembrane pore, and thus disturb the organization of the bilayer. This pore formation hypothesis is shown in Figure 7.2.

Nisin is able to inhibit both vegetative cell growth and the outgrowth of spores. The mechanisms of these inhibitions, however, appears to be different. Substitution of Dha at position 5 with Ala results in a loss of spore outgrowth inhibition, while the activity against vegetative cells remains the same (20).

Because nisin can react with liposomes and EDTA-treated Gram-negative strains, it is believed that this molecule interacts directly with the phospholipid bilayer (21). However, lipid II does act as a docking molecule during the attack. Through the interaction with lipid II on the cell wall, nisin inhibits peptidoglycan synthesis as well as interacts with the cell membrane. This combination of two killing mechanisms explains why nisin has a very low minimum inhibitory concentration (MIC) compared to other lantibiotics (22).

7.2.1.1.3 Nisin Biosynthesis The molecular mechanisms of nisin biosynthesis and regulation have been extensively investigated. It has been observed that nisin biosynthesis in *L. lactis* is inhibited by actinomycin, an inhibitor of RNA synthesis, but not mitomycin, an inhibitor of DNA synthesis (23,24). Protein inhibitors can also inhibit nisin production (25). These experiments provide solid data to demonstrate that nisin is ribosomally synthesized. Two questions remain unanswered at this point. (1) Do the nisin biosynthesis genes reside on a plasmid or on the chromosome? (2) What enzymes and mechanisms are responsible for the post translational modifications seen in nisin's unusual amino acids?

To answer this first question, a DNA degenerate probe based on the amino acid sequence of the peptide was designed to hybridize with plasmid DNA and digested chromosomal DNA of the nisin producer strain. The initial results obtained by different groups were conflicting. Some groups found that this probe hybridized with the plasmid DNA, while other groups showed hybridization with the chromosomal DNA (26–29). Researchers also found that nisin-producing strains are able to ferment sucrose, and that a correlation existed between nisin-production (Nip^+), nisin immunity (Nim^+) and sucrose fermentation (Suc^+) (27). The extra chromosomal genetic location has not been supported by plasmid transformation, while conjugation is successfully conducted between nisin producer and nonproducer. Most researchers now believe that the nisin biosynthesis gene cluster is located on a conjugative transposon within the chromosome.

The second question concerning nisin biosynthesis is how the unusual amino acids are formed after translation. The sequence of the structural gene, *nisA*, shows that the peptide product consists of 57 amino acid residues, none of which are unusual. The N-terminal region of this peptide product shows high homology to known leader peptides. Based on this information, a hypothesis for nisin maturation is proposed in Figure 7.3. A prenisin molecule is synthesized by translation, which includes the N-terminal leader peptide and several cysteine residues. Unusual amino acids are not present at this stage. The first step in modification is water elimination of serine and threonine residues, resulting in Dha and Dhb respectively. The next step is the formation of sulfide ring structures by nucleophilic addition between dehydro residues and cysteine residues. The molecule is now called pronisin. The last step is the cleavage of the leader peptide, and the active, mature molecule is secreted by the producer cells (30). This hypothesis is supported by later research on the nisin biosynthesis genes (26,31).

The organization of the nisin A biosynthesis gene cluster is shown in Figure 7.4. This gene cluster is around 13–15 kb and consists of 11 genes (21,32–35). Both nisin A and nisin Z have similar organization of their biosynthesis genes (34,36). Three promoters have

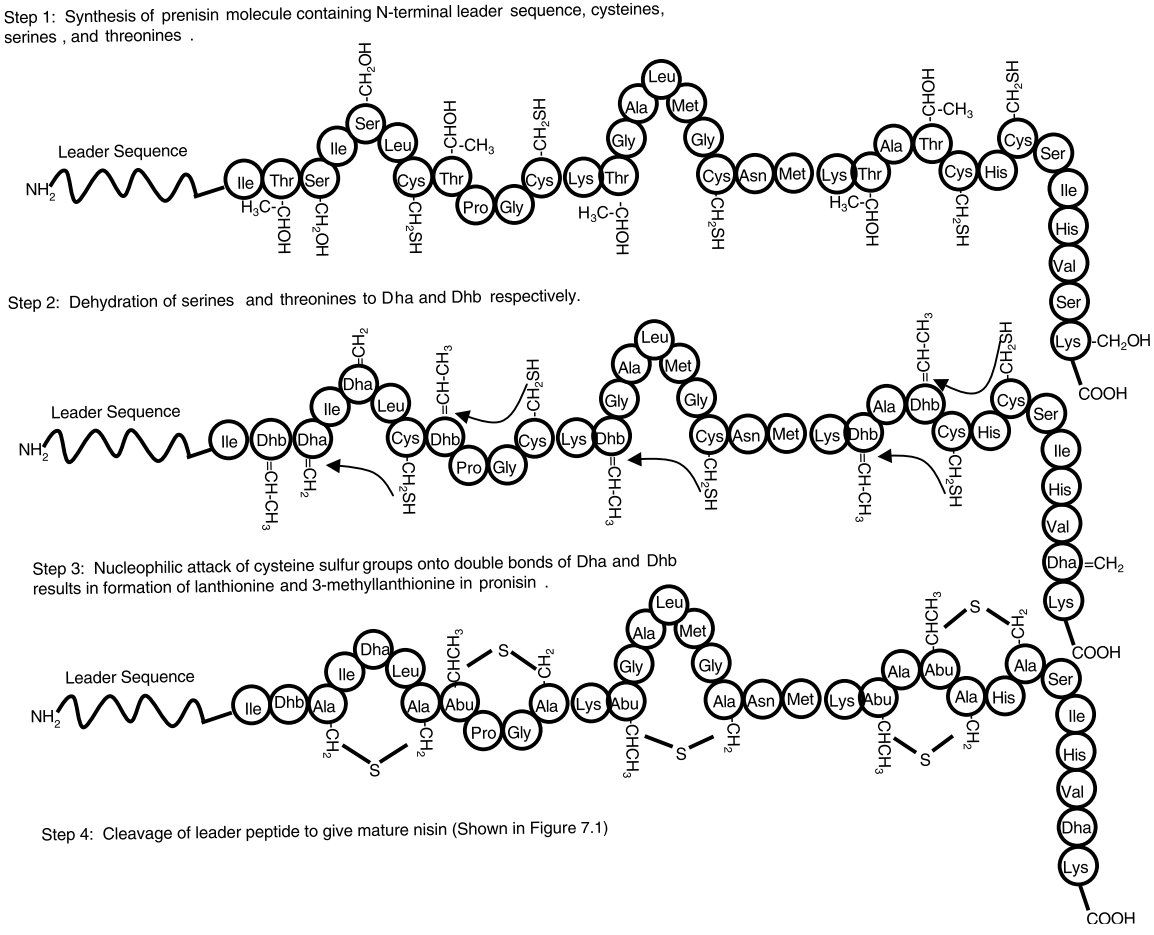

Figure 7.3 Posttranslational modification of nisin. Serine and threonine are dehydrated to form dehydroalanine and dehydrobutyrine respectively. Nucleophilic addition of the sulfhydryl of cysteine to the dehydro residues proceeds with stereo-inversion. Lanthionine and β-methyllanthionine result from the formation of thioether crosslinkages (30).

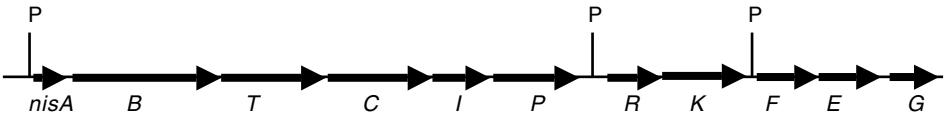

Figure 7.4 Organization of the nisin A biosynthesis gene cluster. Arrows indicate the open reading frames and their transcriptional directions. P represents a promoter site. Gene names and functions are covered in the text.

been detected in the nisin A gene cluster by primer extension, while only two have been detected in the nisin Z gene cluster (37). The first gene, *nisA*, is the structural gene encoding prenisin.

There is an inverted repeat sequence (IR) at the end of the *nisA* gene, suggesting a stem-loop structure on the transcript to control the expression rate of the structural and modification genes. The second gene and the fourth gene in the gene cluster are *nisB* and *nisC* respectively. While *nisB* encodes a protein of 993 amino acid residues, *nisC* encodes a protein of 414 amino acid residues. These two genes do not show any homology to other genes in the database outside of those involved in the biosynthesis of other lantibiotics. Mutational analysis and deletion experiments show that these two genes are necessary for the production of functional nisin and may be involved in dehydration and thioether formation (32,38). Disruption of these two genes abolishes the production of nisin and lowers the immunity of the producer cells (38). Computational analysis predicts several transmembrane alpha helix structures in *nis*B, which is consistent with experimental data showing that the *nis*B protein is membrane bound (34). Similar results have been obtained for *nis*C. Coimmunoprecipitation experiments have shown that anti *nis*C coprecipitates with the membrane fraction of cell extracts (39).

The *nisT* gene encodes a protein of 600 amino acid residues, which shows high homology to known ABC transporters (21,34). The ABC transporters are proteins of a super family that share common functional and structural characteristics (40). All contain ATP Binding Cassettes and are involved in membrane transport. It is reasonable to propose that *nis*T is involved in the secretion of nisin, and this process requires ATP. Experimental data has shown that mutation of the *nisT* gene results in accumulation of nisin within the cytoplasm (41). This same research also showed the *nisT* mutant to have decreased nisin immunity.

The yeast two hybrid system is a widely used tool for the analysis of *in vivo* protein interactions (42–44). Using this system, it has been demonstrated that nisin interacts with *nis*B and *nis*C; *nis*B interacts with *nis*C, and *nis*C interacts with *nis*T (39). Based on this information, a multiprotein membrane associated complex for nisin maturation has been proposed as shown in Figure 7.5.

The *nis*I gene is believed to be involved in immunity to nisin. Expression of *nis*I in a non-nisin-producing strain, *L. lactis* MG1614 conferred a low level of immunity to the host (45). Overexpression of this gene in *E. coli* under the control of the T7 promoter significantly enhances *Escherichia coli*'s resistance to nisin when treated with EDTA (21). The deduced protein sequence of this gene suggests that it is a lipoprotein of 245 amino acids, with its C-terminus anchored in the cell membrane (21).

The *nis*P gene encodes an extra cellular serine protease. This protein has an N-terminal signaling sequence, a serine protease domain, and a C-terminal membrane anchor (46). Expressed in *E. coli, nis*P can cleave the N-terminus of pronisin, releasing active nisin. This experiment also suggests that cleavage of the leader peptide is the last step in nisin maturation, which is confirmed by *nis*P disruption experiments. The *nis*P disrupted mutant secretes fully modified nisin with its N-terminal leader peptide and shows lowered levels of immunity (35). There is no direct evidence that *nis*P interacts with the multi metric complex of *nis*BCT.

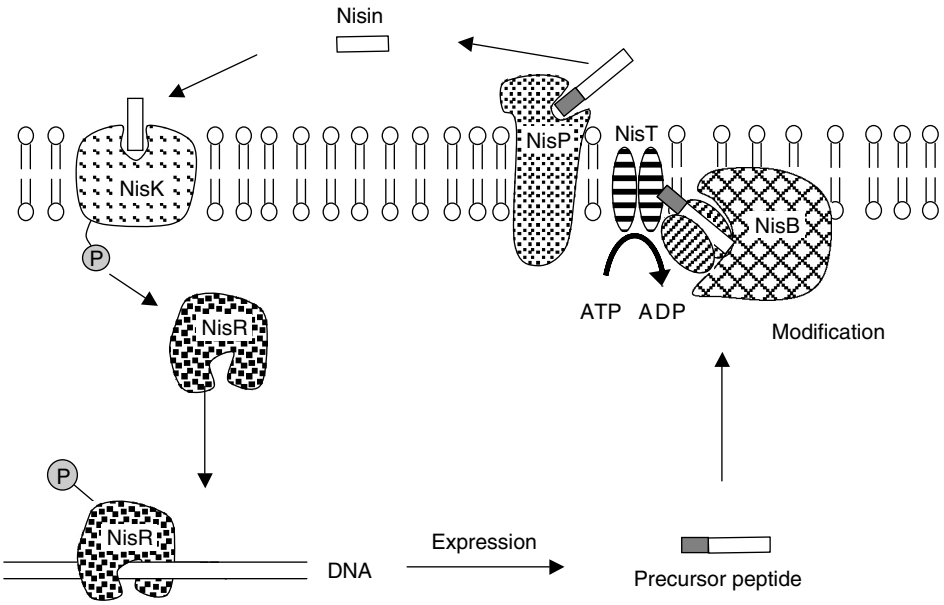

Figure 7.5 Nisin biosynthesis and regulation. (See text for details.)

The products of the *nis*R and *nis*K genes are involved in regulation of nisin biosynthesis. The *nis*R gene encodes a response regulator, and the *nis*K gene encodes a histidine protein kinase sensor (46). Nisin biosynthesis is an auto regulated process, and the mature nisin molecule acts as the signal for upregulation, as shown in Figure 7.5 (47).

7.2.1.1.4 Autoregulation of Nisin Biosynthesis Engelke et al. (1994) have found that an anti nisin antibody can reduce nisin expression levels (45). Disruption of *nis*K abolished the nisin expression in the producer strain. To study the biosynthesis of nisin, *L. lactis* NZ 9700 was constructed by mating the nisin-producing strain and a nonproducing strain *L. lactis* MG 1614, taking advantage of the fact that the nisin biosynthesis gene cluster was located on a conjugate. The resultant *L. lactis* NZ 9700 has only one copy of the nisin biosynthesis gene cluster. A 4 bp deletion in *nis*A was introduced into *L. lactis* NZ 9700 to obtain a nonproduction strain, *L. lactis* NZ 9800 (21). A *gus*A reporter gene driven by the *nis*A promoter was then introduced into *L. lactis* NZ 9800, allowing activation and expression of *gus*A by exogenously supplied native nisin but not with the unmodified nisin precursor. This result suggests that the mature nisin molecule, but not the precursors, activates the expression of its own synthesis genes. It is proposed that the binding of nisin to the membrane anchored *nis*K protein, which is a histidine sensor kinase, causes the phosphorylation of *nis*K. The activated *nis*K then transfers the phospho group to the corresponding response regulator, *nis*R. The transcription of genes, driven by both the *nis*ABTCP and *nis*FEG promoters, is activated by *nis*R–Pi (47). It is not clear whether other kinases are involved in this phosphorelay cascade.

Bacteria, as unicellular organisms, must communicate with each other so that they can behave in a synergistic, multi cellular way. In Gram-positive bacteria, modified oligopeptides are commonly found as signaling peptides (48). These peptides are secreted from the cells and then transported back into the cell to interact with receptors. As this regulatory mechanism is cell density or growth phase dependent, it is also called quorum-sensing regulation. In the case of nisin production, producer cells need to concert their biosynthetic

efforts in order to ensure that enough antimicrobial peptide is produced to kill competing organisms. Meanwhile, the producer cells must also develop sufficient immunity before this high amount of nisin is produced. Studies have yet to examine the interaction between nisin and its membrane bound regulator *nis*K. One question to be solved by this potential research is whether this interaction occurs inside the cell or outside the cell.

A food grade expression system has been developed taking advantage of the nisin autoregulatory system. This is a controlled gene expression system which uses food grade nisin as an inducer. An MG1363 derivative with *nis*RK integrated onto the chromosome, *L. lactis* NZ 3900, is used as the host strain. The target gene is fused downstream of the *nis*A promoter and introduced into the host. High level expression is achieved by addition of nisin to the culture broth (49).

The last three genes in the nisin gene cluster, *nis*FEG, were discovered in 1995. The genes *nis*F and *nis*E appear to encode an ABC transporter, and *nis*G encodes a hydrophobic protein. Mutants with disruption in these genes can still produce nisin, but at decreased levels (35). This result suggests that *nisFEG* are not essential for nisin production. Some researchers have proposed that NisFEG are involved in nisin immunity together with *nis*I. Antisense *nis*EG and antisense *nis*G can effectively reduce nisin immunity, but the expression of *nis*F in *L. lactis* MG 1614 does not provide protection for the host (50). However, the ABC transporter may be indirectly involved in immunity via the nisin signal transduction process. It has been found that an ABC transporter is involved in some Gram-positive bacteria signal transduction processes by transporting the extracellularly modified peptide into the cell where it interacts with receptor proteins to regulate gene expression. An extra copy of *nis*RK-FEG can increase the production of nisin, which may be the result of this upregulation.

Genetic studies of nisin biosynthesis not only brought about the first food grade expression system, but have also provided powerful tools for biochemical studies. Protein engineering of nisin by site directed mutagenesis has been carried out to study and improve nisin properties (51). Introduction of lysine in nisin Z at N27 and H31 improves its solubility while the activity and inhibition spectrum remain similar. Substitution of Dha5 with Dhb gives higher stability toward chemical degradation but at the cost of decreased activity.

7.2.1.1.5 Nisin Resistance Before we start to discuss the mechanism of nisin resistance, it is necessary to clarify the difference between bacteriocin immunity and resistance. Immunity refers to the self protection mechanism by which the bacteriocin producer strains and cells can withstand high concentrations of their own bacteriocin. Most, but not all, bacteriocin producers discovered so far display immunity to their respective bacteriocins, and most of the time the immunity genes sit in the vicinity of the bacteriocin biosynthesis genes. The nisin immunity gene, *nisI*, as shown in Figure 7.4, is located inside the nisin biosynthesis gene cluster. Resistance on the other hand, is conferred by a mechanism developed by nonproducer strains to survive a specific bacteriocin. Two types of resistance are found for nisin. Resistance type Nis^R is encoded by a gene that is neither linked to nor located near the nisin biosynthesis gene. Also, Nis^R has been found on numerous plasmids (52–56). As nisin is a food grade bacteriocin, Nis^R is used as a food grade selective marker in cloning vectors (57). Another type of nisin resistance, Nis^m, is caused by a spontaneous mutation in the sensitive cells. The mutation Nis^m has been reported by several research groups in different genera of nisin sensitive strains (53,54,58,59).

7.2.1.2 Biosynthesis of Other Lantibiotics

Nisin is the most prominent and most studied representative of the lantibiotic family, but many others also exist. Their producer strains include Bacillus, Streptococcus, Staphylococcus, Lactococcus, and Streptomyces (60). Several lantibiotic biosynthesis gene clusters from

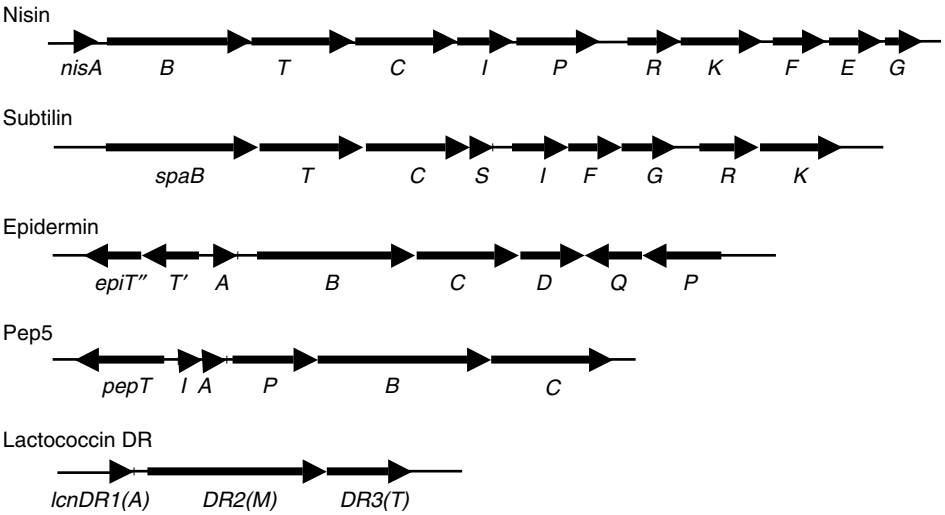

Figure 7.6 Summary of several lantibiotic gene clusters. Arrows indicate the open reading frames and their transcriptional directions.

producer strains such as these have been cloned. Figure 7.6 shows the genetic organization of these gene clusters, which show high homology to the nisin biosynthesis gene cluster. Genes involved in lanthionine formation are only found in the lantibiotic producer strains.

Worth special mention is the biosynthesis of subtilin. Genes involved in subtilin biosynthesis are located on the chromosomal DNA. A 40 kb region from the producer strain, *Bacillus subtilis* ATCC 6633, including the biosynthesis gene cluster, has been transferred to *B. subtilis* 168 (61). *Bacillus subtilis* 168 is a cloning strain, second only to *E. coli* when it comes to the amount of genetic information and tools available for genetic manipulation. Successful expression in this well known cloning strain has facilitated the protein engineering study of subtilin. Site directed mutagenesis was employed to construct a mutant subtilin, in which the Dha at position 5 was changed to alanine. Research examined the post translation processing by NMR, amino acid analysis, and Edman degradation, and found that this substitution did not interfere with the processing. This engineered peptide was fully active when reacted with vegetative *Bacillus cereus* cells, but failed to inhibit the outgrowth of spores. This result suggests that the mechanism by which subtilin attacks vegetative cells and spores may be different (62). Experiments for enhancing the properties of subtilin have also been performed by the same group with site directed mutagenesis. The Glu4 in subtilin was substituted by Ile. The design of this experiment is based on the observation that nisin is more stable than subtilin and has an Ile at position 4 in front of Dha5. Meanwhile, the chemical modification of Dha5 is coupled to a loss of activity (60). This change makes the peptide more stable than the natural one. This is the first example of mutagenesis demonstrating enhancement of a native molecule's properties (63).

7.2.2 Class II Bacteriocins: Small, Heat Stable, Non-Lanthionine-Containing Peptides

Class II bacteriocins are a group of heat stable antimicrobial peptides, which, unlike the lantibiotics, do not contain any modified amino acids. As mentioned before, they can be further categorized into 3 subgroups.

7.2.2.1 *Class IIa Bacteriocins*

Bacteriocins in this family are effective at killing *Listeria* spp. With 16 such antimicrobial peptides found to date, they form the largest group in the class II bacteriocin family. Table 7.2 shows the peptide sequences of the class IIa bacteriocins. They all share a common sequence on their N-terminus, YGNGV, with an overall sequence identity around 40–70% (64).

7.2.2.1.1 Mode of Action and Structure–Function Relationships Class IIa bacteriocins are membrane active peptides. The relationship between their structures and modes of action has been intensely studied. Bacteriocins in this family contain two modules in their primary structures. The N-termini of the peptides are the less hydrophobic modules that display high homology within the family and form β-sheet structures. The C-termini are more hydrophobic, more diverse, and have α-helical structures (65). Fimland et al. (1996) constructed hybrid class IIa bacteriocins by interchanging the N-terminal and C-terminal modules between different bacteriocins in this group. They reported that the hybrid products targeted the same bacteria as the natural bacteriocins from which the C-terminal modules were derived (65). The same research group also found that pediocin activity could be inhibited by a synthesized 15 mer fragment derived from its C-terminal module, while the synthesized fragments derived from the N-terminus did not show significant inhibition of activity (66). This is in agreement with the previous assumption that class IIa bacteriocins interact with receptors on the target membrane (67–69). However, the putative receptor protein has not been identified. Conflicting results have been obtained by other groups, which show that class IIa bacteriocins can interact with lipid vesicles. It may be that a docking molecule interacts with the N-terminus of the peptides. After the N-terminus of the bacteriocins recognize either the receptor or the docking molecule, hydrophobic interactions occur between the C-terminus of the peptides and the lipid acyl chain on the target cell membrane (66,69,70). Following this hydrophobic interaction, the peptides wedge into the membrane to create a more energy

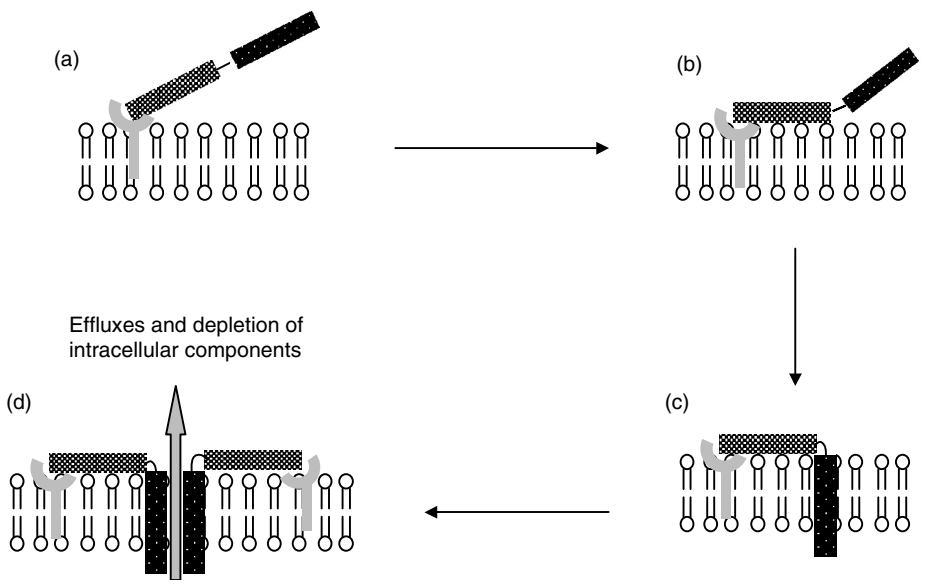

Figure 7.7 Model of class IIa bacteriocins interacting with the cell membrane. (a) Recognition between the bacteriocin and the putative receptor on the cell membrane. (b) Electrostatic interaction between the bacteriocin and the cell membrane. (c) Bacteriocin insertion into the cell membrane. (d) Aggregation of the bacteriocins and pore formation.

stable orientation, which causes the destruction of the cell membrane. Figure 7.7 provides a model of this interaction.

7.2.2.1.2 Pediocin Class IIa bacteriocins are also referred to as pediocin-like bacteriocins, because pediocin is the most intensely studied of the family. Pediocin is produced by *Pediococcus acidilactici*, and the active peptide, pediocin PA-1, has been purified by several different groups (71–78). It has typical bacteriocin properties such as stability at 100°C for 60 minutes and sensitivity to protease, papain, pepsin, and α-chymotrypsin. Pediocin is active against Gram-positive bacteria including *Clostridium* spp., *Staphylococcus* spp., and *Listeria* spp. (79). Early biochemical characterizations based on partially purified bacteriocin samples revealed different molecular weights ranging from 2700 to 16500, and researchers tended to think that they were different molecules. Final identification by peptide sequencing and biosynthesis gene analysis showed that the bacteriocins isolated from different labs were actually the same molecule (72,80,81). The calculated molecular weight based on the peptide sequence is 4624, assuming that the cysteine residues form 2 disulfide bonds; a hypothesis which was confirmed by electrospray mass spectrometry (65). The molecular weight of 16500 may be a result of peptide aggregation.

7.2.2.1.3 Biosynthesis of Class IIa Bacteriocins Biosynthesis of the class IIa bacteriocins consists of two steps. First, a precursor peptide with an N-terminal leader sequence is synthesized on the ribosome. This precursor peptide is biologically inactive, just like the precursor of lantibiotics. This peptide is then cleaved at a specific site, and transported to the outside of the producer cell.

Biosynthesis genes of class IIa bacteriocins are organized in a gene cluster, either located on the chromosome or on a plasmid. Biosynthesis gene clusters of some representative class IIa bacteriocins are shown in Figure 7.8. The genes in the gene cluster can be transcribed in two different directions. In each gene cluster there is a structural gene encoding the bacteriocin peptide and the leader peptide. Although the length and amino acid sequence of the leader peptides are varied among different bacteriocins, most of them have two common glycine residues at the cleavage site of the leader peptide C-terminus. Table 7.3 shows some of the leader peptide sequences in this family.

The maturation process of class IIa bacteriocins consists only of leader peptide cleavage, as no amino acid modifications are involved. Formation of disulfide bonds is a spontaneous process. The leader peptide is cleaved during the secretion process. The cleavage and transport are actually accomplished by the same protein, which is an ABC transporter (82). The genes encoding the transporter proteins, sit either in the same operon as the structural gene, or in the neighboring operon, as shown in Figure 7.8. Deduced from the DNA sequence, ABC transporters have approximately 700 amino acid residues. The transporters, especially the C-terminal ATP-binding site, show significant homology amongst themselves and amongst other bacteriocin ABC transporters. The ABC transporters in the class IIa family have three domains. The 150 amino acids on the N-termini of the proteins are hydrophobic and have proteolytic activity. The ATP-binding sites are on the C-termini. A transmembrane domain is located between these two domains. It is proposed that the transporters form homodimers on the cell membrane. The N-terminal region may recognize the peptide precursor when ATP is bound to the C-terminal domain, and this binding triggers ATP hydrolysis, which in turn induces a conformational change in the protein. The leader peptide is removed, and the mature bacteriocin peptide is exported to the outside of the cell. The double glycine residues are believed to be involved in the precursor recognition (82,83).

Accessory proteins are involved in class IIa bacteriocin translocation. As in the lactococin A transport system, LcnC is the ABC transporter and LcnD is an accessory protein. Most of the accessory proteins consist of 460 amino acids. The pediocin accessory protein,

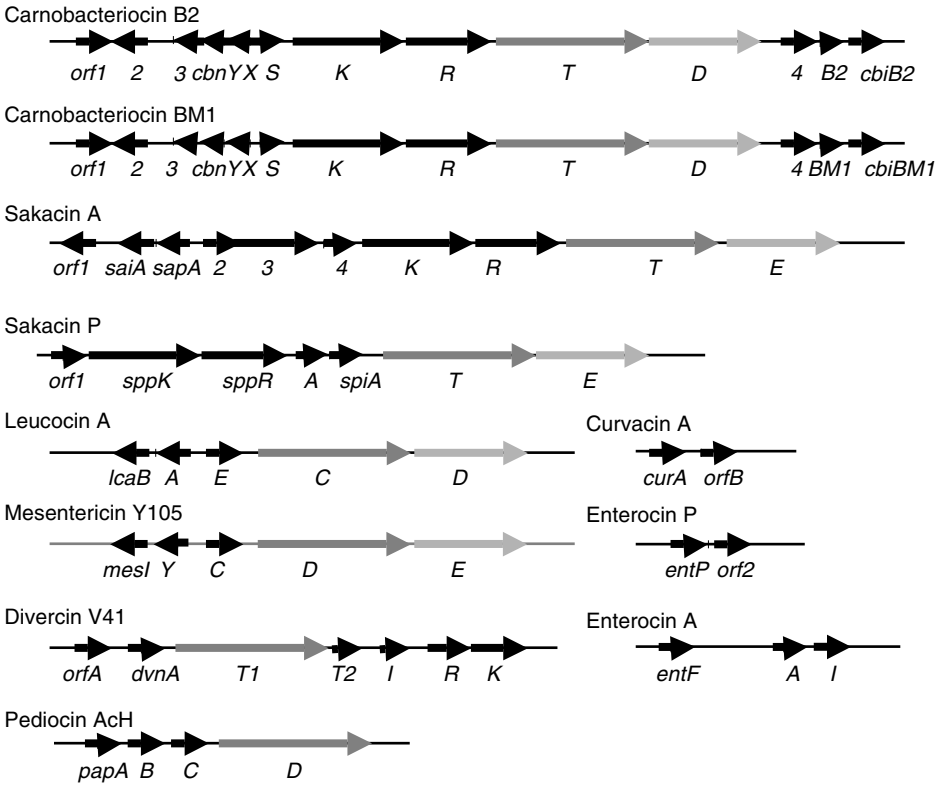

Figure 7.8 Organization of the genes involved in class IIa bacteriocin biosynthesis and immunity. Arrows indicate the open reading frames and their transcriptional directions. Structural genes are named after the corresponding bacteriocins, except that sakacin P structural gene is named A. I/i indicates the immunity gene; R represents the response regulator; K represents the sensor histine kinases. Dark gray arrows show the ABC transporter genes, and the light gray ones are the accessory protein genes. Functions of some ORFs are unknown.

however, is an exception, having only 174 amino acids. The accessory proteins have hydrophobic N-terminal regions and large hydrophilic regions. Experimental data shows that the accessory proteins are required for class IIa bacteriocin secretion (84,85). However, the exact function of this protein has yet to be elucidated.

By exploiting the general secretion pathway to secrete bacteriocin peptides, the producer strain decreases the amount of genetic information required for competition in the environment. Researchers have shown that class II bacteriocins can be transported by a general secretion pathway when their leader peptides are substituted with an appropriate signal peptide (86).

7.2.2.1.4 Class IIa Bacteriocin Immunity As shown in Figure 7.8, the immunity genes of the class IIa bacteriocins are located in the vicinity of the structural genes. In plasmid curing experiments involving the carnobacteriocin B2 producer strain, a loss of immunity was observed in conjunction with a loss of the plasmid containing the carnobacteriocin B2 biosynthetic operon. Homogeneous and heterogeneous expression of the immunity gene in the sensitive strains provides protection from carnobacteriocin B2 (87). Western blot analysis shows that the immunity protein, CbiB2, is mostly located in the cytoplasm. This 111 amino acid protein, deduced from the nucleotide sequence, does not react directly with the bacteriocin and does not provide protection for sensitive cells when added to the medium.

Bacteriocin 31	MKKKLVIGGIIGIGFTALGTNVEAAT	[198]

Producer strains of the class IIa bacteriocins show varying degrees of resistance to the noncognate bacteriocins from the same family (88). The immunity genes, however, do not show high homology. The immunity proteins range from 88 to 114 amino acids in size. There is no correlation between the homology of the bacteriocin sequence and the homology of the immunity protein sequence. Mesentericin Y105 and leucocin A differ in only 2 of 37 amino acids while their immunity proteins show only 74% identity. Sakacin A and carnobacteriocin BM1 show 67% sequence homology while their corresponding immunity proteins show only a 47% identity. However, curvacin A and acidocin, which only have a 34% sequence homology, have a 41.2% identity in their immunity proteins (64).

There is no experimental evidence showing how the immunity proteins provide protection. Based on the observations that the immunity proteins do not directly react with the bacteriocins, and that there may be receptors on the sensitive cells that interact with class IIa bacteriocins, it is reasonable to propose that the immunity proteins interact with the receptor on the producer cell membrane, so that the bacteriocins cannot attach to the same receptors. However, because sensitive cells gain no protection from externally supplemented immunity proteins, and furthermore, because most immunity proteins are localized within their respective host's cytoplasm, a model of external receptor competition seems unlikely. A second mechanism could be that the immunity protein may block the pores formed by the insertion of the bacteriocin molecules in the membrane. More research is needed to accurately determine this mechanism.

7.2.2.1.5 Biosynthetic Regulation The biosynthesis of class IIa bacteriocins, like that of the class I bacteriocins, is regulated by a peptide pheromone dependent quorum-sensing mechanism. Regulatory systems include a histidine protein kinase, a response regulator, and an induction factor (IF). In the nisin regulator described previously, the mature nisin molecule acts as the inducer. In the class IIa regulatory systems, either the bacteriocin or some specific inducer can be used to trigger the biosynthesis machinery, as shown in Figure 7.9. Induction factor (IF) accumulates during the growth of the bacteria. When the concentration reaches a certain critical level, the expression of bacteriocin starts (83).

In the systems using designated IFs, the IFs show some biochemical similarities to their corresponding bacteriocins. They are small, heat stable, cationic, and hydrophobic peptides. They are also synthesized as prepeptides with leader sequences, and are cleaved

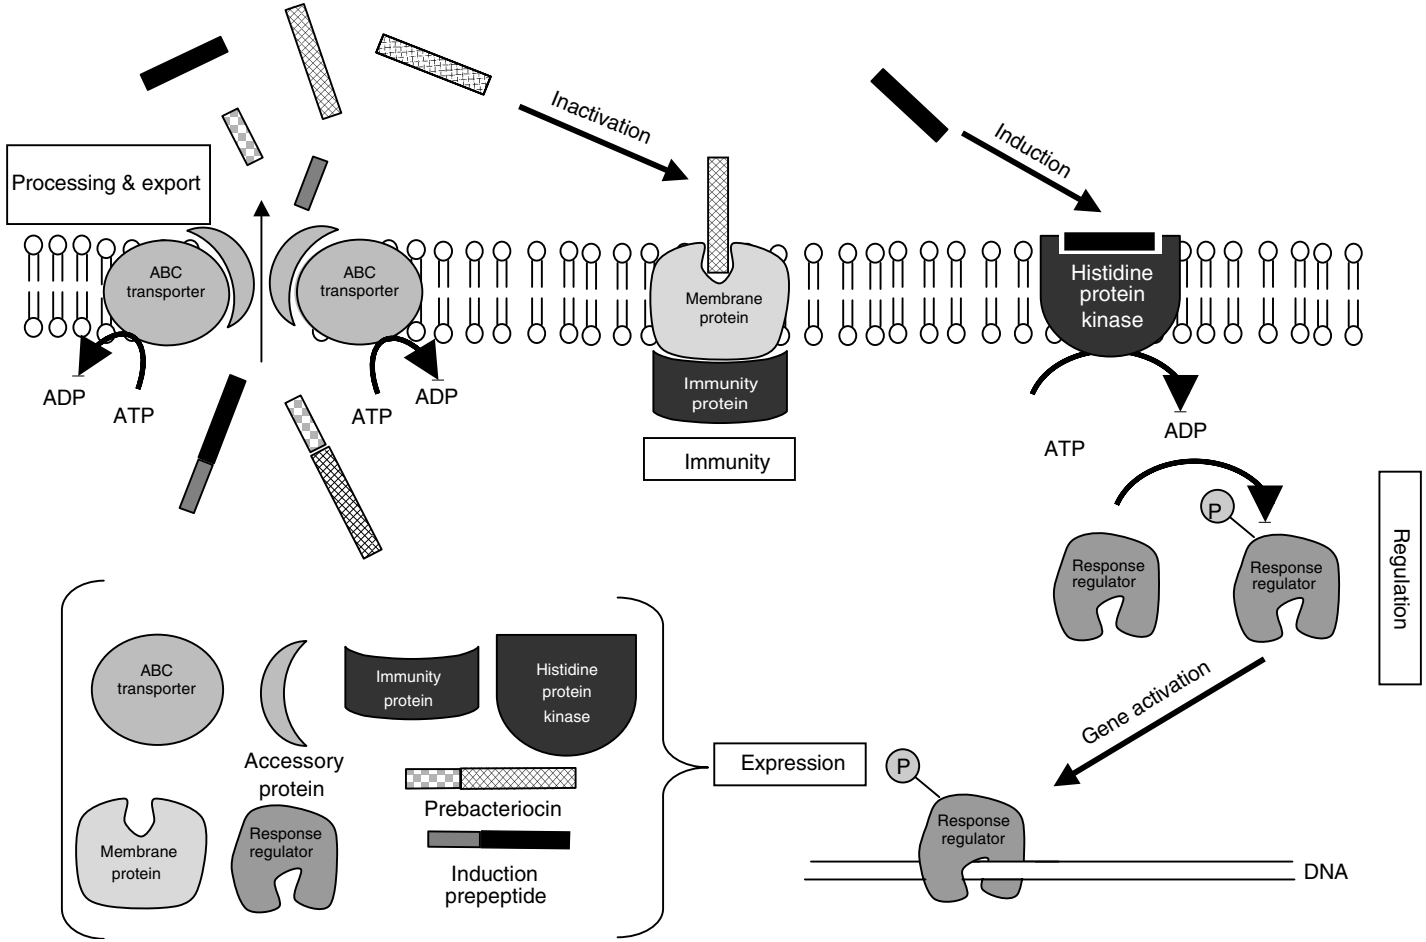

Figure 7.9 Class IIa bacteriocin biosynthetic mechanism. (See text for details.)

at the double glycine site. However, these IFs do not have high homology to the bacteriocins. Table 7.4 shows the sequence of several IFs.

The majority of class IIa bacteriocin biosynthesis is regulated by IFs. This system is also called a three component regulatory system. Divercin V41, produced by *Carnobacterium divergens* V41, also employs a second system in which, like nisin, the bacteriocin serves as the IF of its own expression. This system is also called a two-component system. The production of carnobacteriocin is therefore triggered by both systems. The bacteriocin itself as well as an inducer can trigger biosynthesis (89,90).

7.2.2.1.6 Other Class IIa Bacteriocins *Propionibacterum* spp., like lactic acid bacteria, has a long history of application in dairy fermentation. Several antimicrobial peptides produced by this genus have been found, such as jenseiin G, propionicin T1, and propionicin PLG-1 (91–93). Most of these bacteriocins have a narrow inhibition spectrum, only inhibiting *Propionibacteria* and *Lactobacillus*. Propionicin PLG-1, on the other hand, has a very broad spectrum, including Gram-positive bacteria, Gram-negative bacteria, and even some fungi. All of these peptides are around 10,000 Da and are heat stable. Recent genetic studies of these bacteriocins have revealed that they employ a sec dependent pathway for transportation. The structural genes of propionicin T1 and SM1 both encode prebacteriocins with a typical 27 amino acid signal peptide sequence (92,94). Another interesting aspect of these bacteriocins is that the producer strains may not have an immunity gene, and thus are sensitive to their own bacteriocins.

An antimicrobial peptide from *Propionibacterium jensenii* is found to be activated extracellularly by proteases. This protease activated antimicrobial peptide is encoded as a 225 aa propeptide including a 27 aa signal peptide on the N-terminus which is cleaved by a signal peptidase during export. The 64 aa on the C-terminus is activated by cleavage with proteinase K, proteinase A, trypsin, and subtilisin. None of these proteases are produced by the producer strain, and no immunity gene is detected (95).

The newly discovered enterocin P, from lactic acid bacteria, lacks the double glycine leader peptide typical of the class IIa bacteriocins, and is processed and exported by a general sec dependent pathway (96). Finally, a plasmid encoded bacteriocin from *Listeria innocua* is also a sec dependent bacteriocin (97).

7.2.2.2 Class IIb and IIc Bacteriocins

The class IIb bacteriocins, as summarized in Table 7.5, are a group of dipeptide bacteriocins. Individual peptides sometimes show modest activity, but the combination of paired peptides act synergistically to create a greatly heightened level of activity. Class IIb bacteriocins are membrane active peptides that have bactericidal effect (64). Figure 7.10 shows the mechanism of lactococcin G. When added to sensitive cells, different ratios of the two corresponding peptides yield different levels of activity, with a 1:1 ratio showing the best antimicrobial activity. Structures of lactococcin G, plantaricin E/F, and plantaricin J/K

have been studied by circular dichroism (CD). It has been found that individual peptides are unstructured in aqueous solution and form some alpha helices in a lipid environment (98,99). It was also shown by these researchers that a 1:1 ratio of the two peptides enhances the formation of their dipeptide structure.

Genetic studies have revealed that the two paired peptides are encoded by two different genes that sit adjacent to each other in the same operon. Immunity genes and regulatory genes are also found close to the structural genes. A single immunity protein is encoded to provide protection against the dipeptide complex. The biosynthesis genes for bacteriocins in *Lactobacillus plantarum* C11 have been cloned and sequenced (100). This strain can produce four different bacteriocins: plantaricin A (Pln A), plantaricin EF, plantaricin JK, and another proposed single peptide bacteriocin. Each bacteriocin requires a biosynthetic operon which consists of the structural gene(s) and the immunity gene. Because all four bacteriocins have a double glycine site for cleavage, they share a single ABC transport system whose genes are located in the same region as the structural and immunity genes. The inducer regulating the expression of all the bacteriocins in the producer strain is Pln A.

Lactococcin B is one of the three bacteriocins produced by *Lactococcus lactis* subsp. *cremoris* 9B4 which also produces lactococcin A and M (101). It is a small, membrane-acting peptide with bactericidal effects. Lactococcin B is grouped into class IIc bacteriocins as a thiol activated antimicrobial peptide because previous research showed that a cysteine residue at position 24 must be in the reduced state for activity. This bacteriocin is inactive after oxidation with $HgCl_2$, and its activity is restored after Dithiothreotol (DTT) treatment. This result suggests that Cys24 and its corresponding oxidation state are critical to LcnB activity. However, site directed mutagenesis at Cys24 gave an opposite conclusion (102). Except for positively charged amino acid substitutions at position 24, the mutagenesis resulted in peptides that retained activity. The exact function of cysteine 24 during bacteriocin membrane interaction has therefore yet to be revealed conclusively. The structural and immunity genes of L-*canavanine* B (Lcn B) have been cloned and sequenced. All three, Lcn A, B, and M are encoded by a single plasmid. The Lcn B structural and immunity genes are of 68 and 91 codons respectively (103).

7.2.3 Class III Bacteriocins: Large, Heat Labile Proteins

Class III bacteriocins are large, heat labile proteins that include helveticin J (104), lacticin A and B (105), acidophilucin A (106), and caseincin 80 (107). Because of their sensitivity

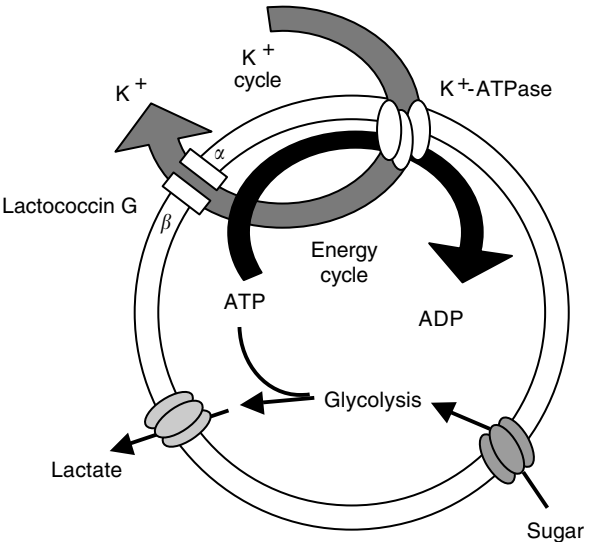

Figure 7.10 Lactococcin G mode of action. (See text for details.) (211).

to heat, they are not good candidates as food preservatives, and thus their biochemistry and genetics properties will be only briefly mentioned here.

7.2.3.1 Helveticin J

Helveticin J is a class III bacteriocin isolated from *Lactobacillus helveticus* 481. This bacteriocin inhibits closely related species, including *Lactobacillus delbrueckii*, *Lactobacillus bulgaricus*, and *Lactobacillus lactis* (104). Helveticin J is sensitive to proteases and heat treatment. Bacteriocin activity in the culture supernatant was inactivated by heating in a boiling water bath within 1 hour, which indicates that it has a high molecular weight.

Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis (SDS-PAGE) gives a molecular weight of around 37 kDa. The producer strain *L. helveticus* 481 harbors only one plasmid and plasmid curing experiments have shown that the biosynthetic operon of helveticin J is located on the chromosome. A genomic library of the producer strain was constructed, from which a 3.8 Kb fragment involved in biosynthesis was cloned (108). This fragment was introduced to *Lactobacillus acidophilus*, and the transformants showed antimicrobial activity similar to helveticin J. This result indicates that this 3.8 Kb fragment is sufficient for helveticin J production. Analysis of this fragment shows 5 putative open reading frames (ORFs). Figure 7.11 shows the organization of these ORFs, one of which, ORF3, encodes a putative hydrophilic protein of 37511 Da, which is very close to the molecular weight of helveticin J. This putative protein shows high glycine content on its N-terminal end. The function of ORF2 has not yet been elucidated. Because of the hydrophilic nature of helviticin J, it has been suggested that ORF2 encodes a protein involved in bacteriocin immunity and secretion. Whether other ORFs are involved in helveticin J production, and, if so, what their potential functions in this production may be, has not been investigated.

7.2.4 Class IV Bacteriocins: Complex, Modified Bacteriocins

Class IV bacteriocins are antimicrobial peptides carrying lipid or carbohydrate moieties. This group is well represented by Leuconocin S and Lactocin 27.

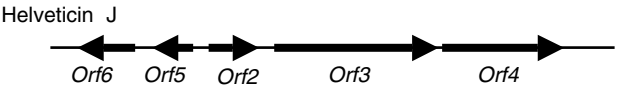

Figure 7.11 Organization of putative helveticin J biosynthesis genes. Arrows indicate the open reading frames and their transcriptional directions. Gene names and functions are covered in the text.

Leuconocin S is produced by *Leuconostoc paramesenteroides*, a strain isolated from retail meat (109). It is capable of inhibiting *Listeria monocytogenes*, *Aeromonas hydrophila*, *Staphylococcus aureus, Yersinia enterocolitica*, and some *Clostridium botulinum* strains (109,110). This peptide is resistant to lipase, but sensitive to α-amylase, trypsin, α-chymotrypsin, and proteinase K. Based on this information, this peptide has been determined to be a glycopeptide. Compared to bacteriocins of other families, leuconocin S is more heat sensitive. Approximately 50% of the activity is lost after heat treatment at 60°C for 60 minutes. The molecular weight of leoconocin S, as estimated by SDS-PAGE, is approximately 10 kDa. It is believed that leuconocin S is a membrane active molecule (109,111). Further information on its peptide sequence and biosynthesis pathway is not yet available.

Lactocin 27, produced by *Lactobacillus helveticus* LP27, is another example of a class IV bacteriocin. It is also a glycopeptide with a molecular weight of approximately 12 kDa (112). This bacteriocin shows bacteriostatic effects against closely related bacteria. It inhibits sensitive strains via inhibition of protein synthesis, Na^+ transport, and K^+ transport (113).

7.3 GRAM-NEGATIVE BACTERIOCINS AND BACTERIOCIN-LIKE COMPOUNDS

While the term bacteriocin is typically reserved for ribosomally synthesized antimicrobial peptides from Gram-positive species (114), it also appropriately includes similar compounds produced by Gram-negative species. The diversity of Gram-negative bacteriocins resembles that of the Gram-positive compounds and is best represented by the colicins and microcins. Because these compounds are produced by Gram-negative bacteria, which, due to their lack of natural occurrence in foods and typical association with fecal contamination, are considered to be nonfood grade, they are not directly applicable to food preservation. Still, despite their lack of direct food application, advances with Gram-negative bacteriocins and their respective modes of action, syntheses, post translational modifications, and bioregulatory mechanisms have proven to be much more rapid than the equivalent studies in Gram-positive species, and thus they provide good models for many of the same characteristics of food grade, Gram-positive bacteriocins. For instance, unlike their structural relatives the lantibiotics, the microcins have been synthesized *in vitro* (114). Furthermore, the membrane pore formation inhibition mechanism of some colicins has emerged as a model system not only for many bacteriocin modes of action, but also for numerous studies of the mechanisms and bioenergetics involved in various aspects of protein membrane interactions (115,116). These advances therefore warrant a brief review of the compounds here.

7.3.1 Microcins

Microcins are low molecular weight, ribosomally synthesized antibacterial peptides produced mainly by *Enterobacteriaceae* (117). They are highly modified and as such closely resemble the lantibiotics (114). Their molecular weights are generally below 5000 Da (118). Compared

with colicins, microcins are less sensitive to proteases. This could be the result of their shorter length and of their amino acid modifications. Microcins are gene encoded and in most cases are plasmid encoded. The structural genes encoding microcins C7 and C51 each consists of 21 base pairs, probably the shortest coding sequences found to date (119,120).

Microcins vary in their structures, shown in Figure 7.12, and modes of action. They are divided into seven groups according to their cross immunity profiles (118,120). Presumably, microcins within the same cross immunity group have the same inhibition mechanism. These mechanisms include inhibition of metabolic enzymes, DNA replication, translation (118), amino acid transport (121), DNA biosynthesis (122), cell division (123), and cell membrane depolarization (124).

7.3.1.1 Microcin Biosynthesis

The biosynthesis and immunity genes of several microcins have been cloned and studied. Most of the known microcin genetic systems are located on plasmids, typically spanning a fragment of approximately 10 kb which includes both the biosynthesis and the immunity genes. As microcins undergo post translational modifications, the biosynthesis genes include both the structural genes encoding the peptides and the genes encoding enzymes responsible for modification. Figure 7.13 shows the biosynthesis gene clusters of several microcins.

The biosynthesis of microcin B17 (MccB17) has been the most thoroughly investigated. The translational product of the structural gene *mcbA*, preMccB17, consists of an N-terminal leader peptide and a C-terminal structural peptide. The gene products of *mcbB*, *mcbC,* and *mcbD* form a multimeric microcin synthetase complex which is responsible for

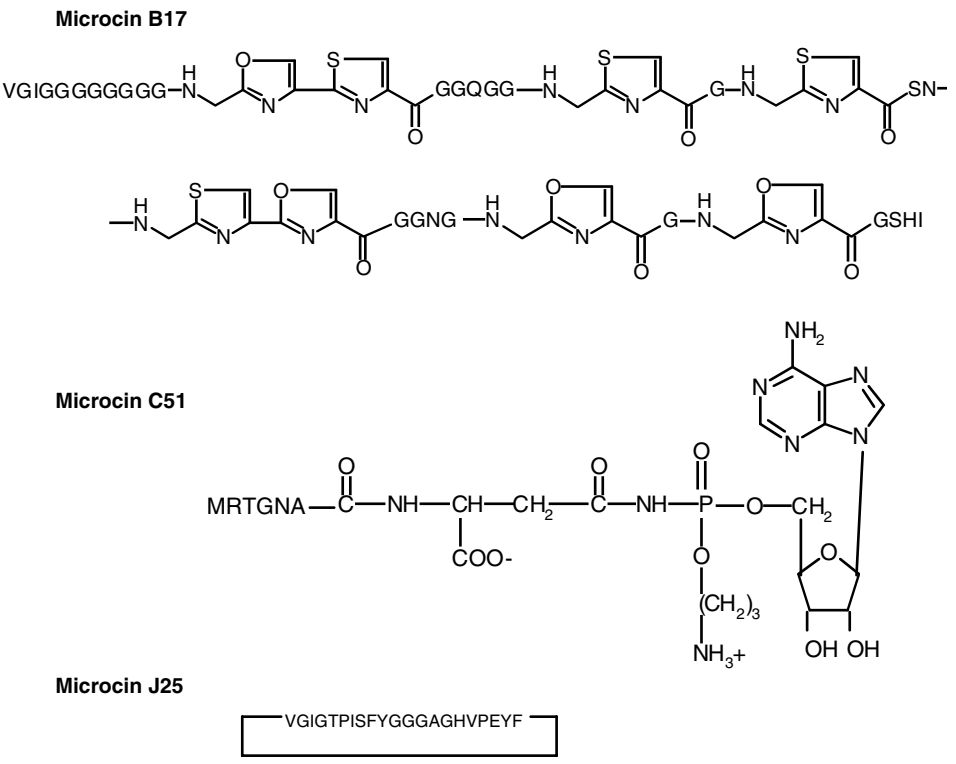

Figure 7.12 Structures of several microcins.

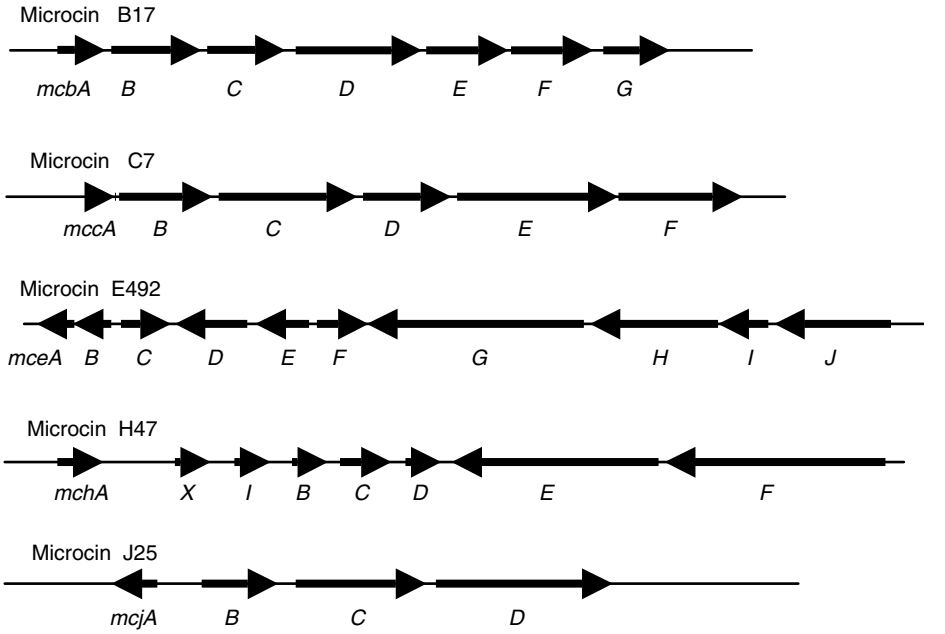

Figure 7.13 Biosynthesis gene clusters of several microcins. Arrows indicate the open reading frames and their transcriptional directions. Gene names and functions are covered in the text.

the formation of thiazoles and oxazoles (125). The leader peptide, along with ATP/GTP, is required for this process (126). The peptide is now called proMccB17. After removal of the leader peptide, the mature microcin B17 is secreted outside the producer cell. Both McbE and McbF are involved in transport of microcin B17.

The microcin E492 gene cluster is located on the chromosomal DNA. The entire gene cluster is around 13kb. The first gene in the cluster, *mceA*, encodes the precursor peptide with its corresponding leader sequence. The gene *mceB* encodes an immunity protein that is associated with the inner membrane (127). Expression of *mceA* and *mceB* is coordinated and occurs mainly in the exponential phase, with a decline during the stationary phase (124). Genes *mceC* and *mceI* show homology to glycosyl transferase and acyltransferase respectively. Gene *mceJ* does not show homology to any known gene. Genes MceC, MceI, and MceJ are necessary for production of active microcin, although microcin E492 does not contain any modified amino acid. Genes *mceG* and *mceH* encode an ABC transporter and its associated accessory protein, respectively (128).

Genes involved in the biosynthesis of microcin H47, which are located on the chromosomal DNA, have been cloned and sequenced. Eight ORFs of different transcriptional directions have been identified. It is proposed that *mchB* is the structural gene, while *mchA*, *C*, and *D* are involved in the maturation process. Genes *mchF* and *E* show high homology to other ABC transporter proteins. MchI is the immunity protein. There is a silent region between *mchA* and *mchI* with an ORF, *mchX,* of unknown function (129).

Four genes have been cloned from a low copy number plasmid that are related to microcin J25 synthesis and immunity. Gene *mcjA* is the structural gene, and *mcjD* is the immunity gene. Genes *mcjC* and *D* probably encode enzymes involved in cyclization of the peptide (130).

Although many of the microcin genes are located on plasmids, chromosomal genes are involved in the biosynthesis and secretory processes. A chromosomal gene *pmbA* is

found to be involved in the maturation of microcins. This gene encodes a cytoplasmic protein that cleaves the leader peptide to yield the mature microcin (131). Microcin H47 is secreted by an ABC transporter, constituted by MchE, MchF, and the chromosomally encoded TolC (132).

The regulatory factors controlling the expression of microcins are encoded by the chromosomal DNA. Microcin B17 expression is activated by an integration host factor (IHF) and outer membrane protein OmpR (133). Expression of microcin C7 and C51 is regulated by cAMP/CRP and RpoS; the latter is an alternative subunit of RNA polymerase (120). Microcin J25 expression is controlled by ppGpp (134).

7.3.2 Colicins

Colicins are single, ribosomally synthesized polypeptides produced primarily by *Escherichia coli* which kill sensitive *E. coli* and closely related species including *Shigella* and *Salmonella*. Colicin production is not completely limited to *E.coli*, however, as several other Gram-negative bacteria also produce colicins, such as colicin U from *Shigella boydii* (135). The molecular weights of colicins range from 29000 to 89000 Da (136,137). This characteristic places them into the class III bacteriocins (colicin V is a small peptide that should be grouped with the class II bacteriocins). Compared with microcins, colicins are not modified except for the cleavage of an N-terminal methionine (115).

7.3.2.1 Structure and Mode of Action

The colicin mode of action is a sensitive cell suicide process which consists of three steps. First, the colicin molecules interact with receptor proteins on the outer membrane of the target cells. Next, the target cells actively uptake colicin into the cytoplasmic membrane or the cytoplasm, depending on the type of colicin. The colicin molecules then execute the killing process (116). Colicins consist of three functional domains which correspond to the three steps in the killing process. The N-terminal domains are important for uptake, the central regions interact with the receptor proteins, and the C-terminal domains are the toxic sites.

Colicins can be divided into two groups based upon their mode of action. The first group consists of the pore-forming colicins A, B, E1, Ia, Ib, K, and N (138). These colicins kill the target cells by forming a channel on the target membrane. Studies have shown that the channels formed by colicins can be up to 9 Å (139). The non-pore-forming colicins execute their killing task in the cytoplasm. Most of the colicins in this group have nuclease activity (115). Colicins E2, E7, E8, and E9 are endodeoxyribonucleases which degrade chromosomal DNA. Colicin E3, E4, E5, and E6 are endoribonucleases that inhibit protein biosynthesis by cleavage of the 16s rRNA (140). Colicin D inhibits protein synthesis by cutting tRNA-Arg (141). Colicin M blocks the biosynthesis of both peptidoglycan and O-antigen and causes autolysis of the cells (136).

Immunity proteins are found in the colicin-producing cells. Because of the differences among colicin modes of action, the protections provided by different immunity proteins are also different. They do, however, share one important characteristic, they all inhibit the colicin activity by binding to the active site of the corresponding colicins (142,143). This aspect makes colicins and their immunity proteins an excellent model system for the study of protein–protein interactions. For the pore-forming colicins, the corresponding immunity proteins are inserted in the membrane. For the non-pore-forming colicins, the immunity proteins are expressed and bound to the colicins inside the producing cells and are secreted with the colicins in their bound forms. The colicin M immunity protein is a membrane inserted protein, but it inactivates colicin M before the toxin reaches the cytoplasmic membrane (144).

7.3.2.2 *Colicin Biosynthesis*

Colicin-producing strains occur with high frequency among natural *E. coli* isolates (145). The genes encoding colicins have been found on plasmids. Biosynthesis genes for colicins A, D, E1 to E9, K, and N are located on small multi copy plasmids which are amplifiable but not self transmissible. Genes encoding colicins B, Ia, Ib, and M sit on large, low copy transferable plasmids that are not amplifiable (115). As shown in Figure 7.14, the colicin structural genes normally sit close to the immunity genes. Most of the nuclease colicins have their structural genes and their immunity gene in the same orientation, while the structural genes encoding the pore-forming colicins are typically in the opposite orientation of their corresponding immunity genes.

What is unique about colicin biosynthesis is the transport mechanism. Colicin secretions do not use the dedicated transport system as do lantibiotics or class IIa bacteriocins, nor do they utilize the universal transport system for other secreted proteins. A small lipopeptide is expressed coordinately with the colicin. This lipopeptide increases the permeability of the envelope, which causes the release of colicin as well as some other proteins.

The biosyntheses of colicins are under tight control because they are toxic to their own producer cells. Expression of colicin structural genes is driven by promoters that are repressed by the LexA protein. Upon UV irradiation or mitomycin C exposure, the resulting DNA damage signals the SOS response. This leads to the activation of RecA protease activity that degrades LexA, thereby allowing for the transcription of the colicin structural genes (146).

7.3.3 Other Gram-Negative Bacteriocins

Yersinia pestis produces pesticin, which is a muramidase (147). The pesticin gene cluster is located on a plasmid with the structural gene (*pst*) and the immunity gene (*pim*) having opposite transcriptional polarity. The expression of pesticin is, like that of the colicins, under the control of the LexA repressor of the SOS system. No lysis protein is detected near the gene cluster (148).

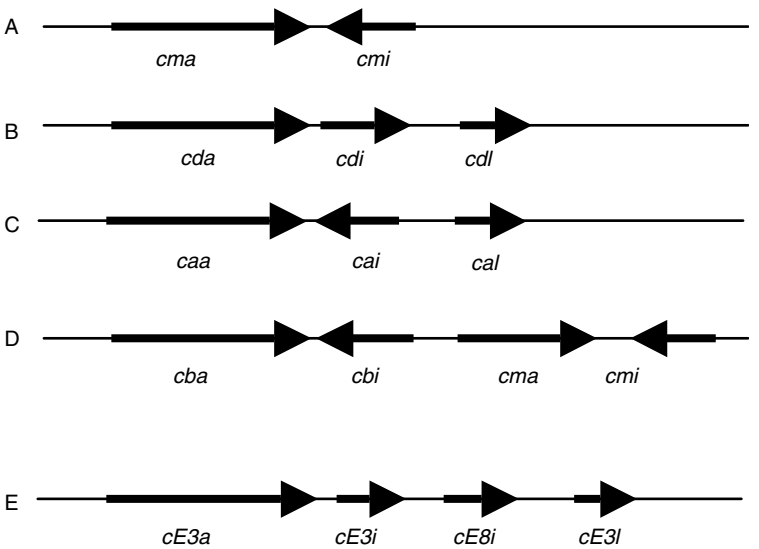

Figure 7.14 Organization of the colicin biosynthesis genes. The structural genes are called *cxa*, where x is the name of the colicin; the immunity genes are called *cxi*, and the lysis genes are *cxl*. The arrows indicate the direction of transcription.

Pseudomonas aeruginosa strains are frequently found to produce pyocin S1, S2, and AP41 (149). They are colicin E2-like bacteriocins with nuclease activity. They also have three functional domains: the receptor-binding domain, the translocation domain, and the DNAse domain (150). The biosynthesis genes of pyocin AP41 are located on a conjugative fragment on the chromosome (151). Pyocin AP41 expression is activated by DNA damage through the RecA pathway (152).

7.4 PEPTIDE ANTIBIOTICS

As previously mentioned, the peptide antibiotics refer to a group of antibiotics that have non-protein amino acids, including D-amino acids, hydroxy acids, or other unusual constituents (6). These unusual amino acids are not formed by post-translation modification as those in lantibiotics, but rather are synthesized along with the entire peptide on huge enzyme complexes. A number of peptide antibiotics have been discovered and studied in detail. Peptide antibiotics produced by *Bacillus* spp. include gramicidin, tyrocidine, bacitracin, and surfactin. The structures of some of these antibiotics are shown in Figure 7.15.

Paenibacillus (formally known as *Bacillus*) produces several different types of polymyxins. Polymyxin B was first isolated from *Paenibacillus polymyxa* (formally known as *Bacillus polymyxa*) in 1947. *Actinomycetes* spp. are known for the production of numerous different antibiotics. Some of these antibiotics also belong to the group of peptide antibiotics, such as actinomycin and bialaphos.

The biosynthesis of peptide antibiotics is quite different from that of ribosomally synthesized polypeptides. It has been found that the biosynthetic pathways of these peptide antibiotics have similar mechanisms that involve a head growth synthesis performed by

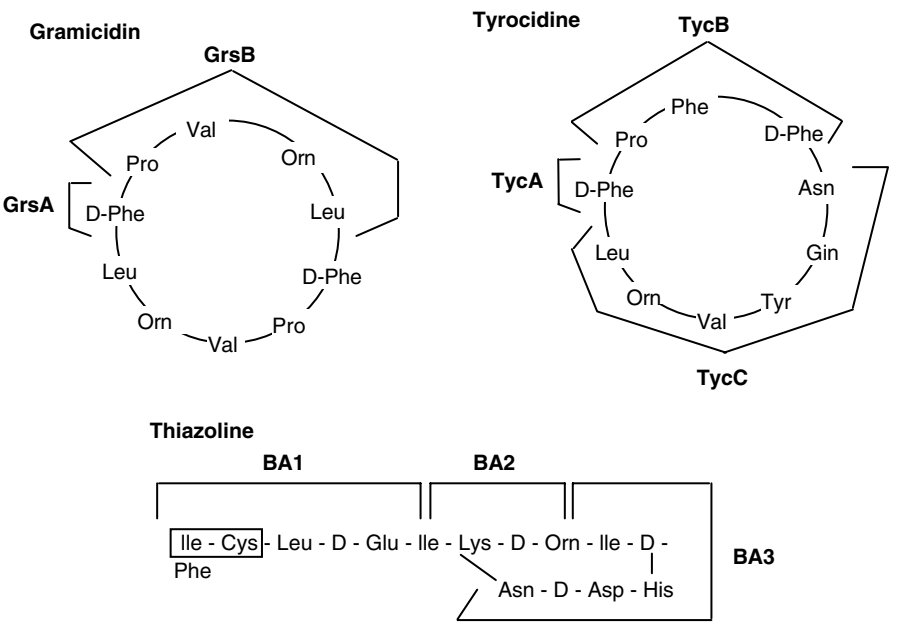

Figure 7.15 Structures of some peptide antibiotics produced by *Bacillus* spp. Indicated here are the peptide sequences of the respective antibiotics along with the NRPS responsible for their synthesis.

ATP consuming nonribosomal peptide synthetases (NRPSs) which utilize a thiotemplate multienzymatic mechanism (153–157).

Like bacteriocins, genes responsible for the biosynthesis of peptide antibiotics are usually organized in a gene cluster. Figure 7.16 shows the biosynthesis gene cluster of gramicidin, which inhibits bacteria by binding to nucleotides. Gramicidin S synthetase is a complex of two subunits. GrsA activates and racemizes L-Phe to D-Phe. GrsB activates Pro, Val, Orn, and Leu. The modules for activating and adding each amino acid are organized linearly on the synthetase GrsB, corresponding to the amino acid sequence of this peptide antibiotic.

Peptide antibiotics are considered secondary metabolites. Except for competitive exclusion, the functions of these antibiotics to their producer strains are not clear. The peptide antibiotics are widely used in the medical field to treat infection, and as such their use in the food industry is not allowed due to fears of propagating resistant strains of bacteria.

7.5 INDUSTRIAL APPLICATIONS OF ANTIMICROBIAL PEPTIDES

Humanity's perpetual coexistence with and codependence upon microbial life has lead to a high degree of necessity for being able to control the presence and actions of these microbes. Two areas where this need for control is particularly important are in the food and medical industries.

Microbes are involved in numerous aspects of the food industry, both good and bad. Many beneficial bacteria, namely lactic acid bacteria, are used to preserve food and to alter the taste content of foods to make them more appealing to consumers. Other, nonbeneficial bacteria, whether naturally occurring or contamination based, have negative effects on the food industry by causing food spoilage or diseases amongst consumers. To control these spoilage and pathogenic microbes, antimicrobial agents in foods are used as additives to prevent food spoilage and enhance food safety. Historically, these additives have been chemical compounds such as nitrites, sulfites, and organic acids (7). However, chemical preservatives such as these can sometimes be allergens, elicit nonallergic consumer sensitivities, alter the sensory properties of food, and have an overall negative impact upon consumers. Numerous alternatives exist to the use of chemical food preservatives, many of which make use of bacteria and their metabolites. Live probiotic bacteria, probiotic bacterial

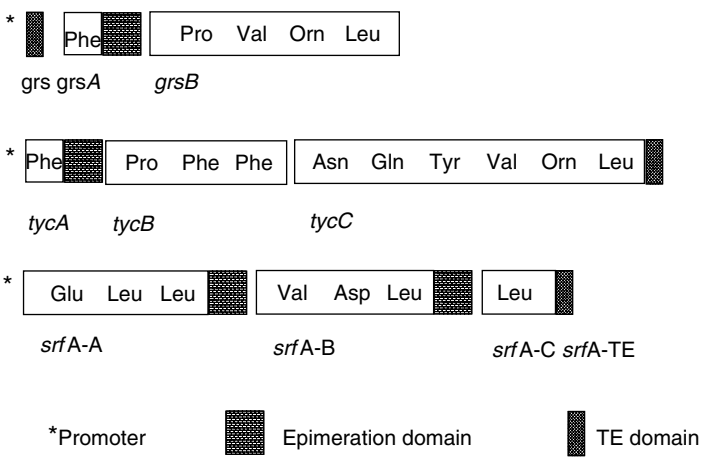

Figure 7.16 Organization of the peptide antibiotic gramicidin S biosynthesis genes.

fermentates, and purified bacterial metabolites have all found applications within the food industry. Amongst these products, antimicrobial peptides, with their selective antimicrobial activity and common sensitivity to harmless degradation by enzymes within the human intestinal tract, have emerged as a highly promising source of food preservatives. Two such compounds, nisin and pediocin, are currently in wide use today.

Nisin, as mentioned earlier, is a class I lantibiotic bacteriocin. It is a widely used antimicrobial peptide in the food industry and inhibits most Gram-positive bacteria, including *Bacillus, Clostridium*, and *Listeria*. It has a broad inhibition spectrum compared to other bacteriocins from Gram-positive bacteria. It can be degraded by several intestinal proteases, such as α-chymotrypsin and pancreatin (158–160), thus rendering it nontoxic to human beings. Its producer strain, *Lactococcus lactis*, is a food grade bacterium commonly found in milk and cheese products, and the purified nisin does not impart any off flavors to the finished products. These characteristics make nisin an excellent food grade preservative. As nisin is very stable at high temperature and low pH, it is perfect for low pH foods that are not suitable for heat processing. Nisin can be used for canned vegetables, high moisture hot plate bakery products, salad dressings, and various dairy products (161). Meanwhile, as nisin is not active against Gram-negative bacteria, it does not disturb the intestinal microflora of humans. More than 50 countries and regions have approved the use of nisin as a food preservative (161). In the United States, the FDA approved the use of nisin as a preservative for processed cheeses in 1989 (162).

Pediocin is a class IIa bacteriocin. It can be added to meat and meat products, milk and dairy products, and liquid whole eggs to inhibit food spoilage bacteria and pathogens (163). Experiments have been conducted to compare pediocin and its producer strains on their ability to control *Listeria monocytogenes*. Pediocin was observed to decrease the population of *L. monocytogenes* faster than the producer strain at first, but its activity was lost afterward. A lower final bacterial count was achieved with the producer strain (164,165). The addition of this peptide during fermentation of kimchi, a Korean fermented vegetable, decreased *L. monocytogenes* counts and inhibited its growth (166). Interestingly, pediocin is not active against *Lactococci*, a bacteria commonly used as a starter culture in dairy products. This makes pediocin a promising food preservative for fermented foods.

Pediocin has been commercially applied in the food industry as pediocin PA-1-containing fermentate (163). Due to the fact that the pediocin producer strains have GRAS status, they and their fermentates can be used in the food industry without special labeling (167). However, it is worthwhile to mention here that nisin is still the only bacteriocin licensed as a food grade preservative. Although pediocin has good *in vitro* activity against *L. monocytogenes*, its *in vivo* activity in food applications is much lower (168). This characteristic makes pediocin an additional safety factor when used together with other food protection methods.

Within the medical industry, the continued evolution of bacterial strains with increased antibiotic resistance has created an ever increasing need for new antimicrobial agents. Peptide antibiotics such as actinomycin, gramicidin, surfactin, and the polymyxins have found applications as both ingestible and topical antibiotics within the medical industry. Some bacteriocins have also found medical uses, many of which are nonantimicrobial in nature. Epidermine and gallidermin are used in the treatment of skin infections. Actagardine inhibits the biosynthesis of peptidoglycan. Ancovenin has a potential use in treatment of high blood pressure because it can inhibit angiotensin-converting enzymes. Cinnamycin shows antiviral activity against type I Herpes Simplex virus. Mersacidin has immunosuppressive activity. The medical applicability of nisin is currently under investigation.

7.6 FUTURE PROSPECTUS

Past and ongoing research surrounding antimicrobial peptides has shown that these compounds have a great deal of potential for applications in both the food and medical industries, and has also provided insights into key areas where the field might make, and should strive to make, strong advances in the future. Continued discoveries of new antimicrobial peptides and increased understanding of the biological systems involved in antimicrobial peptide synthesis, immunity, and regulation should allow for a great deal of advancement within the field, with an emphasis on practical applications to industry.

Bacteriocins, among all antimicrobial peptides, are of great interest to food scientists as potential food preservatives. While a great deal of research has been focused upon biochemical and genetic studies of these peptides, there are still many unrevealed fields yet to be explored. Various bacteriocins have been discovered during the past decades. Among them, only nisin and pediocin have found useful application in the food industry. While adept at inhibiting a wide range of Gram-positive pathogens, these two compounds do little on their own against Gram-negative pathogens. The most serious food borne illnesses, are, however, unfortunately caused by Gram-negative strains, such as pathogenic *E. coli* and *Salmonella* spp. These strains interfere with digestion and cause gastrointestinal problems, such as diarrhea and the more serious sequela. While, as mentioned earlier, nisin, in combination with some treatments such as EDTA or heat treatment can inhibit some Gram-negative bacteria, the processes involved are not always practical. A continued search for new antimicrobial peptides, particularly those with novel inhibition spectrums that include Gram-negative bacteria, as well as possibly yeast and mold, may yield novel compounds for use in the fight to control food spoilage and food pathogenic organisms.

Also, as our search for novel antimicrobial peptides continues, new sources for such compounds have begun to be revealed. While most of the classical research into novel antimicrobial peptides has involved strictly prokaryotic sources, ever increasing amounts of evidence suggests that almost all forms of life produce small peptides with antimicrobial activity. These include not only the bacterially produced bacteriocins, but also similar amphipathic proteinaceous compounds in eukaryotes such as the mammalian defensins and cathelicidins (169,170), as well as magainin, thanatin, and thionin from frogs, insects, and plants respectively. The widespread existence of these compounds suggests that they evolved fairly early in eukaryotic development, and further suggests that they exercise some sort of resistance proof mechanism of action upon susceptible bacteria. Current evidence indicates that this mechanism of action involves membrane pore formation similar to that induced by many bacteriocins (169). These recent data have spawned a great deal of interest into the discovery of both naturally occurring and synthetic antimicrobial peptides, and suggests that such peptides may provide the key to the continued problems of bacterial antibiotic resistance. Increased integration of these research advances with those in the microbial fields could well provide valuable insights for antimicrobial peptides.

Already, these types of discoveries have sparked large scale projects to synthesize a variety of peptides, particularly cyclic peptides, with the potential of possessing antimicrobial properties (171,172). The aims of these efforts might be greatly aided through advances in our understanding of antimicrobial peptide biosynthesis and modification. Such advances might allow for a similar synthesis in a biological setting through the use of protein engineering and interchangeable peptide coding cassettes, creating systems similar to those responsible for the creation and diversity of mammalian antibodies.

Next, there are a large number of known antimicrobial peptides that have been discovered but as of yet have not found a suitable application. More work should be done to investigate the applicability of these compounds, particularly to new areas of both the food and

the medical industry. As previously mentioned, there are already a number of antimicrobial peptides that have shown various uses within the medical field. Along with those compounds already in use, many others are currently under investigation. An increasing wealth of knowledge suggests that the action of antimicrobial peptides can significantly decrease the prevalence of some cancers, particularly colon cancer (173). The mechanism for this prevention is not completely understood but appears to be due to the control of mutagenic compounds within the intestine, either by direct binding of the carcinogens or inhibition of the gut microbes that produce them (174). Also, some bacteriocins, including the colicins and pyocin S2 have even been shown to have anti tumor activities(175,176,177). Further research is needed to expand the knowledge surrounding these potential applications.

Finally, as the size of the antimicrobial peptide repertoire continues to expand, particularly to include compounds with novel inhibition spectrums, and our understanding of antimicrobial peptide immunity and biosynthesis increases, the potential for engineering improved food grade probiotic bacteria which are capable of producing multiple peptides, each of which is capable of inhibiting a specific subset of microbes, become more and more a realistic possibility. Such bacteria could have the potential to help preserve foods, keep them safe, and perhaps even reduce the risk of cancer.

While many of these suggestions are highly speculative, they demonstrate the fact that there is a great deal of potential surrounding antimicrobial peptides, and that more research into the area could very well produce results that could greatly impact and benefit both the food and medical industries.

ACKNOWLEDGMENTS

The authors of this chapter would like to thank Jason Amsel for his graphical assistance.

Phenolic Antimicrobials from Plants for Control of Bacterial Pathogens

Kalidas Shetty and Yuan-Tong Lin

CONTENTS

8.1 PHENOLIC ANTIMICROBIALS FROM PLANTS

Plants are excellent sources of phenolic metabolites. In particular, phenolic antioxidants from food grade plants have potential for long term chemo preventive and therapeutic applications against oxidation linked diseases (1–4) and increasingly have antimicrobial potential (2). Such phenolic metabolites are also broadly called phytochemicals. Phenolic phytochemicals have shown to be associated with antioxidative action in biological systems, acting as scavengers of singlet oxygen and free radicals (5,6). Much of this work has emphasized the role of phenolics from higher plants in relation to human health and in particular cancer and cardiovascular health (3,7,8). Phenolic phytochemicals (phenylpropanoids) serve as effective antioxidants (phenolic antioxidants) due to their ability to donate hydrogen from hydroxyl groups positioned along the aromatic ring to terminate free radical oxidation of lipids and other bio molecules (9). Phenolic antioxidants therefore short circuit a destructive chain reaction that ultimately degrades cellular membranes and in prokaryotes such phenolic antioxidants have potential for antimicrobial activity.

Plant phenolic extracts that impart flavor and aroma also have potential for inhibiting pathogenic microorganisms (10–12). These phenolic secondary metabolites are defensive antimicrobials produced against invading pathogens and stress and therefore the methods for exploiting them have to take this into account. In certain cases the induction is associated with action of diphenolic oxidases, and resulting modified compounds can have antimicrobial activity (13). In other situations dihydroxy phenolics are oxidized to quinones, which can interact with the proteins of the invading pathogens, forming melanoid polymers (13). Quinones are aromatic rings with 2 ketone substitutions and are highly reactive (10). These compounds are responsible for the enzymatic browning reaction of cut fruits and vegetables, and are an intermediate in melanin pigment production in humans (10). The quinones are sources of stable free radicals and complex irreversibly with nucleophilic amino acids and proteins (14) leading to inactivation of protein and loss of function (14). Therefore potential antimicrobial benefits of quinones are substantial (14). The potential targets for inhibition in the bacterial cells are surface adhesions; cell wall polypeptides and membrane bound enzymes (14).

In many herb and spice species investigated so far phenolic derivatives found in essential oils have been largely investigated for antimicrobial activity. Hydrophobic phenolics derived from the terpenoid pathway, thymol, and carvacrol, present in essential oil of thyme, oregano, savory, sage, and related species, have antimicrobial activity (11). The essential oil containing thymol can inhibit *Vibrio parahaemolyticus* (15). The addition of 0.05% of alcoholic extracts of thyme can inhibit the growth of *Staphylococcus aureus (*16*)*. Sage extract was inhibitory to *Bacillus cereus* and *S. aureus* (17). Rosemary extract of 0.1% substantially inhibited the growth of *S. aureus* and *Salmonella typhimurium* (18). Among other types of phenolics, hydroxycinnamic acid derivatives such as caffeic acid, ferulic acid and p-coumaric acid derived from the phenylpropanoid pathway inhibit *E. coli, S. aureus* and *B. cereus* (19). Polymeric phenolics, such as tannins are inhibitory toward *Listeria monocytogenes, E. coli, S. aureus, Aeromonas hydrophila,* and *Streptococcus faecalis* (20). Hydroxylated phenols, such as catechol and pyrogallol, are known to be toxic to microorganisms (10). The site and number of hydroxyl groups is linked to the antimicrobial effect and, in some cases, more oxidized forms are more inhibitory (21,22). In other combination studies, growth of *E. coli, Salmonella spp., L. monocytogenes,* and *S. aureus* were inhibited by oregano essential oils in broth cultures and its effect in emulsion systems depended on pH, temperature, and other environmental factors (23,24). In meat studies essential oil of oregano inhibited *L. monocytogenes* and *S. typhimurium*

(25,26). Other diverse examples of antimicrobial effects of herbs and spices are documented well in Tassou et al. (27).

The mode of action of phenolics against bacterial pathogens has not been defined or clearly understood. It is suspected changes in membrane permeability through lipid compatible hydrophobic phenolics, like thymol from certain essential oils, and membrane localized hyperacidity from water and ethanol soluble phenolics like benzoic acid and rosmarinic acid, may affect proton motive force across the membrane and therefore energy depletion may take place (11,28,29). It is suggested as a result of damage to structural and functional properties of membranes, pH gradient and electrical potential of the proton motive force is disrupted (30,31). The disruption of the proton motive force and reduction of ATP pool lead to cell death (11,31,32). Further, leakage of ions, nucleic acid, and amino acids can occur (27,33–35). It is also proposed that enzyme inhibition by the oxidized compounds through reaction with sulfhydryl groups, or through nonspecific interactions with membrane proteins, may also be the reason for inhibition (10,36). Other proposed mechanisms include formation of Schiff's bases with membrane proteins by aldehyde groups of phytochemicals, which prevent cell wall biosynthesis (37,38), and interaction of ferrous iron with phenolic compounds, which can damage membranes by enhancing oxidative stress (39).

In spite of wide investigations around the world, using many diverse botanical sources, the results of antimicrobial efficacy of phytochemicals are mixed, to very poor, and mechanism of action is poorly understood. The three major reasons for this are:

1. Many phytochemicals have been derived from mixed heterogeneous genetic sources and consistency cannot be guaranteed from batch to batch and from source to source (1,2,40).
2. Many of the antimicrobial phytochemicals, and especially phenolics, are biotic or abiotic stress inducible and, if extracts are used from uninduced states, the efficacy is potentially low.
3. Investigations have largely focused on hydrophobic essential oils and focused solely on disruption of plasma membrane related functions.

Now, with the emergence of antibiotic resistance from overuse of single antibiotics from fungal and bacterial sources, new strategies using plant based sources are promising (10) and urgently needed (2,40). In line with this need, one of our major strategies focus on the hypothesis that high antioxidant phenolics from single seed origin clonal lines of herbs such as oregano, thyme, rosemary, and lavender, and genetically uniform sprouted legumes such as soybean, fava bean, fenugreek, chickpea, pea, and mung bean, which are self pollinating species would have excellent antimicrobial potential. Genetically uniform, high antioxidant phenolic profiles have been screened, evaluated for antioxidant efficacy and targeted to inhibit bacterial pathogens (41,42). In this screening strategy, both the concept of phytochemical consistency through clonal lines in herbs and stress (elicitor) based inducibility of phenolic antioxidants in self pollinating and genetically uniform legumes can be developed to explore the antimicrobial potential against bacterial pathogens. Further, we have targeted only water and ethanol extracted phenolic profiles from these systems that could work effectively and synergistically to inhibit biochemical targets at the cellular membrane and cytosol of the bacterial pathogen at the same time, thereby impacting multiple targets and offering fewer opportunities for resistance by the pathogen.

8.2 POTENTIAL OF *LAMIACEAE* AS SOURCE OF PHENOLIC ANTIMICROBIALS

Extracts from dietary herb species belonging to the family *Lamiaceae* (mint family) have been used by humanity as sources of complimentary medicine and food preservatives for over 4000 years. It is only recently that some of the bioactive components linked to medicinal and preservative function have been determined to be phenolic metabolites (4,43,44). Specific phenolic metabolites from Lamiaceae like rosmarinic acid (from rosemary, spearmint, thyme, lavender, and oregano) and thymol (from thyme and oregano) have anti inflammatory (4,45), antioxidant and antimicrobial properties (11,46–48), respectively. The antioxidant pharmacological functions from food grade dietary phytochemicals from various mint family species could contribute to long term prevention of oxidation influenced disease such as diabetes, cancer, CVD, cognition and inflammatory diseases (1,3,8). In general food processing applications oregano, rosemary, thyme, and lavender has been used widely as a source of flavors and potential food antioxidants (49–51). These herb species are native to the Mediterranean and are widely used in South European cuisine. The beneficial phenolic antioxidants that are being targeted for food and health applications in our research are biphenyl, rosmarinic acid that also has antioxidant, anti inflammatory, and antimicrobial properties (4,45,47), and several other simple soluble phenolic metabolites have antioxidant properties (49,51). The beneficial antioxidant activity from phenolic metabolites was also observed in many food preservation conditions such as in lard (50), salad dressing (52) and other food model systems. The phenolic antioxidants from these herb species also have potential antimicrobial properties (2,11,27,40,47,48) and, being partially ethanol and water soluble, could be effective at inhibiting targets on bacterial cell membrane as well as key dehydrogenase linked metabolic reactions in the cytosol, as opposed to being effective only in the hydrophobic regions as in case of wide variety of plant essential oils. These water and ethanol extracted phenolics are also less volatile and have fewer flavor related problems compared to volatile essential oils targeted to cell membranes. The water and ethanol extractable phenolics are also more compatible in a more diverse array of foods, are less volatile, and have fewer flavor problems.

8.2.1 Control of *Staphylococcus Aureus* by Phenolic Phytochemicals as a Model for Plant Based Antimicrobials

Staphylococcus aureus is an important pathogen in humans that has significant impact in the food chain (11) and high density communities and hospitals (53). The pathogen causes serious infections in open wounds, vascular tissues, bones, and joints (53,54). The importance of *S. aureus* as the etiological agent in catheter related and peritoneal dialysis patients is well known and often requires aggressive antibiotic treatment (55,56). Further it is well known that as a result of antibiotic resistance, it has been difficult to control infections ranging from abscesses, pneumonia, endocarditis, septicemia, and toxic shock syndrome. The one last line of defense is the antibiotic vancomycin (57–59). *Staphylococcus aureus* infections leading to complications from septic and toxic shock syndromes may result in organ failure (60,61). The existence of ecologically abundant hyper virulent clones has suggested that factors promoting ecological fitness of *S. aureus* also increase its virulence (62). The prospects of untreatable *S. aureus* infections have raised the need to search for alternative therapies, and development of a broadly protective vaccine based on an *in vivo* expressed antigen has some merit (63). In addition, consistent clonal profiles of plant phenolic metabolites from food grade herbs and inducible phenolics from legume sprouts can be an important complimentary therapy which can be used in conjunction with other therapies, including new microbial based antibiotics and vaccines.

Studies have indicated the antimicrobial potential of plant phenolic metabolites against *S. aureus*. The addition of 0.05% alcoholic extract of thyme can inhibit the growth of *Staphylococcus aureus* (16). Sage extract was also inhibitory to *S. aureus* (17). Rosemary extract of 0.1% substantially inhibited the growth of *S. aureus* and *Salmonella typhimurium* (18). Hydroxycinnamic acid derivatives such as caffeic acid, ferulic acid, and p-coumaric acid inhibited *S. aureus* (19). Polymeric phenolics, such as tannins, are inhibitory toward *S. aureus* (20). The hypothesis that elicitor inducible phenolic antioxidants from clonal herbs and legumes can also inhibit *S. aureus* holds much promise for improved efficacy and is being currently investigated. We also speculate that plant based phenolic antioxidants of consistent clonal origin have the potential to support human antioxidant enzyme response and therefore reduce human tissue damage from *S. aureus* toxin induced apoptosis (61) and improve host antimicrobial immune response and these investigations on mammalian cell responses are part of our future investigations.

8.2.2 Control of *Listeria Monocytogenes* by Oregano Clonal Extracts as a Model for Developing Herb Phenolics as Antimicrobials

Listeria monocytogenes is emerging to be a major food borne pathogen in post processing environments in meats and dairy foods. One of the many plants studied extensively for antimicrobial activity against *Listeria monocytogenes* is oregano (*Origanum vulgare*) (11,25,26,41,64). Oregano belongs to the family *Lamiaceae*, which also includes thyme and rosemary. Many studies indicated the antimicrobial activity of oregano and two of its major components, carvacrol and thymol, along with enhanced synergy with high rosmarinic acid extract (41). Kim et al. (65) reported that carvacrol was the most antibacterial phenolic compound they tested against five food borne pathogens (*Escherichia coli, E. coli* 0157:H7, *Salmonella typhimurium, L. monocytogenes, and Vibrio vulnificus*) using paper disk assays. Carvacrol was shown to have a larger zone of inhibition than did the other phenolic compounds at the same concentrations (citral, geraniol, terpineol, perillaldehyde, eugenol, linalool, and citronellal). Other studies have shown that nisin, when used in combination with carvacrol, inhibited the growth of *Bacillus cereus* and *L. monocytogenes* (66). One of the results found in this study was that at 20°C, growth of *L. monocytogenes* was completely inhibited in the presence of a concentration of nisin that was 16-fold lower (when used in combination with carvacrol) than when nisin was applied as the sole preservative. Thus, using carvacrol in combination with nisin did increase the effectiveness of the antimicrobial and allowed it to be used at much lower concentrations than it was used previously. Hurdle technology was also used in a study done by Karatzas et al. (67), which showed the combinations of carvacrol and high hydrostatic pressure inhibited *L. monocytogenes*. Other studies have also indicated that phenolic metabolites from oregano and other related herbs can be effective against *Listeria monocytogenes* (11,41).

Therefore the use of herbs and spices as a potential preservative for the food industry does have prospects for improving hurdle technology for controlling food borne pathogens. As discussed previously, due to their natural cross pollination nature, these herbs and spices are genetically heterogeneous (1,2). This heterogeneity results in a high degree of variability in the levels of phenolics in these plants (68). Furthermore, problems associated with climate and diseases can lead to even more quality variation in the plants. This produces many serious problems for the routine use of these plants as a hurdle to inhibit the growth of food borne pathogens in products developed by the food industry. Therefore tissue culture based clonal propagation was developed to develop consistent oregano extracts with antimicrobial activity against *Listeria monocytogenes* (41). Clonal propagation also allows us to obtain more detailed analysis of biosynthetic pathways of primary and secondary metabolites from uniform genetic material. This also allows us to study the

effects of manipulating the pathways, such as adding specific precursors of a pathway or manipulating or deleting key enzymes (1,2).

In order to screen for high phenolic stimulated clonal lines with high antimicrobial activity, microbial elicitors, such as *Pseudomonas* sp., have been employed (69–72) (Figure 8.1). The rationale for this screening approach is that phenolic metabolites are stimulated in response to microbial elicitors (73) and, therefore, any clonal line tolerant to *Pseudomonas* must be a phenolic overexpressing phenotype (72). By using these techniques, it is now possible to obtain a reliable and genetically uniform plant source with excellent functionality for antioxidant and antimicrobial applications that can be used in the food industry. Using this approach we have shown that an elite clonal line of oregano was superior in inhibiting *Listeria monocytogenes* compared to commercial herbs extracts or individual terpenoid pathway derived phenolics normally found in essential oils of oregano (41). We are working further on obtaining *Listeria* specific inducible phenolics from specific clonal lines that could be more effective. In order to develop such *Listeria* specific herb clonal lines we have developed an innovative two layered plate assay to screen specific clonal lines that target

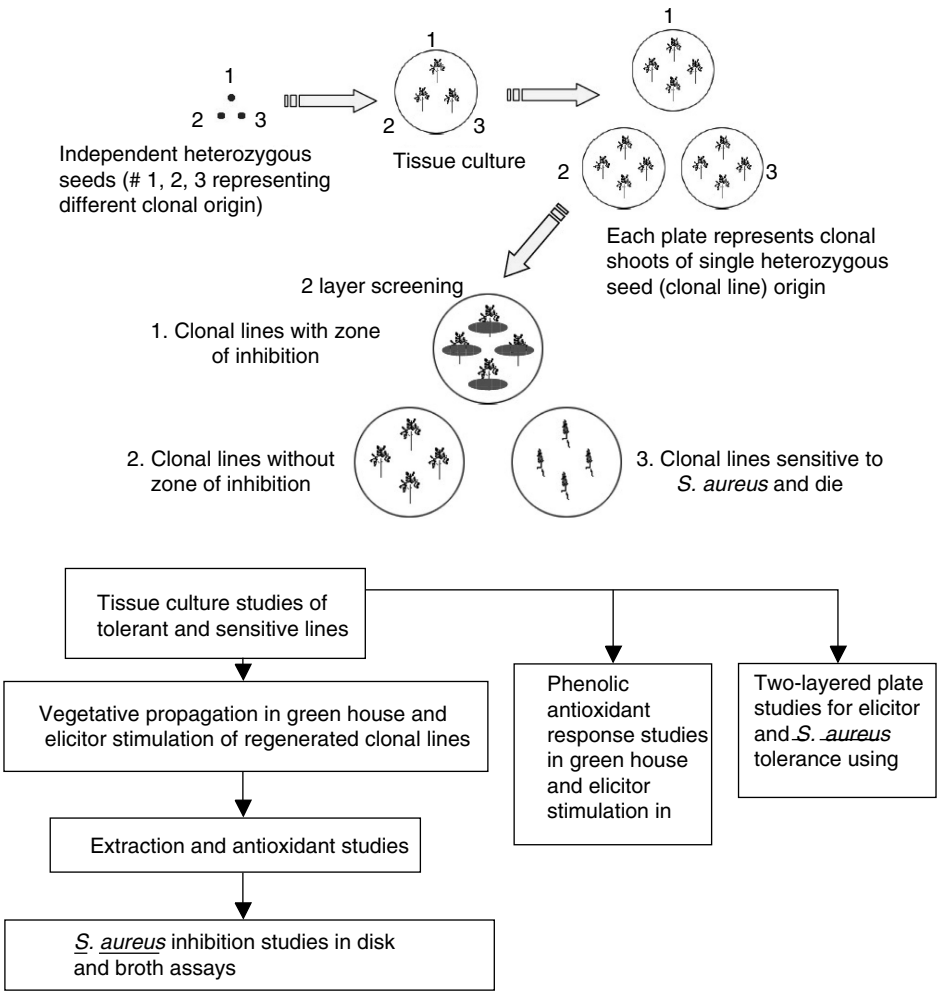

Figure 8.1 Steps for isolation of clonal lines of single seed origin heterozygous seed with potential for high phenolics with antimicrobial activity.

Listeria monocytogenes (Figure 8.2). Further, the hypothesis that elicitor inducible phenolic antioxidants from low flavored clonal lines can also inhibit *L. monocytogenes* holds much promise for improved efficacy and is being investigated. In addition, in our recent studies we have also found in meat systems that ethanol extracted phenolics from clonal oregano are more effective in inhibiting *Listeria monocytogenes* than individual hydrophobic phenolics such as carvacrol that are found in essential oils of oregano (41).

8.3 FILLING GAPS IN ANTIMICROBIAL STRATEGY WITH TISSUE CULTURE BASED SCREENING OF ELITE PHENOLIC PHYTOCHEMICAL-PRODUCING LINES

As mentioned, the major limitation of using dietary food grade herbs like oregano, thyme, and lavender for antioxidant and antimicrobial applications is the inconsistency of phenolic phytochemicals due to the heterogeneity resulting from the natural cross pollinating nature of their breeding characteristics (74). Plants which originate from different heterozygous seeds in a given pool of extract are phenotypically variable, resulting in the substantial phytochemical inconsistency, and therefore leads to unreliable clinical effects as well as inconsistent health benefits and functional value.

In order to overcome the problem of phytochemical inconsistency due to genetic heterogeneity, our laboratory has developed patented plant tissue culture techniques to isolate a clonal pool of plants originating from a single heterozygous seed (75,76) (Figure 8.1). A single elite clonal line with superior phenolic profile (a combination of several bioactive phenolics such as rosmarinic acid and simple phenolic acids) can then be screened and selected based on tolerance to *Pseudomonas* sp. (70–72). This screening strategy is being further developed to select and characterize several elite high antioxidant clonal lines of food grade herbs such as oregano (*Origanum vulgare)*, thyme (*Thymus vulgaris*) and lavender (*Lavandula angustifolia*) based on response to microbial polysaccharide and bacterial pathogen targeted in a 2 layered plate assay (Figure 8.2) and based on tissue culture antioxidant response studies. These elite clonal lines (each clonal line originating from a different heterozygous seed), following large scale clonal propagation (micropropagation) in greenhouse systems are being evaluated for antioxidant profiles and functionality. High and low

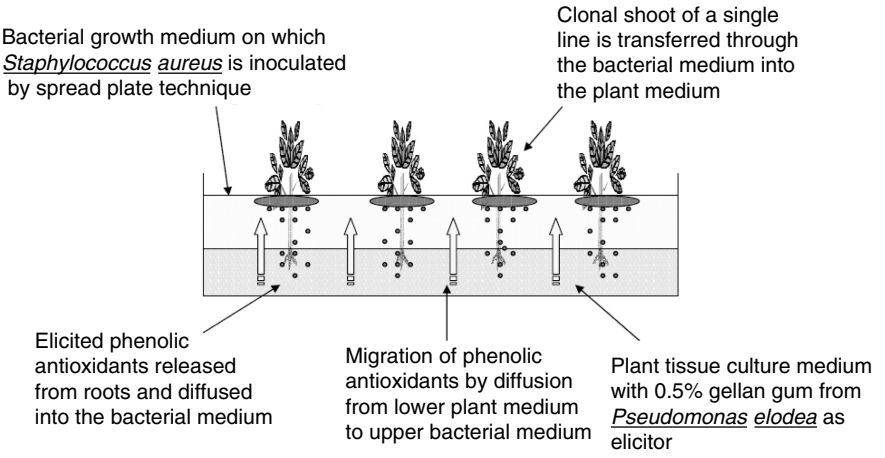

Figure 8.2 Innovative 2-layered plate assay from specific identification of clonal lines of herbs with potential of antimicrobial activity against the targeted bacterial pathogen.

antioxidant signature profiles of different clonal origin (different heterozygous seeds) are compared and targeted as dietary sources of phenolics that have high antioxidant efficacy and therefore potentially have antimicrobial benefits against food borne pathogens as evaluated *in vitro* disk (Figure 8.3) and broth assays. The advantages and importance of this approach is that it provides a rapid nontransgenic approach to obtain genetically consistent clonal lines with high rosmarinic acid as antioxidant in different total soluble phenolic and high antioxidant backgrounds from diverse heterogeneous gene pools that are generated due to natural cross pollination. Once the elite line is isolated by *in vitro* tissue culture methods it can be rapidly clonally propagated by vegetative cuttings for greenhouse and field production and therefore consistent phytochemical extracts of single seed genetic origin can obtained for potential antimicrobial applications against the pathogenic bacteria being targeted. Further, the clonal lines containing higher and lower total or specific phenolic content can be compared for synergistic contribution in different high total soluble phenolic and antioxidant clonal backgrounds. Therefore the approach envisioned in this chapter is excellent for generating consistent phytochemical antioxidant profiles for developing clinically or food safety relevant antimicrobial applications and for consistency of ingredients for food applications as a part of a hurdle technology. In addition, in future studies synergistic antimicrobial activity in combination with antimicrobials from multiple food grade sources can be evaluated against antibiotic resistant pathogens. Because antimicrobial phenolic profiles of single genetic origin are generated they offer consistency and yet have multiple phenolics that will make it difficult for pathogens to develop antimicrobial resistance. This synergy can be further enhanced in combinations with other dietary phenolic profiles. This strategy will be useful against hospital infections or food processing and packaging environments, especially infections from antibiotic resistant strains. Once a clonal profile antimicrobial efficacy is established, individual phenolic phytochemcials contributing to antimicrobial efficacy in specific clonal profiles can be investigated based on the model proposed on the mechanism of action of these phenolic phytochemicals. Such clonal screening is also ideal for screening for more ethanol and water soluble phenolic antimicrobials that can be effective in inhibiting or disrupting biochemical targets both in the plasma membrane and the cytosol.

8.3.1 Novel Model for Mechanism of Action of Phenolic Phytochemicals

Current theory and emerging data suggests that eukaryotes evolved from prokaryotes (77). Genetic evidence suggests that plant organelles like chloroplasts, mitochondria, and even vacuoles may have origins as free prokaryotes. The compartmentalized organization and

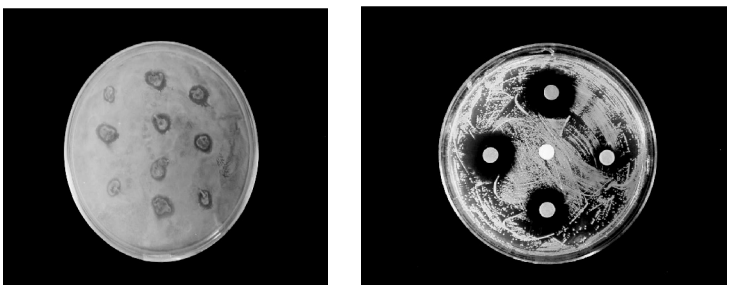

Figure 8.3 (a) Example of antimicrobial zone of inhibition by specific oregano clonal line against *S.aureus* as outlined in Figure 8.2. (b) Dose-dependent inhibition of *S. aureus* by phenolic extracts from mature clonal plants developed from clonal screening as outlined in Figure 8.1.

cellular differentiation (into tissues) of plants apparently evolved in terrestrial environments about 500 million years ago. It is likely that through the millennia, plastic plant species constantly interacted with many microorganisms and environmental stresses, especially UV radiation and oxidative stress. The speculation is that constant environmental stress in many ways may have shaped the antimicrobial and phenolic antioxidant responses of plants through the evolutionary process. Natural selection of plants under various changing environmental conditions over millions of years, in many critical ways (directly or indirectly) may have shaped the current mammalian systems, including human nutrition, health, and dietary evolution (40).

It is from these assumptions that we are exploring the mechanism of antimicrobial action of plant phenolics on prokaryotic pathogens and the activation and maintenance of plant and eukaryotic antioxidant responses, at a similar phenolic concentration needed for bacterial inhibition (40). Plant phenolics and related synthetic food grade phenolics have been suggested to inhibit bacterial pathogens (particularly at low pH) by disrupting the proton motive force (PMF) (40) and through lipid membrane stacking with hydrophobic phenolics (11). This implies that regulation of H^+-ATPases and cofactors at the external membrane is critical, and may be a logical point to study the mechanism of inhibition by plant phenolics. Additionally, plant phenolics may disrupt the electron transport chain or destabilize the plasma membrane (10,11,40). At the same time it is important to investigate the role of plant H^+-ATPases at both the external membrane and organelle (chloroplast, mitochondria, and vacuolar tonoplast) membrane levels to determine their potential involvement in modulation of a phenolic radical and proton linked redox cycle (40). This cytosolic phenolic radical proton linked redox cycle (40) is hypothesized to activate the proline linked pentose–phosphate pathway, to utilize proline as an alternative RE for mitochondrial ATP synthesis, and to generate precursors and cosubstrates ($NADPH_2$ and sugar phosphates) for anabolic reactions, including a phenolic linked antioxidant response and purine synthesis (40). The genetic comparisons of H^+-ATPase alleles from bacterial and eukaryotes could provide clues toward understanding their susceptibility to plant phenolics in bacteria and the antioxidant response linked tolerance of plants and other eukaryotes (40). Such knowledge could facilitate the development of better structure function strategies for the development of better botanical phenolic profiles (i.e., elicitor induced herb and legume clonal extracts) that may provide multiple beneficial activities. A better conceptual understanding of phenolic antimicrobial effects in bacteria and antioxidant responses in eukaryotic hosts could also facilitate the development of diet based nutritional and functional food strategies to control bacterial pathogens with reduced potential for antibiotic resistance due to the concerted effect of a phenolic profile, instead of a single compound, as in case of antibiotics. Such an integrated approach involving phenolic phytochemicals has excellent potential to compliment current antimicrobial strategies (40).

Taking into account this rationale, a phenolic antimicrobial activity model (Figure 8.4) that incorporates the role of proline linked pentose–phosphate pathway provides a better perspective (40) than current putative antimicrobial models for phytochemical action (10). The phytochemical profiles that have the potential to inhibit pathogenic microorganisms (10–12) contain secondary metabolites that are defensive and inducible antimicrobials produced against both invading pathogens and stress. Therefore the methods for exploiting them must take this into account. In certain cases, the induction is associated with action of diphenolic oxidases and resulting modified compounds can have antimicrobial activity (13). In some cases, dihydroxy phenolics are oxidized to highly reactive quinones, which can interact with proteins of the invading pathogens and form melanoid polymers (10). As the compounds responsible for the enzymatic browning reaction of cut fruits and vegetables and an intermediate in melanin pigment production in humans (10), quinones are a

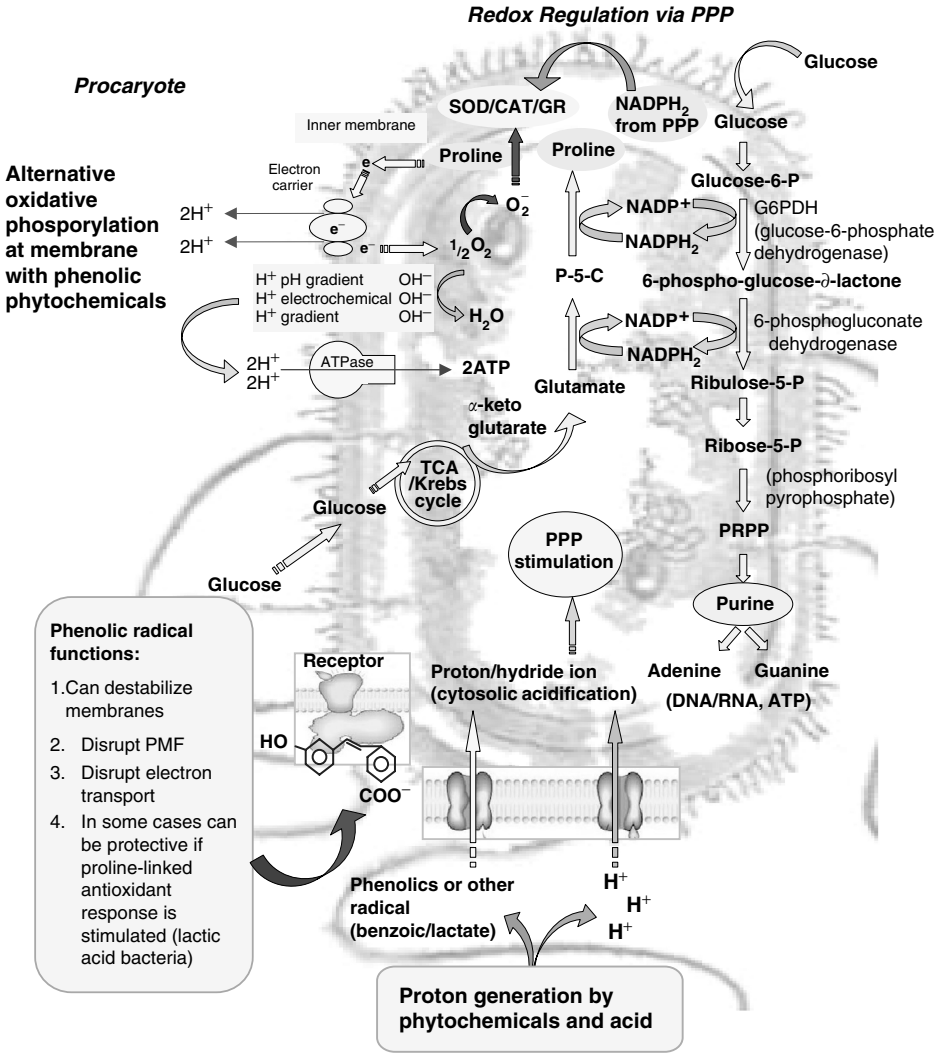

Figure 8.4 Model for inhibition of bacterial pathogens by phenolic phytochemical profiles (containing phenolics that are water soluble and effective in the cytosol as well as partially ethanol soluble phenolics that are effective at the membrane interface) based on membrane changes linked to energy (electron transport and proton flux changes) and cytosolic proton adjustment or lack of it that is linked to praline linked pathways and antioxidant response.

source of stable free radicals and complex irreversibly with nucleophilic amino acids (14) leading to inactivation of proteins and loss of function (10). Potential targets for inhibition in the bacterial cell are surface adhesions, cell wall polypeptides, and membrane bound enzymes (10). In herb species of the Lamiaceae family, phenolic derivatives are largely responsible for antimicrobial activity (2,41,42). Thymol, present in the essential oil of thyme, oregano, savory, sage, and related species, has good antimicrobial activity (11) but has flavor problems and is volatile. Other simple phenolics such as hydroxycinnamic acid derivatives such as caffeic acid, ferulic acid, and *p*-coumaric acid inhibited *E. coli, S. aureus* and *B. cereus* (19) could facilitate more hyper acidification in the cytosol and

could be more effective with phenolics that are membrane targeted. Polymeric phenolics, such as tannins, were inhibitory toward *Listeria monocytogenes, E. coli, S. aureus, Aeromonas hydrophila,* and *Streptococcus faecalis* (20) and could be effective by stacking on the cell membrane and affecting energy function. Tannins could be made more potent in combination with cytosol targeted soluble phenolics. Hydroxylated phenols, such as catechol and pyrogallol, are known to be toxic to microorganisms (10) with a likely mechanism through membrane and cytosolic hyperacidification. The site and number of hydroxyl groups is linked to the antimicrobial effect and in some cases more oxidized forms are more inhibitory (21,22), which could be by inhibiting membrane related functions. In our laboratory we have shown that high rosmarinic acid enriched clonal profiles in ethanol and water extracts are effective in inhibiting *Listeria monocytogenes* (41) and *Helicobacter pylori* (42). We also have had similar success against the same pathogens using elicitor induced or fungal bio processed legume phenolics from soybean and other legumes.

From all the cited studies it is evident that the mode of action of phenolics against bacterial pathogens has not been clearly defined or understood and many modes of action have been suggested. Major mechanism models proposed have focused on the suspected changes in membrane permeability through hydrophobic linked lipid partitioning with certain phenolics to more membrane and cytosolic localized hyperacidity with soluble phenolics, which may affect PMF across the membrane resulting in energy depletion (11,28,29,31,32). Another model has proposed that enzyme inhibition by oxidized compounds through reaction with enzyme sulfhydryl groups or through nonspecific interactions with membrane proteins may explain the inhibition (10,27,36). Even with better models on the mechanism of action, another major limitation of using many phytochemicals is that they are derived from mixed heterogeneous genetic sources and consistency cannot be guaranteed (1,2). Now, with the emergence of antibiotic resistance from overuse of single antibiotics new strategies incorporating plant based antimicrobials are both promising (2,10,40). However, effective development of plant based antimicrobial strategies will require a better model to understand the mechanism of antimicrobial action involving consistent profiles of phenolic phytochemicals that inhibit bacterial pathogens at more than one biochemical steps. This could involve affecting cellular functions both at the membrane level with lipid or cellular interface compatible phytochemicals in conjunction with soluble phenolics that can cause cytosolic hyper acidification that will disrupt dehydrogenases and therefore disrupt the generation of proton motive force for ATP synthesis at an early cytosolic step along with reduced production of reductants for anabolic pathways (40).

An effective strategy proposed in this chapter focuses on the hypothesis that high antioxidant phenolics from single seed origin clonal lines of herbs, sprouted legumes, and fermented fruits would have excellent antimicrobial potential (40). Single seed high antioxidant phenolic profiles that are ethanol and water extracted have been screened, evaluated for antioxidant efficacy, and targeted to inhibit various food borne pathogens and chronic human infections, such as those by peptic ulcer-causing *Helicobacter pylori* (42) and *Listeria monocytogenes* (41). This strategy addresses both the concept of phytochemical consistency through the use of clonal lines and stress (elicitor) based inducible phenolic antioxidants from various developmental phases of growth and also the putative impact on antimicrobial potential. Therefore, using our strategy for developing consistent and inducible phytochemical profiles, an alternative and more robust model (Figure 8.4) for a mechanism of antimicrobial action incorporating the role of a critical control point (CCP) through proline linked pentose–phosphate pathway have been proposed. The mechanism of action of phenolic phytochemicals that may operate in prokaryotes involves the use hyperacidification (protons) from acids and phenolic metabolites and transport protons inside the cell (Figure 8.4), by more acid tolerant prokaryotes (lactic acid bacteria and

some moderately acid tolerant Gram-negative pathogens like *H. pylori*, *Escherichia coli* and *Salmonella*) either passively or through H^+-transport membrane proteins (40). Such acid tolerant prokaryotes may stimulate redox cycling through the proline linked pentose–phosphate pathway and use proline (like the mitochondria of eukaryotes) as an alternative reductant for ATP synthesis at the single outer plasma membrane with oxygen as the terminal electron acceptor (40). As mentioned before, the process of proline biosynthesis could also be coupled to the pentose–phosphate pathway for $NADPH_2$ recycling and to make sugar phosphates for all anabolic needs. By this model, acid tolerant microorganisms could efficiently manage the ATP needs from stress increased oxidative phosphorylation through coupling to pentose–phosphate pathway activity, while recycling excess proton flux from hyperacidification. Proline linked oxidative phosphorylation could excrete excess protons outside the plasma membrane and augment the generation of PMF for ATP synthesis (40). This proline linked metabolism model may occur in acid and phytochemical tolerant lactic acid bacteria (Gram-positive) and in moderately acid and phytochemical tolerant Gram-negative bacteria but is less likely in other acid and phytochemical susceptible Gram-positive bacteria (40). The ethanol, water, and organic acid extracted phenolic antimicrobials would be highly compatible for the given model.

One way to prove this model would be to determine if proline overproducing mutants are more acid tolerant and if this tolerance is associated with increased generation of $NADPH_2$. An important difference in case of prokaryotes is that they have only one outer plasma membrane and no organelles for metabolic adjustment. Depending on the type of membrane modifications that occur between various bacterial species, phenolic radicals may negatively or positively affect membrane related functions, including transport, signaling, receptor modification, and energy metabolism. Membrane related modulation of metabolism could be closely linked to the cytosolic proton linked modulation of proline linked pentose–phosphate pathway. Based on this model, it is likely that Gram-positive bacteria (excluding lactic acid bacteria) would be most susceptible, followed by Gram-negative bacteria, and then by acid tolerant lactic acid bacteria, likely being more tolerant and actually protected by phenolic phytochemicals (as antioxidants) (40).

8.3.2 Control of *Helicobacter Pylori* by Phenolic Antimicrobials from Plants

We have extended our studies on recruiting dietary plant based phenolic antimicrobials in inhibiting food borne pathogens to control and manage ulcer and gastric cancer associated *Helicobacter pylori*. *Helicobacter pylori* induced gastrointestinal disease afflicts millions worldwide, in both developed and developing countries. It was long believed that bacteria could not live in the acidic environment of the stomach, but in 1984, Marshall and Warren (78) reported success in culturing an organism from the gastric mucosal layer of a clinical specimen and proposed that this bacterium, later named *Helicobacter pylori*, was the cause of gastritis and peptic ulcer (78). This proposal has since proved to be correct, as *H. pylori* has been associated with the presence of gastric inflammation (79) and gastric non-Hodgkin's lymphomas (80), and has been identified as a major cause of peptic ulcer disease (81) and of gastric cancer (82).

Helicobacter pylori is a spiral, microaerophilic, Gram-negative bacteria that mainly infects the gastric mucosal layer, but can also enter human primary cells from gastric epithelium, possibly to evade host defenses and antimicrobial treatments (83,84). It infects up to 50% of the global human population (85). *Helicobacter pylori* is associated with gastritis, peptic ulcer and ultimately gastric cancer (80,85,86–89). The infections are mostly asymptomatic, but in all cases involve inflammation of the gastric mucosa, and in about 10% of the infected cases develop duodenal or gastric ulcers leading to cancer of stomach

(90). In developing countries, *H. pylori* infection is as high as 80–90% of the population and this incidence correlates with higher rates of stomach cancers (90). *Helicobacter pylori* infection is currently the highest prevailing bacterial infection worldwide (90). Characteristic traits of *H. pylori* infection are chronic inflammation of the stomach and development of chronic gastritis, which may proceed to gastric cancer (91). An integral part of *H. pylori* infection is the induction of gastric inflammation, which is believed to aid in colonization of the mucosal surfaces (84,92). Pathogenesis of *H. pylori* has also been linked to the presence of an external urease that is embedded on the outer surface of the bacterium (93). Urease is an important enzyme that is produced up to 5–6% of the total protein of *H. pylori* and is linked to its infectivity (90). All clinical isolates of *H. pylori* produce a urease with characteristics unlike those of any other bacterial urease (93–96). Urease negative mutants cannot colonize the gastric tissue environment as evidenced by the failure of urease negative mutants to colonize mice and gnotobiotic piglets (97,98). It is thought that hydrolysis of urea by urease generates ammonia to counterbalance gastric acidity by forming a neutral microenvironment surrounding the bacterium within the gastric lumen (99). This hypothesis is supported by results showing that *H. pylori* survive low pH *in vitro* in the presence of urea and functional urease activity (100,101). A unique feature of *H. pylori* urease is that a significant fraction is found exclusively in the outer membrane (94,102). This urease becomes associated with the surface of *H. pylori* and the urease released as a result of autolysis of a part of bacteria becomes adsorbed to the remaining intact bacteria (99,102). Further research by the same group has indicated that cytoplasmic urease activity alone, though needed, is not sufficient to allow survival of *H. pylori* in acid and the activity of surface localized urease is essential for resistance of *H. pylori* to acid conditions (99). Recent advances, however, have indicated that acidity trigger cytoplasmic urease activity and deletion of the gene *urel* prevents activation of this enzyme (103). Urel protein is a membrane protein with 6 trans membrane segments and is needed for acid stimulated urea uptake triggers the activity of the cytoplasmic urease, which is active down to pH 2.5 (103). Another feature of urease action in addition to sustaining *H. pylori* is the prospect of physical injury in the gastric lumen from ammonia (104,105). Ammonia may also lead to inflammation due to host response or due to other mucosal damage (106). Other factors that may be involved in the pathogenesis of *H. pylori* and the colonization of mucosal surfaces are the adhesion and motility of *H. pylori* (91), the induction of IL-8 and ROS in host cells (83), and the induction of COX-2 in host cells (107). High rates of *H. pylori* infection are associated with low socioeconomic status and high densities of living and prevalence of infection increases with age worldwide (108–110).

8.3.3 Current Treatment Strategies for *H. Pylori* and Its Limitations

Before the link between *H. pylori* and gastrointestinal diseases was discovered, the main course of treatment for these diseases was to assuage the symptoms with acid (proton pump) inhibitors (PPI). Now that a link to *H. pylori* has been established, antibiotics are the current standard of care for patients with gastritis and peptic ulcers, with the rationale that elimination of *H. pylori* will eliminate a major cause of gastric disease and reduce the risk for subsequent development of gastric adenocarcinomas (111). Typical therapy for *H. pylori* infection consists of a first line combination of a PPI and a bismuth compound, and two antibiotics taken for at least 7 days, followed by a second line treatment of four PPIs taken for at least 7 additional days (112). When followed religiously, the antibiotic regimen has been shown to eradicate *H. pylori* in approx. 80–90% of the cases, although there is some debate as to whether *H. pylori* is actually being eradicated or merely suppressed (112).

Difficulties with current *H. pylori* therapies contribute to treatment failure at any age. Despite the high success rate of antibiotic–PPI combination therapy against *H. pylori*,

low compliance due to negative side effects (i.e., diarrhea, drug hypersensitivity, antibiotic associated colitis), not to mention the risk of nephrotoxicity when bismuth is used, continues to be a problem (84,113,114). Cost and practicality of the treatments are also concerns. Primary and acquired resistance of *H. pylori* to the antimicrobial agents is a major reason for the failure of eradication therapies (115). Due to the increasing incidence of antibiotic resistant strains of *H. pylori*, there is still a need for new compounds or alternative phenolic phytochemical strategies to combat *H. pylori* as future therapies.

8.3.4 Dietary Phenolic Phytochemical Strategies for Control of *H. Pylori*

Much recent research has focused on compounds from dietary sources as new or alternative strategies to fight *H. pylori*. Studies have indicated the antimicrobial potential of medicinal herbs and food plant metabolites against *H. pylori*. Highly selective antimicrobial activity of novel alkyl quinolone alkaloids from Chinese herbal medicine, Gosyuyu, against *H. pylori in vitro* has been reported (116). Eradication potential of Chinese herbal medicine, without emergence of resistant colonies, has also been reported (117). Among plant food extracts and ingredients, tea catechins have been reported to have *in vitro* and *in vivo* activities against *H. pylori* (118). Among various catechins, epigallocatechin gallate showed the strongest activity (118). In studies on synergistic antimicrobial effects of garlic, the combination of garlic based on allicin content with omeprazole showed antimicrobial benefits indicating the need for clinical studies (119,120). Susceptibility of *H. pylori* to the antimicrobial activity of manuka honey has been reported (113). Honey is a traditional remedy for dyspepsia and use of phytochemical enriched honey is a traditional practice without a known rational basis (113). Therefore, evaluating the inhibition by honey of *H. pylori* that has been suggested as the probable cause of dyspepsia has merit and results are promising (113). Plant phenolic metabolites like capsaisin from diet are known to be associated with low rate of ulcers through inhibition of *Helicobacter pylori* (121). Another interesting food based inhibition of *H. pylori* is the *in vitro* antibacterial activity of Chilean red wines (122). The main active compound that was suggested to be the antimicrobial compound was resveratrol (122). In other studies, extracts from a yeast fermented soymilk yogurt (123), bee propolis (124), licorice (125), broccoli (126), and turmeric (127), and in our laboratory, clonal oregano (42) demonstrated an ability to inhibit the *in vitro* growth of *H. pylori*. Although the mechanism of action of each extract remains largely unknown, in majority of these cases antibacterial activity was linked to the presence of phenolic compounds.

8.4 DIETARY SOYBEAN APPROACH FOR CONTROL OF *H. PYLORI*

A strong inverse association between consumption of microbially fermented (bioprocessed) soybean (natto, tofu) and *H. pylori* infection (128) and incidence of death from stomach cancer (129) has been observed in Japanese populations. Fermented soybean curd (tofu) is a common source of vegetable protein in Japan (128). Sprouts with inducible phenolics and microbially fermented or bioprocessed soybean are rich in isoflavonoids and phenolics that have antioxidant activity (130–133). Many phenolic antioxidants (in eukaryotic cells) also possess strong antimicrobial activities against prokaryotic bacteria, therefore, phenolic extracts from sprouts and microbially bioprocessed soybean that possess antioxidant activity potentially may also possess antibacterial activity, specifically anti *H. pylori* activity. Therefore the main focus of our investigations is to explore the potential of phenolic rich extracts of sprouted soybean and solid-state bioprocessed defatted soybean by the dietary fungus *Rhizopus oligosporous* (used in tempeh production in

Indonesia and the U.S.*)* to inhibit the *in vitro* growth and pathogenesis related urease of *H. pylori*. Our preliminary results suggest:

LISTThat the phenolic rich, bioprocessed soybean extracts possess strong anti *H. pylori* activity.

That sprouting linked elicitor stimulation of phenolics and bioprocessing of soybean by *R. oligosporous* increases anti *H. pylori* activity in soybean extracts in a manner dependent upon the sprouting stage, elicitor concentration, and duration of solid-state growth of the dietary fungus.

Hint at a mechanism of action which may involve diphenolic and polymeric phenolic antioxidants, which may inhibit urease.

Therefore, the hypothesis that elicitor inducible phenolic antioxidants from sprouted and fermented soybean can also inhibit *H. pylori* holds much promise for improved efficacy and support dietary therapy using soybean phenolic extracts in food systems. Other studies have postulated that antioxidants such as vitamin C and astaxanthin may constitute supportive treatment for controlling *H. pylori* infections through support of host (eukaryotic) response (134). Our preliminary studies suggest that phenolic antioxidants from soybean may be better. They can not only, potentially, provide a supportive redox environment in the stomach (eukaryotic cell) through the antioxidant improved functionality, but more importantly, can be inhibitory to prokaryotic pathogens like *H. pylori,* a prokaryote with a single membrane is susceptible to the same phenolic antioxidant*s*. Further, phenolic antioxidants could be potentially inhibitory against the pathogenesis linked urease and this will be evaluated using a novel plate assay described in this chapter. Through inhibition of urease by phenolics, hyperacidification at the membrane level can be maintained and as discussed for the general model (Figure 8.4), this proton efflux coupled to other functions of dietary phenolics can now be more effective in inhibiting *H. pylori* (Figure 8.5*)*. Because dietary phenolics are offered as phenolic profiles it is likely to reduce the emergence of antibiotic resistance.

Extracts from dietary legumes and other phenolic phytochemicals can be important source of disease preventive phytochemicals which potentially can inhibit the target prokaryotic bacterial pathogens like *H. pylori*, which have a single plasma membrane that also contains the pathogenesis associated urease, and at the same time can be antioxidant, in function, in host eukaryotic cells that have organelle compartmentalization to manage a redox response linked to phenolics, triggering a protective response. Our strategy focuses on the hypothesis that inducible high antioxidant phenolics from clonal herbs screened from heterogeneous sources, seed sprouts of single genetic origin, and phenolic aglycones with high antioxidant activity from fermented dietary botanicals would have excellent antimicrobial potential. Our strategy also addresses the concept of phytochemical consistency through the mobilization of stress (elicitor) inducible phenolic antioxidants in various developmental phases of growth of soybean sprouts and bioprocessed extracts and evaluates the antimicrobial potential against *H. pylori*.

8.4.1 Sprouting of Soybean and Phenolic Antioxidant Stimulation Methods

We are exploring the use of high antioxidant sprout extracts of soybean and other legumes for antimicrobial benefit against gastric cancer linked *H. pylori* and therefore developed a diet based bacterial management strategy. Seeds of soybean are imbibed overnight in bacterial polysaccharide elicitors normally used in foods, such as gellan gum and xanthan gum (135). In earlier work on the legume mung bean (135), there was clear evidence that stress-modulating polysaccharide elicitors will stimulate phenolic content and antioxidant activity during the sprouting stages as a likely protective mechanism for the young

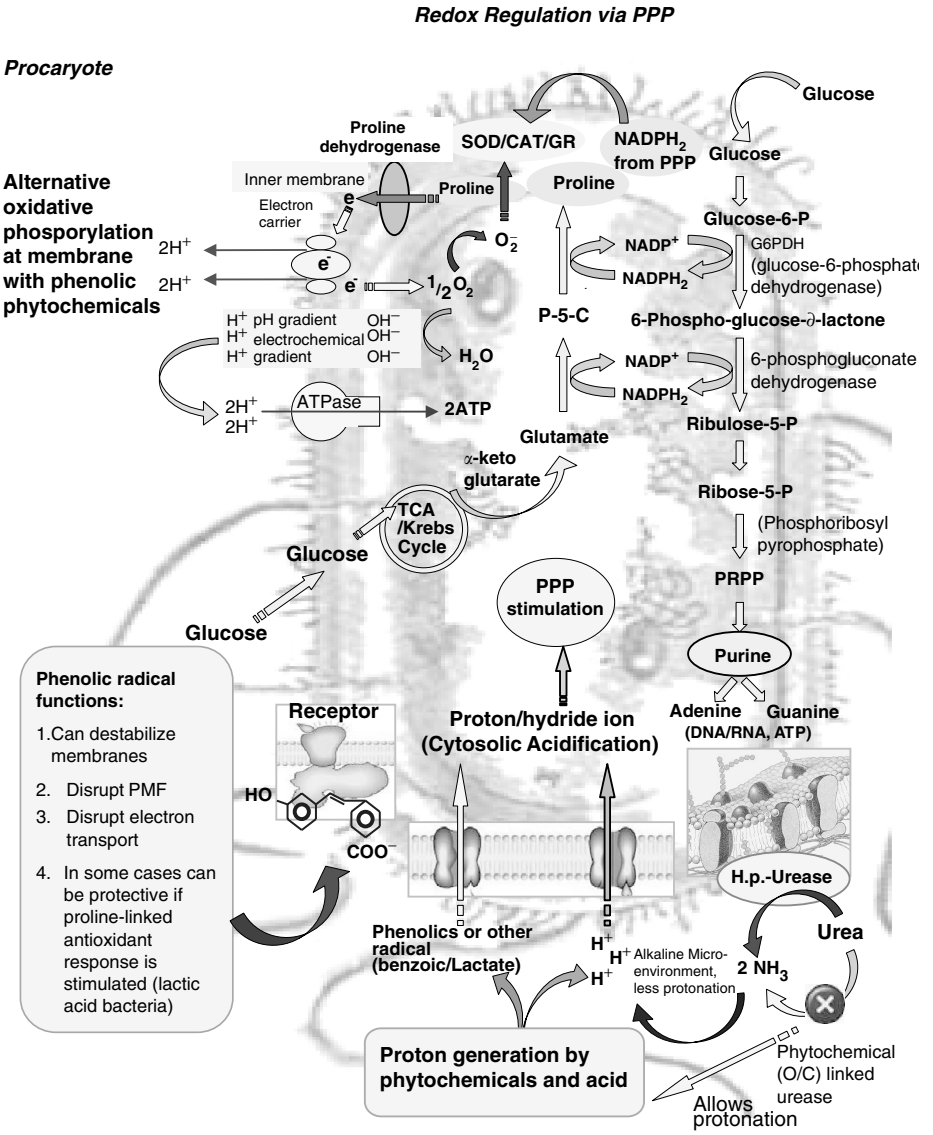

Figure 8.5 Model for inhibition of *Helicobacter pylori* by phenolic phytochemicals as in Figure 8.4 but also takes into account the role of urease.

seedling. Previously it has also been established that the percent of phenolic aglycones were the highest in soybean sprouts (136). The biological activity of the phenolics is stronger in the aglycone form than in the glycoside form. It is thought that isoflavonoids such as genistein and daidzein have a specific role during growth stages of soybean (130,136). Preliminary results from our laboratory have indicated that during dark germination, phenolic content was stimulated (inducible phenolics) by the given elicitors (137). Polysaccharide elicitor extracts from *Pseudomonas elodea* (gellan gum) are currently being tested in the concentration range of 0–500 mg/l of imbibed water. After elicitor treatment for 12 hours, sprouting through a seven day dark germination stage was done in

specially designed plastic containers. Phenolic profiles, antioxidant activity and *H. pylori* inhibition studies was undertaken on extracts of various development stages. Optimized phenolic extracts was used for further *H. pylori* inhibition (137) and in the future for urease inhibition studies. Several soybean varieties from genetic stocks in U.S. and Asia are currently being tested. We have, currently, access to over 50 soy genetic accessions for testing. The basal uninduced phenolic content of soybean is around 1 to 3 mg/g of dry weight (DW) of sprouted and fermenting soybean, which is than stimulated to 4–5 mg/g DW.

8.4.2 Phenolic Response and Characterization of Soybean Extracts Inhibiting *H. Pylori* Urease

Initial preliminary efforts have so far focused on polysaccharide elicitor stimulated soybean seedling extracts, based on the rationale that if an individual clonal line (single seed origin variety soybean is self pollinating) has genetically evolved to produce high phenolics in a heterogeneous background, it may also have the genetic, biochemical and developmental mechanism to tolerate the same high level of phenolics and such high phenolics could have protective antioxidant benefits and antimicrobial effects against the bacterial pathogens or its elicitors. Further, we have also developed an innovative plate assay system to screen phenolic extracts that are inhibitory to *H. pylori* urease. In this assay system we have *H. pylori* medium at pH 5.5 with addition of 10 mM urea and bromophenol blue (0.1 g/L) as pH indicator. *Helicobacter pylori* will survive low pH conditions by using urea from the acidic environment and create a microenvironment of high pH by excreting urease mediated ammonia. When this happens, the bromophenol blue will turn blue as pH moves higher toward neutral. We have evidence that soybean extracts in a concentration dependent (100 μg (micro gram)/disk to 400 μg/disk) manner can inhibit urease activity as indicated the bromophenol blue remaining yellow at pH 5.5.

8.4.3 Solid-State Bioprocessing of Soybean Using *Rhizopus Oligosporus*

Rhizopus oligosporous used in soy Tempeh foods has been developed through solid-state bioprocessing of whole soy and would be a more suitable approach to enhance phenolic metabolites for inhibition of *Helicobacter pylori* (131,137). Using the methods developed in our laboratory (131), phenolic aglycones are being optimized from various varieties of defatted soy, and the fungal growth is carried out in Erlenmeyer flasks over a ten day period. Total soluble phenolics in water and ethanol extracts have been optimized with various specific phenolic ratios as in sprouts and using low, high, and medium phenolic categories of various soybean varieties.

8.5 RECENT PROGRESS AND OTHER STRATEGIES FOR DESIGNING PHENOLICS PHYTOCHEMICALS AS ANTIMICROBIALS

Using the clonal screening strategy we have isolated several high phenolic clonal herbs of oregano, thyme, rosemary, and spearmint of single seed origin. One superior oregano clonal line has been shown to be effective against *L. monocytogenes* in broth and meat system (41) and *H. pylori* in disk assay system (42). Further we have found that oregano extracts optimized on a phenolic basis and combined with cranberry phenolics shows synergistic effect in both broth and food systems against *L. monocytogenes* and *Vibrio parahaemolyticus* (64,138) and in disk assay system against *H. pylori* (139).

The elicitor induced spouting model in seed legumes was used to evaluate antimicrobial potential of various phenolic and antioxidant activity stages of sprouting against

H. pylori. Phenolic extracts of pea (140), chickpea (141), fenugreek (142), soy (137), and mung bean (143) were inhibitory against *H. pylori* in disk assays. Except for fenugreek, in all other sprout extract tested, the antimicrobial activity coincided with likely polymeric stage as indicated by high sprout peroxidase activity, when soluble phenolics were the lowest (137,140,141,143). In case of fenugreek, the highest antimicrobial activity coincided with the stage of highest soluble phenolics (142).

We have also developed solid-state bioprocessing systems using filamentous fungi, where under aerobic conditions phenolics from soy, cranberry, and pineapple substrates were mobilized (137,144–146). In case of soy bioprocessing with Tempeh fungus, *Rhizopus oligosporous* enhanced functional polymeric phenolics, as indicated by laccase activity at 2 days of growth, and had the highest anti *H. pylori* activity (137). In the same study, late stages, even though they had highest phenolics, had reduced antimicrobial activity. In the case of cranberry bioprocessing with *Rhizopus oligosporous* and *Lentinus edodes,* highest antimicrobial activity was found after bioprocessing, and effective antimicrobial activity varied for targeted bacterial food borne pathogens based on nitrogen sources and method of extraction (144,145). It was postulated that the type of phenolics mobilized during bioprocessing could have affect on the antimicrobial functionality (144,145). In other studies, pineapple wastes enriched with soybean and bioprocessed with *R. oligosporous* had effective anti *H. pylori* activity after 10 days of growth.

8.6 SUMMARY

Novel tissue culture techniques for screening high phenolic clonal lines and phenolic phytochemical bioprocessing approaches through sprouting from seed legumes and microbial solid-state mobilization from diverse dietary botanical substrates have been developed to isolate novel dietary and food grade phenolic metabolites as antimicrobials. In this effort only water and ethanol soluble phenolics which can likely create a localized hyper acidification at the cellular membrane interface and cytosol have been extracted and evaluated for antimicrobial effects. The goal is to design dietary phenolics that work at the cellular interface, and cytosol to disrupt the simpler prokaryotic cellular metabolism at membrane, energy, and cytosolic dehydrogenase level. In this model the functional property of dietary phenolics for localized cellular hyperacidification is coupled to a proposed critical control point (CCP), proline linked pentose–phosphate pathway (PLPPP). The presence and management of this PLPPP with membrane linked energy metabolism and cytosolic linked proton management through dehydrogenases serve as the central weak points for antimicrobial strategies. The same phenolics in eukaryotes, due to organelle compartmentalization, are likely to be managed through an antioxidant enzyme response and which in turn can positively support host response to bacterial pathogens (40).

Genetic Mechanisms Involved in Regulation of Mycotoxin Biosynthesis

Michael J. Miller and John E. Linz

CONTENTS

9.1 INTRODUCTION

9.1.1 Mycotoxins

Mycotoxins are a highly diverse family of secondary metabolites synthesized by molds as they grow on a variety of economically important food and feed crops including grains, oilseeds, and spices as well as fruits, dairy products, and meat products (1,2). Mycotoxins are biologically active compounds that can have mild to severe adverse health effects (including death) on animals that ingest contaminated feed (1,2,23,118). A significant body of evidence strongly suggests that mycotoxins have both acute and chronic effects on human health as well (1,2,23,118). Because of the potential health risks, the levels of aflatoxins and deoxynivalenol (DON, a trichothecene mycotoxin) are regulated in food and feed crops in the USA (2). Several countries have regulatory limits for additional mycotoxins including patulin, T-2 toxin, zearalenone, fumonisins, and ochratoxin A. The country specific regulatory limits for various mycotoxins can represent important barriers to international trade of contaminated commodities. The presence of mycotoxins in food and feed results in huge health and economic costs. Up to 25% of the world's crops are affected by mycotoxigenic molds each year, resulting in billions of dollars in losses (1). In the USA alone, losses due to aflatoxins, fumonisins, and deoxynivalenol are estimated at over $900 million annually (2).

Mycotoxin contamination of crops in the US occurs most frequently in specific regions and on specific crops (1) which strongly suggests that the growth environment (that is, moisture, temperature, and light), the genotype of the host plant, and the genotype of the fungal pathogen (or saprophyte) all play important roles in determining the degree of mycotoxin contamination. These factors directly or indirectly control the expression of genes involved in mycotoxin synthesis. An understanding of the genetic mechanisms that regulate mycotoxin gene expression will lead to novel control methods to reduce or eliminate contamination of food and feed crops. This chapter will provide the reader with current information regarding the genetic mechanisms that regulate mycotoxin gene expression in response to the growth environment. Although many mycotoxins are important from an economic and health standpoint, we provide examples primarily from the aflatoxins, trichothecenes, and fumonisins to illustrate key points, because a significant body of information has accumulated regarding the genes involved in their synthesis (23,118,142). Less is known about other groups of mycotoxins and these will be discussed only to a limited extent.

We begin with a summary of each major group of mycotoxins that includes the chemical structure, the primary food or feed crops affected, the mechanism of toxicity, and a brief overview of the biosynthetic pathway. This information provides the necessary framework for the detailed discussion of genetic mechanisms that follows. In this review, we will present fungal gene names by three lower case italicized letters followed by a capital letter locus designation (*aflR, pacC*). Protein names will be presented with a capital letter, followed by two lower case letters (no italics) and the capital letter locus designation (*aflR, pacC*). Exceptions to these conventions are clearly explained in the text.

9.1.1.1 Aflatoxins

Aflatoxins are a family of closely related, polyketide derived difuranocoumarins that are synthesized by several *Aspergillus* species (23,25). *Aspergillus flavus* and *A. parasiticus*

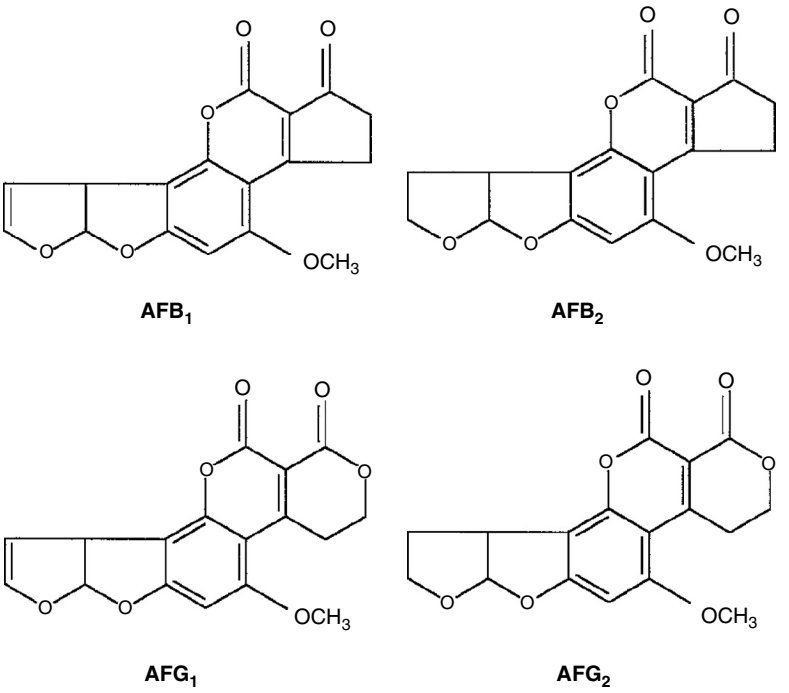

Figure 9.1 Molecular structure of the primary aflatoxins

are the predominant toxigenic species and, under appropriate environmental conditions, they can produce toxin on a variety of economically important host plants including corn, cottonseed, treenuts (almonds, pistachios, and walnuts), peanuts, figs, and spices (1,2). Aflatoxins B_1 (AFB_1), B_2, G_1, and G_2 are the primary aflatoxins observed in contaminated food and feed (Figure 9.1); AFB_1 is the most abundant, toxic, mutagenic, and carcinogenic of the naturally occurring aflatoxins (51).

Human aflatoxin exposure occurs primarily through ingestion of contaminated crops, by ingestion of products derived from animals given contaminated feed, or by inhalation of toxin containing materials (50). In the liver, aflatoxins can be metabolically detoxified by several different enzymes. However, aflatoxins can be converted to the 8,9 epoxide by a specific mixed function, cytochrome p450 monooxygenase (3A4) in the liver after ingestion (51). This highly reactive molecule then can form protein adducts (primarily at lysine) and DNA adducts (primarily at guanine) resulting in abnormalities in protein function and malfunctions in the replication, repair, and expression of DNA (51). The 8,9 epoxide is thought to intercalate into double stranded DNA, allowing reaction with ring nitrogen 7 in guanine (181). In animals, and presumably in humans as well, DNA damage (mutations) can result in development of hepatocellular carcinomas, presumably by activating or inactivating specific genes involved in signal transduction pathways that regulate cell growth (4,46). Another proposed mechanism of toxicity is the generation of reactive oxygen species (ROS) in cells exposed to AFB_1 (133) resulting in lipid peroxidation and cell injury (121). Experimental data clearly demonstrate that aflatoxins are carcinogenic in animals; a significant body of epidemiological evidence also suggests that aflatoxins, together with hepatitis B virus, are risk factors for human liver carcinoma (129).

At least 17 different enzyme activities catalyze AFB_1 biosynthesis (23,108,142,161). These activities are encoded by up to 25 genes clustered on one chromosome in *A. parasiticus*

Table 9.1
Summary of gene names, enzyme names, and enzyme activities in aflatoxin synthesis.

Gene Name	Enzyme Name (Reported)	Activity
fas-2 (aflA)	fatty acid synthase (α)	Converts acetate to hexanoate
fas1 (aflB)	fatty acid synthase (β)	Converts acetate to hexanoate
pksA (aflC)	polyketide synthase	Extends hexanoate to decaketide
nor-1 (aflD)	norsolorinic acid reductase	Converts norsolorinic acid to averantin
norA (aflE)		Converts norsolorinic acid to averantin
norB (aflF)		Converts norsolorinic acid to averantin
avnA (aflG)		Converts averantin to hydroxyaverantin
adhA (aflH)	alcohol dehydrogenase	Converts hydroxyaverantin to averufin
avfA (aflI)		Converts averufin to versiconal hemiacetal acetate (VHA)
estA (aflJ)	esterase	Converts VHA to versiconal
vbs (aflK)	versicolorin B synthase	Converts versiconal to versicolorin B (VerB)
verB (aflL)	desaturase	Converts VerB to versicolorin A (VerA)
ver-1 (aflM)	reductase	Converts VerA to demethylsterigmatocystin (DMST)
verA (aflN)		Converts VerA to DMST
omtB (aflO)	O-methyltransferase	Converts DMST to sterigmatocystin (ST)
omtA (aflP)	O-methyltransferase	Converts ST to O-methylsterigmatocystin (OMST)
ordA (aflQ)	oxidoreductase	Converts OMST to aflatoxin B1
aflR		positive transcription activator
aflJ (aflS)		putative transcription co-activator
aflT		putative toxin efflux pump
cypA (aflU)	p450 monooxygenase	function undetermined
cypX (aflV)	p450 monooxygenase	function undetermined
moxY (aflW)	monooxygenase	function undetermined
aflX	oxidase	function undetermined
aflY	open reading frame	function undetermined

and *A. flavus* (153,168) (Table 9.1, Figure 9.2) and a similar gene cluster in *A. nidulans* (synthesizes sterigmatocystin, a late aflatoxin pathway intermediate) (15). During aflatoxin synthesis, ten molecules of acetyl CoA are polymerized head to tail by a specialized fatty acid synthetase (13,95,157) in association with a polyketide synthetase (32,153) to generate the first stable pathway intermediate, norsolorinic acid. The remainder of the biosynthetic pathway is dedicated to modification of this hydrophobic decaketide molecule to generate the highly reactive bisfuran ring structure and to modification of the coumarin moiety to carry either a cyclopentenone (B aflatoxins) or lactone (G aflatoxins) ring structure (108).

9.1.1.2 Trichothecenes.

Trichothecenes are a large family of sesquiterpene derived mycotoxins synthesized by several species of the filamentous fungus *Fusarium*, several other fungal genera (*Myrothecium*, *Stachybotrys*, *Trichothecium*) and even one plant genus (*Baccharis*) (118). There are over 180 unique trichothecenes which share a common core trichothecene structure (Figure 9.3)

Figure 9.2 Genomic organization of the aflatoxin biosynthetic gene cluster in *Aspergillus parasiticus*. Arrowheads indicate the direction of transcription. Drawn approximately to scale

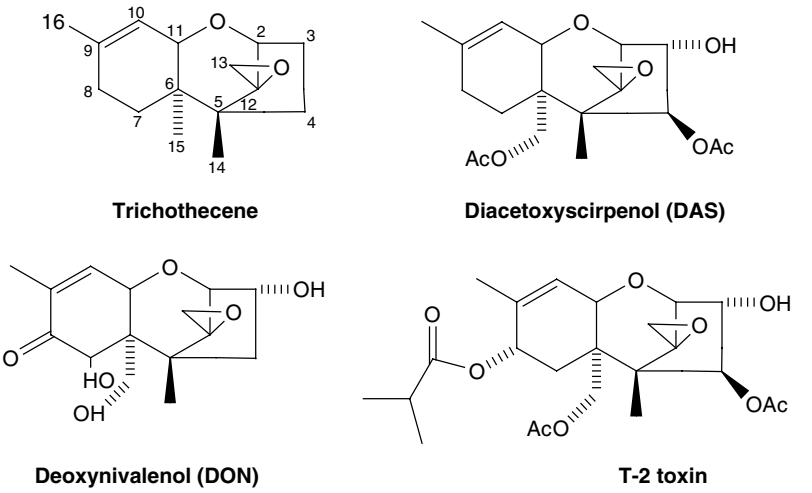

Figure 9.3 Chemical structures of trichothecene toxins

and generally all have an epoxide residue at carbons 12 (C-12) and 13 (C-13) and a double bond between C-9 and C-10. The trichothecenes are placed into four separate groups based on modifications to the core trichothecene molecule (154). Trichothecene contaminated grains, including wheat, barley, maize, and rye, represent the most important sources for human and animal exposure. Of the trichothecenes, DON is among the most commonly encountered in terms of frequency and concentration in grains (123).

Trichothecenes are potent protein synthesis inhibitors. This inhibition results in numerous acute toxic effects on animals including diarrhea, nausea, vomiting, dysfunction of the central nervous system, necrosis of lymphoid tissue and bone marrow, and death (1). Specific trichothecenes have been shown to have dose dependent effects on immune system function. For example, low doses of DON stimulate IgA synthesis in mice resulting in symptoms reminiscent of IgA nephropathy in humans (10). At higher doses, DON induces apoptosis in lymphocytes (163) and suppresses immune system function, resulting in increased susceptibility to bacterial and viral infection (10).

The trichothecenes are synthesized by polymerization of the isoprenoid intermediate farnesyl pyrophosphate by a trichodiene synthase (47). The remainder of the pathway involves a series of modifications of trichodiene to generate a variety of end products including DON (*F. culmorum*), T-2 (*F. sporotrichioides*), and diacetoxyscirpenol (*F. sporotrichioides*) (Figure 9.3). Like the aflatoxin pathway, the genes involved in trichothecene biosynthesis, called *tri* genes, are clustered and appear to be coordinately regulated (81,118).

9.1.1.3 Fumonisins

Fumonisins are aminopolyol mycotoxins synthesized by several *Fusarium* species including *F. moniliforme*, *F. anthophilum*, *F. dlamini*, *F. napiforme*, *F. nygamai*, *F. oxysporum*, and *F. proliferatum* (110,118). Fumonisins consist of a 20 carbon eicosane backbone with an amino group at C-2 and hydroxyl groups at C-3, C-5, or C-10 (Figure 9.4). Other modifications include methyl groups at C-12 and C-16, and propane-1,2,3 tricarballylic acid moieties esterified at C-14 and C-15. The fumonosins are placed into 2 major groups based on structure, group B and group A (amino group is acetylated). Fumonisin B_1, in group B, is the most abundant and is produced predominantly by *F. moniliforme* and *F. proliferatum* growing on

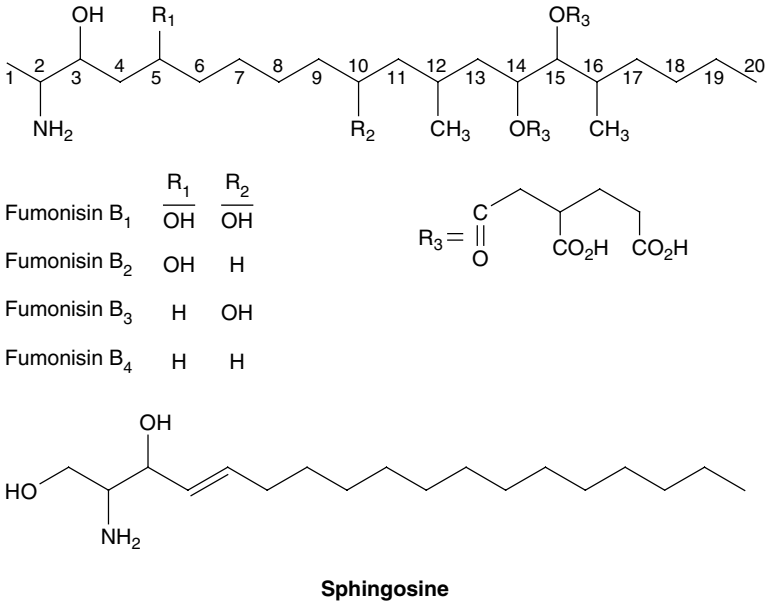

Figure 9.4 Chemical structures of fumonisins

maize. Ingestion of fumonisin contaminated maize has been epidemiologically associated with human esophageal cancer in China and South Africa (96). In animals, fumonisin ingestion has been linked to cancer in rats, pulmonary edema in swine, and leukoencepahlomalacia in horses (96). This mycotoxin also causes apoptosis in a variety of cell types in culture and in kidney and liver cells in rats *in vivo* (150,151). It has been proposed that the toxic effects of fumonisins arise due to disruption of sphingolipid metabolism (126). In support of this hypothesis, fumonisins inhibit the activity of sphinganine n-acetyltransferase, which converts sphinganine to dihydroceramide and sphingosine to ceramide (156). The altered sphinganine/sphingosine balance presumably alters sphingolipid signaling which influences cell growth and death Following the pattern established for aflatoxins and trichothecenes, the currently identified genes involved in fumonisin biosynthesis, called *fum* genes, are coordinately regulated and clustered on a single chromosome (130). Although information on the details of the biosynthetic pathway is still limited, fumonisin synthesis is predicted to include at least five steps: (1) synthesis of a linear polyketide; (2) condensation of the polyketide with alanine; (3) reduction of a polyketide carbonyl group to hydroxyl; (4) hydroxylation of up to 4 polyketide carbons; and (5) esterification of tricarboxylic acid moieties to two hydroxyls (130). Cloning and functional analysis of several clustered genes encoding a polyketide synthetase (130), a cytochrome p450 monooxygenase, a type III alcohol dehydrogenase, a class II " amino transferase, and a dioxygenase (130) provide an important framework for developing a more detailed understanding of the synthesis of this polyketide derived mycotoxin.

9.2 MECHANISMS OF MYCOTOXIN GENE REGULATION

9.2.1 Transcriptional Regulation

Mycotoxins are secondary metabolites produced by several species of fungi. As secondary metabolites, mycotoxins are not constitutively synthesized. Rather, mycotoxin biosynthesis

is a complex process that responds to developmental, environmental, and nutritional cues. One primary means that fungi utilize to regulate mycotoxin biosynthesis appears to be transcriptional regulation of the mycotoxin biosynthetic genes. Aflatoxin and trichothecene biosynthesis are the most characterized of the mycotoxins. Information gathered about aflatoxin and trichothecene biosynthesis has been helpful for researchers studying other mycotoxin biosynthetic pathways. In the following sections, the regulation of aflatoxin and trichothecene biosynthesis gene transcription is reviewed with brief mention of other mycotoxin pathways.

9.2.1.1 Aflatoxin Synthesis

9.2.1.1.1 AflR – Discovery Using parasexual analysis, a mutation in the *afl2* locus in *A. flavus* strain 650 was mapped to linkage group VII which contained nine other putative aflatoxin genes providing preliminary evidence for an aflatoxin gene cluster (8). The parental strain accumulated norsolorinic acid (Table 9.1) whereas *A. flavus* 650 did not accumulate this early pathway intermediate (8). Metabolite feeding studies and enzyme activity measurements of *A. flavus* 650 demonstrated that several aflatoxin biosynthetic enzymes were not present, suggesting that perhaps the mutation in *afl2* affected a regulatory gene and was responsible for the phenotype (116). The gene was later cloned in *A. flavus* by complementation and named *aflR* (116). Subsequently, *aflR* homologues were identified in *A. parasiticus* (31) and *A. nidulans* (169).

9.2.1.1.2 AflR – Function Several independent lines of biochemical evidence indicate a regulatory role for *aflR*. Metabolite feeding studies and enzymatic activity measurements with *A. flavus* 650 (*aflR* mutant) and wild-type *A. flavus* demonstrated that *aflR* is necessary for the aflatoxin biosynthetic enzyme activities to be detected (116). Later, studies demonstrated that *aflR* is required for aflatoxin biosynthetic gene transcript accumulation (169). Insertion of an additional copy of *aflR* into an *A. parasiticus* O-methylsterigmatocystin producing strain resulted in the overproduction of pathway intermediates including O-methylsterigmatocystin (31). In addition, insertion of an additional copy of *aflR* in *A. parasiticus* resulted in the transcription of pathway genes under aflatoxin noninducing conditions (34). Use of *aflR* linked with an inducible promoter in *A. nidulans* demonstrated that induction of *aflR* under aflatoxin noninducing conditions could activate genes in the biosynthetic pathway (169). Based on amino acid sequence identity, AflR was proposed to belong to a common class of fungal transcription factors called zinc binuclear cluster proteins that includes Gal4 (160). While the aminoterminus of AflR contains a DNA binding domain, the carboxyl terminus has a highly acidic region that functions as a transactivation domain (37). However, the total acidity in this region was not a major determinant in AflR transactivation (37).

DNA binding by AflR has also been investigated. Using methylation interference footprinting and electrophoretic mobility shift assays (EMSA), the palindromic AflR binding site was first identified as TCGNNNNNCGA in the *stcU* promoter in *A. nidulans* (62). The consensus AflR binding site was later defined as TCGSWNNSCGR (S = C/G, W = A/T, R = A/G) based on *in vitro* binding studies with recombinant AflR (61). Recombinant AflR binds to several aflatoxin biosynthetic gene promoters *in vitro* (52,54,62,105). AflR *cis*-acting sites have been shown to be necessary for transcriptional activation of several aflatoxin biosynthetic genes *in vivo* including *stcU* (62), *pksA* (55), *avnA* (26) and *nor-1* (116). Based on these and other data, AflR is proposed to be necessary for transcriptional activation of several, if not all, aflatoxin biosynthetic genes.

9.2.1.1.3 AflR – Regulation Aflatoxin synthesis is affected by environmental and nutritional factors such as pH, temperature, carbon source, and nitrogen source (93,94,107).

Because AflR is a pathway regulator, the simplest model for mediating the effects of these environmental and nutritional signals on aflatoxin gene transcription is directly through the *aflR* promoter. In support of this model, the timing of expression of *aflR* in response to these stimuli mimicked the expression of aflatoxin structural genes (93,107). *Aspergillus parasiticus* AreA (major nitrogen regulatory protein) was shown to bind to the AflR promoter *in vitro*, yet *in vivo* significance is unknown (38). A PacC (pH sensing) *cis*-acting site has also been identified in the *aflR* promoter using *in vitro* methods (52). A functional AflR binding site was located in the *aflR* promoter and is necessary for *aflR* transcription *in vivo,* suggesting autoregulation (52). Additional studies on the transcriptional regulation of *aflR* are needed in order to understand how environmental, nutritional, and even developmental stimuli affect aflatoxin biosynthesis.

9.2.1.1.4 Evidence for Other Transcription Factors Though AflR is necessary for transcriptional activation of several, if not all, aflatoxin biosynthetic genes (26,55,62,15), there is evidence for the involvement of additional transcription factors. Studies with the *pksA* promoter (55) provided evidence that the transcription factors PacC (pH sensing) and BrlA (sporulation) can impact *pksA* transcriptional regulation through *cis*-acting sites in the *pksA*/*nor-1* intergenic region (Figure 9.5). However, deletion of the consensus *cis*-acting sites for PacC and BrlA did not affect *nor-1* transcriptional regulation in *A. parasiticus* in submerged culture (105).

The *A. nidulans* gene *stcU* (*A. parasiticus ver-1* homologue) also appears to be regulated by additional transcriptional factors besides AflR. A full length *stcU* promoter fused to a glucuronidase (GUS) reporter resulted in only a two- to threefold increase in activity when transformed into a wild-type strain compared to transformation into an *aflR* mutant strain (62). In addition, substitution of both AflR binding sites in this promoter only resulted in an approximately fivefold reduction (not reduced to baseline expression levels) in GUS activity (62). Due to the relatively high activity in the *aflR* mutant strain and the moderate decrease resulting from binding site substitution, the possibility exists that other transcriptional activators besides AflR are involved in *stcU* transcriptional activation (62). For *avn*A in *A. parasiticus*, substitution of the AflR binding site resulted in a tenfold decrease in promoter activity (26). While there is no evidence of other transcriptional activators in the *avnA* promoter, a potential *cis*-acting site for a repressor of aflatoxin biosynthesis was located (26). Deletion of 78 bp upstream of an AflR binding site in an *avnA*::GUS reporter construct resulted in a threefold increase in reporter activity (26). In addition, protein extracts collected under nonaflatoxin inducing conditions demonstrated specific binding to this region (26).

The *nor-1* gene is perhaps the most studied of all the aflatoxin structural genes. A detailed analysis of the *nor-1* promoter has identified several *cis*-acting sites including AflR1, AflR2, a putative TATA box, CRE1 and NorL (116,117) (Figure 9.5, Figure 9.6).

Figure 9.5 Schematic of the *nor-1/pksA* intergenic region in *A. parasiticus*. The numbers indicate the number of nucleotides included upstream from the primary transcriptional start site of *nor-1*. Several potential *cis*-acting sites are indicated including the AflR binding sites AflR1, AflR2 and AflR3 and PacC1 and BrlA3. The location of an open reading frame (ORF3) of unknown function is also shown (Adapted from Miller et al., 2003)

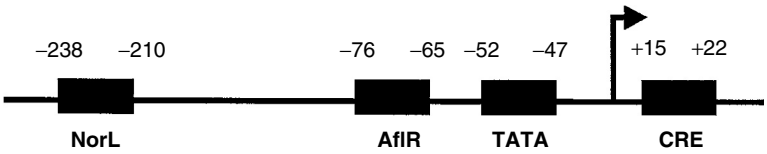

Figure 9.6 Identification of *cis*-acting sites in the *nor-1* promoter of *A. parasiticus*. The numbers indicate the number of nucleotides from the primary transcriptional start site of *nor-1*. (Adapted from Miller et al., 2003)

Although putative TATA boxes have been identified in aflatoxin biosynthetic promoters, the *nor-1* TATA box was the first to be rigorously tested for functional significance (106). Substitution of the TATA box in the context of a larger promoter resulted in nondetectable GUS activity (106). A novel *cis*-acting site (NorL) was identified that is necessary for maximum *nor-1* transcriptional activation *in vivo.* Using EMSA, specific protein binding to NorL was demonstrated (106). EMSA also identified another potential *cis*-acting site, CRE1, in the *nor-1* promoter (Roze et al., in preparation) (106,107). Both the NorL binding protein (NorLbp) and CRE1 binding protein (CRE1bp) appeared to rely on functional AflR for maximum DNA binding (106,107). Based on these observations, Miller proposed that the transcriptional regulation of *nor-1* involves additional proteins besides AflR (106).

9.2.1.1.5 Open Reading Frame 3 (ORF3), nor-1, and pksA Transcriptional Activation Reporter studies with *pksA*::GUS (55) and *nor-1*::GUS (105) both demonstrated that inclusion of the *cis*-acting site AflR2 (Figure 9.5) resulted in greater transcriptional activation. Miller and Linz proposed two alternative models to explain these data: (1) AflR2 works synergistically with AflR1 and AflR3 to mediate transcription of the *nor-1* and *pksA* promoters respectively; or (2) AflR2 mediates expression of ORF3 (potentially encodes a polypetide of approximately 300 amino acid residues) (Figure 9.5) directly downstream from AflR2 which directly or indirectly impacts transcription of the *nor-1* and *pksA* promoters (106). Identification of a cDNA corresponding to ORF3 in an *A. parasiticus* cDNA library strongly suggests it represents a functional gene. Interestingly, blast searches using ORF3 as a query sequence did not provide solid clues regarding potential function. Model 2 prompted two related predictions regarding *nor-1* and *pksA* promoter function (106): (1) Because fungal isolates carrying *nor-1*::GUS or *pksA*::GUS constructs with promoter fragments that include a functional AflR2 and ORF3 showed the highest GUS expression levels, accumulation of additional ORF3 protein in strains with two copies (native plus plasmid copy) overcomes a protein threshold resulting in extreme up regulation of *nor-1* and *pksA* promoter activity. (2) Loss of ORF3 function due to AflR2 deletion in the second copy accounts for down regulation (or lack of up regulation) of both *nor-1* and *pksA* expression. Similar results are seen with the insertion of an additional copy of *aflR* (31,34,98) suggesting a possible regulatory role for ORF3. Future experiments will determine the function of ORF3 and how AflR2 impacts *pksA* and *nor-1* transcriptional activation.

9.2.1.1.6 AflJ The function of *aflJ* in aflatoxin biosynthesis is still not entirely clear. The *aflJ* gene resides adjacent to *aflR* in the aflatoxin gene cluster with the two genes being divergently transcribed. An *A. flavus aflJ* knockout strain did not make aflatoxin, and lacked the ability to convert several aflatoxin intermediates to aflatoxin (103). However, the *aflJ* knockout strain did accumulate several aflatoxin biosynthetic transcripts under aflatoxin conducive conditions, suggesting that *aflJ* is not involved in the transcriptional regulation of aflatoxin biosynthesis (103). Sequence analysis of *aflJ* did not reveal any enzymatic function but did identify three potential membrane spanning domains and a putative microbody

targeting signal (103). Consequently, Meyers et al. (103) proposed two hypotheses regarding the function of the AflJ protein: (1) AflJ is involved in either transmembrane transport of aflatoxin pathway intermediates through intracellular compartments; or (2) AflJ is involved in the localization of pathway enzymes to an organelle. In contrast to these studies, AflJ more recently has been shown to interact with AflR in a two hybrid assay (37). Insertion of an additional copy of *aflR* and *aflJ* into *A. parasiticus* resulted in greater aflatoxin biosynthesis than insertion of *aflR* alone, whereas insertion of *aflJ* alone had no affect on aflatoxin biosynthesis (30). Consequently, Chang et al. (30) described *aflJ* as being a transcriptional coactivator. Strong support for this idea was provided by a recent study by Chang (29). More work is needed to clearly define the activity of AflJ.

9.2.1.2 Trichothecene Synthesis

9.2.1.2.1 Tri6 – Discovery Following the identification of three trichothecene biosynthesis genes, *tri5* (74), *tri4* (75) and *tri3* (101), it was realized that they all resided in a 9 kb region and that the trichothecene biosynthesis genes might be clustered (77). The location of *aflR* within the aflatoxin biosynthetic gene cluster suggested the possibility that other mycotoxin gene clusters, including trichothecene, may be regulated by a gene present within the cluster (116). While the discovery of *aflR* relied on complementation of a regulatory mutant (31), the initial identification of *tri6* as a gene encoding a putative trichothecene biosynthesis transcriptional activator relied on nucleotide sequence analysis of the trichothecene gene cluster (120). Found immediately upstream of *tri5*, *tri6* encodes an open reading frame of 217 amino acids with regions similar to Cys_2His_2 zinc finger proteins (120). The Cys_2His_2 zinc finger is a common motif for transcription factors including BrlA from *A. nidulans* (3).

9.2.1.2.2 Tri6 – Function Several lines of evidence, in addition to sequence data, demonstrate that the Tri6 protein is a transcriptional activator for trichothecene biosynthesis. *tri6* expression mirrored the expression of other trichothecene genes including *tri3 and tri4* (120). Disruption of *tri6* resulted in a strain with greatly reduced trichothecene production, trichothecene enzyme activities, and trichothecene biosynthetic transcript steady states (120). Tri6 protein functioned as a transcriptional activator in *Saccharomyces cerevisiae* when fused to the DNA binding domain of the yeast transcription factor Gal4 (120). The Tri6 binding site was identified in *Fusarium sporotrichioides* as YNAGGCC using EMSA with Tri6 produced *in vitro* (76). The Tri6 binding site was confirmed *in vivo* using *F. sporotrichioides tri4* reporter strains (76). All of the trichothecene biosynthetic genes identified in the *F. sporotrichioides* and *F. graminearum* clusters have the Tri6 binding site located in their promoter regions except for *Tri10* (14,76).

9.2.1.2.3 Tri10 – Discovery Located upstream of *tri5* in the trichothecene gene cluster (Figure 9.7), expression of the gene *tri10* mirrored the timing of several trichothecene genes including *tri6*, *tri5* and *tri4* (144). A *tri10* disruption strain accumulated significantly less trichothecene biosynthetic transcripts (144). Conversely, transformants that had increased *tri10* expression resulted in significantly increased trichothecene gene expression (144). As noted, *tri10* lacks a consensus Tri6 binding site (14) and is significantly up regulated in the

Figure 9.7 Schematic of the sugar utilization gene cluster in *A. parasiticus*. The *moxY* gene is at one end of the aflatoxin gene cluster. The spacer regions on either side of the sugar utilization cluster do not contain open reading frames. Map is roughly to scale (Adapted from Yu et al., 2000a)

tri6 disruptant strain (144). Tag et al. (144) postulated that *tri10* is not positively regulated by Tri6 but instead may be negatively regulated by unknown mechanisms when Tri6 is present. The impact of Tri10 extends to genes involved in the primary metabolic steps that generate trichothecene precursors including *Fpps* (144). While Tri10 protein lacks any known transcription factor motif, its function is clear as an essential regulator in trichothecene gene regulation (144). Future investigations are focused on determining the precise mode of action of Tri10 and on further identification of the regulatory circuits defined by Tri10 (144).

9.2.1.3 Other Mycotoxins

Although most information regarding mycotoxin gene regulation is centered on aflatoxin and trichothecene biosynthesis, other mycotoxin related transcription factors have been identified. In fact, information about aflatoxin and trichothecene biosynthesis pathways have aided in the analysis of different mycotoxin pathways. For example, a Tri6 homologue has been identified (MRTri6) in the distantly related trichothecene pathway of *Myrothecium roridum* (76). *Dothistroma pini* synthesizes dothistromin, a difuranoanthraquinone toxin similar to aflatoxin, with several analogous genes (11). Bradshaw et al. (11) hope to identify the dothistromin pathway regulator by using *A. parasiticus aflR* as a probe or by sequencing the entire dothistromin gene cluster. Sequencing of the paxilline biosynthesis cluster in *Penicillium paxilli* identified two predicted transcription factors, *paxR* and *paxS* (164). Like *aflR*, both *paxR* and *paxS* contain the uniquely fungal $Zn(II)_2Cys_6$ binuclear cluster DNA binding motif (164). The exact function of *paxR* and *paxS* in paxilline biosynthesis is currently unknown.

9.2.1.4 Activation and Inactivation of Transcription Factors

In the budding yeast *Saccharomyces cerevisiae*, a zinc finger transcription factor, Mig1p, in part mediates glucose signaling by binding to the promoters of glucose repressible genes (140). This carbon catabolite repression is released after phosphorylation of Mig1p by an Snf1p protein complex as part of the signaling cascade. Clues are beginning to emerge that phosphorylation of transcription factors also may play a role in mediating expression of genes involved in secondary metabolism. For example, phosphorylation of AflR is believed to inactivate this positive regulator of aflatoxin synthesis, and perhaps increase its susceptibility to proteolytic cleavage (N. Keller, personal communication). Similarly, phosphorylation of CRE1bp, a novel transcription factor proposed to mediate the cAMP, induced upregulation of at least one aflatoxin gene, *nor-1*, and appears to influence binding to a specific DNA binding motif in the *nor-1* promoter (124).

9.2.2 Posttranscriptional Regulation

Gene regulation studies in filamentous fungi have primarily focused on transcriptional mechanisms. Significantly less is known about posttranscriptional regulatory mechanisms in filamentous fungi (127). For example, recent data strongly suggest that regulation of aflatoxin synthesis may be mediated by at least three such mechanisms: (1) proteolytic cleavage; (2) protein localization; and (3) RNA processing.

Western blot analysis detected full length and proteolytically cleaved forms of OmtA in extracts of *A. parasiticus* SU-1 grown on yeast extract plus sucrose agar medium (YES; supports aflatoxin synthesis) (89); the proteolytically cleaved form of OmtA was observed in increased abundance in older cells within the colony (closer to the center of the center inoculated colony) as compared to younger cells (outer margin of the colony). The extent of cleavage was significantly greater in cells grown on solid medium than in cells grown in submerged liquid culture. In contrast, Western blot analysis of protein extracts of SU-1 grown in submerged liquid culture in YES liquid medium demonstrated that Nor-1 (173)

and Ver-1 (92) proteins may be subject to at least one proteolytic cleavage under these culture conditions. However, Nor-1 and Ver-1 did not show a similar degree of proteolytic cleavage in colonies of SU-1 grown on YES agar medium. The specificity and timing of expression of the proteolytic enzymes and the role of cleavage in activation and inactivation of aflatoxin enzymes is clearly of interest for future studies.

In fungal tissues analyzed by immunofluorescence microscopy with highly specific polyclonal antibodies to Nor-1, Ver-1, and OmtA, the majority of the fluorescent signal was located in the cytoplasm of thin sections of paraffin embedded fungal tissue (89). Transmission electron microscopy using gold labeled antibodies confirmed the cytoplasmic location. In cells located near the basal surface (substrate surface) of the colony, OmtA antibodies generated an intense labeling in small and large organelles proposed to be vacuoles (175). Together these data suggest that specific aflatoxin enzymes may be targeted to specific organelles during synthesis. The protein composition and function of these organelles is one focus area for future work.

Certain strains of *Aspergillus parasiticus,* including SU-1, carry two copies of *aflR* (*aflR-1* and *aflR-2*) encoding an important positive regulator of aflatoxin synthesis (AflR). In analyzing the potential function of AflR-2 in transcriptional regulation of aflatoxin synthesis, Cary et al. (24) genetically disrupted *aflR-1*. The experiment demonstrated that AflR-2 alone is not effective as a positive regulator of aflatoxin synthesis. However, a basal level of transcription of *nor-1*, *ver-1*, and *omtA* was observed in the knockout strain using reverse transcriptase PCR (RT-PCR). Of particular interest, the transcripts in the knockout strain did not appear to be spliced to remove the introns, suggesting that an AflR dependent splicing factor was not expressed. Confirming the activity and specificity of the proposed splicing factor is a focus of future experimentation.

9.2.3 Overview of Regulatory Inputs

Filamentous fungi encounter a myriad of growth conditions in their natural environment, and have developed regulatory circuits to allow appropriate levels of gene expression in response to changes in their environment. Among these regulatory circuits are those that mediate alterations in mycotoxin production. As secondary metabolites, mycotoxins are synthesized predominantly during a transition from active growth to stationary phase by fungi. Although many factors are known to influence mycotoxin gene expression, this section will review those factors that have been shown to directly or indirectly modulate gene expression via the alteration of the expression or activity of positive or negative acting transcription factors that bind to specific *cis*-acting sites in mycotoxin gene promoters.

9.2.3.1 Nutrients

A vast array of chemical, nutritional, and environmental factors have been demonstrated to influence aflatoxin gene expression (23,42,49,56,68,115,152,170). Of these factors, most studies at the molecular level have focused on the effects of carbon, nitrogen, trace elements, and pH. Early on, it was demonstrated that transcripts for most, if not all, aflatoxin genes accumulate at the highest rate in a transition between active growth and stationary phase (liquid shake culture), suggesting that the aflatoxin genes are coordinately regulated (153). Based on pioneering work on the influence of carbon source on aflatoxin synthesis by Buchanan (16,17,159), Skory et al. (139) confirmed that *nor-1* and *ver-1* gene expression in *A. parasiticus* (liquid shake culture) was regulated at the level of transcript accumulation and that glucose appeared to be a key factor in mediating this influence. Using *A. flavus* and *A. parasiticus* strains carrying GUS (glucuronidase) reporter constructs, Flaherty et al. (65,179) and Liang et al. (92) showed that the regulatory influence on aflatoxin gene

expression was, at least in part, at the transcriptional level. This set the stage for monitoring the interaction of specific transcription factors (such as AflR) with *cis*-acting sites on aflatoxin gene promoters and analyzing the influence of environment on transcription factor expression and activity.

9.2.3.1.1 Carbon Source It is well established that glucose and other simple sugars have an important regulatory influence on aflatoxin synthesis (17,18,159) although the molecular mechanisms that mediate this response are only now beginning to be understood. Glucose and other easily utilizable carbon sources are known to influence fungal gene expression via carbon catabolite repression (125). In *Aspergillus* species, carbon catabolite repression of genes involved in primary metabolism (e.g., *xlnA*, *alcA*) (87,114) requires CreA (48), a zinc finger protein that is reported to be homologous to Mig1 in *Saccharomyces cerevisiae*. A consensus binding site for CreA has been reported (5′-SYGGRG-3′) in the *alcA* promoter. A *creA* homolog, *cre1* has been shown to mediate carbon catabolite repression in the filamentous fungi *Trichoderma reesei* (141) and *Sclerotinia slerotiorum* (155) suggesting that the main components of this regulatory scheme are conserved among the filamentous fungi.

Possibly the most unusual feature of carbon regulation of aflatoxin synthesis is that glucose stimulates aflatoxin synthesis in contrast to the glucose mediated catabolite repression of another *Aspergillus* secondary metabolite, penicillin (12). Liu and Chu (93) reported that the level of AflR protein is increased in the presence of glucose. This positive regulator appeared at significantly lower levels in cell extracts from the fungus (liquid shake culture) when peptone was included in place of glucose (with ammonium sulfate as sole nitrogen source). Reduced levels of AflR protein were also observed with increased temperature, reduced levels of zinc, and when sodium nitrate was used to replace ammonium sulfate as the sole nitrogen source (similar culture conditions) suggesting that multiple nutrients and environmental factors influence AflR protein accumulation directly. This could influence aflatoxin synthesis indirectly by reducing AflR interaction with its *cis*-acting sites.

9.2.3.1.2 Nitrogen Source Like the carbon source, the nitrogen source has a large influence on the expression of specific fungal genes such as those involved in nitrate utilization (21,97). The effects of nitrogen are reported to be mediated by the function of a positive acting global nitrogen regulator encoded by *areA* in *Aspergillus* and by the homologous genes, *nit2* and *NRE*, in *Neurospora* and *Penicillium*, respectively. These GATA-type transcription factors bind specific consensus sites (so called GATA sites) in nitrogen regulated promoters. In addition, positive acting, pathway specific regulators such as those encoded by *nirA* in *Aspergillus* and *nit4* in *Neurospora* fine tune the expression of the nitrogen responsive genes. Early work on regulation of aflatoxin synthesis clearly demonstrated that the identity and concentration of the sole nitrogen source has a significant influence on the accumulation of aflatoxin and pathway intermediates in liquid shake culture (78,112). The nitrogen regulatory scheme in *A. flavus* and probably *A. parasiticus* is complicated by the fact that it is also strongly influenced by the pH of the growth medium (41) . This is important because growth of *A. flavus* in the presence of sodium nitrate (and with glucose or sucrose as the sole carbon source) results in a sharp increase in pH in liquid shake culture, while growth in the presence of ammonium sulfate results in a decrease in pH (78).

Western blot and Northern hybridization analyses and use of aflatoxin gene reporter constructs demonstrated that *nor-1* and *ver-1* are not expressed at detectable levels when sodium nitrate is used as the sole nitrogen source (with glucose as the sole carbon source), but these genes are expressed at normal levels with ammonium sulfate suggesting that this regulatory influence is mediated at the transcriptional level (105–107). This is likely in part explained by the observation that sodium nitrate did not support the accumulation of *aflR*

transcript (105) or AflR protein (93). This regulatory scheme again is in direct contrast to the regulation of genes involved in penicillin biosynthesis in *Aspergillus*. Here the preferred nitrogen source, ammonium sulfate, represses penicillin gene expression while sodium nitrate stimulates expression (60). This allows one to predict that AreA protein, which is normally a positive global regulator, may act as a negative regulator of aflatoxin gene expression. A small quantity of available data appears, at least on the surface, to support this hypothesis.

Analysis of the intergenic region between *niaD* (nitrate reductase) and *niiA* (nitrite reductase) in *A. parasiticus* identified several HGATAR sequences that represent the consensus binding site for AreA, but also two copies of a palindrome, TCCGTGGA, which act as a binding site for the *N. crassa* Nit4 nitrogen global regulator (33). Later, Chang et al. (38) cloned and characterized the gene encoding AreA in *A. parasiticus*. The authors generated a recombinant AreA DNA binding domain fusion protein that bound cooperatively to single HGATAR sites in the *niaD - niiA* intergenic region. Of particular interest, this fusion protein also bound to the AflR - AflJ intergenic region which contains several consensus HGATAR sequences. However, binding to specific sites was not demonstrated. Because growth of *A. parasiticus* in the presence of sodium nitrate was shown to significantly reduce *aflR* expression at the level of protein (93) and transcript (106,107), these data combined are consistent with a negative regulatory role for nitrate in aflatoxin gene expression mediated by AreA. Clearly, followup will focus on the specificity of AreA binding and the regulatory consequences of binding to AflR/AflJ expression and activity.

An interesting wrinkle to the nitrogen regulatory scheme was presented by Feng and Leonard (61). They reported that sodium nitrate stimulated synthesis of sterigmatocystin (ST) and expression of the biosynthetic genes *stcA* (homologous to *pksA*), *stcE* (homologous to *nor-1*) and *stcD* in *A. nidulans* (liquid stationary culture) in contrast to expression of *pksA* and *nor-1* which were inhibited in *A. parasiticus*. Although these data suggest differential regulation of AF and ST biosynthesis with regards to nitrogen regulation, the use of stationary culture conditions (in contrast to liquid shake) may have had an influence on these observations.

Based on recent evidence, Chang et al. (34) proposed a model in which aflatoxin gene expression is regulated not only directly by influencing the level of AflR protein (perhaps via AreA), but also indirectly by interaction with a putative repressor protein that binds to existing AflR protein and blocks its interaction with AflR consensus sites in aflatoxin gene promoters. A second copy of *aflR* was introduced into the *A. parasiticus* SU-1 genome via transformation. One resulting transformant, SU-1N3(pHSP), was grown in minimal salts medium (liquid shake culture) with 1mM sodium nitrate as the sole nitrogen source. The accumulation of aflatoxin and pathway intermediates as well as the expression of *aflR*, *nor-1*, *ver-1*, and *omtA* were significantly increased in SU-1N3(pHSP) in comparison with SU-1, the parent strain. They hypothesized that excess levels of AflR produced in SU-1N3(pHSP) titrated a fixed level of negative acting repressor protein leaving unbound AflR to activate the aflatoxin gene promoters. Possibly in agreement with these data, high level constitutive expression of AflR in *A. flavus* relieved nitrate repression of aflatoxin gene expression (65). Nitrate did reduce the accumulation of aflatoxin in the overexpressing strain, suggesting that aflatoxin synthesis is not solely regulated at the level of transcription.

In support of this model, Chang et al. (36) generated a plasmid construct carrying the carboxyl terminus of AflR (AflRC) expressed from the *niaD* promoter. This plasmid was transformed into *A. parasiticus* SRRC 2043 and isolates with a copy of the construct located at both *aflR* and *niaD* were isolated. These dual integrants overproduced aflatoxin pathway intermediates regardless of nitrogen source. Increased aflatoxin intermediate

production correlated with increased expression of the AflRC and native AflR suggesting that the excess AflRC protein titrated a negative regulator of AflR activity. Direct evidence for this repressor has yet to be presented. However, in *N. crassa*, an analogous regulatory mechanism to that proposed for aflatoxin synthesis has been experimentally demonstrated. In this organism, a negative acting repressor, called NMR, interacts directly with Nit2, the positive acting pathway specific regulator of nitrate metabolism (165). This interaction reduces the ability of Nit2 to bind to nitrogen regulated promoters and positively regulate the structural genes involved in nitrate metabolism.

Recent data now suggest that there is significant variability in nitrogen response between strains of *Aspergillus* (53). Two different groups of *A. flavus* isolates, called S_B (synthesize the aflatoxin B group only) and S_{BG} (synthesize both B and G group toxins) were grown in the presence of either sodium nitrate or ammonium sulfate as the sole nitrogen source. The growth medium was buffered over time to maintain a final pH range between 5.7 and 6.1, to reduce changes in pH that accompany N source metabolism and to eliminate pH as a variable. The quantity of aflatoxin synthesized, the dry weight, and the quantity of *aflR* and *aflJ* transcripts (adjacent and divergently transcribed genes in the aflatoxin gene cluster) were monitored under these culture conditions in the S_B and S_{BG} isolates (three isolates of each group). The authors concluded that nitrate reduced (repressed) aflatoxin B and G synthesis in the S_{BG} isolates but did not significantly reduce aflatoxin B synthesis in the S_B isolates. As a proposed explanation for these data, the ratio of *aflJ* transcript on ammonium versus *aflJ* transcript on nitrate, was approximately five-fold higher in the S_B isolates than in the S_{BG} isolates. In contrast, there was not a significant difference in *aflR* transcript ratio on the same media between the S_B and S_{BG} isolates. The authors observed that there was a larger number of HGATAR sites in the *aflR*/*aflJ* intergenic region in the S_B isolates (three consensus sites) than in the S_{BG} isolates (one consensus site), prompting them to propose that nitrate increased the level of AreA which had a larger inhibitory effect on expression of *aflJ* in the S_B isolates due to the larger number of *cis*-acting sites. The connection between increased *aflJ* transcript and increased aflatoxin accumulation is tentative and needs to be clarified. This interesting model also deserves a closer look by expanding on these observations and directly testing AreA quantities and promoter binding in both groups of *A. flavus* isolates.

Unlike aflatoxins, fumonisin synthesis appears to be regulated in *Gibberella fujikoroi* by a typical nitrogen catabolite repression pathway (134). At low levels of ammonium phosphate (1.25 or 2.5 mM), *G. fujikoroi* produced fumonisin B_1 as early as 15 hours in a defined medium (liquid submerged culture). Increasing the level of ammonium phosphate (10 or 20 mM) resulted in a delay in toxin synthesis for 75 to 125 hours. The specific effects of ammonium on fumonisin gene expression or the expression and activity of pathway specific transcription factors has not been reported to date.

9.2.3.1.3 Trace Elements Several studies clearly demonstrated that *A. parasiticus* requires zinc for aflatoxin synthesis to occur at optimum levels in culture (9,149). For example, addition of zinc sulfate at concentrations ranging from 50 to 400 mM resulted in several fold (greater than eightfold at 150 mM) increases in aflatoxin accumulation in liquid shake culture (149). Consistent with these observations, when zinc was omitted from the growth medium, no aflatoxin intermediates were detected in a mutant strain (accumulates versicolorin) of *A. parasiticus* in liquid shake culture (9). Furthermore, omission of zinc from the growth medium resulted in lower quantities of AflR protein detected in cell extracts of *A. parasiticus* (93). Although the mechanism for zinc regulation has not been clearly defined, these data suggest that zinc is required for AflR DNA binding activity in line with its proposed function as a positive acting zinc binuclear cluster transcription factor (160). Because AflR appears to up regulate its own expression (52) as well as the expression of most if not all pathway genes

(23), it appears likely that zinc limitation reduces aflatoxin synthesis via a reduction in AflR expression and DNA binding activity. Miller (106) also reported that zinc limitation results in limitation of growth and increased proteolysis. He proposed that these two factors likely play a role in reduction of aflatoxin synthesis under conditions of limited zinc.

9.2.3.2 Environment

9.2.3.2.1 pH The growth environment has been previously shown to have a great impact on the expression of genes involved in secondary metabolism in filamentous fungi. For example, pH strongly regulates penicillin biosynthesis in *Aspergillus* (58). One major regulator involved in pH mediated regulation is PacC, a zinc finger protein that acts as a positive regulator of alkaline expressed genes and a repressor of acid expressed genes at ambient alkaline pH in the growth medium. PacC is reported to require activation as a result of a signaling pathway encoded by the *pal* genes (58). Proteolytic cleavage of PacC appears to be in part responsible for its activator and repressor activity (113). Specific mutations in PacC obviate the requirement for pH signal transduction (146). The mechanism by which PacC can act as an activator and repressor on different sets of genes was recently clarified (64). In the simplest case, PacC *cis*-acting binding sites in alkaline expressed genes allow PacC interaction and activation of transcription. In acid expressed genes, such as *gabA* (involved in synthesis of gamma aminobutryrate), binding of PacC to double PacC binding sites blocks interaction of the pathway activator, IntA (mediates T amino acid induction), with its *cis*-acting site on the *gabA* promoter.

pH has also been shown to influence the level of aflatoxin synthesis (41) on a defined solid growth medium. A comparison was made between aflatoxin synthesis and sclerotial development on media containing either sodium nitrate or ammonium sulfate in buffered or unbuffered media (with glucose or sucrose as the sole carbon source). Metabolism of nitrate by *A. flavus* resulted in an alkaline pH, enhanced sclerotial development, and reduced aflatoxin synthesis, whereas metabolism of ammonium resulted in an acidic pH, reduced sclerotia, and high levels of aflatoxin synthesis. Buffering of the growth medium during growth to prevent a change from the initial pH (6.5) resulted in reduction of aflatoxin synthesis in ammonium and enhancement of aflatoxin synthesis in nitrate (relative to unbuffered levels in the same medium), suggesting that both nitrogen source and pH affect the levels of aflatoxin produced on solid medium.

In the closely related species *A. nidulans* and *A. parasiticus*, expression of homologous genes in the sterigmatocystin (*stcU*) and aflatoxin (*ver-1*) biosynthetic pathway was strongly influenced by pH (80). Transcripts for these genes accumulated at higher levels at acidic pH than at neutral or alkaline pH, and transcript levels correlated directly with the level of mycotoxin detected in culture. Mutation in the *A. nidulans* PacC gene (constitutive PacC activity) resulted in a tenfold decrease in sterigmatocystin as compared to the wild type (80). However, the level of *stcU* transcript was not affected in the PacC mutant, suggesting that PacC might not be solely responsible for the pH regulation of aflatoxin biosynthesis.

Indirect evidence for a role for PacC in aflatoxin gene expression in *A. parasiticus* was obtained using an *aflR* gene disruption strain (25). Transformation of the knockout strain with plasmid constructs carrying specific mutations in the *aflR* promoter identified three sites that were important for *aflR* expression; an AflR binding site, a PacC binding site, and a GA rich region near the transcriptional start site of *aflR*. Later, EMSA supported the functional significance of the PacC site by demonstrating that a protein in a nuclear extract of *A. parasiticus* interacted with this site in the *aflR* promoter. A PacC site also was shown to be functionally significant in a structural gene in the pathway called *pksA* (55) (encodes the polyketide synthase). In this study, the PacC site in the *pksA* promoter was

replaced with nonrelated nucleotides resulting in a fivefold decrease in *pksA* promoter activity. These data are of particular interest because the pH of the growth medium in this study was acidic. These data suggest that PacC may operate as a positive regulator of genes involved in secondary metabolism in contrast with its usual positive activity at alkaline pH in regulation of genes involved in primary metabolism.

Although little is known about the molecular mechanisms that mediate the regulatory influence of pH on trichothecene synthesis, one study provided preliminary evidence that, in specific growth media (Fries Medium supplemented with corn steep liquor), higher levels of DON accumulate in liquid shake culture at pH above 8.0 suggesting a potential contrast in pH regulation of this biosynthetic pathway (117). However, maximum levels of fumonisins were observed in liquid shake culture under nitrogen limited conditions (82) between pH 3 and 4. When the growth medium was limited for oxygen, no fumonisins were produced, even at optimum pH.

9.2.3.2.2 Temperature *Aspergillus parasiticus* synthesizes aflatoxins at maximum levels in the temperature range between 25 and 30°C (75). Growth of an aflatoxin blocked mutant (accumulates the pathway intermediate versicolorin A, VA) at 37°C completely blocked VA accumulation on an aflatoxin inducing growth medium (138). As mentioned, high temperature down regulates AflR protein accumulation providing, at least in part, a potential explanation for a down regulation of toxin synthesis (93). Butchko et al. (20) reported a similar temperature sensitivity for sterigmatocystin synthesis in *A. nidulans* but the nonpermissive temperature was higher (42°C) than that observed for *A. parasiticus* (37°C).

9.2.4 Signal Transduction Pathways

Two pioneering studies stimulated interest in research on the role of signal transduction pathways in regulation of secondary metabolism. The first reported a positive influence of exogenous cAMP on AFB_1 accumulation in culture (145). The second reported an inverse relationship between ethylene synthesis and aflatoxin accumulation in *A. parasiticus* (132). With the development of molecular tools in filamentous fungi, progress has been made in discerning the molecular mechanisms that mediate these regulatory circuits. Understanding signaling pathway input into mycotoxin synthesis in filamentous fungi is of fundamental interest because it is currently unknown if the signaling pathways that control primary metabolism and secondary metabolism are the same, completely different, or modified during growth to accomplish different regulatory functions. At the applied level, signaling pathways present logical focus areas for study because they sense external signals at low concentration. In addition, external signals are often received by receptors in the cytoplasmic membrane, abrogating the need for potential inhibitors to enter the cell. These characteristics suggest that identification of molecules that interfere with signaling pathway function at the receptor level could be an important component in the development of novel and effective strategies to control toxin synthesis in food and feed products.

9.2.4.1 G-Protein and Protein Kinase A (PKA) Signaling

9.2.4.1.1 Coregulation of Toxin Synthesis and Sporulation in Aspergillus The filamentous fungus *A. nidulans* provides an excellent model system to study asexual sporulation at the genetic and molecular genetic level. As a result of early studies on this developmental process, a variety of mutant strains defective in the early stages of sporulation was generated. Hicks et al. (73) took advantage of this panel of early developmental mutants to provide the first strong evidence tying signal transduction pathways and regulation of both sporulation and mycotoxin synthesis. Biochemical and genetic data had previously suggested that mycotoxin synthesis and asexual sporulation (conidiation)

are coregulated in *Aspergillus spp.* For example, mycotoxin synthesis was observed to begin concurrently with conidiophore formation and conidiation (91,173). In addition, conidiation mutants such as *fan*, *fluffy*, *fluP*, *fadA*^{G42R}, *fluG*, *flbA*, and DGP10 were also impaired in mycotoxin synthesis (7,25,71,73,79,173,174). Further, many compounds that inhibited conidiation also decreased mycotoxin synthesis. For example, fluoroacetic acid (200–400 mg/ml) completely inhibited conidiation in *A. parasiticus* and reduced aflatoxin synthesis with no detectable effect on hyphal growth (122). Similarly, a competitive inhibitor of ornithine decarboxylase, diaminobutanone (50 mM), completely blocked the onset of both conidiation and aflatoxin synthesis in *A. parasiticus* with little effect on hyphal growth (71).

9.2.4.1.2 cAMP, fadA, and PKA in A. nidulans and A. parasiticus Based on early studies performed in *A. nidulans*, Hicks et al. (73) proposed a model for signaling pathway regulation of growth, conidiation, and sterigmatocystin biosynthesis in *A. nidulans*. According to this model, Fa dA, a subunit of a heterotrimeric G protein, binds GTP and transduces a signal which promotes growth and inhibits conidiation and sterigmatocystin synthesis. FlbA, a GTPase activating protein homolog, negatively regulates FadA by stimulating GTP hydrolysis, blocking G protein signaling, decreasing growth, and triggers initiation of conidiation and sterigmatocystin synthesis. In support of this model, Shimizu and Keller (82) reported that an activated allele of *fad*A (*fad*A^{G42R}) down regulated aflatoxin synthesis and conidiation, resulted in a fluffy phenotype in *A. flavus* (personal communication), and decreased norsolorinic acid (an aflatoxin pathway intermediate) accumulation and conidiation in TJYP1-22, a *fad*A^{G42R} derivative of *A. parasiticus B62*.

Shimizu and Keller (136) recently reported genetic evidence that FadA/FlbA regulation of sterigmatocystin synthesis and conidiation is mediated by a cAMP dependent protein kinase (PKA) in *A. nidulans*. Overexpression of *pka*A (encodes one catalytic subunit of PKA) eliminated transcripts of two genes involved in sterigmatocystin synthesis (*stcU* and *aflR*) and sterigmatocystin accumulation; conidiation was reduced to levels below wild type. Deletion of *pkaA* increased conidiation, inhibited growth, and delayed expression of *aflR* and *stcU* on a minimal growth medium. Deletion of *pkaA* in a strain with an activated *fadA* allele (*fadA*^{G42R}) restored conidiation but not sterigmatocystin synthesis. These data prompted the authors to expand the previous model to propose that FadA up regulates PKA which then has a negative regulatory influence on AflR expression and conidiation. It was also proposed that additional signaling pathways and factors may influence sterigmatocystin synthesis and conidiation. Neither sterigmatocystin promoter activity nor intracellular cAMP levels were measured. In addition, no distinction was made between basal PKA activity (fraction of PKA activated by endogenous cAMP *in vitro*) and total PKA activity (PKA activated by exogenous cAMP *in vitro*). Here, we define activation as binding of cAMP to 2 PKA regulatory subunits resulting in the release of 2 active PKA catalytic subunits.

In contrast to these data reported for *A. nidulans*, Tice and Buchanan (145) suggested a positive regulatory role for cAMP signaling (theoretically via PKA) in regulation of aflatoxin synthesis in *A. parasiticus*. Addition of cAMP, but not cGMP, to the growth medium, resulted in a dose dependent stimulation of aflatoxin accumulation in stationary liquid culture; neither intracellular cAMP levels nor the effect of cAMP on conidiation were evaluated. In support of these data, Roze et al. (176) observed increased levels of aflatoxin accumulation and conidiation in *A. parasiticus* after addition of the PKA activators cAMP or DcAMP (a cAMP analog) to the growth medium.

To clarify these apparently contrasting data, Roze et al. (178) then studied the role of FadA, cAMP, and PKA in the regulation of conidiation and aflatoxin synthesis in *A. parasiticus*. *A. parasiticus* strain D8D3 (contains a *nor-1*::GUS reporter construct;

wild-type with respect to aflatoxin synthesis), and *A. parasiticus* TJYP1-22 (an isogenic strain containing an activated allele of *fadA*; *fadA*^{G42R}) were grown in the presence or absence of cAMP or DcAMP in liquid stationary culture or on GMS solid growth medium (with glucose and ammonium sulfate). Growth, conidiation, aflatoxin accumulation, intracellular cAMP levels, *nor-1* promoter activity, and basal and total PKA activity were measured. The data suggested that treatment of *A. parasiticus* D8D3 with exogenous cAMP or DcAMP increased intracellular cyclic nucleotides to nonphysiological levels. This down regulated total PKA activity and up regulated conidiation (fivefold) and AflR dependent aflatoxin synthesis (tenfold). Activation of FadA generated intermediate physiological intracellular cAMP levels and high basal and total PKA activity. This down regulated conidiation and aflatoxin synthesis. The studies provided direct evidence for involvement of FadA in regulation of intracellular cAMP levels and basal and total PKA activity, and prompted the authors to propose that FadA/PkaA regulation of mycotoxin synthesis occurs via similar regulatory mechanisms in *A. parasiticus* and *A. nidulans*. They also concluded that intracellular cAMP levels, at least in part, mediate a PKA dependent regulatory influence on conidiation and aflatoxin synthesis in *A. parasiticus*.

9.2.4.1.3 Identification of a cAMP Response Element Binding Protein (CRE1bp)

EMSA was conducted to determine if specific transcription factors mediate the cAMP induced up regulation of aflatoxin synthesis and *nor-1* promoter activity (176). Using a subfragment of the *nor-1* promoter (*norR)* as probe and cell extracts from *A. parasiticus* strains D8D3 or TJYP1-22 (*fadA*^{G42R}) grown on GMS (glucose as sole carbon source; inducing conditions) or PMS (peptone as sole carbon source; noninducing conditions) agar medium, a single DNA and protein complex with similar mobility was observed in both extracts under the 2 different aflatoxin noninducing conditions (complex PS1 from D8D3 grown in PMS; complex FS1 from TJYP1-22 [*fadA*^{G42R}] grown in GMS). A complex of lower mobility (complex GS1) was generated by extracts of D8D3 grown on GMS agar (GS1; inducing conditions) but was not present under the noninducing conditions. Roze et al. (176) hypothesized that complexes PS1 and FS1 are structurally and functionally similar. Because TJYP1-22 (*fadA*^{G42R}) stimulated intracellular cAMP levels and down regulated AFB_1 synthesis and *nor-1* promoter function, they reasoned that a putative repressor was part of PMS1 and FS1, and this bound to a cAMP response element (CRE). Binding of additional proteins (or modification of bound proteins) converted the complex to GS1 in inducing conditions and up regulation of *nor-1* promoter activity. In support of this hypothesis, the authors identified a candidate CRE (named CRE1), *cis*-acting site (TGACATAA; nucleotide residues +15 to +22) in *norR* (−117 to +55) based on sequence similarity to a consensus CRE from yeast (TGACGTCA) (66,73,122). They then tested possible DNA binding activity at the CRE1 site *cis*-acting site using competition EMSA. A 250-fold excess of oligonucleotide containing the putative CRE1 site completely competed with both PS1 and FS1 complexes, while mutants containing 3 changed residues of this site (TGTGATAT) or 2 changed residues (TGTGATAA) were significantly less effective. A mutant containing 5 changed residues (CTAGCTAG) was totally ineffective at competing with these DNA/protein complexes. The consensus CRE from eukaryotic cells with flanking sequences from the *nor-1* promoter also completely competed with the shifted complexes, while oligonucleotides containing the AflR binding site and the TATA box could not compete. The fact that the pattern observed in competition EMSA was the same for complexes PS1 and FS1 strongly supported the hypothesis that they contained the same protein(s). Roze et al. (176) named this CRE binding protein, CRE1bp (cAMP response element binding protein). It now appears as though this CRE1 site has functional significance. A CRE replacement mutation in the *nor-1*::GUS reporter construct (2 nucleotide

changes in the putative CRE1 site confirmed by sequence analysis) did not respond to exogenous cAMP to the same extent as wild type (about a threefold reduction).

Because a direct correlation was observed between PKA activity and complex FS1 in TJYP1-22 (*fadA*^{G42R}), Roze et al. (176) reasoned that phosphorylation of CRE1bp may be associated with DNA binding activity. They generated direct evidence for CRE1bp phosphorylation using supershift EMSA. Monoclonal antibodies to phosphoserine and phosphothreonine supershifted complex FS1 but phosphotyrosine did not. Clearly, followup is necessary to identify the amino acid residues that are phosphorylated and the influence on DNA protein complex formation and aflatoxin gene expression.

9.2.4.1.4 G protein signaling The effects of a constitutively activate *fadA* allele on penicillin biosynthesis in *A. nidulans* and trichothecene biosynthesis in *Fusarium sporotrichioides* were also analyzed (143). In contrast to aflatoxin and sterigmatocystin synthesis, the *fadA*^{G42R} allele stimulated expression of one gene in penicillin biosynthesis and increased accumulation of this antibiotic. Similarly, expression of the same allele in *Fusarium sporotrichioides* increased trichothecene gene expression and accumulation of this mycotoxin. These data strongly suggest that one signaling pathway can have diverse effects on different secondary metabolite pathways. The molecular mechanisms underlying this regulatory circuit are clearly a focus for future work.

9.2.4.1.5 Ras Proteins and Conidiospore Germination Because of the close regulatory association between mycotoxin synthesis and asexual sporulation in *Aspergillus,* it is worth mentioning a recent study that analyzed the effects of cAMP and *ras* signaling on conidial germination (63). Strains carrying mutations in adenylate cyclase (CyaA) or protein kinase A (PkaA) demonstrated altered kinetics of spore germination, together with several alterations in colony morphology. *Aspergillus nidulans* mutants overproducing a dominant activated form of RasA (a homologue of the human *ras* protooncogene) produced giant swollen spores with multiple nuclei that failed to germinate.

9.2.4.2 Lipids and Psi Factors

9.2.4.2.1 Aflatoxins and Lipids The effects of lipids on aflatoxin synthesis were reviewed recently (23). As a useful illustration of the phenomenon, Mellon et al. (102) demonstrated that cottonseed storage lipids were found to support growth and toxin synthesis by *A. flavus*. When the lipids (primarily triglycerides) were removed from the medium by ether extraction, aflatoxin production dropped by more than 800-fold. Keller and colleagues (19) provided a framework for integrating a large body of data related to the propensity of *Aspergillus* to produce mycotoxins on oilseed crops. Because *Aspergillus* species contain lipoxygenase (LOX) activities involved in synthesis of pheromones which regulate development, they proposed a theory which attempted to connect pheromone synthesis, development, and toxin synthesis on oil seed crops. *A. nidulans* contains LOX activities involved in synthesis of psi (precocious sexual inducers) factors, which regulate sexual and asexual sporulation in this organism (28). Deletion of *odeA* that encodes a delta 12 desaturase in *A. nidulans* resulted in a strain depleted in polyunsaturated fatty acids and psi factors derived from linoleic acid (22). The connection to the host plant was provided by the observation that host plants also contain LOX activities and the plant LOX metabolites strongly activate mycotoxin synthesis (43). Based on the existing evidence, it was reasonable to propose that peroxides of unsaturated fatty acids in oilseed formed during storage, or by host lipoxygenases during seed development, mimic the activity of fungal psi factors and alter fungal development and mycotoxin synthesis. Keller's group (19,67) has generated significant laboratory evidence in support of this theory, although

more information is required to understand the importance of the lipids in regulation of mycotoxin synthesis in the field and during crop storage.

9.2.4.2.2 CP2 Inhibits Aflatoxin Gene Expression Support for the lipoxygenase theory was provided by studies on a naturally occurring compound identified as an aflatoxin synthesis inhibitor. Using a rapid two dimensional TLC assay, Annis et al. (6) discovered a compound (CP2) in black pepper extract (*Piper nigrum*) that down regulates *nor-1*:: GUS expression at the level of transcription. CP2 also inhibited *nor-1* and *ver-1* transcript accumulation, suggesting that multiple aflatoxin promoters are affected. CP2 exhibited dose dependent inhibition of AFB_1 synthesis but did not inhibit expression of a β-tubulin::GUS reporter (housekeeping gene) nor accumulation of $-tubulin transcripts. CP2 appears to be relatively specific for the aflatoxin promoters. Gas chromatography mass spectroscopy (GC-MS) analysis revealed that CP2 is a C18 fatty acid that is structurally similar to the linoleic acid derived psi factors (27,28,99) that govern development of cleistothecia (structures for production of sexual spores) and conidiophores in *A. nidulans*. The authors proposed that CP2 acts via mimicry of the hormonal effects of psi factors and down regulates mycotoxin formation in *A. parasiticus*. Dr. Keller (19) has shown that hydroperoxide derivatives of linoleic acid can have opposing effects on sterigmatocystin synthesis in *A. nidulans*. A 13S hydroperoxy derivative of linoleic acid inhibited ST production, while a 9S hydroperoxy derivative did not inhibit ST synthesis but did stabilize mRNA transcripts derived from toxin genes. Of note, CP2 did not affect conidiation in *A. parasiticus,* which suggests that the association of psi factor to sexual development and toxin synthesis is complicated and requires further study.

9.2.4.3 Ethylene Signaling

9.2.4.3.1 Ethylene Inhibits AFB1 Synthesis Plants use ethylene signaling to regulate flowering and ripening of fruits and vegetables (131,137). Binding of ethylene to specific receptors influences the ethylene signaling pathway, initiating the ethylene response. Methyl cyclopropene (MCP) blocks ethylene/receptor interaction and inhibits the ethylene response (131,137). Roze et al. (177) showed that ethylene gas inhibits AFB1 biosynthesis and nor-1 promoter activity up to tenfold in a dose dependent manner, but the compound had no statistically significant effect on conidiation. Methyl cyclopropene added to A parasiticus enhanced AFB1 synthesis up to fivefold under 3 different growth conditions (193). Ethylene (0.5 PPM) also blocked the cAMP mediated stimulation of AFB1 synthesis but did not affect the number or viability of conidiospores. Based on these data, the authors hypothesized that A. parasiticus has ethylene receptors that mediate regulatory effects of ethylene on AFB1 synthesis; the group is currently attempting to clone the ethylene sensor or receptor based on presumed identity with ethylene receptors from plants (128).

9.2.4.4 Other Volatiles

Similar to ethylene, workers at the USDA in New Orleans have observed strong regulatory effects of a variety of plant volatiles, including alkenal and alkanal compounds on aflatoxin synthesis (69,162,171,172). Although such compounds hold potential in reducing toxin levels in food and feed, the mechanisms by which these compounds affect aflatoxin synthesis are currently not known.

9.2.4.5 Cyclins

9.2.4.5.1 Fumonisins and Cyclins Cyclins are a family of proteins involved in cell cycle control in eukaryotic organisms. Evidence for a role for one specific cyclin, FCC1,

in regulation of fumonisin biosynthesis in *Fusarium verticelloides* was presented by Shim et al. (135). The authors observed that disruption of the gene, *FCC1*, reduced conidiation and expression of FUM5, which encodes a polyketide synthase in fumonisin biosynthesis on laboratory growth medium or corn kernels. The role of cyclin signaling and the exact mechanism by which the down regulation occurred are areas of focus for future work.

9.2.5 Gene Clusters and Positional Effects

While common in prokaryotes, the linkage of functionally related genes is relatively rare in higher eukaryotes. In filamentous fungi, however, the clustering of genes is a common feature for several metabolic pathways. Examples of gene clusters in secondary metabolism include aflatoxin (153), trichothecene (14), penicillin (45), fumonisin (130), dothistromin (11), paxilline (164), and several others. Several nutrient utilization pathways are also clustered in filamentous fungi including ethanol (64) and nitrate (182) utilization in *A. nidulans*. The physical linkage of related genes suggests two possible hypotheses: (1) linkage of metabolic pathway genes provides a means to regulate pathway gene transcription; and (2) linkage provides a means for genetic transfer of entire pathways between species.

9.2.5.1 Organization of Gene Clusters

9.2.5.1.1 Aflatoxin Gene Cluster Parasexual analysis of aflatoxin pathway mutants first established the likely clustering of at least some of the aflatoxin biosynthetic genes (8). Subsequently, the first two aflatoxin genes cloned, *nor-1* and *ver-1*, were found to be genetically linked on the same *A. parasiticus* cosmid (139). Analysis of overlapping cosmid and phage clones allowed the aflatoxin (sterigmatocystin) gene clusters to be mapped in *A. parasiticus* (153), *A. flavus* (168), and *A. nidulans* (15). As candidate genes in the aflatoxin cluster were identified, the timing of transcript accumulation from these cluster genes was observed to be consistent with their involvement in aflatoxin biosynthesis (15,153). To date, most cluster genes have been studied in detail and been confirmed to be involved in aflatoxin biosynthesis. Interestingly, the aflatoxin gene clusters of these three related organisms are not organized identically. For example, the distance between *aflR* and *ver-1* is 32 kb in *A. nidulans* but 8 kb in *A. parasiticus* and *A. flavus*. The maintenance of gene clusters despite changes in gene order suggests that gene clustering has functional significance for the fungi.

A 5 kb spacer region was identified at one end of the aflatoxin gene cluster (166,167). The spacer region contains no open reading frames and has a sugar utilization cluster located on the opposite side (Figure 9.8). Aflatoxin production is closely linked to the carbon source, with simple sugars like glucose and sucrose able to induce aflatoxin biosynthesis (17). Consequently, the localization of this sugar utilization cluster near the aflatoxin cluster suggests a regulatory connection between the two clusters. However, of the four genes in the sugar cluster, only *hxtA* (proposed hexose transporter protein) expression was shown to be concurrent with aflatoxin pathway cluster genes (166). It is unknown if there are any functional AflR *cis*-acting sites in the sugar cluster gene promoters. In addition, the border at the other end of the aflatoxin gene cluster has not yet been defined.

9.2.5.1.2 Trichothecene Gene Cluster Two overlapping cosmid clones were able to complement different trichothecene mutants, suggesting that the trichothecene genes are clustered in *Fusarium sporotrichioides* (77). More recently, a 23 kb trichothecene gene cluster was sequenced for both *F. sporotrichioides* and *F. graminearum*,which contains 12 genes (14). All of the 12 clustered genes studied so far have been shown to be involved in trichothecene biosynthesis [Figure 9.8 (a)] (14). Yet, the 12 genes in the identified trichothecene gene cluster are insufficient to account for all known trichothecene structures (14), leading

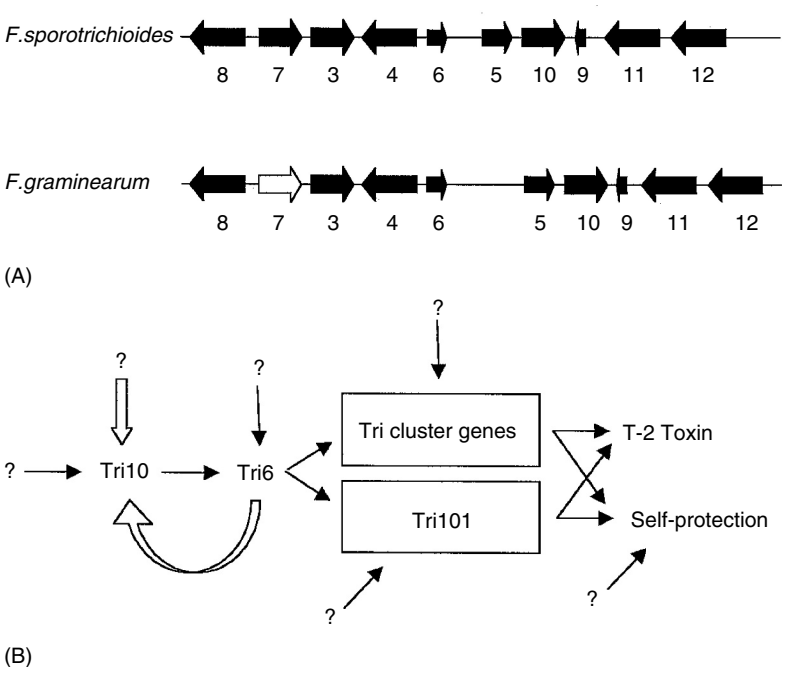

Figure 9.8 (A) Genomic organization of the trichothecene biosynthetic *tri* gene cluster of *Fusarium sporotrichioides* and *F. graminearum*. Arrowheads indicate the direction of transcription and the number underneath each arrow refer to the specific gene. Genes with the same number from both *Fusarium* species are homologues. *tri7* in *F. graminearum* is non-functional. Map is roughly to scale. (Adapted from Brown et al., 2001) (B) Proposed regulatory model for trichothecene biosynthesis. Solid arrows indicate positive activators while open arrows indicate inhibitory activities. Question marks indicate other proposed but unknown regulatory signals or factors (Adapted from Tag et al., 2001)

to two hypotheses: (1) additional trichothecene biosynthesis genes are located beyond the flanking sequence of *tri8* and *tri12*; and (2) all trichothecene genes are not located within the gene cluster. Because most, if not all, of the genes necessary for aflatoxin biosynthesis are located within the aflatoxin gene cluster, it would be reasonable to sequence beyond *tri8* and *tri12* to potentially identify additional trichothecene genes. In addition, it will be interesting to determine if there is an extended spacer region that forms a border of the trichothecene gene cluster as there is with the aflatoxin gene cluster.

tri101 exists outside of the 23 kb cluster in both *F. sporotrichioides* (100) and *F. graminearum* (85) and is the only known trichothecene gene to exist outside of the cluster. The genes on either side of *tri101* (UTP-ammonia ligase and phosphate permease) are not involved in trichothecene biosynthesis and *tri101* is at least 35 kb from either end of the identified trichothecene cluster in *F. graminearum* (84). Tri101 is a 3-O-acetyltransferase that is required for T-2 production in *F. sporotrichioides* (100). Because the enzymatic products of Tri101 are less toxic than the substrates, it was originally proposed that the purpose of Tri101 is to protect the fungus (83). Expression of *tri101* in yeast (83,100) and plants (109) resulted in increased tolerance for trichothecenes. Yet, a *F. sporotrichioides tri101* disruptant could both germinate and grow in the presence of trichothecenes, suggesting that *tri101* is not an essential self defense mechanism for *F. sporotrichioides* (100). The evolution of *tri101* is discussed in later sections.

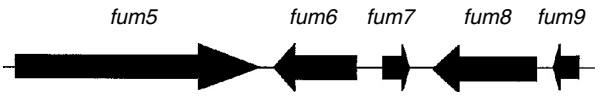

Figure 9.9 Schematic of the fumonisin biosynthetic gene (*fum*) cluster in *Fusarium verticillioides*. Arrowheads indicate the direction of transcription. Map is roughly to scale (Adapted from Seo et al., 2001)

9.2.5.1.3 Fumonisin Gene Cluster The identification of the fumonisin gene cluster utilized allele tests with three different *Fusarium monoliforme* fumonisin mutants (44). Subsequently, a polyketide synthase gene, *fum5*, was isolated and shown to be required for fumonisin biosynthesis (119). Based on the structure of fumonisin B1, at least 8 different enzymatic steps are needed for fumonisin biosynthesis (130). Sequencing downstream from *fum5* identified four additional ORFs, *fum6*, *-7*, *-8* and *-9*, whose expression is correlated with fumonisin production (Figure 9.9). Gene disruption analysis of *fum6* and *fum8* revealed that they are necessary for fumonisin biosynthesis (130). Nucleotide sequence analysis in the DNA regions flanking *fum5* and *fum9* may identify additional fumonisin biosynthetic genes. Based on aflatoxin and trichothecene gene clusters, it is reasonable to expect that a transcriptional activator specific for fumonisin biosynthesis located within the fumonisin gene cluster will be found with the additional sequencing.

9.2.5.2 Gene Cluster Dependent Regulation

Preliminary evidence for a role for clustering in aflatoxin gene regulation was reported by Liang et al. (92). The promoter of the aflatoxin biosynthesis structural gene *ver-1* was fused to GUS to generate a reporter plasmid (pHD6.6) that contained *niaD* (encodes nitrate reductase) as a selectable marker (92). pHD6.6 integrated predominantly at the *ver-1* or *niaD* locus via homologous recombination (92). Single copy integration of pHD6.6 at *niaD* resulted in a 500-fold reduction in *ver-1* promoter activity when compared with single copy integration at the *ver-1* locus; however, the temporal pattern of expression appeared to be similar at both loci (92). One explanation for reduced *ver-1* promoter function at the *niaD* locus is that location in the aflatoxin cluster results in positive, position dependent regulation of *ver-1* exression. An alternative hypothesis is that the expression of *ver-1* integrated at *niaD* is negatively influenced by *niaD* regulation. In the absence of preferred nitrogen sources and in the presence of nitrate, *niaD* is expressed. Under the rich growth conditions tested by Liang et al. (92), *niaD* may have been repressed, and therefore the lack of *ver-1* expression at the *niaD* site could have resulted from *niaD*-dependent regulation.

Subsequently, the promoter of the aflatoxin biosynthesis gene *nor-1* was fused to GUS to generate a reporter plasmid, pAPGUSNN-B, containing *niaD* as a selectable marker (40). Transformants with pAPGUSNN-B integrated at the *niaD* locus had no detectable GUS activity, while *nor-1* integrants had GUS activity (46). In addition, the cloned *nor-1* promoter functioned similarly to the native *nor-1* promoter when it integrated at the *nor-1* locus (40). Because *niaD* dependent regulation could account for the absence of expression at *niaD* for both *nor-1*::GUS (40) and *ver-1*::GUS (101), a third chromosomal location was analyzed using pAPGUSNP, which contained *nor-1*::GUS plus *pyrG* (encodes OMP decarboxylase) as a selectable marker (40). GUS expression was detectable only when pAPGUSNP integrated at *nor-1* and was not detectable at *pyrG*, even under growth conditions that required *pyrG* expression (40). While the mechanism is unknown, *nor-1* and perhaps other aflatoxin biosynthetic genes are susceptible to aflatoxin gene cluster dependent regulation.

The genome of some strains of *A. parasiticus* includes a partial duplication of the aflatoxin gene cluster (35). The region from *aflR* to *ver-1* plus *omtB* is duplicated in *A. parasiticus* SU-1 (35). It is unknown why the genes between *ver-1* and *omtB* are not part of the duplicated region. All of the duplicated genes appear to have mutations in them that would make them nonfunctional except for *aflR-2* and *aflJ-2* (35). Northern and RT-PCR analyses of RNA indicated that *aflR-2* is expressed at much lower levels than *aflR-1* (24). Nucleotide sequence analysis upstream of the *aflR-2* translational start codon revealed that the AflR binding site was intact and that there were few base changes (2%) compared to the corresponding region of *aflR-1* (24). Cluster dependent regulation may explain the poor expression of *aflR-2* (24,35). It is currently unclear if the other genes in the duplicated region are expressed at similar levels to their cluster counterparts. Reporter constructs that can integrate into the aflatoxin gene cluster and the duplicated region may provide valuable insight into cluster dependent mechanisms of regulation.

Trichothecene biosynthesis genes are also clustered (77), and there is some evidence for position dependent regulation with the pathway regulator *tri6* (39). Introduction of a plasmid containing a *tri5*::GUS fusion with a functional *tri6* resulted in 50- to 100-fold more GUS activity with *tri5* integration compared to ectopic integration (39). However, there were no differences in GUS activity between *tri5* and ectopic integration of a *tri5*:: GUS plamid without a functional *tri6* (39). Integration of a *tri4*::GUS fusion into the *tri4* locus resulted in two to fivefold more GUS activity than ectopic integration (76). Additional experiments are necessary to clarify the significance of cluster dependent regulation in trichothecene biosynthesis.

It is currently unknown if cluster dependent regulation occurs with other mycotoxin gene clusters like fumonisin. However, cluster dependent regulation appears to be less significant with trichothecene biosynthesis than with aflatoxin biosynthesis. Except for aflatoxin biosynthesis, the description of mycotoxin gene cluster dependent regulation needs further study. While the construction of plasmids with mycotoxin promoters fused to reporter genes is useful in identifying *cis*-acting sites in the mycotoxin promoter, they also provide a means to determine differences between mycotoxin cluster integration and ectopic integration.

9.2.5.3 Significance of Gene Cluster Dependent Regulation

The targeting of reporter constructs to specific chromosomal locations for promoter analysis has been suggested by other investigators studying expression of fungal genes (72,148). The gene cluster dependent regulation seen with the aflatoxin gene cluster emphasizes the importance of determining the site of integration for mycotoxin reporter plasmids. In addition, screening transformants by genotype (site of integration) rather than phenotype (reporter activity) will prevent possible sampling bias. A rapid method for screening the site of integration for *A. parasiticus* has been described (40) that makes screening by genotype feasible.

Although the mechanisms of position dependent gene expression have not been fully elucidated in filamentous fungi, it has been hypothesized that enhancer elements may be responsible for the position dependent effect (86). Studies performed on the SpoC1 gene cluster in *A. nidulans* showed that clustered genes can be coordinately expressed during development, and that placement of cluster genes at ectopic chromosomal locations results in the loss of that coordination (104,147). The hypothesis that positive *cis*-acting factors have regional control over the transcription of aflatoxin genes is reasonable, because removal of aflatoxin reporter fusions from the aflatoxin gene cluster results in reduced GUS expression.

More recently, studies with the mammalian β-globin gene identified a region named a locus control region (LCR) (70). The β-globin LCR was identified as a region that was necessary to confer positional independence of a β-globin transgene (70). Subsequently, several additional LCRs have been identified (90). We hypothesize that aflatoxin gene expression is influenced by a locus control region. However, a locus control region has not been identified in fungal gene clusters. If an LCR does influence the regulation of *nor-1* transcription, it is located at least 3 kb upstream from the transcription initiation site in the 5′ *nor-1* region, at least 1.8 kb downstream of the transcription termination site in the 3′ region of *nor-1*, or within the *nor-1* coding region. Because similar position dependent expression is observed with the *ver-1*::GUS reporter construct (92), it is possible that the same LCR element is influencing the regulation of both *nor-1* and *ver-1*. Comparison of steady state levels of mRNA transcripts from genes present in the aflatoxin gene cluster and the duplicated region (i.e., *ver-1A* vs. *ver-1B*) may help narrow the search for the LCR(s). It will be interesting to determine if the duplicated region includes the LCRs necessary for cluster dependent regulation. In addition, the 5 kb spacer region at one border of the aflatoxin gene cluster is a tempting place to look for possible boundary elements. Boundary elements appear to provide a functional boundary for both accessible and inaccessible chromatin (88). The possible boundary element in the spacer region would prevent the LCRs from affecting transcriptional activation of genes in the sugar cluster or beyond.

While solid evidence for cluster dependent regulation has only been shown for aflatoxin biosynthesis, it is reasonable to predict that several other mycotoxin gene clusters will also be subject to cluster dependent regulation. Consequently, the proper use of reporter plasmids to study mycotoxin gene transcriptional regulation must include the identification of the site of integration of the plasmids to ensure proper data interpretation.

9.2.5.4 Evolution of Mycotoxin Gene Clusters

9.2.5.4.1 Origin of the Aflatoxin Gene Cluster The occurrence of fungal pathway gene clusters may result from horizontal gene transfer from prokaryotes where clustering of pathway genes is common (81). Perhaps the strongest case for the horizontal gene transfer of an entire secondary metabolic pathway from bacteria to fungi is with penicillin biosynthesis (5,158). The G+C content of the penicillin gene cluster is more similar to *Streptomyces* than the producing fungi and the fungal penicillin genes lack introns which is generally a characteristic of bacteria (81). Horizontal gene transfer is unlikely with the aflatoxin biosynthetic pathway due to the presence of introns and similar G+C content inside and outside of the aflatoxin cluster (15). Yet the changes in gene order within the aflatoxin gene cluster of different *Aspergilli* suggest that there is selective pressure to keep the aflatoxin genes clustered. *Dothistroma pini*, a fungal pine pathogen, produces the mycotoxin dothistromin that is structurally similar to versicolorin A, an intermediate in aflatoxin biosynthesis (11). Four genes identified in the *D. pini* dothistromin gene cluster all have high similarity with known aflatoxin biosynthesis genes (11). Detailed analysis of the dothistromin and aflatoxin gene clusters may provide clues to help understand the evolutionary history of the aflatoxin gene cluster.

9.2.5.4.2 Origin and Diversity of Trichothecene Gene Clusters The current literature provides few clues for the origin of the trichothecene gene cluster. The ten trichothecene genes identified so far in the cluster (*tri*3 through *tri*12) contain a total of 37 introns (14) suggesting that horizontal gene transfer from prokaryotes is unlikely. While there are many different trichothecenes that are produced by various fungi, *Fusarium* species appear to be the primary source of trichothecenes in agricultural products (76). The mechanism for how different Fusarium species produce different trichothecenes is unknown. The T-2 gene

cluster in *Fusarium sporotrichioides* and the deoxynivalenol gene cluster in *F. graminearum* are very similar (Figure 9.7) in that the 23 kb region included 12 homologous genes (14). However, the Tri7 protein (acetylates the oxygen on C-4) is nonfunctional in *F. graminearum* (14) suggesting a possible mechanism for generating trichothecene structural diversity. The origin of the noncluster *tri101* gene may be different than the clustered trichothecene genes (85). Kimura et al. reasoned that a translocation event was unlikely to explain the location of *tri101* because it is flanked by essential primary metabolism genes (84). In addition, homologues of *tri101* were found in *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* (84). Consequently, Kimura et al. reasoned that it is feasible that trichothecene producers have acquired *tri101* through horizontal gene transfer (84).

9.2.6 Summary

This chapter has reviewed recent data related to molecular mechanisms that regulate mycotoxin gene expression in a variety of filamentous fungi. The overarching goals of this research are to increase our understanding the basic biology and chemistry of fungal secondary metabolism, and at the same time to identify practical methods to reduce mycotoxin contamination of food and feed. In this regard, we propose that research on the positive and negative regulators of mycotoxin gene expression and the signaling pathways that mediate environmental influences on these regulators hold considerable promise. Work on identification of food safe, natural plant compounds may have an important impact on mycotoxin contamination by down regulating toxin gene expression, and may move us closer to realizing a safer food supply. Clearly, the data reviewed illustrate important strides in achieving the overarching goals. However, a great deal more work remains to achieve a safe food supply.

3.10

Application of ELISA Assays for Detection and Quantitation of Toxins in Foods

Robert E. Levin

CONTENTS

10.1 INTRODUCTION

ELISA assays by definition are enzyme linked immunosorbent assays and are presently used to detect and quantitate a wide variety of organic molecules such as hormones, pharmaceuticals, and toxins. The major advantages of ELISA assays involve a high level of specificity due to the immunological nature of the assays, extraordinary sensitivity, frequently in the picogram (pg) range of detection, and small sample size. All ELISA assays require at least one source of antibody (Ab). Most such antibodies involve the immunoglobulin G (IgG) fraction of antisera but are not necessarily restricted to the G fraction. Antisera are produced by the injection of suitable animals with the immunogenic molecule of interest. The rabbit is the conventional laboratory animal of choice for the small scale production of polyclonal antibodies (pAbs); mice are used for production of monoclonal Abs (mAbs) in conjunction with hybridoma methodology (1). Antisera to specific antigens are often additionally available commercially from larger animal sources such as the goat, cow, horse, sheep, cat, and dog. In general, the larger the animal, the less expensive is the antiserum. The rat, mouse, and poultry are additional sources of commercially available antisera. In addition, the industry produces a wide variety of anti immune sera, e.g., rabbit antisera that will react with all IgGs from the goat and vice versa. The availability of such a wide variety of anti immune sera greatly facilitates the development of antiglobulin sandwich ELISA assays.

10.2 HAPTENS AND THEIR CONJUGATION TO PROTEINS

Organic molecules having a molecular weight of less than 5000 are usually not immunogenic. Many of the organic toxins occurring in foods have molecular weights well below this value. The problem can be readily circumvented by covalently conjugating the small toxin molecule (hapten) to a large protein molecule or carrier. Bovine serum albumin (BSA) having a molecular weight of 67,000 Da is most frequently used as a protein carrier because of its high degree of purity, abundant availability, and low cost. Keyhole limpet hemocyanin (KLH, mol. wt. ~7 million kDa) and polylysine (mol. wt. 70,000–150,000 Da) are alternate protein carriers. Because of its large size, KLH may precipitate during cross linking which can create handling problems. BSA is readily soluble but is itself highly immunogenic. Ovalbumin (OVA, mol. wt. ~45,000 dalt.) is another suitable

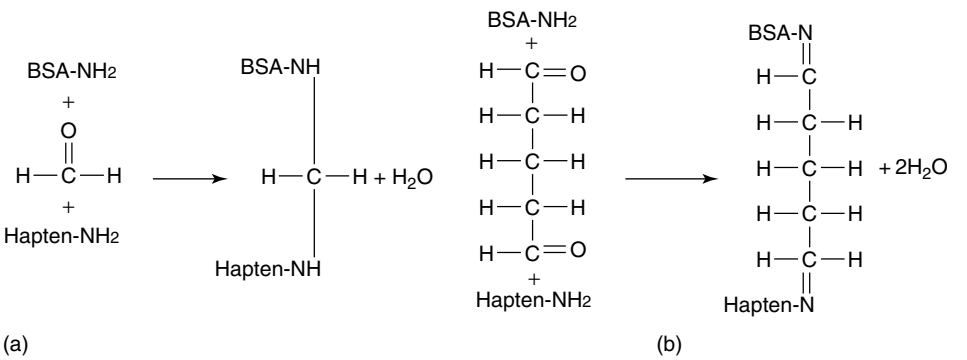

Figure 10.1 Aledyhdye conjugation reactions. (a) formaldehyde conjugation of hapten to BSA. (b) gluteraldehyde conjugation if hapten to BSA.

carrier and is ideal for a second carrier (as in antiglobulin ELISA sandwich assays) where BSA is used for primary antibody production.

If a free amino group is available on the hapten it can be readily conjugated to BSA using formaldehyde or gluteraldehyde as a covalent bridge (Figure 10.1). Reaction mechanisms are also available for conjugating through available –OH, -CHO, -COOH and -SH groups (2,3).

Injection of a mammal with such a purified conjugate will result in a family of Ab molecules, each directed against a specific domain of the conjugate. Some Ab molecules will be directed against overlapping domains of the BSA while others will be capable of recognizing the hapten. Such a family of Abs is referred to as polyclonal in that each Ab molecular species is produced by an individual B lymphocyte. Higher levels of immunological specificity can often be obtained with the use of monoclonal antibodies that are homogeneous, in that all the Ab molecules present are identical and will recognize the same domain of an antigen. The origin and methodology involving the production of monoclonal antibodies has been described in detail by Zola (1).

10.3 THE USE OF ENZYMES IN ELISA ASSAYS

The second critical component of all ELISA assays involves the use of an enzyme reaction to produce a visual or spectrophotometrically detectable indication of the presence or absence of the target antigen. The principle enzymes presently in use with ELISA assays are alkaline phosphatase, horse-radish peroxidase (HRP), and β–galactosidase (Table 10.1). The fastest response is usually with HRP because it has the highest turnover number (largest number of substrate molecules attacked per unit of time by a single enzyme molecule) and because it exhibits the highest level of heat resistance. This elevated heat resistance can be used to advantage with HRP by raising the incubation temperature for the enzyme reaction to 55°C so as to greatly accelerate the reaction rate and result in a colored reaction product within 5 to 10 min. HRP is cheaper than the other two enzymes but requires two substrates, H_2O_2 plus a proton donor such as ABTS, OPD, or TMB (Table 10.1). Among these three proton donors, TMB is preferred because it is nonmutagenic in the Ames assay (4). For an enzyme to be suitable for use in ELISA assays it should possess a high turnover number and have available a suitable colorless substrate that is converted to a stable, soluble, and colored end product. For quantitative ELISA assays, the product of the enzyme reaction must be soluble.

The enzymes are usually conjugated to specific or anti immune antibodies. Conjugation reactions that allow retention of enzyme activity usually involve the use of gluteraldehyde in a one step reaction (5) or with a two step reaction (6). The two step gluteraldehyde method results in enzyme and antibody being present in equal amounts in the conjugate resulting in enhanced sensitivity (7). Periodate conjugation (8) is also widely used.

10.4 THE USE OF MICROTITER PLATES IN ELISA ASSAYS

Most ELISA assays are presently performed using microtiter plates with 72 or 96 wells per plate, with each well having a capacity of 300 µ1. The resulting miniaturized volume of ELISA assays results in a considerable saving of antibody preparations and other costly reagents. The multiple wells allow large numbers of samples to be simultaneously processed. The availability of microplate readers with variable wavelengths and optional internal incubation at a variety of temperatures greatly enhances the efficiency of processing multiple samples.

Table 10.1
Enzymes available for ELISA assays and their substrates

Enzyme	Substrate	Comments
Horseradish Peroxidase	2,2′ Azino-di[3-ethylbenthiazoline sulphonate] (ABTS)	Water soluble green product which absorbs light at 410nm and 650 nm. ABTS (1 mM) used with H_2O_2 (0.002% v/v) in phosphate / citrate buffer pH 4.3. Stop reaction with sodium azide (1.5 mM) in citric acid (0.1M).
	O-Phenylene diamine (OPD)	Water soluble absorbs light at 492nm. OPD (4mM) used with H_2O_2 (0.004% v / v) in citric acid (0.02M) Na_2HPO_4 (0.05M) buffer pH 5.0. Stop reaction with H_2SO_4 (0.1M).
	3,3′,5,5′-Tetramethylbenzidine (TMB)	Water soluble yellow product which absorbs light at 450nm. TMB (0.4mM) used with H_2O_2 (0.004% v / v) in 0.05M acetate buffer pH 6.0. Stop reaction with H_2SO_4 (2M).
Alkaline phosphatase	P-nitrophenyl phosphate (PNPP)	Water soluble yellow reaction product which absorbs lighter at 405nm. PNPP (2.5 mM), plus $MgCl_2$ (0.5mM) in diethanolamine buffer (10 mM) pH 9.5. Stop reaction with EDTA (0.1 M).
b-Galactosidase	O-nitrophenyl-b-D-galactopyranoside (ONPG)	Water soluble yellow product which absorbs light at 410nm. ONPG (3 mM), plus $MgCl_2$ (10 mM), 2-mercapto-ethanol (0.1M) in phosphate buffered saline, pH 7.5. Stop reaction with Na_2CO_3.
	4-methyl-umbelliferyl-β-D-galacto-pyranoside (MUG)	Water soluble product which fluoresces at 45nm. 4-MUG (0.1 mM) in NaCl (0.1 M), $MgCl_2$ (1 mM), 0.1% bovine serum albumin, sodium phosphate (10 mM), pH 7.0. Stop reaction with glycine (0.1 M), pH 10.3.

Polystyrene microtiter plates are most frequently used and harbor electrostatic binding sites on their surface that will bind proteins in a nonspecific manner. This is taken advantage of by the addition of diluted antiserum (or the hapten conjugated to a carrier protein) to wells (usually 100 µl) to achieve nonspecific binding of Abs or the hapten to the bottom of the well. Nonspecific binding of Abs to the wells often requires several hours and is most conveniently achieved by allowing binding to occur overnight in a refrigerator with the covers in place to prevent evaporation. The unbound Ab (or hapten-protein conjugate) molecules are then rinsed out and blocking solution (300 µl) is then added to completely fill the wells. Blocking solutions consist of any suitably inexpensive protein that will bind nonspecifically to the surface of the wells so as to prevent further nonspecific binding of ELISA reagents thereafter. An advantage of polystyrene plates is that blocking solution need only be added once. After 15 min., the blocking agent is rinsed out and thereafter only immunospecific binding will occur on the surface of the wells. Blocking agents consist of 0.1% BSA, 0.1% fat free skimmed milk (FFSM), or 0.1% gelatin. The latter two are readily available at food

markets in powdered form. If FFSM is used it is first prepared as a 1.0% (w/v) solution in 0.1M phosphate buffer, pH 7.5 containing 8.5% NaCl. Boiling in the presence of phosphate salts solubilizes the casein. It is then diluted tenfold with distilled water for use. BSA should not be used as a blocking agent if the original hapten conjugate used for injection to produce Abs involved BSA as the protein carrier.

The sensitivity of ELISA assays can be significantly increased if the antibody portion of antiserum is purified before being bound to polystyrene wells or conjugated to an enzyme. This is readily achieved with the use of affinity chromatography involving protein A bound to agarose beads in miniature columns and frequently results in about a 100-fold purification of the IgG fraction of the antiserum.

It is important to keep in mind that all ELISA assays consist of a series of additions of reagents, and that after the addition of each reagent and the required incubation time, the wells are thoroughly washed with a washing solution consisting usually of 0.02% Tween 20 in 0.05M phosphate buffer (pH 7.5) containing 0.85% NaCl. In addition to Tween 20, Triton-X-100 and Nonidet-40 are also employed. These are nonionic detergents that are used to prevent the hydrophobic adsorption of proteins to the surface of the wells and to decrease the hydrophobic aggregation of proteins (9). Three commonly used ELISA formats using microtiter plates are presented in Figure 10.2. In the direct ELISA [Figure 10.2(a)], antigen or a hapten-protein conjugate is bound to the surface of the well followed by the addition of Ab-enzyme conjugate, and then substrate for the enzyme is added. The intensity of the color reaction after a predetermined incubation time is then directly related to the amount of antigen bound to the well. In the indirect ELISA [Figure 10.2(b)] antigen or a hapten-protein conjugate is first bound to the well followed by the addition of primary

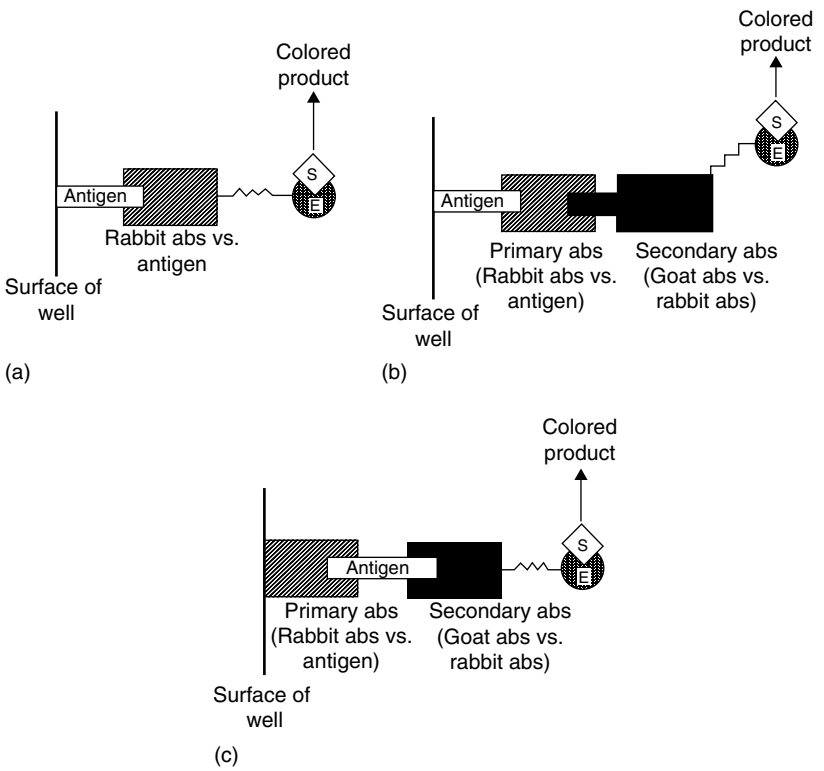

Figure 10.2 Fundamental ELISA techniques.

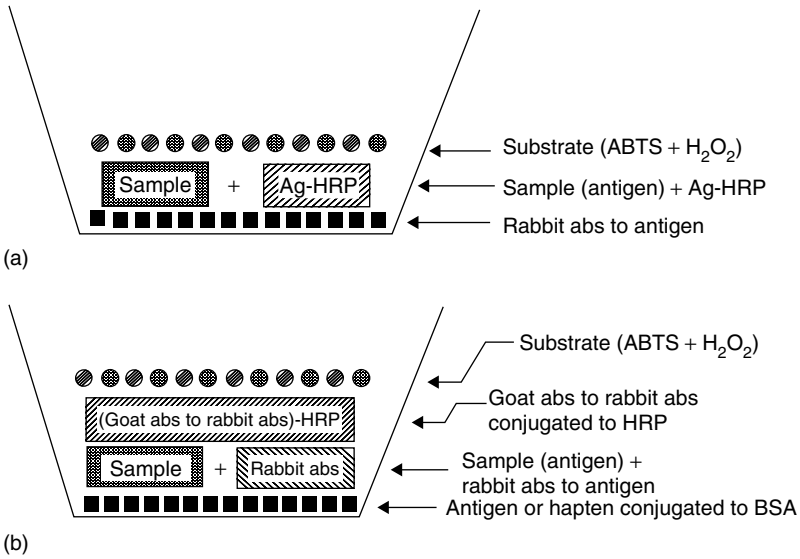

Figure 10.3 Direct and indirect competitive ELISA techniques.

antibody, then secondary antibody, then enzyme, and finally substrate. The advantage here involves the use of commercially available secondary Ab already conjugated to the enzyme. This mode is particularly useful if you are producing your own antibodies for research in rabbits or mice in that the primary antibody is not conjugated to the enzyme. The indirect ELISA assays are particularly useful for assaying antibody titers. The indirect sandwich ELISA [Figure 10.2(c)] is particularly useful if a hapten by itself is not capable of binding to the surface of the well. Here, primary Abs are bound initially to the well, followed by the addition of antigen (sample), then secondary Abs conjugated to the enzyme, and then the substrate. The competitive ELISA assays are the most sensitive and also facilitate the addition of samples to the wells. In the direct competitive ELISA [Figure 10.3(a)], Abs are first bound to the surface of the well followed by the simultaneous addition and incubation of the sample (antigen) and antigen-enzyme conjugate. These two components then compete for binding to the Abs bound to the well. The intensity of the final color developed is inversely related to the amount of antigen in the sample. In the indirect competitive ELISA [Figure 10.3(b)] antigen or hapten-protein conjugate is first bound to the surface of the well. This is then followed by the simultaneous addition and incubation of the sample (antigen) and primary Abs against the antigen. The primary Abs then compete for the soluble antigen in the sample and for the antigen bound to the well. After rinsing, secondary Ab-enzyme conjugate is then added followed by rinsing and the addition of substrate. The intensity of the final color developed is inversely related to the amount of antigen in the sample.

10.5 THE USE OF THE AVIDIN-BIOTIN SYSTEM IN ELISA ASSAYS

10.5.1 Nature of the Avidin-Biotin Complex

Avidin is a glycoprotein derived from egg white containing four identical subunits, having a combined mol. wt. of 66,000 kDa. Each subunit is capable of binding one biotin molecule.

One molecule of avidin therefore binds four molecules of biotin via a noncovalent interaction with an extremely low dissociation constant of 10^{-15}.

$$AB \xrightarrow{K} \frac{[A]\,[B]}{[AB]} = 10^{-15} \tag{10.1}$$

This extremely high binding affinity of avidin for biotin constitutes the strongest noncovalent bonding known. The avidin-biotin complex forms rapidly and spontaneously when both components are mixed in solution and greatly facilitates the formation of strong bonding complexes in ELISA assays without the need for a covalent reaction. The ability of avidin to bind four molecules of biotin is taken advantage of in greatly increasing the sensitivity of ELISA assays nearly 100-fold (10). Streptavidin is a molecule produced by *Streptomyces avidinii* which also binds four molecules of biotin with a similarly low dissociation constant. It is comprised of four subunits with a combined m. wt. of 47,000 kDa. Because avidin contains a carbohydrate moiety and has a pI = 10 it tends to bind nonspecifically. Streptavidin has a pI = 6.0 and therefore has almost no charge, and because it has no carbohydrate moiety it exhibits less nonspecific binding. An advantage of avidin is the higher enzyme activity of avidin-enzyme conjugates.

10.5.2 Biotinylation of ELISA Components and Conjugation of Avidin and Streptavidin to Proteins

Antibodies, antigens, and enzymes can be readily covalently bonded to biotin (biotinylation). Antibodies and antigens are usually biotinylated through their available amino groups although the sulfhydryl groups of both and the oligosaccharide components of Abs can also be used. The most common method used for biotinylating antibodies and protein antigens involves the use of the biotin derivative biotinyl N-hydroxysuccinimide (BNHS) which usually furnishes a satisfactory intervening spacer arm separating the biotin molecule from the reactive site of the protein. A detailed discussion of all commonly used methods for biotinylation of antibodies has been presented by Bayer and Wilchek (11). The conjugation of the proteins avidin and streptavidin to antibodies and enzymes involves the same conjugation chemistry as that of proteins in general. A number of methods for producing a variety of avidin derivatives and conjugates have been developed (12–15). Microtiter plates are also available precoated with streptavidin or poly D-lysine to facilitate the use of a wide variety of protocols.

There are three fundamental avidin-biotin techniques. The labeled avidin-biotin (LAB) technique involves adding an enzyme labeled avidin conjugate to a biotinylated primary (direct assay) or secondary antibody (indirect assay). Figure 10.4(a) illustrates the indirect (ILAB) reaction scheme. This method is commonly used for screening monoclonal antibodies from hybridoma cell lines. The bridged avidin-biotin assay (BRAB) results in amplification by using a sandwich technique where the avidin is not conjugated to the enzyme [Figure 10.4(b)]. Avidin is used as a bridge between a biotinylated antibody and the enzyme. This increases the amplification further by complexing more biotinylated enzyme than the ILAB assay. The avidin-biotin complex (ABC) technique is the most sensitive [Figure 10.4(c)]. Here, the biotinylated enzyme is preincubated with avidin, forming large complexes. When this solution is added to the wells, any remaining biotin-binding sites on the avidin will bind to immobilized biotinylated antibody. This leads to an increased number of enzyme molecules bound to the surface of the well resulting in maximum amplification.

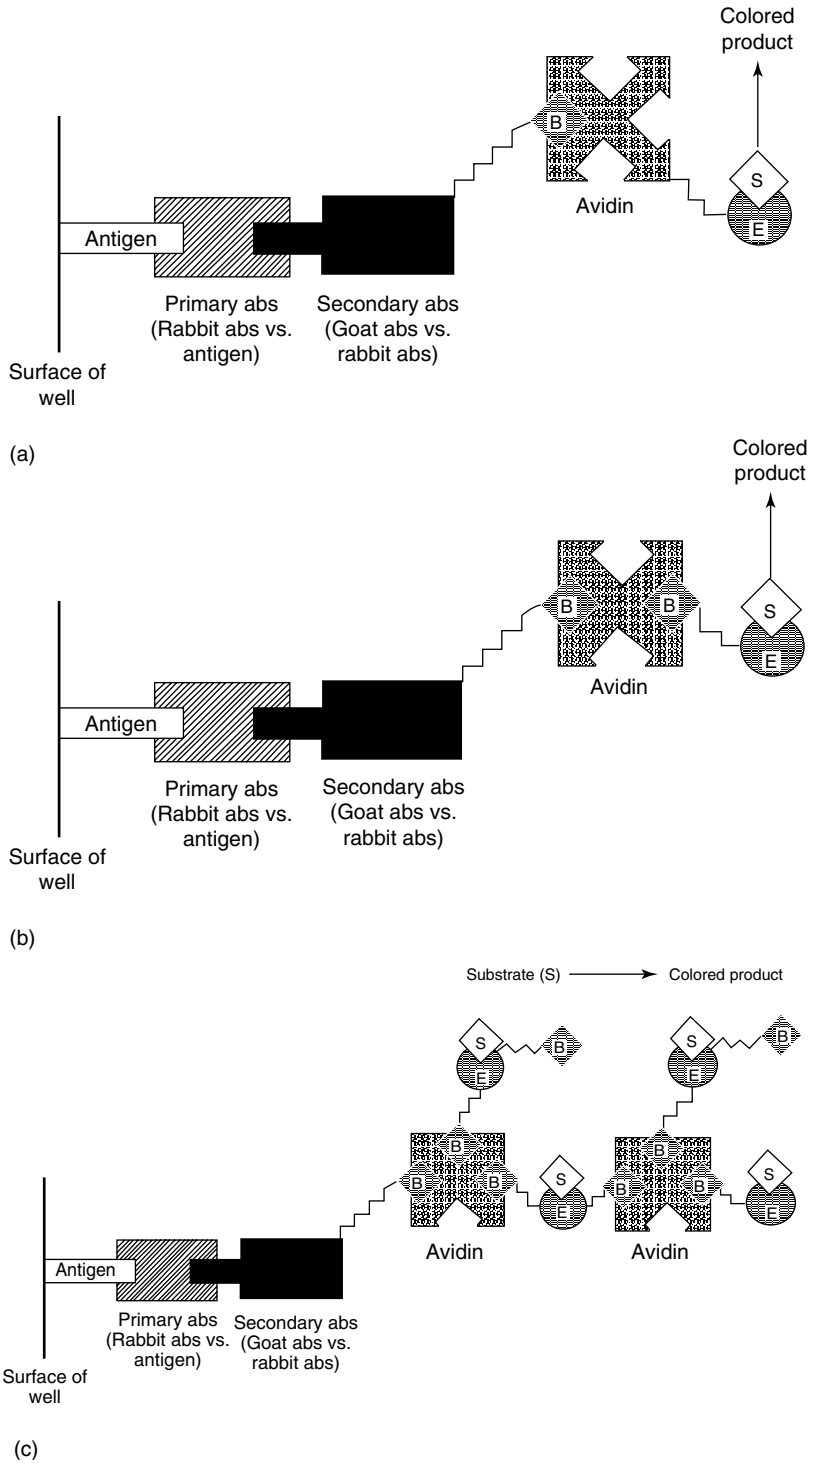

Figure 10.4 Fundamental avidin-biotin ELISA techniques.

10.6 ELISA DETECTION OF TOXINS IN FOODS

10.6.1 Seafood Toxins (Figure 10.5)

10.6.1.1 Saxitoxins

Saxitoxin (STX) is the most potent of a family of at least 18 known homologs (16) produced by single celled microscopic marine algae presently designated *Alexandrium tamarense* and *Alexandrium catenellum* and certain related organisms. These organisms are consumed by filter feeding shellfish such as clams, oysters, mussels, and other mollusks, and are the cause of red tides at sea that result from periodic blooms of these organisms. Consumption of shellfish containing elevated levels of saxitoxin and its homologs results in paralytic shellfish poisoning, hence the designation paralytic shellfish toxins (PST). These toxins resist boiling and function neurologically as sodium channel blocking agents, resulting in symptoms starting with paresthesia and leading to ataxia. In extreme cases, respiratory or cardiac failure has led to death. The lethal dose of STX for humans has been estimated to be between 0.5 to 4 mg (17). The U.S. Food and Drug administration has set the legal limit of STX in shellfish of 80 μg /100 g of edible tissue.

An indirect competitive ELISA for STX was developed using antibodies from rabbits generated by immunizing with an STX-BSA formaldehyde mediated conjugate (18). STX conjugated to BSA or polylysine was used to coat the wells, followed by simultaneous incubation with standard toxin and anti STX Abs. The amount of Ab bound to the solid phase was determined by incubation with goat anti rabbit Abs conjugated to peroxidase followed by H_2O_2 plus ABTS. The assay was found capable of detecting 2–10 pg of STX in a pure buffer solution (Figure 10.6). The detection limit for STX added to clam and mussel tissue was 50–100 ppb. There was little interference of the assay by clam tissue but mussel meat exhibited notable interference.

Davio et al. (19) conjugated STX to BSA, KLH, horse IgG, human IgG, and egg albumin with 1.4% formaldehyde. Only BSA and KLH bound significant quantities of STX and only KLH-STX induced STX binding antibodies in an ELISA assay. STX conjugated to KLH by formaldehyde with STX-BSA bound to the solid phase was used to develop a competitive indirect ELISA having a detection limit of 20 ppb (20).

Usleber et al. (21) coupled STX to HRP using a novel adaptation of the periodate reaction for the development of a direct ELISA assay that resulted in a detection limit for STX of 0.35 pg per assay and 3 ng per gram of shellfish tissue. This was about ten times more sensitive than the indirect ELISA (19) with the same antiserum due presumably to the absence of a methyl bridge resulting from formaldehyde coupling of STX to HRP. Only neo-STX showed cross reactivity (about 10% relative to STX) while several additional homologs of STX exhibited no cross reaction.

Kralovec et al. (22) precoated the wells of Maxisorp microtiter plates with BSA and obtained direct binding of STX in 0.01 M piperazine-glycylglycine buffer at pH 10.0. This yielded greater sensitivity with a competitive ELISA for detection of STX compared to binding of an STX conjugate. A protocol for the use of a direct competitive ELISA using either anti saxitoxin STX/STX-HRP or anti neo STX/STX-HRP pairs was found to detect 211 of 1450 (13.6%) naturally contaminated samples of shellfish as positive compared to 175 (11.3%) by the standard mouse bioassay (23).

A commercially available ELISA for detection of PST was found to exhibit unpredictable cross reactivities to a mixture of gonyautoxins (GTXs), and underestimated the toxicity of some naturally contaminated shellfish (24).

10.6.1.2 Ciguatoxin and Maitotoxin

Ciguatera poisoning refers to the neurological symptomology resulting from the ingestion of tropical fish contaminated with the polyether toxins ciguatoxin and maitotoxin. These fish include snappers, groupers, marine eels, jackfish, reef sharks, barracuda, sturgeon fishes, and occasionally others found in the Caribbean and tropical Pacific (25). Maitotoxin (MTX) is the predominant toxin in the tissues of such fish with ciguatoxin (CTX) occurring usually at one tenth the concentration of maitotoxin. Both toxins are produced by the dinoflagellate *Gambierdiscus toxicus*. MTX has a m. wt. of 3424 Da, contains 160 carbon atoms (26), and is the most potent of all marine toxins, having an LD_{50} for mice of 50 ng/kg body wt., I.P (27). MTX functions as a neuroexcitor by opening Ca^{++} channels causing an influx of calcium ions into neurons resulting in the release of the neuromuscular transmitter acetylcholine exciting both smooth and cardiac muscle tissue (28). Symptoms can last for many years. The major problem associated with the chemical detection and quantitation of maitotoxin is that it occurs at notably low concentrations in fish (28 μg/kg) (27) and requires initial extraction with methanol, solvent partitioning, and repetitive HPLC chromatography to achieve purification (26). Complete purification of ciguatoxin was achieved in 1989 (29).

Among a series of monoclonal antibodies derived from partially purified MTX and applied to an indirect ELISA assay, some reacted with various pigments present in the MTX extracts while others reacted in direct proportion to measured toxicity (30).

Mouse polyclonal antibodies derived from a CTX-1B fragment conjugated to BSA and OVA in indirect and direct competitive ELISA assays yielded similar antibody titers and a detection limit of 7 picomoles for CTX-1B in crude lipid extracts of fish tissue (31). Resulting antibodies reacted with CTX-1B but did not significantly cross react with brevitoxin-3 (PbTx-3) or other related polyether structures. Conjugation of the N-hydroxysuccinimide

ester of the carboxylic acid CTX-1B fragment to the protein carriers was achieved using a standard carbodiimide condensation procedure.

10.6.1.3 Brevitoxins

The marine dinoflagellate *Ptychodiscus brevis* (formerly *Gymnodinium breve*) is responsible for production of a family of at least 10 polyether toxins referred to as brevitoxins (PbTx-1 to PbTx-910) (32–34). These toxins are grouped into two subgroups (type 1 and type 2) based on backbone structure. The organism is responsible for production of toxic red tides along the Gulf of Mexico and Texas (35) resulting in mass mortality of exposed fish. Consumption of toxic shellfish results in neurotoxic shellfish poisoning. Algal blooms along the shore have been found to produce an aerosol irritating to the respiratory tract (33). PbTx-3 functions by opening sodium channels resulting in depolarization of the axon membrane (36).

One of the earliest ELISA assays for brevitoxin was developed by Trainer and Baden (37). PbTx-3 was purified by HPLC and a carbodiimide derivative of PbTx-3 was prepared and conjugated to urease and to HRP for competitive ELISA assays. With the urease conjugate, the pH indicator bromcresol purple was used for observation of the color change from yellow to purple resulting from the release of ammonia by urease activity. Both systems yielded linear responses for quantitation with an operational range of 1 pmole to 10 nmoles of PbTx-3 per well. The urease conjugate however lacked enzyme stability and was abandoned in favor of the HRP conjugate.

Naar et al. (38) converted a minute amount of PbTx-3 (400 μg) to an hemisuccinate derivative and then conjugated to BSA and OVA in a reversed micellar medium for Ab production in mice. In competitive ELISA assays, both polyclonal and monoclonal Abs exhibited strong cross reactivity to other PbTx-2-type toxins (PbTx-2 and 9) but low or moderate cross reactivity to a PbTx-1-type toxin (PbTx-1). Monoclonal antibodies exhibited a low cross reactivity with okadaic acid but no significant cross reactivity was observed with two ciguatoxins (CTX-1B and CTX-3C). The monoclonal based assay resulted in a detection limit of 5 ng per well, with a working range of 8–150 ng per well. The assay appears to be a suitable alternative to the mouse bioassay for routine shellfish monitoring.

10.6.1.4 Domoic Acid

Domoic acid (DA) is the causative agent of amnesic shellfish poisoning and functions as a neuroexcitatory analog of glutamic acid causing lesions and neuronal necrosis in the hippocampus portion of the brain (39–41). Persistent short term memory loss is a frequent symptom. The pennate diatoms *Nitzschia pungens* (42*)* and *Nitzschia pseudodelicatissima* (43) have been found responsible for formation of domoic acid. A direct ELISA assay for domoic acid was developed by Kitts and Smith (44). Lower limits of detection in human plasma, urine, and milk were 0.25 mg/ml, 0.2 mg/ml, and 10 mg/ml respectively. The assay was also applicable for detection of domoic acid in shellfish tissue.

Garthwaite et al. (45) raised ovine antibodies against conjugates linked through the secondary amino group of domoic acid together with activated ester derived conjugates of domoic acid as a plate coater, for development of an indirect competitive ELISA. The assay had a working range for quantitation of 0.15–15 ng/ml of super(-1) DA, the lower limit being 500 times lower than the maximum permitted level in shellfish tissue in New Zealand.

10.6.1.5 Okadaic Acid

Okadaic acid (OA) and its seven homologs (46) are the causative agents of diarrheic shellfish poisoning (DSP) and are produced by dinoflagellated algae such as *Dinophysis* spp.

and *Prorocentrum* spp. An indirect competitive ELISA with electrochemical detection was developed for okadaic acid by Ramsay et al. (47). Soluble sample antigen competed with immobilized antigen for soluble antibody, followed by the addition of a secondary antibody labeled with alkaline phosphatase. The enzyme label hydrolyzed phenyl phosphate to yield phenol which was oxidized at +870 mV vs. Ag/AgCl and yielded a response inversely proportional to the soluble antigen concentration.

Total OA (OA plus methylOA) in clones of several dinoflagellates was determined by Morton and Tindall (48) using HPLC-fluorescence, the UBE ELISA test kit, and the Rougier Bio-Tech ELISA test kit, both of which involve use of monoclonal Abs. All three methods yielded consistent results for *P. hoffmannianum* which produces only OA. Results of the three methods however, were not consistent for *P. lima* which produces both OA and methylOA. The UBE ELISA demonstrated little or no cross reactivity with methyOA; whereas the Rougier ELISA demonstrated varying degrees of cross reactivity with that analog. Nonokadaic acid producing species yielded negative results. The authors concluded that both ELISA kits may underestimate total okadaic acid present in shellfish.

Nunez and Scoging (49) found that HPLC, a colorimetric protein phosphatase inhibition assay, and the mouse bioassay correlated well for detection of OA. In contrast, a commercial ELISA kit failed to accurately and consistently detect low levels of OA from the hepatopancreas of shellfish.

Lawrence et al. (50) using an indirect competitive ELISA found that a mAb detected with equal sensitivity OA, dinophysistoxin-4 (DTX-4) and dinophysistoxin-5 (DTX-5), and an OA diol ester.

Chin et al. (46) studied the affinity of the anti OA Ab from the Rugier test kit for OA and several of its homologs. Dinophysistoxins–2 and –1 could be detected by the assay but at concentration ranges 10- and 20-fold higher, respectively, than for OA. Dinophysistoxin-3, calyculin A, and brevitoxin-1 could not be detected. The working range of the assay for OA was 5 pg to 0.5 ng per well.

Usagawa et al. (51) developed an indirect competitive ELISA using mAb to OA derived by conjugating OA to ovalbumin for mouse injection. The assay involved binding OA-BSA to the surface of wells, followed by the simultaneous addition of AO containing samples and commercial alkaline phosphatase conjugated to rabbit anti mouse IgG+IgA+IgM (H+L) prior to myeloma cell fusion. Three mAbs were obtained against OA and were designated OA-1, OA-2, and OA-3. All three reacted with dinophysistotoxin-1 (DTX1) to the same extent as with OA , and failed to react with 7-*O*-acyl-OA but reacted slightly with Yessotoxin. Extraction of OA from shellfish tissue with higher than 45% methanol resulted in significant inhibition of the ELISA. Sensitivity was 0.25 ng per assay well.

Vale and Sampayo (52) found that a commercial ELISA test kit based on the methodology described by Usagawa et al. (50) was more sensitive, specific and faster than HPLC for determination of OA in shellfish tissue. No problems were encountered when using hydrolyzed semi purified tissue extracts to detect esters of OA. Sensitivity for OA was 0.25 ng per assay well. The assay kit also detected dinophysistotoxin-2 (DTX2) at a level of sensitivity about 50% below that for OA.

10.6.1.6 Seafood Allergens

Shiomi et al. (53) used an ELISA assay to asses the ability of sera from five fish sensitive patients to react with partially purified extracts from nine fish species. Allergenicity was found to vary among the fish species and individual patients. The major allergens in Japanese eel and bigeye tuna were found to be parvalbumins and higher molecular weight substances.

Ishikawa et al. (54) compared the allergens from fish species of shellfish using a competitive ELISA assay. Cross reactivity was recognized between shellfish allergens and the oyster allergen Cra g 1, suggesting that, irrespective of species, the major allergen in shellfishes is tropomyosin.

10.6.2 Fungal Toxins (Figure 10.7)

10.6.2.1 Aflatoxins

Aflatoxins are carcinogenic toxins that fluoresce brightly under long wavelength ultraviolet light. There are four major toxins in this group designated B1, B2, (fluoresce blue) and G1, G2 (fluoresce green yellow). B1 is the most potent carcinogen and mutagen of the group.

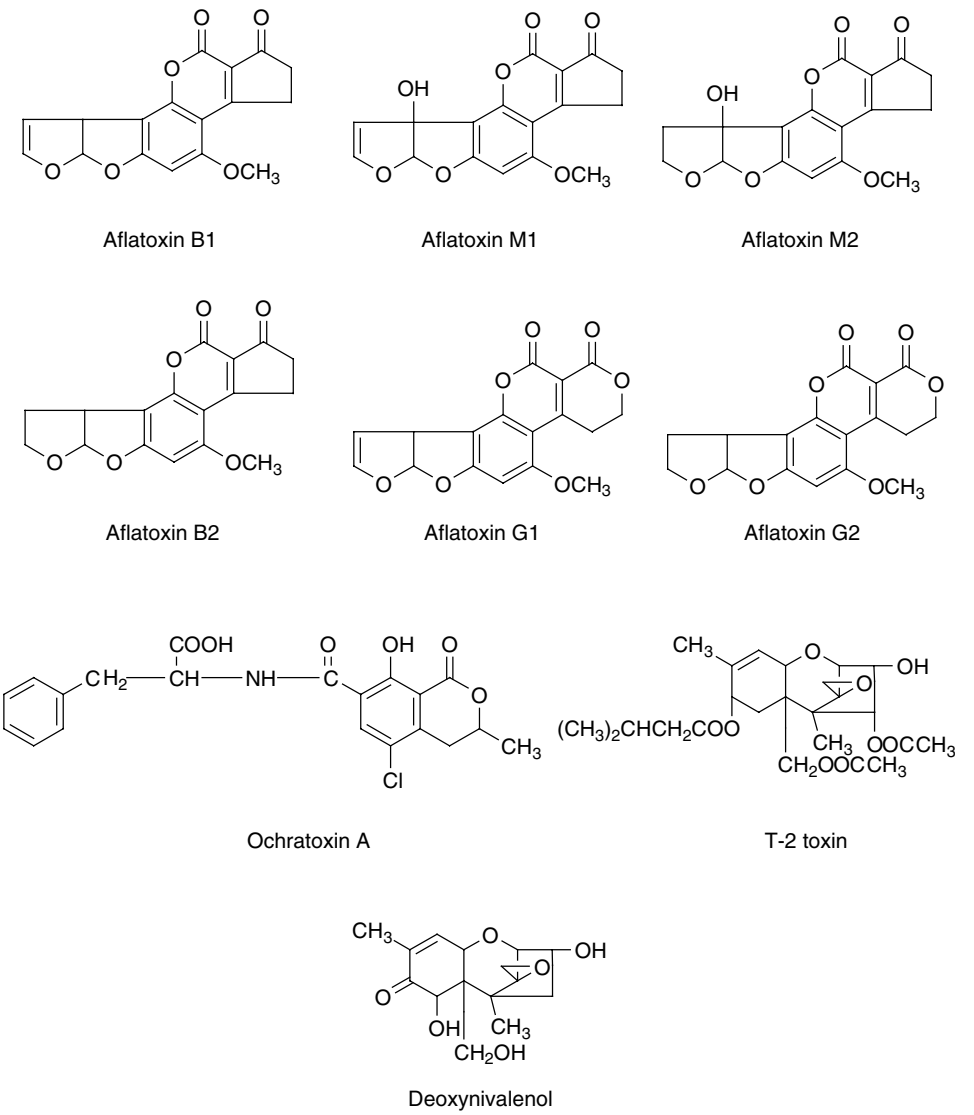

Figure 10.7 Structures of major fungal toxins.

M1 and M2 are produced by bovine tissue from B1 and can be found in milk. B2a and G2a are precursors. *Aspergillus flavus* and *Aspergillus parasiticus* are the major aflatoxin producing molds. These molds are typically green due to the color of their conidiospores. The attack of peanuts by these organisms prior to harvest as a result of rainfall and warm weather frequently occurs and may continue beyond the harvest period if sufficient moisture is present during storage. Peanut butter frequently contains detectable levels of aflatoxins. Corn, wheat, and other grains are also subject to attack by these molds with their B1 content being readily measured by ELISA (55). The limit in the U.S. for aflatoxins is 20 ppb in food, feeds, and nuts, and 0.5 ppb for milk (56).

Lawellin et al. (57) developed the first reported ELISA assay for aflatoxin B1. The assay was found capable of measuring between 100 to 1 pg of B1. Antiserum to B1-BSD conjugate was first bound to the surface of polystyrene tubes (16 x 125 mm). Samples containing free B1 were added and the B1 was allowed to bind. After rinsing, B1 conjugated to HRP was added, followed by rinsing and the addition of orthotolidine as substrate for the bound HRP. B2 resulted in complete inhibition, G1 and M1 resulted in 50% and 7.5% inhibition respectively.

Burkin et al. (58) used an indirect ELISA involving immobilization of a B1-BSA conjugate and polyclonal antibodies and obtained low relative cross reactivity against B2, G1, G2, M1, B2a, G2a and sterigmatocystin with a sensitivity of 0.04 ng per well or 4.0 ng/ml of sample.

Several interlaboratory collaborative studies have led to the acceptance of ELISA as an official method of quantitation of aflatoxins by the AOAC (59–61) and the development of commercial test kits. The development of monoclonal antibodies for aflatoxins has further increased the sensitivity of ELISA assays (62).

Devi et al. (63) reported that hybridomas that secreted antibodies for aflatoxin B1 were selected using two immunization protocols referred to as A and B. Protocol A is a standard immunization method and resulted in the selection of only two clones that produced monoclonal antibodies against aflatoxin B12. In protocol B, a unique immunization schedule was used which resulted in the generation of 10 hybridomas. Of the 10, one antibody was highly specific for B1, four antibodies reacted equally strongly with B1, and G1 but weakly with B2. Another four reacted strongly with B1 and weakly with B2 and G1. One clone reacted equally strongly with B1, G1, and B2. All of the 10 antibodies exhibited little or no cross reactivity with G2.

Monoclonal Ab (mAb) was found to be more accurate than pAb for determination of free and adducted B1 in urine samples (64). The ELISA had a sensitivity of 1 pg/ml compared to HPLC sensitivity of 0.1 ng/ml with a fluorescence detector and 4.5 ng with a UV detector.

Kim et al. (65) reported on the occurrence of M1 in Korean pasteurized milk and dairy products with the use of a direct competitive ELISA assay and HPLC. The limit of detection with ELISA was 2 pg/ml and with HPLC was 10 pg/ml. Among a total of 180 samples, the incidence of M1 in pasteurized milk, infant formula, powdered milk and yogurt was 76, 85, 75, and 83%, respectively, with mean concentrations of 18, 46, 200, and 29 pg/g, respectively.

An extremely unique approach was used by Devi et al. (66) for eliminating the requirement of a B1-BSA conjugate in an indirect competitive ELISA assay for B1 utilizing random peptide libraries displayed on bacteriophage. Peptides were fused to a coat protein of a suitable phage which also carried the encoding DNA for the peptide. Phage were then selected possessing a peptide capable of binding to mAb directed against B1. For two of the three mAbs tested, phage clones were isolated that bound specifically to mAb 24 (specific for B1 and G1) and mAb 13 (specific for B1, G1, and B2). The third

mAb failed to react with any of the phage displayed peptides. Phage borne peptides that mimic antigen in binding antibodies are termed mimotopes. Their indirect competitive ELISA assay consisted of coating wells with phage harboring the requisite B1 mimotope. After washing and blocking, the wells were incubated simultaneously with mAb (to B1) plus various concentrations of B1 (representing samples). Following incubation and washing, goat anti mouse Ab conjugated to alkaline phosphatase was added, followed by incubation, washing and the addition of p-nitrophenyl phosphate as substrate.

Yong and Cousin (67) developed an ELISA assay to detect molds producing aflatoxins in maize and peanuts using an antibody to extracellular antigen from *A. parasiticus*. This antibody recognized species with phenotypic similarities to *A. parasitucus, A. flavus, A. sojae,* and *A. oryza.* For naturally contaminated maize samples, low and high levels of aflatoxin corresponded with low and high ELISA readings for mold antigens. *A. parasiticus* could be detected before the production of aflatoxins. The assay appears suitable for early detection of responsible molds before detectable aflatoxin is produced.

10.6.2.2 Ochratoxin

Ochratoxin is a toxic metabolite of certain strains of *Aspergillus ochraceu* and *Penicillium viridicatum* found on grains, legumes, peanuts, and green coffee, causing enteritis, renal necrosis (also known as Balkan nephropathy), and an increase in liver glycogen with an LD_{50} in rats of 20 mg/kg (68). The toxin is also carcinogenic.

A flow through membrane based direct competitive ELISA for the rapid detection of ochratoxin A in wheat was developed by De Saeger and Van Peteghem (69). An immunodyne 0.45 μ ABC membrane was first coated with rabbit anti mouse Abs and placed onto an absorbent pad, the membrane was blocked, followed by a competitive ELISA involving the addition of ochratoxin-mAb, washing, addition of ochratoxin (a standard solution or sample extract) plus ochratoxin A-HRP conjugate, washing, and the addition of HRP substrates. A portable colorimeter was used to confirm and quantify the color intensity. A wheat sample spiked with 4 μg/kg resulted in complete color suppression. Passage of 600 μL of sample extract through the membrane facilitated maximum binding of all ochratoxin present to the membrane in addition to the advantage of greatly reducing reaction times by bringing reactants into intimate contact in the matrix of the membrane by elimination of the dilution factor involved with reaction volumes. With coated membranes, the assay could be completed in less than 15 min. Sibanda et al. (70) subsequently applied this flow through ELISA assay to the detection of ochratoxin in samples of green coffee beens. The assay had a sensitivity of 8 ng/g and correlated with HPLC results.

Tirulamala-Devi et al. (71) developed an indirect competitive ELISA for ochratoxin A using pAbs capable of detecting 0.1 ng/ml or 0.06 ng of ochratoxin A per assay. The Abs did not react with ochratoxin B, coumarin, 4-hydroxycoumarin, L-phenylalanine, or aflatoxin B1.

10.6.2.3 Trichothecenes

Trichothecenes constitute a group of potent toxins that are esters of sesquiterpene alcohols having in common a trichothecene ring structure and an epoxide group. The trichothecenes are divided into three groups: the type A trichothecenes, which includes T-2 toxin, the type B trichothecenes, which includes deoxynivalenol, and the type C or macrocyclic trichothecenes, also known as satratoxins. Trichothecenes are responsible for severe outbreaks of mycotoxicosis, including alimentary toxic aleukia (ATA) and stachybotryotoxicosis in Russia, red mold poisoning in Japan and moldy corn toxicosis in the U.S. (72). Among the several dozen trichothecenes isolated to date, T-2 toxin, and deoxynivalenol are most frequently associated with

human illness. Trichothecenes are produced by a number of fungal species and genera (73). The most important T-2 producer is *Fusarium tricinctum*. All members of the genus *Fusarium* produce characteristic sickle shaped conidiospores. T-2 is toxic to certain plants, fungi, brine shrimp insects, fish, and mammals. The i.p. LD_{50} in mice is 5.2 mg/kg (73). Toxic effects of T-2 result from inhibition of protein synthesis and with mammals include dermal necrosis, apoptosis, inflammation, and hemorrhaging of the gastrointestinal tract, edema, leucopenia, degeneration of the bone marrow, and death.

Attempts to produce mAbs to T-2 involving conjugating T-2 through the functional hydroxyl group at the C-3 position have been found to result in low levels of immunogenicity and low affinities for T-2 (74). The low level of immunogenicity was found to be due to the release of T-2 from the protein carrier with resulted toxicity to lymphoid cells. When T-2 was coupled at the C-8 position and the hemisuccinate of 3-acetyl-neosolaniol used for conjugation to BSA mAb the resulting conjugate was highly immunogenic and yielded mAb that was cross reactive with most group A trichothecenes (75). An indirect ELISA allowed the detection of 0.05 ng of T-2 (76).

Gendloff et al. (77) used the method of Chu et al. (78) for conjugating T-2 to BSA in the development of a competitive ELISA. The assay was used to screen for T-2 in *Fusarium sporotrichioides* infected corn. The assay detected T-2 in diluted methanol extracts of corn samples at a concentration of 0.05 ng/ml (detection limit of 1 pg per assay). HPLC and ELISA estimates were similar.

Nagayama et al. (79) developed an indirect mAb ELISA assay for the screening of T-2 toxin producing species of *Fusarium*. The minimum detection limit was 5 pg per assay.

10.6.3 Natural Plant Toxins

10.6.3.1 Ricin

Ricin is an extremely lethal heat labile toxin derived from the castor bean, and consists of two polypeptide chains designated A and B connected by a disulfide bridge. It is an irreversible inhibitor of protein synthesis. Both polypeptides have molecular weights of about 30,000 Da (80). The B chain, a lectin, with binding affinity for galactose, binds to the mammalian cell wall allowing entry of the A chain into the cell. The A chain is destructive to eukaryotic ribosomes by functioning as an N-glycohydrolase, which inactivates ribosomes by an enzymatic deadenylation of rRNA (81). A single molecule is considered sufficient to kill a mammalian cell and accounts for the notably low mouse MLD (i.p) of 0.001 μg of ricin D nitrogen per gram of body wt. In recent years, the A-chain coupled to antibodies has been used experimentally to target *in vivo* tumor cells. The tumor specificity is provided by the antibody of choice, while the cellular entry of the A-chain provides selective destruction of the tumor cells. The first ELISA assay for ricin was a sandwich method with a sensitivity of 6.8 ng/ml in buffer and was about tenfold less sensitive (60 ng/ml) if the ricin was assayed in rabbit body fluids (81). An ELISA for ricin, having a sensitivity of about 10 ng/ml, utilizing affinity purified rabbit antiserum, was developed for ricin assay in rat tissue after ricin injection (82). Later ELISA assays were reported with sensitivities of 25 pg/ml in plasma (83) and 200 pg/ml of tissue extracts (84). Poli et al. (85) developed an avidin/biotin alkaline phosphatase ELISA for ricin based on affinity purified goat antibodies. The minimum detection level was 1 ng/ml (100 pg/well). In this same study, the authors developed a chemiluminescence assay by replacing the substrate p-nitrophenyl-phosphate with Lumiphos-530 and were able to accurately quantitate the presence of 100 pg/ml (10 pg/well) of ricin. Lipps (86) injected mice with one half the predetermined lethal dose of ricin (1 μg), four times at two week intervals. An ELISA assay was used to assess the potency of the antitoxin. Because of the high antibody titers

produced after three injections of this minute dose, the author concluded that ricin is a super antigen.

10.7 SUMMARY

ELISA assays for detection and quantititation of a variety of toxins in foods represents a reliable and highly sensitive technique that usually correlates closely with HPLC analysis. The use of mAbs affords an additional level of specificity and sensitivity to complement the use of pAbs, particularly when various homologs of a given toxin may be present. The present state of the immunological industry, and its wide range of products, serves to greatly facilitate the continued development and application of additional ELISA systems for the detection and quantitation of toxins in foods.

3.11

Biosensors for Food Quality Assessment

Michele Del Carlo, Mihaela Nistor, Dario Compagnone, Bo Mattiasson, and Elisabeth Csöregi

CONTENTS

11.1 INTRODUCTION

11.1.1 Background

As agriculture and food technology have advanced, analytical and regulatory problems have become more and more complex. Food industries, operating in a highly competitive market are stimulated, on one side, to maintain and guarantee the characteristics of the

existing products, and on another side, to innovate or introduce new products. Reliable data on the nutrient composition of foods consumed by people are critical in many areas: health assessment, the formulation of appropriate institutional and therapeutic diets, nutrition education, food and nutrition training, epidemiological research on relationships between diet and disease, plant breeding, nutrition labelling, food regulations, consumer protection, as well as for a variety of applications in trade, research, and development.

Improving the preservation, or increasing the yield, of agricultural products is a common aim for the producers, normally realized by using herbicides, insecticides, antibiotics or hormones. However, the use of these xenobiotics clearly represents a potential threat for consumers' health and people have always been concerned about the safety and quality of the food they eat. Additionally, there has always been a risk of fraud since food became a trade object, and despite the great progress of technology and preservation strategies, microbial contamination still remains a problem in food industry and distribution chain.

More recently, functional foods have been introduced on the market, when ingredients or components (e.g., vitamins, vaccine) are added to a product to tackle health and bad eating habit related issues, or from which possibly adverse components have been removed, thus introducing the need of monitoring an increasing number of various parameters.

Food quality comprises mainly three aspects:

1. Safety: A food product must not contain levels of contaminants, such as pathogens or toxins, likely to cause illness upon consumption
2. Shelf life: A food product must not contain contaminants at a level at which it becomes organoleptically spoiled in an unacceptably short time
3. Consistency: A food product must be of consistent quality with regard to both safety and shelf life, for example, the consumer will not accept products, which display large batch to batch variations in shelf life (1)

Obviously, the concern on the safety issue is a key aspect for food industry, regulatory agencies, and control laboratories. It is difficult to separate food quality from food safety, and the two aspects are, in fact, strictly related and the availability of analytical tools for assuring both is highly required. Regulatory agencies and the food industry are the two bodies most actively interested in determining and controlling the quality of food products. The regulatory authorities must fulfil their statutory responsibilities in order to protect the public from hazardous or inferior goods. The extent to which they are involved in food production and supply depends on the existing regulations and laws of the country in which they operate. Food stuff producing companies are equally interested, because association of their brand with products that are consistently good and safe will protect and enhance their good reputation on the market. The control is generally carried out by periodic chemical and microbiological analysis using standard reference procedures demonstrating the obvious need for highly sensitive, reliable, rapid, and affordable methods to determine an increasing number of compounds (2).

11.1.2 Food Products as Analytical Samples

The food industry is a process industry; suitable sensors for monitoring and control of key parameters are necessary not only for the characterization of the final product, but also for monitoring during the manufacturing process, both for process optimization and alarm in case of process failure. Food analysis comprises many aspects, including characterization of nutritional facts (product specific information on serving size, calories, content of fat,

carbohydrates, proteins, vitamins, and minerals), microbial content (both pathogenic, i.e., *Salmonella*, *Listeria*, *Campylobacter*, *Escherichia coli O157*, *Yersinia*, *Shigella*, or *Vibrio* species, and spoilage, index or indicator organisms, i.e., *Bacillus cereus*, *Staphylococcus aureus*, *Faecal streptococci*, *Clostridium perfringens*, or *Pseudomonas sp.*), food additives (aspartame, saccharin, benzoate, sorbate, ascorbate, and sulphur dioxide), or pesticide and veterinary residues. Besides the characterization of the composition and properties of food products, the analytical methodology must also deal with possible chemical changes they might undergo during handling, processing, and storage. However, the difficulty of food analysis arises not only from this great number of components which need to be determined, but also by the complexity of the specific target food products, the analyte(s) of interest being always masked by a great number of matrix components, in a wide range of chemical classes and concentration levels. Moreover, food products might be liquids, pastes, or solids, the last two forms being incompatible with common existing analytical methodology, so that a suitable extraction method needs to be employed, in order to remove a great deal of matrix components and to bring the analyte(s) of interest in a liquid environment.

A successful analytical method requires the following characteristics: high selectivity and sensitivity; reliability; short assay times; stability; simplicity, low cost for operation and storage, and possibly a potential for miniaturization and facility of automation. Within the rapid method of analysis, biosensors are expected to play a prominent role in food processing, quality, and safety control, because they meet most of the criteria mentioned. The aim of this work is to review the development and application areas of biosensors in the food industry, their current situation, and future possibilities.

11.2 GENERAL ASPECTS OF BIOSENSORS

Biosensors are analytical devices incorporating a biological or biologically derived sensing element either integrated within or intimately associated with a physico-chemical transducer. Specific interactions between the target analyte and the complementary bio recognition layer produces a physico-chemical change that is detected and may be measured by the transducer (3,4).

The usual aim of using a biosensor is to produce a signal which is related to a single analyte or a related group of analytes.

The biological sensing elements used in biosensors are typically enzymes or binding proteins, such as antibodies, nucleic acids, bacteria and single cell organisms and even whole tissues or higher organisms. The choice of the biosensing element is decided by the substrate of interest (target analyte).

The physico-chemical transducers may take many forms depending upon the parameters being measured; electrochemical, optical, mass, and thermal changes are the most common. If the selectivity is mainly decided at the biosensing element, the transducer often determines the sensitivity of a biosensor (3,4) (See Figure 11.1).

Biosensors offer a number of advantages over traditional methods, such as high performance liquid chromatography and gas chromatography, which require high maintenance costs, expert operators, and long analysis times, making them less practical for food process monitoring. The measurements performed with a biosensor, are very *sensitive* and *selective*, due to the extraordinary nature of the biological interaction. The required equipment is generally simple, suitable for on site analysis and automation (5), and suitable for a quick food diagnosis.

11.3 POTENTIAL APPLICATIONS

Since the pioneering work of Clark and Lyons in 1962 (6), and Updike and Hicks in 1967 (7), there has been a phenomenal growth in the field of biosensors, with amperometrics dominating the literature. The application possibilities are very wide, medical and pharmaceuticals, food industry, and the environmental field being the three major categories. Table 11.1 presents some of the most important biosensors in the area of food analysis, described during the last six years (1999–2004).

11.3.1 Biosensors for Food Components Analysis

Application of biosensors to food component analysis has been recently reviewed covering the period 1997–2001 (49,50). In this section, the follow up is reported for the years 2001–2003 covering advancements in biosensor development and applications for the detection of carbohydrates, alcohols, phenols, carboxylic acids, and amino acids in food.

Carbohydrates (51–55) as well as alcohols, especially ethanol (23,56,57) still remain important targets for innovative biosensors. Both groups of analytes are key components in fermentation process industry, in addition to the prominent role of sugars in fruit juices, dairy products, soft drinks, and honey production. Within the biosensor area, the concept of multianalyte biosensor is gaining consideration and some attempts in this respect have been described for ethanol–glucose sensing (51,52). Most of the recently published reports are oriented to the use of chemically modified electrodes (CMEs), combined with enzymes. The aims of this chemical modification are: to reduce the working potential (23,51,52), to cast a diffusion membrane to reduce interferences (57) or to improve enzyme retention at the electrode surface (55).

Despite a certain interest in determining polyphenols using tyrosinase based biosensors during the late nineties (58,59), no recent papers have appeared on that topic, possibly due to the poor selectivity of the method; further development in that area is needed to address issues such as class specific determination, sensor stability, and selectivity.

Amino acid composition and total protein content are two important parameters that are studied in food component analysis and are related to food quality control. Total protein determination can be performed either using traditional methods such as Kjeldalh and its instrumental modification, or by commercially available photometric protein test kits. A recently developed biosensor for total protein composition based on the coupling of two enzymes, protease and L-amino acid oxidase (L-AAO) resulted in a rapid method (4 minutes/sample), requiring only 10 μl of sample and operating in the working range 0.17–1.0 mg/ml (60). A similar method, with comparable performance was developed by Kwan et al. in 2002. In addition, this method was applied to the determination of aspartame, by coupling L-AAO with pronase (61).

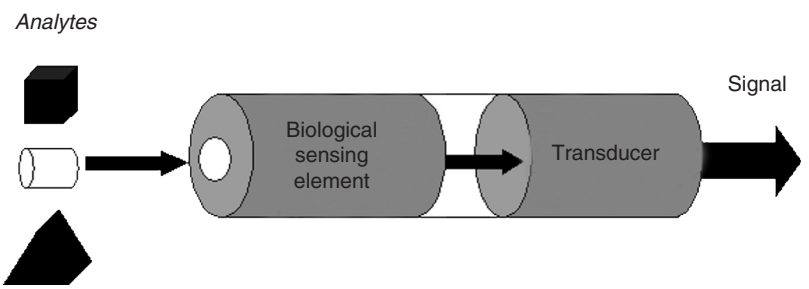

Figure 11.1 Schematic presentation of the biosensor principle

Table 11.1
Applications of the biosensors for food analysis.

Analyte	Biological Molecule	Transducer Type	Characteristics	Application	Ref.
Food components					
(Sugars, alcohols, phenols, carboxylic acids, aminoacids, biogenic amines, organic and inorganic ions, etc.)					
Glucose	Glucose oxidase	Amperometric E = +0.6 V vs. Ag/AgCl	S: 4.51 μA/mM LR: 0 – 0.5 mM	Mustard, Mayonnaise Soya souse	(8)
Glucose	Glucose oxidase	Amperometric E = −0.05V vs. Ag/AgCl	S: 3.9 mA/M cm^2 LR: 0.05 – 6 mM	Peer juice Peach juice Ananas juice	(9)
Glucose Ethanol Glycerol	Glucose dehydrogenase Alcohol dehydrogenase Glycerol dehydrogenase	Amperometric E = +0.2 V vs. Ag/AgCl	S_G: 87 mA/M cm^2 LR_G: 20 – 800 μM S_E: 220 mA/M cm^2 LR_E: 2.5 – 250 μM S_G: 32 mA/M cm^2 LR_G: 1 – 200 μM	Different types of wine	(10)
Glucose	Glucose oxidase	Optical (λ = 720 nm)	S: 0.036* U/mM LR: 0.05 – 2 mM	Apple juice Wine Coca-cola	(11)
Glucose	Glucose oxidase	Thermal	S: 1.4* mm/mM LR: 5 – 25 mM	Coca-cola Fruit Juice	(12)
Glucose Lactate	Glucose oxidase Lactate oxidase	Amperometric E = +0.6 V vs. Ag/AgCl	S_G: 9.9 nA/mM LR_G: 0.5 – 100 mM S_L: 7.2 nA/mM LR_L: 0.5 – 20 mM	Tomato juice	(13)
Glucose	Glucose oxidase	Amperometric E = +0.4 V vs. Ag/AgCl	S: 2.31 μA/mM LR: 0.1 – 9.6 mM	Soft drinks	(14)

(*Continued*)

Table 11.1 (*Continued*)

Analyte	Biological Molecule	Transducer Type	Characteristics	Application	Ref.
Sucrose	Invertase	Amperometric	S_S: 55* nA/mM	Grape juice,	(15)
Glucose	Mutarotase	E = +0.7 V vs. Ag/AgCl	LR_S: 1 – 40 mM	Coca-cola,	
	Glucose oxidase		S_G: 33* nA/mM	Orange juice,	
			LR_G: 1 – 100 mM	Kiwi juice	
Glucose	Glucose oxidase	ISFET	LR_G: 1 – 10 mM	Fruit drinks	(16)
Ascorbic acid	Horseradish peroxidase		LR_{AA}: 0.25 – 2 mM		
Citric acid	Urease		LR_{CA}: 5 – 100 mM		
Lactose	β-Galactosidase	Manometric	S_L: 0.57 kPa/mM	Milk	(17)
Glucose	Glucose oxidase		LR_L: 0 – 5 mM		
			S_G: 0.95 kPa/mM		
			LR_G: 0 – 5 mM		
Lactulose	β-Galactosidase	Amperometric	S_L: 324 nA/mM	Milk	(18)
Fructose	Fructose dehydrogenase	E = +0.38 V vs. Ag/AgCl	LR_L: 0.01 – 5 mM		
			S_F: 352 nA/mM		
			LR_F: 0.001 – 5 mM		
Fructose	D-Fructose dehydrogenase	Amperometric	S: 70 nA/mM	Jam, Honey,	(19)
		E = +0.2 V vs. SCE	LR: 0.05 – 1 mM	Chocolate,	
				Biscuit, Juice,	
				Wine	
Sucrose	Sucrose phosphorylase	Amperometric	S: 1 nA/mM	Pineapple juice	(20)
	Phosphoglucomutase	E = +0.15 V vs. Ag/AgCl	LR: 1 – 100 mM	Orange juice	
	Glucose-6-phosphate			Peach juice	
	1-dehydrogenase				
Glucose	Glucose oxidase	Amperometric	S_G: 125* nA/mM	Wine	(21)
Malic acid	Malic enzyme	E = +0.0 or 0.2 V vs. Ag/AgCl	LR_G: 0 – 5 mM		
			S_{MA}: 640 nA/mM		
			LR_{MA}: 0.05 – 3 mM		

Ethanol Methanol	Alcohol oxidase Horseradish peroxidase	Amperometric E = +0.0 V vs. Ag/AgCl	S_E: 259 nA/mM LR_E: 0.2 – 20 μM S_M: 5 nA/mM LR_M: 0.02 – 1.5 μM	Wine Beer Liquor	(22)
Ethanol	Alcohol dehydrogenase	Amperometric E = +0.3 V vs. Ag/AgCl	S: 336 mA/M cm^2 LR: 1 – 250 μM	Wine fermentation process	(23)
Polyphenols	Horseradish peroxidase DNA	Amperometric E = −0.05 V vs. Ag/AgCl	S: 181 nA/μM cm^2 LR: 1 – 50 μM	Vegetables	(24)
Polyphenols	Tyrosinase	Amperometric O_2-type Clark	S: 1* ΔDO(%)/μM LR: 0.5 – 6 ppm	Olive oil	(24)
Lactate Acetaldehyde	D-Lactate dehydrogenase Aldehyde dehydrogenase	Amperometric E = −0.15 V vs. Ag/AgCl	S_L: 589 nA/mM LR_L: 0.075 – 1 mM S_A: 1100 nA/mM LR_A: 0.01– 0.25 mM	Wine	(26)
Lactate Malate	L-Lactate dehydrogenase L-Malate dehydrogenase Diaphorase	Amperometric E = +0.3 V vs. SCE	S_L: 1.66* nA L/mg LR_L: 0.01 – 1.1 mM S_M: 1.16* nA L/mg LR_M: 0.01– 1.3 mM	Wine	(27)
Lactate	Lactate oxidase Peroxidase	Amperometric E = +0.0 V vs. Ag/AgCl	S: 424 nA/mM LR: 0.002 – 1 mM	Wine Yogurt	(28)
Acetate	Acetate kinase Pyruvate kinase Pyruvate oxidase	Amperometric E = −0.4 V vs. SCE	S: 0.07* μA/mM LR: 0.05 – 20 mM	Wine	(29)
Citric acid Pyruvic acid Oxaloacetic acid	Citrate lyase Oxaloacetate decarboxylase Pyruvate oxidase	Amperometric E = +0.65 V vs. Ag/AgCl	L_{CA}: 0 – 100 mM L_{PA}: 0 – 6 mM L_{OAA}: 0 – 6 mM	Synthetic samples	(30)
L-Ascorbic acid	Ascorbate oxidase	Amperometric O_2-type Clark	S:3*ΔDO(mg/L)/mM LR: 0.05 – 1.2 mM	Fruit Juices	(31)

(*Continued*)

Table 11.1 (*Continued*)

Analyte	Biological Molecule	Transducer Type	Characteristics	Application	Ref.
Folic acid	Antifolic acid antibody	Optical (SPR)	Accuracy 88 – 101 %	Milk powder, Cereal samples	(32)
Cholesterol	Cholesterol oxidase	Optical (oxygen transducer)	LR: 0.07 – 18 mM	Butter	(33)
Tryptophan Leucina Serina Valine	Amino acid oxidase	E = 0.0 V vs. Ag/AgCl	LR_T: 10 – 250 μM LR_L: 10 – 1200 μM LR_S: 50 – 500 μM LR_V: 25 – 500 μM	Grapes	(34)
Lysine	Lysine α-oxidase	Amperometric E = +0.1 V vs. Ag/AgCl	LR: 2-125 μM	Sample fermentation	(35)

More recently, a biosensor array based on photo patternable enzyme membranes for the simultaneous measurement of glucose, lactate, glutamate, and glutamine has been described and applied to fermentation broth (62). The microsystem consists of an upper glass chip with the integrated biosensor array, and a bottom part, comprised of a gold counter electrode, a 300 μm thick seal, and electrical interconnection lines. The flow device has a total internal volume of 2.1 or 6 μl when integrated with a mixer on the chip.

Finally, it is important to mention, that despite the number of relevant papers already present in the literature, new format biosensors for fish freshness evaluation are still under development, using electrochemical (63), or QCM (64), approaches.

Taking into account the extensive number of possible applications for biosensors in food analysis, the following section will discuss, in more detail, a few examples of biosensors developed in our laboratory.

11.3.1.1 Monitoring of Wine Quality: Biosensors for Ethanol, Glucose and Glycerol

Wine is a complex mixture of several hundred compounds, present simultaneously, at different concentrations. The dominants ones are water, ethanol, glycerol, sugars, organic acids, and various ions. Except ethanol and glycerol, other aliphatic and aromatic alcohols, amino acids, and phenolic compounds are present at much lower concentrations.

Three different PQQ-dehydrogenases [glucose dehydrogenase (GDH), alcohol dehydrogenase (ADH), and glycerol dehydrogenase, (GlDH)] newly isolated and purified from *Erwinia* sp. 34-1 or *Gluconobacter* sp.3-3 (65–67) have been used for development of biosensors for determination of key compounds in wine (10). The enzymes have been integrated in redox hydrogels by cross linking them to an Os complex modified nonconducting polymer (PVI_{13}dmeOs) using poly (ethyleneglycol)–diglycidyl ether (PEGDGE) as the cross linking agent. Due to the structural similarities of the studied enzymes, a common sensing mechanism could be proposed for the three biosensors (see Figure 11.2). Thus, the main enzyme substrate (glucose for GDH, glycerol for GlDH and ethanol for ADH) is firstly oxidized while the enzyme's cofactor is simultaneously reduced. The active form of the enzyme is regenerated via the interaction with the electrochemical mediator (Os modified redox polymer), which is maintained in its oxidized form by the positive potential applied at the electrode.

The developed biosensors were integrated in a single manifold flow injection line and the analytes were manually injected into the carrier flow and transported to the electrochemical cell equipped with the working, reference, and auxiliary electrodes respectively (10). The working potential of the enzyme modified electrodes have been controlled by a potentiostat. The electrodes were optimized with regard to their composition (enzyme/polymer cross linker ratio), flow rate, and pH. and evaluated first using standard solutions.

Table 11.2

Biosensors characteristics. Symbols: DL - detection limit (calculated as three times the signal-to-noise ratio), DR, DRwine - dynamic range, I_{max} and K_m^{app} were evaluated from Michaelis-Menten equation: $I = (I_{max}*[A]) / (K_m^{app}+[A])$, [A] - analyte concentration; S - sensitivity (calculated as I_{max} / K_m^{app}*Electrode surface)

Type of Sensor	Km (mM)	I_{max} (nA)	S (mA/M cm^2)	DL (μM)	DR (μM)	DR_{wine} (M)
Glucose	0.80	4963	88.62	9	20–800	0.002–1
Ethanol	0.60	9400	223.8	1.2	2.5–250	1–3.5
Glycerol	1.31	1797	19.5	1	1–200	0.01–0.1

Table 11.3
Content of ethanol, glucose and glycerol in Dunavár wine, Hungary, 1998.

Type of Sensor	Biosensor Analysis	Spectrophotometric Analysis
Ethanol	12.5 ± 0.3%	12%
Glucose	0.32 ± 0.01 g/L	0.30 g/L
Glycerol	7.8 ± 0.8 g/L	8.1 g/L

Next, the optimized electrodes were evaluated using real samples (wine) with declared content of the targeted analytes. The main characteristics of the developed biosensors are presented in Table 11.2.

The results obtained with the optimized biosensors were also compared with those yielded by other conventional analytical techniques. Thus, the results delivered by the developed biosensors have been validated and the applicability for the determination of these key compounds in wine samples could be successfully demonstrated (see Table 11.3).

Evaluation of the biosensors in terms of stability has been performed. While about 90% response of the ethanol sensor was kept after a continuous operation for 100 h, the other two electrodes were less stable, maintaining only 80% (glycerol sensor) and 60% (glucose sensor) of their initial signal after 20 h of continuous substrate injection. The storage stability was good for all three biosensor, less than 20% of their initial response being lost after one month of storage at 4°C (results not shown).

11.3.1.2 Monitoring of Fish Quality: Biosensors for Biogenic Amines

Biogenic amines are organic bases with aliphatic, aromatic, or heterocyclic structures that can be found in many foods such as meat, fish, cheese, wine, and milk, in which they are mainly produced by microbial decarboxylation of amino acids. Excessive consumption of these amines can be of health concern because they can generate different degrees of

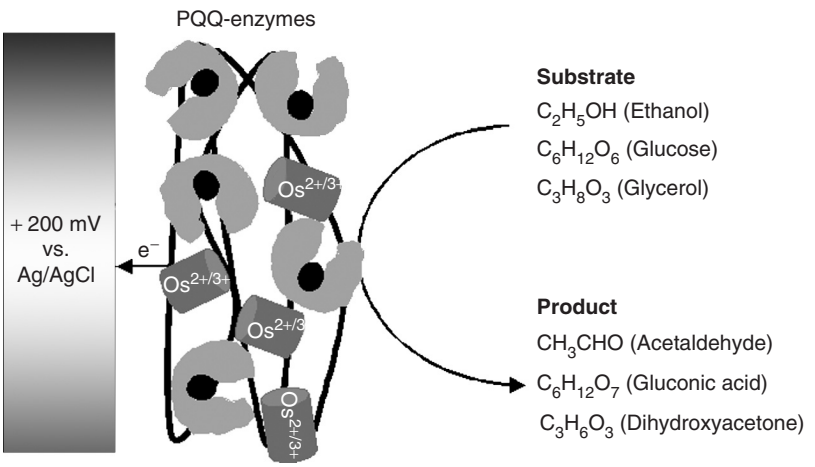

Figure 11.2 Proposed mechanism of bioelectroconversion of the substrate on PQQ-dehydrogenase modified electrodes; Electrodes composition: GDH-, ADH-, or GlDH-PQQ enzyme, $PVI_{13}dmeOs$ and PEGDGE

Table 11.4
Bioelectrochemical characteristics obtained for AO/HRP/ PVI_{13}-dmeOs/PEGDGE electrodes. Symbols as in Table 11.2.

Electrode Type	Analyte	K_m^{app} (μM)	I_{max} (μA)	S (mA/Mcm^2)	DL (μM)	LR (μM)
AO/HRP/PVI_{13}-dmeOs/PEGDGE	Histamine	901 ± 85	4.85 ± 0.41	73.74 ± 1.7	0.33	1–150

diseases determined by their action on nervous, gastric, and intestinal systems and blood pressure (36,68).

The developed biosensor for the determination of biogenic amines was based on the direct coupling of two enzymes; amine oxidase (AO) and HRP (horseradish peroxidase) and their cross linking (PEGDGE) to a redox polymer (PVI_{13}-dmeOs). The operating potential of the resulting biosensor was 50 mV *vs.* Ag/AgCl. The electron transfer mechanism is outlined in Figure 11.3.

Different parameters, e.g., applied potential, flow rate, pH, and composition of the sensing film, have been optimized before testing the sensor in real samples. The kinetic parameters and the main biosensor characteristics obtained for the optimal electrodes are presented in Table 11.4.

The biosensors were also characterized with regard to their selectivity and response time, as well as operational and storage stability (36), showing a higher signal for aliphatic amines than for aromatic ones, a short response time (less than 1 minute) and a good operational stability (30% and 50% decrease in sensor activity for histamine and putrescine, respectively, after 10 h of continuous operation, at a sampling frequency of 30 injections h^{-1}) and long term stability (10% and 15% decrease in sensitivity for histamine and putrescine, respectively, after 10 days of storage).

Finally, the optimized biosensor was considered for monitoring of biogenic amines in real samples. The differentiation between the signals given by different amines is, however, not possible, only the total amine content of the sample was determined. Fish muscle samples, kept for 10 days at 4ºC and 25ºC were analysed by direct injection in the flow system after extraction in a phosphate buffer. The total amine content expressed in histamine equivalents is presented in Figure 11.4. The maximum accepted limit for total amine concentration in food products is 0.1 to 0.2 g kg^{-1} sample, and a concentration of 1 g kg^{-1}

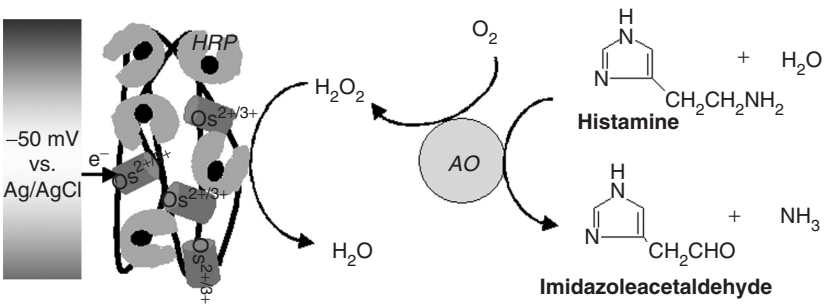

Figure 11.3 Proposed mechanism of bioelectroconversion of histamine on a bi-enzyme (amine oxidase (AO)/horseradish peroxidase (HRP)) electrode; Electrodes composition: AO, HRP, PVI_{13}dmeOs and PEGDGE

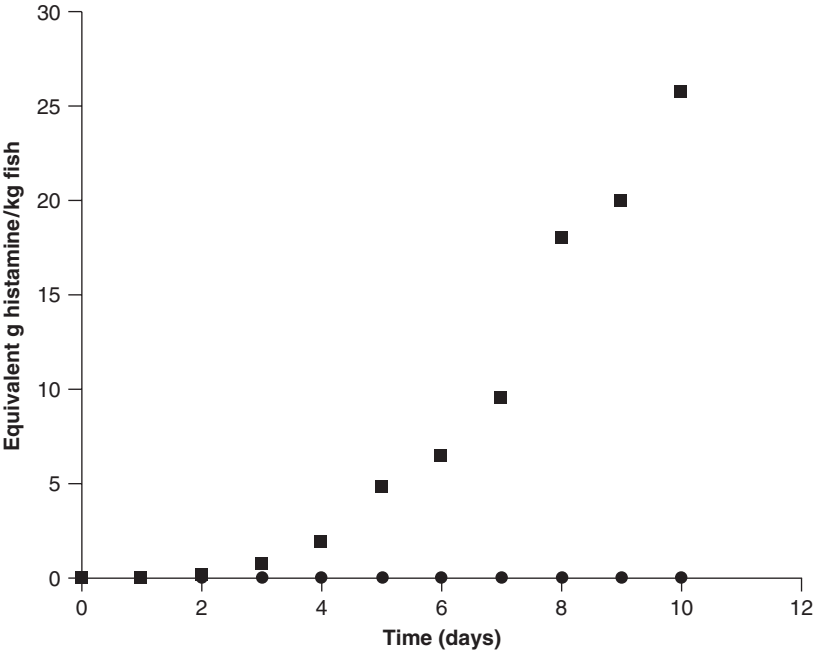

Figure 11.4 Monitoring of fish freshness using amine oxidase-based electrodes; Total amine content recorded for fish kept at 4°C (■) and 25°C (•), respectively; The total amine concentration was expressed in histamine equivalent units

is considered to be toxic. As seen, after 3 days of storage at room temperature, the fish became improper for consumption, while even after 10 days of storage at 4ºC there were no major changes observed in the total amine concentration.

11.3.2 Biosensors for Food Contaminants Analysis

Water is omnipresent in foodstuff and the surrounding atmosphere. Determination of water content is one of the most frequent analyses performed in food industry. The range of water concentrations in food is very broad, starting with a fraction of a per cent and reaching more than 98%. Fresh products and liquid food usually contain large amounts of water, whereas baked and dry products are poor in water. In many products the water is constitutive, but there are numerous food products in which water is added during processing.

The water present in food products affects their safety, stability, quality, and physical properties. Water is a vehicle for the transmission of many infectious agents, such as microorganisms, and continues to cause significant outbreaks of disease world wide.

11.3.2.1 Microorganisms in Food

Microorganisms, such as bacteria and viruses, are widely spread throughout the environment at any level such as marine and estuarine waters, soil, and the intestinal tracts of humans and animals, and they are present also in food. Many of these organisms have an essential function in nature, but certain potentially harmful microorganisms can have profound negative effects on both animal and human health. It is estimated that infectious diseases cause a significant number of total annual deaths worldwide, ranging between 15 and 75% depending on the geographical area (69). In addition, nonfatal infections afflict

more than 200 million people each year (70). Food safety issues are continuously boosted by emerging concerns. Recently, recalls due to food poisoning bacteria such as *Listeria monocytogenes* (71,72) have evidenced the need for more rapid, sensitive, and specific methods of detecting these microbial contaminants to be used as early warning systems.

The detection and identification of bacteria is mainly based on specific microbiological and biochemical identification. Pathogens typically occur in low number in food. Some of the standard methods can be sensitive, inexpensive, and give both qualitative and quantitative information on the number and the nature of the microorganisms tested (73,74). Their main disadvantage, especially as warning systems, is the length of the procedures, which usually need the following steps: preenrichment, selective enrichment, biochemical screening, and serological confirmation. Other approaches are directed to identify and quantify microorganisms through the detection of characteristic DNA sequences using the polymerase chain reaction (PCR) (75–80). Nucleic acid based assays are effective identification tools, though they are limited, in that they will indicate the presence of a microorganism, but do not give any information on effective toxins or virulence (73). Finally, immunological techniques are used to detect microbes by their unique antigenic determinants. Polyclonal and monoclonal antibodies can be raised relatively quickly and cheaply (81). Immunological detection of microbial contamination has become more sensitive, specific, reproducible, and reliable with many commercial immunoassays available for the detection of a wide variety of microbes and their products such as biotoxins (82). It is also important to stress that antibody based techniques give only information on the presence of antigens regardless of whether the microorganims are viable or not. The Hazard Analysis Critical Control Point (HACCP) methodology requires, for its effective application, analytical devices that can be operated outside the laboratory by trained but not professionally skilled people. Particularly, the microbiological safety of food still needs rapid, user friendly and reliable tools. Biosensors offer the potential of detecting pathogens in near real time mode, but often this methodology still requires preenrichment in order to detect low numbers of pathogens.

11.3.2.1.1 Label Free Methods A label free method relies on the monitoring of analyte at the solid (i.e., sensor) or liquid (analyte solution) interface. The basis of this detection mode is the physical phenomena occurring on the transducer's surface during the biochemical reactions (e.g., change in optical or electrical features). Regardless of the large amount of literature produced on this topic, only a few articles report on the analysis of bacteria in real food matrices. A method based on the refractive index variation upon antigen antibody binding has been applied to the detection of *Salmonella typhimurium* in chicken carcass wash fluid (83). Based on the same assay principle, a method for the detection of *Staphylococcus enterotoxin A* in potato salad, canned mushroom, hot dog, and milk, has been described, quoting a total assay time of 4 minutes (84).

11.3.2.1.1.1 Optical Approaches for Microbial Detection Optical transducers are particularly attractive for label free detection of bacteria. Several optical techniques have been reported for the detection of bacteria including: monomode dielectric waveguides (85), surface plasmon resonance (86–89), ellipsometry (90), resonant mirror (91), and interferometry (92).

11.3.2.1.1.2 Bioluminescence Sensors The bioluminescence phenomenon is based on the ability of certain enzymes to emit photons as a product of enzymatic reactions. The basis of the assay scheme consists of the introduction of the gene encoding for the enzyme luciferase in the genome of a bacteriophage (a bacterial virus). When a host bacterium is infected, the luciferase encoding gene can be transferred to the bacteria, conferring bioluminescence to a previously nonbioluminescent organism. A wide range of microorganisms have been detected using this approach. Literature reports describe the detection of *Salmonella*

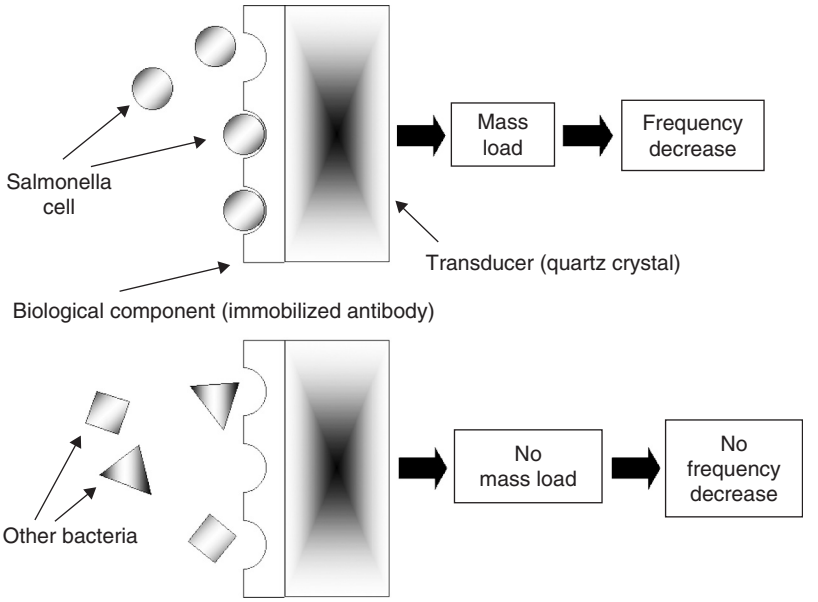

Figure 11.5 Working principle of the *Salmonella* piezoelectric biosensor

sp. (93,94), many *Listeria* strains, *Listeria monocytogenes* (95), *Salmonella newport*, and *E. coli* (96). The main advantage of this approach is its inherent ability to detect viable cells; the main limitation remains the poor sensitivity, which leads to lengthy protocols requiring a preenrichment step.

11.3.2.1.1.3 Piezoelectric Sensors Piezoelectric (PZ) biosensors are analytical tools that may be operated in a label free fashion.

The theoretical basis of piezoelectricity and the practical application to biosensors development are illustrated in a series of reports (97,98). The binding of the analyte to receptor (e.g., antibody) previously immobilized onto the surface, increases the mass on the sensor and determines a proportional decrease of the oscillation frequency of the piezoelectric crystal (Figure 11.5). Piezoelectric sensors surfaces can be functionalized with antibodies raised against the whole microbial cells, surface expressed antigens, microbial toxins, or even DNA specific sequences.

In the last 15 years, methods based on this approach (antibody) have been described for *Candida albicans* (99), *Salmonella typhimurium* (100,101) *Listeria monocytogenes* (102). Great efforts have been devoted toward sensors development to enhance and optimize analytical performance (103,104).

In one case, a flow injection set up was used for the detection of the *Staphylococcal Enterotoxin B* using polyclonal antibodies (105). Sensor surfaces have also been coated with specific antigens for the detection of serum antibodies and with microbial DNA probes for the detection of strain specific PCR amplified sequences (106). These sensors have also been used in the detection of several other microbial contaminants including *Candida albicans* (107), *L. monocytogenes* (108,109) and *Vibrio cholerae* (110). Most of the sensors have been applied to aqueous suspensions. Examples of the use of piezoelectric sensors in real matrices have been recently reported (111). The authors described the detection of *Salmonella enteriditis* in chicken and eggs using the biosensor as a diagnostic tool in veterinary medicine.

11.3.2.1.2 Indirect Detection of Bacteria Typically, the indirect biosensing of bacteria is based either on the use of a labelled molecule or on microbial metabolism tracking. The former approach is able to detect viable and nonviable cells, while the latter, using the cell metabolism, responds to viable cell concentrations. Among the indirect methods, electrochemical biosensors seem the most promising, because they are relatively low cost, operate even in turbid media, are amenable to miniaturization, and can be easily adapted to flow or flow injection systems. The sensors can be grouped in antibody based biosensors, DNA based biosensors, and metabolism based biosensors.

11.3.2.1.2.1 Antibody Based Biosensors Immunosensors, and immunochemical methods based on electrochemical detection, couple the specificity of the immunological reaction with the simplicity, rapidity, and sensitivity of the electrochemical detection. Immunosensors offer the potential to increase sensitivity and selectivity but lack a form of inherent signal amplification (112,113).

Different approaches have been used as assay scheme reflecting technological advancement. Mirhabibollahi et al. (114) described an enzyme linked immunosensor for the detection of *Staphylococcus aureus* and *Salmonella* in pure cultures using the two site immunometric approach (Figure 11.6).

An original improvement was introduced in 1995 by Kim et al. (115). They used the ability of hemolytic bacteria to disrupt a lipid membrane to design and develop a selective immunosensor for hemolytic organisms. Specific antibodies for *Listeria monocytogenes, Listeria welshimeri,* and *Escherichia coli* were immobilized on the surface of a platinum working electrode. After the capturing step, liposomes containing an electrochemical mediator were added to the medium. The presence of hemolytic organisms determined the rupture of the lipid bilayer of liposome, releasing the electrochemical mediator in the medium.

Another interesting approach for the detection of *Salmonella typhimurium*, consisted in the use of super paramagnetic material to perform antibody based separations. In this case, antibodies were immobilized onto magnetic beads and the secondary alkaline phosphatase labelled antibody for the analyte of interest formed the typical sandwich. Thereafter, with the aid of a magnet, the complex was placed onto the surface of the working electrode of a disposable electrochemical sensor where the assay medium was removed by aspiration and the enzyme substrate solution was added. Using this approach 8×10^3 cells/ml was detected in 80 minutes (112). Brewster and Mazenko (116) have developed an immunoelectrical sensor, coupled with filtration capture, for the rapid detection of *E. coli O157*. The sensor has a detection limit of 5000 cells/ml and an assay time of 25 min. The immunological complex is formed on the surface of a cellulose acetate membrane that is brought in contact with the electrode surface. Five min. after substrate addition, cells can be detected by the conversion of substrate (para-aminophenyl phosphate) to an electro active product (para-aminophenol).

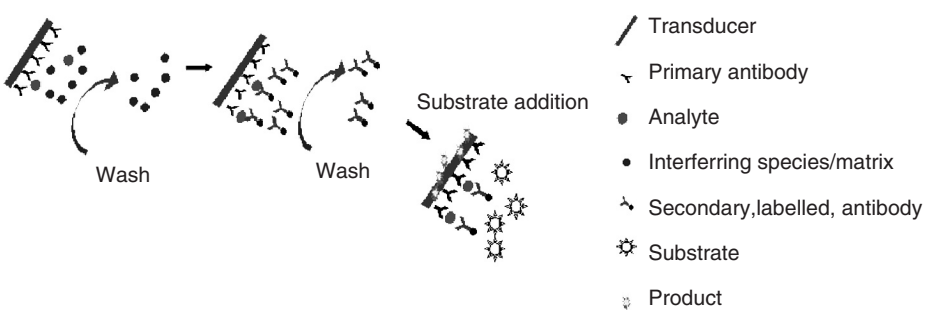

Figure 11.6 Schematic drawing of one of the "two site immunometric" immunosensors

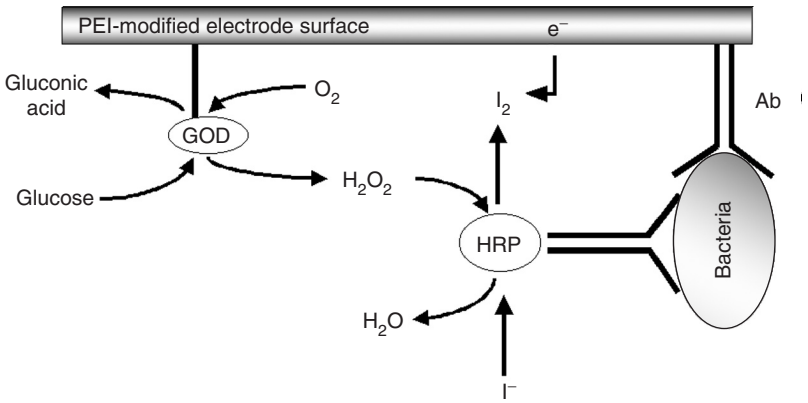

Figure 11.7 Separation-free, amperometric enzyme channeling immunoassay for *Staphylococcus aureus* with immobilized antibody and glucose oxidase (GOD) on the PEI-modified electrode surface

Rishpon and Ivnitski (117), have developed a separation free amperometric enzyme channelling immunosensor for the detection of *Staphylococcus aureus*. The immunosensor consists of a carbon electrode with anti Protein A antibodies, which detect *Staphylococcus aureus*, and the enzyme glucose oxidase immobilized on its surface. The test solution containing *Staphylococcus aureus*, a horseradish peroxidase (HRP) labelled anti Protein A antibody and iodide is then added. Upon antibody–antigen–antibody sandwich formation, hydrogen peroxidase is brought in contact with glucose oxidase at the electrode surface. After addition of glucose in solution, HRP catalyses the reaction of H_2O_2 and iodide ions. The reduction of iodide ions at the electrode surface allowed detection of *Staphylococcus aureus* to a limit of 1000 cells/ml of pure culture in 30 min. This assay format offers the advantage of being pseudo homogenous, i.e., without a washing step, as the polyethylenimine (PEI) membrane used discriminates between the analytical signal from the bound immunocomplex and background noise from HRP– H_2O_2 reacting in solution away from the electrode. Signal amplification is also facilitated through enzyme channelling (Figure 11.7).

Recently, Ivnitski et al. (118) have developed an amperometric immunosensor based on a supported planar lipid bilayer for the detection of *Campylobacter*. The artificial bilayer membrane, which served for the anti *Campylobacter* antibodies immobilization, was deposited on a stainless steel working electrode. Conformational changes, occurring when the antigen antibody is formed, allowed the ion to pass through the channel. The current produced by ions migration could be amperometrically measured. In addition to acting as a matrix for antibody, the lipid membrane also acts as a very thin electrical insulator and suppresses nonspecific binding of ligand. The biosensor shows a strong signal amplification effect, defined as the total number of ions transported across the bilayer. This is 10^{10} ions/s, which leads to a theoretical limit of detection of 1 cell in an assay time of just 10 min. The sensor may have potential for the detection of other microorganisms provided that high quality antibodies are available. Recently (119) conventional amperometry at an antibody-containing polypyrrole film electrode was found to be unsuccessful in detecting levels below 10^6 cells ml^{-1}. This sensor was capable of reproducibly detecting *Listeria* at levels of 10^5 cells ml^{-1} in 30min.

11.3.2.1.2.2 DNA/RNA Based Biosensors DNA electrochemical biosensors, coupling the high specificity of DNA hybridization with the inherent sensitivity of electrochemical transducer, hold great promise for the rapid screening of viral and bacterial pathogens in different samples matrices including food.

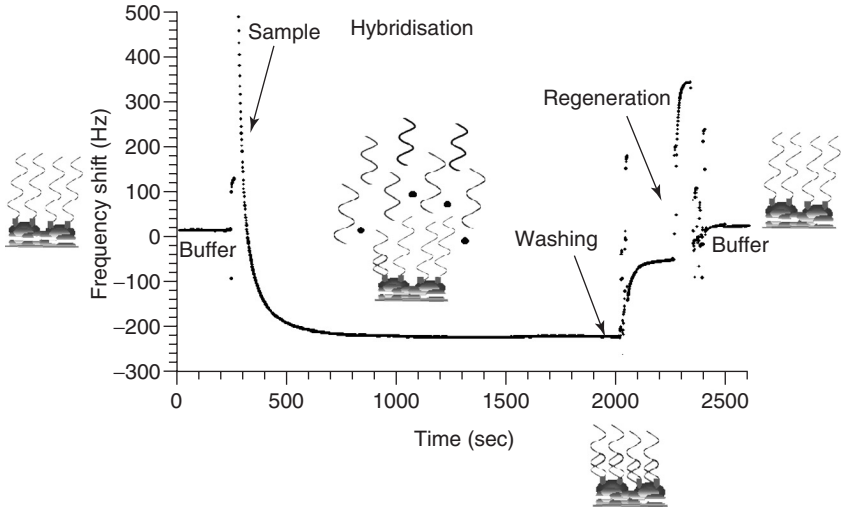

Figure 11.8 Typical response obtained for DNA hybridization detection using piezoelectric microbalance. The hybridization reaction generates a diminishment of the frequency of the oscillating that is proportional to the mass bound to the sensor surface. The sensor surface can be regenerated using appropriate washing buffers (Adapted from Mannelli, I., M. Minunni, S. Tombelli M. Mascini, *Biosens. Bioelectron*. 18:129–140, 2003)

A highly sensitive and specific RNA biosensor was developed for the rapid detection of viable *E. coli* as an indicator organism in water. The biosensor is coupled with protocols developed earlier for the extraction and amplification of mRNA molecules from *E. coli* (120). The biosensor was a membrane based DNA/RNA hybridization system using liposome amplification.

The biosensor resulted in a portable, inexpensive, and very easy to use device, which makes it an ideal detection system for field applications.

An excellent correlation to a much more elaborate and expensive laboratory based detection system was demonstrated, which can detect as few as 40 *E. coli* cfu/ml. Finally, the assay was tested regarding its specificity; no false positive signals were obtained from other microorganisms or from nonviable *E. coli* cells. Other recent application of DNA biosensors for bacteria detection have been described based on either fiber optic transduction mode (121,122) or piezoelectric microbalance (123) (Figure 11.8).

11.3.2.1.2.3 Metabolism Based Biosensors The detection of microorganism through the electrochemical monitoring of their metabolism is an interesting approach as it gives information on the viable cells. The main drawback which limits this approach is related to the poor selectivity which makes it applicable to well defined samples. Moreover the response is usually slow. The measurement scheme is based on the redox reactions of the metabolic pathways mediated via an electrochemical mediator. To date, 25 years of bacterial biosensing using this strategy led to a plethora of formats (124–127). The transducer can either detect the consumption of oxygen or of another electro active metabolite. Takayama et al. 1993 (125) showed that mediators such as $K_3Fe(CN)_6$ and dichlorophenol indophenol are able to accept electrons from glucose dehydrogenase (GDH) or from other enzymes of the respiratory chain, and that this mean can be used to detect viable bacteria.

11.3.2.2 Pesticides in Food

Since the end of World War II, in order to increase the production of both vegetal and animal products, chemicals have been extensively used both to control pests and microorganism infections. Today, over 500 compounds are registered worldwide as pesticides, or metabolites of pesticides.

A great number of pesticides are now used to raise crop productivity. It is calculated that the losses would double if pesticides were put out of use. However, the use of pesticides requires great care and control as they can pollute the environment and harm human health either directly or through the food chain.

Herbicides are by far the most commonly used pesticides, followed by insecticides and fungicides. This pesticide use, and additional environmental pollution caused by industrial emissions, has resulted in the occurrence of residues of these chemicals and their metabolites in food commodities, water, and soil. Legislations were enacted in the USA, the European Union (EU) and other countries to regulate pesticides in food products.

Multi residue methods (MRMs) of analysis, able to detect simultaneously more than one residue have been developed mainly based on chromatographic techniques. Two groups of MRMs are used: (1) multiclass MRMs that involve coverage of residues of various classes of pesticides, and (i2) selective MRMs, which concern multiple residues of chemically related pesticides (e.g., N-methyl carbamate pesticides (NMCs), carboxylic acids, and phenols). As foods are usually complex matrices, all of the preanalytical steps (matrix modification, extraction, and clean up), are often necessary.

Beside the instrumental methods, other analytical approaches, usually used as screening tests, are required because of the need of continuous monitoring of food commodities.

Organophosphate and carbamate pesticides are inhibitors of acetylcholinesterase, and therefore they are neurotoxic agents. The anticholinesterase activity of pesticides has been used as the basis to build a number of detection schemes for these classes of compounds. A large number of applications in pure standard solution or in environmental samples have been published (128) but only a few applications on real food samples have been reported. In spite of the significant demand for sensing of different analytes in food samples, it seems that the use of biosensors penetrate very slowly in the food industry.

Most of the inhibition bioassays or biosensors for organophosphate and carbamate pesticides are based on the amperometric detection of the enzymatic reaction product. Other detection techniques were also described, such as photo thermal analysis using excitation laser operating at 488 nm and 120 mW. This biosensor was tested for detection of carbofuran, propamocarb, oxydemeton–methyl, and parathion–ethyl in samples of salad, iceberg lettuce, and onion. The developed photo thermal biosensor offers a low cost mean to detect low concentrations of pesticides in vegetable samples with high throughput and little or no sample pretreatment (129).

Applications of amperometric biosensing strategies for pesticide detection in real or spiked food samples were recently reported. Most of the applications have been developed for vegetable matrices. Different formats of biosensors have been used: disposable screen printed choline oxidase biosensors (130) using acetylcholinesterase in solution, were utilized to detect pesticides in real samples of fruit and vegetable. Potato, carrot, and sweet pepper samples spiked with aldicarb, propoxur, carbaryl, carbofuran, and methomyl tested with this acetylcholinesterase biosensor, exhibited acceptable recoveries (79–96%) (131).

An interesting application on spiked (aldicarb, carbaryl, carbofuran, methomyl, or propoxur) fruit and vegetable samples was based on screen printed electrodes chemically modified with a carbon paste mix of cobalt(II) phtalocyanine, and acetylcellulose (132).

In this paper, a solventless extraction procedure of the spiked samples is reported. This was performed by mixing the fruits and passing the resulting juice through a sieve. No effect of matrices pH on the biosensor performance is reported. Screen printed sensor developed using photolithographic conducting copper track, graphite–epoxy composite and either acetylcholinesterase or butyrylcholinesterase were also used in the analysis of spiked (paraoxon and carbofuran) samples of tap water and fruit juices at subnanomolar concentration (133).

A recent application of a chemically modified electrode for the development of a biosensing device for chlorpyrifos methyl was developed by Del Carlo et al. (134). This method was demonstrated to detect the active molecule both in standard solution and in commercial products (Reldan® 22) with comparable sensitivity. The analytical protocol was then applied to vine and vine leaves samples in order to improve safety in wine making process (134) (Figure 11.9).

Other food samples that have been recently investigated with electrochemical biosensor based on acetylcholinesterase inhibition are infant foods. Considering the multitude of risks associated with pesticides intake by infants, the European Union has set a very low limit (10 μg/Kg) for pesticide in infant food (135). An amperometric biosensor which met the requirements set by the European Union, both for infant food and orange juice, with respect to detection limits has been developed. The method included an oxidation step of phosphorothioates pastiches to produce the oxygenated derivative, which represent the active pesticide molecule. Moreover the biosensors could be regenerated (i.e., the acetylcholinesterase activity could be recovered) through a chemical activation with pyridine-2-aldoxime methochloride (PAM). The biosensors performed well in solvent extract containing water, though it showed reduced recovery in food with lower water content (136).

Successive work by the same group addressed some of the major problems arising when electrochemical biosensors are in contact with food matrices: pH effect, and particle effect. Both problems were solved treating the biosensor surface with a Tween20®/phosphate buffer solution (pH 7.5) after the pesticide incubation. The treatment removed the

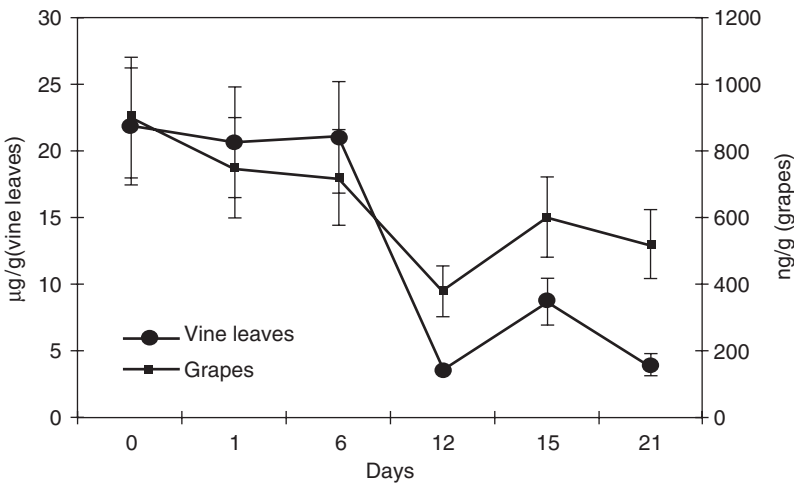

Figure 11.9 Analytical results obtained using an electrochemical method based on chemically modified screen printed electrodes for the detection of chlorpyriphos methyl in vine and vine leaves samples (redrawn from) Del Carlo, M., M. Mascini, A. Pepe, D. Compagnone, M. Mascini, *J. Agric. Food Chem*. 50:7206–7210, 2002.)

particulate and the correct pH was established while the pesticide enzyme inhibition was retained. A large number of samples (137) were analyzed and the results compared with reference standard methods.

As shown, there are only a few reports on cholinesterase based biosensors applied to food samples. Many other amperometric detection chemistries have been described that could be of potential use for food sample analysis, but the possibility to successfully apply these methods is closely related to their ability to overcome the matrix effect which leads either to complicated multistep sample preparation or to poor pesticide recovery.

11.3.2.3 Antibiotics in Food

The treatment of bacterial infections in cattle, sheep, pigs, and poultry with antibiotics, such as streptomycin and penicillin, is widely used in modern agriculture. Apart for their use in farming they have also been used in the protection of fruit trees. Public health concerns and perceptions of indiscriminate use of veterinary drugs have been supported by the presence of undesirable residues in some products.

The apprehension of the food industry on this topic is related to safety issues but also to technological problems that can arise from antibiotic contaminated products.

Residues of these antibiotics may present a potential hazard to the consumers in terms of toxicity, allergic reaction and the development of bacterial resistance. Moreover, in the dairy industry, milk contaminated with antibiotics can inhibit the starter cultures used in the production of yogurt and cheese thereby inflicting severe economic losses.

Regulatory authorities have established maximum residue limits (MRLs) for streptomycin and dihydrostreptomycin in milk, porcine kidney, and muscle, although none have yet been set for honey. Both the European Commission and the Codex Alimentarius MRLs have been set at 200μg/kg in both bovine and ovine milk, 1000μg/kg in porcine kidney, and 500μg/kg in porcine muscle. In contrast to the Commission MRLs, Codex MRLs are combined for streptomycin and dihydrostreptomycin. In the United States, a tolerance limit for dihydrostreptomycin has been set at 125μg/kg in milk, 2000μg/kg in porcine kidney, and 500μg/kg in porcine edible tissue.

Various analytical methods exist currently: high performance liquid chromatography (HPLC), gas chromatography mass spectroscopy (GC-MS) and liquid chromatography mass spectroscopy (LC-MS) have been described for confirmatory analysis, however, the long and tedious sample preparations involved prior to HPLC analysis also limit sample throughput.

Microbial inhibition assays, and immunoassays, are commonly employed as screening tests, however, recently the efficiency of agar diffusion techniques has been questioned.

A recent optical approach describes the use of white light interference for the detection of glycopeptides antibiotics in a fermentation process (138). Biosensor systems using the detection principle known as surface plasmon resonance (SPR) are an important addition to analytical instrumentation and have been shown to be versatile, robust, and capable of producing rapid and reliable results for the analysis of drug residues in complex matrices with minimal sample preparation (139–142). Among these approaches only reference 142 is applied to food samples. In particular, this was applied to accurately determine streptomycin and dihydrostreptomycin residues in milk, meat, and honey; results correlated well with a commercially available enzyme immunoassay (EIA) kit and a published confirmatory HPLC method.

11.3.2.4 Heavy Metals in Food

Heavy metals are a class of contaminants that can produce undesirable effects even if they are present in extremely minute quantities. All forms of ecological systems are

affected to varying extents by heavy metals. They are the most insidious pollutants because of their nonbiodegradable nature and ability to persist for long periods.

Heavy metals from consumer's products may enter the environment either from natural sources or as discharge of the metallurgic industry, thus representing an almost ubiquitous environmental problem. They may contaminate fruit and vegetable constituents with different mechanisms, thus entering the food chain. Moreover, heavy metals are accumulated and stored in living organisms; especially in the marine organisms a very high bioaccumulation of heavy metals can take place. Finally they can be found in animal feedings. Recently European Community has established maximum admissible levels for metals in feeding stuff (European Directive 2002/32/CE), to prevent hazards to consumers health. Hence it is evident that, in a safety approach to food consumption, heavy metals must be monitored at various level of the food production process.

Various instrumental methods such as atomic absorption spectroscopy, inductively coupled plasma optical emission spectrometry, and inductively coupled plasma mass spectrometry (ICP-MS) are in wide use. These methods require sophisticated instrumentation and skilled personnel; therefore, there is a need for simpler methods of analysis. Classical electrochemical methods for metal ions determination include the use of ion selective electrodes, polarography, and other voltammetric techniques. The electrochemical methods are generally capable to selectively detect bioavailable heavy metal ions, that is, the free ion forms of metals. In this respect these methods deliver useful information on the potential hazards of metals.

Biosensors are promising analytical devices, and several different configurations have been described in the past for heavy metal detection. Three fundamental strategies can be outlined for biosensing of heavy metals: enzyme inhibition, cell based biosensor and chelating proteins as capture molecules.

11.3.2.4.1 Enzymes Inhibition Heavy metals are well known to inhibit the activity of enzymes. The main advantage of this inhibition mechanism for the determination of hazardous toxic elements consists in that the reduction of enzyme activity by a single inhibitor molecule can be large due to the amplification effect of the enzymatic reaction, leading to high sensitivity. Moreover, enzymes are often selective to the inhibitor and in many cases the inhibition effect of investigated pollutants is related to its biological toxicity. So the inhibition of enzymatic activity may offer a good choice as a simple and sensitive screen test for bioavailable metal ions. In these cases the choice of the enzyme leads to a certain degree of specificity with respect to the analyte. The postulated mechanism of enzyme inhibition by heavy metals is based on the interaction of metal ions with exposed thiol or methylthiol groups of protein amino acids often forming the active site of enzyme. The strongest interaction takes place in the case of mercury, copper and silver, and therefore those metals exhibit the largest inhibition effect.

Biosensors for mercury determination have been mainly developed, possibly due to its important toxicological profile. Numerous enzymes have been used for inhibition based determination of mercury traces, e.g., peroxidase (143,144), xanthine oxidase (145), invertase (146–148), glucose oxidase (149), butyrylcholinesterase (150), or isocitric dehydrogenase (151), but the most frequently applied is urease, as it is relatively cheap and easily available.

11.3.2.4.2 Cell Based Biosensors In cell based biosensing of heavy metals, two alternative strategies are prevalent: specific monitoring and the effect measurement. The former is obtained by means of one or more enzymes functionality in the cell on an inhibition basis; alternatively, a microbial strain that is deficient for a certain metal enzyme cofactor, is supplied with a medium containing the specific element. In this case the microbial metabolism strongly reacts. The latter is exemplified by Biological Oxygen Demand (BOD) measurements. Effects of heavy metal ions on cell metabolism may be quantified in such a manner.

11.3.2.4.3 Chelating Proteins as Capture and Transducer Element The use of metal–binding proteins can lead to the development of new generation of biosensors of varying specificity. It is believed that a large conformational change takes place when heavy metal ions bind to certain proteins. A suitable transducer should be able to detect this change directly. The use of strategies based on protein with distinct binding sites for heavy metals has been described. In this approach the conformational change induced by the selective binding of either Hg^{2+}, Zn^{2+}, Cd^{2+}, and Cu^{2+}, was used combined with a capacitive signal transducer which could detect the capacitance change in response to metal binding (152). All the metals could be detected as low as 10^{-15} M in standard solutions.

Despite the unanimously recognized need for the development and application of rapid, low cost, and easy to use methods for food analysis no application of biosensors to heavy metals detection has been so far described.

11.4 COMMERCIALLY AVAILABLE BIOSENSORS FOR FOOD ANALYSIS

Though a high number of publications, regarding the development and the applications of biosensors, appear every year, only very few devices are commercially available. Different studies on the biosensor market showed that 92% are sold in the clinical sector (90% being glucose sensors) while only 6% are commercialized in the food industrial sector (153). This high difference might be at least partially explained by the type of matrix in which the tests are carried out: medical biosensors are applied mainly on samples with a low variation of the matrix composition (blood or urine), whereas the biosensors in food industry must be adapted to a wide range of diverse matrices, each of them bearing particular difficulties in terms of matrix effects and concentration range of interest.

Biosensors for determination of food components, pathogens, toxins and pesticides are commercially available. Some examples and a summary of the biosensors characteristics are presented in Table 11.5.

The great majority of the biosensors available on the market are enzyme based, but antibody, receptor, or DNA based sensors are also commercialized. Among the first group, the working mechanism is generally based on a reaction catalyzed by an oxidase. Dehydrogenases are usually avoided, maybe because of the high cost and difficulty of immobilization of their cofactor, $NAD(P)^+$. Electrochemistry is the main principle of detection employed, with either the oxygen consumption or hydrogen peroxide formation, being amperometrically measured in combination with an immobilized oxidase. The principle of change in electrical conductance of the media caused by the growth of microorganisms has been exploited in the Malthus 2000 (Malthus Instruments Ltd) device for determination of coliform bacteria, yeasts, or fungi. The surface plasmon resonance principle of BIACORE® allows detection in real time of the specific interaction between an immobilized bio recognition element (antibody, receptor) and a variety of analytes (vitamins, hormones, and antibiotics). The biosensors are available in several forms, such as autoanalysers, manual laboratory instruments, and portable devices.

Even though the commercially available biosensors for determination of food components, pathogens and toxins are in continuous development, in regards to the principles of analysis, number of analytes that can be simultaneous measured, or sensors characteristics (sensitivity, selectivity, and robustness), the food industry is still not very receptive to biosensor technology. This limited acceptance might be due to the basic difference between classical analytical methods and bioassays in general, the latter requiring special conditions of operation, characterization, and data interpretation, due to the extraordinary

Table 11.5
Examples of commercial available biosensors used in food analysis.

Biosensor	Analytes	Biorecognition Element	Food Sample	Comments	Company	Ref.
ABD 3000	Ethanol	Alcohol oxidase	Beverages	- The enzyme is immobilized between two membrane layers;	Universal Sensor Inc., USA and Ireland	http://intel.ucc.ie/sensors/universal/
Biosensor Assay System	Ascorbate	Ascorbate oxidase	Cereal products, Cookies	- O_2 or H_2O_2 sensors;		
	D-Glucose (Dextrose)	Glucose oxidase	Cereal products	- The biosensor assay is not affected by color, turbidity, particulates or pH and the sample requires little or no preparation;		
	Galactose	Galactose oxidase	Syrups, Cereals, Cheeses			
	Lactose	Galactose oxidase	Cheeses, Syrups, Cereal Products			
	L-Lysine	L-Lysine oxidase	Grains, Potatoes, Syrups	- Analysis time: 1-2 min;		
	Sucrose	Invertase/Mutarotase/ Glucose oxidase	Potatoes, Cereals, Cookies	- $<$ 100 μL sample size;		
				- $>$ 500 assays or 6 months;		
				- Economical: ~10 cents per test;		
				- Reproducibility: $>$ 3 %.		
SensAlyser-α	Alcohol	Alcohol oxidase	Beer and Wine production	- Analysis time: $<$ 3min;	SensAlyse Ltd., UK	http://www.sensalyse.com
				- Compact and portable;		
				- No reagents are required.		
AM2 & AM3 Alcohol Analyser	Alcohol (Ethanol)	Alcohol oxidase	Cider, Beer, Wine, Spirit	- Analysis time: 20–25 sec;	Analox Instruments, UK and USA	http://www.analox.com/
				- Clark-type amperometric oxygen electrode;		
				- Sample size: 5–10 μL;		
				- Reagent stability: 9–15 months unopened and stored at 0–5 °C.		

LM5 Lactate Analyser	Lactate	Lactate oxidase	Milk and Milk products			
GM10 Glucose Analyser	Dextrose (D-Glucose)	Glucose oxidase	Beverages			
	Lactose	β-Galactosidase/ Glucose oxidase				
	Sucrose	Invertase/Glucose oxidase				
YSI 2700 Select Food Analyser	Glucose	Glucose oxidase	Milk, Potatoes	- 10–25 μL sample size;	Yellow Springs Instruments, USA	http://www.ysi.com
	Lactose	Galactose oxidase	Cheese	- The enzyme is immobilized between two membrane layers, polycarbonate and cellulose acetate;		
	Galactose	Galactose oxidase	Fermentation process			
	Sucrose	Invertase/Mutarotase/ Glucose oxidase	Potatoes, Molasses, Cereal products, Ice cream			
	L-Lactate	L-Lactate oxidase	Lunch meat	- H_2O_2 formed is oxidized to a Pt electrode;		
	L-Glutamate	L-Glutamate oxidase	Tomatoes, Chicken broth			
	L-Glutamine	Glutaminase/ L-Glutamate oxidase	Pet foods	- Precision CV (n=10) ~2 %; - Analysis time: 1 min; - Number of samples which can be analysed automatically: 24;		
	Choline	Choline oxidase	n.a.			
	Ethanol	Alcohol oxidase	Beer			
	Methanol	Alcohol oxidase	Fermentation process			
	Starch	Amyloglucosidase/ Glucose oxidase	n.a.			

(*Continued*)

Table 11.5 (*Continued*)

Biosensor	Analytes	Biorecognition Element	Food Sample	Comments	Company	Ref.
SIRE® Biosensor P100	Ascorbic acid	Ascorbate oxidase	Cereal products	- Sensors with injectable recognition element; - Analysis time: 1 min; - The formed H_2O_2 gives an analyte concentration dependent of electrical signal - Repeatability: 1–3 %; - Reproducibility: 3–5 %;	Chemel AB, Sweden	http://www.chemel.com
	L-lactate	Lactate oxidase	Baby food samples, Tomato paste			
	Glucose	Glucose oxidase	n.a.			
	Ethanol	Alcohol oxidase	Beverages			
SensLab 1a	Alcohols	Alcohol oxidase	Beverages	- Analysis time: 1min; - 5 μL sample size; - LR: 0–1 mM;	SensLab GmbH, Germany	http://www.senslab.de
	Glucose	Glucose oxidase	Beverages			
	Lactate	Lactate oxidase	n.a.			
	Ascorbate	Ascorbate oxidase	n.a.			
The Answer 8000	Glucose	Horseradish peroxidase/ Glucose oxidase	Potatoes	- Automatic calibration; - Insulating cartridge filled with graphite, enzymes and ferrocene; - Analysis time: 20 sec.	Gwent Sensors Ltd., UK	http://www.g-s-l.co.uk/
OLGA	Glucose	Glucose oxidase	Juice, Beer	- On-line general analyser based on principles of the sequential-injection mode; - Automatic calibration and dilution of sample; - Simultaneous analysis;	Sensolytics GmbH, Germany	http://www.iba-go.com/iba_us/olga/index.php?ol_intro.html
	Sucrose	n.a.	Juice, Beer			
	Ascorbate	Ascorbate oxidase	n.a.			
	Alcohol	Alcohol oxidase	Juice, Beer			

PerBacco 2000	Glucose Fructose	Glucose oxidase Fructose dehydrogenase	Must, Wine	- Solid binding matrix based composite transducers; - Filtration and dilution of the sample is recommended for red wines; - Remaining selectivity after 1 month of storage: $>$ 90 %;	BioFutura S.R.L., Italy	http://www.biofutura.com
PerBacco 2002	Lactic acid Malic acid	Lactate dehydrogenase Malate dehydrogenase				
Biacore®Q	Folic acid Biotin Vitamin B12	Antibody, Enzyme, DNA or Receptor	Milk, Cereal, Juice, Flour, Jam, Pasta, Rice	-Surface plasmon resonance based biosensors; - Fully automated; - Quick and easy to change between different assays; - Analysis time: 2–10 min;	Biacore SA, Sweden	http://www.biacore.com
	Hormones Antibiotics	Antibody, Enzyme, DNA or Receptor	Meat and Milk production			
Freshness Meter KV-101	Adenosine Triphosphate	n.a.	Fish, Meat	-Soluble enzymes and a Clark oxygen electrode; - Analysis time: 5–6 min;	Oriental Electric, Japan	(49,154)
Analyte 2000	E. coli 0157: H7, viruses, spores	Antibody	Hamburger, ham	- Evanescent-wave fluoroimmunoassay; - One sample per second;	Research International	http://www.resrchintl.com

nature of the bio recognition interaction. This attitude is, however, about to change, and can be directly related to numerous efforts on improving the biosensors robustness, by developing better stabilization and immobilization methods for the existing bio recognition elements, or by employing new artificially designed enzymes or antibodies.

11.5 CONCLUSIONS

Can we realistically imagine biosensors become widely applied analytical tools in food analysis?

In order to answer this question we have to consider two aspects: what is requested from the food industries, control agencies, and consumers, and how these needs will evolve in the next future, and secondly, the status of biosensors technological evolution, sample throughput, associated costs and acceptance by regulatory authorities.

Food industries have to play in a global market where the main characters are: costs, innovation, marketing, and fraudulent competition. Food industry needs analytical tools, characterized by ease of operation, low cost, and fast response to pursue safety and quality goals. Control Agencies operate as risk assessors, a duty of the risk managers, the politicians, from whom the consumers demand part of their request for control.

Consumers may act at two levels, asking the politicians to enforce warrant legislation and drive investment in control and safety, and exploiting actions of self assessment.

At present the main focus is certainly on safety, though it is difficult to separate this concept from quality. Recent food crisis, BSE in British beef, the tragic death of consumers as a result of *E. coli O157* in Scottish beef and the Belgian dioxin scandal in egg and chicken meat, which have been extensively reported by media and insufficiently coped with by authorities, had reduced consumer confidence toward food safety.

The controls cover all areas of chemical composition, hygienic aspects, and authenticity. In all of these, biosensors could possibly play an important role. In some cases, i.e., the electrochemical antibody based biosensors for *E. coli* O157 and *Campylobacter* (DETEX®) or others as described, biosensors are already a reality.

The potential value of biosensors technology in food safety and quality is basically related to their peculiar features: low cost per analysis can lead to increase the number of tests that industry can afford, with no consequence on the product price, fast response, and reduced sample preparation can increase the throughput of control laboratories enabling wide screening tests, ease of operation can enable consumers (distributors and end users) to perform their own tests (i.e., meat freshness or pesticide residue in vegetables or fruit).

Biosensor technology will have an impact on food safety and quality if the developed devices will be able to produce extensive data for anticipatory studies (i.e., emerging or new pathogens), regulatory (i.e., general toxicity index associated to group of contaminants), historical series (i.e., geographical area of risk).

An emerging area that will need appropriate regulations, in the next future, is that of the functional foods and nutraceuticals. These are foods where functional (i.e., antioxidants, probiotics) constituents or ingredients are present. Exaggerated or even fraudulent claims, in the form of marketing or labelling, are currently used by industry to drive consumer's choice. There is a trend to bind health issues with food consumption, orienting the market choice toward new food. This may represent a risk when the consumption of certain foods supposed to have beneficial effects on health is not supported by sound scientific evidences. In this area it is essential to gain exact knowledge of the functional constituents of food, its availability, and its metabolic fate before any health claims can be made.

In this respect, both catalytic and affinity biosensors can provide information on the activity of such constituents as the analytical response is produced by a biological reaction that can be adapted to gain functional information (i.e, protection with respect to an oxidising stress agent).

Possibly in the next years chemical sensor technology, and biosensors, will enter the HACCP procedures enabling an active approach to hazard analysis, creating the basis for an evolution of that approach to food safety and quality.

According to a survey published in 1999 when consumers were asked who they believe, the answer were: Environmental organizations (23%), Consumers organization (16%), Agricultural organization (16%), National authorities (4%), Industry (1%). And, even more notably, 75% believe that nobody can be fully trusted to speak the truth. It is evident that the poor trust toward national authorities and industry can be improved with a multilateral approach comprehensive of educational, communicative, and technical aspects. The availability of alternative and cheaper analytical tools can help to reduce the outbreaks of food related incidents and contribute to regain the consumers trust.

All of these actions require innovation (i.e., *new* analytes), improvement (i.e., selectivity, sensitivity), or simplification (i.e., sample pretreatment, analyte extraction) of the analytical protocols. Whether biosensor research will be able to tackle the challenges of the future depends on the ability of scientists to understand which technological aspects need further improvement and development.

It is a fact that biosensors are now increasingly becoming part of the main stream real time analytical measurement tools as detailed.

There is a clear need to develop biosensors for food analysis, both for screening a group of analytes (e.g., total amino acids and pesticides) and for identification of individual analyte within a group (e.g., different amino acids or single pesticide molecule) simultaneously. The technology to develop these types of class specific or single analytes detection schemes is available for many classes of compounds (e.g., mycotoxin, organophosphate and carbamate pesticide, polychlobiphenyls). However, for a biosensor, it is not only the new or enhanced transducer element that will form the basis of future sensors released onto the market, but also new sensing elements. Major limitations to the spreading of the use of biosensors, included the ones mentioned, are the instability of the (biological) sensing element and the cost that still remain noncompetitive. An important step forward is expected to come from the research on innovative biological recognition elements, such as engineered enzymes and abzymes (antibody possessing enzymic activity). In the affinity biosensors field, which seems the most promising with respect to commercial applications, the alternative physicochemical recognition elements, in their young age for sensing applications, are synthetic peptides and protein, nucleic acids, and molecular imprinted polymers (MIPs). Unlike antibodies or enzymes, the MIPs are inherently more stable and do not degrade under harsh environmental conditions; the active site can be regenerated many times without loss of recognition affinity and are relatively inexpensive to produce. Currently, however, their limitations include the use of high template concentrations in the production step leading to problems of incomplete template removal and hence, leaching of the target analyte causing high background noise. More research is needed before scale up procedures for the production of the MIPs can enter diagnostic companies.

Finally, there are at least two other issues that have to be considered to understand the potential impact of biosensors in the area of food analysis; automation and miniaturization. Nanotechnology (75–78) coupled with the laboratory on a chip (LOC) (72–74) concept appears to be able to change the entire way of considering chemical analysis and process control. Nanotechnology refers to exploitation of processes (e.g., physical, chemical,

mechanical, and biological) to generate and utilize structures, components, and devices with a size range of about 0.1 nm (atomic and molecular scale) to about 100 nm (or larger in some cases) by control at atomic, molecular and macromolecular levels. It has been suggested that nanoscale sensors (e.g., monitoring of living cell metabolism at atomic level) and ultraminiaturized sensors (e.g., monitoring of a range of chemicals) could lead to the next generation of biotechnology based industries. In this context, a nanosensor (also referred to as an ion channel switch biosensor), which functions like a simplified cell membrane that is able of highly sensitive and rapid analytical measurements by monitoring changes in the electrical conductivity, has been reported (79). The concept of LOC entails miniaturization of all the essential components of analytical instrumentation (e.g., sample preparation, resolution of the components, reaction with appropriate reagents and detection) by microfabrication on a chip. Some of the components in LOC technology have already been released on the market (e.g., LabChip1 and GeneChip1 from Caliper Technologies and Af-matrix, respectively). A limitation to the full exploitation of lab-on-chip possibilities is sampling strategy and sample preparation. Going to the micronanoscale, in fact, gives the possibility to run several parallel assays in very small volumes but a careful sampling strategy is needed for food samples due to their extreme heterogeneity in most cases. Additionally, in many applications the sample preparation time, not the biosensor response is the rate determining step of the analytical process. Extreme pHs and ionic strength are noncompatible with most biosensors, thus a dilution or neutralising step is necessary. In the case of solid, or hydrophobic, food stuff an extraction procedure is required. Miniaturization of extraction procedure using microfluidic flow systems will enable to move the sample preparation closer to the biosensor in the LOC approach. In any case, new sampling and extraction procedures need to be pursued to fully utilize the potential of biosensors. Application of biosensors in organic solvents has been described and also the improvement of this possibility can enlarge the market for biosensors.

Six years ago, Luong (154) concluded his review on biosensors in food analysis on Tibtech with these words: "Biosensors must be inexpensive, reliable, robust enough to operate under realistic, and perhaps hostile, conditions, and possibly form part of highly integrated analytical system. This aspect is both technically challenging and mandatory for a successful commercialization of biosensors in this conservative and competitive industrial sector."

We have shown that in the period 1997–2003, the use of biosensors in the food area has received a considerable attention. Many devices have been developed and tested for application in food samples, some of which have entered the market. The results obtained in the challenges detailed, such as biocomponent stability, device robustness, LOC, and miniaturization development will determine the success of biosensor methods of analysis in the food sector over the next year.

3.12

Enzymatic Bioprocessing of Tropical Seafood Wastes

Rupsankar Chakrabarti

CONTENTS

ABSTRACT

A large quantity of fish in the tropical countries of the globe is being used for nonfood purposes. The tropical nations in South and South East Asia are the major exporters of aquaculture products to the developed nations in Europe, Asia, and the USA. Improper disposal of solid waste and untreated effluent or waste water from processing factories causes environmental hazards. The present status of enzymatic bioprocessing of seafood wastes along with underutilized unpopular species is discussed. The small and bony fish of South East Asia can be processed to popular fish paste and sauce using papain or bromelain to accelerate the enzymatic process. Unpopular fish species and the filleting waste of popular species can be used to prepare bitterness free fish protein hydrolysate using proteolytic enzymes in single preparations or in combinations. This product can be used as an ingredient in food or beverage formulations. The enzymatic hydrolysate from shellfish waste, and tuna head and viscera waste can be used as a flavoring agent and also as an ingredient in animal, fish, and shrimp feeds. Proteases can be used efficiently to remove protein in the extraction of (1) good quality chitin, (2) carotenoprotein from shell fish waste and (3) guanine crystals from fish scales. Technology transfer to industry is too slow due to the acceptability of new formulations over traditional products.

12.1 INTRODUCTION

With the stagnation of the global marine catch, aquaculture plays a key role in meeting the increasing global demand for fish products. Developed countries are the major importers of processed fish products; whereas the developing and underdeveloped nations are the major exporters. Tropical Asian countries namely, Taiwan, China, Thailand, India, Bangladesh, Malaysia, Singapore, and Indonesia are making rapid progress toward sustainable aquaculture, generating employment and export income. These countries contribute more than 50% of the world shrimp production and more than 70% by aquaculture (1). Other tropical nations, such as Saudi Arabia, are also trying to perfect aquaculture technology with available resources. There were only a few fish processing factories in tropical South and South East Asian nations before the mid twentieth century. With the growing demand for marine and aquaculture products, numerous export oriented fish processing factories were established in this region during the second half of the twentieth century. National laboratories in these countries are actively addressing the quality standard of finished products and the utilization of waste byproducts in an effort to maximize fishery resources for the human population needs.

Table 12.1 shows the nonfood use of total fish production by tropical countries (2). Central American countries such as Mexico, and Nicaragua reduced nonfood use (fish meal, feed and bait) of total fish production from 46% in 1980 to 26% in 1995, while their total catch and aquaculture remains almost stagnant. In South American countries the nonfood use of fish products increased from 60% in 1980 to 77% in 1995 due to increasing trends of total fish production. Since 1960, attempts have been made worldwide to use the total available catch as food for human consumption (3,4). For example, Table 12.2 shows

the composition of meat from some unpopular species in the Indian Coast (5). However, the transfer of biotechnology is taking place at too slow a pace in some countries to provide a benefit.

Improper disposal of solid waste and untreated effluent or waste water from fish processing factories, including fish meal plants, causes an environmental hazard. Every nation has adopted regulatory standards for the disposal of fish processing waste. Several products have been developed in national laboratories from fish processing waste; but, again the transfer of biotechnological applications to industry is too slow. However, prospective entrepreneurs are being encouraged to start model environmentally friendly processing plants to use processing waste to make valuable products for human and animal consumption.

In the tropical countries, technologies of enzymatic processing of seafood wastes have been developed for the recovery of proteinaceous matter, pigment, flavorants, and chitosan (6–11). In other parts of the world, different research programs such as the Bay of Bengal Program were instigated to carry out work on tropical fishery products and tropical fishery waste (12–14). Research workers also reported using enzymes as food processing tools (for instance, proteases have been used in reduction of viscosity of stick water, a byproduct from fish meal, to improve drying rate). This chapter describes the role of enzymes in processing of seafoods into various products to be used either as human food or as an ingredient for preparation of human food.

12.2 TROPICAL FISHERY WASTE

12.2.1 Fishing Vessel Catch Waste

In ordinary pelagic fishing vessels, sorting of the catch is done as soon as the fish are taken on board in order to remove fish unsuitable for human consumption. Owing to the shortage of space in fishing vessels, these unsuitable fish are rarely brought to port for fishmeal manufacture. Gutting commences as soon as the catch comes on deck. The guts are thrown overboard, which could cause a serious pollution problem when the vessel is close to public beaches or inhabited areas. Big fishing vessels have separate and adequate facilities for freezing fish and reducing processing wastes into fishmeal on board. Table12.3 shows the weight loss during beheading, degutting, and trimming.

Shrimp trawling produces a large bycatch, that is, a catch of undesirable nontarget species, which comprises 80–90% of catch volume. Removal of shrimp heads at sea reduces the bacterial load on the shrimp product, and is more economical for icing and storage space. Weight loss due to beheading is 30–40% of the whole shrimp. Substantial quantities of shrimp bycatch and processing wastes are discarded at sea (15). High capital and operating costs mean that the operation is only profitable if revenues are high. Therefore, the industry focuses on shrimp and high value fish. The major portion of bulk catches of low priced fish is discarded at sea for the following reasons:

1. Limited ice and storage capacity
2. Lack of onboard processing facilities
3. Possible contamination of shrimp
4. Shortage of labor
5. Difficulty in selling large quantities of fish at port and thereby delay in transporting shrimps to processing facilities
6. Risk in transferring bycatch to another boat at mid sea

Table 12.3
Typical yield of edible flesh and organs as percentage of whole fresh fish

Species	Head (%)	Viscera* (%)	Skin (%)	Bones and Cartilages(%)	Flesh (%)
Horse mackerel	23–26	8–24	3–5	8–10	41–55

*Viscera include gonads and liver.

Source: Clucas, I.J. *Fish Handling, Preservation and Processing in the Tropics, Part 2*. London: Tropical Development and Research Institute, 1982, pp.18–20; Zaitsev, V., I. Kizevetter, L. Lagunov, T. Makarova, L. Minder, V. Podsevalov. *Fish Curing and Processing*. Moscow: Mir Publishers, 1969, pp 460–485.

When lobsters are not landed alive, the tail and cephalothorax are separated as soon as they are brought on board. Whole lobsters deteriorate rapidly after death. If crabs are not landed alive, these crabs are cooked whole on board, or butchered by means of debacking and removal of viscera and gills. Enzymatic deterioration in dead crabs takes place very fast. The waste from crab processing may account for up to 70% of the original crab weight. In some big fishing vessels, cephalopods are immediately transferred to processing areas on board. After careful evisceration, the removal of eyes, mouth, skin, tentacles, and heads followed by deboning and trimming are common steps in processing of cuttlefish and squid. The edible portion is washed and stored in ice. The visceral content of cephalopods contains a large concentration of digestive enzymes and spoilage microorganisms. These will cause marked deterioration of quality if not removed in time. The trunk and tentacles, the edible portion, is only about 70–75% of the whole squid. The processing wastes of crabs and cephalopods are typically thrown overboard.

12.2.2 Waste During Handling at Landing Centers at Shore

Small and medium size fishing vessels engaged in short term voyages or daily fishing bring commercially important fish in on ice, while the remaining catch is not iced. The fresh fish are rejected if they are known to contain harmful, decomposed, or extraneous substances above acceptable levels. Diseased fish are discarded, and acceptable fresh fish are auctioned and transported to different processing units.

12.2.3 Waste from Filleting Units

Whether mechanical or manual filleting methods are used, the gutting of fish must be completed immediately on arrival in order to remove all pieces of gut, liver, blood, and backbone before the filleting operation. The fillets are processed into frozen products for domestic and export markets. All waste materials from filleting plants are collected

immediately into suitable watertight and lidded containers, which are emptied regularly by manual or mechanical means.

12.2.4 Waste from the Freezing Units

Japan, the U.S. and European countries are the major importers of frozen shrimps. China, Hong Kong, Malaysia, and Singapore are the major importers of frozen fin fish from other developing nations of South and South East Asia. On average, India exports about 100 thousand tons of frozen shrimp, 120 thousand tons of frozen fish and 66 thousand tons of frozen cephalopods each year (16). Frozen fin fish include white pomfret, black pomfret, sea bream, and reef cod. Annually, fish and shrimp processing waste spread along the 8000 km coastline of India include 60–80 thousand tons of shellfish waste, 40–50 thousand tons of processing waste from fin fish and 30–35 thousand tons of cephalopod waste.

12.2.4.1 Waste During Processing of Fin Fish

The fresh or iced fin fish are degutted and the gills are removed. The dressed fish are thoroughly washed prior to freezing. The processing waste is 15–20% of the total fish weight. The waste washwater contains mainly blood and body slime.

12.2.4.2 Wastes from Peeling and Deveining of Shrimps and Lobsters

It is desirable to peel large shrimp by hand. When very small shrimp are peeled by machine, yields are reduced due to a high proportion of breakages. The wastes from heading, peeling, and deveining operations are processed for fertilizer, animal feed, and fish food. Heading, shucking, and deveining of raw or cooked lobster are performed thoroughly, so that no viscera are left to spoil the flavor of the final product. The processing waste may account for up to 60% of the original weight of raw materials. The dressed products are mainly processed into frozen products for export.

12.2.4.3 Waste from Processing Units of Crabs and Cephalopods

After butchering crabs, any remaining viscera and gills are removed by brushing and washing. Most crab species will throw off their legs and claws if placed directly in boiling water or steam. Back shells, viscera and other shell wastes (70% of original crab weight) are removed continuously from the processing area. Crab meat is picked by hand from dressed body parts and then frozen for export. During the dressing, gutting, and trimming of cephalopods all waste materials are collected immediately in suitable containers which are emptied regularly. The dressed cephalopods are graded and then frozen for export.

12.2.5 Wastes from Fish Canning Units

Only the edible portion of fish is used for canning. For large and medium sized fish, it is usual to cut off head, fins, and tail, and remove all viscera, and sometimes also the spinal column and skin. Small sized fish are headed, tailed, and partially gutted. Yield of dressed fish depends on the species, biological state, and size of fish. Table 12.3 shows the waste on the percentage of total fish weight. With small fish (sardines, small herring), the gut is pulled out without cutting open the belly; a cut is made at the neck and vertebra severed. When the head is pulled off, the pectoral fins and alimentary tract come away together with most of the guts. Preprocessing operations such as boiling in brine or frying in oil improve the taste, texture, and appearance of canned products through protein coagulation and partial extraction of moisture.

Protein coagulation and the breakdown of cells during boiling causes the release of fat, moisture, water soluble nitrogenous substances, vitamins, and minerals from fish flesh.

These losses are directly proportional to the duration and temperature of cooking, and inversely proportional to the fat content of the flesh. During canning of sardines in oil, processing losses amount to 35–38% (degutting and dressing) and 22–24% (steaming) on wet basis.

The yield of canned crabmeat varies from 17–28% of the wet crab, with cooking wastes of 11% on average. Crab processing produces 60–70% waste on a wet basis. Raw meat content in fresh shrimp varies from 24–41%; the yield of canned shrimp meat ranges from 18–32%. Shrimp waste ranges from 53–72% (cephalothorax and abdominal shell) of white shrimp.

The wet body weight of mollusks is 20–32% of the total weight. The edible parts are the fleshy foot, the adductor muscle, and the mantle (12–17% yield). When cooked, these mollusks lose 35–54% in weight. Mollusk wastes contain shells (60–80%) and inedible portions (8–12%). The shell is composed of calcium carbonate.

The edible parts (trunk, head, tentacles) of squid account for 68–75% of total weight. The squids are gutted and washed. After cooking (4% NaCl; 15 min), they are skinned, the eyes are removed, the mantle cavity is cleaned, and the appendages are separated, thoroughly washed, and put into the membrane (mantle) cavity for filling in cans. The processing waste includes the ink bag (6–10%), chitin plates (0.2–0.3%), liver (2–6%) and other organs (12–15%).

Octopi are dressed by slitting the mantle, body, and head and then removing the intestine, mouth apparatus, and eyes. With octopus larger than 2 kg, the fleshy parts of the tentacles are slit. Waste from dressing amounts to 11–20% of the wet weight.

12.2.6 Losses During Salting

Preserving fish in salt or brine begins with washing gutting, and splitting (for large fish), and ends with a second washing and mixing the fish with salt or brine in containers. The amount of protein and nitrogenous matter passed into brine depends on the salting conditions. When the fish are surrounded with a low brine concentration, more proteins and their fractions diffuse from the fish in larger quantities than with a high brine concentration. The proportion of nitrogenous matter in brine increases with the days of brining. Higher than ambient temperature increases enzyme activity and leads to increase losses of organic matter. Nitrogenous matter loss goes up to 10% of total amount of the available nitrogenous matter. Thus the food value of the product is appreciably reduced.

12.2.7 Losses During Reduction to Fishmeal

Table 12.1 shows the nonfood use of fish products, including fish from commercial catch and aquaculture. In South American countries 60–77% of total fish production is used for nonfood purposes (such as reduction to fish meal and use for feed and bait). In Central American tropical countries, 25–46% of total fish production is used for nonfood purposes. Nonfood use varies from 10–22% and 9–15% of total fish production in African and Asian tropical countries respectively. The raw materials used for nonfood use are divided into three main categories:

1. Fish caught for the sole purpose of fish meal production (e.g., anchovies in Peru, anchovies and pilchards in South Africa),
2. Low priced or unused fish from prawn bycatch, and
3. Fishery wastes from processing operations (e.g., damaged commercially important fish; trimmings from filleting operations; heads, guts, and scale from processing factories).

With expanding world populations and stagnation of fish catch in capture fishery, emphasis has been placed on increasing fish production through aquaculture; but water bodies suitable for aquaculture are limited. The search for development of new products from low valued, low priced, or wasted fish for human consumption is therefore increasing in importance.

12.2.8 Waste from Meat and Bone Separator Units

Many of the fish of shrimp bycatch are small and occur in relatively large quantities. There are a number of machines capable of flesh removal, generally known as meat and bone separators. Whole, ungutted fish produces nonwhite mince containing gut contents and blood. However, fish can be gutted and washed before separation in meat and bone separators to produce clean white meat. The wastes from these units include skin, scales, gut, gills, bones, and heads, which accounts for 50–60% of the whole fish. In developing countries, a major area of interest is minced meat and fish mince for the production of various value added products suited for internal and export markets.

12.2.9 Losses from Surimi Plants

Surimi is a minced and washed raw fish meat paste. The global demand for surimi based products, such as crab leg analogs and shrimp analogs, has increased every year. Losses of suspended solids and soluble solids, including soluble protein in washwater and presswater from surimi plants may accounts up to 35% of the solids entering the washing stage.

12.3 PRODUCT DEVELOPMENT FROM WASTE

Proteolytic enzymes or proteases are hydrolytic enzymes that catalyze degradation of specific peptide bonds in protein molecules. The applications of specific proteases in the processing of seafood waste are summarized in Table 12.4.

12.3.1 Products from Small and Bony Fish

12.3.1.1 Fish Protein Hydrolysate

The bycatch of shrimp trawlers consists of mostly small and bony varieties of miscellaneous unpopular fish. The use of proteolytic enzymes to liquefy fish protein has been found to be a feasible method to isolate protein easily from unused or underutilized fish. The enzymes can be from plants (papain, bromelain, or ficin), animals (trypsin or pancreatin), or microbial sources (pronase or alcalase). Sen et al. (17) defined digestion conditions using papain and found that at pH 7.0 maximum solubilization occurred in the first ten hours of hydrolysis. Hale (18) measured the relative activities of more than twenty commercially available enzymes for digestion of a washed and freeze dried fish protein substrate. The standard 24 hour test (concentration of enzyme required to effect 60% digestion in 24 hours) was carried out at near optimum conditions of temperature and pH for each enzyme. Hale (18) reported that pepsin, papain, and pancreatin in combination showed good activity at moderate cost (pronase exhibited greatest activity per unit weight). Mackie (19) used trypsin and bromelain for removal of fish protein from raw codfish. By conducting the digestion at relatively high temperature (50–60°C), it was possible to obtain a liquefied fish milk after a digestion of 30 minutes, which was long enough to dissolve the skin. Yanez et al. (20) employed hake as raw material for production of protein hydrolysate and used it for the supplementation of cereal protein. Iyer et al. (21) and Thankamma et al. (7) reported the preparation of good quality protein hydrolysate (even

bacteriological peptone grade) from miscellaneous trash fish such as thread fin bream, using papain at 55°C for 30 minutes. Venugopal and Lewis (8) reported maximum solubilization of low cost lean fish using pepsin. Warrier et al. (22) employed spray drying of the hydrolysate from deboned dhoma *(Johnius dussimeri*) meat using papain at 55°C for 2hrs, which yielded product with a creamy color and 90% protein. The process of the preparation of fish protein hydrolysate is outlined in Figure 12.1. During the process the loss of tryptophan, tryrosine, and lysine was reported by many workers (7,19).

Hevia (23) reported bitterness and glutamic acid taste in fish protein hydrolysate. He also reported that pronase hydrolysate was less bitter than that from bromelain or ficin. Bitter hydrolysate contained more basic n-terminal peptides residues (glycine, leucine, isoleucine, phenylalanine, and valine). Liquefied fish protein with negligible bitterness could be obtained using protease from *Aspergillus niger* (24). Lalasidis et al. (25) prepared fish protein hydrolysate with low molecular weight peptides, using bacterial endopeptidase: alcalase, followed by

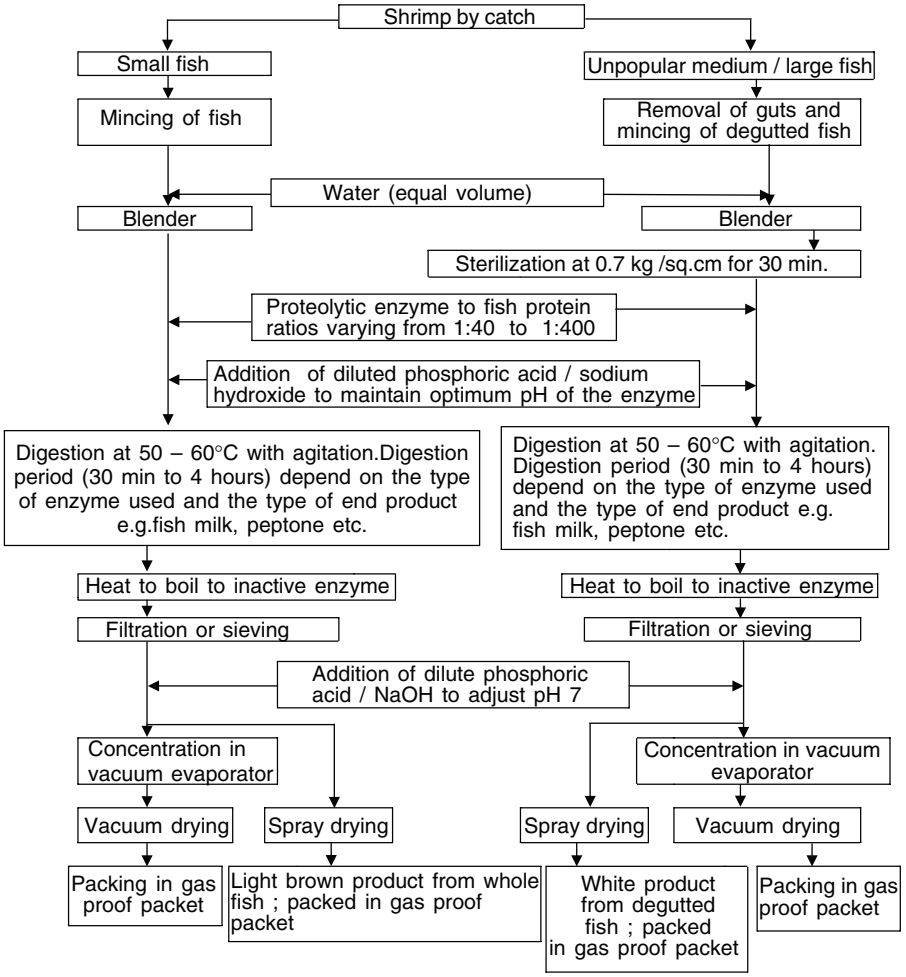

Figure 12.1 Outline of procedure for liquefying fish by proteolytic enzyme (Based on Mackie, 1974; Tankamma et al., 1979; Warrier et al., 1996)

pancreatine. This bitterness free hydrolysate had an average molecular weight of more than 1000. As an alternative method, Lalasidis and Sjoberg (26) reported the use of azeotropic secondary butyl alcohol (SBA) for removal of bitter compounds from bitter fish protein hydrolysate. An azeotropic mixture of 72.8% SBA and 27.2% water (v/v) was used, and when water levels reached 36% (v/v) a two phase system developed. SBA is not only a costly solvent, but its residue may also pose some human health problems. Chakrabarti (27) reported the use of food grade ethyl alcohol to remove bitter peptides from bitter fish protein hydrolysate. A solvent containing ethyl alcohol and water in the ratio 400:70 was used to remove bitter fractions from concentrated fish protein hydrolysate prior to vacuum drying. After debittering, the fish protein hydrolysate can be used in the wide range of food or beverage formulation. The solvent containing bitter fraction was concentrated in a vacuum evaporator and then vacuum dried. Chakrabarti (28) reported good growth of *Staphylococcus aureus, Escherichia coli* and *Bacillus subtilis* in media containing the bitter fraction of fish protein hydrolysate.

Quaglia and Orban (29) reported the sensory properties of fish protein hydrolysate prepared by alcalase were better than that prepared by papain. Kilara (30) reported

bacterial neutral and alkaline proteases were about 140% more efficient than papain. Rebeca et al. (31) reported the use of several microbial proteases for the production of fish protein hydrolysate from mullet. Alkaline proteases (pH 6.5–11.0) from *Bacillus subtilis* were found to be more efficient than neutral proteases from the same bacterium, solubilizing more than 80% of the protein.

12.3.1.2 Fish Paste and Fish Sauce

12.3.1.2.1 Fish Paste Small and commercially unimportant fish, which can not be sold as fresh fish, are used as raw materials for preparation of fish paste. The common raw materials for fish paste production are round scad (*Sardinalla fimbriata*), herring (*Spiratelloides japonicus*), sardine (*Sardinella longicaps*), anchovy (*Stolephorus indicus*), small slipmouth (*Leioganathus*); tiny shrimps are used for bagoong, and belachan (6,32). In the Philippines and other South East Asian countries, fish paste or begoong is a semiliquid product obtained from the liquefaction of whole fish in a salt mixture. This is widely used as a condiment and also as a protein food for the poor section of the population. The method of preparation involves mixing fish and salt in the proportion of 1:3 or 2:7 (by weight). Fish proteins are broken down into their soluble constituents. Guevara et al. (33) reported an increased fermentation rate with the addition of 0.1–0.5% papain. They observed crude protein increase in the liquid portion of bagoong made from anchovy with the increase in enzyme concentrations. The hydrolysis was fastest at 45°C.

Autolytic enzymes are present at higher concentrations in the viscera and head than in other tissues (34,35). Thus their concentration during processing is influenced by the timing and completeness of beheading and evisceration, or by using whole uneviscerated fish if maximum enzymatic activity is required. The amount of indigenous enzymes can be reduced by beheading and evisceration. Commercial proteolytic enzymes, or fruit rich in enzymes (papaya or pineapple), can be used in controlled amounts to accelerate the enzymatic process, but their use is yet to be adopted by producers (6,13).

Some typical fish or shrimp pastes from South East Asian countries are ngapi of Mayanmar,, pra-hoc and mams of Cambodia, belachen of Malaysia and trassi of Indonesia. In general, fish or shrimps are pounded with 4–10% (w/w) of salt to form a paste, and this paste is subjected to varying periods of sun drying before being packed tightly in wooden tubs or boxes, excluding all air bubbles. The paste ferments upto 7 days and then is sun dried for 3–5 hours. The paste is then minced again and returned to the wooden tubs for an additional 30–90 days fermentation. It is then minced a third time and packed in blocks wrapped in cellophane or polyethylene paper. The moisture content and salt content in the paste vary from 35–50% and 13–18% respectively. The yield of paste is 40–50% in case of raw *Acetes* shrimps (14).

12.3.1.2.2 Fish Sauce In this process the fermentation of fish is carried out for a longer period than that in manufacture of fish paste. The classic fish sauces are nuoc-mam of Vietnam and Cambodia, nam-pla of Thailand and patis of Philippines. The best sauces are made from anchovies (*Stolephorus* species). The sauces are liquid containing a mixture of amino acids and other protein degradation products. A typical process is outlined in Figure 12.2. The use of uneviscerated fish ensures maximum autolytic enzyme activity; the combination of a salt concentration above 20% and anaerobiosis will totally inhibit any microbial growth during the production of sauce. In the production of most traditional high salt fish sauces, enzymes from external sources are not used. However, in certain parts of Vietnam nuoc mam is produced from eviscerated fish to which fresh pineapple juice is added, because of the lower content of the enzyme (34). In Japan koji (a preparation of cooked rice bearing growth of *Aspergillus orygae*) is used as a source of proteases in

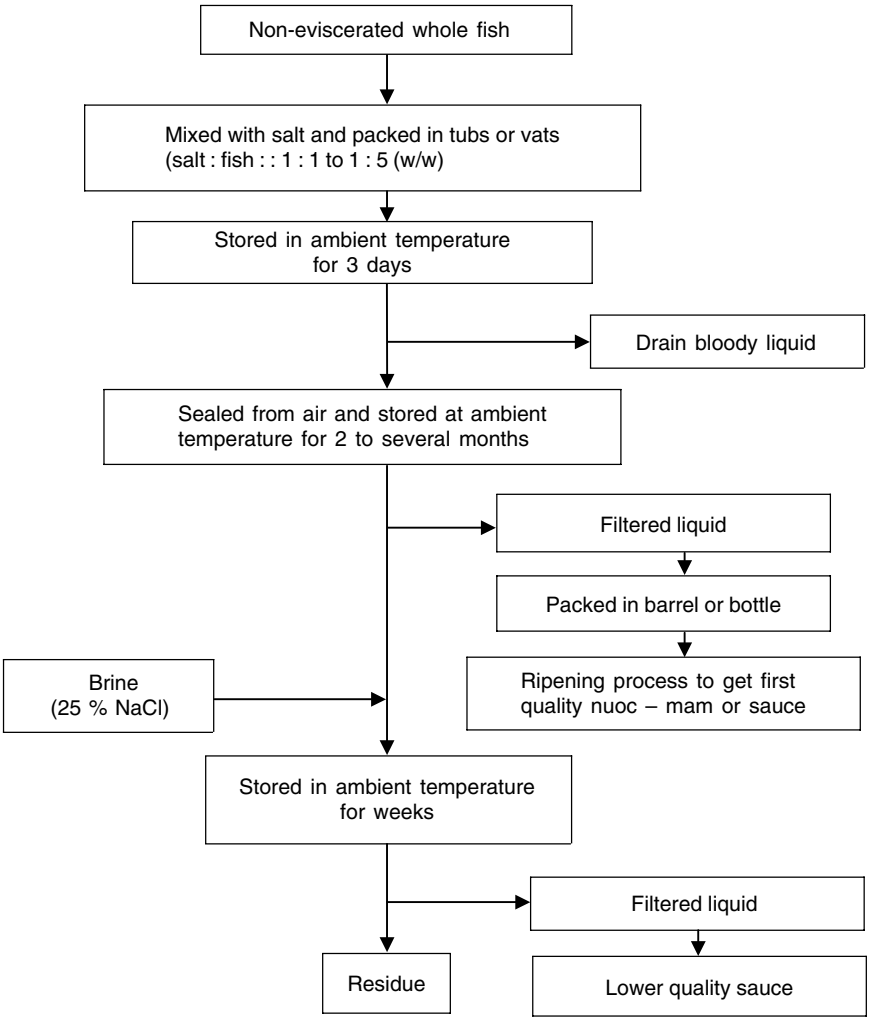

Figure 12.2 Flow diagram for production of sauce (Based on Clucas, 1982; Owen and Mendoza, 1985)

some traditional products (36). The cepalin fish sauce, prepared by using hepatopancreas as a source of proteases, is highly acceptable and preferable to commercial products from the Philippines (37).

12.3.2 Products from Filleting Waste

Filleting waste consists of heads, skins, skeletons with adhering flesh, and belly flaps. The waste is mostly discarded because of the difficulty in recovering the residual meat. Mackie (19) reported the use of trypsin and bromelain in hydrolysate preparation of minced raw filleting waste from cod. Hydrolyses were carried out with enzyme to protein ratios varying from 1:40 to 1:400 at 60°C for bromelain and 45°C for trypsin. Bromelain was found to be more effective than other enzymes at obtaining liquified product in 30 minutes, which was just long enough to disperse the proteins but not long enough to dissolve skin. Digestion was stopped by heating at 100°C for 10 minutes. The filtered protein suspension

could be used either as sterilized liquid suspension or as spray dried powder, which was either white or light brown in color. The addition of lipid containing antioxidant is reported to be a very effective method of distributing antioxidaint rapidly throughout the homogenized tissue. The probable potential products are milk substitutes for both animals and humans.

Lalsidis et al. (25) prepared low molecular weight enzymatic fish protein hydrolysate from deboned cod fillet waste, by alcalase treatment at 50°C in the ratio 1:150 (enzyme:protein) followed by pancreatin at 37°C in the ratio 1:75 (enzyme:protein); the yields of soluble nitrogen were between 80 and 90%. Though the alcalase hydrolysis was continued for 3 hours, the pancreatin hydrolysis was continued for more than 8 hours to get product free from bitterness. The hydrolysate protein had an average molecular weight of over 1000.

Nair et al. (38) reported the use of papain and minced fresh pineapple as a source of bromelain, for hydrolysis of jewfish *(Juhnius* species*)* filleting waste. The filleting waste was homogenized with water (1:1), boiled for 5 minutes, and then cooled. The proteolysis was carried out separately with papain (activity 10 units/mg enzyme) at 55°C in the ratio 1:400 (enzyme:waste), and bromelain (minced fresh pineapples) at 30°C in the ratio 1:2 (mined pineapple:waste). Digestion was continued for two hours and then stopped by boiling for 10 minutes. The whole mixture was cooled, neutralized (using dilute sodium hydroxide) and filtered. The hydrolysate was concentrated on a water bath and dried in vacuum; the yield was 8–11%. The product prepared using papain was bitter and brown in color; but the product prepared using pineapple had better taste and better acceptability. The proximate compositions of jewfish waste and hydrolysate from waste are given in Table 12.5.

Ferreira and Hultin (39) used an acidic fungal protease (Newlase A from *Rhizopus niveus)* to recover protein from cod filleting waste. The enzyme hydrolysed the fish proteins at 40–50°C, at pH 3.5, within 75 minutes. Kim et al. (40) reported the use of a crude proteinase from tuna pyloric caeca for a period of 12 hours at 50°C to recover up to 80% of the protein from cod filleting waste.

12.3.3 Products from Head and Viscera Waste

Fishery wastes such as head and viscera, especially during on board processing, are discarded at sea, and the same wastes on land are largely unutilized or converted into manure. Mackie (19) reported the preparation of hydrolysate from cod offal using commercially

Table 12.5

Source: Nair, A.L., P.T. Mathew, P.V. Prabhu, in *Harvest and Post Harvest Technology of Fish*, Ravindran, K., N.U. Nair, P.A. Perigreen, P. Madhavan, A.G.G. Pillai, P.A. Panicker, M. Thomas, eds., Cochin: Society of Fisheries Technologists, 1985, pp 596–599

available proteolytic enzymes such trypsin and bromelain. He used 0.1 g enzyme to 200 g cod offal at 65°C for one hour. A 95% yield of nitrogen was recovered from the offal. In the offal hydrolysate the glycine and proline concentrations were correspondingly high at 569 and 323 mg/g total nitrogen respectively due to the greater amount of collagen and connective tissue present in the offal. Lalsidis et al. (25) reported the preparation of low molecular weight enzymatic bitter free hydrolysate from cod offal by treatment with alcalase followed by pancreatin. The yields of soluble nitrogen were between 80 and 90%. The hydrolysate had an average molecular weight of more than 1000 and a free amino acid content of 15–45%.

Rao et al. (41) reported the use of head and viscera of fresh water fish such as *Labeo rohita* and *Labeo calbasu*, and the viscera of mackerel for preparation hydrolysate to be used as bactopeptone. The process is outlined in Figure 12.3. The total yield of the dried

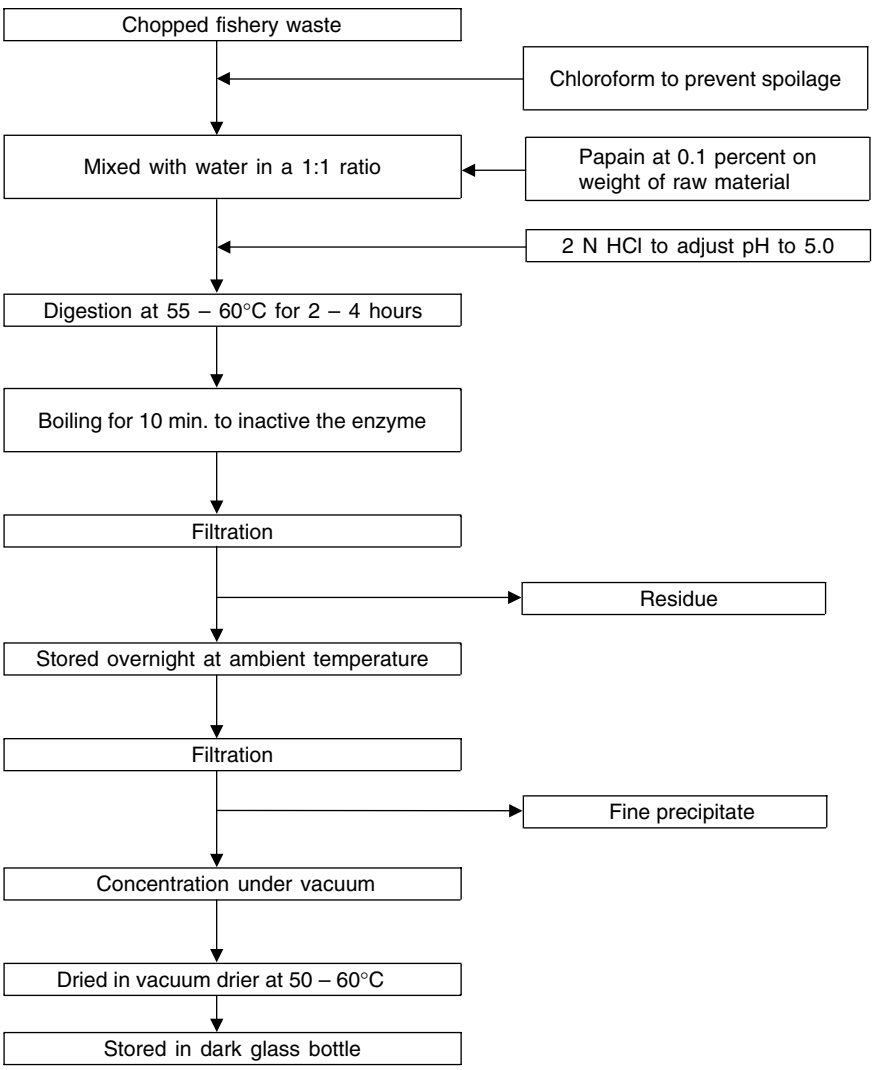

Figure 12.3 Flow diagram for production of bactopetone from head and viscera (Based on Rao et al., 1978)

product varied from 11–12.4%, whereas total nitrogen and ∝-amino nitrogen in the product varied from 12.3–12.6% and 24–34% of total nitrogen respectively. These pale yellow hygroscopic dried products were found to be equal to Oxoid bactopeptone in growth promotion of *Lactobacillus arabinosus* and *Streptococcus faecalis.*

Some tuna canning companies in Thailand manufacture tuna viscera powder (42) from enzymatic hydrolysis of tuna guts followed by dehydration and pulverization. It is typically dark brown in color, has the odor and flavor of tuna, and is highly hygroscopic. It is a soluble protein with components of water (<10%), protein (>60%), fat (8–18%) and ash (1%). It is used as a fish flavoring agent and also an ingredient in feed products for animals, fish, and shrimp.

12.3.4 Use of Red Meat from Tuna Waste

Tuna is abundantly available in tropical seawater. Commercially important and more available species are albacore, bigeye, and northern and southern bluefin and yellowfin species. Unlike other fishes, tuna contains a high proportion of red meat (about 11% of the body weight). Substantial quantities of white tuna meat are canned, while the red meat is discarded. Processing of tuna for canning gives 45–50% waste which can be used for preparing various products. Preparation of enzymatic hydrolysate from tuna waste was reported by Thankappan et al. (43) using alcalase. Approximate compositions of red meat and hydrolysate are given in Table 12.6.

After separation of the white meat, the remaining material was minced with potable water (1:2) in a meat mincer for 5 minutes. The pH of the slurry was adjusted to 8.0–8.5 for alcalase and 6.0–7.0 for papain in separate containers. The enzymes were added at a level of 0.5% of the material protein content. The enzymatic reaction was carried out for 60 min at 50–55°C with continuous stirring. The reaction was stopped by increasing the temperature to 85°C for 15 minutes for alcalase, and 95°C for 30 minutes for papain. The slurry was passed through filter cloth, and then filtered through Whitman No.1 filter paper. The filtrate was neutralized, concentrated, vacuum dried, and packed in sealed containers. The yield of hydrolysate using alcalase was 11.4%, and that using papain was 8.4%. Hydrolysate prepared by papain was bitter but that prepared by alcalase was less so.

12.3.5 Waste Water from Surimi Plants

Surimi making requires a large quantity of fresh water during the washing process. This ranges from 10–20 times the weight of the deboned meat, depending on the species. Presently, all the wash water is discharged as waste water. The waste water contains an

average of 3.4 g protein per liter; about 80% of the protein present is water soluble. Watanabe et al. (44) reported that the total protein loss accounted for approximately 30% of the deboned meat weight and varied from processing plant to plant. When correctly handled, the waste water is treated by an activated sludge method, alone or in combination with a dissolved air flotation method. Protein recovery by the air flotation method is aided by coagulants such as sodium polyacrylate and chitosan (45).

12.3.6 Product from Stick Water

Fish juice is a byproduct of the cooking procedure for canned products. Byproduct fish juice contains excess gelatin and has diluted fish flavor. Fish oil is removed from the byproduct juice and the stick water is concentrated to less than 50% moisture. Occasionally whole stick water is hydrolyzed to increase the capacity of the evaporation plant (for instance, addition of about 0.2% commercial preparation of proteolytic enzymes) (9).

Stick water is a byproduct obtained during the production of fish meal. The use of stick water including blood water from fishmeal plants is always recommended by regulatory authorities to avoid pollution. It may amount to 18–20% of the final fish meal solids. The protein content of stick water presents a problem during evaporation. Aguilera and Cortes (46) reported the use of enzymatically hydrolyzed whole stick water (containing blood water) to increase protein content and to depress water activity in fish meal. Hydrolyzed whole stick water concentrate was spray dried into a free flowing powder and then mixed with fish meal. Jacoben and Rasmussen (47) reported the addition of alcalase 0.6 L or neutrase 0.5 L at 0.2% to the stick water at neutral pH and 50°C for significantly reduced viscosity, which enabled further evaporative concentration.

12.3.7 Recovery of Chitin and Protein from Shellfish Waste

The shell fish waste is a good source of chitin. In India, the quantity of such waste from shrimp processing units amounts to 60 to 80 thousand tons annually. Wet shellfish waste contains 4–5% chitin. Recovery of chitin from the waste requires adhering proteinaceous matter removal followed by demineralization. Traditionally dilute alkali is used for deproteinization, which may cause a partial deacetylation and even polymer hydrolysis, resulting in a final product with inconsistent properties (48). Proteolytic enzymes or proteases can be used efficiently to remove protein from shellfish waste. Simpson et al. (49) used chymotrypsin for effective removal of protein from the waste. He maintained the enzyme to substrate ratio at 7:1000 (w/w) at pH 8, with a reaction time of 72 hours at 40°C. Wang and Chio (10) reported the use of a microbial protease from *Pseudomonas aeruginosa* for removal of protein from shrimp shell and crab shell powder. A solid-state fermentation of the materials for a period of 5–10 days removed protein in the range of 46–81%. Alcalase was found to be efficient in removal of 70% of the protein from shrimp shell waste. The product has a light color, less bitterness, and an acceptable appearance (50). The process of chitin and protein recovery from shellfish waste is outlined in Figure 12.4.

12.3.8 Extraction of Carotenoprotein and Protein Isolate from Shellfish Waste

The shrimp industry throughout the world produces enormous quantities of industrial waste in the form of shrimp heads and shells. Significant worldwide increase in crustacean aquaculture in the South and South East Asian countries has added tremendously to that waste. Shrimp shell waste ranges from 53–72% of whole shrimps. The major components of the shrimp shell waste are protein, chitin, flavorant protein, carotenoid protein, and minerals

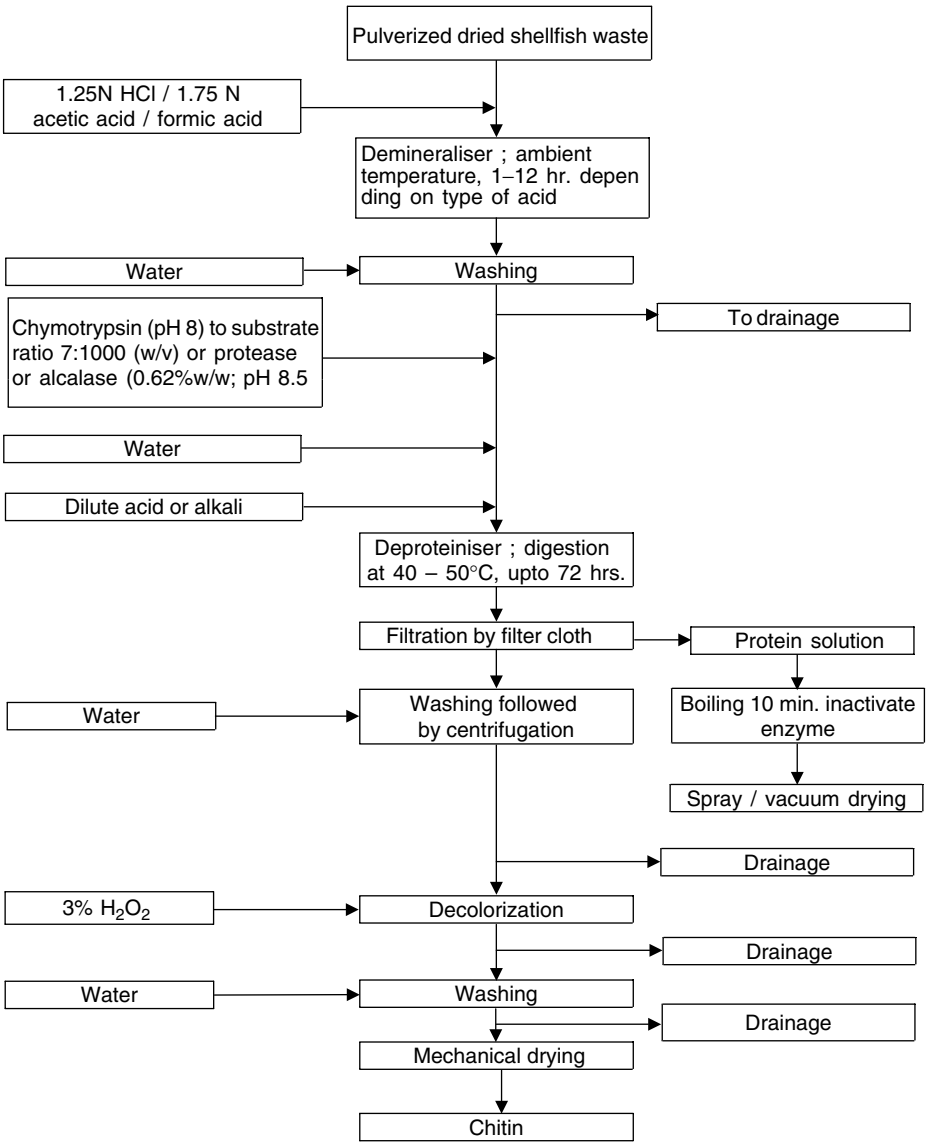

Figure 12.4 Flow diagram of recovery of chitin and protein from shellfish waste (Based on Simpson et al., 1994; CIFT, 1999; Madhavan and Nair, 1974)

(Table 12.7). The processing of shell waste not only resolves environmental problems, but also helps to produce valuable products such as carotenoid pigment, chitin, chitosan, and protein isolate. Simpson and Haard (51) reported the use of 25% bovine trypsin and 0.5 N ethylene diamine tetra acetic acid (EDTA) in an extraction medium at pH 7.7 and 4°C to recover 65% of the protein and 49% of the astaxanthin, a carotenoid pigment, from shrimp waste. He recovered the astaxanthin in the form of stable carotenoprotein complex. At higher temperatures the speed of carotenoprotein extraction increased and EDTA was not required. Cano-Lopez et al. (52) reported the use of cod trypsin at 4°C under identical conditions; the recovery of protein and astaxanthin increased to 81% and 64% of shrimp waste respectively. The study also indicated that only purified Atlantic cod trypsin was a more

effective extraction aid than bovine trypsin for recovering carotenoprotein. However, the purified enzyme is too expensive. Haard and Simpson (53) reported the use of antioxidant in extraction media to stop oxidative activity and to retain the bright red orange color of carotenoprotein. Protein associated with astaxanthin is more resistant to oxidation and it is deposited in rainbow trout skin and flesh more efficiently than free pigment.

Chakrabarti (11) reported that trypsin showed maximum recovery (55%) of carotenoid pigment in 4 hours at 28±2°C from brown shrimp shell waste, but pepsin and papain showed about 50% recovery of the pigment during the same period. The yield and composition of carotenoprotein cake and protein paste are shown in Table 12.8. Though trypsin recovered the maximum amount of protein, the percentage of protein recovery by papain and pepsin was close to that of trypsin. The process is outlined in Figure 12.5. During the storage of the products at tropical ambient temperatures, Chakrabarti (11) reported the loss of carotenoid pigment from carotenoprotein cake with different enzymes was in the order of pepsin > papain > trypsin. He also mentioned that papain could be used for moderate recovery of stable carotenoprotein and good quality protein concentrate at lower cost from shrimp shell waste prior to its conversion to chitin or chitosan. The vacuum dried soluble protein paste, which contains good flavorants and concentrated protein (44–56%) can be used as an ingredient in food, feed, and beverage preparation.

An enzymatic method was developed to recover the carotenoid along with the protein from crab waste by Manu-Tawiah and Haard (54) using proteolytic enzyme. Wang and Chio (1998) reported the use of microbial proteases from *Pseudomonas aeruginosa* for protein removal, yielding up to 55% from crab shell powder during fermentation for a period of 7 days.

12.3.9 Production of Seafood Flavorings

Seafood flavor can be used as an additive in surimi based products such as crab analog and shrimp analog, and cereal based extrusion products. Seafood flavor can be extracted from shell and other raw materials by enzymatic reaction. The taste and volatile components of shrimp heads were recovered by enzymatic digestion using corolase N and Koji, or bacterial strain with high proteolysis rates followed by spray drying (53). The product contained 9–12% amino acids, mainly taurine, arginine, glycine, proline, and IMP.

In many fish processing procedures, the fish is boiled in brine or plain water. The water is drained and used as a food because it contains fishy flavor and some soluble nutrients. In Vietnam, a shrimp extract is prepared from dried shrimp heads and shells. The shrimp waste is boiled in water for several hours. Sugar is added and the liquid is concentrated to a thick syrup, producing a condiment. Similar condiment products are produced

in Hong Kong from dried oysters, in Indonesia from anchovies, and in the Minicoy islands of India from tuna (14).

12.3.10 Pearl Paste

Artificial pearls are made by coating glass beads with guanine crystal in lacquer. Pearl paste, a suspension of guanine crystals, is prepared from fish scales; preferably from various carps, herring, and other variety species of silvery fish. Scales are collected and preserved by storing in weak brine, but they must not be dried. The crude guanine crystals are removed by mechanical scrubbing and centrifuging. The crude guanine, which contains extraneous proteins, is treated with pepsin to digest the proteins. This process takes between 40–50 hours. The guanine is then washed in water, pressed, and freed from the oil by solvent extraction. The refined guanine is mixed with lacquer or organic solvent and sealed in glass containers (35).

12.3.11 Products from Liver Waste

Evisceration of fish either on board or at landing centers is the essential step for fish preservation and processing into various products. Liver is an important organ in the discarded viscera or waste in fish processing industries. The major components of fish liver are proteins, lipids, glycogen, carotenoids, vitamins, and minerals. Cod liver and shark liver are

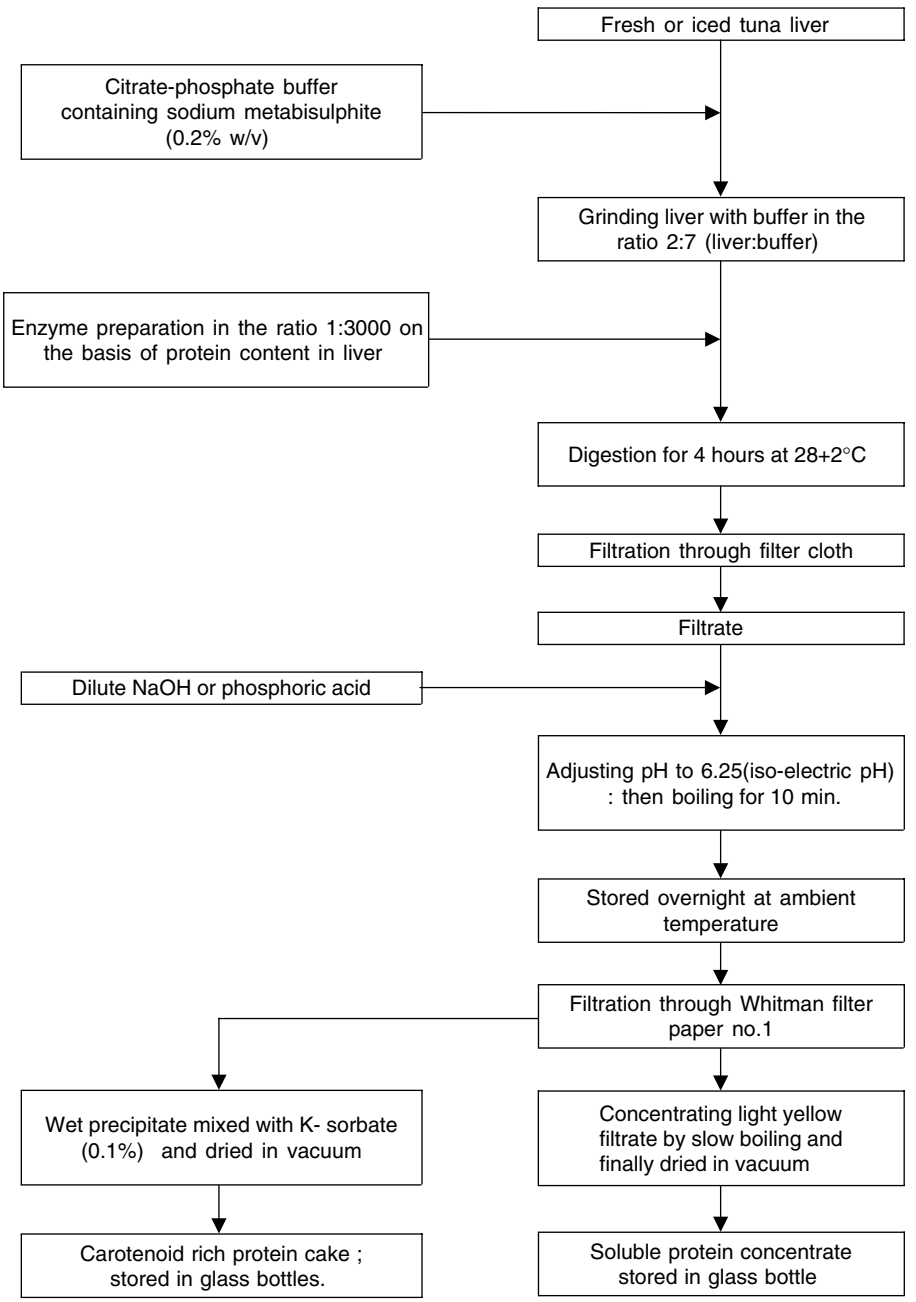

Figure 12.6 Flow diagram of processing of tuna liver to valuable products (Based on Chakrabarti, personal communication, 2002).

Table 12.9

widely used as a source of Vitamin A. However, the livers of other commercially important fish are either discarded with viscera or used as manure. Thankappan (43) reported tuna is abundantly available (24000 tons) in Indian Exclusive Economic Zone. Substantial quantities of tuna are canned and a portion is processed as masmin, a dark colored smoked product. CIFT (55) reported the use of tuna liver separated from tuna processing units waste in the preparation of carotenoid rich protein cake and soluble protein concentrate. Generally, the weight of liver in tuna is 1.1–2.0% of total body weight. Composition of raw tuna liver (*Enthynnus affinis*) is given in Table 12.9. The percentage of protein recovery from tuna liver by pepsin, trypsin, and papain was 91.0, 91.8 and 88.6% respectively, at the end of 4 hours at 28 ± 2°C. Carotenoids, which also include vitamin A and its isomers, can be recovered at 66 to 70% in 4 hours from tuna liver using the mentioned enzymes. The process is outlined in Figure 12.6 (R. Chakrabarti, personal communication, 2002). The vacuum dried carotenoid rich protein cake (62–70% protein; 108–152 ppm carotenoids) can be used as an ingredient in food and feed preparation. Soluble protein concentrate (63–71% protein; 4.3–5.6% ∝-amino nitrogen) can be used as an ingredient in the media preparation of sulphite reducing anaerobes such as *Clostridium* species. (56).

3.13

Cold Active Enzymes in Food Processing

Rajni Hatti-Kaul, Hákon Örn Birgisson, and Bo Mattiasson

CONTENTS

13.1 INTRODUCTION

Foods have been processed since ancient times using extracts of vegetables or microorganisms rich in enzymes. However, it was only in the nineteenth century that the various biological conversions that occurred during processing were ascribed to the action of enzymes, when isolation from malt of an enzyme complex "diastase" that converts gelatinized starch into sugars was reported. Soon afterward, the digestive enzyme pepsin was isolated from the calf stomach. The first major breakthrough for microbial enzymes in food industry occurred in the early 1960s with the launch of glucoamylase that allowed complete conversion of starch to glucose (1,2). The enzymatic methods have now become an important and indispensable part of the food industry (3). The specificity of their action and ability to function under mild conditions are the main advantages of using enzymes. The later part of the twentieth century has seen tremendous increases in enzyme production capacity of microorganisms as a result of advances in gene technology, and enzymatic processing has been extended to several novel applications (1). Of the estimated worldwide sales of $1.8 billion of the industrial enzymes in 2002, over 45% was accounted for by consumption in the food and feed industry, the main consumers being starch and dairy industries, while baking, brewing, fruit juice, animal feed, flavors, fats, oils, and protein hydrolysis, accounted for most of the rest (4).

The success of several processes, especially in the starch industry, has been due to the availability of enzymes with good activity and stability at high temperatures. In some cases, the operational stability of the enzymes was improved by means of immobilization, an important example being glucose isomerase. The enzymes from thermophilic and hyperthermophilic microorganisms that are naturally thermostable by way of adaptation to the high temperature environments was another focus (5). With the discovery of new enzymes, the temperature limits of the enzyme activity and stability reached unbelievable extremes. Protein engineering has also been used with a primary goal of increasing thermostability of the biomolecules.

In contrast to this, the interest in "cold activity" of enzymes is relatively recent, and has been promoted as a result of intense research activity on cold adapted organisms isolated from low temperature environments. One such attempt has been a rather large project sponsored by the EU Fourth Framework research program during the 1990s to examine enzymes from microorganisms isolated in Antarctica, both with respect to fundamental studies on cold adaptation and biotechnological applications. Simultaneously, laboratory evolution techniques have provided an alternative and powerful strategy to modify existing enzymes to function at lower temperatures. A number of reviews on cold active enzymes and mechanisms enabling low temperature activity have appeared in recent years (6–17). The applications of enzymes for low temperature processing may provide various benefits. These include:

lower energy requirements
protection of substrates or products from degradation
minimization of side reactions
prevention of the destruction of other substances associated with raw material
reduced risk of microbial spoilage
inactivation of the enzyme after completion of the process by a mild increase in temperature

13.2 COLD ADAPTED ORGANISMS AS A SOURCE OF COLD ACTIVE ENZYMES

The traditional means of obtaining cold active enzymes has been through screening of naturally occurring cold adapted prokaryotic and eukaryotic organisms for enzymatic activities of interest (18,19). Considering that a major part of Earth, including the vast extent of permanently cold environments such as the Antarctic, Arctic, and mountain regions, as well as the deep sea waters covering three quarters of the planet surface, is exposed to low temperatures (i.e., below 5°C) for a large part of the year, organisms inhabiting such environments should represent a significant portion of the living world (13,20). Some amazing examples of locations where microbial life has been found include super cooled cloud droplets in high altitude, and below 3500 meters of ice in the Antarctic subglacial Lake Vostok (21,22).

Most microorganisms that inhabit permanently cold environments are either psychrotolerant (also called as psychrotrophic) or psychrophilic. Psychrotolerant organisms grow well at temperatures close to the freezing point of water, but have optimal growth rates above 20°C while psychrophiles grow fastest at temperature of 15°C or lower but are unable to grow above 20°C. Metabolic fluxes displayed by such organisms are more or less comparable to those exhibited by mesophiles. A major challenge for such organisms is to counteract the reduction in chemical reactions due to low temperatures, and the best strategy to maintain sustainable activity under such conditions is to produce cold adapted proteins. Enzymes with up to tenfold higher specific activity are synthesized by psychrophiles to compensate for the low reaction rates. The specific activity is, however, generally lower than that of the mesophilic enzymes at 37°C. Furthermore, the temperature for apparent maximal activity is shifted toward the low temperatures, reflecting the weak stability of these proteins that are prone to unfolding and inactivation at moderate temperatures (17,23).

Besides cold habitats, other interesting sources of cold active enzymes include many fish, squids, and other aquatic creatures, which are adapted to environments that are permanently cold (24). For example, Greenland cod remains biologically active at about 0°C throughout the year living in sub-Arctic latitudes. Digestive enzymes from cold adapted fish possess unique activity and stability features for use as food processing aids at relatively low temperatures (25,26), and because they are obtained from edible animal tissue they have an advantage over microbial enzymes in that no toxicological testing of the raw material is needed to demonstrate their safety (24). A number of laboratories are developing commercial processes for isolating enzymes from fish processing offal. One company, KS Biotec-Mackzymal in Tromsö, Norway, produces such enzymes for use in food processing and other areas (27).

13.3 BASIS OF COLD ACTIVITY

Significant advances have been made during recent years in the study of proteins and enzymes from cold adapted species that have helped in providing insights into their molecular and functional adaptations to low temperature. This has been facilitated by the availability of recombinant enzymes for analysis by x-ray and biophysical techniques, and comparison with mesophilic and thermophilic homologues.

13.3.1 Kinetic and Thermodynamic Adaptations

In order for the cold active enzymes to maintain reaction rates at low temperature that are comparable to mesophilic enzymes at mesophilic temperatures, the loss of kinetic energy

at low temperatures needs to be overcome. As revealed by the kinetic data available for the various enzymes from Antarctic or Arctic fish and by exoenzymes from Antarctic microorganisms, optimization of catalytic efficiency (k_{cat} /K_m) is the main physiological adaptation for the enzymes to be active at low temperatures (6,28). In the presence of high substrate concentration, optimization of k_{cat} should be the most relevant parameter, which is true for microbial extracellular enzymes (29–31). On the other hand, enzymes from marine or freshwater organisms secreted in a substrate poor medium should have highly optimized K_m values (6,32). Some enzymes can also improve both k_{cat} and K_m parameters as a way of adaptation (28).

In thermodynamic terms, the basis of increasing the reaction rate at a given temperature corresponds to reduction in activation free energy, ΔG, which has indeed been shown to be the case for enzymes from cold adapted species (33). The contribution of enthalpic and entropic energies to ΔG may further reflect adaptations to the low temperature environment in which these enzymes function ($\Delta G = \Delta H - T\Delta S$). The decrease in activation enthalpy (ΔH) seems to be the main adaptive feature of all cold enzymes studied so far, which reduces the dependence of k_{cat} on temperature and the inhibitory effect of low temperatures on enzyme reaction rates (according to Arrhenius' law) (17,34,35). Decrease in the number of enthalpy driven interactions also contributes to increased flexibility of the active site (17). The active site flexibility affects the substrate binding ability, providing a broader distribution of the ground state enzyme–substrate complex (ES), leading to increased entropy of this state as compared to the mesophilic enzymes (9,35). This feature of the cold enzymes requires lower activation energy for transforming the ground state ES complex to the activated form; i.e., k_{cat} will be increased at the expense of K_m. This is true for the cold adapted enzymes displaying the same substrate-binding site and active site makeup as the mesophilic enzymes (36). Greenland cod trypsin and psychrophilic α-amylase and subtilisin seem to make use of this strategy (6).

However, some enzymes seem to have undergone amino acid substitutions within the active site to maintain or improve the substrate binding affinity to meet their physiological requirements. The chitobiase from Antarctic bacteria was shown to display 8 times higher k_{cat} value, and its K_m for the substrate is 25 times lower than that of the mesophilic enzyme at 5°C, resulting in a nearly 200 times higher k_{cat}/K_m (28). The two tryptophan residues in the active site that serve as the substrate binding ligands in the mesophilic enzyme are replaced in the psychrophilic enzyme by polar residues that are able to perform stronger interactions as the temperature decreases.

13.3.2 Flexibility Versus Stability

Higher structural flexibility has been assumed to be a prerequisite for catalytic activity of the enzymes from cold adapted organisms at low temperatures (6,8). In a normal mesophilic enzyme, the molecular motions become restricted at lower temperatures, which interferes with catalysis. Higher flexibility in cold enzymes would overcome this restriction, but would lead to poor thermostability (37). The low stability has been demonstrated by a significant decrease in optimum temperature of activity and a higher susceptibility to unfolding at moderate temperatures (6,38). The difference between conformational stability of psychrophilic and mesophilic α-amylases has been estimated to be of the order of 30 kJ mol^{-1}. The balance between flexibility and stability represents one of the most crucial points in the adaptation of a protein to environmental temperature. However, the homologous enzymes from different temperature environments have nearly identical conformational plasticity under their respective optimal temperature working conditions (39).

13.3.3 Active Site of Cold Active Enzymes

The data available from increasing number of three dimensional structures of cold adapted bacterial and fish enzymes solved during past years (40–48) reveals that the cold adapted enzymes do not display any unusual structure, so that only minor structural modifications may be necessary to adapt a mesophilic or thermophilic homologue to cold. For example, the α-amylase from the Antarctic bacterium shares more than 40% identity with its mesophilic analogue from pig pancreas (49). All the active site residues involved in the reaction mechanisms are strictly conserved, suggesting that the fundamental reaction pathway is not modified among homologous enzymes adapted to different temperatures and that the molecular basis of adaptation lies elsewhere in the molecule. The structural changes necessary for cold adaptation often involve changes in the overall conformational properties and dynamics of the molecule (11,50).

The greater catalytic efficiency of cold active enzymes has been explained by better accessibility of the active site to the substrate, which may be achieved by one or more differences like small deletions in loops bordering the active site or replacement of bulky side chains for smaller groups at the entrance. (17,47). This may lead to the accommodation of substrates at lower energy costs, and hence reduce the activation energy required for the formation of the enzyme–substrate complex. Further, a relatively broad specificity and lower binding constants for the cold adapted enzymes may result, as shown in case of elastase from Atlantic salmon in contrast to mammalian elastases (12). Easier release of the product may also be facilitated from a larger active site. Cold adapted enzymes have further been shown to exhibit improved electrostatic potentials near the active site region when compared with their mesophilic or thermophilic counterparts, which would facilitate interaction with oppositely charged substrates (12,43,46,47,51–53).

13.3.4 Structural Adaptations

There is no consensus for a common paradigm of structural changes that confer cold activity. Structural models of cold active enzymes have been quite useful in revealing the specific strategies used in each enzyme, consisting of a set of structural adjustments to adapt to cold (6,17,52,54). These involve a decrease in proline residues in loops, arginine content, salt bridges, ion pairs, H-bonds and aromatic interactions, ion binding constants and hydrophobic interactions, changes in α-helix dipole interactions, increased clustering of glycine residues, and insertions (e.g., leading to extra surface charges) or deletions (resulting in weaker subunit interactions) of loops (47,48,52). The binding of stabilizing ions like calcium can be significantly weaker than in mesophiles. The compactness of the protein interior is often lowered due to smaller size and relative hydrophobicity of nonpolar residue clusters forming the protein core. Calculation of the solvent accessible area showed that some psychrophilic enzymes expose a higher proportion of nonpolar residues to the surrounding medium. This leads to increased destabilization, due to the reorganization of water molecules around the hydrophobic side chains (42,46,48). An excess of negative charges on the surface of the molecules, and more acidic isoelectric points, frequently noted in cold active enzymes as compared to that of mespophilic or thermophilic homologues, has been related to the improved interactions with the solvent, which could be of prime importance in rendering flexibility near zero degrees (55). Only a few of these structural alterations are used to acquire the required flexibility, but they do lead to a lowered stability of the protein molecule.

13.3.5 Mutational Analysis of Cold Activity

Comparison of crystal structures of extremophilic enzymes indicate a clear increase in the number and strength of all known weak interactions and structural factors involved in

protein stability from psychrophiles to mesophiles and thermophiles. Very slight variations by site directed mutagenesis in a psychrophilic sequence can establish or mask the psychrophilic character of mutants that may affect the active site flexibility through changes in various conformational constraints (56). Site directed mutagenesis experiments on *Alteromonas haloplanktis* amylase to produce additional weak interactions found in its mesophilic homologue from pig pancreas, and analysis of the mutants, revealed that single mutations were not sufficient to modify the stability and catalytic parameters of the cold adapted enzyme drastically enough to obtain a true mesophilic α-amylase (50). However, accumulation of these mutations transformed the psychrophilic α-amylase into a true mesophilic enzyme. Even if the reaction pathway of the α-amylase has not been modified, the ability of the active site residues to perform catalysis has been altered, probably by modulating the plasticity of the whole catalytic cleft. Based on these studies, it has also been proposed that the lower temperature dependence of the activity in cold active enzymes arises from fewer interactions that need to be broken during the catalytic cycle, which is also responsible for a heat labile activity and higher entropic contribution (9).

Recent experimental results have indicated that relationships between stability, specific activity and flexibility is much more complex than expected. It seems that some elements of the protein structure control protein stability, while other regions are important in conferring flexibility, giving rise to an optimal catalytic efficiency at the environmental temperature. It is therefore probable that both a high specific activity and a good stability can be conferred to a cold adapted enzyme. This has even been supported by site directed mutagenesis experiments, where stabilities of enzymes were improved while the original catalytic properties were retained (30,57). This would support the hypothesis that organisms growing in stable cold environments would not encounter selective pressure to maintain enzyme stability at higher temperatures. So, although many cold active enzymes are thermolabile, this feature is not necessarily a prerequisite for the structural changes resulting in cold adaptation of the enzymes, but may simply be due to the lack of selective pressure (11,58,59).

13.4 DIRECTED EVOLUTION AS A TOOL FOR CREATION OF COLD ACTIVE ENZYMES

In contrast to selecting enzymes from a natural diversity of cold adapted organisms, laboratory evolution has contributed significantly toward modifying enzyme properties and functions. This evolution involves introduction of random mutations in a gene and screening the resulting library for the acquisition and improvement of a specific property. Cold adapted forms have been created from mesophilic enzymes by artificial evolution. A mesophilic subtilisin-like protease was converted into a cold active enzyme; only 4 amino acid substitutions were needed to obtain a mutant enzyme with a catalytic efficiency 9.6 times greater than that of its parent at 10°C (60). Even the catalytic activity of thermostable enzymes from hyperthermophilic organisms has been improved at low temperature by DNA shuffling and directed evolution (61,62). In contrast to the natural evolution, where selection takes place guided by the survival requirement and the protein properties are evolved to fit the existing environment, the selection conditions in the laboratory evolution are more defined. Mutated enzymes with high activity and stability can be selected from all combinations of activity and stability. Random mutagenesis thus proves that the fundamental characteristics of activity and stability are independent and not physically linked in proteins. However, mutations that simultaneously increase activity and stability are very rare and have proved to be extremely complex to obtain.

Evolutionary engineering based on the Darwinian sequential program of mutagenesis and selection has been used to produce cold active proteases with no change in thermal stability (63–66). The procedure consists of random mutagenesis for obtaining proteases with enhanced activities at low temperature, via multistep mutations with a combination of primary mutation causing activity loss and secondary mutation causing recovery of activity. Miyazaki et al. (58) combined random mutagenesis, saturation mutagenesis, and DNA shuffling to obtain variants of a psychrophilic subtilisin S41 with improved stability, that maintained the wild-type activity at 25°C.

13.5 COLD ACTIVE ENZYMES OF INTEREST FOR FOOD PROCESSING

Much of the efforts in research on cold active enzymes have so far gone into understanding the factors underlying cold activity. Hence, the use of cold active enzymes is not yet widespread in food processing or other applications. The exceptions are the digestive enzymes isolated from fish. The breakthrough for cold active enzymes in food processing relies on the applications involving heat sensitive foods and where residual enzyme activity is not desired due to potential changes in the product. Proteases and glycosidases are the main groups of enzymes with diverse applications, and several cold adapted candidates have been studied, some of which are described here.

13.5.1 Proteases

Enzymatic modification using proteases is often an attractive means of obtaining better functional and nutritional properties of food proteins, and for making a variety of new and valuable products (1,25,67). Table 13.1 lists many of the important applications of proteases in food processing, where low temperatures are preferred. Various proteases are widely used for manufacturing protein hydrolysates and extracts with improved functional properties from cheap vegetable, meat, and fish byproducts.

The fish industry uses proteases as gentle processing aids in a number of operations to yield products of high quality, and these proteases have in many cases replaced the alternative mechanical, chemical, or manual treatment procedures (Table 13.1) (24,68). For example, caviar produced using proteases has the advantages of better recovery, less damage to the eggs, cleanliness of products with no residues, less required labor, and good hygienic conditions compared to caviar produced mechanically. The enzymes used are the digestive enzymes isolated from fish, and the processing is invariably done at low temperatures. Experiments at Icelandic Fisheries Laboratories indicated that the scales from haddock could be removed without affecting the skin or flesh after incubating the fish with a protease at 0°C, followed by spraying with water (70).

In the dairy industry, rennets are used for coagulation during cheese production, while other proteases are used for accelerating cheese ripening, for modifying functional properties of some dairy products, and for modifying milk proteins to reduce the allergenic properties of cow milk products. Milk oxidation is an undesirable phenomenon in the dairy industry, and treatment of milk with trypsin improves its stability to oxidative rancidity, presumably through improved copper binding by the enzyme modified protein (73). Furthermore, enzymatic hydrolysis of milk proteins results in products with functionally important properties (Table 13.1). Specific bioactive peptides have been reported to have various positive effects on the human body, such as reduction of blood pressure, inhibiting effects on blood clotting, antibacterial effects, inducing effects on the immune system, and even reducing the craving for fat food (71,72,74,75).

Table 13.1
Food processing operations suitable for cold active proteases

Foods	Application	Ref.
Fish	Production of fish protein hydrolysates used to fortify the nutritional value of cereal-based foods, as dietetic and hypoallergenic agents, and as basic ingredient in milk substitutes for young animals	(24,68–70)
	Removal of skin from fish and squids that are difficult to de-skin by mechanical or manual means	
	Removal of scales without affecting the skin or flesh, e.g., from haddock	
	Removal of surface bacteria and extending the shelf life of stored fish	
	Removal of membranes and organs from seafood products	
	Production of caviar	
	Extraction of carotenoprotein pigment from shellfish processing discards for use as feed supplement in rations of farmed fish or as a colorant and flavorant for use in food products	
	Accelerating ripening of fermented products such as "maatjes" and fish silage	
Meats	Production of blood cell hydrolysates	(1)
	Production of meat extracts	
	Meat tenderization	
	Cleaning of bones	
	Upgrading of fresh bones to produce gelatin and meat protein hydrolysates	
Milk	Cheese production	(1,71,72)
	Hydrolysis of milk and whey proteins to produce non- and low allergenic cow milk products for baby foods as substitutes for mothers' milk	
	Production of various physiologically functional peptides such as opioid peptides, immunostimulating peptides and angiotensin I-converting enzyme (that play an important role in blood pressure regulation) inhibitors	
	Treatment of milk to protect against oxidative rancidity	
	Production of whey protein hydrolysates	
Vegetables	Limited hydrolysis of soy protein isolates to produce functional protein hydrolysates with better foam-expansion and –stability, good whipping properties, and potential use as egg white substitutes	(1)

Prevention of cloudiness or haze formation in beer during chilling that occurs as a result of the formation of complexes of peptides with polyphenolic compounds is among other interesting applications of proteases (1).

Most of the cold active proteases known so far originate from fish sources, while some enzymes developed by mutagenesis have also been obtained.

13.5.1.1 Cold Active Proteases from Fish

The digestive proteolytic enzymes can be recovered as byproducts from fish processing wastes. The cold active proteolytic enzymes like pepsin, trypsin, chymotrypsin, and elastase, have been isolated from the stomach of cold water species such as Atlantic cod (*Gadus morhua*), Polar cod (*Boreogadus saida*), Greenland cod (*Gadus ogac*), and Arctic fish, capelin. These enzymes invariably have a relatively lower optimum temperature of activity, higher catalytic efficiency, and much lower stability than their mammalian counterparts. Table 13.2 provides a comparison of the kinetic parameters of some of the cold adapted proteases with their homeothermic homologues. Pepsins isolated from the stomach of the fish species mentioned exhibit temperature optima of activity around 37–40°C and high instability above 40°C (27). Intestinal elastase isolated from Atlantic cod was shown to possess an optimal temperature of 40°C and about 3.5-fold higher k_{cat} and nearly fivefold higher catalytic efficiency than porcine elastase (79). Cod chymotrypsin also displayed higher activity at 3–15°C than the bovine enzyme (78). Trypsins from Antarctic fish (76), Greenland cod (77,80), Atlantic cod (81), and Atlantic salmon (82) are all shown to be catalytically efficient at all temperatures studied, but also in general much less stable at high temperatures, compared to other mammalian counterparts.

X-ray structures of Atlantic salmon trypsin and elastase and cod pepsin have been reported (40,44,45). Investigations on trypsins showed that the enhanced catalytic efficiency is mostly a result of lower K_m, indicating a better substrate affinity, which results in a 4- to 35-fold higher efficiency for the cold adapted fish trypsins (83). The increased substrate affinity is probably due to a lower electrostatic potential in the binding pocket and from the lack of five hydrogen bonds adjacent to the catalytic triad (52). Trypsins from fish and other species of marine origin are generally unstable at low pH values and stable under alkaline conditions, hence differing from mammalian proteases. The most notable difference in the cold trypsins with respect to their warm counterparts is a reduced hydrophobicity of internal residues accomplished by an apparently systematic substitution of smaller and less hydrophobic residues. In particular, a reduced number of isoleucines and a correspondingly increased number of valines is notable, which results in a less densely packed core and an increased rotational and vibrational freedom of the internal groups. The number of both charged and other polar amino acids is significantly higher in the cold trypsins. A difference in flexibility of a few loops, a higher number of methionine residues, and fewer interdomain hydrogen bonds and stabilizing interactions in helices are also observed (52). All these changes contribute to the low thermal stability of the cold trypsins; however, these substitutions do not fully explain the increased catalytic efficiency (83).

Cold active cod proteases are commercially available and are being applied in a number of processes. Preparation of fermented squid with supplements of Greenland cod trypsin has been found to be better than conventional process because of the higher molecular activity at low temperatures (4°C) during the early stages of fermentation. Cod trypsin was also more effective for the extraction of carotenoprotein than bovine trypsin at 4°C. Trypsin from cold adapted fish has an advantage in the treatment of milk for preventing oxidative rancidity, because thermal instability of the enzyme would avoid subsequent hydrolysis of milk proteins (25). Cod pepsins have been used as rennet substitutes in cheese production, in skin removal from fish, and as a digestive aid in fish feed (84). Pepsins from Atlantic cod (*Gadus morhua*) and orange roughly (*Hoplostecthus atlanticus*) have been used for caviar production from the roe of the same species in New Zealand (24,85).

Table 13.2
Kinetic parameters of some proteases from cold adapted fish as compared to the homeothermic homologues

Protease	Source	Substrate	Temp (°C)	K_m	k_{cat}	k_{cat}/K_m	Ref.
Trypsin	Antarctic fish (*Paranotothenia magellanica*)	N-benzoyl-L-arginine-p-nitroanilide	5	121 μM	29 min^{-1}	0.24 $min^{-1}.\mu M^{-1}$	(76)
			25	25	125	0.6	
	Bovine		5	170	5.4	0.03	
			25	2445	109	0.04	
	Greenland cod (*Gadus ogac*)	p-tosyl-L-arginine-methyl ester	5	0.14 mM	5.2 U/μM	37 $min^{-1}.\mu M^{-1}$	(77)
			25	0.15	14.7	98	
	Bovine		5	0.05	1.7	35	
			25	0.05	9.1	182	
Chymotrypsin	Atlantic cod (*Gadus morhua*) (isoenzyme A)	N-benzoyl-L-tyrosine ethyl ester	10	0.12 mM	117 s^{-1}	975 $s^{-1}.mM^{-1}$	(78)

			25	0.7	16	22	

13.5.1.2 Proteases Made Cold Active by Mutagenesis

Mucor rennin, often used as a substitute for calf chymosin, possesses a high thermostability that causes survival of the enzyme activity after the curd is cooked, and thus may cause bad flavor in cheese during long maturating periods. Mutagenesis of the fungus *Mucor pusillus* was done to produce a mutant enzyme with decreased thermostability, which is desirable for the enzyme as a milk coagulant for cheese manufacturing (86). The marked decrease in thermostability was attributed to the mutation of Gly186 to Asp. Mutations involving exchange of Gly186 with various amino acids by site directed mutagenesis led to a decreased thermostability, indicating involvement of the residue to maintain conformation of the enzyme. Further, a double mutant, involving changes to Ala101Thr and Gly186Asp showed the lowest thermostability without decrease in enzymatic activity, as well as the best relative ratio of clotting to proteolytic activity.

Taguchi et al. (65,66) have used evolutionary engineering to double the activity of a cold active proteinase at 10°C by using sequential random mutagenesis and a screening program. A temperature dependent increase in the k_{cat} value was observed for the mutant enzyme.

13.5.2 Glycosidases

Although the starch industry accounts for a significant part of the applications requiring heat stable glycosidases (glycoside hydrolases), various other processes are potential targets for cold active enzymes.

The hydrolysis of lactose in milk and whey using β-galactosidase is a well known process to obtain better quality dairy products and ones that are more easily digested by lactose intolerant individuals. Another emerging application of the enzyme in the food industry is the production of galactooligosaccharides for use as prebiotics. β-galactosidase preparations such as Lactozyme from Novozymes (Bagsvaerd, Danmark) are commercially available. The use of a cold active enzyme would allow the treatment of milk in a refrigerated state.

Pectinases are now an integral part of fruit juice industries, being used to facilitate juice extraction and clarification. They can be used in combination with cellulases, hemicellulases, and amylases. In 1998, pectic enzymes alone accounted for about one quarter of the world's food enzyme production (87). Apple, orange, pear, grape, strawberry, raspberry, blackberry, lemon, mango, apricot, guava, papaya, pineapple, and banana are some examples of fruit juices that have been treated with pectinases (88). The enzyme treatment not only improves overall yields, but also reduces processing costs (87). For maceration of plant tissue during preparation of pulpy juices and nectars, baby foods, and ingredients for yogurts and puddings, enzymatic degradation of pectin after a mild mechanical treatment often improves product properties (88). Acidic pectic enzymes used in the fruit juice industry often come from fungal sources, especially *Aspergillus niger*. Some of the commercial enzyme preparations available are Pectinex from Novozymes (Bagsvaerd, Danmark) and Gammapect from Gamma Chemie (Darmstadt, Germany).

In bread making, the concentrations of starch, hemicelluloses, and gluten are very important for the quality of baking products. Amylases, along with xylanases and proteases, have therefore been applied in baking processes (1,89). These enzymes can be used to reduce the dough fermentation time and to improve the properties of dough and crumb, and can aid in the retention of aromas and levels of moisture. A clear advantage of cold active enzymes here is the ease of inactivating the enzymes by heat, so that the enzymatic activity can be controlled better and a prolonged action of the enzymes prevented, which otherwise can result in the crumb becoming too soft or too sticky (8,90). Fungal α-amylase

is used, as it is less heat stable. Apart from the higher loaf volume, the enzyme treatment results in a softer crumb.

Glycosidases with antimicrobial activity have a clear potential for prolonging the shelf life of foods stored in cold or ambient temperatures. For example, lysozyme has been used as a food preservative in food products such as cheese and sausages because of its antibacterial activity (91).

Several glycosidases from cold adapted microorganisms have been isolated and characterized, and some even crystallized. Cold adapted features of a few glycosidases are listed in Table 13.3, where they are compared with other mesophilic and thermophilic counterparts. Optisize® Amylase and IndiAge® Super cellulase produced by Genencor are claimed to be active at low temperatures; however their source is not revealed (95).

13.5.2.1 Cold Active β-galactosidases

Several cold adapted organisms including *Arthrobacter* species (96–100), *Bacillus subtilis* (101), *Carnobacterium piscicola* (102), *Planococcus* sp. (103), and *Pseudoalteromonas haloplanktis* (34) with β-galactosidase activities have been reported.

Detailed characterization of the β-galactosidase from *P. haloplanktis* isolated from Antarctica has revealed significant similarities with the mesophilic enzyme from *Escherichia coli*, including the multimeric form and subunit mass, active site residues involved in catalysis, and strict requirement for divalent metal ions (34). However, the turnover (K_{cat}) of the enzyme toward its substrate is significantly higher than that of the *E. coli* enzyme in the temperature range of 0–40°C. As a result of increased k_{cat} and decreased K_m for its substrate lactose, the specificity constant k_{cat}/K_m at 25°C is increased 90-fold. The enzyme also exhibits a 10°C lower optimum temperature of activity and a weaker thermal stability as compared to the *E. coli* β-galactosidase. Increased flexibility of the cold-active β-galactosidase has been attributed to insertions of certain residues, lower Arg and Pro content, and stacking of Gly around the catalytic residues of the enzyme. A study on treatment of milk at 4°C with *P. haloplanktis* β-galactosidase led to 33% lactose hydrolysis after 50 min whereas only 12% lactose was hydrolysed under similar conditions by *Kluyveromyces lactis* enzyme (34). Application of the enzyme in an immobilized form has also been investigated (104).

The *Arthrobacter* isolates have been found to have two or more β-galactosidase isoenzymes (100,105,106). An isoenzyme of psychrotolerant *Arthrobacter* sp. C2-2 was shown to exhibit characteristics rather similar to that of the *P. haloplanktis* enzyme. It retained 20% of maximal activity at 10°C, and was further seen to catalyse not only lactose hydrolysis but also transglycosylation to produce galactooligosaccharides, predominantly trisaccharides. One of the isoenzymes of *Arthrobacter psychrolactophilus* β-galactosidase has a subunit mol wt of 71 kDa in contrast to 116 kDa typically encoded by *lac*Z family, and the gene encoding the enzyme differs from other members of the *lac*Z family but has regions similar to β-galactosidase isoenzymes from *Bacillus stearothermophilus* and *B. circulans*. It does not have a role in lactose utilization.

Carnobacterium piscicola β-galactosidase was shown to exhibit 49% amino acid identity with β-galactosidase from the thermophilic *B. stearothermophilus* but with an optimum temperature of activity at 30°C, while the *Planococcus* enzyme was most closely related to an enzyme from *B. circulans* (103). The latter enzyme is also a dimer with a mol wt of 155 kDa, no metal requirements, an optimum pH of 6.5 and optimum temperature of 42°C. It is active at NaCl or KCl concentrations up to 4 *M*. The enzyme is stable during storage at 5°C for several months, and undergoes irreversible inactivation after incubation for 10 min at 55°C.

Table 13.3
Activity and stability parameters of some cold active glycosidases in comparison with their mesophilic and thermophilic counterparts

Glycosidase	Organism	Opt. Temp (°C)	T_m(°C)	K_m	k_{cat}	k_{cat}/K_m	Ref.
β-galactosidase	*P. haloplanktis*	45	48	2.4 mM	33 s^{-1}	13.7 $s^{-1}.mM^{-1}$	(34)
	E. coli	55	56.5	13	2	0.15	
α-Amylase	*Alteromonas haloplanctis*	30	44	1.27 g/l	1363 s^{-1}	1075 $s^{-1}.g^{-1}.l$	(29,92,93)
	Porcine	50	65.6	1.12	326	292	
	Bacillus amyloliquefaciens	85	85.7				
Xylanase	*P. haloplanktis*	35	52.6	28 mg/ml	1247 s^{-1}	44.5 $s^{-1}.mg^{-1}.ml$	(35,94)
	Streptomyces sp. S38	62	63.1				
	Clostridium thermocellum	80	81.4				
Xylanase	*Cryptococcus adeliae*		48	3.8 g/l	46 s^{-1}	12 $s^{-1}.g^{-1}.l$	(6,31)
	Cryptococcus albidus		62	2	21	10.5	

Kinetic parameters determined at 25°C, using as substrates: lactose for β-galactosidase, soluble starch for α-amylase, birchwood xylan for bacterial xylanase and oatspelts xylan for yeast xylanase.

T_m: melting temperature determined by differential scanning calorimetry.

13.5.2.2 Cold Active Pectinases

Reports on pectinases from cold adapted organisms were until recently restricted to psychrotolerant spoilage bacteria such as different strains of *Pseudomonas fluorescens* (107). Endopolygalacturonases from psychrophilic fungi, *Sclerotinia borealis* and *Mucor flavus* have been reported which are active on both polygalacturonic acid and esterified pectin to different extents (108,109). Their molecular mass of ~40 kDa and optimum activity at low pH (pH 3.5–5.5) is similar to those from other fungal sources. Optimum temperature of their activity is around 40–50°C but the enzyme activity and stability is lowered rapidly at temperatures above 50°C. *S. borealis* polygalacturonase exhibited 30% of its optimal activity at 5°C and was very stable at this temperature for over 2 years (108). Recently, cold adapted polygalacturonase producing yeasts, *Cystofilobasidium lari-marini*, *Cystofilobasidium capitatum*, *Cryptococcus macerans* and *Cryptococcus aquaticus* have been reported (110). The enzymes were easily inactivated at 50°C.

Production of pectate lyases by the psychrotolerant bacteria *Chryseomonas liteola* and *P. haloplanktis* has been described (111,112). The latter organism isolated from seawater in Antarctica showed the presence of two pectate lyases, both of which showed maximal activity at 30°C, and 25–35% of activity at 5°C. One of the enzymes was stable at 30°C while the other had a half life of 4 h.

13.5.2.3 Cold Active α-amylase

The α-amylase from psychrophilic *A. haloplanctis* is an enzyme that has been examined in great detail with respect to its structure and thermodynamic properties (36,41,42,50,55,92, 93,113–115). It has the classical three domain structure of the other α-amylases, comprising an $(\alpha/\beta)_8$ barrel in the major domain A, a small β-pleated domain B, and a globular domain C made up of 8 β-strands (41,113). The catalytic triad of two aspartyl and one glutamyl residue, the 24 residues most intimately involved in forming the active site and the aromatic residues at the active site, are strictly conserved in the cold active α-amylase compared with the porcine enzyme (41,42). The amylase is among the most thermolabile enzymes known. The apparent temperature optimum of the psychrophilic enzyme is approximately 30°C lower than the mesophilic porcine enzyme, and at 4°C and 25°C its catalytic efficiency (k_{cat}/K_m) is 6.6 and 3.7 times greater, respectively. Both enzymes require a chloride ion for activity, which, however, is bound with tenfold lower affinity in the cold active enzyme and does not influence its thermostability in contrast to the porcine enzyme (92,114).

13.5.2.4 Cold Active Xylanase

Cold adapted xylanases belonging to families 8 and 10 from Antarctic psychrophilic bacteria *P. haloplanktis* and yeast *Cryptococcus adelia*, respectively, have been investigated (31,35,94). The enzymes exhibit high activity at low temperature, poor stability, and high flexibility, like the other cold adapted biocatalysts. The yeast family 10 xylanase displays lower activation energy and higher catalytic efficiency (threefold) in the range 0–20°C than its mesophilic homologue from *Cryptococcus albidus*, and loses 95% activity within 5 min at 50°C (31,116). The mature glycosylated enzyme secreted by the yeast shares 84% identity with its mesophilic counterpart. Analysis of computerized molecular models indicates that adaptation to cold consists of discrete changes in the tertiary structure. Among the 53 amino acid substitutions, 22 are presumably involved in the adaptation process. These changes lead to a less compact hydrophobic packing, the loss of one salt bridge, the loss of a charge dipole interaction, and to increased solvent interaction due to relative abundance of surface charge (31).

The crystal structure of the *P. haloplanktis* enzyme has recently been solved at 1.3 Å resolution (48). The parameters conferring cold-adapted properties were indicated to be fewer salt bridges, an increased exposure of hydrophobic residues, optimization of electrostatic potential at the active site, and an increased flexibility of the aromatic residues lining the subsites.

13.5.2.5 Cold Active Endoglucanases

Very few reports are available on cold active endoglucanases (cellulases) from cold adapted organisms. Two endoglucanases, CelG and EGD, from a ruminal bacterium *Fibrobacter succinogenes,* were found to have optimum temperature of activity at 25°C and 35°C, and to retain about 70% and 18% of the maximal activity, respectively, at 0°C (117). CelG has a 33-fold higher k_{cat} and a 73-fold higher k_{cat}/K_m value, and exhibits low thermal stability that has been ascribed to the presence of small amino acids around the putative catalytic residues. The presence of a cold active enzyme in a mesophile has been explained as a result of lateral gene transfer from a psychrophile or the origin of the *F. succinogenes* from the marine environment.

It was only very recently that a psychrotolerant *Clostridium* sp., isolated from a cold adapted cattle manure biogas digester, was shown to produce cellulolytic as well as xylanolytic enzymes, having temperature optima of 20°C (118). Also, crystallization of a cold active cellulase from the Antarctic psychrophile *P. haloplanktis* has been reported (119).

13.5.2.6 Cold Active Lysozyme

A cold active lysozyme-like ~11kDa enzyme designated chlamysin has been isolated from viscera of the marine bivalve *Chlamys islandica* that is a marine species located 20 m or deeper in the southern part of an arctic region having sea temperatures rarely exceeding 4°C (120). The protein was highly efficient in hydrolysing *Micrococcus luteus* cells only at low pH (pH 4.5–6.2) and at low temperature (4–35°C). Interestingly, the enzyme was completely stable during storage at room temperature for a month as well as after heating to 70°C for 15 min, suggesting high structural stability.

13.5.3 Lipase

Lipases are mainly used in the treatment of fats and oils for which activity at high temperature is normally desirable due to the solubility characteristics of these materials. Lipases are also used to some extent in cheese ripening. A lipase from an Antarctic psychrophilic bacterium *Psychrobacter immobilis* sp. has been described (121). When compared to the lipase from a mesophilic strain of *Pseudomonas aeruginosa*, it exhibits a limited thermal stability with a half life of 2 min at 60°C. Its apparent temperature optimum for activity is lowered by at least 30°C to around 35°C and its activation energy is reduced by a factor of 2. Several features characteristic of cold adapted enzymes have been revealed in the three dimensional model of the psychrophilic lipase, such as low proportion of arginines as compared to lysines, low proline content, a small hydrophobic core, fewer salt bridges, and aromatic–aromatic interactions.

13.5.4 Catalase

The enzyme catalase is important in the treatment of dairy and liquid egg products for the removal of residual hydrogen peroxide used for low temperature pasteurisation (122). The enzyme's own oxygen-generating capacity is also exploited in its application as a leavening agent for baked goods. So far, one psychrophilic bacterium exhibiting high catalase

activity has been reported (123). The optimum temperature of the enzyme activity is 30°C, which is about 20°C lower than that for bovine catalase activity.

13.5.5 Other Potential Applications

There are other enzymes used in the processing of foods to achieve varying effects, but for which no cold active counterpart has been reported so far. Some examples include transglutaminase, α-L-rhamnosidase and laccase.

Transglutaminase is used to impart unique rheological and functional properties, such as increase in elasticity and firmness, texture improvement, gelation capability, and water holding capacity, by forming cross links between protein molecules (124). A bacterial (*Streptoverticillium* sp.) transglutaminase is widely used in seafood surimi (fish paste) products, meat products (sausage and ham), dairy products, and baked goods, and has potential in the manufacture of yogurt, cheese, and frozen dairy products with improved quality.

Alpha-L-rhamnosidases and laccases are applicable in the processing of fruit juices. The former enzyme degrades the bitter compound naringin in the juice to L-rhamnose and prunin – a compound three times less bitter than naringin (125,126). Alpha-L-rhamnosidases can also be used to dissolve hesperidin crystals, which sometimes form in fruit juices and make the juices cloudy (127). Laccases have antioxidant effects, as they facilitate removal of oxygen, thereby preserving the flavor and color of the juice (128).

13.6 ASPECTS ON PRODUCTION OF COLD ACTIVE ENZYMES

Application of cold active enzymes places demand on their cost effective production. Cloning and expression in *Escherichia coli* has provided sufficient quantities of the enzymes from cold adapted organisms to facilitate structural studies. It has been observed that recombinant psychrophilic enzymes may not be expressed or may be inactivated as a result of the high temperature (37°C) used for their expression (8). Furthermore, their properties seem to be altered as a result of misfolding or the occurrence of an inactivated population (115). It has, however, been possible to express recombinant psychrophilic enzymes in an active form, by growing the mesophilic host at the lowest possible temperature, even though its growth rate is drastically lowered (17). For example, significant amylase activity of recombinant *A. haloplanktis* cold active amylase could be found at growth temperatures for *E. coli* only below 25°C (115). When expressed at a sufficiently low temperature (15–18°C), a recombinant psychrophilic enzyme is indistinguishable from its wild-type parent molecule as regards kinetic parameters, folding properties, and three dimensional structure (42,115).

Some efforts are being made to develop cloning or expression systems in cold adapted bacteria that may circumvent the low stability of the product encountered during heterologous production in mesophilic hosts. Antarctic strains have mainly been tried as expression hosts (129,130). These organisms have been screened for characteristics like optimal temperature and ranges of growth temperature, survival after cryopreservation, natural resistance to antibiotics and transformation efficiency of broad host range plasmids. Some strains were shown to exhibit high gene transfer efficiencies, and induction levels up to 250-fold could be achieved at 4°C and 15°C (129). The cold active *P. haloplanktis* A23 α-amylase was produced and secreted in *P. haloplanktis* TAC 125 (which lacks the endogeneous amylase), using a cold adapted shuttle expression plasmid in which the gene coding for the amylase precursor gene was still subjected to the mesophilic lacZ promoter

transcription regulation (130). For the purposes of producing enzymes for food processing, the choice of an expression host would also be dictated by reasons other than attaining high amounts by overexpression. For example, the GRAS (generally recognized as safe) status of the organism would need to be considered.

Subsequent to their production, strategies for purification of cold active enzymes need to be carefully evaluated because of their sensitive nature. Use of separation techniques allowing rapid and gentle purification are essential to minimize losses (104). Eventually, conditions for storage of the purified enzymes prior to their use would also need to be considered in specific cases.

In conclusion, it may be stated that cold active enzymes, even though having existed as long as the existance of life in cold environments, have been "discovered" relatively recently. Their potential in food processing is yet to be fully exploited. It is very likely that evolution in the laboratory will be used to assist the natural evolution or even gain preference in the design of cold active enzymes with required stability for the applications of interest.

3.14

Biotransformations as Applicable to Food Industries

B. Suresh, T. Ritu and G. A. Ravishankar

CONTENTS

14.1 INTRODUCTION

Biotransformations are chemical reactions used to carry out specific conversion of complex substrates using plant, animal, or microbial cells or purified enzymes as catalysts. This is different from biosynthesis, where complex products are assembled from simple substrates by whole cells, organs or organisms. This is also different from biodegradation, in which complex substances are broken down to simple ones (1). Biotransformation has great potential to generate novel products or to produce known products more efficiently (2).

Biotransformation has the following goals:

1. Specific modifications of substrate structures via selective transformation reactions.

2. Partial degradation of substrates into desirable metabolites by means of controlled cultured cell reactions or reaction pathways.
3. Use of biosynthetic reactions to produce novel compounds

14.1.1 Potential of Microbial Cells and Plant Cells to Carry Out Biotransformation

Plant cell cultures exhibit a vast biochemical potential for the production of specific secondary metabolites. Some cultures may retain the ability to transform exogenous substrates into products of interest. The chemical compounds that can undergo biotransformation mediated by plant enzymes include phenyl propanoids, steroids, alkaloids, coumarins, terpenoids, lignans, and other molecular species. It is not necessary for the compounds to be natural intermediates in plant metabolism; they can be of synthetic origin also.

Plant cell cultures and enzymes have the potential to transform cheap and plentiful substances, such as industrial byproducts, into rare and expensive products. Multistep processes catalyzed by cell or organ culture often generate intermediary metabolites, which help to establish biosynthetic pathways (3).

Biotransformation capabilities of microorganisms and their enzymes for the production of a variety of fine chemicals are well known. Microbial systems are advantageous because biomass doubling time is short and production of biomass can be achieved quickly (4). In addition, methods for genetic manipulation of microbes are well established. Plant systems, on the other hand, produce a more limited range of enzymes, and undifferentiated plant cells have longer doubling times than microbial cells. The desired enzymes also are often produced in minute quantities (4). Despite these drawbacks, the plant kingdom contains some unique enzymes, which produce a variety of chemicals.

14.1.2 Reactions Involved in Biotransformation

Microorganisms employ both constitutive and inducible enzymes to degrade and synthesize great variety of chemical compounds, for not only their viability and reproduction, but also their secondary metabolism. A particular enzyme in a highly complex and well coordinated metabolic pathway catalyzes each reaction. In addition to their usual substrates, many of these enzymes accept other structurally related compounds and thus catalyze unnatural reactions when foreign substrates are added to the medium (Table 14.1). Reaction products, which are not further degraded, can usually be isolated from the fermentation medium.

Table 14.1
Reaction types mediated by microorganisms during biotransformation

Oxidations	Hydroxylation, epoxidation, oxidation of alcohols and aldehydes, oxidative degradation of alkyl, carboxyalkyl or ketoalkyl chains, oxidative removal of substitutes, oxidative deamination.
Reductions	Reduction of organic acids, aldehydes, ketones and hydrogenation of C=C bonds, reduction of hetero functions, dehydroxylation, reductive elimination of substituents
Hydrolysis	Hydrolysis of esters, amines, amides, lactones, ethers, lactams; hydration of C=C bonds and epoxides
Condensation	Dehydration, O- and N-acylation, glycosidation, esterification, lactonization, amination.
Isomerization	Migration of double bonds or oxygen functions, racemization, rearrangements

14.1.3 Advantages of Biotransformation

Biotransformation provides a number of advantages (1) such as:

1. Production of novel compounds.
2. Enhancement in the productivity of a desired compound.
3. Overcoming the problems associated with chemical analysis
4. Studies on biotransformation can lead to basic information to elucidate the biosynthetic pathway.
5. Catalysis can be carried out under mild conditions like ambient temperature and without the need of high pressure and extreme conditions, thus reducing undesired byproduct, energy needs, and cost.
6. Independence of geographical and seasonal variations and various environmental factors.
7. Rapidity of production.

So far, a few reports are available on scaleup of biotransformation. In the food area, the development of a process for making high fructose corn syrup using single step biotransformation, hydrolysis of lactose in milk using β-galactosidase from *Saccharomyces lactis* using a plug flow reactor, and production of L-aspartic acid from fumaric acid by using aspartase enzymes from *E. coli* for the synthesis of aspartame are some industrial examples.

14.1.4 Design of Biotransformation Processes

For a successful biotransformation, it is necessary that the substrate molecules come into contact with the enzymes such that the catalytic capability of microorganisms is not inactivated by the substrate or its product. Therefore, the ideal substrate should be soluble in the fermentation medium and able to pass the cell membrane without being toxic to the microorganism. Such a substrate is usually added to a growing culture as a sterile concentrated solution.

14.1.4.1 Selection of Microorganism

The first task in designing a biotransformation process is to find the microorganism or cell line that catalyzes the reaction of interest with the highest possible yield. Usually it is necessary to perform an extensive screening with a great number of pure cultures, which can be obtained from culture collections or isolated from natural sources. Sometimes it is desired or necessary to identify new strains of microorganisms that are capable of carrying out certain biotransformations (5).

14.1.4.2 Methods for Carrying Out Biotransformation Process

14.1.4.2.1 Biotransformation with Growing Culture The substrate is added to the fermentation medium at the time of inoculation or during a later phase of microbial growth. It is an easy method, and total time of incubation is relatively short because growth and biotransformation take place simultaneously.

14.1.4.2.2 Biotransformation with Resting Cells At first, the microorganisms are cultivated under conditions allowing optimum growth; then the biotransformation is performed in a second step. This method offers some advantages, such as:

1. Each step can be individually optimized.
2. Optimum conversion rate can easily be determined.
3. Biotransformation step is usually not susceptible to infection by contaminant microorganisms, and so can be conducted under nonsterile conditions.

14.1.4.2.3 Biotransformation with Immobilized Cells Immobilization can be done with different techniques:

1. Entrapment in a polymerous porous network (polyacrylamide, k-carrageenan, alginate, chitosan, collagen, agar, cellulose, or urethane).
2. Surface adsorption to a water insoluble, solid support (DEAE-cellulose, concanavalin A, ion exchange resins, or metal oxide).
3. Covalent attachment to a carrier material (e.g., carboxymethyl cellulose).
4. Induction of cell aggregation by physical or chemical cross linking (such as with gluteraldehyde).

For small scale laboratory procedures as well as for large scale industrial application, entrapment into polymerous matrix material has been most extensively applied. Biotransformation with immobilized cells has higher operational stability than cells free in solution, and the active cells are easily removed from the reaction mixture and can be used repeatedly. Furthermore, the product formation rate is high and the inhibitory influences are minimal.

On the other hand, the catalytic activity of immobilized cells is generally reduced due to damage occurring during the immobilization procedure. Increasing cell density can compensate for this loss of catalytic activity.

14.1.4.2.4 Biotransformation with Purified Enzymes In some cases, it may be advantageous or necessary to carry out a biotransformation with a purified enzyme. This is appropriate if

1. The membrane of intact cells prevents proper substrate or product permeation.
2. Further product degradation or undesirable side reactions take place due to the presence of other enzymes systems.
3. The enzyme of interest is excreted by the cells and can easily be purified from the medium after biomass removal.
4. Techniques for enzyme immobilization are well established and permit the repeated use of the biocatalyst and the opportunity to run continuous reactors.

Industrial applications of immobilized enzymes are mostly restricted to reactions like hydrolysis or isomerization (e.g., amino acylase, lactase, glucose isomerase, and glucoamylase). Immobilized enzyme technology is commercially used for lactose hydrolysis in milk by lactase from *Kluyveromyces* species. By far the largest industrial application is the isomerization of glucose from hydrolyzed corn starch to yield fructose, a sugar with increased sweetness (6).

14.1.4.2.5 Biotransformation with Multiphase Systems Biotransformation of substrates with low solubility in water has been successfully carried out with two liquid phase systems consisting of water and a poorly water miscible solvent (7). For this purpose, an ideal organic solvent should be practically immiscible in water, but should exhibit high solubility for the substrate and product. Furthermore, it should not exert an inhibitory effect on the biocatalyst. For reason of safety, nonflammable solvents are preferred. Organic solvents such as n-alkanes, cyclohexanes, toluene, benzene, carbon tetrachloride, chloroform, and methyl chloride have been used for biotransformation with intact cells or enzymes (8).

14.1.4.2.6 Combination of Two Sequential Biotransformation Steps Catalyzed by Different Microorganisms Biotransformations involving two (or several) sequential steps that are catalyzed by different microorganisms are favorably carried out as a

one stage process using a mixture of both microorganisms in a single reactor. If the two microorganisms require different fermentation conditions, a two stage fermentation can be considered (9).

14.1.5 Improvement of Biotransformation Process

14.1.5.1 Optimization of Environmental Conditions

Enzyme formation and enzyme activity are heavily influenced by environmental conditions, such as medium composition (kind and concentration of nutrients; substrate product concentration) temperature, pH, and dissolved oxygen (depending upon aeration and agitation).

If the conditions for growth and associated enzymes synthesis are not optimal for the biotransformation, both processes must be separated and optimized individually, as in biotransformation with resting cells. For industrial processes, economic aspects (cheap raw material, short reaction time, increased substrate concentration, and low energy consumption) have to be considered (10).

14.1.5.2 Strain Improvement

Strain improvement is done for the amplification of beneficial properties or the elimination of detrimental properties of microorganisms involved in biotransformation. This can be done by inducing genetic modifications and selecting for mutants that improve the biotransformation by increasing the enzyme production, enhancing substrate or product tolerance, increasing membrane permeability, facilitating substrate transport into the cell and product efflux from the cell, as well as inactivation of the enzyme catalyzing side reaction or product degradation. The traditional method of strain development is from mutagenesis by commonly used agents (e.g., UV light or chemical mutagens) and subsequent selection for superior strains among survivors.

Screening efficiency can be considerably enhanced by adopting a screening strategy, which selects superior strains that give higher yields of the desired enzyme. Recombinant DNA technology provides new prospects of strain improvement. Plasmid or phage vectors can transfer any DNA fragment from eukaryotic, prokaryotic, or even synthetic origin into suitable recipient microorganisms (11).

14.1.5.3 Elimination of Side Reactions

Side reactions in a biotransformation process are observed if a substrate or its product is attacked by undesirable enzyme activities present in the cell. Suppression of such side reactions is desired in order to increase the yield of target product.

In order to eliminate side reactions selectively, cells have to be treated under conditions suppressing the activities of undesired enzymes while maintaining the desired biotransformation activity. Physical (heat) or chemical (pH shift) treatment of biomass can cause selective inactivation of enzymes that are responsible for side reactions.

A more laborious technique is mutagenesis and screening of mutants that have lost the ability to form enzyme systems responsible for side reactions.

14.1.6 Downstream Processing or Product Isolation

Usually biotransformation products are extracellular compounds of low or medium molecular weight. They are dissolved or suspended in the fermentation medium and can be isolated from the broth or (preferably) from a supernatant after removal of biomass (Table 14.2).

Table 14.2
Basic operations and common methods for the isolation of biotransformation product

	Basic Operation	Method
Fermentation broth	Removal of biomass and other solids (if necessary)	Centrifugation, Filtration, Sedimentation Sieving.
Raw Product	Concentration, Fractionation	Extraction, Ion exchange, Adsorption, Precipitation Distillation
Final product	Final purification	Chromatography, Distillation Decolorization Crystallization Drying

14.2 HIGH FRUCTOSE CORN SYRUP

Glucose is almost 65% as sweet as sucrose on a weight basis. Fructose is 120–180%, as sweet, depending upon the conditions of testing. Glucose can be obtained from readily and cheaply available corn starch, either by acid or enzymatic hydrolysis (Figure 14.1). Further, it can be converted into high fructose syrup, which has more sweetness. Fructose plays an important role in the diet of diabetics, as it is only slowly reabsorbed by the stomach and intestinal tract, and does not influence the blood glucose level (12).

Until 1976 the main sweetener used in the world was sucrose, obtained from sugar beets (40%) and sugarcane (60%). In 1974, the price of sugar skyrocketed, making the cost of high fructose corn syrup (HFCS) production competitive. By the time the cost of sugar came down, the enzyme route production of HFCS was able to reduce cost enough to remain competitive (13).

14.2.1 Biotechnology Involved in Process

The possibility of using an enzyme to isomerize the dextrose in corn syrup into fructose has been recognized for some time. Marshall and Kooi (14) had reported the microbial enzyme capable of isomerizing dextrose into fructose. A number of different microorganisms from the genus *Streptomyces* have also been reported as being capable of producing glucose isomerase. Other microorganisms reported in literature include those from the genera *Pseudomonas, Aerobacter, Lactobacillus, Pasteurella* and *Bacillus*.

A process was developed for isomerizing dextrose into fructose using glucose isomerase from *Streptomyces* (Figure 14.2) (15) and for obtaining increased yields of glucose isomerase from *Streptomyces*.

14.2.2 Source of Enzyme for Production

The only commercially employed enzymes for HFCS production are D-xylose isomerase, and D-xylose ketol isomerase (EC 5.3.1.5). These enzymes have various advantages, such as fewer secondary reactions, high specific activity, a high temperature optimum (~80°C,) and not needing cofactors (ATP, NAD^+).

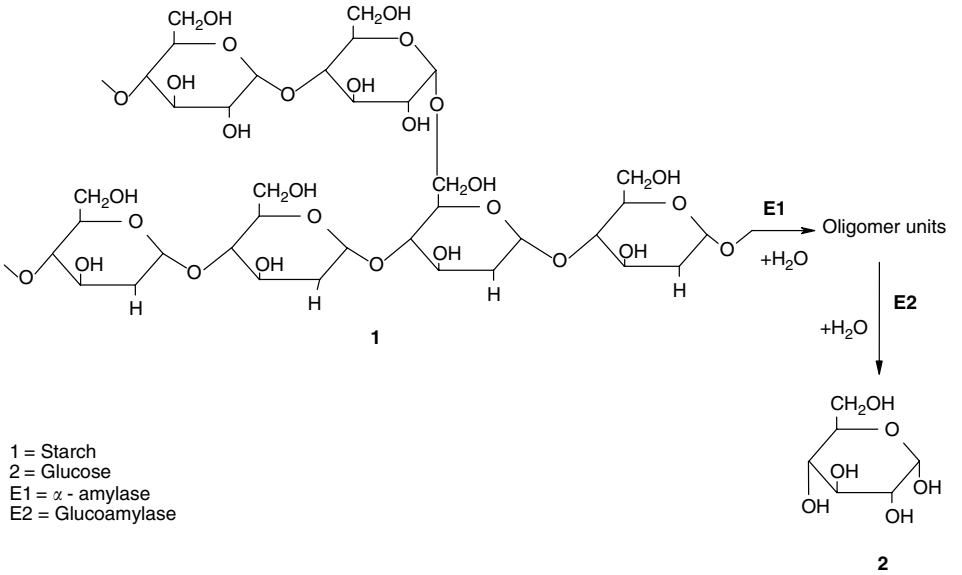

Figure 14.1 Hydrolysis of starch to produce Glucose syrup

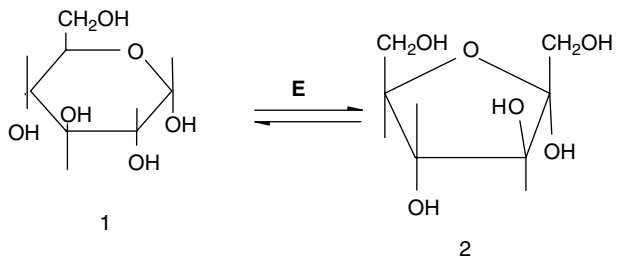

Figure 14.2 Isomerization of Glucose to Fructose

Glucose isomerizing enzyme has been shown in at least 50 different microorganisms (16). Among these strains with xylose isomerase activity, the following are of commercial interest today: *Bacillus coagulans, Arthrobacter* species*, Actinoplanes missouriensis, Streptomyces olivaceus,* and *Streptomyces olivochromogenes.*

14.2.3 Production of HFCS and Immobilization of Enzyme

As an intracellular enzyme, glucose isomerase is harvested after cultivation with the cells by centrifugation or filtration. The washed whole cells may be used for isomerization as such, after heat fixation of enzyme or immobilization. Enzyme immobilization can either be accomplished with the enzyme or with glucose isomerase bearing cells by the following procedures:

1. Covalent binding to an insoluble carrier
2. Adsorption to an insoluble carrier

3. Entrappment in a matrix
4. Immobilization within the cells

Commercially, glucose isomerases are obtained from different microorganisms, and vary in their properties (Table 14.3).

To prepare high fructose corn syrup, starch is first hydrolyzed into glucose using various hydrolytic enzymes (Table 14.4, Table 14.5, and Table 14.6). This syrup, containing 96% glucose, is subjected to conversion from aldose sugar to ketose sugar by the enzyme isomerase. The syrup is filtered through activated carbon and then passed through an ion exchange resin to remove soluble impurities before being evaporated to 40–45% dry solids. The pH of evaporated syrup is adjusted to 7.5–7.8 with NaOH, and the temperature is maintained at 55–60°C. The syrup is passed through a packed bed reactor containing immobilized glucose isomerase. After isomerization, the pH is adjusted to between 4.0 and 5.0. The syrup, containing 42% fructose, is again filtered and evaporated to 70–80% dry

Table 14.3

solids. From this, HFCS 90 and HFCS 55,containing 90% and 55% fructose respectively, can be produced (17) (Figure 14.3).

14.2.4 Salient features of xylose isomerase and glucose isomerase

The process is a part of the production of high fructose corn syrup.

- This process provides an effective way for an important, low cost sugar substitute derived from grain.
- The corn kernels are softened by treatment with sulphur dioxide and lactic acid bacteria to separate oil, fiber and proteins. The enzymatic steps are cascaded to yield the product for the invertase process after liquefaction in continuous cookers, debranching and filtration.
- The process ends if all starch is completely broken down to limit the amount as oligomers of glucose and dextrins. Additionally, recombination of molecules has to be prevented.
- The thermostable enzymes can be used up to 115°C. The enzyme needs Ca^{2+} ions for stabilization and activation.
- Because several substances in corn can complex cations, the cation concentration is increased requiring a further product purification causing the necessity to refine the product.
- The commercially important varieties show superior affinity to xylose and are therefore classified as xylose isomerase.
- Because the isolation of the intracellular enzyme is very expensive, whole cells are used. In almost all cases the enzymes or cells are immobilized.
- Purified glucose (dextrose syrup) is the product from the saccharification stage.
- Isomerases belong to the group of metalloenzymes, as they require Co^{2+} and Mg^{2+} for their activity.
- To limit byproduct formation, the reaction time must be minimized. This can be done economically only by using high concentration of immobilized isomerase
- Several reactors are operated in parallel or in series, containing enzymes of different ages. The feed to a single reactor is controlled by the conversion of this reactor.
- The product has to be highly purified (by filtration, adsorption on charcoal, or ion exchange) to prevent fast deactivation and clogging of the catalyst bed.
- Plants producing more than 1,000 t of HFCS/day typically use at least 20 individual reactors.
- The product HFCS contain 42% fructose (53% glucose) or 55% fructose (41% glucose) as dry matter.

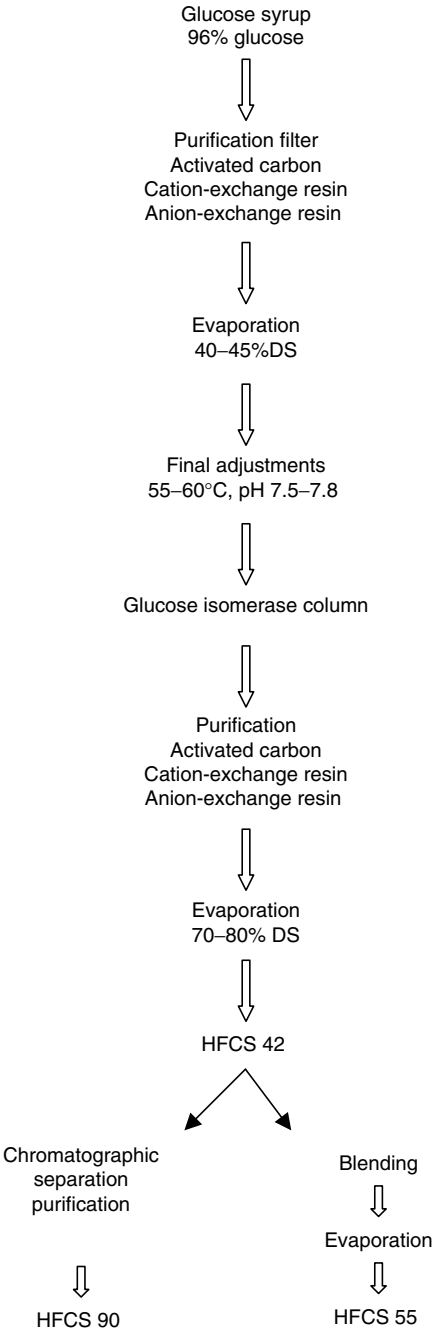

Figure 14.3 Isomerization of corn syrup

- Glucose isomerases have half lives of more than 100 days. To maintain the necessary activity, the enzyme is replaced after deactivation of about 12.5% of the original amount.
- The reaction temperature is normally above 55°C to prevent microbial infection, although enzyme stability is lowered.

According to Hartley et al. (18), current commercial glucose (xylose) isomerases can operate at 60°C and produce 45% fructose syrup. More thermally stable glucose isomerase would be useful for production of 55% fructose syrup at temperatures greater than 90°C. Glucose isomerase isolated from *Thermus thermophilus* (19) has a high temperature optimum (95°C) and can tolerate a neutral pH. A thermostable glucose isomerase isolated from thermophilic *Streptomyces* SK strain had a wide pH range with optima of 6.0 at 60°C and 6.2 at 90°C. It was optimally active at 95°C and completely stable at 80°C for at least 5.5 hours, with a half life of 5 hours at 90°C (20).

14.2.5 Process Parameters

The conversion of Glucose to fructose can be carried out under these conditions:

1. Reactor type – Continuous, fixed bed
2. Residence time – 0.17–0.33 hours
3. Downstream processing – 55% fructose

There are a number of companies producing xylose isomerase (Table 14.7). Several products based on HFCS are available (Table 14.8), and their list is growing. The importance of HCFS technology is evident from the number of patent application with innovation in the enzymatic processes and process engineering (Table 14.9).

14.3 OLIGOSACCHARIDES

Oligosaccharides are usually defined as glycosides that contain between three and ten sugar moieties (21). In general, food grade oligosaccharides are not pure products, but mixtures containing oligosaccharides of different degrees of polymerizaiton, the parent polysaccharide or disaccharide, and monomer sugars. Oligosaccharides provide several health benefits, which make their use as food ingredients particularly attractive.

Worldwide, there are 12 classes of food grade oligosaccharides currently in commercial production. Oligosaccharide production was estimated at 35,000 t in 1990 and 65,000 t in 1995. Food grade oligosaccharides are manufactured using enzymatic processes, with the exception of soybean oligosaccharides (which are produced by direct extraction), and lactulose (which is produced using an alkali catalyzed reaction). They are either built up from simple sugars, such as sucrose or lactose, or by transglycosylation reactions; or formed by controlled hydrolysis of polysaccharides, such as starch, inulin, or xylan.

14.3.1 Classification of Oligosaccharides

Oligosaccharides can be divided into the following classifications:

1. Galactooligosaccharides: Produced commercially from lactose using the galactosyl transferase activity of β-galactosidase (EC 3.2.1.23), which dominates lactose hydrolysis at high lactose concentrations.
2. Lactulose: An alkali isomerization process is used to convert the glucose moiety in lactose to a fructose residue. The resulting disaccharide, lactulose, is not digested by humans and promotes the preferential growth of *Bifidobacteria* in the colon.
3. Lactosucrose: Lactosucrose is the third bifidogenic oligosaccharide that is produced using lactose as a raw material. This trisaccharide consists of a lactose molecule to which a fructose moiety is joined at the glucose residue by a $\beta(2\rightarrow1)$ glycosidic bond. It is manufactured from a mixture of lactose and sucrose using a transfructosylation activity of enzyme β-fructofuranosidase.
4. Palatinose (isomaltulose): Palatinose is produced from sucrose using an immobilized isomaltulaose synthase (EC 5.4.99.11).
5. Glycosyl sucrose (coupling sugar): The trisaccharide glycosyl sucrose (coupling sugar) is manufactured from the disaccharides maltose and sucrose using the enzyme cyclomaltodextrin glucanotransferase (EC 2.4.1.19).
6. Maltooligosaccharides: Maltooligosaccharides contain 2-10 α-D-glucose residues linked by α(1-4) or α(1-6) glycosidic linkages. They are produced commercially from starch by the action of α-amylase (EC 3.2.1.1).
7. Cyclodextins: Cyclodextrins are cyclic β(1-4) linked maltooligosaccharides consisting of 6–12 glucose units. They are formed from starch digest by the action of cyclomaltodextrin glucanotransferase.
8. Gentiooligosaccharides: Gentiooligosaccharides consist of several glucose residues linked by $\beta(1\rightarrow6)$ glycosidic bonds. They are produced from the glucose syrup by enzymatic transglucosylation.

9. Soybean oligosaccharides: Unlike other oligosaccharides, soybean oligosaccharides are extracted directly from the raw material and do not require enzymatic manufacturing processes.
10. Isomaltooligosaccharides: Like maltooligosaccharides, isomaltooligosaccharides are produced using starch as the raw material. Isomaltooligosaccharides consist of α-D-glucose residues comprising of α(1→6) linkage.
11. Xylooligosaccharides: The raw material for xylooligosaccharide synthesis is the polysaccharide xylan, which is extracted mainly from corncobs. The xylan is hydrolysed to xylooligosaccharide by the controlled activity of the enzyme endo-1, 4,β-xylanase (EC 3.2.1.8) to produce higher purity oligosaccharide products.

14.3.2 Fructooligosaccharides

Fructooligosaccharies represents one of the major classes of bifidogenic oligosaccharides in terms of their production volume. They are manufactured by two different processes, which result in slightly different end products.

In the first method, fructooligosaccharides are produced from the disaccharide sucrose (Figure 14.4) using the transfructosylation activity of the enzyme β-fructofuranosidase (EC 3.2.1.26) (22). A high concentration of the starting material is required for efficient transglycosylation. The fructooligosaccharides formed in this process contain between two and four β(1→2) linked fructosyl units linked to a terminal α-D-glucose residue. These are named 1-kestose (Glu-Fru_{20}), 1-nystose (Glu-Fru_3) and 1^F-fructosylnystose (Glu-Fru_4).

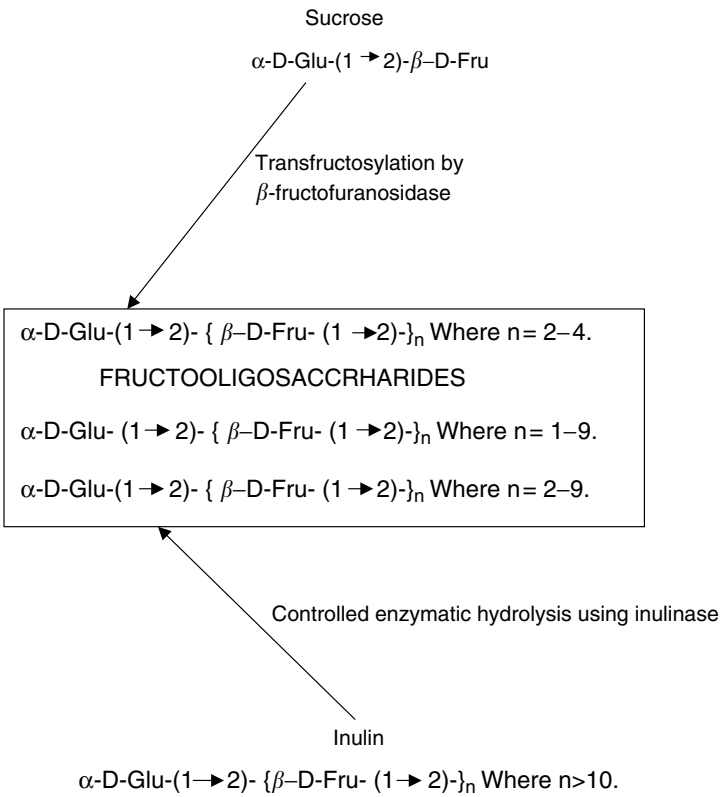

Figure 14.4 Production of Fructooligosaccharides

Glucose and small amounts of fructose are formed as byproducts in the reaction, as well as unreacted sucrose, and removal of these from the oligosaccharide mixture using chromatographic procedures is carried out to produce fructooligosaccharide products of high purity.

The second method used for fructooligosaccharide production is the controlled enzymatic hydrolysis of the polysaccharide inulin (inulin oligofructose) the fructooligosaccharide mixture formed by this process closely resembles the mixture produced from the transfructosylatin process (23). However, not all of the $\beta(1\rightarrow2)$ linked fructosyl chains end with a terminal glucose. Additionally, the oligosaccharide mixture is produced by the sucrose transfructosylation process.

14.3.3 Microbial Source for Enzyme Production

The industrial production oligosaccharides is a field that offers tremendous scope and opportunity. Meiji Seika (Japan) was the first company to meet success with commercial fructooligosaccharide production, with fructooligosaccharide production using fructosyl transferase from *Aspergillus* or *Aeureobasidium pullulans* M/S Cheils Food and Chemical Company (Korea) has been successful with Fructooligosaccharide production using immobilized cells of *A. pullulans*. Microbial production of oligosaccharides provides a convenient, cost effective alternative to chemical synthesis. The enzyme involved can be either intracellular or extracellular. Some microorganisms that can be used in fructooligosaccharide production are as follows.

1. *Aspergillus phoenicis:* Enzymes produced are sucrase-1^F-transferase (EC 2.4.1.99) under optimal conditions of 55°C; pH 8.0 for 8hrs, corresponding 60% (w/w) fructooligosaccharides i.e., 1-Ketose is obtained from sucrose (24).
2. *Aureobasidium pullulans*: Jung et al. (25) demonstrated that sucrose was an excellent carbon source for the production of intracellular fructosyl transferase. There was a tendency for the enzyme production to be increased as sucrose concentration is increased.
3. *Pencillium rugulosum*: Barthomeuf and Pourrot (26) used 70–85% sucrose in0.1M sodium acetate buffer at pH 5.0, 5.5 or 6.0, and an enzyme concentration between 2 and 10 Fructosyl transferase units/g.
4. *Aspergillus japonicus*: The reaction conditions of pH 5.0 and temperature 55°C; sucrose is the best carbon source and yeast extract is the best nitrogen source for the β-fructofuranosidase (EC 3.2.1.26) production (27).
5. *Penicillium citrium*: A novel syrup containing Neofructooligosaccharides was produced from sucrose (Brix 70) by whole cells of P. citrium. The efficiency of fructooligosaccharide production was more than 55%.
6. Mixed Enzyme System: A technique to produce high content fructooligosaccharide by the mixed enzyme system of fructosyltransferase and glucose oxidase has been studied. The mixed enzyme reaction has been carried out in a stirred tank reactor containing 40% (w/v) sucrose with 10 units of fructosyltransferase and 10 units of glucose oxidase per gram sucrose for 25h at 40°C and pH 5.5 Highly concentrated fructooligosaccharides (up to 90%) were obtained by the mixed enzyme system (28) (Table 14.10).

14.3.4 Properties of Oligosaccharides

Oligosaccharides are water soluble and mildly sweet, typically 0.3–0.6 times as sweet as sucrose. They exhibit low water activity, which is convenient in controlling microbial contamination. They are shown to be strong inhibitors of starch retrogradation. Many oligosaccharides are not digested by humans (29).

Table 14.10
Total Sugar Comparison of Fructooligosaccharides (FOS) and High content fructooligosaccharides (HCFOS)

Sugar	FOS % w/w	HCFOS % w/w
Fructose	1.0	1.31
Glucose	36.33	2.33
Sucrose	10.49	5.86
GF_2 (1-kestose)	32.32	50.13
GF_3 (Nystose)	24.78	38.19
GF_4 (fructofuranosylnystose)	1.68	2.18
$\sum^{4}_{n=2} GF_n$	52.18	90.4

Food grade oligosaccharides

Class of Oligosaccharides	Estimated Production in 1995(t)	Major Manufacturers	Trade Names
Fructooligosaccharides	12000	Meiji Seika Kaisha (Japan)	Meioligo
		Beghin-Meiji Industries (France)	Actilight
		Golden Technologies (USA)	NutraFlora
		Cheil Foods and Chemicls (Korea)	Oligo-Sugar
		ORAFTI (Belgium)	Raftilose and Raftiline
		Cosucra (Belgium)	Fibruline

14.3.5 Applications of Oligosaccharides

The major use of oligosaccharides is in the preparation of beverages. Oligosaccharides are being included in probiotic yogurts and yogurt drinks to produce symbiotic products. They are used as low cariogenic sugar substitutes in confectionery and baking, because they are not utilized by mouth microflora to form acid or polyglucans. Moreover, they can be used as bulking agent in desserts such as jellies and ice creams; bakery products including biscuits, breads, pastries; and also in infant milk formulas (29).

Some of the companies producing food grade oligosaccharides are given in Table 14.11 and the representative patents in Table 14.12.

14.4 VANILLA FLAVOR

Vanilla, which originated in Mexico, is a tropical orchid belonging to the family orchidaceae. About 110 species have been identified, but only three have been reported to be important in terms of commercial cultivation. *Vanilla fragens* or *Vanilla planifolia, Vanilla pompona* and *Vanilla tahitensis*. Among these, *V. planifolia* is the most valued for its flavor qualities, and is therefore widely cultivated and used for the production of food additives. The fully grown mature fruits of vanilla are called beans or pods.

Vanillin (4-hydroxy-3-methoxy benzaldehyde) is the characteristic organoleptic aroma compound of the cured vanilla pod, where it contributes to about 2% (w/w) of dry

matter. The proposed biosynthetic pathway of vanilla flavor metabolites formation from various phenyl propanoids is given in Figure 14.5.

14.4.1 Production of Vanillin by Biotransformation

The increasing trends towards natural foods ingredients have helped to maintain high demand for natural vanilla; therefore, a need was felt to develop alternative natural biological sources of vanilla flavoring. The production of vanilla flavor is possible from vanilla tissue culture; another possibility is biotransformation mediated production using either plant cell or microorganisms (30). Microbial transformation of natural precursors could provide the desired biovanillin, which may offer the natural status required by the European legislation (European Directive 88/388/CEE, Jo, No 184, 22nd of June 1988). The production of a natural biotechnological vanillin requires a natural precursor such as ferulic acid.

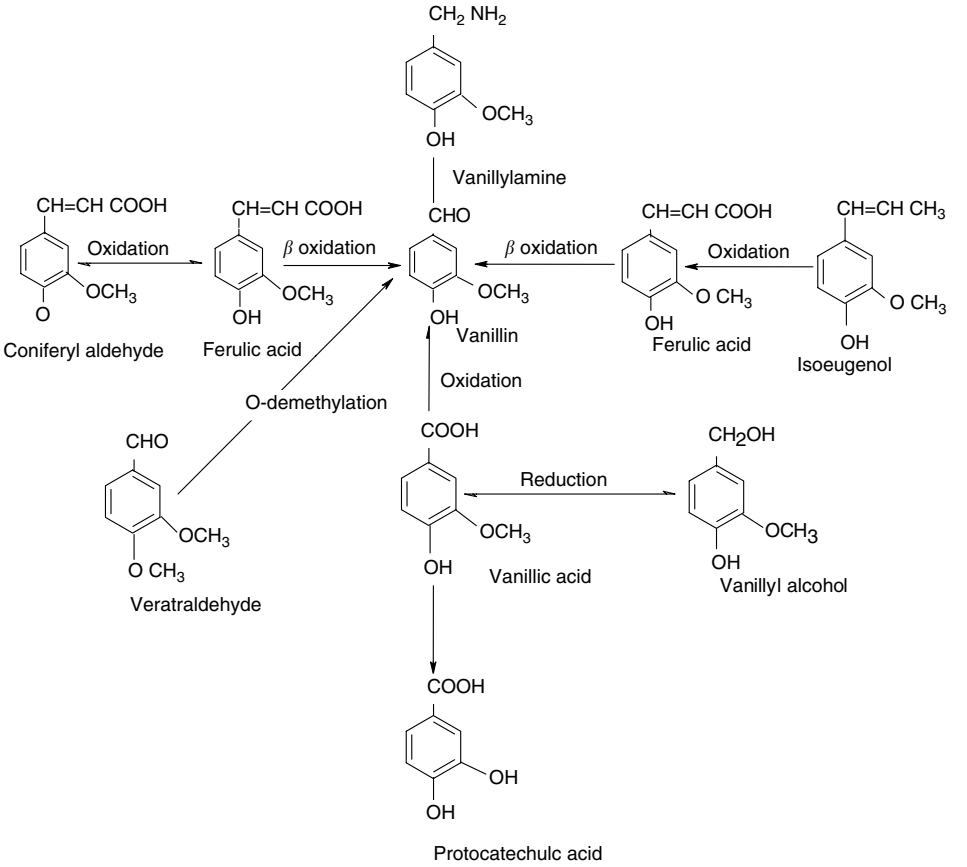

Figure 14.5 Proposed biosynthetic pathway of vanilla flavor metabolites formation from various phenylpropanoids

14.4.2 Vanilla Tissue Culture Studies

The rationale for the production of flavor compounds from cultured plant cells is based upon their unique biochemical and genetic capacity and on the totipotency of plant cells. Every cell of a vanilla plant contains the genetic information necessary to produce the numerous chemical compounds (or their precursors) that constitute natural vanilla flavor; feeding intermediates of the biosynthetic pathway can enhance the production of vanilla flavor metabolites by precursor biotransformation.

Feeding of cinnamic acid and ferulic acid to cell suspension cultures of *Vanilla planifolia* resulted in the formation of traces of p-hydroxy benzoic acid and vanillic acid (31). Processes have been reported (Table 14.13) for producing natural vanillin from ferulic acid precursors with aerial roots and charcoal as a product reservoir, developed by Westcott et al. (32). Organized aerial roots of *V. planifolia* plant detached and cultured in nutrient medium were used as biocatalysts in transforming ferulic acid to vanillin in the presence of charcoal.

14.4.3 Biotransformation of Lignin

Lignin is one of the most abundant natural sources of aromatic compounds. White rot fungi *Pycnoporus cinnabarinus* are able to delignify wood and decompose the lignin

Table 14.13
Biotransformation of Ferulic acid to vanilla flavor metabolites using microorganisms.

polymer to yield vanillin, dehydrovanillin, vanillic acid, coniferyl aldehyde, ferulic acid, P-hydroxy cinnamyl aldehyde, and other compounds. The enzyme lignin peroxidase, which is responsible for lignin depolymerization, was isolated from *Phanerochaete chrysosporium*. However, in all reports of fungal degradation of lignin, vanillin has been detected only in trace amounts (33).

14.4.4 Biotransformation using Cell Culture of *Capsicum frutescens*

Production of vanilla flavor metabolites was observed when both freely suspended and immobilized cell cultures of *Capsicum frutescens* were treated with phenyl propanoid pathway intermediates like ferulic acid and vanillylamine. Vanillin is also produced by treating the cell cultures with protocatechuic aldehyde, caffeic acid, isoeugenol, coniferyl aldehyde, and veratraldehyde (30).

14.4.5 Biotransformation using Microorganisms

Various phenyl propanoid precursors, like ferulic acid, eugenol, isoeugenol, vanillyl alcohol, vanillyl amine, coniferyl alcohol, and veratryl alcohol can produce vanilla flavor metabolites by a large number of microbes such as bacteria, fungi, and yeast.

14.4.6 Biotransformation of Eugenol and Isoeugenol

Eugenol is the main constituent of the essential oil of the *Syzygium aromaticum* tree. It is a cheap commerciall available raw material for biotransformation. The first biotransformation of isoeugenol to vanillin was achieved with *Aspergillus niger* ATCC 9142 but it gave relatively low yield, because the efficiency of this transformation was only 10% due to further degradation of vanillin to vanillyl alcohol and vanillic acid. Strains of *Klebsiella, Enterobacter* and *Serratia* were used to transform eugenol and isoeugenol into vanillin. Biotransformation of isoeugenol and eugenol to vanillin and vanillic acid was shown in cultures of the microalga *Spirulina platensis* (34).

Recently a strain of *Bacillus subtilis* was isolated from soil that converts isoeugenol to vanillin with a molar yield of 12.4%. Rabenhorst (35) demonstrated with *Pseudomonas* species that they were capable of growing on eugenol as the sole carbon source and found vanillic acid, ferulic acid and coniferyl alcohol as metabolic intermediates. The conversion of isoeugenol to vanillin was also reported with cell cultures of *Capsicum frutescens*, however the yields were relatively low.

14.4.7 Biotransformation of Vanillic Acid

Vanillic acid is a main intermediate in lignin and ferulic acid degradation; in contrast to vanillin, it is often accumulated in remarkable amounts. With *Pseudomonas fluorescens* BF-13, a yield of 95% vanillic acid was obtained from ferulic acid within 5 hours.

The metabolism of vanillic acid has been intensively studied in *Sporotrichum pulverulentum* and *Pycnoporus cinnabarinus*. Vanillic acid is reduced to vanillin and vanillyl alcohol. Vanillic acid can be oxidatively decarboxylated to methoxy hydroquinone, which is the main problem with the vanillin production process using *P. cinnabarinus*. This problem was overcome by the addition of cellobiose prior to vanillic acid supplementation. The vanillin yield was further improved by use of high density cultures and different types of bioreactors.

14.4.8 Economic Considerations

The annual consumption of the world flavor market is about 6000 tons, out of which only about 0.2% originates from botanical sources. The main production is by chemical synthesis from guaiacol and lignin. The price of chemically synthesized "Nature identical" vanillin is very low (about U.S. $12/kg) compared to the price of cured vanilla pods (between U.S. $30/kg and U.S. $120/kg, which usually contains about 2% (w/w) vanillin. In the method described for biovanilla or biovanillin production by microbial biotransformation, the cost will be on the order of U.S. $1000/kg (30). The uses of vanilla flavor range from food to medicinal value.

14.4.9 Uses of Vanilla

Vanilla is the world's most popular flavoring for sweetened food.

Pure vanilla extracts are widely used as a flavorant for ice cream, soft drinks, chocolates, confections, candy, baked foods, pudding, cake, cookies, and liquors and as a fragrance ingredient in perfumery. It enhances the flavor of caramel, coffee, and some dairy products. It also has medicinal value as antimicrobial agent and antioxidant.

The demand for vanilla flavor has resulted in commercial companies establishing their own processes for the production of vanilla and vanilla flavor components from natural vanilla bean and from various substrates through biotransformation (Table 14.14). Similarly, there are increasing patent applications in the area of biotransformation for vanillin production (Table 14.15).

14.5 MONOTERPENES

Monoterpenes are naturally occurring branched chain C-10 hydrocarbons formed from two isoprene units. They are widely distributed in nature and over 400 different naturally occurring monoterpenes have been identified. In particular, oxygenated derivatives of terpenes, commonly known as terpenoids, have strong and pleasant odors. Many of these terpenoids are considered as GRAS (Generally Recognized As Safe) and when obtained from natural sources, they can be added to foods without being considered as additives (44).

On the other hand, various available monoterpenes, such as (-)-α– pinene, (-)-*β*– pinene, and (+) – limonene are used in large quantities in the chemical industry for conversion into more valuable terpenoids. During the past decade, new information has become available on the purification and description of several enzymes involved in monoterpene degradation (Table 14.16). The genes encoding some of these enzymes have also been cloned and sequenced, opening up the possibility of doing single step biotransformation in a neutral background.

14.5.1 Monoterpene Biotransformation

Problems encountered in Monoterpene biotransformation:

1. Chemical instability: Monoterpenes readily undergo spontaneous chemical autooxidation, cis-trans isomerization, racemization, hydration, cyclization, rearrangement, and polymerization reactions.
2. Low solubility: Monoterpenes are poorly soluble in water, which will affect the biotransformation rate.
3. Volatility: Monoterpenes are volatile in nature.
4. Toxicity: The problem associated with terpene biotransformation studies in the toxicity of monoterpenes to whole cells. Addition of the terpenes to the cell cultures has been observed to inhibit growth and the addition of high concentrations of monoterpenes can result in cell lysis.
5. Stability: Absence of product accumulation and product degradation.
6. Purity: Multiple metabolic pathways resulting in the formation of mixture of products.
7. Scarcity: Low product concentration and yields (e.g., in mg/L of culture media), resulting in high downstream processing costs.
8. Enzyme activity at times not detectable in cell extracts.
9. Long incubation times: Many bioconversions, especially those involving fungi, take many days to reach appreciable yield. The longer the fermentation time, the greater the cost and increased possibility of contamination by unwanted microorganisms.
10. Durability: Short lifetime of the biocatalyst.

14.5.2 Limonene

Limonene is monocyclic terpenoid, which besides pinene is the most widely distributed terpene in nature. The microbial transformation of limonene has been studied in detail by Dhavalikar et al. (45) and a large number of neutral and acidic metabolites have been isolated and identified. Several of these are of industrial importance such as carveol, carvone, dihydrocarvone, perillyl alcohol, and perillaldehyde. Dhavalikar et al. (45) proposed three pathways in the conversion of limonene.

An effort to increase the value of cheap (+)(–) limonene isolated from citrus was described by Bowen (5). Pure cultures of *Pencillium digitatum* and *P. italicum* were isolated

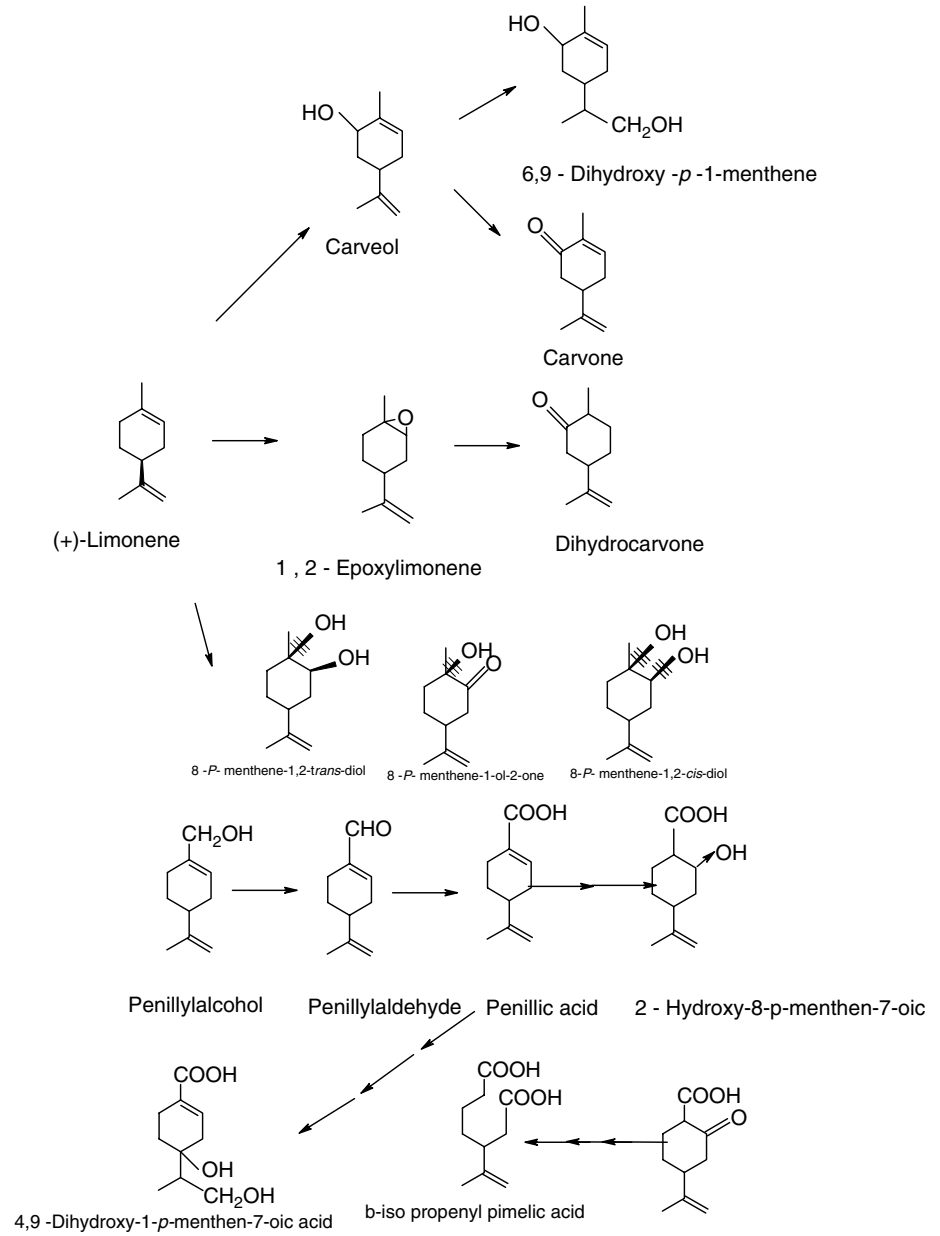

Figure 14.6 Pathway for degradation of (+) – Limonene in *Pseudomonas* sp. L

from overripe oranges by enrichment culture techniques on Czapek-Dox Broth containing 1% limestone as the sole carbon source. Transformation by *P. italicum* (Figure 14.6) yielded the following products: *Cis*- and *trans*-carveol (26%), carvane (6%), *cis*- and *trans*-p-menthe- 2.8-dien-1 – ol (18%), p-mentha-1,8-dien-4-ol (4%), penillyl alcohol (3%), and P-mentha-8-ene 1,2-diol (3%).

Noma et al. (46) used *Aspergillus cellulosae* M-77 for biotransformation of (+)(-) limonenes to major products like (-)– Perillyl alcohol, (-)– limonene-1, 2 trans-dilol

and (-) – neodihydrocarveol. Biotransformation of limonene by *Xanthobacter* species C 20 into a novel limonene is described by Werf et al. (47).

Separate enantiomers of Limonene exhibit the characteristic Limonene odor profile: (R) – (+) with fresh, natural, citrus, orangelike odors, and (S) – (-) with harsh turpentine lemonlike notes.

14.5.3 Isolation and Identification of the Metabolites

The metabolites are separated and purified by a combination of column chromatography on silica gel and gas chromatography. The products are identified by comparison of the gas chromatography and mass spectra with those of authentic specimens (46).

14.5.4 Future Trends

The microbial transformation of terpenoid compounds has considerable potential for practical application in the flavor and fragrance industry. Nevertheless, microbial transformations of various monoterpenes have challenging industrial possibilities. There are three areas in the biotechnological production of monoterpene that can play an important role:

1. Formation of terpenoids from cheap and readily available monoterpenes such as (+) – limonene (−) -α- pinene.
2. Biotransformation of terpenoids with a high flavor impact that are not readily available from other biological or chemical sources.
3. Production of novel (natural) flavors with unique organoleptic properties.

In the future, genetic engineering techniques may provide modified strains catalyzing a single pathway to the desired product resulting in the production of pure aroma chemicals. As many of the characterized enzymes involved in monoterpene degradation appear to have broad substrate specificities, these systems might also be used for the production of closely related terpenoids. Furthermore, by means of genetic engineering, the control of biosynthetic pathways and the exploitation of the regulatory mechanisms can improve the yield of the processes.

14.5.5 Application of Biotransformation of Limonene

The transformation products of limonene yield (+)-cis-carveol and (+)-carvone, which are important constituents of caraway seed and dill seed oils, in addition to 1-p-menthene-6, 9-diol (-) – carvone which contributes to spearmint flavor. The other transformation products are perillyl alcohol, perillaldehyde, and perillic acid, constituents of various essential oils used in the flavor and fragrance industries. The selected patents in the area of monoterpene production are given in Table 14.17.

14.6 STRUCTURED LIPIDS

Interesterification is a process which is used in the oils and fat industry to modify the properties of triglyceride mixtures using enzyme or chemical catalysed reactions. Structured lipids (SL) will indicate any lipid that has been modified to change the fatty acid position or composition from the native stage. They are produced for commercial use by chemical hydrolysis of the natural oils and random reesterification, or by interesterification.

Structured lipids may be the most effective means of delivering designer triglycerols with desired fatty acids as nutraceuticals, functional foods, and medical foods to target specific diseases or metabolic conditions, and for optimal nutrition.

Table 14.17
Patent Applications

Year	Patent No.	Authors	Topic

1997	US 5652137	Chang, HC; Oriel PJ	Process and bacterial cultures for the preparation of perillyl compounds

By exploitation of the specificity of the lipases, it is possible to produce useful glyceride mixtures that cannot be obtained by conventional chemical interesterification processes.

14.6.1 Enzymatic Synthesis

Lipases catalyze direct esterification and transesterification reactions at mild reaction conditions with little or no side products. Lipases can catalyze the incorporation of specific fatty acids and specific positions of the tricylglycerides.

Lipids with maximized functionality do not occur in nature at the proportions required for their functional use; therefore, enzymatic restructuring is a viable means of producing structured lipids with specific fatty acids at specific positions.

14.6.2 Substrate Specificity of Microbial Lipases

Extracellular microbial lipases (Glycerol ester hydrolases EC 3.1.1.3) are excreted by microorganisms into their growth medium to assist in the digestion of lipid material. They catalyze the hydrolysis of fats to give free fatty acids, partial glycerides, and glycerol.

The naturally occurring triglycerides of long chain fatty acids are water insoluble, and lipases are characterized by the ability to catalyze rapidly the hydrolysis of ester bonds at the interface between the insoluble substrate phase and aqueous phase, in which the enzyme is soluble.

The microbial lipases can be placed in three groups: nonspecific lipase, specific lipase and fatty acid specific lipase.

The first group shows no marked specificity. These lipases catalyze the complete breakdown of the triacylglycerol into fatty acid and glycerols, but diglycerides and monoglycerides appear as intermediates of reactions. Examples of this type are the lipases from *Candida cylindracae, Corynebacterium acnes* and *Staphylococcus aureus*.

The second group of lipases catalyzes the release of fatty acids specifically from the outer 1- and 3- positions of glycerides with these lipases. Triacyglycerides are hydrolysed to give free fatty acids, 1,2 (2,3)- diglycerides and 2-monoglycerides as reaction products. 1,3-specificity is common amongst microbial lipases and examples of enzymes from this group are the lipases from *Aspergillus niger, Mucor javanicus* and various *Rhizopus* species.

The third group of lipases catalyzes the specific release of a particular type of fatty acid from glyceride molecules. The lipase produced by *Geotrichum candidium* has been shown to possess a very marked specificity for the hydrolysis of esters of a particular type of long chain fatty acid.

14.6.3 Lipases as Interesterification Catalysts

Because lipase reactions are reversible, hydrolysis and resynthesis of glycerides occur when lipases are incubated with oils and fats. This hydrolysis and resynthesis causes acyl migration between glyceride molecules and gives interesterified products. Under conditions in which the amount of water in the reaction system is restricted, hydrolysis of the fat can be minimized so that lipase catalyzed interesterification becomes the dominant reaction (48).

If a nonspecific lipase is used to catalyse the interesterification of a triglyceride mixture, the triglycerides produced are similar to those obtained by chemical interesterification. However, with a 1, 3-specific lipase as catalyst, acyl migration is confined to the 1 and 3 positions, and a mixture of triglycerides that is unobtainable by chemical interesterification is produced. Mixtures of triglycerides and free fatty acid can also be used as reactants for lipase catalyzed reactions. In these cases, free fatty acid exchanges with the acyl groups of the triglycerides to produce new triglycerides enriched in an added fatty acid. With nonspecific lipases enrichment of all three glyceride positions occurs, but with 1,3-specific lipases the reaction is confined to the 1 and 3 positions of glycerides. If a fatty acid specific lipase is used, a particular fatty acid from a mixture of fatty acids can be selectively introduced.

The ability to produce novel triglyceride mixtures using specific lipases is of interest to the oils and fat industry because some of these mixtures have properties that make them valuable. For example, 1,3-specific lipase catalyzed interesterification of 1,3-dipalmitoyl-2- monooleine (POP), which is major triglyceride of the mid fraction of palm oil, with either stearic acid or tristearine gives products enriched in the valuable 1, (3) Palmitoyl-3(1) stearoyl -2-monooleine (P O St) and 1,3 distearoyl -2-monooleine (St O St). P O St and St O St are the main components of cocoa butter, and it is therefore possible by the interesterification reaction to produce a valuable cocoa butter equivalent from cheaper starting materials.

14.6.4 Interesterification Reaction Systems

The catalysts used for enzymatic interesterification are prepared by addition of a solvent such as acetone, ethanol, or methanol to a slurry of an inorganic particulate material such as kieselghur, hydroxylapatite, or alumina in buffered lipase solution. The precipitated enzyme coats the inorganic particles and the lipase coated particles are collected by filtration, then dried and stored. In the dried form the particles are almost inactive as interesterification catalysts, and to obtain high catalytic activity it is necessary to hydrate the particles by addition of up to 10% water prior to their use in the interesterification reaction systems.

14.6.5 Process for the Modification of Oil and Fats Via Enzymatic Interesterification

Most studies for the enzymatic oils and fats by lipase catalyzed interesterification have used the Stirred Tank Reactor process. Fuji oil used a Stirred Tank Reactor for the large scale production of cocoa butter equivalent by lipase catalyzed interesterification. The schematic arrangement of the process is shown in Figure 14.7.

Lipase catalyzed interesterification reactions can also be performed continuously using packed bed reactors. For operation of the packed bed reactors, the feed stock mixture, dissolved in petroleum ether, is treated to remove particulate materials and enzyme catalyst inhibitors and poisons, and then partially saturated with water prior to being pumped through a bed of hydrated catalyst particles. The lipase catalysts are reasonably stable under the conditions prevalent in the packed bed reactors, and it is possible to operate these reactors continuously for up to 600 hr with minimal loss of catalytic activity.

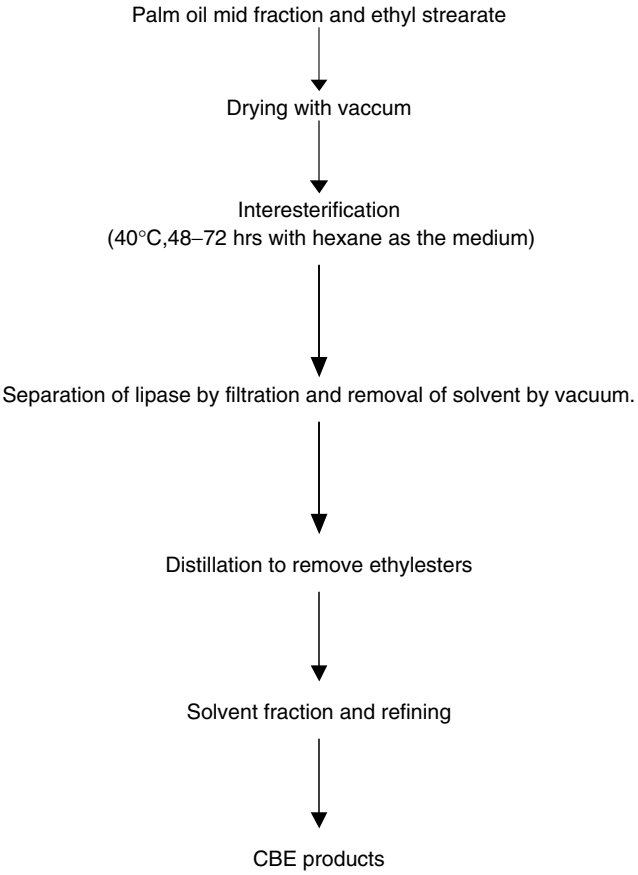

Figure 14.7 Process scheme for the production of cocoa butter equivalents (CBE) via lipase catalysed interesterification in a stirred tank reactor

14.6.6 Downstream Processing

At the end of reaction period, the catalyst is filtered off and a fraction containing the 1,(3)Palmitoyl-3(1)stearoyl-2-monooleine and 1,3 distearoyl-2-monooleine triglycerides isolated by conventional fat fractionation techniques such as countercurrent, liquid–liquid extraction, and crystallization from solvents. The catalyst is washed free of fatty material, dried and then reused in subsequent interesterification reactions. Use of the same catalyst particles in 10 successive batch interesterification reactions has proved to be possible. Some reported benefits of structured lipids are given in Table 14.18. A number of companies involved in the production of structured lipids are shown in Table 14.19. There are a number of patents in this area (Table 14.20) which are of great utility for the production of value added food products.

14.7 LACTOSE HYDROLYSIS

Lactose or milk sugar is a disaccharide found in milk. Lactose itself is less sweet and soluble than sucrose and it cannot be absorbed directly from the intestine. Lactase (β-galactosidase) hydrolyzes lactose into glucose and galactose (Figure 14.8), which have

Table 14.18
Some Reported benefits of Structured Lipids

*Enhanced absorption of the fatty acid at the Sn-2 position, e.g., 18 : 2n – 6 in cystic fibrosis patients.
*Improved absorption of other fats.
*Reduction in serum TAG, LD-Cholesterol and cholesterol
*Hypermetabolic response to thermal injury
*Reduced calorie fat
*Improved immunofunction
*Prevent thrombosis
*Reduced risk of cancer
*Lipid emulsions for parenteral feeding

Table 14.19

Procter and Gamble, USA.

a combined sweetening power of about 0.8 relative to sucrose; the hydrolyzed product is also three to four times more soluble than lactase, and the mono saccharides are easily and directly absorbed from the intestine (49). The hydrolysis of lactose to form glucose and galactose is of interest from several points of view:

1. A significant percentage of population of the world has β-galactosidase deficiency and are intolerant to lactose.
2. Due to its tendency to crystallize, its low solubility and compatible low sweetness, lactose would be impractical as a food sugar.
3. Prehydrolysis of milk with lactase would shorten yogurt and cheese production time by 20%, as well as increase the yield and sweetness.
4. During the hydrolysis of lactose, glucose and galactose are produced. The enzyme responsible for the reaction is β–D-galactoside galactohydrolase (Lactase, hydrolactase, β-galactosidase). The type of reaction is O-glycosyl bond hydrolysis. β-galactosidase is produced by a number of microorganisms which include yeast, fungi, and bacteria (Table 14.21).

14.7.1 Fermentation for Lactase Production

Fermentation methods include:

1. *Aspergillus niger*: The fermentation process can be solid-state or submerged fermentation. Solid-state fermentation can be done with wheat bran. Inoculation is done with *A. oryzae* spores, and the mixture is incubated for seven days at 30°C. Yields in solid-state fermentation are much higher than in submerged fermentation.

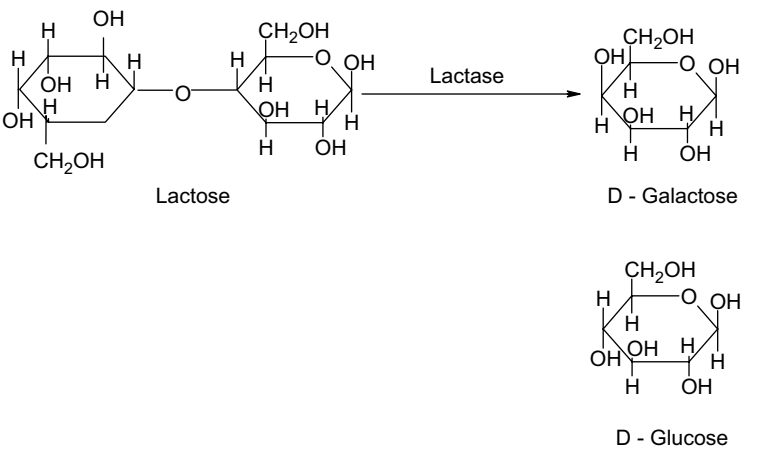

Figure 14.8 Hydrolysis of lactose to produce Glucose and Galactose

Table 14.21
Microorganisms producing lactases

Yeast
Kluyveromyces lactis, K.fragilis, Candida pseudotropicalis, Zygosaccharomyces lactis, Saccharomyces anamensis
Fungi
Aspergillus oryzae, A. niger, Mortierella vinacea, Penicillium multicolour, Curvularia inaequalis, Fusarium moniliforme, Mucor pusillus, Humicola grisea, Torula thermophila.
Bacteria
Bacillus coagulans, B. stearothermophilus, B. circulans, E. coli, Lactobacillus bulgaricus, L. thermophilus
Those microorganisms most important for commercial production are: *Kluyveromyces lactis, Kluyveromyces niger, Aspergillus oryzae, E. coli.*

2. *Escherichia coli*: Submerged fermentation is at pH 7.0. Enzymes can be isolated by centrifugation and precipitation.
3. *Bacillus stearothermophilus*: The lactases of *Bacillus stearothermophilus* are very thermostable. The organisms grow while aerated at 65°C in a batch fermented process or under continuous conditions.

A lactose free, low cost culture medium for the production of β–D Galactosidase by *Kluyveromyces macianus* was formulated in which sugar cane molasses is added as the carbon source.

14.7.2 Immobilization of Lactase

Lactase has been immobilized by a variety of procedures including adsorption, entrapment, and covalent linkage. Supports used are agar gel, alumina, carbon, cellulose, chitin, chitosan, collagen, glass beads, ion exchange resin, nickel, nylon, phenol-formaldehyde resin, polyacrylamide sephadex, and silk fibronin. (49). Immobilization is essential for reducing the cost of lactose hydrolysis as well as enabling changes of operational condition (pH, temperature, half life) (50).

Conditions for biotransformation: The conditions for biotransformation depend on the properties of microbial lactases. The optimal process conditions for the lactase derived from the dairy yeast *Kluyveromyces lactis* which is at present the most widely used commercial lactase preparation, is at 35–40°C temperature and pH 6.6–6.8, which are close to the natural temperature and pH of milk, and so it is most useful in the treatment of milk and sweet cheese whey. The properties of microbial lactases are given in Table 14.22.

14.7.3 Process Parameters

The synthesis of β–galactosidase by *K. lactis* has a conversion efficiency of 70–81%. The process can be operated as a fluidized bed in a column 3 inches in diameter. For industrial biotransformation, plug flow reactors are used, which have capacity of about 8000 L/d (at Central del Latte, Italy).

The first large scale pilot plant for the lactose hydrolyzing process was by Snam Progetti dairy plant in Milan, Italy. The second process for the production of lactase hydrolyzed whey has been developed by Corning Glass Works, USA.

Table 14.22
Properties of Microbial Lactases

Source	pH Optimum	pH Stability	Temperature Optimum °C	Km for Lactose	Cofactors Needed
A. niger	3.0–4.0	2.5–8.0	55–60	85	None
A. oryzae	5.0	3.5–8.0	50–55	50	None
K. fragilis	6.6	6.5–7.5	37	14	Mn2+, K+
K. lactis	6.9–7.3	7.0–7.5	35	12–17	Mn2+, Na+
E. coli	7.2	6-8	40	2	Na+, K+
Lactobacillus thermophilus	6.2	-	55	6	-
Leuconostoc citrovorum	6.5	-	60	7.8	None

Table 14.23
Companies using β–galactosidase

Sumitomo chemical industries, Japan
Snow brand milk products co. Ltd, Japan
Central del Latte, Italy
Rapidase Tokyo Tanaben, Japan
Miles Lab, Germany
Novo Industries, Denmark
Gist Brocades, Netherlands

Recently there are many companies that are producing lactose hydrolyzed whey, some of which are given in Table 14.23.

14.7.4 Application of Lactases

Lactases find their application in several areas, such as milk for people with lactose intolerance problems, especially infants; milk specific for cheese for cheese and yogurt making; whey or lactose for the production of sweeteners and soluble hydrolyzed whey syrups; concentrated milk products such as condensed milk; and for preventing the gritty texture of ice cream made with lactose.

Several patents on lactases have been obtained, and some representative ones are given Table 14.24.

14.8 D-TAGATOSE

A rare ketohexose, D-tagatose, is one of the D-galactose isomers. D-tagatose is a bulking agent in food, a noncalorific sweetener (sweetness 0.92), and tastes almost similar to sucrose. In addition, D-tagatose does not show a laxative effect, unlike other polyols. Zero energy or low energy alternative carbohydrate sweeteners play an important role in energy restricted diets. Alternative sweeteners are mainly used to control calorie intake in food and beverages, in the management of diabetes, to assist in the control of dental caries, and to enhance the usability of pharmaceuticals and cosmetics. Although D-tagatose occurs

naturally, the amounts are too small for economic recovery. D-tagatose is a generally recognized as safe (GRAS) substance under FDA regulation (Table 14.25).

Several methods have been studied for the manufacture of D-tagatose. D-galactose could be converted into D-tagatose by a calcium catalyst. Although chemical synthesis is an economical process, this process also has the disadvantage of needing high temperature and high pressure. Biological production of D-tagatose has been studied intensely in recent years (51).

14.8.1 Reaction Involved in Biotransformation

D-tagatose production from galactitol using galactitol dehydrogenase is well known. Galactitol however, is more expensive than galactose and seems to have only little potential for commercial production (52). The D-tagatose is obtained by the biotransformation of D-galactitol and Bioconversion of D-galactose. During the biotransformation of D-Galactitol to D-tagatose the oxidation reaction takes place.

14.8.2 Microorganisms for Biotransformation to D-Tagatose

The first microorganism used was *Arthrobacter glabiformis* (53). The yield of D-tagatose, which accumulated in the medium from D-galactitol, was as high as 85%. Other microorganisms which can carry out the transformation are *Mycobacterium smegmatis, Enterobacter agglomerans* and *Gluconobacter oxydans* (Acetic acid bacteria) (53,54).

Bioconversion of galactose into tagatose can be achieved by the L-arabinose isomerase gene (*Ara A*) from *Escherichia coli, Bacillus subtilis,* and *Salmonella typhimurium* which could produce D-tagatose from D-galactose (52).

The cells of *Mycobacterium smegmatis* were grown on various sugar polyalcohols, but oxidation activity was found only in case of D-galactitol, and D-galactitol and D-tatitol. L-sorbose induces the enzymes for D-tagatose fermentation (53). Oxidation activity for D-galactiol (Figure 14.9) gives a yield about 60%. The intact cells and immobilized cells with calcium alginate have virtually the same activity with respect to D-tagatose production. The conversion rate from *Enterobacter agglomerans* was about 92% when 2% galactitol was used (54). At 5% substrate concentration, the conversion was about 86%. Better results have been obtained by adding galactitol to 24 hour old cultures of *Gluconobacter oxydans* the time corresponding to the stationary growth phase (51).

14.8.3 Downstream Processing

The reaction mixture containing D-tagatose is centrifuged to remove the bacterial cells. The supernatant fluid is deionized and then concentrated at 40°C under vacuum. After 2 days of standing in absolute ethyl alcohol at 5°C, white crystals of D-tagatose are obtained (51).

14.8.4 Status of D-Tagatose Development

Because D-tagatose is a full bulk noncalorific sweetener, it may play a significant dual role in helping people realize the health and longevity benefits of diet restriction and also in deterring the specific aging effect of glycosylation (55).

In future, the use of D-tagatose as a limited substitute for sucrose may prove feasible. Chocolates and chewing gum, both of which were successfully formulated by substituting D-tagatose for sucrose in each, are planned as initial products along with the use of D-tagatose as a tabletop sweetener for coffee and tea, and in single use packets.

14.9 CONCLUSION

The scope of biotransformation is wide and the use of biotransformation is beyond doubt. A number of products are already on the market, such as high fructose corn syrup, oligosaccharides, vanilla flavor, structured lipids, and lactose hydrolyzed milk. For a new product to be introduced, it needs safety data; and therefore although several reactions and biocatalytic agents have been identified, they may not be immediately commercialized.

The demand for natural, nature identical molecules is increasing. Therefore, the use of biotransformation processes for the production of novel compounds of utility value assumes greater importance. The advantage of utilizing transgenics will further enhance the efficiency of biocatalytic processes. Further, direct modification of enzymes using site directed mutagenesis would enhance the efficiency of the process to suit process conditions like thermostability and more affinity toward substrates.

The most important feature of biotransformation is to obtain highly desirable food constituents which are of use as ingredients in developing the targeted food or designer foods for humans such as functional foods and nutraceutical.

The number of patents which have been taken in recent times, and the investments that have been made by multinational companies, are indications of the commercial potential of biotransformation processes to produce desired products. Moreover, utilization of the products of biotransformation in traditional foods would be an attractive proposition. Hence from a futuristic point of view, the scenario is bright.

Solid-State Bioprocessing for Functional Food Ingredients and Food Waste Remediation

Kalidas Shetty

CONTENTS

15.1 INTRODUCTION

Solid-state bioprocessing (SSB) is an aerobic microbial metabolic process and is generally referred to as the process in which 1) microbial growth and product formation occur, 2) on suitable solid substrates, 3) in the near absence of free water or in low water that is absorbed within the solid substrate matrix (1–3).

Therefore, referring to this process as a solid-state fermentation (SSF) is a misnomer. Fermentation generally refers to growth with no oxygen, as in alcoholic or lactic acid

fermentation. Solid-state bioprocessing deals with the utilization of water-insoluble materials for microbial growth and metabolite production (1). However, suitable materials are those that absorb well and have sufficient moisture to support aerobic growth (1). The SSB system has been widely used in Asia for over 2000 years for products like Koji for soy sauce and miso, as well as tempeh, and is being increasingly modernized and applied to production of other industrial products, including enzymes and pharmaceuticals (1). In the west, an SSB-like process is used in meat preservation, bread making, and cheese and mushroom production (4). This chapter will be limited to the discussion of certain unique applications of SSB for development of ingredients for functional foods, and some aspects of solid waste remediation for food processing wastes. A more detailed conceptual discussion of SSB-like process is covered elsewhere in the book.

15.2 MODERN APPLICATIONS

Since the late nineteenth and early twentieth century, SSB has been used for the production of many enzymes by microorganisms (4,5). It was also extended to the production of important metabolites, such as gluconic acid, citric acid, and gallic acid (4,5). Later, in the mid twentieth century, SSB was extended to the production of antibiotics and steroid transformation. Today it has many applications, especially the production of value added products from agricultural and food processing byproducts, which otherwise have very low value. Select examples of such applications, where SSB is required for initial aerobic breakdown, include the production of fertilizer and soil amendments (6,7), animal feed in the form of single cell proteins (8–12), mushrooms (13–15), ethanol (16–19), methane (bio) gas (20,21), citric acid (22–25), butanol (26), flavor and aroma volatiles (27), and enzymes (28–30). In terms of food applications, there is continuous contemporary improvement in the use of pure cultures and in metabolic processing for bread yeasts (31), cheese (32) and fermented sausage (33,34), Koji production for soy products (35), and tempeh (36,37), along with means of enhancing nutritional quality with such products as carotenoids (38), reducing toxins (39,40), and moderating antinutritional factors (41).

15.3 SSB FOR FOOD WASTE BIOPROCESSING AND APPLICATIONS

Solid-state bioprocessing (SSB) has been used for composting and sewage treatment since early in the twentieth century, because the early phases of waste breakdown requires the decomposition of polymeric substrates by aerobic processes (1–3). This concept has been extended to producing fertilizer and soil amendments (6,7) and to mushroom production (14,15). Another development of a value added product is the conversion of fruit processing wastes to fungal inoculants for agricultural and environmental applications (42–45). With suitable combinations of fruit processing wastes and fishery wastes, beneficial microorganism rich amendments can be developed for reclamation of marginal soils, and to provide proper addendum for efficient composting at landfills and the waste remediation of pollutants.

15.4 COMPLEXITY OF SSB SYSTEMS AND NEED FOR "SYSTEMS BIOLOGY" APPROACHES

Solid-state bioprocessing (SSB) systems, in almost all cases, involve complex microecosystems that have multiple components and variables; such complex systems require a more

integrated "Systems Biology" approach. Systems Biology as described by Hood (46) is the study of the relationships of all elements in a biological system, rather than of each element one at a time. In the case of SSB systems, this can be extended to the consideration of a "microecosystem" with multiple substrates and a succession of microbial processes and metabolic interconversions. Further extending the concept of Systems Biology, Kitano (47) has looked at Systems Biology as being similar to understanding the overall workings of a machine or modern mechanical device, as a car or airplane. According to Kitano (47), to understand biology at the systems level one must examine the structure and dynamics of cellular and organismal function, rather than the characteristics of isolated parts. He elegantly provides four key properties from which systems level understanding of biological systems can be derived; these are:

1. Understanding systems structures such as genes, enzymes, and pathways
2. Understanding the dynamics of the pathways and interrelationships
3. Understanding control mechanisms that determine function
4. Understanding of control points

Once these four key properties are understood, one can design or redesign the overall function, the basic structure, and the functional relationships of each biological system (47). Various elements of this Systems Biology perspective, based on parallels to the workings of modern mechanical devices, have merits. However, the complexity and diversity of the process of designing and redesigning biological systems and biological and microbiological ecosystems for human applications require a more comprehensive perspective of evolutionary relationships across the mosaic of prokaryotes and eukaryotes, and the eco-evolutionary development and interrelationships that span two or three billion years. In particular, the perspective will have to start from fundamental energy production and the management of various biological systems individually and in an ecosystem. Further, the variations of energy and redox management from oxygen rich environments to low oxygen and anaerobic environments in complex ecosystems, such as are found in several SSB systems, have to be tackled before we can move on. From fundamental insights into metabolic critical points in energy and redox management across biological systems, we have a better framework to link and connect genetic, signal, enzyme, protein, and related metabolic critical points that drive the overall biological systems and the multiple biological systems in an ecosystem. This energy and redox management based Systems Biology rationale is a suitable way to determine critical control points (CCP) in SSB systems involving complex biological substrates and microbial systems, in order to better design and fine tune SSB systems for any applications.

15.5 SSB IN TRADITIONAL FOOD PRODUCTS AND IMPLICATIONS

To develop an energy and redox management based Systems Biology in SSB systems for food product design and functional food applications, it would make sound and logical sense to go back to over 2000 years of empirical SSB systems, and understand how they have been established in our modern food and cultural mosaic. In this book these concepts have been highlighted by insights into select traditional SSB systems from human development in Africa, China, India, and the Mediterranean. Examples of improvements in bioprocessing in these traditional SSB systems that have come with the knowledge of modern biology, especially

microbiology, nutrition, the metabolic biology of energy management, and molecular biology, can provide the framework to adapt more integrated Systems Biology approaches.

15.6 APPROACH FOR DEVELOPMENT OF FUNCTIONAL FOODS AND INGREDIENTS USING SSB

Knowledge of traditional SSB systems can provide the principles, safe biological systems, and framework to develop functional foods (improvement of conventional foods with added health benefits) and ingredients. In line with this thinking, and based on the rationale of incorporating a more integrated Systems Biology approach, several innovative SSB systems have been developed for harnessing the potential of phenolic functional ingredients from safe and established dietary sources. In this chapter discussion will focus on the cultivation of soybeans, fava beans, and cranberries.

In these approaches, SSB systems have been adapted, over a period of more than 2000 years, to enrich phenolic metabolites from soybean, fava bean and cranberry crops for enhanced health benefits. In the case of cranberries, there is cross cultural integration of a traditional American Indian medicinal berry with Asian SSB based food processing using modern metabolic biology principles. In the case of soybeans and fava beans, we have used the traditional Asian tempeh SSB system and adapted it to enriching the beans with functional phenolics that have diverse health application potential. These strategies offer unlimited potential to capture the phytochemical potential of diverse dietary botanicals with well developed traditional microbial processing systems, using modern microbiology, metabolic biology, molecular biology, nutritional biochemistry, and analytical methods.

15.6.1 Soybeans

Epidemiological research has associated high soy intake with a lower risk for certain types of cancer (48,49). Soybean is a rich source of phenolic antioxidants with isoflavonoids being major components. The chief isoflavonoid found in soybean is genistein. Research has shown the chemopreventive properties of purified and synthetic genistein (50–54). However, more recent research has shown that fermented soymilk, developd through bioprocessing, performed better at reducing the incidence of mammary tumor risk than a similar mixture of its constituent isoflavonoids, suggesting that the food background may play a positive role in the chemopreventive actions of soy, in addition to the resident isoflavonoids like genistein (55). As fermented soymilk is rich in phenolic aglycones, which are more active and more readily taken up than their β-glycosides, increasing the free phenolic content of soy-based food through microbial bioprocessing may positively affect its medicinal and nutritional value (56–59). Thus, SSB of soybean substrates by a dietary fungus such as *Rhizopus oligosporus* or *Lentinus edodes* has been developed to mobilize free phenolic antioxidants (60–62). This concept was later extended to mobilization of phenolic antioxidants in soy kefir milk fermentation (63).

When SSB by *Rhizopus oligosporus* of whole soybean was undertaken based on the tempeh bioprocessing model, it was found that while total soluble phenolic content increased 120–135% in the extracts, increased antioxidant activity based on a free radical scavenging assay was limited to the early growth period (60). Higher antioxidant activity was linked to increased glucosidase and glucuronidase activity. Overall results based on phenolic antioxidant and enzyme activities suggested a possible involvement of lignin remobilization and degradation activities, potentially as a part of a detoxification pathway by *Rhiozpus oligosporus* (60).

Phenolic mobilization by SSB using *R. oligosporus* was further investigated, using defatted soybean powder. In this SSB system, phenolic content increased 41% in water extracts and 255% in ethanolic extracts after 10 days of growth (61). In this system beta-glucosidase was the main carbohydrate-cleaving enzyme that is required for efficient phenolic mobilization from defatted powdered soybean (61). This tempeh SSB model was extended to *Lentinus edodes*, which is a slow growing fungus used in shiitake mushroom (fruiting phase of *L. edodes*) production that grows only in the vegetative mycelial phase in soybean (62). It was determined that *L. edodes* SSB was effective in mobilizing phenolic antioxidants from defatted soybean powder (62). Postprocessing phenolic content had increased 90% to 11.3 mg/gram dry weight in water extract and 232 % to 5.8 mg/gram dry weight in ethanolic extracts. Furthermore, phenolic antioxidant mobilization by *L. edodes* was related to the activities of the carbohydrate-cleaving enzymes alpha-amylase and beta-glucosidase, as well as laccase, an enzyme involved in lignin biodegradation (62).

Further, in another study, phenolic mobilization by *L. edodes* was associated with manganese peroxidase and laccase (64). Taken together, these results so far indicate that adapting traditional tempeh fermentation using the same food grade fungus *R. oligosporus,* or exploiting the slower growing vegetative mycelial organism of Shiitake mushrooms, *L. edodes*, phenolic ingredients can be mobilized from soybean whole beans or defatted powders. The functional relevance of these phenolic metabolites were confirmed when it was clear that the phenolic mobilization by *R. oligosporus* on day 2 of SSB growth, that coincided with an increased laccase activity, also had the highest phenolic antioxidant activity and antimicrobial activity against ulcer bacteria *Helicobacter pylori* (65) and the food borne bacterial pathogen *Listeria monocyotogenes* (McCue et al., unpublished results). Results also indicate that phenolic mobilization by *L.edodes* vegetative mycelium enhanced DNA protection using a plasmid model system and had antihypertension potential (McCue et al., unpublished results).

15.6.2 Fava Beans and Other Legumes

Dopamine has several key physiological and biochemical roles in human health and well-being. The role of dopamine as a hormone for urinary and vasodilatory function has been postulated (66). The renal production of dopamine has been shown to be an important factor in the control of blood pressure (67). Further, the importance of dopamine for controlling normal motor functions is evidenced by the abnormality of the basal ganglia in Parkinson's disease, where marked loss of these dopamine linked neurons has been observed (68). A recent interesting article has proposed a general theory that attributes the origins of human intelligence to an expansion of dopaminergic systems in human cognition (69). According to Previc (69), "Dopamine is postulated to be the key neurotransmitter regulating six predominantly left hemispheric cognitive skills to human language and thought such as motor planning, working memory, cognitive flexibility, abstract reasoning, temporal analysis /sequencing and generativity."

L-Tyrosine is considered to be the initial precursor in the biosynthesis of dopamine via L-DOPA (68). Natural L-DOPA is found in significant quantities in fava beans. Studies have shown an antiParkinson effect of fava bean consumption (70–72). There is documentation of a substantial increase in plasma L-DOPA levels following consumption of fava beans, which correlated with substantial improvement in motor performance of patients (70). In a recent clinical case study, fava bean consumption prolonged on periods in patients with Parkinson's disease who had on–off fluctuations (73). This prolonged on period was not observed when higher levels (800–1000 mg) of pure, synthetic L-DOPA was given (73), suggesting that L-DOPA in the fava bean background is significant in the positive clinical benefits observed.

L-DOPA has been identified in seedlings, pods, and beans of the fava bean plant (74). A substantial clinical improvement in 6 patients with Parkinson's disease was observed after ingestion of 250 g of the fava bean fruit that included pods and seeds (70). A separate study has shown that the amount of L-DOPA in seedlings is up to 20 times higher than in seeds (75). Verad et al. (74) suggested that germinated seedlings have other advantages, such as ease of use and fewer side effects (i.e., flatulence, cramping). While a previous study (70) reported that consumption of boiled pods and seeds of the fava bean provided substantial improvement in the debilitating effects of Parkinson's disease, a later study (74) showed that consumption of germinated seedlings was even better, and that high plasma L-DOPA levels consistent with substantial clinical improvements were observed. The study is important, because germinated fava bean sprouts could be grown and used any time of the year and may be particularly useful for lower income populations. According to these studies, germinated sprouts of the fava bean offer an excellent and complimentary dietary approach to the management of Parkinson's disease, along with other prescribed treatments. In addition, we have explored the use of SSB fava bean systems using *Rhizopus oligosporus*, which offers more potential for enhanced functionality from phenolic enrichment by recruiting the complex metabolic interactions of fungal colonization of fava beans.

A fava bean SSB system was adopted from the soybean tempeh model using *Rhizopus oligosprous* (76). The L-DOPA content in the SSB fungal grown fava bean increased significantly, to approximately twice that of the control, accompanied by moderate phenolic linked antioxidant activity and high fungal superoxide dismutase (SOD) activity during the early stages of growth (76). This indicated that L-DOPA can be mobilized and formed from fava bean substrates by fungal SSB and this also contributed to the antioxidant functionality of such extracts. A high SOD activity during early and later growth stages indicates likely oxidation stress of the initial fungal colonization and in late stages is likely due to nutrient depletion, when levels of free soluble phenolics are high (76). High levels of soluble phenolics during late stages correlated to an increase in beta-glucosidase activity, indicating that the enzyme plays a role in the likely release of phenolic alycones and the high antioxidant activity of late stages. Therefore use of SSB for fava bean using *R. oligosporus* can improve antioxidant functionality and Parkinson's relevant L-DOPA content (76).

15.6.3 Cranberry

Pioneering investigation has shown that phenolic glycosides in cranberries can be hydrolyzed by enzyme glycosidases using food grade fungus *Lentinus edodes* during SSB (77). Further, preliminary results have shown that during the SSB there is a strong correlation between high antioxidant activity of the fruit extracts and glycosidase activity (78). Based on these preliminary results, the phenolic antioxidant content and activity is being investigated in fruit extracts and pomace byproducts of the cranberry using *R. oligosporus* and *L. edodes* (78,79). In this investigation, the food grade fungi *L. edodes* and *R. oligosporus* are used to mobilize the release of functional phenolic antioxidants linked to beta-glucosidase during SSB of cranberry fruit pulp extracts and pomace byproducts. This helps enhance the value of cranberries and other fruits as a source of food grade health ingredients that can be used and reconstituted in a wide array of processed food. Specifically, this approach has allowed the development of high ellagic acid enriched extracts, with enhanced antimicrobial activity against food borne pathogens (80,81) and ulcer associated *Helicobacter pylori* (82). This process not only enhances the economic value of fruits and fruit ingredients, it could provide an abundant source of health relevant phenolic antioxidants with nutraceutical value. This

value added SSB approach has substantial implications for improving the functional value of food products and could be extended to a wide array of foods and food byproducts. We have expanded on these studies to regulate flavonoids and diphenyls in other important fruits, such as apples, raspberries, strawberries, and grapes.

15.6.4 Enzymes in Phenolic mobilization and Metabolic Biology of PLPPP

Phenolic mobilization from soybean substrates has been linked to the activity of carbohydrate-cleaving enzymes alpha amylase and beta-glucosidase (62), and to lignin degrading enzymes, such as laccase and peroxidase (64). Based on the low phenolics and the high antioxidant activity linked to peak laccase activity in early phase of *R. oligosporus* growth, it has been suggested that polymeric forms of phenolic may have more functional activity. It is likely that the polymeric form is the form with the most potent health benefits, as seen in anti*Helicobacter pylori* inhibition studies (65). These studies are now being extended to inhibition studies in breast cancer cell culture models (McCue et al., unpublished results). Based on carbohydrate mobilization and likely polymeric phenolic forms produced at early stages, it is likely that a growing fungus has to adjust to these conditions metabolically.

In this chapter a model is proposed that as free soluble sugars are enhanced during fungal growth and as polymeric phenolic forms are enhanced, the fungus likely switches to an alternative stress induced pathway. The polymeric phenolic forms may stack on the outer membrane of the fungal mycelia and some degraded phenolics may be have the ability to both enter the cytosol and donate protons to the cytosol through a localized hyperacidification and transport through H+-transporters (Figure 15.1). When these combinations of events occur the fungus switches to an alternative proline linked pentose–phosphate pathway (PLPPP).

By switching to a praline linked oxidative phosphorylation for ATP synthesis (away from a NADH based one that requires full operation of the tricarboxylic acid cycle), the fungus avoids entering a futile cycle, and at the same time supports the pentose phosphate pathway to supply the reductant $NADPH_2$ for anabolic pathways. In this way, $NADPH_2$ can not only meet the needs of proline, which can enter the mitochondria through proline dehydrogenase, but also meet the needs of an antioxidant enzyme response through superoxide dismuatase (SOD) and catalase (CAT). This is also likely linked to the glutathione redox flux (83). This PLPPP critical control point is hypothesized to be important in the adaptation of all fungal systems, including yeast based bioprocessing (both SSB and liquid). It may be especially important under high oxygen conditions, when oxygen pressure coupled to soluble sugar uptake is high. It could also be closely tied to the functional activities of phenolics from substrates on which these microorganisms grow. This concept is being investigated for fungal and yeast growth in the bioprocessing of soybeans, fava beans, cranberries, apples and black tea, and could be extended to any substrates where phenolic mobilization from botanical or other food substrates are involved.

15.7 EXTENSION OF PLPPP STRATEGIES FOR LIQUID YEAST FERMENTATION AND LACTIC ACID BACTERIA

Investigation has confirmed the involvement of lignin-degrading enzymes in phenolic antioxidant mobilization during yogurt production from soymilk by active probiotic kefir cultures (63). Kefir cultures contain a consortium of lactic acid bacteria and a yeast,

Saccharomyces fragilis (63). This approach was based on the rationale that fermented soymilk is rich in phenolic aglycones, which are more active and more readily taken up than their β-glycosides. Therefore, increasing the free phenolic content of soy based food through microbial bioprocessing may positively affect its medicinal and nutritional value (56–59). During the investigation, total soluble phenolic content and free radical scavenging antioxidant activity was measured every 8 h for 48 h. Further, the activity of several enzymes (β-glucosidase, laccase, peroxidase) associated with the microbial degradation of polymeric phenolics and lignin and previously linked to phenolic mobilization from soybean during solid-state bioprocessing by dietary fungi (62,64) were also investigated. Soluble phenolic content increased with kefir culture time and was strongly correlated to total peroxidase and laccase activity. However, phenolic content dropped sharply at 48 h. Antioxidant activity increased with kefir culture time and was strongly correlated to decreased soluble phenolic content over the same time period.

This research has important implications for the optimization of functional phytochemicals in commercial soymilk based yogurts, which can be targeted for disease chemoprevention strategies. This soymilk model can be extended to mobilization of phenolics in other liquid fermentation systems such as those for producing wine, beer, apple cider, buttermilk and any other process involving fermented yeast and acidic fermentative bacteria that utilizes an initial aerobic and subsequent low or no oxygen fermentation systems. In such systems the adjustment to initial oxygen stress and subsequent switch to low oxygen or no oxygen involves adjustment to ethanol or organic acids that are produced on the growing liquid substrates.

In the case of yeast, the fungal PLPPP model (Figure 15.1) described earlier, with modifications based on oxygen stress, may be involved. In the case of acid-producing fermentative bacterial systems which are prokaryotes, the fundamental energy metabolism and redox management takes place between the outer plasma membrane (like an independent mitochondria) and cytosol. It is conceivable that the acid-producing bacteria have evolved a high proton management cytosolic dehydrogenase system that can take the inward proton flux and protons generated from new lactic acid production under reduced oxygen and couple it to plasma membrane driven oxidative phosphorylations or substrate level phosphorylations linked to organic acid. It would make sense for this dehydrogenase linked energy and reductant management to occur through the same proline linked pentose–phosphate pathway (PLPPP), with the adjustment within the simpler prokaryotic coupling between the plasma membrane and cytosol (Figure 15.2). The ultimate efficiency and need for such a control point is the same as for mitochondrial linked systems in yeast or filamentous fungi. In these systems, energy metabolism through proline and reductant needs for anabolism through $NADPH_2$ from the pentose phosphate pathway can be provided during the initial crucial switch from high oxygen conditions to low and no oxygen conditions, when substrate level phosphorylation linked to alcohol or organic acids predominate.

It is also conceivable that organic acid-producing prokaryotes are more versatile in this redox switch, and therefore could have evolved a coupled mechanism to better survive high oxygen, high stress, and eventually high organic acids under much reduced oxygen. This rationale could be used in developing antimicrobial systems against pathogenic bacteria, where combinations of exogenous acids and hyperacidifying, proton-donating phenolic metabolites could be recruited to inhibit or kill pathogenic bacteria (83). Using the same logic, organic acid and phytochemical enriched SSB and liquid fermentation systems could be effective ways to design antimicrobials against pathogenic bacteria for improving food safety, as seen in many traditional fermented foods. In such a situation critical points at the level of energy and reductant management between the plasma membrane and cytosol become important, whether involving our hypothetical PLPPP or an alternative model.

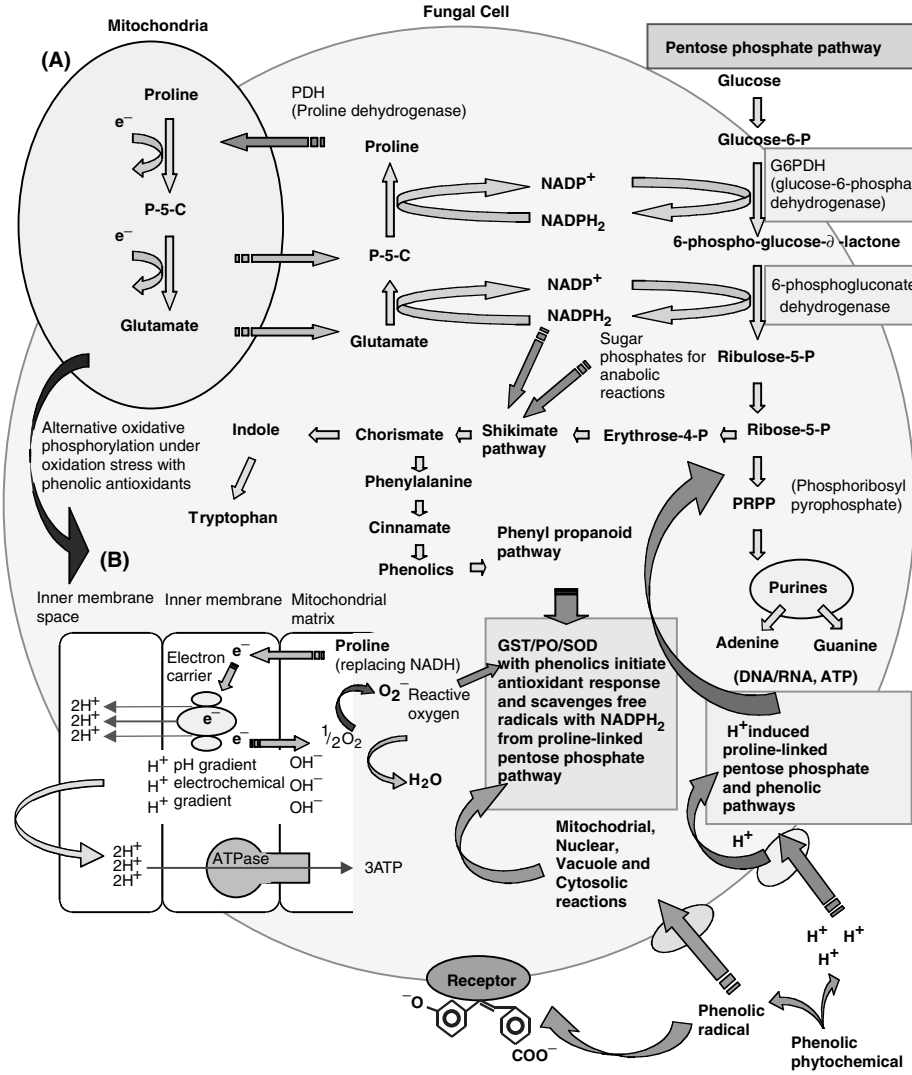

Figure 15.1 Extension of plant proline linked pentose–phosphate pathway model for the effect of external phenolic phytochemicals in yeast and fungal systems during solid-state bioprocessing under aerobic exposure when oxidation stress is maximum and sugar uptake in rapid. (Abbreviations: P5C; pyrroline-5-carboxylate, GST;Glutathione-s-transferase, PO;peroxidase, SOD;superoxide dismutase)

15.8 CONCLUDING PERSPECTIVES

More than 2000 years of microbial based bioprocessing (aerobic and fermentative–anaerobic) of foods and beverages in diverse food cultures around the world has provided us with many complex food substrate and microbial systems for developing functional foods and ingredients. In addition, value added food waste remediation systems have been developed. These food substrates and microbial systems can be further developed for human health benefits and environmental management using the Systems Biology approach of modern biology. These complex systems involve complex consortia of microbial ecosystems and metabolic biology acting on multiple food substrates. To understand these complex systems,

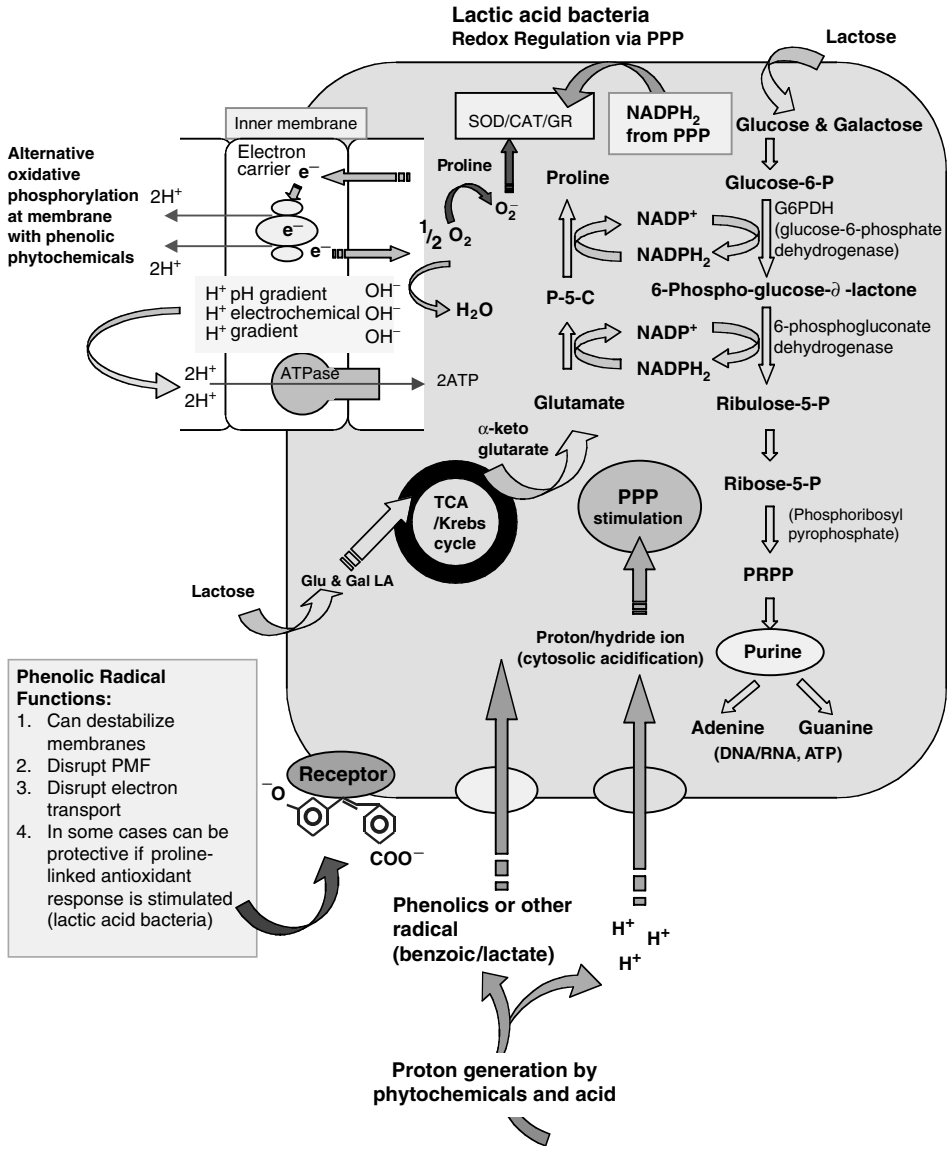

Figure 15.2 Extension of plant proline linked pentose–phosphate pathway model for the effect of external phenolic phytochemicals in prokaryotic organic acid producing bacterial systems, where released phenolics from fermenting substrates could contribute to a redox response and tolerance to acidity, unlike nonacid tolerant bacteria, which are inhibited by phenolics (Abbreviations: P5C;pyrroline-5-carboxylate, SOD;superoxide dismutase, CAT;catalase, GR;glutathione reductase, PPP;pentose phosphate pathway; Krebs {TCA-tricarboxylic acid} cycle), Glu; Glucose, Gal; Galactose, LA;lactic acid

a more integrated Systems Biology approach that first requires understanding of critical control points in energy and redox management across individual organisms to consortia is essential. An understanding of ecoevolutionary relationships of energy and redox metabolic biology across prokaryotes to eukaryotes from oxygen rich to low oxygen and to fermentative environments is also required. This energy- and redox-linked metabolic biology based

platform can help us integrate exciting information from the genetic, signal, and enzyme–protein fields. Such an approach gives us a better understanding of the critical control points that define the functioning of organisms and ecosystems. The understanding of such control points can be utilized to better design functional food and ingredients using SSB systems.

Among many possible critical energy and redox-modulating pathways, we have focused on the relevance of the proline linked pentose–phosphate pathway (PLPPP) in SSB systems. Under the diverse stresses of high or low oxygen environments, organisms likely use PLPPP as an alternative pathway, with proline as a reductant, for oxidative phosphorylation at outer plasma membrane in prokaryotes and mitochondria in eukaryotic yeast and fungi. At the same time the pentose–phosphate pathway is utilized for redox management in the cytosol, to drive reductants such as NADPH2 for anabolism, including antioxidant enzyme response pathways involving superoxide dismutase and catalase. The phenolics mobilized from food substrates will, in many ways, define the behavior of the microbial energy and redox responses. The metabolic and cellular biology of these interrelationships can be harnessed to maximize enhancement and optimization of functional foods and ingredients.

3.16

Fermentation Biotechnology of Traditional Foods of Africa

N. A. Olasupo

CONTENTS

16.1 INTRODUCTION

African countries require food processing technologies that will meet the challenges of the peculiar food security problem in the continent (1). Such technologies however, should be low cost to be affordable by the poor majority of the continent and should be the type that can address the perennial problems of food spoilage and food borne diseases, which are prevalent in the environment. Fermentation is one important food processing technology that meets these challenges. Fermentation is not new to the African countries, as most of the traditional foods in the community are fermented before consumption (2). The process of fermentation has been used in the preparation of many traditional foods in the countries of Africa for centuries. Fermentation as a means of improving the keeping quality of food has been used for more than 6000 years (3). Probably no other process has had such an impact on the nutrition habits and food culture of mankind. Fermentation performs a number of functions which assist the overall improvement of food quality and safety. First and foremost however, it serves to improve the shelf life and safety of foods and enables people in the moderate and cooler regions to survive winter seasons and drought periods. Moreover, it can be assumed that, because safe drinking water supplies were not always available in densely populated areas, fermented beverages with an extended shelf life, such as beer and wine (4), served as safe sources for consumption.

In addition to the preservation effect, fermentation serves as a means of improving sensory quality and acceptability of many raw materials to such an extent that many foods are preferred in a fermented state (e.g., iru, rather than the unfermented African locust bean; gari, rather than unprocessed cassava). Further attributes obtained from fermentation include reduction of toxic food components (e.g., linamarin in cassava and undesired antinutritional factors in legumes). Fermentation adds value and enhances nutritional quality and digestibility through nutritional enhancement. Furthermore, it provides dietary enrichment through aroma and flavor production. The production of fermented foods in Africa is largely home based and it is left to chance inoculation from the environment. The processes are not standardized, with little or no control involved in the processing. The fermentation vessels, utensils, and materials used for preparation or part of previous ferments usually serve as the source of inoculum for the initiation of the fermentation. The use of starter cultures is rare in the production of traditional foods in Africa but old stocks of previous ferments are used in some cases to initiate fermentation in new batches (a process called back slopping) (3). Because of the methods of preparation, indigenous fermented foods in Africa are faced with problems ranging from poor shelf life, doubtful hygiene status, and inconsistent quality to safety risk.

16.2 FERMENTED FOODS IN AFRICA

Many African foods are fermented before consumption. Over 50 different African fermented foods have been recorded. These foods can be classified into five groups (2):

1. Starchy root crops (fermentation)
2. Nonalcoholic cereal substrate (fermentation)

3. Alcoholic beverages
4. Fermented vegetable proteins
5. Fermented animal proteins

Detailed lists of the foods are shown in Table 16.1 to 16.5. The microorganisms involved in African food fermentation are restricted to a few groups of yeasts and bacteria.

Table 16.1
Fermented starchy root products (2,5,6)

Product	Area of Production	Substrate	Microorganisms Involved
Gari	West Africa	Cassava	*Streptococcus lactis* *Geotrichum candidum* *Corynebacterium manihot* Lactic acid bacteria
Lafun	Nigeria	Cassava	Yeast and lactic acid bacteria
Fufu	Nigeria	Cassava	Lactic acid bacteria
Chikawngue	Zaire	Cassava	Lactic acid bacteria and yeast
Cingwada	East and Central Africa	Cassava	Not known
Kocho	Ethiopia	Ensette (*Ensette Ventricosum*)	Lactic acid bacteria and yeast
Kivunde	Tanzania	Cassava	Lactic acid bacteria and yeasts
Agbelima	Ghana	Cassava	*Lactobacillus plantarum* *Bacillus sp.* *Candida tropicalis* *Geotrichum candidum* *Penicillium sp.*

Table 16.2
Fermented nonalcoholic cereal based foods (2,7,8)

Product	Area of Production	Substrate	Microorganisms Involved
Ogi	Nigeria-Benin	Maize, Sorghum, or Millet	*Lactobacillus* sp. and Yeast
Koko and Kenkey	Ghana	Maize, Sorghum, or Millet	*Lactobacillus* sp. and Yeast
Mahewu (Magou)	South Africa	Maize, Sorghum, or Millet	*Lactobacillus delbrueckii, L. bulgaris*
Uji	East Africa	Maize, Sorghum, or Millet	*Lactobacillus* sp.
Kisra	Sudan	Sorghum	Lactic acid bacteria
Injera	Ethiopia	Sorghum	*Candida guillermondii*
Ting	Botswana	Sorghum	Lactic acid bacteria
Obusera	Uganda	Millet	Lactic acid bacteria
Mawe	Benin	Maize	*Lactococcus lactis* *Lactococcus lactis,* *Pediococcus pentosaceus* *Lactobacillus plantarum*
Bogobe	Botswana	Sorghum	Unknown
Kunu-zaki	Nigeria	Millet, Sorghum	Lactic acid bacteria

Table 16.3
Fermented alcoholic beverages in Africa (2)

Product	Area of Production	Substrate	Microorganisms Involved
(1) From Sugary Substrates			
Palmwine	Nigeria (south)	Palm sap	Yeasts
Tej	Ghana	Honey	Yeasts
(2) From Starchy Substrates			
Pito	Nigeria Ghana	Guinea corn And maize	Molds, yeast and *Lactobacillus* sp.
Kaffir beer	South Africa	Kaffir corn or maize	*Lactobacillus* sp. and yeasts
Busaa (maize beer)	East Africa (Kenya)	Maize	Yeast and *Lactobacillus* sp.
Malawa beer	Uganda	Maize	*Candida Krusei*
Zambia opaque maize beer	Zambia	Maize	Yeasts
Merissa	Sudan	Sorghum	Lactic acid bacteria Acetic acid bacteria
Sheketch	Nigeria (south)	Maize	Unknown
Bouza	Egypt	Wheat (or Maize)	Unknown
Talla	Ethiopia	Sorghum	Unknown
Kishk	Egypt	Wheat or milk	*Lactobacillus* sp. yeasts and *Bacillus* sp.
(3) From Other Substrates			
Agadagidi (Plantain wine)	Southwestern Nigera	Plantain	Yeasts and Lactic acid bacteria
Cacao wine	Nigeria	Cacao	Yeasts
Alcoholic spirit	Kenya, Nigeria	Molasses or Cane sugar	Yeasts
Chang aa (Nubian gin)	Nigeria, Ghana	Palm wine	Yeasts
Ogogoro (Alpeteshi)	Nigeria, Ghana	Palm wine	Yeasts

Lactic acid bacteria (LAB) particularly *Lactobacillus* are involved in the fermentation of many African starchy foods. (Fermentation of foods involving lactic acid bacteria is very common in Africa.) Table 16.6 further corroborates the role of LAB in food fermentation.

16.2.1 Production Procedures of Foods

In Africa, the raw materials used for the production of indigenous fermented foods include cereals, root crops, (especially cassava) milk, and vegetables. However cereal and cassava based foods are usually large in number compared to food products from other raw materials (1). In Africa, fermentation of food is carried out through traditional, village art methods (2). Processing usually involves either soaking of raw materials in water contained in a fermenting vat, usually clay pots, for a period of time or an initial size reduction of the raw material by grating or milling in the wet form before being allowed to ferment. These two fermentation approaches have been described by Oyewole and Odunfa (9) as traditional submerged and solid-state fermentation methods.

Table 16.4
Fermented vegetable proteins in West Africa (2)

Product	Area of Production	Substrate	Microorganisms Involved
Iru	Southwestern Nigeria	Locust bean (*Parkia biglobosa*), Soybean (*Glycine max.)*	*Bacillus subtilis* *B. licheniformis*
Ogiri	Southwestern Nigeria	Melon seed (*Citrullus vulgaris*)	*Bacillus sp. (predominant)* *Proteus*, *Pediococcus*
Ogiri-nwan	Southeastern Nigeria	Fluted pumpkin bean (*Telfairia occidentalis)*	*Bacillus sp. (proteolytic)*
Ogiri-Igbo (same as ogiri-agbor)	Southern Nigeria	Castor oil seed (*Ricinus Communis*)	Various Bacillus sp; *B. subtilis, B. megaterium* *B. firmus*
Ogiri-Saro	Sierra Leone	Sesame seed *(Sesamum indicum*)	*Basillus* sp.
Ugba/Apara	Eastern Nigera (Igo); Southwestern Nigeria (Egabados)	Oil bean *(Pentaclethra macrophylla)*	*Bacillus subtilis* *Micrococcus* sp.
Kawai	Sudan	*Cassia obtusifolia*	*B. subtilis*

Table 16.5
Fermented animal proteins of Africa (2,8)

Product	Area of Production	Substrate	Microorganisms Involved
Maziwa Lala	East Africa	Milk	*Streptococcus lactis* *S. thermophilus*
Nono (Milk curd)	Northern part of West Africa	Milk	Lactic acid bacteria
Guedi	Senegal	Fish	Not known
Bonone (Stink fish)	Ghana	Fish	Not known
Leban (Sour milk)	Morocco	Milk	*Lactic streptococci* *Leuconostoc lactis* *L. cremoris*
Wara	West Africa	Milk	*Lactococcus lactis* *Lactobacillus* sp
Ergo	Ethiopia	Milk	*Lactobacillus* sp *Lactococcus sp*

There are numerous reports (2,10) on the methods of preparation of African fermented foods. Figures 16.1 to 16.6 show the flow charts for the preparation of some very common fermented foods in the continent of Africa.

16.2.2 Problems Associated with African Fermented Food

Because the production of fermented foods in Africa is usually a traditional family art, some problems are associated with the food products. The problems range from microbiology in processing, production environment, process control and nutritional to toxicological status (11).

Table 16.6
Food fermentations that use Lactic Acid Bacteria

Product	Typical LAB Involved
Cheeses and Fermented Milks	*Lactococcus lactis* subsp. *lactis*
	L. lactis subsp. *cremoris*
	L. lactis subsp. *lactis* var. *diacetylactis*
	Streptococcus thermophilus
	Lactobacillus helveticus
	Lb. acidophilus
	Lb. casei
	Lb. delbrueckii subsp. *bulgaricus*
	Leuconostoc cremoris
Meat Fermentations	*Lb. plantarum*

	Lb. brevis
	Lb. platarum
	Lb. fermentum
Indigenous Fermented Foods	Various LAB

16.2.2.1 Microbiology of Process

Much of the information on the microbiology of the process of production is faulty. The following factors make it difficult to assure a consistently contamination free environment for fermentation:

1. Unknown microbial composition of the inocula
2. Identification of type
3. Identity of the contaminating microbes

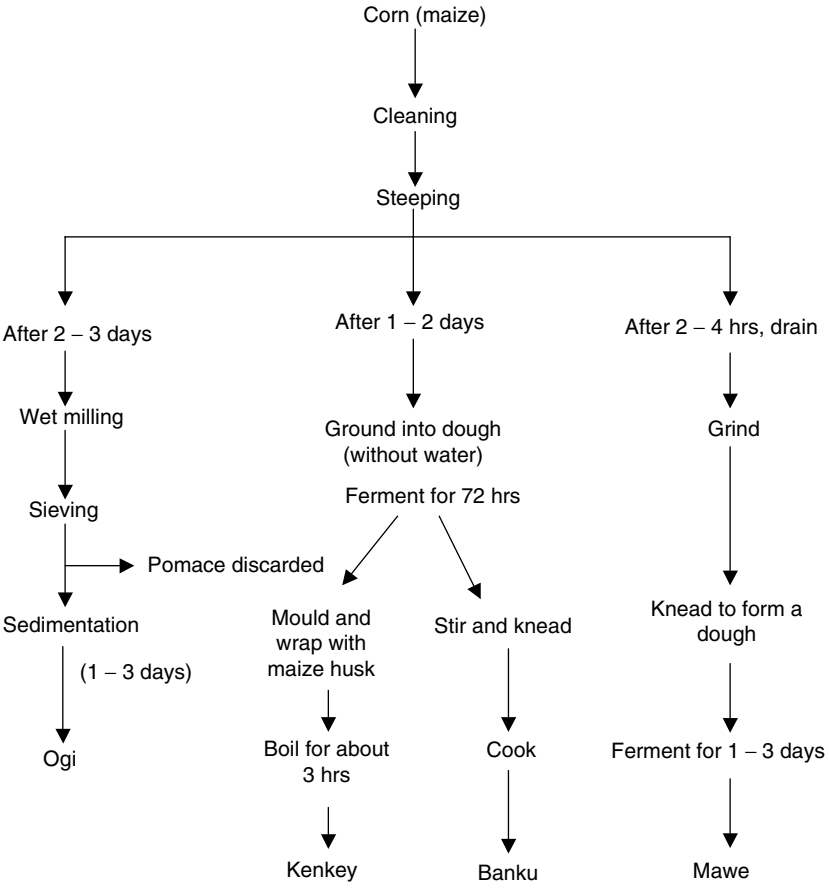

Figure 16.1 Flow chart for the preparation of Ogi, Kenkey, Banku, and Mawe

4. Age and purity of each culture
5. The predominant organisms
6. The conditions of pH
7. Temperature
8. Ionic strength
9. Information on food enhancing microbial performance in fermentation

16.2.2.2 Production Environment

Since the production of the foods is basically a traditional household practice, the processing environment is highly unpredictable because the equipment used is rudimentary (e.g., leaves, clay pot, calabash, baskets, earthenware, and cloth). The hygienic status of the handlers, equipment, and materials for preparation (especially water) is usually not checked. A tropical climate (especially the temperature and humidity) cannot be said to be optimum for fermentation and storage purpose.

16.2.2.3 Process Control

The practice of good process control is difficult to maintain because the processing procedures do vary from one ethnic group to another. Fermentation periods are sometimes

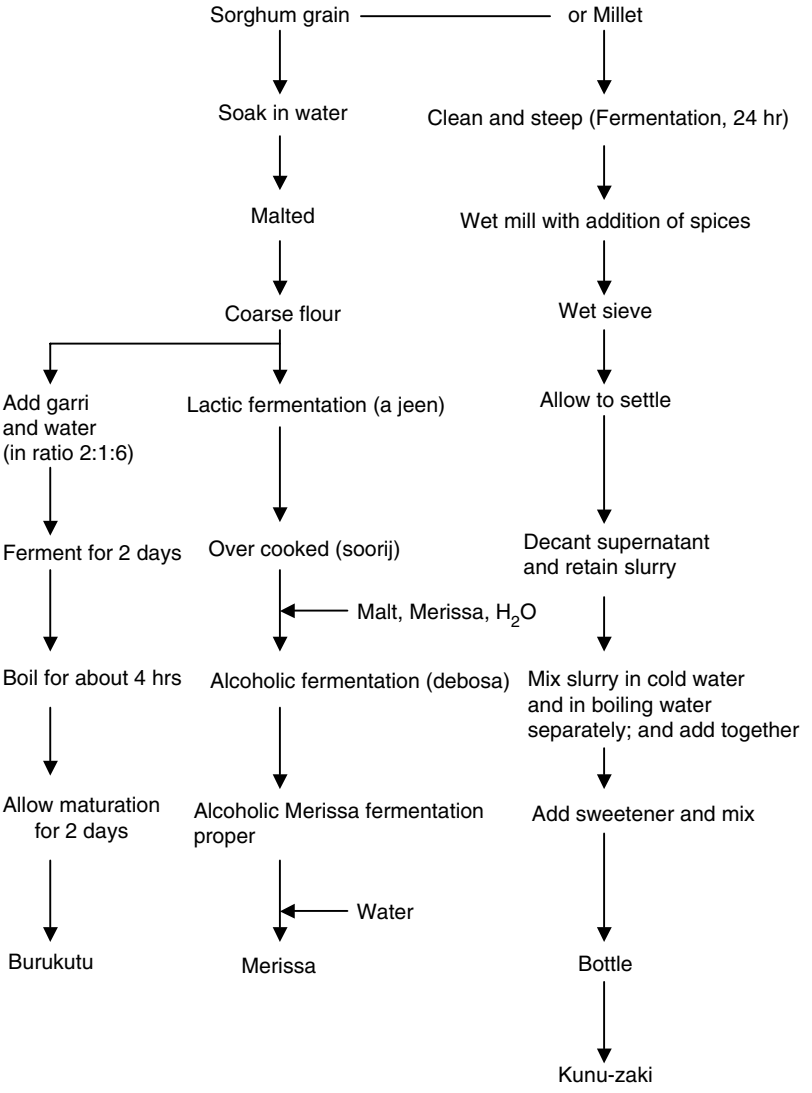

Figure 16.2 Flow chart for the preparation of Burukutu, Merissa, and Kunu-Zaki

chosen according to human judgement. The quality and quantity of water and substrate used are not usually regulated or standardized. Heat processes are not controlled or measured. The effect of all these factors is a finished product with inconsistent quality.

16.2.2.4 Nutritional and Toxicological Status

The dearth of information on the effect of fermentation on the nutritional and toxicological status of the traditional foods in Africa is a major problem, because the consumers are usually unaware of the actual nutritional quality and level of toxicity of the foods except the organoleptic attributes. Information guiding the consumers on the type and possible degree of danger posed by the consumption of fermented foods is not available.

Figure 16.3 Flow chart for the preparation of Kisra, Injera, and Bogobe

16.3 TAXONOMY OF FERMENTING ORGANISMS

In the fermentation of indigenous foods, the organisms usually encountered are the lactic acid bacteria, yeasts, and molds. The type of predominant organisms present depends on the type of fermentation required for the production of the finished food product. If the food product is sour, the type of fermentation is usually lactic fermentation with LAB being the predominant fermenting organisms. However, if the final product is alcoholic in nature, the fermenting organisms usually include the yeasts.

The taxonomy of LAB has been well investigated (12). Several new genera have been added. Furthermore, the genera *Lactococcus, Leuconostoc, Lactobacillus,* and *Pediococcus*, as the classical groups of organisms involved in food fermentation are evolutionary well defined. The genera are gram positive and are located in the so called *Clostridium* branch

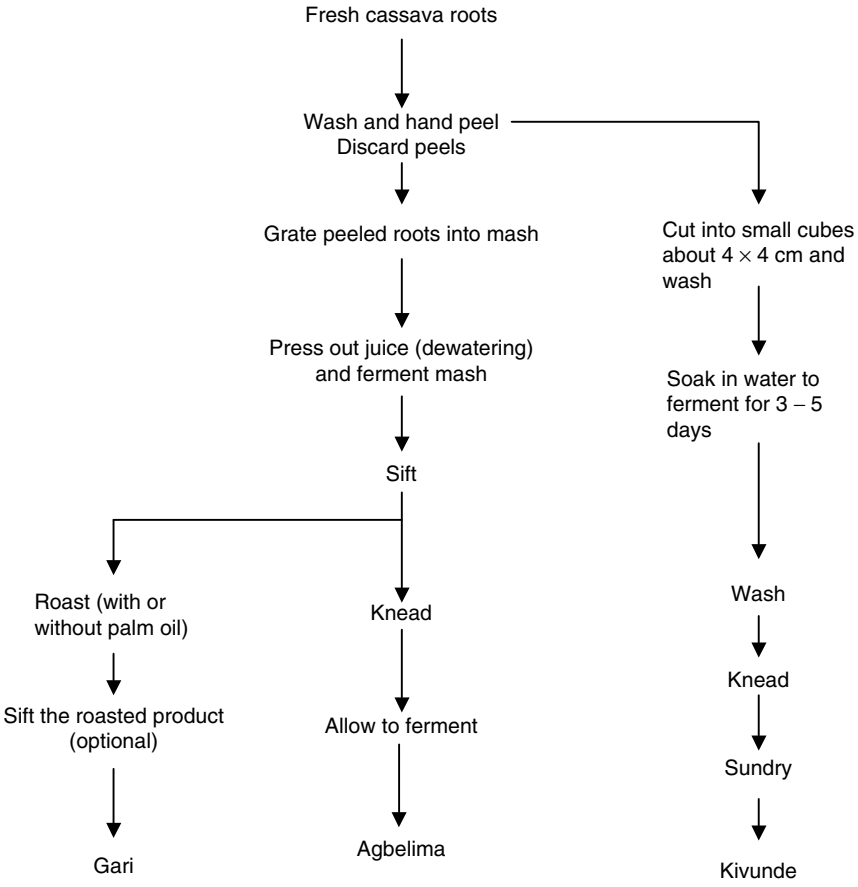

Figure 16.4 Flow diagram for the preparation of Gari, Agbelima, and Kivunde

of evolution (13), which is characterized by a low % G+C in their DNA (<55%). One group, the bifidobacteria, belongs to the high % G+C group of the *Actinomyces* branch. The LAB are characterized by a fermentative metabolism and derive their energy from the breakdown of sugars into metabolites, among which lactic acid is the most paramount. The homo fermentative LAB produce more than 85% of lactic acid while the hetero fermentative organisms produce less than 50%.

While information is available in Africa on the type and identity of organisms useful in traditional food fermentation, the methods for the identification of the organisms are usually inadequate and in most cases give wrong and confusing identity of strains. Very few works make use of more reliable and comprehensive identification methods to ensure correct species identification. Olasupo et al. (8) reported the identification of the lactic strains associated with the fermentation of some Nigerian fermented foods. The study showed that *Lactobacillus fermentum* was the predominant organism in the fermentation of wara, nono, iru, and kunun zaki. Similarly Amoa-Awua (6) identified different species of *Bacillus*, lactic acid bacteria, yeasts, and molds during the fermentation of Agbelima, a Ghanaian fermented cassava product.

In mawe, a Benin fermented maize product, Hounhouigan et al. (14) identified the predominant lactic organisms as *Lb. fermentum* (biotype cellobiosus), *Lb. fermentum,* and

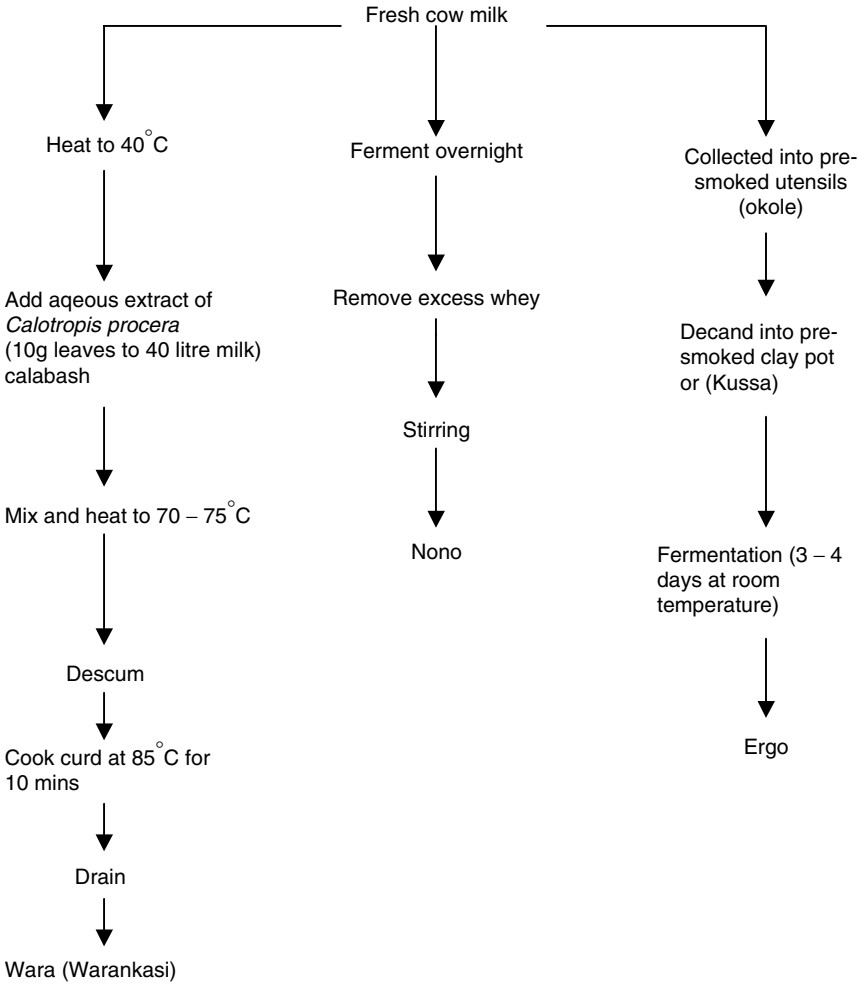

Figure 16.5 Flow Chart for the preparation of Nono, Ergo, and Wara

Lb. brevis while yeasts dominating the fermentation were *Candida* species which include *C. krusei* mainly, *C. kefyr* and *C. glabrata. C. Krusei* and *S. cerevisiae* were found together with lactic acid bacteria during the fermentation of busaa, a Kenyan opaque maize millet beer (15). Odunfa and Adeyele (16) found *Lactobacillus sp.* and *Lactococcus lactis* together with *C. krusei* and *Debaryomyces hansenni* during the fermentation of ogi-baba, a West African fermented sorghum gruel. Adegoke and Babalola (17) found *S. cerevisiae* together with *L. fermentum, L. brevis,* and *Enterococcus faecalis* in the fermentation of ogi, while Akinrele (18) found that corynebacteria *S. cerevisiae, E. cloacae,* and *L. plantarum* were predominant organisms in ogi. Halm et al. (19) found obligately hetero fermentative lactobacilli closely related to *L. fermentum,* and *L. reuteri*, in association with yeasts dominated by *Candida sp.* and *Saccharomyces sp.* in kenkey, a Ghanaian fermented maize dough.

The taxonomy of fermenting organisms in local food fermentation in the continent of Africa indicated close protobiotic association of lactic acid bacteria and yeasts, especially in cereal based foods.

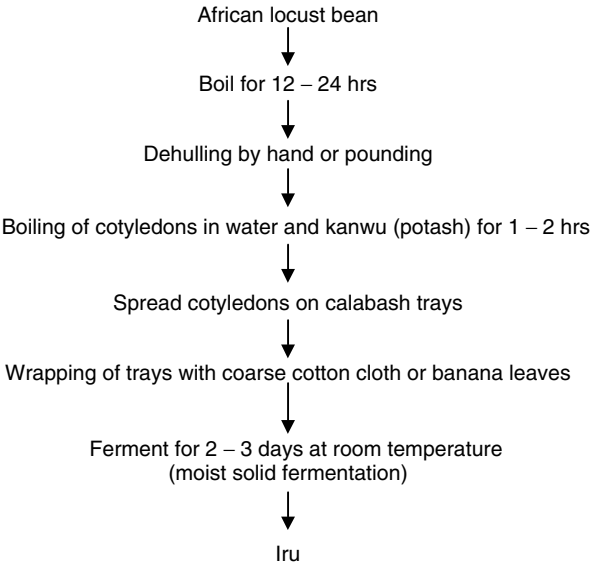

Figure 16.6 Flow Chart for the preparation of iru

16.4 POTENTIAL OF FERMENTATION FOR THE REDUCTION OF MICROBIAL RISKS AND SHELF LIFE IMPROVEMENT

16.4.1 Antimicrobial Factors and Inhibition of Undesired Microorganisms

Food fermentation has been practiced and developed over several thousand years, first and foremost for the prevention of spoilage and the extension of shelf life of foods. Lactic fermented foods serve as special examples of safe and wholesome foods, and the production of lactic acid during fermentation results in acidification of the foods to pH values generally <4.2. This constitutes a major preservation and safety factor (3). In addition, several other antimicrobial metabolites (e.g., acetic acid, hydrogen peroxide, and bacteriocins) may also be produced during fermentation and thereby further contribute to the safety of lactic fermented foods (20). As is illustrated in Table 16.7, Gram-negative bacteria, including pathogens, putrefactive, and spoilage bacteria, are particularly inhibited by organic acids.

Bacteriocins of LAB and their possible role in food safety assurance have become a major focal point in studies toward food safety improvement. Nisin, a bacteriocin produced by some *Lactococcus lactis* strains and hitherto the one only approved for commercial use, is probably the best known and most studied bacteriocin. The possibility of using nisin producing strains of *Lact. lactis* subsp. *lactis* for protection of food against pathogenic organisms was first suggested by Hirsch et al. (21). They used nisin-producing strains that successfully prevented gas production ("late blowing") by clostridia in certain cheese varieties, and were able to show that nisin producing strains could also prevent the growth of *Staphylococcus aureus* in cheese. In addition, some other bacteriocinogenic LAB have been shown to effectively inhibit the growth of Gram-positive pathogens and toxinogens such as *Listeria monocytogenes, Staphylococcus aureus, Bacillus cereus,* and different *Clostridium* app. (see Table 16.8), even under *in situ* conditions (20). Information

Table 16.7
Metabolic products of lactic acid bacteria with antimicrobial properties (20, modified)

Product	Main Target Organisms
Organic acids	
Lactic Acid	Putrefactive and Gram-negative bacteria, some fungi
Acetic acid	Putrefactive bacteria, clostridia, some yeasts, and fungi
Hydrogen peroxide	Pathogens and spoilage organisms, especially in protein rich foods
Enzymes	
Lactoperoxidase system with H_2O_2	Pathogens and spoilage bacteria (milk and dairy products)
Low molecular weight Metabolites	
Reuterin (3-OH-Propionaldehyde)	Wide spectrum of bacteria, molds, and yeasts
Diacetyl	Gram-negative bacteria
Fatty acids	Different bacteria
Bacteriocins	
Nisin	Some LAB and Gram-positive bacteria, notably endospore formers
Other	Gram-positive bacteria, inhibitory spectrum according to producer strain and bacteriocin type

available in the literature generally shows a low frequency (from 0.6% to 22%) of bacteriocinogenic strains among food associated LAB (Table 16.9). A recent study by Olasupo et al. (22) indicates the frequency of bacteriocinogenic LAB in African fermented food within the same range (Table 16.9). A bacteriocin-producing strain of *Enterococcus faecium* isolated from wara, a traditional fermented diary product from West Africa, was found to produce a heat stable bacteriocin (enterocin) that showed antimicrobial activity against *Listeria monocytogenes* and *Enterococcus faecalis* (23). A *Lactococcus lactis* strain also isolated from wara, was found to produce a bacteriocin, structurally similar to nisin, the first to be confirmed for a traditional product from Africa (24). The bacteriocin inhibited notable food borne pathogens such as *Listeria monocytogenes* and *Bacillus cereus*.

Fermented dairy and meat products serve as examples of protein rich foods with extended shelf life and safety resulting from lactic fermentation. Olasupo et al. (25) reported extension of shelf life of agidi (solid form of ogi, the most common weaning food in Nigeria) from 6 days to 11 days at room temperature using bacteriocin-producing *Lactobacillus* starter in the fermentation of the food product.

Hounhouigan et al. (14) reported that lactic acid fermentation for the production of máwe (a fermented cereal of Bénin), reduced the Enterobacteriaceae population below the detection level ($<\log_{10}1.7$ cfu/g) after 24h of fermentation.

16.4.2 Food Borne Pathogens

Diarrheal diseases have frequently been indicated as a major cause of child morbidity and mortality in developing countries; the main aetiological agents of which include *Escherichia coli* (ETEC, EHEC, and EPEC strains), *Shigella, Salmonella, Campylobacter jejuni, Vibrio cholerae,* protozoa (e.g., *Entamoeba histolytica),* and rotavirus. These food borne infections often result from the fecal contamination of foods (26,27,28). The view of Metschnikoff, at the beginning of the century, that fermented foods such as yogurt could inhibit enteropathogens has been confirmed also for traditional lactic fermented foods.

Table 16.8
Bacteriocins of LAB with activity against Gram-positive food-borne pathogens (adapted from Holzapfel and Olasupo, in press)

The inhibition of food borne pathogens in lactic fermented cereal gruels have been highlighted by various workers (29,30,31,32). Fermented mixtures of water and whole flour of either maize or sorghum with a final pH of 3.8 and a lactic:acetic acid ratio of 9:1 were found to inhibit Gram-negative intestinal pathogens such as enterotoxigenic *Escherichia coli, Campylobacter jejuni, Shigella flexneri,* and *Salmonella typhimurium* (33). Lactic fermentation of cereal gruels was shown to inhibit *Salmonella typhimurium, Campylobacter jejuni, Yersinia enterocolitica,* ETEC, EPEC, *Shigella flexneri,* and *Shigella sonnei* (30,32,34,35). Other examples of inhibition of fermented foods include salmonellae, *E. coli, Shigella sonnei,* and *Staph. eureus* in rice based weaning food (36), and salmonellae, *E. coli,* and *Staph. eureus* in dairy products (37,38,39,40). Most of these antimicrobial activities may be termed 'unspecific' and are related to acidification and one or more of the factors summarized in Table 16.7. Antimicrobial activities against bacteria causing diarrhea have been related to LAB involved in fermentation of uji, a Kenyan indigenous fermented cereal gruel (41). Several studies have shown that pH values <4.0 will inhibit diarrhea causing pathogens in ready-to-eat fermented food products (42).

16.4.3 Inhibition of Toxin Production

Microbial toxins in a food usually result from growth and metabolic activities of toxinogenic bacteria and molds. Inhibition or elimination of these organisms either in the raw materials, or in the final product, may prevent the formation of these toxins. A number of reports indicate the feasibility of fermentation for reducing or preventing growth or metabolism of toxin producers.

Svanberg et al. (33) observed that a sustained inhibition of *Staphylococcus aureus* during fermentation of cereal gruels at $pH<4.0$ had been supported by an additional factor, probably a bacteriocin. Acid production and other antimicrobial metabolites have been suggested by Mbugua and Njenga (41) as inhibiting factors against *Staph. aureus* and some Gram-negative enteropathogens during uji fermentation. During lactic fermentation of cereal gruel, the level of *Staph. aureus* was strongly reduced at pH values <4.16 (30). Yusof et al. (36), showed the decisive importance of a high initial level of LAB for successful inhibition of *Staph. aureus* in a rice-based weaning food. Inhibition of *Staph. aureus* by LAB in typical fermented foods of industrialized countries has been sufficiently documented, both for fermented dairy products (37,39) and fermented meat products (43,44,45).

Even in nonfermented ready-to-eat foods such as salads, mere inoculation with *Lb. Plantarum* strains resulted in a decline of *Staph. aureus,* especially at refrigeration temperatures (46).

The inhibition of other bacterial toxinogens by LAB during fermentation has been particularly studied in fish and seafood with regard to *Bac. cereus* (34,46) and *Cl. botulinum* (48).

In contrast to antibacterial interactions of LAB, their antimycotic and antimycotoxinogenic potential – i.e., inhibition of either mold growth or metabolic activities resulting in mycotoxin production – has received relatively little attention thus far. Yet a number of reports strongly indicate the potential of *Lactobacillus* spp. (e.g., *Lb. acidophilus, Lb. delbrueckii ssp. bulgaricus, Lb. casei,* and *Lb. plantarum*), and *Streptococcus thermophilus* to inhibit mold growth and mycotoxin production. Special attention was given to inhibition of aflatoxin produciton and aflatoxinogenic molds such as *Aspergillus parasiticus* and *Aspergillus fumigatus* and, to a lesser extent, of *Aspergillus flavus* (49,50). Equivocal results were obtained with *Lactococcus lactis,* also suggesting stimulation effects on molds under particular conditions of pH and substrate composition (49). The mechanism of the inhibition of aflatoxin synthesis seems to be relatively complex and may not be explained only by low pH, depletion of nutrients, and microbial competition. It rather appears that lactic acid and other LAB metabolites (probably low molecular weight, heat stable compounds) play an important role (51). Relevant aspects have been excellently reviewed by Gourama and Bullerman (52).

16.5 THE FATE OF MICROBIAL TOXINS IN FERMENTATION

Food invaded by toxinogenic bacteria or fungi constitute a potential health risk. Fermentation may however contribute to toxin degradation (detoxification) during processing and thereby assist to reduce possible toxic safety risks. The role and potential of fermentation in reducing microbial toxins in food raw materials are discussed in what follows.

16.5.1 Toxins of Bacterial Origin

Because of their frequent production during fermentation, the biogenic amines (BA) probably constitute the most important bacterial metabolites that may pose a safety risk in traditional fermented foods. For this discussion they are considered together with typical bacterial toxins. Although the lactic fermented foods are generally considered safe, these fermentations are regularly accompanied by the production varying levels and types of BA, although generally at a low rate. The effect of the fermentation process on BA in such foods has been highlighted earlier (53,54). One of the few reports on biogenic amines in traditional fermented foods is the study by Nout et al. (53) on the presence of biogenic amines in kenkey, a Ghanaian fermented maize product. The study showed the level of biogenic amines in kenkey to be quite low (<60ppm). These levels however, increased up to tenfold when the food product was improved by addition of cowpeas. The addition of red cowpeas increased the level of biogenic amines in kenkey to a total concentration of ca.200ppm (mainly cadaverine and tyramine) and, with the addition of white cowpeas to ca.500ppm (mainly putrescine and tyramine). These increases were attributed to the presence of precursor amino acids in the respective cowpea varieties. In addition, polyphenols in the seed coats may have inhibited the activity of monoamine oxidases. Nout et al. (53) employed strains of *Lb. plantarum, Lb. confusus, Lb.brevis,* and *Ped. pentosaceus*, previously isolated from kenkey. However, no pure culture studies on biogenic amine production in traditional fermented foods have been conducted yet. Prolonging the cooking process during kenkey production may contribute only slightly to lowering of the amine levels (53).

Studies on the biogenic amine formation in Sauerkraut have showed that pure culture inoculation with *Lb. plantarum* significantly reduced putrescine formation during fermentation (54).

The report of Westby et al. (55) also showed histamine toxicity to be associated with poorly handled scombroid fish, but this has not been reported in fermented fish products.

Recent studies (56) have however showed the potential of some LAB strains to detoxify such BA by the action of monoamine oxidases.

Very little, if any, attention has thus far been given to the fermentative degradation of bacterial toxins. Their sensitivity to other factors such as heat, pH, and enzymes has however been the subject of extensive studies. This may be explained by the fact that, in contrast to mycotoxins, raw materials for fermentation are generally not contaminated with bacterial toxins.

16.5.2 Mycotoxins

Mycotoxins, especially aflatoxins, fumonisins, and citrinin, are a major risk factor in stored cereals and legumes, typical raw materials for fermented foods in Africa (3,55,57). Even with strict regulations on maximum tolerance levels, control mechanisms in developing countries are insufficient and very difficult to apply at the household and small scale levels to any significant extent. Increasing, although still controversial, reports indicate that some mycotoxins may be degraded or inactivated during fermentation of cereals and legumes. Recent information has been reviewed by Westby et al. (55) and is summarized in Table 16.10, indicating some of the effects of fermentation on the aflatoxin content of contaminated raw materials. The reduction of aflatoxin during the preparation of some traditional Nigerian fermented foods has been shown by Ogunsanwo et al. (58,59). They showed that, at low levels (16.4 ppb), aflatoxin B1 was completely destroyed in watermelon seeds during 4 days of fermentation in the preparation of ogiri (58). In addition, they found that fermentation of soya bean flour to produce soyogi reduced the initial aflatoxin B1 level of 0.3ppm (59). In a study by Adegoke et al. (60), >70% reduction was observed in the aflatoxin B1 level during the fermentation of maize and sorghum flour for the preparation of ogi, a popular weaning food in West Africa.

In contrast to the mentioned reports, Jespersen et al. (61) could not detect any decrease in the aflatoxin level during dough fermentation for kenkey preparation. Kpodo et al. (57) showed aflatoxins and citrinin to occur frequently in kenkey, with levels as high as 289 μg/kg for total aflatoxins and 584 μg/kg for citrinin, but only low levels of ochratoxin A and neither zearalenone nor α-zearalenol. Aflatoxin levels were reported to increase significantly during the initial stages of fermentation. However, traditional cooking of the maize dough for 3h was reported to result in a 80% reduction of aflatoxin B1 and G1 levels, 35% in the B2 and G2 levels, and a disappearance of citrinin.

Studies in the Institute of Hygiene & Toxicology in Karlsruhe, Germany (see Table 16.11) have shown the ability of single LAB strains isolated from Ghanaian aflata (for kenkey processing), to significantly reduce the amount of *Alternaria* toxins under defined conditions. In addition, some authetic LAB strains, and some isolated from traditional fermented Turkish foods, studied on semisynthetic medium, have been shown to play a significant role in the reduction of patulin concentration by more than 60% (62).

A reduction of patulin and ochratoxin A has also been reported during the fermentation of cider and beer (55). Other mycotoxins, such as zearalenone, ochratoxin A, T-2 toxin, deoxynivalenol, and diacetoxyscirpenol, have been shown to be degraded significantly particular fermented foods. In view of these reports, the potential contribution of fermentation to improved toxicological safety of some food products seems promising and should not be ignored. For some fermentation, metabolic action of microorganims has clearly been shown to contribute to the reduction of mycotoxins in some raw materials. The mechanisms of mycotoxin reduction by fermenting organisms are still not sufficiently understood. It may be partly explained by (hydrolytic) degradation, partly by inactivation and partly by

Table 16.10
Examples of the reported effects of fermentation on mycotoxins in raw material (Westby et al., 1997)

Toxin	Raw Material/Product	Type of Fermentation	Naturally Contaminated/Spiked	Extent of Reduction
Aflatoxin	Maize/Kenkey	Lactic acid		None
Aflatoxin	Sorghum/ogi	Lactic acid	Natural with B1	12–16%
Aflatoxin	Wheat/bread	Yeast (dough)	Spiked with B1	19%
Aflatoxin	Milk/yoghurt	Lactic acid	Natural with M1	None
	Milk/kefir	Lactic acid	As above	Decreased
Aflatoxin	Milk/yoghurt	Lactic acid	Spiked with B1, B2, G1, G2 and M1	None
Aflatoxin	Melon seed/*ogiri*	*Bacillus* spp.	Natural with B1 and G1	Complete removal after 4 days
Aflatoxin	Peanut press cake/ pure mould cultures	*Neurospora sitophila* and *Rhizopus oligosporus*	Not stated	50% and 70% respectively
Aflatoxin	Maize/Ogi Sorghum/Ogi	Lactic fermentation	Natural with B1	Greater than 70%
Alternariol and Alternariol-Monomethylether	Pure culture isolates from kenkey	Lactic acid bacteria	Spiked laboratory media	Reduction greater than 50% by all tested strains

Table 16.11
Degradation of Alternaria toxins by LAB strains isolated from Aflata (for Kenkey production)

Strains	Reduction as % of Original	
	Alternariol	Alternariol-monomethylether
Lb. plantarum 91	24	43
Lb. fermentum 85	26	38
Ped. acidilactici 100	47	29
Lb. fermentum DSM 20174	37	59

The purified toxins were added to basal MRS medium. Incubation was at 30ºC and the Alternaria toxins were determined by HPLC. All tested LAB strains showed reduction of alternariol and alternariol monomethyl ether by more than 50%.

adsorption of the mycotoxin to the cellular surface. The best long term approach to the mycotoxins problem in fermented food products would obviously be the prevention of the contamination of the raw materials used in the preparation of such foods (63). This goal may however not be achieved in the foreseeable future, and other measures, including controlled fermentation and the use of specially selected starter cultures, may contribute to an improvement in the reduction or elimination of mycotoxins in fermented foods.

16.6 NATURALLY OCCURING TOXINS AND ANTINUTRITIVE FACTORS IN FOOD FERMENTATION

16.6.1 Naturally Occurring Toxins

16.6.1.1 Cyanogenic Compounds in Cassava

Linamarin and lotaustralin are cyanogenic glucosides typically found in cassava, and may because of severe intoxications associated with the consumption of raw or unprocessed cassava (3). In Africa, methods of cassava processing usually involve peeling, soaking, heaping (a solid-state fermentation, with mainly molds involved) sun drying, and grating, typically followed by submerged (soaked) lactic fermentation. In addition to the endogenous linamarinase enzymes present in cassava, detoxification is mainly achieved by microbial action. Microorgnisms important in cassava fermentation include *Lactobacillus* (25,64), *Bacillus* (65,66), and yeasts and molds (66,67). The role of fermentation in the detoxification of cassava has been demonstrated by several workers with particular reference to traditionally processed fermented food products of Africa. Amoa-Awua (6) reported on significant detoxification of cassava during the processing of cassava into Ghanaian agbelima (Table 16.12). The cyanogenic glucosides in cassava (119.3 mg/kg) were completely removed by the fermentation process. Observations by Vasconcelos et al. (68) on gari preparation indicate the breakdown of linamarin in grated roots to be primarily due to the endogenous linamarinase activity. Cellular damage during grating was shown to release linamarase. Further clarification on the role of fermentation was provided by Westby and Choo (69), showing microbial growth to be essential for efficient cyanogen reduction in soaked cassava roots.

The use of selected strains of *Lb. plantarum* starter culture for controlled submerged fermentation of cassava into typical Tanzanian kivunde, was found to significantly enhance detoxification, (Table 16.13) as compared to spontaneous and back slopping operations

Table 16.12
Effect of inoculum on the cyanogenic glycosides content (mg/kg) of cassava during fermentation (6)

Sample	Cyanogenic Potential[b]	Cyanogenic Glucosides[c]	Cyanohydrins	Free Cyanide[d]

(5). Mechanisms of cyanogen reduction and the role of different microorganisms during fermentation of cassava, have been reviewed by several workers, and notably by Westby and coworkers (69,70,71,72).

The most important aspects regarding the different mechanisms and potential improvements are summarized in Table 16.14.

Table 16.14
Summary of mechanisms of cyanogen reduction during fermentation of cassava (Westby et al., 1997, modified)

Type of Fermentation	Role of Fermentation in Reducing Cyanogens	Mechanism of Cyanogen Reduction	Potential Improvements to Fermentation	Other Potential Improvements
Acidic fermentation of grated roots	None	-Mechanical grating brings linamarase into contact with linamarin -Acid stabilises cyanohydrin	-None required for linamarin hydrolysis -Organisms with hydroxynitrile lyase activity	-Ensure varieties have high linamarinase activity -Ensure efficiency of grating -Develop suitable post fermentation processing techniques to remove cyanohydrins plus HCN
Acidic fermentation of soaked roots	Major	Microorganisms cause cellular breakdown which facilitates leaching and probably contact between linamarin and endogenous linamarase	-Use of conditions favourable to growth of microorganisms with ability to degrade cellular structure and linamarin -Potential use of starter cultures with cell wall degrading activity -Use of microbes with hydroxynitrile lyase activity	-Ensure varieties have high linamarase activity -Ensure sufficient time is left for leaching
Solid substrate fermentation	Major	Microorganisms cause cellular breakdown which facilitates contact between linamarin and endogenous linamarase	-Use of conditions favourable to growth of microbes with ability to degrade cellular structure -Potential use of cultures with cell wall and linamarin degrading activity	-Ensure varieties have high linamarase activity -Ensure sufficient time for diffusion of HCN

The purified toxins were added to basal MRS medium. Incubation was at 30°C and the Alternaria toxins were determined by HPLC. All tested LAB strains showed reduction of alternariol and alternariol monomethyl ether by more than 50%.

16.6.2 Antinutritive Factors

The role of fermentation in the reduction of antinutritional factors in traditionally fermented foods from cereals and legumes, has been well documented (3,31,42,73,74,75,76). However, most of these reports indicate only a limited reduction of these undesired factors. Some of this information is highlighted in what follows.

16.6.2.1 Phytic Acid

Phytate (phytic acid) is a typical component of cereals, legumes, and some roots and tuber crops used in the preparation of such foods as garri, ogi, and iru. Its presence may reduce the bioavailability of iron and other minerals in foods and also result in reduced solubility and digestibility of proteins. The approximate phytate content of maize, millet, sorghum, and cowpeas on a dry matter basis (77) is presented in Table 16.15. Phytases hydrolyze phytate into lower inositol phosphates and are present in most cereals (78). These enzymes are activated during germination (e.g., during the soaking process in traditional household level processing) and fermentation. Phytate was shown to be completely hydrolyzed after fermentation of germinated white sorghum and as a result the amount of soluble iron was found to be strongly increased (79). The reduction of phytate by lactic acid fermentation has also been reported in maize (80), pearl millet (81,82), germinated finger millet (83), and in Indian idli (84). Similarly, Reddy and Salunkhe (85) observed almost complete elimination of phytate phosphorus within an 8 hr fermentation of rice (Table 16.16).

Information on the role of fermentation in phytate reduction for traditional African commodities is relatively sparse. Aderibigbe and Odunfa (86) reported on the contribution of fermentation to phytate reduction, but, did not find any phytase activity associated with the

Table 16.15
Approximate phytate content of sorghum, maize, millet, and cowpeas on a dry matter basis (77)

Product	Range (%)
Sorghum	0.57–0.96
Maize	0.44–1.2
Millet	0.85–1.1
Cowpeas	0.89–1.5

Table 16.16

Control, raw	1.89	0.97	0.00
Control, soaked In water 2h	1.96	0.65	32.99
Fermented:			
4h	1.75	0.07	92.78
8h	1.79	0.00	100.0

Bacillus spp. involved in the fermentation of African locust bean *Parkia biglobosa* for the preparation of iru or dawadawa. However, Eka (87) observed appreciable reduction in phytic acid during the fermentation of locust bean to produce iru (dawadawa) (see Table 16.17). Studies carried out at the Institute of Hygiene and Toxicology, Federal Research Centre for Nutrition in Karlsruhe, Germany on strains isolated from Ghanaian lactic fermented cereals and cereal–cowpea mixtures revealed this ability to be relatively rare among pure cultures. The HPLC analysis for quantification, showed that some *Lb. Plantarum* strains were, however, able to significantly reduce the phytic acid concentration in a synthetic medium containing sodium phytate after incubation at 37ºC for 120hrs. Enzymes of LAB responsible for such degradation may be acid phosphatases.

16.6.2.2 Tannins

As a component of cereals and legumes, tannis interact with proteins, and thereby inactivate digestive enzymes and decrease protein digestibility. Little has thus far been reported on their fermentative reduction in traditional African foods. Relative to other processing steps, (e.g., dehulling and cooking), microbial metabolism during fermentation does not appear to contribute significantly to tannin degradation. The underlying mechanisms, however, are still insufficiently understood (84).

16.6.2.3 Oligosaccharides (Flatus-producing Sugars)

Cereals and especially legumes contain oligosaccharides such as raffinose, stachyose, and verbascose, which may cause flatulence, diarrhea, and indigestion. Table 16.18 shows the typical levels of these oligosaccharides in legumes. These oligosaccharides, as members

Table 16.17

of the raffinose family, are usually resistant to cooking and other small scale processing steps, and possess α-galactosidic bonds which may be hydrolyzed by α-galactosidases produced by a number of molds and by bacteria associated with the digestive tract and with fermented foods. The role of fermentation in the degradation of these oligosaccharides has been well reported. According to Shallengerger et al. (88), stachyose was gradually hydrolyzed by fermenting molds, e.g., *Rhizopus oligosporus* during tempe production. However, the tempe molds could not utilize sucrose and raffinose (89).

The effect of fermentation of oligosaccharides has been well highlighted by the work of Odunfa (90). The study showed significant reduction or elimination of oligosaccharides such as sucrose, raffinose, and stachyose in fermented locust bean (iru) (see Table 16.19).The typical yogurt bacteria *(Lb. bulgaricus* and *Streptococcus thermophilis)* have been shown to reduce the stachyose content of yogurt produced from soy milk by almost 27% (91). In a related study on LAB strains isolated from fermented maize products in Ghana (92), showed the majority of the *Lb. plantarum* strains to ferment raffinose (Table 16.20).

No. 91: from Agbelima, after cooking.
No. 100: from Aflata (for Ga-Kenkey) after fermentation.

16.6.2.4 *Protease Inhibitors*

Increased availability of essential amino acids including lysine, leucine, methionine, isoleucine, and tryptophan has been reported to be associated with lactic acid fermentation of cereal porridges and of Ghanaian kenkey (93,94). LAB strains isolated from lactic fermented foods in Ghana, showed varying abilities to degrade trypsin inhibitor under defined laboratory conditions, reaching up to 50% reduction by a *Leuconostoc* strain (3) (see Table 16.21). Furthermore, lactic acid fermentation has been reported to improve the *in vitro* protein digestibility of nontannin cereal grains (95,96) and of high tannin varieties (96,97). In children, the protein digestibility was reported to increase from 47% to 73% after lactic acid fermentation of whole grain nontannin sorghum flour that was prepared in Nasha, a traditional Sudanese fermented food for infants and young children (98). The effect of fermentation may be related to a reduction in proteinase inhibitors (e.g., trypsin inhibitor) in legumes, a reduction of tannins and of high levels of disulphide cross linkages in sorghum prolamine proteins (82,99).

16.7 FERMENTATION AND NUTRITIONAL IMPROVEMENT

Malnutrition and deficiency in micronutrients are highly prevalent and even increasing in different parts of African countries (101). It is estimated that more than 500 million people (mainly children) are underweight and even more are affected by micronutients deficiencies. Some reasons put forward to explain this situation include high population density, poverty, inadequate access to good sanitary and health facilities, and unavailability of adequate quantity and quality of food. Factors of immediate and direct influence on these nutritional problems are inadequate food consumption and diseases, which usually interact in a mutually reinforcing manner (Figure 16.7).

Several methods have been employed to improve the nutritional quality of cereals (73,76). These include genetic improvement, amino acid fortification, and supplementation with protein rich sources. Of equal importance is the application of various processing technologies to increase the bioavailability of indigenous nutrients in grains such as protein, starch, and minerals. However, numerous investigations have shown that one such household level technology that is widely used in many developing countries to improve the sensory and nutritional qualities of cereals and their products is fermentation.

The different ways by which fermentation process can affect the nutritional quality of foods include improving the nutrient density and increasing the amount of the bioavail-

Table 16.21
Degradation of trypsin inhibitor (TI) by lactic acid bacteria isolated from Aflata in Ghana (3)

Isolates	Reduction of TI (mg)	% Reduction
Lb. Plantarum 91	2.41	48.0

ability of nutrients. The latter may be achieved by degradation of antinutritional factors, predigestion of certain food components, synthesis of promoters for adsorption, and by influencing the uptake of nutrients by the mucosa (76).

Fermentation of cereals with pure yeasts or lactic cultures has been shown to increase the protein, amino acid, and free sugar contents of the fermented products (102,103,104,105). In the production of ogi with *Lactobacillus* sp. starter (103), considerable increase in protein content was observed in ogi fermented with starter cultures over the one fermented naturally (Table 16.22). Similarly, Odunfa et al. (104) recorded up to a threefold increase in the lysine content of ogi using a *Lb. plantarum* starter. Furthermore, Teniola and Odunfa (106) reported significant increase in lysine and methionine content of ogi fermented with lactic and or yeasts starters. [Figure 16.8(a) and Figure 16.8(b)].

The changes in B-group vitamins of cereals and cereal–legume blends during natural fermentation have been investigated (107,108,109). Table 16.23 shows that thiamin, riboflavin, and niacin content increased significantly during natural fermentation of cereals: sorghum, rice, Pearl millet, and finger millet. Similarly increase in vitamins content during fermentation of African locust bean for iru production (see Table 16.17) was reported by Odunfa (90). The increase or decrease of vitamins varied with the nature of raw materials, temperature, nature of microflora, length of fermentation, and determination methods of these vitamins.

In a program to improve the digestibility of protein in iru (a Nigerian fermented proteinaceous food used as condiment), Aderibigbe and Odunfa (86) identified proteases producing strains of *Bacillus* with promising potential in the breakdown of protein.

The proteases are hydrophobic in nature which is an ideal property for solid-state fermentation.

16.8 SCOPE FOR IMPROVEMENT OF FERMENTED FOODS

Traditional fermented foods are produced on the household scale in a majority of African countries. Growing industrialization and urbanization trends in these countries will however dictate the need for larger scale production of fermented foods having consistent quality. Furthermore, variation of the quality attributes of fermented foods to meet the demands of the complicated and varied palates of industrialized communities will eventually be

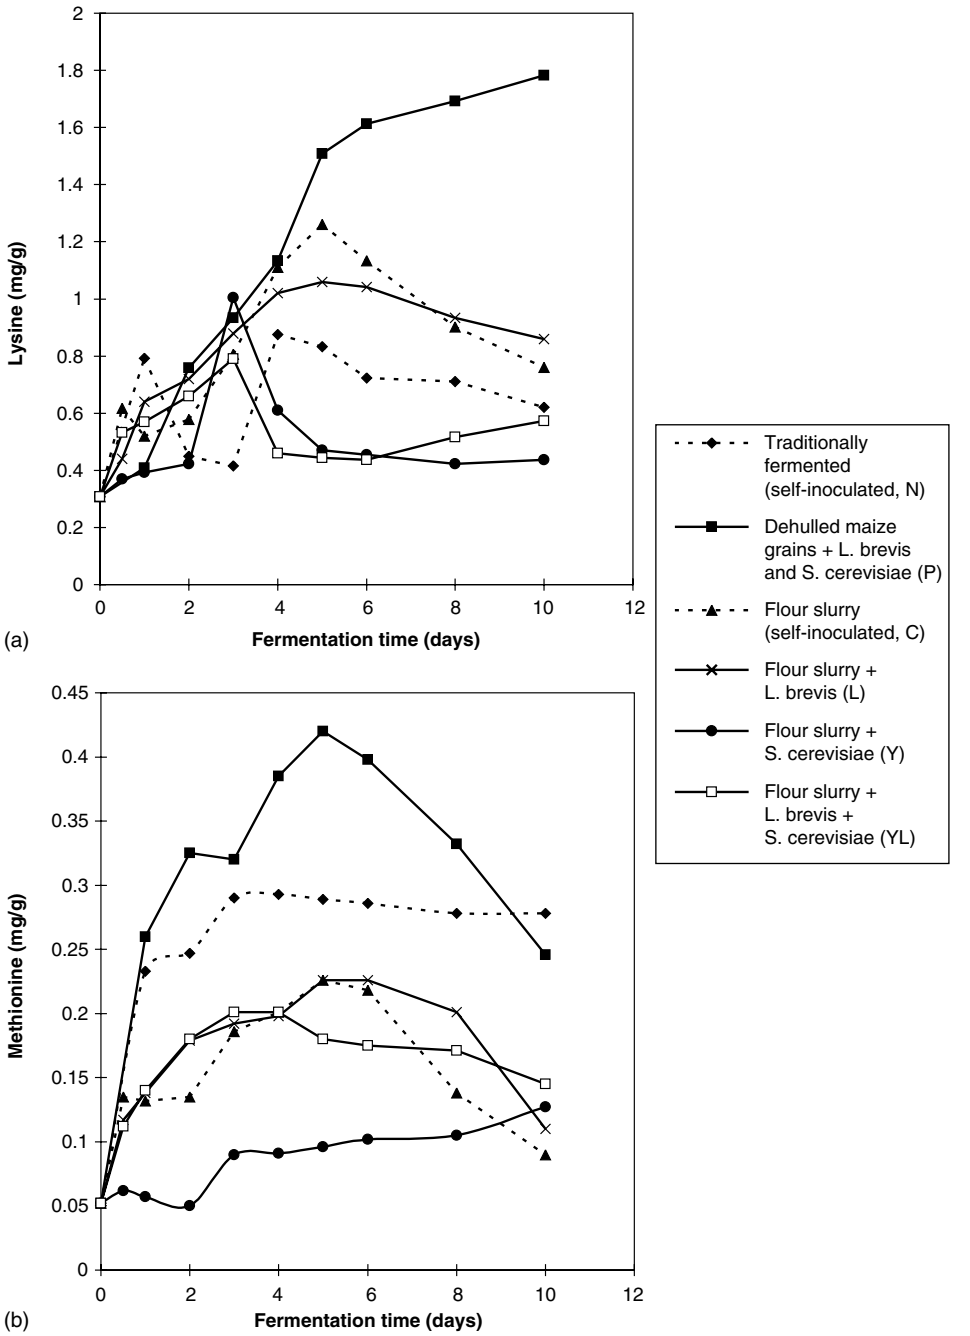

Figure 16.8 (a) Changes in lysine levels during ogi fermentation with different starter cultures. (b) Changes in methionine levels during ogi fermentation with different starter cultures

needed. Upgrading the production of fermented foods from the household to the industrialized level will necessitate several of the following critical steps (110):

1. Isolation and identification of the microorganisms associated with fermentation. Microorganisms associated with indigenous fermentations need to be isolated,

properly identified and preserved preferably in a recognized culture collection for future use.

2. Determination of the role(s) of the microorganism(s). The biochemical role(s) of microorganisms associated with food fermentations needs to be determined through chemical analysis of products released by the microorganisms under controlled laboratory conditions.
3. Selection and genetic improvement of microorganisms. Microorganisms responsible for effecting important changes in the food during fermentation should be selected and subjected to genetic improvement geared toward maximizing desirable quality attributes in the food and limiting any undesirable attributes.
4. Improvement in process controls for the manufacture of fermented foods. Improvements in the quality and quantity of fermented foods may be achieved by manipulating environmental factors such as temperature, moisture content, aeration, pH, and acidity, which influence the activity of microorganisms during the fermentation process.
5. Improvement in the quality of raw materials used in the production of fermented foods. Both the quality and the quantity of fermented foods may be improved by choosing raw materials other than those traditionally used for their production.
6. Laboratory simulation of the fermented foods. Prior to pilot scale production, and (ideally) after all the five stages have been well studied, fermented products may be produced under laboratory conditions. Laboratory simulation of fermented foods will involve the production of fermented foods by inoculating microbial isolates having desirable properties, into raw materials.
7. Pilot stage production. The pilot stage is the first clear departure from small scale production and should be based on the result of laboratory experiments.
8. Production or industrial plant stage. The production stage is the culmination of all the previous efforts and should lead to the availability of food of predictable and consistent quality on a larger scale.

16.9 CONCLUSION

Traditional small scale fermentation technologies offer considerable potential for stimulating development in the food industry of African countries in the light of their low cost, scalability contribution to food safety and nutrition, minimal energy and infrastructural requirements, and the wide acceptance of fermented products in these countries (111). In many traditional approaches, the advantages of some form of inoculation of a new batch, e.g., by back slopping or the repeated use of the same container (e.g., calabash) is appreciated and generally practiced. Still, the benefits of small scale starter culture application as a means of improved hygiene, safety, and quality control, in support of HACCP approaches, are not yet realized in small scale fermentation operations.

The introduction of appropriate starter culture techniques may constitute one major step toward improved safety, quality, and security of traditional small scale fermentation. The increasing scientific information on microbe substrate interactions and particularly on beneficial properties of LAB strains typically associated with fermentation, this potential is expected to be exploited to a much greater extent in the future.

Fermentation Biotechnology of Traditional Foods of China

Zuoxing Zheng, Changlu Wang, and Yang Zheng

CONTENTS

17.1 INTRODUCTION

Fermentation is one of the oldest, and remains one of the most economical, methods of producing and preserving traditional foods in China. These delicacy foods are made from ordinary agricultural products or byproducts through microbial fermentation to generate unique flavors and aromas. In China, there are many kinds of traditional fermented food products, which have a history that is centuries long. The main products include alcoholic beverages such as white wine and yellow wine, fermented condiments, and foods such as

soy sauce, vinegar, cooking wine, Jiang, fermented tofu, Chinese bread, fermented meats and vegetables, as well as fermented tea. These fermented Chinese foods, in a broader term, have played a very important role in Chinese cuisines for thousands of years. They have not only contributed greatly to the unique palatability of Chinese foods, many of them are of beneficial to human's health and wellness. Today as the natural sciences and technology are rapidly advancing, the ancient methods of making fermented foods in China are also changing gradually through modern microbiology and biotechnology.

17.2 HISTORY OF FERMENTATION TECHNOLOGY IN CHINA

The earliest fermentation technology in China can be traced back to about 4,000 years ago when Jiu, a Chinese wine, was first made, followed by vinegar and Jiang (fermented soybean paste), which were originally made about 2,000 years ago (1,2). Today there are hundreds of fermented foods in China. The development history of fermentation technology in China can be divided into three stages: traditional, modern, and contemporary stages.

The traditional fermentation processes in China have two types: submerged fermentation and solid-state fermentation. The traditional oriental fermented foods are mostly made through solid-state fermentation processes. Examples of natural solid-state fermented foods include soy sauce, Chi (soybean paste), fermented tofu, red rice, and Mantou. Fermented vegetables can be made through either solid-state or submerged fermentation processes. Traditionally, such fermentation occurs naturally and the microorganisms come from local micro flora, therefore the fermented products often have very unique indigenous flavor characteristics. For example, a typical Chinese fermented vegetable is made by putting vegetables in a sealed tank containing salted water left at room temperature. The salt in the water inhibits the growth of many spoilage bacteria in vegetables while the lactic acid bacteria will grow and the resulting lactic acid further inhibits the growth of spoilage organisms, and eventually the lactic acid bacteria will outgrow and produce organic acids and flavor compounds in the products. Such natural fermentation processes are still used today in China.

The modern fermentation stage is characterized by controlled fermentation with selected pure cultures. Since about 100 years ago, as modern microbiology has rapidly advanced in the world, Chinese scientists have been able to study the mechanisms of fermentation and isolate microorganisms from natural fermented foods. Many pure cultures, including bacteria, mold, and yeast have been obtained and used commercially for mass production of traditional fermented foods in China. Some of the naturally isolated cultures have been undergone further improvement through natural breeding processes such as hybridization and mutation. Such improved strains are not genetically modified organisms, but are metabolically enhanced flavor producers or high yield producer strains. They have been widely used in food and fermentation industries in China. Mutation technology also can alter the natural metabolic pathways of microorganisms, thus certain natural metabolites can be inhibited while other natural metabolites are selectively "forced" to be overproduced. This technology is called metabolically controlled fermentation. Such technology has been widely used in China to commercially manufacture many industrial chemical products such as citric acid, polysaccharides, amino acid, vitamins, and ethanol. In addition to microbial isolation and improvement, the fermentation process has also been changed during this modern fermentation stage. For example, the fermentation medium, temperature, pH, moisture content, and fermentation time have all been optimized for maximal yield and best quality of targeted products. Some traditional fermentation processes have been changed from batch process to a continuous fermentation process.

Mechanical and analytical development has also made traditional fermentation process easier to control. Pure and improved culture and optimized process have significantly increased the productivity, quality, and safety of traditional fermented foods in China.

The contemporary fermentation technology is the result of the development in biotechnology, especially DNA technology. Since the mid twentieth century, the rapid advances in microbial physiology, cell infusion technology, immobilized cell and enzyme technology, genetic engineering, metabolic engineering, bioreactor design, and purification technology have dramatically promoted development of contemporary fermentation technology in China. Development in biosensors has made automation possible in fermentation process control to some extent. The fermentation products have been greatly expanded, and the concept of fermentation has also been changed. Fermentation is not limited to traditional fermented products or even food products any more; rather, many specialized products for applications in agricultural, food, chemical, and pharmaceutical industries have been commercially produced through microbial fermentation. Examples include various industrial enzymes such as amylases and proteases, organic acids such as lactic acid, acetic acid, propionic acid, malic acid, amino acids such as glutamic acid, phenylalanine and asparagines, nucleotides such as inosine and 5′-inosinic acid, vitamins such as ascorbic acid and vitamin B12, coenzyme A, glycerin, ethanol, and single cell protein. These fermentation products are well beyond the scope of traditional fermented Chinese foods, and the introduction of computerized control system to such fermentation and downstream process is becoming more and more popular in today's China.

The purpose of this article is mainly to introduce and review the process and technology development of some typical traditional Chinese fermented foods.

17.3 FERMENTED ALCOHOLIC BEVERAGES

Fermented alcoholic beverages in China are called "Jiu," which includes distilled and nondistilled spirits, wine, and beer. Jiu manufacturing has a very long history in China and is still a very important industry today. There are many varieties of the fermented alcoholic beverages in china, such as white wine, yellow wine, sweet wine, and cooking wine.

17.3.1 White Wine

Chinese white wine is recorded in Bencao Gangmu, a Chinese encyclopedia of medicinal herbs compiled by Shizhen Li during the Yuan Dynasty (2). There are different varieties of white wines according to different materials and processes used. They are classified as Big-Qu and Small-Qu wines. The Big-Qu wines are made with large usage level of Qu (starter culture) through solid-state fermentation, while the Small-Qu wines are made with smaller usage level of Qu through solid-state or submerged fermentation. They are also categorized into six major groups by the types of aroma: the light-scented type, the heavy-scented type, the fermented-sauce aroma type, the mixed-aroma type, the fermented-rice aroma type, and miscellaneous aroma type. The famous brand names of Fen, Luzhou Tequ, Maotai, Xifeng, Guilin Sanhua, and Dong represent each type, respectively.

The Chinese white wines are made from sorghum, wheat, and rice with Qu as the saccharification agent and fermentation starter culture through solid-state fermentation and distillation processes. The Qu is made from wheat inoculated with mother cultures obtained from naturally occurring wild type microorganisms. A typical Big-Qu making process is shown in Figure 17.1.

The Big-Qu has a history of several thousand years and it was originally used to make yellow wines. It was then used to make white wines. Many well known white wines,

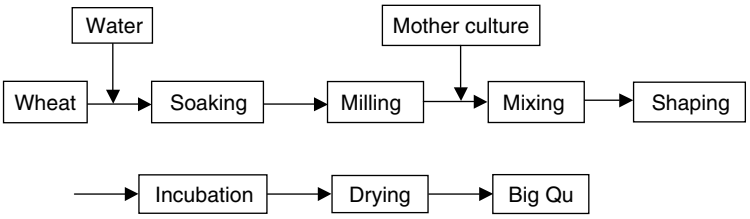

Figure 17.1 Flow chart of a typical Big Qu making

including Maotai, Fen Jiu, Luzhou Laojiao Tequ, Xifeng Jiu, Wuliang Ye, Lang Jiu, and Gujing Gongjiu are all made with Big-Qu.

Maotai is one of the best white wines made in China. Maotai Brewery is located in Maotai Village, Renhuai County in Guizhou Province. Maotai Jiu is made from sorghum through fermentation with Big-Qu and it involves repeated fermentation–distillation cycles for as many as 8 times. The Maotai brewing process is shown in Figure 17.2.

Because the repeated fermentation and distillation process, great quantities of Big Qu are required in Maotai making, almost equal to the amount of the raw material sorghum. The wine collected between the third and sixth distillations is the best, and the one collected last is the worst in quality. All collections will be mixed and adjusted to standardization prior to storage for at least one year before going to market (3–6).

Maotai wine has a strong yet elegant flavor which is believed to be generated from Big-Qu during fermentation. It is a typical example of Big-Qu wines with a soy sauce type aroma. The climate of Maotai Village in China is mild and humid, which provides ideal conditions for the growth of microorganisms and may contribute to the specific quality of the very famous brand wine.

The conversion rate, or the utilization efficiency, of starch used to produce white wines is relatively low in traditional processing. In order to increase productivity and conserve cereal grains, Chinese brewery scientists have conducted research on isolation and identification of fermentation microorganisms from traditional manufacturing environment and process samples. They obtained several pure cultures of *Aspergillus oryzae* and *Saccharomyces* species for fermentation. As a result of pure culture fermentation, the starch utilization efficiency was increased from 40–50% to 70–80% in wine fermentation process. Recently, wheat bran has been used to replace wheat in the traditional Big-Qu making process, and a submerged liquid culture was used in the fermentation process to increase the alcohol output. Although the productivity was increased, the aroma of the finished product was not as good as the one produced by the traditional methods.

To compensate for the quality, compromised by productivity increase, and improve the flavor of wine products, some new flavor enhancing techniques have been developed in China. Aroma stripping and aroma blending are the most commonly used methods. In aroma stripping process, a traditional fermented aroma concentrate called Xiangpei, is made separately, and is placed near the vapor outlet of the distillation apparatus during white wine process. When the alcohol vapor passes the aroma source Xiangpei, it strips some of the flavors and lets them cocondense in the product. This method still requires some traditional operations and it loses some alcoholic content when passing through the aroma source. Aroma blending method is a kind of artificial method. The alcohol used for blending is deodorized with active carbon before artificial flavorants are added. The ingredients of the artificial flavors used often contain acetic acid, butyric acid, lactic acid, citric acid, ethyl acetate, isopentyl alcohol, and glycerol. Usually, 10% traditional white wine is added to the product. Although the overall manufacturing cost of such wines is

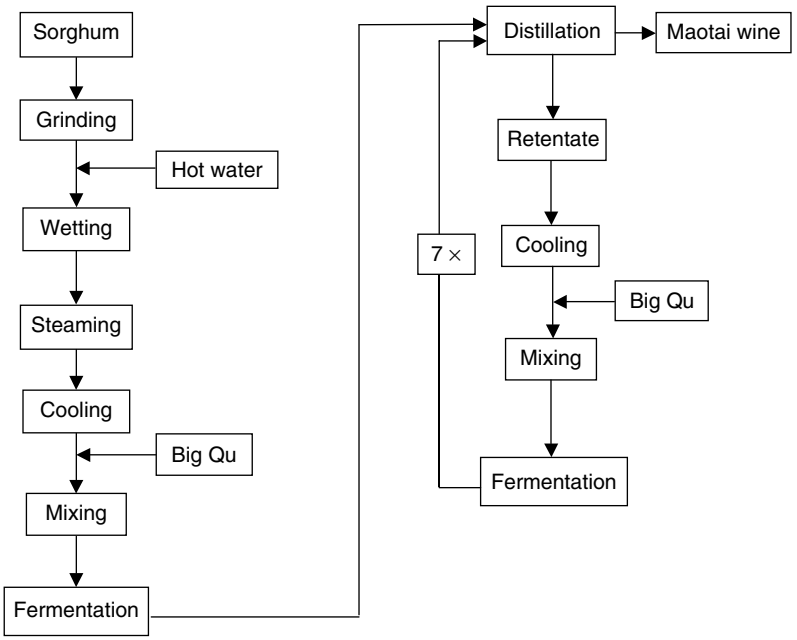

Figure 17.2 Flow chart of a Chinese white wine Maotai making

significantly reduced, the quality of such artificially blended wines is not as good as the traditional wines.

In 1975 the Mongolian Institute of Light Industry and Chemical Engineering isolated a caproic acid producing bacteria *Bacillus* species from the black soil of old wine-making cellars. This *Bacillus* isolate is strictly anaerobic and requires alcohol and sodium acetate as the major carbon source to produce caproic acid and other critical aroma compounds. This strain has been used commercially in white wine industries in China, and the resulting finished products contain high level of hexyl acetate and other flavors characteristic to the white wines. The sensory evaluation results for such products are fairly close to those of the strong-scented type of Big-Qu white wines.

17.3.2 Yellow Wine

Yellow wine is made from the fermentation of rice. It is called "yellow wine" because of the yellowish color of the finished product. It contains about 15% alcohol, and is rich in amino acids. The lysine content in yellow wine is much higher than that in beer, or grape wine. Routinely drinking certain amount of yellow wine is good for health. Sometimes it is used as extraction solvent of Chinese medicinal herbs for medical applications. More often however, yellow wine is used as a condiment in cooking for many Chinese cuisines. Yellow wine making is very popular in southern China where rice is the major cereal food. In yellow wine making, the three major materials, rice, Qu and water, are often referred as the "meat, bone, and blood" of yellow wine. The quality of these materials determines the quality of the wine. The ideal rice is rich in starch especially the branched starch, and low in protein and fat. Among many kinds of rice, the sticky rice, or glutinous rice, is considered the best. The water used for brewing should have a pH range of 6.8–7.2, with the hardness of 2–7°DH, and a very low level of minerals. Qu is made from fermentation of wheat, therefore, the wheat quality is important too. Sometimes 10–20% barley is added to wheat for Qu-making to improve aeration and microbial and enzymatic activities during

fermentation. The amino acids, especially glutamic acid in the wheat, are the main source of the delicious taste in the yellow wine.

Just like white wine, yellow wine has many varieties. However, all varieties share some common characteristics. They are all made from rice or sorghum through steaming, saccharification, fermentation, press filtration, and storage processes. Qu and yeast are used as key saccharifying and fermenting agents, while many other natural microorganisms are also involved in the brewing process for the complicated flavor development. Saccharification and fermentation usually occur simultaneously at relatively lower temperatures. Starch is converted to sugars by Qu and the sugars are subsequently transformed to alcohol by yeast. Other microbial metabolites such as organic acids, amino acids, esters, and various alcohols are also formed during fermentation. They contribute significantly to the distinctive flavor of the finished product. Some well known brand names of yellow wines in China, such as Shaoxing Jianfan and Chengang Jiu are also found available on the market in the United States.

A typical process of manufacturing yellow wine is shown in Figure 17.3. The pasteurized yellow wine is hot filled in jugs and the jugs are usually stored for about 1 year of ripening before they enter the market. Some premium yellow wines are required to be aged for as long as 3 years. This storage period is similar to ripening processes in cheese making. During ripening, the fresh wine undergoes various chemical reactions to form esters and many other aroma compounds. The ripened yellow wine is very mild and balanced in aroma and taste. In general, fermented alcoholic beverages can enhance the pleasure of eating. Their nutritional roles include indirect contribution through subjective enhancement of appetite and a variety of other physiological effects (7).

17.4 FERMENTED CONDIMENTS AND FOODS

17.4.1 Soy Sauce

Soy sauce is probably man's oldest prepared seasoning and its exact origin is prehistoric and just like most other fermented foods it was initially used to prevent food spoilage and

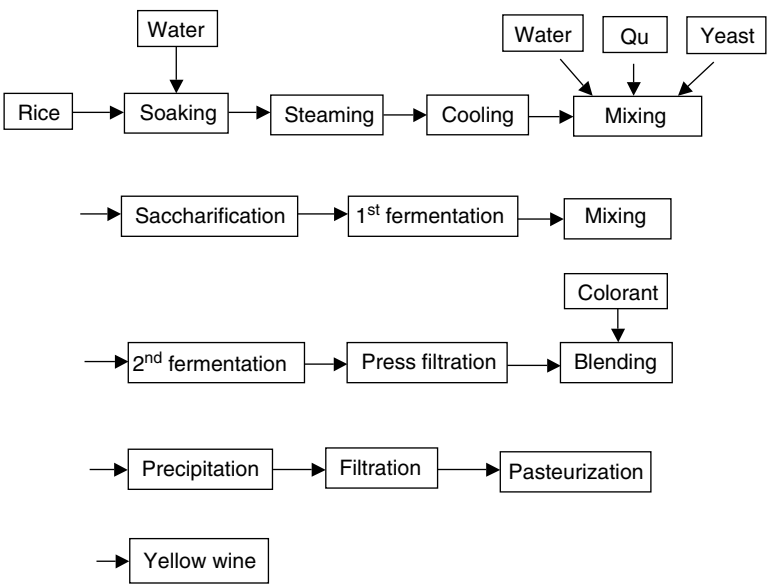

Figure 17.3 Flow chart of a typical yellow wine making process

preserve food. The origins of soy sauce, like other fermented foods, go back millennia. The first recorded reference to the soybean, from which soy sauce is made, is thought to be Shen Nan's *Materia Medica*, produced in China in 2838 B.C. (8). In the sixth century, Buddhism came to Japan from China. Along with this new religion came a vegetarian seasoning, a salty paste of fermented beans (9). This is the earliest direct ancestor of soy sauce. Soy sauce is known as Shoyu in Japan and Jiang-yiu in China. It is mainly used as all purpose seasoning in China and East Asia. Soy sauce has been regarded as one of the most popular condiments in the long history of China. It is estimated that, at present, more than 2 million tons of soy sauce are produced every year in China (2). Soy sauce is now well known in the western world, particularly in North America, where it has been popularized by communities with Chinese origins. It is also becoming popular in the U.S. as a sauce for barbecue, steaks, and hamburgers.

In China there are two types of soy sauce: fermented soy sauce and blended soy sauce. Fermented soy sauce is made from soybean, wheat, and wheat bran through natural fermentation. Blended soy sauce is made by blending 50% or more of fermented soy sauce with acid hydrolyzed vegetable proteins and other food additives (10,11). In addition to salt, soy sauce contains 18 amino acids and polypeptides, sugar, polysaccharides, organic acids, alcohols, aldehydes, esters, phenolic compounds, vitamins, and minerals (12).

Soy sauce fermentation process can be carried out in liquid state, semisolid state, or solid-state fermentation. In China, solid-state fermentation is most widely used in soy sauce manufacturing, and it accounts for more than 70% of total soy sauce produced in China. The typical manufacturing process is shown in Figure 17.4.

For thousands of years, Chinese soy sauce was produced by using soy sauce Qu, a natural fermented product, and the precursor of soy sauce. In 1930, a pure culture of

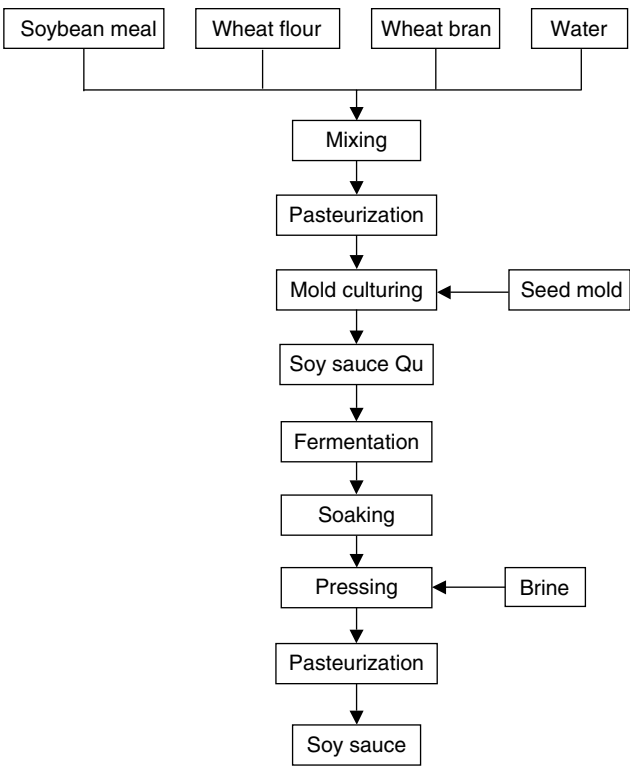

Figure 17.4 A typical manufacturing process of Chinese fermented soy sauce

Aspergillus oryzae was isolated from Qu and a new Qu fermentation method, using the pure culture, was developed for soy sauce manufacturing. The new pure culture fermentation significantly shortened the ripening time for soy sauce from 1 year to 2 months. Another invention of a no salt, soy sauce making process made it possible to reduce the fermentation time further down to 1–2 days, but the problem with temperature control has yet to be resolved. A low salt concentration and heat preservation method was then developed and fermentation time was about 10 days. This has become the most popular manufacturing method in the soy sauce industry in China today. Recently submerged liquid culture method has also shown some success and a promising future in soy sauce making.

To improve the quality of soy sauce, culture screening is one of the important activities in soy sauce research in China. Better species with a higher protease activity are still desired. The cytoplasmic fusion and *in vitro* gene recombination and other advanced techniques have been explored to screen and obtain a microorganism which possesses multifunctional enzymes, such as high activities of protease, glucoamylase, glutaminase and cellulase. The widely used pure culture of *Aspergillus oryzae* has a high protease activity, which hydrolyzes soy and wheat proteins to peptides and free amino acids including glutamic acid that are mainly responsible for soy sauce flavor and taste. Other characteristic flavor compounds found in soy sauce are the tautomers of 4-hydroxy-2-ethyl-5-methyl-3-furanone and 4-hydroxy-2-methyl-5-ethyl-3-furanone which exist in a ratio of approximately 3:2, and their content was found to correlate positively to the quality of soy sauce (13).

To increase the conversion rate and improve flavor in the product, Zheng (14) had tried to obtain a hybrid strain of *A. oryzae* and *A. niger* through protoplast infusion technology. The *A. niger* strain was a starter culture for vinegar production, and had a high amylase activity. The objective was to incorporate some properties of a vinegar culture into a soy sauce culture. The hybrid strain combined both high protease activity and high amylase activity from parent strains, and was able to shorten fermentation time and increase soy sauce yield as well as improve the flavor of soy sauce. Another approach to improving soy sauce quality is to use adjunct cultures such as yeast and lactic acid bacteria during fermentation to produce rich flavor in soy sauce.

Savory nucleotides such as 5′-inosine mono phosphate (IMP) and 5′-guanosine mono phosphate (GMP) are great flavor enhancers. The commercial production of 5′-nucleotides from enzymatic hydrolysis of poly nucleotides or through microbial fermentation has been successfully achieved (2,15). Addition of these nucleotides to soy sauce has created a product with superior flavor, which enjoys a good market. The conversion of 5′-xanthosine mono phosphate to 5′-IMP, and phosphorylation of inosine to 5′-IMP and the production of savory nucleotides directly by soy sauce fermentation, are among the efforts to optimize soy sauce processing and achieve premium quality.

17.4.2 Jiang

Jiang is fermented paste of soybean and wheat flour. The traditional process of Jiang making is similar to soy sauce making, except that the ripened fermented mash is consumed directly without brine treatment and drip-washing, which are necessary in soy sauce making. In the modern Jiang making, a pure culture of *Aspergillus oryzae* is used in the fermentation of the raw material simulating Qu making. Salt is added upon completion of the fermentation, followed by naturalization, which is a slow cooling process. A typical process is shown in Figure 17.5.

Because soybean Jiang making shares the same principle as soy sauce making, their processes both depend on the function of enzymatic saccharification and protocolization by microorganisms during fermentation. Large scale Qu can be made by solid-state fermentation or liquid fermentation. Both methods use the same culture of *Aspergillus oryzae*.

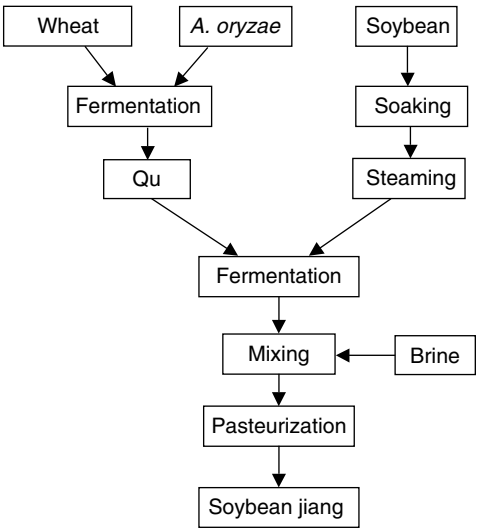

Figure 17.5 A typical manufacturing process of soybean Jiang

In solid-state fermentation, *A. oryzae* is introduced into powdered Qu, which is then used as a starter for Jiang making. The same starter can also be used in wheat Jiang making, in which the wheat flour is hydrated and steamed, then mixed thoroughly with powdered Qu and fermented at 45–50°C for a period of 10 days. During solid-state fermentation, the internal temperature could reach as high as 65°C on 8th day. This way, about 2 kg of Jiang can be made from every 1 kg of wheat flour. Although *A. oryzae* plays a key role in Jiang fermentation, many other microorganisms including molds, lactic acid bacteria, and yeasts are also involved during aging process to contribute to the overall flavor and taste of the finished product, Jiang (16).

17.4.3 Soybean Chi

Soybean Chi is a traditional fermented food in China and is widely distributed in most southern provinces such as Zhejinag, Fujian, Sichuan, Hunan, Hubei, Jiangsu, and Jiangxi, as well as some northern provinces in China. Although the exact origin of Chi is unknown, ancient Chinese literature indicates that Chi making existed before the Qin Dynasty (2). The traditional Chi making relies on natural fermentation of soybean. April and May are the best months for Chi making, followed by late July and August. Summer is not a good time for Chi making because it is difficult to control temperature.

In traditional Chi making, soybeans are sorted and steamed until they are soft. After cooling they are spread on mats on house floors. The thickness of the material and frequency of agitation depend on the temperature of the material. After a few days, yellow color mold will appear on the surface of the soybeans. After the mold spreads all over the soybeans, the material is mixed with salted water and is transferred to an earthen jar. The jar is tightly sealed and stored for a few months for ripening. The Chi produced in this way has a strong flavor similar to that of soybean Jiang.

Today, Chi is produced by fermentation with pure cultures, which can be either *Aspergillus, Mucor,* or bacteria, with *Aspergillus* predominating. Some selected *Aspergillus* cultures used in Chi industry today are obtained by natural screening or artificial mutation breeding. Such strains are usually able to produce better flavor and savoriness, with less off flavors.

17.4.4 Fermented Tofu

Fermented bean curd (Tofu) is called Doufuru or Furu in Chinese. It is one of the most famous Chinese fermented foods. It is flavorful, tasteful, and nutritious, and has been consumed for more than 1,000 years in China (2). Fermented tofu is produced all over the country in China and many provinces have their own characteristic Furu.

Traditionally, fermented Tofu is made by natural fermentation of Tofu. The process is still used in many places today. Tofu is nonfermented soybean curd and is very popular in China and Japan and is gaining popularity in the United States. Doufuru making consists of three major processes, i.e., tofu-making process, mold fermentation process, and brining and aging process, as shown in Figure 17.6. The soybeans are washed and soaked in water, and then milled into slurries. The slurries are diluted with warm water and pressed to obtain soymilk with 5–6% total solids. The soymilk is boiled and then a small amount of coagulant ($CaSO_4$ or $MgSO_4$) is added to the hot soymilk to precipitate the proteins. Immediately, the coagulated soymilk is placed in cloth bags and the bags are pressed in a mold. Stones or wooden planks are often used to squeeze off the water (soymilk whey). After the curd is formed it is sliced into different sized pieces. Recently, glucono-δ-lactone has been used widely as a new coagulant, instead of calcium sulfate or

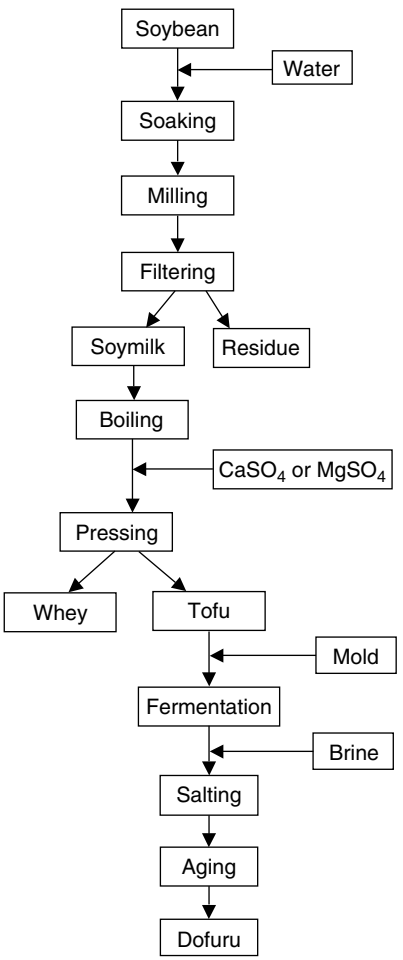

Figure 17.6 Manufacturing process of Doufuru

magnesium sulfate, because it needs less skill to form a high quality Tofu curd. In general Tofu contains 88% moisture, 6% proteins, and 3.5% oil. The regular Tofu curd is fragile and perishable and therefore is not suitable for Doufuru making. In Doufuru making, the Tofu is made so that its water content may be less than 70%, so that the texture of Tofu is much firmer than that of regular Tofu. The Tofu thus prepared is cut into 3 cm cubes and then heated. The purpose of heating is to pasteurize the cubes and to reduce moisture content on the cube surfaces, on which mold strains are inoculated. In mold fermentation, the molds belonging to the genus *Mucor* or *Actinomucor* are usually used, but the molds belonging to the genus *Rhizopus* are also used sometimes. For instance, *A. elegans, M. hiemalis, M. silvaticus, M. praini, M. subtilissimus, and R. chinensis* are used for the inoculation. The time of mold fermentation differs depending on the varieties of mold, and it normally takes about 7 days at 12°C for *R. chinensis*, 3 days at 24°C for *M. hiemalis* and *M. silvaticus*, and 2 days at 25°C for *M. praini* (17).

The last process of Doufuru making is salting and ripening in a dressing mixture. The freshly molded cubes are placed in various types of brining solution depending on the flavor desired (18). Normally the brining solution consists of salted fermented rice mash, soy sauce mash, and fermented soy paste. The time of ripening ranges from 1 to 12 months depending upon the varieties of brining solution. The salt content in the brining solution is very critical in ripening process. Salt inhibits the enzymatic ripening process for protein and lipid hydrolysis. Increasing the salt content will increase hardness and elasticity while reducing adhesiveness, whereas decreasing the salt content increases the free fatty acid content. In general, lowering the salt content will reduce ripening time, which may benefit manufacturers, but if the salt content is below 5%, the fermented tofu may become spoiled during ripening (19). Finally the product is bottled with the brine, sterilized and marketed as Doufuru.

Doufuru has a creamy cheese like texture, and has a strong flavor and taste and therefore it not only can be used as condiments in oriental cuisine, but also may be used in the same way as blue cheese is used in salad dressing.

17.4.5 Vinegar

A very detailed description of vinegar making was recorded in an ancient Chinese book, *Qimin Yaoshu*. Just like soy sauce, vinegar is another important condiment in Chinese cuisines. In China, Shanxi aged vinegar and Zhenjiang scented vinegar are considered the best among the traditional Chinese vinegars. Both of them were fermented using a mixed solid culture. Similar to wine making, the solid-state fermentation of vinegar employs Big-Qu fermentation and Small-Qu fermentation. Shanxi aged vinegar is a typical example of Big-Qu fermentation. Big-Qu is a fermentation starter, brick shaped, and is made of wheat, barley, or green peas. In such fermentation, large amount of Qu is used and a longer fermentation and aging time is needed. During fermentation, saccharification and alcoholic fermentation occur at a low temperature. The freshly obtained vinegar is then placed outdoors, heated in summer by the sun and frozen in the winter. The ice formed in winter is removed. After aging through a hot summer and a severe winter, the final product of Shanxi aged vinegar is ready, it is viscous in texture, dark purple in color, sweet in taste, and has a long shelf life. On the other hand, the Zhenjiang scented vinegar presents a typical example of Small-Qu fermentation. In the past, distilled yellow wine mash was used as the raw material. Regular rice or waxy rice is now used. The whole procedure includes alcoholic fermentation, fermented mash making, drip washing of the vinegar, and many minor steps. The whole process normally takes about 60 days. The finished product is famous for its delicate combination of color, fragrance, sourness, mellowness, and richness.

However, both Big-Qu and Small-Qu fermentation are a result of naturally mixed culture fermentation. They also suffer the similar disadvantage of low production rate because of

a long, labor intensive fermentation process. Many modifications and improvements have been made to speed up the fermentation cycle, replace the manpower with machines, and increase the utilization efficacy of the raw materials. Figure 17.7 represents a typical process of vinegar making in today's vinegar manufacturing industry in China. Basically, it uses ground rice and rice bran as the raw materials for regular alcoholic fermentation. It also employs pure cultures for both alcoholic and acetic acid fermentation. In the fermentation tank, a removable perforated bottom is installed to facilitate the drip washing. The liquid washed off from the fermentation tank is the final product of vinegar, which contains 5% acetic acid, 1.32% total sugar, and 0.52% total nitrogen. The product has a reddish brown color and a sweet sour taste. The quality is comparable to Zhenjiang scented vinegar.

Submerged liquid fermentation was also developed to reduce the fermentation time and make it easier for automation in vinegar making. The alcoholic fermentation using ground rice as the raw material remains the same. The fermented alcoholic mash is then piped into a stainless steel fermentor, and the acetic acid fermentation starts with the addition of 10% acetobacter culture broth containing *Acetobacter lovaniensis*. The temperature is maintained at 32–35°C for 65–72 hours for the whole acetic acid fermentation process. The final product is obtained after the addition of salt followed by filtration, sterilization, and blending. A total of 3.5 kg of vinegar with acetic acid concentration of 5% can be obtained from 1 kg of rice. The advantages of submerged fermentation over solid-state

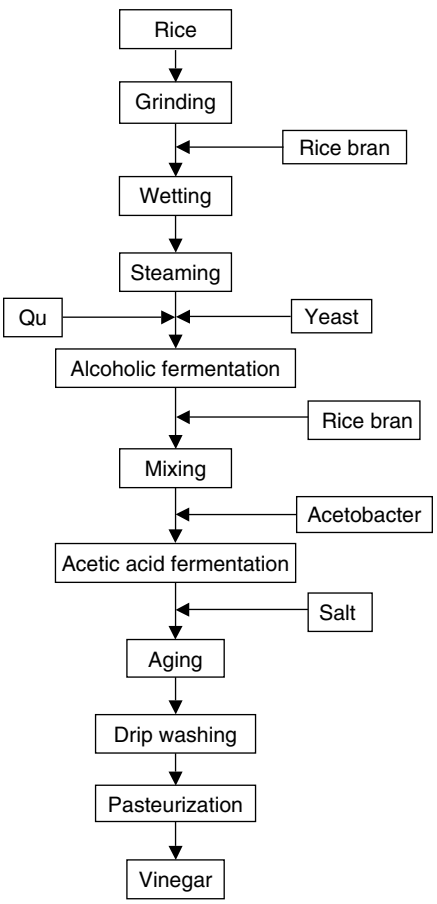

Figure 17.7 Vinegar manufacturing process

fermentation include shorter production cycle and higher extent of automation. However, the vinegar produced by submerged fermentation has fewer flavors than the one made by solid-state fermentation.

New technology development in vinegar making includes culture screening using protoplasmic fusion and genetic engineering techniques to obtain a hybrid which can resist high acetic acid concentrations up to 12% and which can produce good flavor comparable to that of established vinegar brands. Application of immobilized acetobacters for vinegar production has also been investigated in China.

17.4.6 Red Rice

Red rice, or Hong-Qu in Chinese, is a fermented product of rice with various fungal strains of *Monascus purpureus*. It was apparently first noted in the Yuan Dynasty (20). The detailed process information on red rice was first recorded in a Chinese famous ancient book Tiangong Kaiwu by Song Yingxing of the Ming Dynasty (1637 A.D.) (2).

Traditionally, red rice is made by natural fermentation. Rice is washed and soaked in water for 5–7 hours and then drained, steamed, and cooled on bamboo mats. The same procedure of steaming and cooling is repeated the next day. It is then mixed with Qu-starter, a milled and cream-like mash made from fermented rice, and moved into a fermentation room. The ambient conditions of the fermentation room are controlled at 30°C with moisture content of 45%. The inner temperature of the material is about 35°C. The mixture is turned over four to five times daily and the thickness of the layer is gradually reduced to 10–13 cm to compensate for the heat generated during fermentation. There are some little vent holes in the walls to adjust temperature of the windowless Qu-making room. On the third day, the material is taken out of the room and immersed in water for 10–15 minutes and then brought back to the room to continue the natural fermentation. On the fifth day, it is immersed in water again for 2–3 minutes. On the sixth day, it is sprayed with water and then transferred to an ordinary room, where the natural fermentation continues for 3 more days. It is dried in the sun on the ninth day. The dried fermented rice has a deep-red color on the surface and a reddish-white color inside. It can then be milled to powder and the red powder is called red rice or red-Qu. It contains *Monascus* and can be stored for a long time without deterioration.

The traditional method depends on the quality of the Qu-starter. The modern method simplified the whole process by using the pure culture of *Monascus* species. The pure culture is grown on rice to make high concentration starter. The starter is then used for inoculation in red rice fermentation. The fermentation time is shortened from about 8 days to 4 days.

The red rice is widely used as an enzymatic agent in alcoholic fermentation, as a condiment and colorant in cooking, and as a medicine in certain disease treatment in China. It is used in wine making in Fujian and Taiwan provinces, and the products are noted for their red color and mellow taste. The residue of the red rice alcoholic fermentation is called red Zao, and it is an ideal condiment in Chinese cuisine. The established Chinese dishes such as red Zao chicken, red Zao fish, and red Zao meat are among favorite menus in many Chinese restaurants.

Because the red rice powder is very rich in red pigment, it is often used as a natural food colorant. For example, it is used as a red colorant for fermented tofu (Doufuru). The red pigments obtained from *Monascus* are natural products and safe to be used as food grade color. Several high pigment-producing strains of *Monascus* species have been isolate for commercial production of food colorants (21,22).

The red rice also has antimicrobial activities against many spoilage microorganisms and therefore it is widely used for food preservation. Both the color and taste of the food can be well preserved by red rice. Fermented rice products including red rice have been

used in traditional Chinese medicine too. A recent study demonstrated that the *Monascus purpureus* fermented red rice reduced serum total cholesterol and triglycerides in animal models of hypercholesterolemia and hyperlipidemia (23). It was also reported that an antibiotic, called Hongqu-mycin, was found in red rice (2). The antibiotic in the red rice is probably one of the key functional compounds in its medicinal applications, for its well known effectiveness in curing chronic enteritis and dysentery diseases in China. In addition, red rice is claimed to assist in digestion and blood circulation, and to benefit the spleen and stomach functions (2).

17.4.7 Chinese Bread

Chinese bread, called Mantou in Chinese, is white steamed yeast leavened dough. The making process of Mantou is very simple, and almost every Chinese family can make it during daily cooking. Traditionally, a Mantou starter (dried fermented dough, usually left from last Mantou preparation) is soaked in warm water until it is dissolved. Then it is mixed with wheat flour and water to make dough. The mixed dough is then placed in a warm place or in a water bath at a temperature of about 25–30°C for a few hours. During yeast fermentation, the dough is greatly expended in volume and it is mixed a few times to facilitate homogeneous fermentation inside the dough. A spongy dough texture and a distinct yeast flavor from the dough should be easily noticed. After the fermented dough is ready, it is then molded to an appropriate size and shape (usually hemisphere shape), and steamed for about 20–30 minutes. The steamed Mantou is ready to eat. Compared with bread, the Chinese bread or Mantou is bland in taste, because no sugar or additives are added to the dough. Usually a small portion of the fermented dough before molding is saved and dried in the air, and will be used as a Mantou starter for the next time preparation. Due to the nature of the natural fermentation, the Mantou starter contained yeast and many naturally occurring bacteria such as lactic acid bacteria. These bacteria are normally beneficial to improving the flavor and taste of the Mantou. However, sometimes they produce too much acid during dough fermentation, and in this case a small amount of soda powder is added to the fermented dough to neutralize the acid. The quality of the Mantou largely depends on the microbial content in the starter. Today dried pure yeast is readily available on the market, making it much easier to prepare Mantou at home.

17.5 OTHER FERMENTED PRODUCTS

Other fermented food products such as fermented vegetables, meats, and tea also have a long history and are still very popular in China. For example, according to Chinese history record, as early as 1200 A.D., pickles were consumed and loved by the King and the celebrities. Traditionally, the Chinese pickles are made by natural fermentation of vegetables soaked in a sealed earthen jar. The "starter" cultures are those native microbials naturally living on vegetables. The tightly sealed jar provided an anaerobic environment, and initially many anaerobic bacteria will grow but eventually the acid produced by *Lactobacillus* species such as *L. plantarum* will inhibit the growth of other bacteria and become dominant. As the pH drops, the growth of *L. plantarum* will slow down and other more acid tolerant lactic acid bacteria will continue to grow until the pH drops to as low as 3.6–3.8. Low pH and high acid in the pickles effectively prevent them from spoilage and they can be stored for months.

Fermented meats have a long history in China too. A well known Chinese fermented pork product called Jinhua Huotui is becoming increasingly popular in Asia. It is a traditional Chinese fermented food product made from aged, fermented ham, and is used in

stock. Jinhua Huotui contains approximately 24% water, 24% protein, and 44% lipid. Comparing with commercial ham, although the total amino acid content in Jinhua Huotui is not different from that of ham, Jinhua Huotui contains more free amino acids, particularly glutamic acid, and high amounts of 5′-inosinic acid, which are responsible for its distinct delicious flavor and taste (24). The fermentation of Jinhua Huotui involves many kinds of mold, but the genus *Aspergillus* plays an important role in the decomposition of protein, and the genus of *Penicillium* is important in lipid degradation (25).

Tea growing originated in China and East Asia. In China, tea has been used as a beverage for 2,000–3,000 years, and it only later spread to other Asian countries, East Africa, the Middle East, and South America (26). The popularity of tea is derived from its delicate exotic aroma and possibly from the mild stimulating effects induced by caffeine. Some types of tea, such as green tea, are made by directly roasting tea leaves, while others such as black tea and oolong tea involve fermentation of tea leaves before drying. Green tea is roasted or steamed to stop enzymatic activity. For black tea, the leaves are allowed to ferment and this develops the aroma and color of the beverage. Oolong tea has the characteristics of both black tea and green tea, and the fermentation is only partial. Black tea processing involves four major steps:

1. Withering, in which tea shoots are placed in 30 cm deep beds or trays with forced circulation of warm air at a temperature of between 15 and 35°C for 4–18 hours until the leaf moisture is reduced from 75–80% down to 55–65%.
2. Leaf rolling or maceration, in which the leaf is broken into smaller particles and thus liberates its contents for the enzymes and catechins to mix and expose to the atmosphere resulting in enzymatic oxidation.
3. Fermentation, in which the sifted broken leaves are placed in fermentation drums or boxes with a constant supply of air for 30 minutes to 5 hours. During the natural fermentation, the leaf pieces darken and the flavor is developed further.
4. Drying, which stops the enzymatic and microbial activities. Either a fluidized bed system is employed or trays of leaves are placed in a hot air dryer at a temperature between 80 and 95°C. The final moisture of tea leaves is reduced to 3–5%. After drying, the finished product is graded and packaged for marketing. Fermented tea is now gaining more popularity in China, Japan, and many other countries.

This chapter discussed some major fermented foods in China. Of course there are many more fermented foods and beverages in China. Due to the long history of cultural evolution and huge geographic differences and large population in China, even the same fermented food can have many different varieties, and it is very difficult, if not impossible, to cover every aspect of the fermented food products in China. However, from the examples of the traditional fermented foods described in this chapter, one could draw a pretty good picture on an array of traditional Chinese fermented foods.

17.6 CONCLUSION

The ancient methods of making fermented foods are changing gradually through modern microbiology and other technologies. The fermentation technology passed down by ancient Chinese is a priceless treasure. However, some of the principles behind the technology still remain a mystery today. As a matter of fact, the making of Chinese fermented foods is really a combination of both science and art. Considerable progress has been made

in the area of microbiology; however, some of the microorganisms involved in fermentation are yet to be isolated and identified. Unfortunately, today we understand that there are many microorganisms living in nature which are actually viable, but nonculturable by today's technology. This is probably one of the important reasons why the pure culture fermented products usually do not have as good flavor as the natural fermented products. Despite the sophisticated analytical techniques and equipment we have today, the functions and identities of many trace flavor compounds in the fermented foods remain unknown. Biochemical and biological interrelationships between different microorganisms are still beyond our present knowledge. In light of all these facts, it is not surprising to find that although the use of pure culture fermentation has greatly reduced the process time and increased the yield of the products, their qualities often are compromised. Therefore, even today, the best quality fermented foods such as Maotai wine and Luzhou Tequ are still produced by traditional processes in China.

The traditional process is a natural mixed fermentation in which some complicated biochemical and biological changes are made by multiple cultures. The superior quality thus produced must be a joint result of different metabolic and physiological processes by various microorganisms involved in the natural fermentation. To surpass the traditional processes not only in speed and efficiency but also in quality remains a great challenge and this area is still wide open for further research.

Generally speaking, traditional foods are closely related to the regional food cultures and eating habits and therefore some of their flavor might be considered to be unacceptable for the people who do not belong to these food cultures. However, these traditional foods are products which have been developed through thousands of years and had been selected through a long experience of the people. Thus, these flavors would be acceptable eventually for most of the people, even though unacceptable at the first trial. In fact, many oriental fermented foods have entered into the U.S. market and are gaining more and more popularity in the West. For example, the consumption of soy sauce in the United States is rapidly growing in recent years. The steady penetration of Chinese traditional fermented foods to the American population might be proof that a traditional fermented flavor in one area can also be accepted by most of the people in another area. Wider acceptance of Chinese fermented foods in the world will also stimulate research activities and promote technology development to finally benefit food industries and the consumers alike.

3.18

Fermentation Biotechnology of Traditional Foods of the Indian Subcontinent

E. Rati Rao, S.V.N. Vijayendra, and M.C. Varadaraj

CONTENTS

18.1 INTRODUCTION

Mankind's eating habits have been a challenging area of scientific and technological developments. As advancements are made in food science and technology, man has made changes in his diet habits. In recent years, there has been a growing interest in traditional fermented foods, both at national and international levels. It is very well known that Asians and Africans are pioneers in utilizing fermentation as a means to preserve a wide variety of foods, including cereals, legumes, vegetables, milk, and meat. Early human civilizations, with no concept of microorganisms, were remarkable not only in developing the products, but also safely maintaining the cultures through centuries. These fermented foods are prized for the palatability and wholesomeness and are important components of diets in many parts of the world, especially in the Indian subcontinent.

Studies of the traditional fermented foods have established the multiple advantages as they pertain to nutritive values, therapeutic properties, and sensory attributes (1,2). In all these fermented foods, the process of fermentation is initiated mainly by lactic acid bacteria (LAB), and in a few of them, the fermentation is initiated by yeasts (3). In general, fermented foods are characterized by the accumulation of metabolites of microbial activities such as lactic acid, acetic acid, traces of ethanol, and other compounds collectively called as flavors. These secondary metabolites contribute to the overall acceptability of the final fermented product and also provide preservative effects.

India is a vast country on its own, and along with other countries of the subcontinent, has been the home of varied groups of people with and diverse living and dietary habits. This diversity accounts for a large number of traditional fermented foods. Nearly 90% of such traditional foods remain highly secretive in their preparation and tend to be regionalized, with most of these foods prepared at the household level. Very few of these traditional foods have been explored from the scientific and technological point of view. Some of these traditional foods and beverages have been studied, not only for their commercial value, but they have the potential to improve human health. These efforts have resulted in the preparation of products with uniform and consistent quality. This processing has the added benefit of providing healthy and safe foods for human consumption. The significance of the traditional fermented foods of India, an extensive review on the microbiological and biochemical aspects of selected fermented foods (4), as well as a comprehensive overview of the historical and technological developments of Indian foods is presented (5).

18.2 BIOTECHNOLOGICAL IMPETUS IN FOOD FERMENTATIONS

Fermented products are being produced throughout the world by converting desirable substrates into unique products through the action of desirable microorganisms, giving rise to acceptable products, both in terms of nutritional and sensory attributes. In many of these

preparations, the mechanism of the conversion is not well defined nor understood. With the changes in eating patterns, wherein emphasis has been toward natural, healthy, and safe foods, the impetus has been on fermented foods, either of the ready to process or ready to eat nature. Therefore, demand is increasing for the production of traditional fermented foods on a large scale. As a result, problems of maintaining quality and safety of the products arise. This leads to a need for better understanding of the fermentation processes, through which the production processes can be made more reliable and predictable. In order to meet the demands of quality and safety, appropriate biotechnological developments, and an analysis of the basic microbiological parameters (6) is required.

Optimization of starter culture performance and elimination of the factors that can impede the fermentation process are the essential steps to improve the quality and safety of the finished products. Although considerable research has been carried out with regard to the improvement of starter cultures used in cheese preparation at the industrial level (7), very little effort has gone into the improvement of the starter cultures responsible for the preparation of quality traditional fermented products. The development of typical flavor in these foods is the major driving force behind the popularity of traditional foods. Under the prevailing circumstances, the biotechnological inputs toward obtaining consistent quality traditional fermented foods needs to be fully exploited.

Although manipulation of proteolytic system of certain lactic acid bacteria has been reported (8,9), the mechanism of flavor development has been less understood. To a certain extent, the role of proteases, peptides, and lipases, in flavor development has been established. Genetic engineering of the strains of lactic acid bacteria to produce derivatives with new attributes has been a challenge for food biotechnologists. In an era of scientific and technological advancements, there is definitely a need to look into the following aspects, which when achieved, can significantly place traditional fermented foods on the global map (10,11):

1. Desirable polysaccharides in enhanced levels to meet the quality parameters of body and texture of products
2. Desirable acid production in a shorter period
3. Increased therapeutic properties
4. Genetic stability and improved resistance to antibiotics and pesticides
5. Desirable production of dietary fiber
6. Threshold levels of desirable flavor components with stability during storage

Lactic acid bacteria have already been used as potent vehicles for vaccine delivery as a means to improve immunity in humans (12). Besides, genetic engineering studies with lactic acid bacteria have shown the approach to be positive in achieving the requisite attributes in traditional fermented foods.

18.3 FERMENTED FOODS OF THE INDIAN SUBCONTINENT

18.3.1 Milk Based Foods

Milk is the most important foodstuff for a mammal and has always been the first food of the newborn. Fermentation of milk, either knowingly or unknowingly, has occurred since early times, resulting in various fermented milk products. Fermented milk products are known for their taste, nutritive value, and therapeutic properties. The nature of these products

has differed from region to region depending on the indigenous microflora, which in turn depends upon the surrounding environmental factors (13).

Although the origin of the cultured dairy products is not very clear, it dates back to the dawn of civilization. Milk from different species of domesticated animals has been used for the preparation of fermented products. The oldest traditional fermentations applied to the production of fermented milks depended on climatic and regional characteristics where human populations dwelled. The methods of fermentation were also influenced by old customs carried over from generation to generation. The most popular traditional fermented products of Indian subcontinent are *dahi, mishti doi, lassi* and s*hrikhand*. Although these products are being prepared at the household level and in an unorganized dairy sector, the large scale production by industries is on a slow pace.

Traditionally, fermented milk products have been consumed either as beverages or as a part of meals. The preparation of these products, either at households or in unorganized sector, involves use of previous day's product as a starter, which invariably is a mixed culture, wherein there is no or little control on the fermentation process. On the contrary, the use of desired microorganisms as in the case of controlled fermentation would greatly enhance the chances of obtaining products with uniform and consistent quality products of acceptable attributes (1). Generally, the fermented milk products are prepared using freshly obtained milk of various milk animals. However, use of refrigerated milk stored up to four days have been found to be more suitable than fresh milk in obtaining fermented milks such as cultured milks, yogurt and probiotic yogurts with improved quality (14).

The increased activity of the lactic acid bacterial cultures in refrigerated milks has been attributed to heat stable enzymes and protein degradation products elaborated by psychrotrophic bacteria during refrigerated storage (15). The nutritional aspects (fermentation of lactose, hydrolysis of protein and lipids, vitamins, minerals) and therapeutic (physiological and health benefits) of indigenous peoples of the Indian subcontinent have been studied compared to the fermentation processes used by Western cultures (16). Use of genetically improved lactic cultures to improve the shelf life and safety of fermented milk products is envisaged in a few of the studies (17). Further attempts are being made to isolate lactic cultures having more health benefits. The work carried out on probiotic cultures in the Western world has influenced researchers in the Indian subcontinent. As a result, research has been focused on this angle to improve the nutritional and therapeutic quality of indigenous fermented milk products such as *dahi*, *lassi* and other cultured products, which have been documented in reviews (16,18).

18.3.1.1 Dahi

Dahi is one of the most popular fermented milk products of the Indian subcontinent, liked for its mild acidic taste and pleasant flavor. It can be consumed directly or along with other foods such as boiled rice and *chapathi*, a traditional wheat based pancake. Sushrut Samhita, the Indian medical treatise, describes *dahi* as a food promoting appetite and strength. It is prepared by lactic fermentation of pasteurized or boiled buffalo's or cow's milk through the action of single or mixed lactic cultures (19,20). The conventional method of *dahi* preparation is shown as a flow diagram in Figure 18.1.

A good quality *dahi* is of firm and uniform consistency with a sweet aroma and a clean acid taste. The surface is smooth and glossy and usually a cut surface is trim, free from cracks and gas bubbles. The nutritional and therapeutic values of *dahi* are rated as high when compared to that of the milk used for its preparation. It is easy to prepare, even at the household level. *Dahi* is easy to digest and it has been found to reduce the risk of cardiovascular problems and cancerous tumors, besides strengthening general immunity (21).

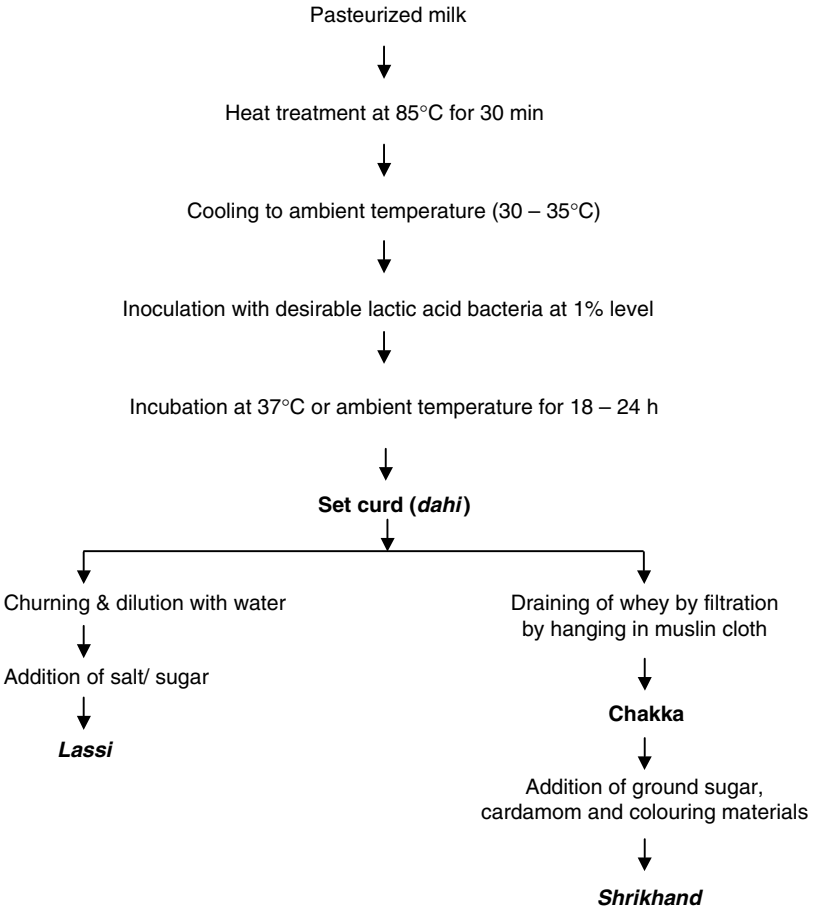

Figure 18.1 Traditional method of preparation of *dahi*, *lassi* and *shrikhand*

The composition and quality of *dahi* varies from place to place, as it is prepared under different domestic conditions. The earliest work (22) had established the average composition of *dahi* prepared from whole milk is as follows (on percentage basis): water 85–88%, fat 5–8%, protein 3.2–3.4%, lactose 4.6–5.2%, ash 0.7–0.75%, lactic acid 0.5–1.1%, calcium 0.12–0.14% and phosphorus 0.09–0.11%. The basic aspects, such as the quality of raw milk, processing parameters, starter cultures, biochemical and nutritive changes, shelf life and packaging have been well reviewed (1,23).

The commonly associated lactic acid bacterial cultures in the inoculum are strains of *Lactococcus lactis* ssp. *lactis, Lc. lactis* ssp. *cremoris, Lc. lactis* ssp. *diacetylactis, Leuconostoc cremoris, Lactobacillus delbrucecki* ssp. *bulgaricus, Lb. acidophilus,* and *Lb. helveticus.* Many studies have focused on several important aspects such as determining lactic microflora in homemade and marketed samples of *dahi*, isolation of lactic acid bacterial cultures from *dahi*, suitability of lactic cultures in preparing the product with acceptable quality with storage quality, and changes occurring during fermentation (22,24–26).

Selection of a good starter culture is important to obtain a good flavor with desirable characteristics. Use of both mesophilic and thermophilic starters in various combinations has been reported (27,28). Addition of probiotic cultures such as *Lb. acidophilus* and *Bifidobacterium bifidum,* along with the regular lactic cultures for *dahi* preparation, help

to increase the therapeutic and nutritional value of *dahi* (29). *Dahi* was found to be a potential source of lactic acid bacteria, mainly species of *Lactobacillus,* active against food borne pathogenic and spoilage bacteria such as *Staphylococcus aureus, Bacillus cereus, B. licheniformis* and *Klebsiella* sp., and *Pseudomonas* sp. (30). Further, a strain of *Lb. delbruecki* ssp. *bulgaricus* producing a heat stable bacteriocin, having broad spectrum antibacterial activity with a potential for use as a food biopreservative, was isolated from *dahi* (31).

Presence of both spoilage and pathogenic microorganisms has been reported in market samples of *dahi* (32,33). Contrary to this, a good quality of *dahi* can be produced under varied incubation periods and temperatures such as 2–4 h at 40°C or 4–6 h at ambient temperature or 8–10 h at 25°C using a mixed culture obtained from a household (34). A shorter incubation was found to be sufficient to get a good quality *dahi*, as prolonged incubation may favor the growth of several undesirable microorganisms, which can affect the quality of *dahi*. This product was shown to have higher antibacterial activity against pathogens such as *Escherichia coli, Bacillus subtilis,* and *S. aureus.* Although many reports are available on genetic improvement of lactic cultures of dairy products, so far their use in the preparation of traditional fermented products has not been put into commercial use.

In India, very few cooperative milk federations are now taking up commercial scale production of *dahi*. The preparation of *dahi* by organized dairies has been on a slow pace, but it is making a brisk progress in the commercial market. However, the commercial success, to a large extent, is dependent upon producing uniform and consistent quality products. Heating of milk at 85°C for 30 min or 90°C for 5–15 min has been put into practice for the preparation of *dahi* on a commercial scale as a means to improve textural characteristics and water binding capacity due to denaturation of whey proteins and its interactions with casein fraction (19).

As a means of exploring alternatives or bringing in convenience*, dahi* powder has been made by spray drying of homogenized curd prepared from standardized buffalo milk of about 3.5% fat and 30% total solids (TS). Uniform quality *dahi* is prepared by reconstituting one part of *dahi* powder with three parts of lukewarm water and cooling for about one hour at refrigerated temperature (35).

In Sri Lanka, the traditional preparation of curd involves use of wide mouthed clay pots for production and distribution as well. The containers used are either wrapped with newspaper or with polyethylene, which cannot prevent contamination, resulting in a very poor quality of curd. Presence of coliforms, *E. coli, S. aureus* in high percentages has been reported (36).

Development of new innovative methods for rapid detection of emerging food pathogens such as *E. coli, Yersinia enterocolitica, Listeria monocytogenes*, and the absence of *Salmonella* spp. in dairy products is extremely important in obtaining a safe product. Implementation of quality management programs such as Hazard Analysis Critical Control Points can assure a uniform and consistent quality product with emphasis on food safety. Application of biotechnological approaches such as use of immunological assays, Deoxyribo Nucleic Acid (DNA) probe based assays, polymerase chain reaction (PCR) based pathogen detection systems, and use of biosensors in quality assurance of dairy products to improve the quality has also been shown to hold promise (37).

18.3.1.2 Mishti doi

Mishti doi is a popular variety of sweetened *dahi* available in the eastern region of India. It is also known as *lal dahi* or *payodhi*. It is generally characterized by light brown color and firm body with cooked or caramelized flavor. Two formulations for the preparation of *mishti doi* are identified (38). One combination involves use of *Streptococcus salivarius* ssp. *thermophilus, Lb. acidophilus* and *Lb. delbrueckii* ssp. *bulgaricus* and the other

formula has *Lb. acidophilus, Lc. lactis* ssp. *lactis* and *Saccharomyces cerevisiae.* Microbiological examination of market samples revealed the presence of yeasts such as *Saccharomyces, Candida and Rhodotorula*, besides the LAB like *Lactobacillus, Lactococcus* and *Streptococcus.* The yeast count reported was 5×10^4 cfu/g of *mishti doi* and the coliform count was 46 cfu/g.

Proteose peptone (pp), a minor protein of milk, plays a very important role in imparting the brown color to milk products. The pp content changes significantly during the preparation of m*ishti doi*. A positive correlation was observed between pp content of fresh concentrated milk (before fermentation) and intensity of brown color in m*ishti doi*, with a correlation coefficient of 0.93 (significant at $p<0.01\%$ level). The pp content (mg/100g) of raw buffalo milk, after boiling for 30 and 40 min and m*ishti doi* are found to be 112, 290, 365 and 200.9, respectively (39).

18.3.1.3 Lassi

Lassi, also known as buttermilk, is another popular lactic fermented milk based beverage product of the Indian subcontinent, which is consumed mainly during summer months. It is a byproduct obtained during the preparation of ghee (country butter) from *dahi* by churning. It is also made by breaking the set *dahi* with the agitator and the addition of a required amount of water, sugar, or salt and flavor compounds. It is prepared by local vendors, in the small shops in market areas, and in households. The traditional method of lassi preparation is shown as a flow diagram in Figure 18.1.

The composition of *lassi* varies based on the type of milk used, the extent of dilution during churning, and the efficiency of fat removal. The average composition (on percentage basis) of *lassi* is as follows: water 96.2%, fat 0.8%, protein 1.29%, lactose 1.2%, lactic acid 0.44%, ash 0.4%, calcium 0.6%, and phosphorus 0.04% (40).

As the preparation and vending at many places are not done under hygienic conditions, high incidence of aerobic sporeformers such as *Bacillus subtilis*, *B. megaterium, B. cereus, B. licheniformis, B. coagulans. and B. pumilus* have been isolated from market samples of *lassi* (41). The shelf life of *lassi* has been extended by more than six days at 37°C by the addition of 0.03–0.35% sodium metabisulfite and the sulfur flavor imparted by this preservative could be masked by the addition of 0.07–0.09% crushed green ginger and 0.5–0.7% salt (42).

The preservative effect of nisin in enhancing the shelf life of *lassi* has been studied (43). The shelf life of lassi was up to 32–48 h at 30°C with the addition of Nisaplin at a concentration of 200–500 IU/ml, whereas, the stability was 8–10 days at refrigerated storage. To enhance the therapeutic value of *lassi*, a method has been standardized to prepare *lassi* using probiotic culture of *Lb. acidophilus* along with *Str. thermophilus* to get a desirable flavor in the final product (44). This product could be stored at refrigerated temperature for twenty-one days with acceptable sensory quality. Significant changes in the lactic counts during storage were not observed at the end of the storage period. The average lactobacilli count reported was 20.4×10^7 cfu/g, which is normally sufficient to be effective as a human dietary adjunct.

18.3.1.4 Shrikhand

Shrikhand is a sweetened lactic fermented product widely consumed in western and northern parts of India. It is a product having a refreshing taste with pleasant aroma, and smooth and homogenous texture and firm consistency. The traditional method of s*hrikhand* preparation is presented in Figure 18.1. *Shrikhand* preparation involves products of curd (*dahi*) by lactic fermentation of whole milk, either cow's or buffalo's milk, followed by the draining of whey

from the curd through a suspended muslin cloth bag for 6–8 h. The resulting solid mass (known as *Chakka*) is uniformly mixed with ground sugar (44–45%) and made into a semi-solid mass to which flavoring substances such as cardamom and saffron are added. The product has a long shelf life of about 35–40 days at 5°C, while storage at ambient temperature results in a very short shelf life of 2–3 days.

The composition of S*hrikhand* is as follows (on a percentage basis): moisture 34.48–35.66%, fat 1.93–5.56%, protein 5.33–6.13%, reducing sugar 1.56–2.18% and nonreducing sugar 55.55–53.76% (1). Although it is prepared in households on at very small scale, successful attempts have been made to develop an industrial process for the manufacture of *Shrikhand* and it is available in the markets all over India. Buffalo milk is preferred to cow's milk for the manufacture of *chakka*, because of higher yield and consumer preference (45).

The lactic cultures used are of mesophilic lactics, the same as those involved in the preparation of *dahi*. A culture combination of LF 40 was found to be most suitable for *shrikhand* preparation (46). The technological and microbiological aspects of *shrikhand* preparation are reported in an earlier study (47). Preparation of dietetic *shrikhand* using buffalo skim milk fermented with a 2% combined culture of *Lb. acidophilus* (NDRI-AH1) and *Str. salivarius* ssp. *thermophilus* (NDRI-YHS) was reported to reduce the high fat content in the final product (48). During this process, the total solids recovered in the *chakka* were 54.46%.

To increase the yields (23% more than the traditional process) and for easy automation and process control for large scale production of *shrikhand*, a patented process has been developed to remove whey by an ultrafiltration technique (49). A comprehensive review on *shrikhand* preparation and its quality has been published (50). Fat was found to be the most important compositional parameter that affects the acceptability of s*hrikhand*. It influences the flavor quality of the product. The fat and sugar contents between 7–9% and 33–39%, respectively, had higher acceptability (51).

Studies on the production of enterotoxin by *S. aureus* in *shrikhand* revealed that this organism, when occurring as a preprocessing contaminant in the milk, could grow and produce enterotoxin even in the presence of lactic cultures (52). More recently, the behavioral pattern of toxin producing pathogens like *E. coli* and *L. monocytogenes*, which can enter the product as a postprocessing contaminants in *shrikhand*, was predicted through response surface plots generated by using polynomial equations (53,54).

A change in the profile of mineral content from milk to the final product of *shrikhand* was studied. The fermentation of milk brought about highly significant changes in mineral content during transition from colloidal to soluble phase during *shrikhand* preparation. This process was faster and greater in buffalo's milk than in cow's milk (55).

Postproduction heat treatment (PPHT) of *shrikhand* at 70°C for 5 min enhanced the shelf life up to 15 days at 35°C and above 70 days at 8–10°C (56,57). The overall quality also improved, as the heat treatment decreased the microbial count. PPHT stabilized the product against microbial and biochemical changes with concomitant improvement in the shelf life of the product as revealed by the superior sensory scores of these samples. Dehydrated *shrikhand* has a shelf life of 90 days when stored at 30°C in gas packed containers.

Shrikhand powder was prepared by subjecting the product to spray drying at 160–170°C of inlet temperature and 100°C of outlet temperature (58). Similarly, standardization of *shrikhand* powder preparation was carried out using a colloid mill to grind the *chakka*, adding 25 kg of sugar per 100 kg of *chakka*, adjusting the total solids to 30%, and drying with inlet and outlet temperatures of 190°C and 95°C, respectively (59). For packaging of *shrikhand*, cups made of polypropylene or polystyrene form-fill-seal containers have been used successfully (60).

18.3.1.5 Sewsew

Sewsew is an anaerobically fermented yak's milk product produced by Sherpa communities of Nepal. It is used in making soup and consumed with the *dhindo* (a curd meal). The whole yak milk is boiled and set using lactic culture. The fermented milk is churned the next day. After removing butter, the buttermilk is boiled to precipitate the buttermilk solids, called *sher*. *Sher* is mixed with one third the amount of milk and kneaded. The kneaded mass is filled in clean, dry earthen pots and sealed by covering with leaves and plastering clay on top. The product could be consumed after a month or even after a year with a perception that older the product, the better the quality (61).

18.3.1.6 Churpi

Churpi is a traditional cheese-like product, which is commonly consumed by different ethnic groups of people in the Himalayan regions of the Darjeeling hills, Sikkim, and Ladakh in India, Nepal, Bhutan, and Tibet (62). It is available in two forms — soft and hard. Soft *churpi*, also known as *kachcha churpi* is prepared from cow's milk. The milk, either boiled or unboiled, is kept in a wooden vat at ambient temperature for 24 h. Often the cream is allowed to separate and the milk is curdled by boiling. The casein is wrapped tightly in a piece of muslin cloth and allowed to drain for 3–5 h. This is consumed as a condiment by mixing with it sliced radish or cucumber. It is also mixed with meats, vegetables and spices to prepare curry. The average per capita consumption of soft variety *chupri* is 6.9 g/day in the Darjeeling hills and 9.9 g/day in Sikkim (63).

The optimal process parameters for controlling the preparation of *churpi* have been documented (64). Also, the microbial population and predominant lactic acid bacteria profiles of the soft variety of *churpi* have been identified (65). The lactic acid bacteria, yeasts, and viable mesophilic microbial numbers ranged from 7.6–7.9, 7.0–7.4 and 7.7–8.0 $\log_{10}$ cfu/g, respectively. The predominant lactic microflora are *Lb. plantarum, Lb. curvatus, Lb. fermentum, Lb. paracasei* ssp. *pseudoplantarum and Leu. mesenteroides*. Most of these strains showed high hydrophobicity, which indicates the potential of adhesion to gut epithelial cells, one of the important features of a probiotic culture. The absence of proteinases (trypsin and chymotrypsin) and presence of high peptidase and esterase–lipase activities of the predominant organisms isolated from *churpi* was observed, which are the traits of desirable quality for their use in accelerated ripening of cheese and production of typical cheese flavors (66).

The hard variety of *churpi* is made from skimmed milk of cow or yak milk. The skimmed milk is boiled and curdled by adding whey. After filtration, the casein is wrapped tightly with a cloth and cured at ambient temperature (15–20°C) for 2–3 days under pressure of about 0.25 kg/cm^2 made with the aid of heavy stones. The cheese is sliced and allowed to dry in sunlight for 2–3 weeks. This type of *churpi* becomes very hard and can be stored for a number of years (62). The preparation of both varieties of *churpi* is shown in Figure 18.2.

18.3.2 Vegetable and Fruit Based Foods

Natural microbial flora of fruits and vegetables are capable of altering these foods for human consumption. Fruits are a rich source of sugars and are slightly acidic, which make them suitable for yeast growth leading to alcoholic fermentation, which is omitted from the preview of this chapter. Relatively few fruits with low sugar content undergo lactic fermentation. Lactic fermented fruits are usually consumed as condiments accompanying main dishes.

Vegetables, unlike fruits, have low sugar content, neutral pH and their composition is not favorable for spontaneous growth of lactic acid bacteria. However, over centuries people have traditionally developed lactic fermentation methods that stabilize and improve

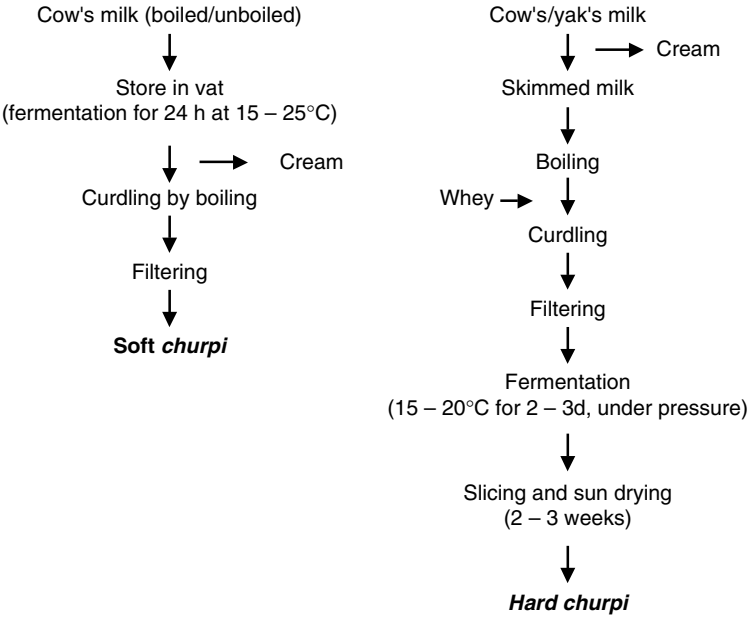

Figure 18.2 Flow sheet showing the differences in *churpi* preparation

nutritional quality of vegetables. Fermented vegetables represent an essential element of human diet worldwide. In Eastern and in many developing countries, fermented vegetables are staple foods, because they represent the traditional dietary element, which is easy to process. Lactic acid fermentation that enhances the organoleptic and nutritional quality of the vegetables has remained a household or small scale process. A few of the common lactic fermented products based on fruits and vegetables are shown in Table 18.1.

To promote lactic flora and to reduce initial microbial population from raw material, washing is essential. Natural inhibitors such as solanin in unripe tomatoes, phaseolin in beans, and oleuropein, the bitter glycoside in olives, needs to be eliminated. Choosing ripe tomatoes, blending the beans and adopting alkali treatment to olives prior to lactic fermentation eliminates the undesirable inhibitors. Certain ingredients are used in lactic fermentation such as sugar, mineral salts, and vitamins to promote the growth of desirable bacterial species. The lactic acid bacteria restrict other microbes by regulating the effect on pH or by producing inhibiting agents such as organic acids and bacteriocins during vegetable fermentation. Spices and herbs have a fine flavor determining role in fermented vegetables. Aromatic compounds in spices (including terpenes and polyphenols) often have antimicrobial effect, which selectively promote lactic bacteria. Certain spices such as garlic, cloves, chillies, — both unripe and red chillies — inhibit undesirable microflora. Many sulfur compounds (as in garlic) have antibacterial properties. Mustard seed contains allyl isothiocyanate, a volatile aromatic compound with antibacterial and fungal properties, which are known to inhibit yeasts. In India, ground mustard seed or oil is widely used in traditional lactic fermentation for prolongation of shelf life of the product. Chemical preservatives such as sorbic, benzoic acids and salts have sometimes been used in industrial production of cabbage, olives, and cucumbers (67).

Salting is an essential step in lactic fermentation. Salt concentration usually ranges from 20–80 g/l or up to 160 g/l as in the case of stored vegetables. Salt concentration induces plasmolysis in vegetables, thus promoting anaerobiosis for proliferation of lactic acid

Table 18.1
List of fruits and vegetables fermented by Lactic acid bacteria

Type	Example
Brassicaceous vegetables	cabbage, cauliflower, braceolis mustard vegetables.
Root vegetables	carrot, turnip, beetroot, radish
Vegetable fruits	cucumbers, olives, tomatoes, peppers, okra, beans, peas
Bulbs	onions, garlic
Vegetable juices	carrot, beetroot pepper, tomato pulp, mushrooms for sauces
Fruits	apples, pear, raw mango, immature plums, lemons, banana fruit pulp

bacteria. Salting is done either by adding dry salt or by using brine. In India, *jaggery* (unrefined cane sugar called *gur*) is added during lactic fermentation of the sweet turnip. Adding 1–2 g% sucrose or gur to shredded turnip along with 6 g% each salt and mustard seed increases lactic flora (68). At higher concentration, sucrose (25 g%) acts as inhibitor of lactic fermentation. Traditionally, to increase lactic flora, cooked rice, flour, whey, or cereal brans have been used. Buffering of the medium with an acetic acid calcium acetate buffer system for vegetables (with high sugars) in order to stabilize pH of the medium during fermentation is useful. Calcium ions are released by acetate, complexed with pectin in vegetables, thus protecting them from enzymatic hydrolysis and enhance texture of the product.

The common fermented foods based on vegetables and fruits are presented in what follows, individually, to stress the importance of these foods in the diversified cultures of the Indian subcontinent.

18.3.2.1 Sauerkraut

In India, sauerkraut fermentation does not exist as a traditional art. However, several studies on lactic fermentation of cabbage for sauerkraut are available. Suitability of cabbage varieties for the preparation of sauerkraut has been identified (69,70). Six varieties of cabbage namely GoldenAcre, Sel 8, NL401, NL501, Alfaco, and Pusa synthetic were evaluated. Five kg heads of each variety were trimmed, cleaned, cored, cut into 2.5 mm thick shreds, salted at 2.25% (w/w), mixed thoroughly, filled into glass jars, covered, sealed with proper weight, and allowed to ferment at ambient temperature (25–30°C) for 7 days. The resultant sauerkraut was pasteurized for 5 min and preserved either with sodium benzoate (500 ppm) or potassium metabisulfite (350 ppm) at ambient and refrigeration temperature. A sauerkraut with a pH in the range of 3.5–3.1 and acidity values of 1.10–1.15% was attained in case of NL401 and NL501, which was low as compared to1.5–1.6 in case of quality sauerkraut. This could be attributed to high ambient temperature (25–30°C), which promotes wild yeast that oxidizes lactic acid. Sensory evaluation revealed that sauerkraut from NL 501, NL401, and Sel 8 were the best with regard to texture, flavor, and overall acceptability. The golden yellow color of kraut could be better retained by using potassium metabisulfite (KMS) as compared to sodium benzoate.

Pasteurized kraut could be stored at refrigerated temperature for more than six months. In cases of kraut stored at ambient temperature, browning was a problem (70). Temperature plays a vital role in production of good quality kraut. The effect of temperature on the quality of sauerkraut showed that kraut prepared at 18–25°C from either variety of cabbage (red cabbage or Pusa drum head) was superior in color, texture, flavor, and taste when compared to those prepared at 34°C or 12°C (71). The development of surface yeast

called as *Mycoderma* during storage of sauerkraut results in the loss of acidity, development of off flavor and softening of the product. Accordingly, the tolerance limits of *Mycoderma* to various additives to prolong the storage life of kraut was studied (72). The study revealed that the wild yeast was tolerant to high salt (16%). In acidic slurry (1.5% lactic acid), its growth could be effectively controlled in low concentrations of salt (3%) in combination with low concentration of acetic acid (0.2%), sodium benzoate (300 ppm) or sorbic acid (100 ppm). Other (mustard-like) condiments and be added and they not only impart flavor and taste, but also act as a preservative. In India, mustard is extensively used in pickles. The addition of mustard powder, turnip, cabbage, and cucumber was shown to increase the rate of lactic fermentation (68,69).

18.3.2.2 Gundruk

Gundruk is a nonsalted fermented acidic vegetable product indigenous to the Himalayas (73). The fermenting substrate for *gundruk* is usually rayo (*Brassica campestris* L var *cumifolia* Roxb) leaves. Other leaves such as radish (*Raphanus sativus* L), shimrayo (*Cardamine hirsute* L var *sylvatica* Link), cauliflower (*Brassica oleracea* L var *botrytis* L) and mustard (*Brassica juncea* L) are also used. The word *gundruk* is derived from the newari word "gundru" (the Newaris being one of the ethnic groups of the Nepalese). *Gundruk,* though originally confined to Nepal, has become popular among all the ethnic groups of Darjeeling and Sikkim in India.

Gundruk is usually prepared during the months of December to February when the climate is less humid and an ample supply of vegetable is assured (62). The leaves are dried under sunlight (1–2 days), crushed mildly, soaked briefly in hot water, and hand pressed in perforated tin or earthen jars with heavy stones to remove excess water. The leaves are then kept in a warm, dry place for 15–22 days for fermentation. In the village process, a hole (about $1m^3$) is dug in the ground and dried by fire. Banana or bamboo leaves are spread in the bottom (about 30 cm) on which the dried crushed leaves of the vegetables to be fermented are placed and covered on top by banana or bamboo leaves. Heavy stones are placed to compress the substrate. The holes are sometimes covered with a layer of cow dung. The leaves are allowed to ferment *in situ* until a fermenting odor develops (15–22 days). The *gundruk* is taken out and dried under sunlight for 2–4 days. It has a shelf life of one year.

An almost similar product known as *pani* (water) *gundruk* is commonly prepared and consumed in the Redong area in the Kalimpang subdivision of Darjeeling district of the West Bengal State of India. *Rayo* leaves are dried under sunlight for 2–3 days, crushed lightly, soaked in hot water, drained and kept in vats containing warm water (30–35°C) for only 3 days. They are then squeezed and dried under sunlight for about 7 days. Inhabitants of this region prefer *pani gundruk* for its sour taste, easier preparation, and greater resistance to spoilage microflora. *Gundruk* is typically used as a base for soup and as pickles (62). During *gundruk* fermentation *Lb. cellobiose* initiates the fermentation, followed by homofermentative *Pediococcus pentosaceus*, *Lb. casei* and finally by *Lb. plantarum*, producing lactic acid and acetic acid, which lower the pH of the substrates (74).

18.3.2.3 Sinki

Sinki is a unsalted traditional lactic acid fermented radish root product of Nepal. Recently, this fermented food is becoming popular in the Darjeeling district of West Bengal State and Sikkim of India, and in Bhutan. Like *gundruk*, *sinki* is prepared during the months of winter, when the climate is least humid and the supply of vegetables is assured (75). The method of preparation is similar to *gundruk*, except that the substrate is the taproot of radish (*Raphamus sativus* L) and the fermentation takes 30–40 days. In the traditional method,

fresh tap roots of radish are washed, wilted by sun drying for 1–2 days until they become soft, shredded, washed, and placed tightly into earthen jars with the help of heavy wooden pestles. The jars are covered by radish leaves with earthen lids and kept in a warm, dry place for 15–30 days. In some places as in *gundruk* preparation, a pit (1 m^3 size) is dug in the ground, which is covered with dried leaves of bamboo, banana or radish. The shredded taproots are placed in it, pressed tightly and covered with dried leaves and heavy stones are placed for compression. The top of the pit is plastered with mud or cow dung. After 30–40 days, the fermented mass is removed and sun dried. *Sinki* has a shelf life of one year if dried in sunlight from time to time.

Studies (76) undertaken to assess the proximate composition and microflora of samples of *sinki* procured from markets of Darjeeling, Kalimpang and Gangtok showed the average moisture of 22.0, 20.4 and 21.3%, respectively. The protein, fat, and ash content are approximately 14.5, 2.5 and 11.5%, respectively. The pH of the products were 4.45, 4.28 and 4.40, with acidity at 0.65, 0.80 and 0.72%, respectively. The microbiological analysis of market samples showed the presence of *Lb. plantarum* and *Lb. brevis*. These isolates did not hydrolyze protein, fat, and starch, indicating that none of these substrates were utilized during fermentation. The development of acidity in *sinki* is attributed to the utilization of free sugars of the substrate by lactobacilli. Traditional process parameters optimization with respect to fermentation temperature (20, 30, and 40°C), utilization of different containers (glass jar, earthen jar, polythene bags) and the period of fermentation (7, 12, 20 d) have been studied (76). The optimum conditions of fermentation were at 30°C for a period of 12 days in glass jars. The product had a pH value of 3.0 and an acidity of 1.28% with highest organoleptic scores. The succession of microflora showed the initiation of fermentation by heterofermentative *Lb. fermentum,* followed by another heterofermentative *Lb. brevis* and finally succeeded by homofermentive *Lb. plantarum*. *Sinki* prepared under optimized condition could substantially reduce the fermentation time to 12 days, compared to the traditional method which takes about 30–40 days.

18.3.2.4 Khalpi

Khalpi is a fermented cucumber pickle of Sikkim and Himalayas. The ripe cucumber is wilted (1–2 days), peeled, sliced, and mixed with mustard oil; spices and salts were added and pressed tightly into a container, covered and fermented (5–7 days). *Khalpi* is a sour acidic pickle, which can be stored for several days (73).

18.3.2.5 Fermented Cucumber

A laboratory scale process for lactic fermentation of cucumber was standardized (77). Firm immature cucumbers were kept in glass jars with 5% brine. After 3 days, the brine was drained and replaced by 6% brine. Subsequently, at weekly intervals, brine concentration was raised to 10, 12 and 15% level. Salt stock cucumber has a storage life of several years. It could be used for the preparation of sweet, sour, sliced, or a mixed type pickle after desalting. Garg et al. (77) removed the cucumbers from the salt stock and preserved them in 2% acetic acid for 3 months at ambient temperature of 33–38°C as sour pickles, which could be consumed directly as pickles. However, reduction of acidity to 0.55% by treating with 5% $CaCl_3$ (overnight) gave desirable organoleptic characteristics, firm texture, and flavor for the pickles.

18.3.2.6 Kanji

In northern parts of India, a ready to serve traditional fermented beverage popularly known as *kanji* is prepared from roots of the black carrot (*Daucus carota* L). The traditional

method for the preparation of *kanji* involves natural fermentation of longitudinally slit carrots suspended in an excess quantity of water (15–20 times the weight of the carrot) along with salt, chillies, and crushed mustard in an earthen pot. The product acquires acceptable taste and an attractive crimson color after seven days. The shelf life of the beverage is limited to about seven days and thereafter flavor degenerates (78).

Berry et al. (78) prepared *kanji* by both natural fermentation and controlled fermentation using *Lb. plantarum*. The fermentation medium for *kanji* contained the following: 1 kg of grated carrots mixed with 7 kg of water, 200 g of common salt, 40g of crushed mustard, and 8g of red chilli powder. One lot was subjected to natural fermentation; another lot was fermented using *Lb. plantarum*. The third lot also was subjected to fermentation with *Lb. plantarum* but without the crushed mustard. All three batches were fermented at ambient temperature (20–23°C) for 10 days and heat processed for 25 min in boiling water. The acidity increased from 0.18 to 0.43, 0.35 and 0.3%, respectively, with the total sugar at 1.94% in all the three batches. The bottled beverage was stable at ambient temperature (13–42°C) for six months. The natural fermented beverage was rated as the best, followed by the *Lb. plantarum* fermented batch containing crushed mustard. The beverage prepared using the dehydrated (0.7% moisture) black carrots, after three months storage, was also found to be satisfactory with respect to sensory quality attributes. Thus *kanji* may be made available to the consumer during off seasons when fresh carrots are not available.

Attempts have also been made to standardize the method of fermentation of *kanji* using preservatives such as sorbic acid or a combination of sodium benzoate and potassium metabisulfite. Fermentation of carrots in 2% brine with sorbic acid (0.1%) and calcium chloride (0.1%) at 30°C ± 2, for 6 days yielded an acceptable product in which 60% carotenoids were retained at the end of four months at ambient temperature of 30 ± 2°C (79).

A standard recipe for preparing concentrated fermented carrot juice using 3% brine, 1% mustard and sodium benzoate (0.015%) and potassium metabisulfite (0.01%) with a shelf life of 6 months at ambient is available (80). Microbiological and biochemical changes during fermentation of 1.5% sliced crimson colored carrots in 3 liter 3% brine with 4% mustard powder at ambient temperature (20 ± 2°C) for 15 days to obtain *kanji* was studied (81). *Leuconostoc mesenteroides* and *Leu. dextranicum* predominant during natural fermentation with occasional appearance of *Pediococcus* spp. were found. The total sugars increased up to 200 μg/ml. The pH dropped from 7.2 to 4.0 after four days of fermentation. The production of ethanol was 2–5% after 3 days, which dropped due to oxidation by acetic acid bacteria. At the end of 14 days, the *kanji* had an acidity of 0.3% and a pH of 4.0.

18.3.2.7 Mesu

Mesu is a salted fermented bamboo shoot product, traditionally consumed by the people in the bamboo growing regions of Nepal and in the Darjeeling hills of West Bengal and Sikkim in India (82). The Lepchas call it "sitit." Young edible shoots of bamboo (*Dendrocalamus humiltonii* Nees and Arnolt, *Bambusa tulda* Roob, and *Dendrocalamus sikkimesis* Gambli, locally known as "choya bans" or tama; "Karati bans" and bhalubans, respectively) are defoliated, chopped, pressed tightly with leaves of bamboo or other wild plants, and left at ambient temperature (20–25°C) to ferment for 7–15 days. The fermented product has typical *mesu* flavor, i.e., a strong ammoniacal flavor and sour taste.

Mesu is usually prepared in the months of June to September when bamboo shoots sprout. It is commonly used as a pickle by mixing it with salt, mustard oil, and green chillies. It is also used for preparing curry by frying it and mixing it with cooked meat. The fresh *mesu* has a shelf life of about 6 days, while its pickle can be stored for more than a year (82). Microbiology of *mesu* samples collected for different weekly markets of

Kalimpang (Darjeeling hills) and Gangtok (Sikkim) revealed *Lb. plantarum, Lb. brevis* and *Pediococcus pentosaceus*, among 327 strains of lactic acid bacteria from 30 samples. *Mesu* was dominated by *Lb. plantarum,* followed by *Lb. brevis*. Succession of microbial microflora in bamboo shoots during fermentation to produce *mesu* revealed dominance of *Ped. pentosaceus* in the early stages, followed by *Lb. brevis* and then again the domination of final product by *Lb. plantarum*. During fermentation, acidity increased from 0.04–0.95% and pH declined from 6.4–3.8.

18.3.2.8 Kachampulli

Kachampulli is a traditional souring concentrate made from fruits of malbar tamarind (*Garcinia cambogia*) used in culinary dishes in the Coorg district of Karnataka, India. These fruits are valued for their acidic and medicinal properties (83). The traditional method of making *kachampulli* involves softening of fruits (1–2 weeks) in specially made bamboo baskets. Softened fruits are pressed by wooden rollers to expel juice, which is filtered and concentrated by heating in earthen pots. Succession of microorganisms during *kachampulli* production is not studied. The modified process for *kachampulli* involves the use of the pectinase enzyme (0.5–1.0%) to soften the fruit, vacuum, or open pan evaporation of the juice to obtain *kachampulli*, a dark brown viscous concentrate of 50° Brix having 39% acidity (83). Fruit residues are used for byproducts. Juice from the seed and placenta were extracted using pectinase enzymes. Culture of *Saccharomyces cerevisiae* was used to complete fermentation (3 days) to yield low alcohol (5%) wine of pink color with a fruity aroma. The seeds were dried, cracked, and a low melting point (30–40°C) fat was extracted by boiling the seeds in water.

18.3.2.9 Indian Kinema

Fermentations involving highly alkaline products are generally safe if properly fermented. The organisms are proteolytic and proteins are hydrolyzed to peptides and amino acids. Ammonia is released and the pH rapidly reaches as high as 8.0 or higher. The combination of high pH and free ammonia along with very rapid growth of essential microorganisms at relatively high temperature (above 40°C) make it very difficult for other organisms to grow. Thus, the products are quite stable and well preserved especially when dried. These are safe foods even though they may be manufactured in an unhygienic environment (1).

Kinema is a soybean based fermented sticky, slightly alkaline product with slight ammonia-like flavor produced by bacterial fermentation. Tamang (84) has dealt in detail with the socio-economical aspects of *kinema*. It has been traditionally prepared in the Himalayan region of Nepal, India, and Bhutan for centuries. Soybean, locally known as "bahtmas" is a major summer crop grown under rain fed conditions in upland terraces up to an altitude of 1500 m. Indigenous local varieties of soybeans (*Glycine max*, L. Merrill) yellow cultivar, and dark brown cultivars are cultivated. The *kinema* may have originated from the "Limbu" (one of the castes of ethnic Nepalis) dialect kinambaa, "ki" meaning fermented and "nambaa" meaning flavor (74). In traditional process of *kinema* preparation, soybean is soaked in water overnight, cooked until it can be pressed easily, excess water is drained off, and cooked beans are transferred to wooden mortar and crushed moderately by a wooden pestle (locally called "okhali"). They are transferred to bamboo basket lined with jute bags and layers of fern (*Athyrium* sp.) leaves; about 1% wood ash is added to the soya bean grits before folding the fern leaves and sack clothes. The mixture is left to ferment naturally at ambient temperature (25–40°C) for 1–3 days above an earthen oven in the kitchen.

Kinema production has been confined to the rural household level. *Kinema* consumption in Sikkim is 2.2 g and in Darjeeling hills it is 3.3 g per day according to the

estimate of 1997–1998 (85). The presence of *B. subtilis*, *Enterococcus faecium*, *Candida parapsilosis* and *Geotrichum candidum* in *Kinema* samples was reported (86). *Bacillus subtilis* was found to be the dominant microflora in *Kinema*. During *kinema* production, remarkable increase in water soluble nitrogen and trichloroacetic acid content was observed (87). Total amino acids, free amino acids and mineral contents increased and the ratio of free amino acid to total amino acids was 11.4% (88,89). A laboratory scale production of *Kinema* using *B. subtilis* KK-2:B10 (MTCC 2756) and GK-2:B10 (MTCC 2757) isolated from naturally fermenting *kinema* was optimized (90). The quality of *Kinema* was maintained with pure culture fermentation by *B. subtilis* KK-2:B 10 at 40°C for 20 h followed by maturation at 5°C for 1 day (91). A ready to use pulverized starter culture of *B. subtilis* was developed for *kinema* production (84).

18.3.2.10 Pickles

Cauliflower (*Bracica oleracea* var. *botrytis L*) is an important vegetable crop, which is popularly used for the preparation of pickles in India. The effect of mustard and its components on the fermentation of cauliflower was studied (92). In one study, whole mustard flour (fat free), mixed with total volatile oil of four species of mustard namely *Brassica juncea, B. nigra, B. campestris* var. *toria* and *B. campestries* var. *dichotoma* were studied for their suitability during lactic fermentation of cauliflower. Increasing the proportion of salt (2–12%) progressively decreased the rate of acid production and delayed spoilage by surface yeast. The maximum acidity was developed in 4% salt when used either alone or along with 2% mustard. On the other hand, increasing the proportion of mustard from 1 to 2% helped to increase the rate of acid production. The complement role of whole mustard was better than the residue flour or volatile oil. The mustard variety *B. nigra* showed better preservative action than *B. juncea "sarson"*or "*toria*."

In comparison to the previous example, the popular types of pickles consumed by the human population of India have been those based on unripe mangoes, gooseberries, lemons, *Decalepis hamitonii,* and a variety of mixed vegetables. In general, most of these pickles are prepared at the household level by subjecting the vegetable or fruit to natural fermentation. In one of the specific type of pickles, wherein preservation is achieved through high concentrations of salt and lactic acid fermentation, the raw materials are washed well, cut into suitably sized shapes and mixed with salt at a level of two times more than that of weight of the raw materials as well as a requisite spice powder. The specie powder mix mainly consists of chillies, mustard, and coriander seeds. The mouth of the containers are closed properly and kept for 7–8 days at ambient temperature (20–30°C) for the natural fermentation to take place *in situ*. During the storage period, acidity develops and a certain amount of aging provides the acceptable organoleptic attributes to the pickles. The amount of acid produced and time period is dependent upon the type of produce used in pickle preparation. Although not much research has been done into the nature of microflora and other attributes, it is thought that the microflora mainly comprises lactic acid bacteria and to a certain extent acetic acid bacteria. On similar lines, pickles are also prepared from a variety of vegetables.

In contrast to the previous discussion, wherein the final product is in the form of fermented vegetables or fruits immersed in liquid formed due to the presence of high salt and spice mixture, there is another specific type of pickle which is devoid of any liquid. In this case, the raw materials for pickle preparation are the same as described previously and preservation is through high concentration of salt, spice mix and edible oil. The raw materials, such as unripe mangoes, gooseberries, and lemons, either whole or cut pieces, are cleaned well and mixed with salt and spice mix as in the previously described pickle preservation.

This mixture is subjected to frequent mild frying with oil. After 3–4 similar treatments, the whole mixture is placed in a clean container and the mouth of container is closed properly. It is very essential to see that the pickle mixture is layered with sufficient quantity of edible oil, which is usually sesame oil or mustard oil depending upon the regions of preparation. In this specific type of preparation, fermentation occurs naturally. Generally, the lactic acid bacteria microflora is comprised mainly of those species that can survive and grow in presence of high salt concentrations.

Regardless of the type of pickle preparation, the shelf life is quite reasonable extending even up to periods of 6 months and beyond, if proper practices of hygiene and sanitation are taken. In the absence of any microbiological studies of the nature of pickle fermentation, from the product profile, it would appear that species of *Pediococcus* tend to predominate over the other lactic acid bacteria.

Traditionally, most of the vegetables, either in single or in combination with spices, are subjected to natural fermentation. This preparation has been more or less on a home scale operation, which contribute toward many health benefits without much scientific knowledgebase. Controlled fermentation of bitter gourd (*Momordica charantia*) and fenugreek leaves (*Trigonella foenum graecum*), individually, with an antagonistic culture of *Ped. pentosaceus* resulted in a more acceptable product with increased levels of pyridoxine, ascorbic acid and vitamin B_{12} (93).

18.3.3 Cereal and Legume Based

Cereal and legume based foods are a major source of economical dietary energy and nutrients, worldwide. Often, the regional specific cereals or legumes are subjected to natural or controlled fermentation to obtain desirable final products which are nothing but fermented foods. The involvement of desirable microorganisms, particularly those of lactic acid bacteria, yeasts, and fungi have been well documented (1,94,95).

A major proportion of the cereal and legume based foods are fermented by lactic acid bacteria, wherein these organisms possess the ability to increase palatability, keeping quality, safety, and nutritive value of the raw materials, either cereals or legumes or both. The successive growth phase of microorganisms in fermenting cereals and legumes also favors yeast growth, which often occurs as a component of mixed microflora and imparts specific characteristics for the product (3).

In general, the low pH resulting from lactic fermentation suppresses excess activity of alpha amylase and other enzymes during cereal fermentation. In addition, the fermentation process contributes to the bioavailability of minerals by phytate degradation (96,97,98). A good lactic acid fermentation process depends upon two important factors, namely soaking and cooking of raw materials (ingredients), and salting. The soaking and heating process causes solid losses, but it leaches out or inactivates certain factors that are detrimental to nutrition, such as phytic acid, flatus-causing oligosaccharides and trypsin inhibitors (99,100). The process also reduces the *in situ* microbial contaminants. Salting is a common step in almost all types of fermented foods. In addition to imparting a salty taste, sodium chloride acts as a preservative and bears a selective action on the microorganisms that prevail in the fermentation substrate.

One of the oldest human civilizations has been in the Indian subcontinent and in particular, India, being a vast country, has been the home of innumerable sects of human population. The diversity in cultures accounts for a large number of traditional fermented foods with the majority of them being region specific. Nearly 90% these cultures are highly secretive in their preparation of such fermented foods and tend to be regionalized, with many of the foods being prepared at the household level. Under these circumstances, very few of these traditional foods have been explored from scientific and technological

angles. Most of these fermented foods are being prepared according to the traditional knowledge without any knowledge of technologically advanced methods.

Researchers have attempted to determine the nature of fermentation process, microflora involved, and the role played by these organisms in a variety of Indian fermented foods. The popular and widely consumed cereal and legume based fermented foods of the Indian subcontinent are presented in Table 18.2. A few of these fermented foods are presented with details relating to biotechnological aspects.

18.3.3.1 Idli

Among the closely related types of traditional fermented foods based on cereal and legume combination is that of *idli*. *Idli* is a white, fermented (acid leavened), steamed, soft and spongy texture product, widely popular and consumed in the entire South India. It has been documented that *idli* batter fermentation has been in use since 1100 AD (101). Recently, *idli* is also becoming popular throughout India, as well as in neighboring countries such as Sri Lanka and others. *Idli* is the resultant product from the naturally fermented batter made from washed and soaked milled rice (*Oryza sativus*) and dehulled Blackgram dhal (*Phaseolus mungo*). From a nutritional and health status point of view, *idli* appears to be an ideal human food for people of all ages and at all times. Considering the energy requirements of a diet for preschool children as well as women who lack proper diet intake, this traditional fermented food can play a vital role as a supplementary food.

Considering the importance of this traditional fermented food, exhaustive reviews have been published (1,4,102) covering all the aspects relating to preparation, microbiology, biochemistry and nutritional of *idli* batter fermentation. Investigations into the primary aspects of *idli* batter fermentation were initiated as early as 1955 at the Central Food

Table 18.2
Popular cereal and legume based fermented foods of the Indian subcontinent

Fermented Food	Region of Origin/ Popular/Consumed	Ingredients (Cereals/Legumes)	Microorganisms Involved
Ambali	India	Finger millet flour and rice cake	Lactic acid bacteria
Appamam/ Uttapamam	India, Sri Lanka	Blackgram dhal, rice, wheat flour	Lactic acid bacteria, Yeasts
Batura	India	Wheat flour	Yeasts, Lactic acid bacteria
Dhokla/Khaman	India	Bengalgram dhal, Blackgram dhal, rice	Lactic acid, bacteria Yeasts
Dosa	India	Blackgram dhal, rice	Lactic acid bacteria, Yeasts
Idli	India	Blackgram dhal, rice	Lactic acid bacteria, Yeasts
Jelaebi	India, Pakistan	Blackgram dhal	Lactic acid bacteria, Yeasts
Kadhi	India	Bengalgram flour, curds	Lactic acid bacteria
Kenima	Nepal, India	Soy beans	Yeasts and molds
Kulcha	India, Pakistan	Wheat flour	Yeasts
Papadam	India	Blackgram dhal rice, spices	Lactic acid bacteria
Poko	Nepal	Fermented rice	Yeasts, molds and Lactic acid bacteria
Punjabi warri	India	Blackgram dhal, spices	Lactic acid bacteria
Rabadi	India	Pearl millet flour	Lactic acid bacteria

Technological Research Institute, Mysore, India. These studies have not only been initiated by Indian researchers, but also by researchers in other developed countries for the purpose of scientific understanding and technological improvements.

The traditional method of preparation of *idli* is shown in Figure 18.3. *Idli* is prepared from a mixture of milled rice and Blackgram dhal with their proportions varying to a slight extent based on the regions of preparation. Several researchers have used different proportions of Blackgram cotyledons to rice, i.e., from 4:1 to 1:4 weight to weight (w/w) for making *idli* (102). Desikachar et al. (103) and Steinkraus et al. (104) used proportions of rice to Blackgram cotyledons of 2:1 to 4:1 and reported a preference for 2:1 and 3:1 over 4:1. The proportion of rice to Blackgram grains used in *idli* fermentation ranges from 1:4 to 4:1. Studies at the Central Food Technological Research Institute, Mysore have optimized the proportion of ingredients for *idli* batter fermentation during the years 1955–1960. Lewis et al. (105) tested rice to Blackgram ratios of 2:1 to 4:1 and preferred 2:1 and 3:1 over 4:1, where the rice flavor predominates. Radhakrishnamurthy et al. (106) also preferred a 2:1 ratio of rice and Blackgram dhal. The traditional method of *idli* preparation uses rice and Blackgram dhal in the proportion of 3:1.

Invariably the ingredients are soaked separately in water at ambient temperature for 6–8 h. Soaked ingredients are wet ground separately, mixed, and subjected to natural fermentation at ambient temperature ranging from 10–12 h, with overnight being the traditional time interval for *idli* and the like. Here also, the amount of water added to rice and Blackgram dhal batter as well as salt is variable. The amount of water required to prepare the batter of desirable and uniform consistency varies from 1:5 to 2:2 times the dry weight of the ingredients (103).

In traditional practice, rice and Blackgram dhal are soaked separately in water at ambient temperature for 5–10 h prior to grinding for batter preparation. The soaked ingredients

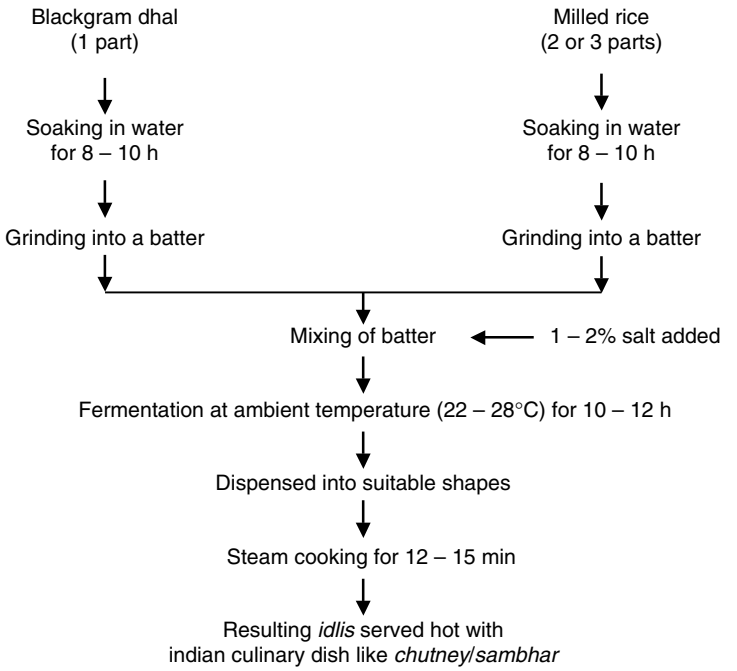

Figure 18.3 Preparation of *idli* by traditional method
Source: Yajurvedi, R.P., *Ind. Food Packer* 34: 33–38, 1980.

are ground wet, in a hand operated roller or stone grinder (107–109). In the laboratory, an electric grinder also can be used to provide the proper texture. In recent times, an electrically operated mixer or grinder is used in varied scale of operations, including home kitchens (1,108). As a means of convenience, in recent times instead of using milled rice, followed by soaking and grinding into a batter, requisite quantity of rice semolina (grits) is directly mixed into the Blackgram dhal batter prior to subjecting to natural fermentation.

In general, *idli* batter fermentation is carried out at ambient temperature. In the tropics, this generally means a temperature of 25–30°C, which is the optimum for a desirable fermentation (1,103). The fermented batter is prepared into suitable shapes and steamed for 10–15 min. The resultant product is known as *idli*, which is served hot along with compatible traditional culinary dishes such as chutney and sambhar.

Studies have demonstrated the optimum fermentation conditions for obtaining good i*dlis* as well as the physiochemical and microbiological changes taking place over intermittent periods of incubation at varying temperatures (103,108,109). Usually, the microorganisms that develop during the initial and later soaking of the ingredients are sufficient to bring about the fermentation. The microbiological changes during the fermentation period have shown the involvement of varied genera and species of lactic acid bacteria and yeasts. The microflora associated with *idli* batter fermentation has been the subject of several investigations, both at the national and international levels (4,104,107,109–112). The bacterial organisms, identified as a part of the microflora, included *Leuconostoc mesenteroides*, *Lactobacillus delbrueckii, Lb. fermentum, Lb. lactis, Lb. brevis, Streptococcus faecalis* and *Pediococcus cerevisiae*, while the yeast flora comprised *Torulopsis candida, T. holmii*, *Candida cacaoi, C. fragicola, C. kefyr, C. tropicalis, Hansenula anomala,* and *Rhodotorula graminis*. Further, these studies have shown the predominance of major flora at various stages of fermentation in *idli*.

Studies (107) have shown that during *idli* batter fermentation, there is a rapid disappearance of the common aerobic contaminants during the initial soaking of the ingredients. Following this, *Leuconostoc mesenteroides* and *Streptococcus faecalis* develop concomitantly during soaking and continue to multiply following grinding and they play a significant role in *idli* fermentation. In the later stages, the number of these two microorganisms decreases and *Pediococcus cerevisiae* develops. A similar approach has been presented by Thyagaraja et al. (109).

Two significant changes occurring in *idli* fermentation are acidification and leavening of the batter. These two parameters are being used as the criteria for judging the progress of fermentation. Comprehensive studies on the various changes accompanying *idli* batter fermentation have shown that besides successive increase in microbial populations, the pH declined to 4.4–4.9 from an initial pH of 6.6 (4,109). Several attempts have been made to improve the *idli* fermentation by standardization of various physiochemical factors. An increasing rate of *idli* batter fermentation was observed to accompany a rise in temperature (103). Fortification of *idli* batter with glucose at 1% level showed a beneficial effect on gas production and leavening during fermentation (113).

Successive changes in microflora and accompanying biochemical changes during *idli* fermentation have been the subject of several studies (1,4,101,114,115). Results on the effects of fermentation on methionine and cystine content of the substrate mixture showed variable levels, with *idlis* prepared using rice and Blackgram dhal in 1:1 ratio resulted in an apparent increase in levels of methionine and cystine. Similarly, the relationship between the type of microflora and the biochemical attributes has also been studied, wherein there was an increase in the water soluble group B vitamins during *idli* fermentation (114).

Research investigations have been attempted to alter the preparation for the sake of convenience and for achieving uniform and consistent quality *idlis*. As a step toward

convenience in the preparation, the concept of a dry blend mixture was put forth as early as 1960 by Desikachar et al. (103). A dry mix composition of one part of finely ground Blackgram flour (-52 + 56 B.S.I. mesh) and two parts of rice semolina (-18 + 20 B.S.I. mesh) and containing 2.8% sodium chloride were mixed together and stored. As and when required, the batter was prepared from this stock by uniformly dispersing it in the requisite quantity of water into a homogeneous consistency.

In order to obtain a more uniform and consistent quality *idlis*, the concept of controlled fermentation was attempted as early as 1960 (106). For the inoculua studies, Blackgram flour (120 g) was sterilized by autoclaving at 121°C for 60 min on two successive days, extracted with sterile water (800 ml), centrifuged twice at 2000 rpm and the centrifugate again autoclaved. Blackgram flour or rice semolina (120 g) was prefermented with 400 ml of distilled water for 5.5 hours at 30°C and agitated in a mechanical shaker for 30 min, after adding 400 ml more distilled water. The slurry was then centrifuged twice at 2000 rpm and the clear extract was used. For each study, 55 ml of the centrifugated mixture representing the microbial inoculua and the solubles that were extracted from 8.3 g of Blackgram flour or 16.6 g of rice semolina was taken.

In a similar approach, a process relating to an improved means of providing inoculua (lactic acid bacteria and yeast) in ready to use form *idli* fermentations has been developed (116). The novelty of the process is making available the inoculua for fermented foods in a ready to use form. The inoculua, which comprise microbial cultures, are made using a simple and easily affordable substrate. The growth of microbial cultures is achieved in the substrate by a series of steps which involve certain newer and simpler methods, as well as conditioning of the microbial rich substrate approach which does not require heating. This nonheating approach enables retention of high cell density of viable microbial cultures, which is lacking in other drying methods. The final ready to use product is a free flowing high volume with a high stability at low temperature storage.

In a direction towards reducing the fermentation time of *idli* batter and increasing the shelf life of fermented *idli* batter, an improved process for the preparation of shelf stable *idli* batter has been filed as an Indian patent (117). The novelty of the process lies in using optimal cell densities of defined microbial cultures, either to accelerate the fermentation time or to achieve fermentation of *idli* batter. It is then packed in polyester laminate pouches with a shelf life of 10 ± 2 days at 28–32°C and 3 ± 1 days at 40°C. Simultaneously, the flavor profile of such controlled fermented *idli* batter has shown the presence of desirable flavor compounds such as ketones, diols, and acids for a period of 8 days of storage. This flavor profile can be a reliable qualitiative and quantitative parameter for objective assessment (118).

In *idli* batters prepared by accelerated fermentation time period (6 h) using high cell densities of defined microbial cultures, a marginal increase in proteinase activity and a significant increase in alpha amylase activity was detected as opposed to the initial and 6 h naturally fermented batters. Similarly, there was an increased protein content in the extracted globulin from 6 h accelerated fermented *idli* batter and a reduced prolamin level (Varadaraj, unpublished data).

Under certain circumstances, the final product may not appear to be acceptable in terms of the quality attributes. This occurs due to the predominance of undesirable microbial contaminants over that of desirable lactic and yeast microflora. Studies on the inhibition of such undesirable bacterial species have revealed that plantaricin LP84, a bacteriocin produced by *Lb. planatrum* NCIM 2084, was able to retard the growth of the food borne pathogens such as *Bacillus cereus* F 4810, *Escherichia coli* D 21, and *Staphylococcus aureus* FRI 722 during *idli* batter fermentation. However, these pathogens occurring as contaminants in *idli* batter can survive and grow under conditions of natural fermentation (119).

In an effort to utilize certain nutritionally well balanced legumes such as soybeans in *idli* preparation, a few studies have shown its potential (101). *Idlis*, prepared replacing Blackgram with soybeans, has shown an increased roughage, amino nitrogen, and free sugars, while the resultant product had a somewhat different flavor and sticky surface (120). Soybean based *idli* batters have shown increased levels of biochemical attributes including B-group water soluble vitamins.

18.3.3.2 Dosa

Dosa is a fermented, thin, crisp, fried, pancake-like product widely consumed in South India, parts of Western India. It is becoming popular in other parts of India as well as in the Indian restaurants elsewhere in the world. The batter preparation for *dosa* has been almost the same as that of *idli* batter, except for the proportion of milled rice and Blackgram dhal. The product is prepared by soaking separately equal quantities of milled rice and dehulled Blackgram dhal for a period of 6–8 h at ambient temperature (25–30°C) and then grinding them together into a fine paste with requisite quantity of water (2.0–2.5 parts w/w). The batter is then allowed to undergo natural fermentation for a period of 10–14 h at ambient temperature (25–30°C). The fermented batter is then fried using oil into a thin, crisp, pancake-like product.

In almost similar to *idli* batter fermentation, traditional *dosa* batter fermentation has revealed the occurrence and role of lactic acid bacteria in combination with yeasts in bringing about various biochemical changes (121,122). The predominant species identified were *Leu. mesenteroides*, *Lb. fermentum*, *Lb. delbruecki*, *Ped. cerevisiae*, *Sacc. cerevisiae*, *Hansenula anomala,* and *Kluyveromyces* sp. Usually, these microorganisms come from the raw materials — rice and Blackgram dhal (4). *Dosa* batter fermentation also resulted in increased biochemical attributes, including that of water soluble group-B vitamins such as thiamine, riboflavin, and cyanocobalamin.

As in the case of *idli*, attempts were made to prepare *dosa*-like products by replacing Blackgram with other legumes like soybeans. Soybean-based *dosa* batter was found to be nutritious, but less preferred organoleptically (123).

18.3.3.3 Kadhi

Kadhi is a traditional fermented culinary food item with a mild acidic taste and a typical cooked flavor, widely consumed in most parts of India as a culinary food item. Traditionally, *Kadhi* is prepared by boiling stirred *dahi* (lactic fermented) with 5–8% (w/w) Bengalgram dhal flour (*besan*) as a thickening agent. The traditional method of *kadhi* preparation is presented in Figure 18.4. Microbiological studies in *kadhi* have been lacking.

Most of the traditional fermented foods are prone to contamination with food borne pathogenic and spoilage bacterial species. Such a situation is more frequently encountered due to the prevailing environmental factors aided by inconsistent quality raw materials. Considering the potential use of antagonistic LAB, studies have been undertaken to evaluate the effectiveness of antibacterial properties of selected LAB toward food borne pathogenic and spoilage bacterial species occurring in preprocessing and postprocessing contaminants in *kadhi* (124,125).

The potential use of antagonistic cultures of *Lb. delbruecki* ssp. *lactis* CFR 2023 and *Lb. delbruecki* ssp. *bulgaricus* CFR 2028 as biopreservatives in *kadhi* was established, wherein growth inhibition of *B. cereus*, *E. coli* and *S. aureus* (foodborne pathogens) occurred, when introduced, both as preprocessing and postprocessing contaminants in the product. In *kadhi* prepared using nonantagonistic cultures of *Lc. lactis* ssp. *lactis* CFR 2039 and market *dahi*, similar levels of growth inhibition of these pathogens were not

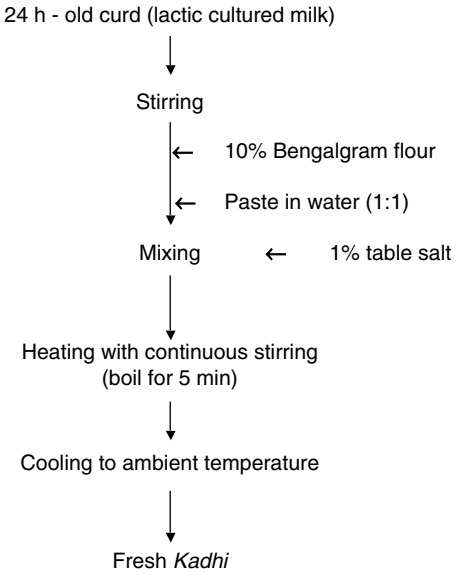

Figure 18.4 Flow sheet for *Kadhi* preparation (conventional method)
Source: Balasubramanyam, B.V., PhD Dissertation, Univ. Mysore, Mysore, 1996.

observed, but the increase in counts was very marginal. The study emphasized the benefits of using pure cultures of antagonistic LAB in the preparation of *kadhi*, with advantages of preservation and desirable quality attributes (124).

In a similar approach, the antagonistic cultures of *Lb. delbruecki* ssp. *bulgaricus* CFR 2028 and *Lb. delbruecki* ssp. *lactis* CFR 2023 were able to retard the growth of spoilage bacterial species such as *B. laterosporus*, *B. licheniformis,* and *B. subtilis* occurring as preprocessing and postprocessing contaminants in *kadhi*. However, these contaminants were able to grow and reach reasonable levels of population, when a nonantagonistic culture of *Lc. lactis* ssp. *lactis* CFR 2039 was used as the culture in *kadhi* preparation (125).

The efficacy of the antagonistic cultures of *Lactobacillus* species was evaluated in terms of microbiological and sensory parameters in *kadhi* during storage at ambient and refrigeration temperatures. *Kadhi* prepared individually with antagonistic cultures of *Lb. delbruecki* ssp. *bulgaricus* CFR 2028 and *Lb. delbruecki* ssp. *lactis* CFR 2023 were both (1) hot packed in laminates of polyester or aluminum foil or polyethylene, and (2) processed *in situ* using polypropylene pouches. The processed samples were then stored at 25–30°C and 6°C, separately. Stored samples of *kadhi* for 14 d at 25–30°C and 21 d at 6°C were stable from the microbiological point of view and in terms of sensory attributes, the products compared well with fresh *kadhi* (control) with no significant difference as evaluated by statistical analysis of mean scores recorded for individual sensory attributes (126).

Research studies have been attempted to enhance the nutritional status of ingredients that go into product preparation. Modification in the preparation of *kadhi* was achieved to provide better nutritional status through the use of lesser quantities of Bengalgram flour obtained from presoaked seeds. Considering the enhanced nutritional status of presoaked seeds, Bengalgram flour obtained from such seeds was used at lower concentrations relative to the level of flour obtained from resting seeds (*besan*) in *kadhi* preparation. On the basis of sensory attributes and the characteristic consistency of *kadhi*, the product prepared using Bengalgram flour (from presoaked seeds at 40 mg/g) was found to have better acceptance as apposed to the product prepared by conventional method using 100 mg/g of *besan*.

The alpha amylase and proteinase activities, as well as 11S globulin content (Table 18.3), varied in the samples of *Kadhi* prepared with Bengalgram flour obtained from soaked seeds using the strain of *Lb. delbruecki* ssp. *lactis* CFR 2125 and the sample prepared with commercially available *besan* (Varadaraj, unpublished data).

18.3.3.4 Dhokla

Dhokla, a steamed fermented product, is a traditional food popular in Western India, particularly in the States of Gujarat and Maharashtra. The product has a soft and spongy texture which is prepared from a mixture of Bengalgram dhal (*Cicer arietinum*), dehulled Blackgram dhal (*Phaseolus mungo*) and milled rice in the ratio of 2:1:1. The traditional method of *dhokla* preparation is presented in Figure 18.5. The mixture of legumes and cereal, after 6–8 h of soaking in water, is then ground into a grainy consistency. The resulting batter is mixed with curds in 1:1.5 (w/w) and allowed to ferment for 16–18 h. The

Table 18.3
Biochemical characteristics associated with *Kadhi* prepared using *Lb. delbruecki* ssp. *lactis* CFR 2125

Sample	Alpha Amylase Activity ($\times 10^2$ U/g Sample)	Acid Proteinase Activity (U/g Sample)	11S Globulin Content (mg/g Sample)
Kadhi A	12.3	1.6	1.8
Kadhi B	7.9	2.2	3.3

Kadhi A prepared with Bengalgram flour obtained from soaked seeds
Kadhi B prepared with commercially available besan

fermented batter is prepared into suitable shapes and steamed. The steamed product is then seasoned with oil, spices and greens (coriander leaves) prior to consumption (1,101).

In the background of limited studies, in one of the earlier studies (127) on the microbial and biochemical changes occurring during naturally fermented *dhokla* batter, it was established that the population levels of LAB and yeast increased during 0–18 h of fermentation period. The microflora usually comprised *Lb. fermentum*, *Leu. mesenteroides* and *Hansenula silvicola*. The increase in microbial counts was accompanied with the changes in pH, titratable, acidity and volatile fatty acids.

Studies with the use of antagonistic isolates of *Lactobacillus* spp. in the preparation of *dhokla* batter revealed that spoilage bacterial species, for example, *B. laterosporus*, *B. licheniformis,* and *B. subtilis* occurring as preprocessing contaminants were unable to increase in their population levels, while the same spoilage organisms were able to survive and increase in their population levels in *dhokla* batters prepared using nonantagonistic isolate of *Lactococcus* sp. (125).

In a similar type of study (126), the use of antagonistic cultures of *Lactobacillus* spp. to prepare *dhokla* batter resulted in the growth inhibition of food borne pathogenic bacterial species such as *S. aureus* and *B. cereus*. In an approach similar to *kadhi*, *dhokla* batters prepared with the antagonistic cultures of *Lactobacillus* spp. and heat sealed in laminate pouches revealed acceptable sensory attributes in a storage period of 7 d at 25–30°C and 14 d at 6°C. The stored batters were free from spoilage and pathogenic bacteria (126).

In the case of *dhokla*, alpha amylase and proteinase activities were on a higher side in batters prepared using the bacteriocinogenic culture of *Lb. delbruecki* subsp. *lactis* CFR 2125 as opposed to the one prepared from a commercial curd used as inoculua (Table 18.4). On the other hand, 11S globulin content was almost same in both the types of *dhokla* batters (Varadaraj, unpublished data).

18.3.3.5 Punjabi Warri

Punjabi warri, a legume based fermented and dried product is a very popular product in North India. *Warries* are spicy, hollow, brittle, fried balls of about 5–8 cm diameter each and are generally used as a condiment in cooking with vegetables, soup, or Indian *sambhar* (dhal based spicy liquid). The conventional method of *punjabi warri* preparation is presented in Figure 18.6. Dehulled Blackgram dhal (*Phaseolus mungo*), after being washed and soaked overnight in water, are ground to a batter of pasty consistency, which is then supplemented with a variety of spices, molded into small balls which are then subjected to fermentation and drying in open atmosphere for 4–8 d (128).

Microbiological and biochemical aspects associated with *punjabi warri* have been the subject of study in a few research investigations (4,128). These studies have established that the development and prevalence of microorganisms were affected by the seasons;

Table 18.4
Biochemical characteristics associated with *Dhokla* batters prepared using *Lb. delbruecki* ssp. *lactis* CFR 2125

Sample	Alpha Amylase Activity ($\times 10^2$ U/g Sample)	Acid Proteinase Activity (U/g Sample)	11S Globulin Content (mg/g Sample)
Dhokla A	3.9	6.7	0.4
Dhokla B	1.6	5.2	0.6

Dhokla A prepared with *Lb. delbruecki* ssp. *lactis* CFR 2125
Dhokla B prepared using curd of a commercial source

Source: Balasubramanyam, B.V., PhD Dissertation, Univ. Mysore, Mysore, 1996.

summers being more favorable for bacteria, and winters for yeasts. These microbial types tend to increase significantly with the progress in fermentation. The microorganisms which bring about acidification and leavening in *warries* are those of *Leu. mesenteroides*, *Lb. fermentum,* and *Str. faecalis*. In addition, the yeast flora encountered were those of *Sacc. cerevisiae*, *Pichia membranaefaciens.* and *Trichosporon beigelii*. The microbiological changes have been associated with biochemical and nutritional changes. An increase in the amylase and proteinase activities was observed during warri fermentation, during which period there was also an appreciable increase in levels of water soluble B-vitamins such as thiamine, riboflavin, and cyanocobalamin.

The use of LAB as biopreservative in *punjabi warri* has been the subject of few studies. Although *warri* preparation involves the simultaneous process of natural lactic fermentation and drying, the conditions may not be ideal for the production of antibacterial factors by LAB. In order to enable the benefits of biopreservatives in *warries*, the product was prepared using antagonistic isolates of *Lb. delbruecki* ssp. *bulgaricus* CFR 2028 and *Lb. delbruecki* ssp. *lactis* CFR 2023. In these *warries*, the spoilage bacterial species of *B. laterosporus*, *B. licheniformis* and *B. subtilis* were retarded in their growth during the storage period of 10 d at 25–30°C, which happens to be the traditional method of simultaneous fermentation and drying (125). Similarly, the cultures of antagonistic *Lactobacillus* spp. resulted in the inhibition of selected food borne pathogenic bacterial species during *warri* fermentation (126).

18.3.3.6 Poko

Poko is a traditional rice based fermented food of Nepal characterized by a creamy color, soft and juicy, sweet and sour taste with slightly alcoholic and aromatic flavor. *Poko* is widely consumed by the rural populations in central Nepal, particularly during festivals and other celebrations. Nepalese people believe that consumption of *poko* promotes good health. Although these foods are commonly consumed, their production is confined to home or cottage scale operations. Traditionally, *poko* fermentation is brought about by

murcha starters, the rice based starters known as *mana.* A few studies have revealed that mixed microflora consisting of the mucorales group of molds, yeasts, and LAB occur in *murcha* starters (75,129,130). The *murcha* starters are also used to prepare alcoholic beverages such as *jnard* and *rakshi*, respectively (131).

Preparation of *murcha* is regionalized and is kept as a close secret by certain sects of the Nepalese population and passed onto their next generation. The *murcha* starter cakes are of two types, namely *manapu* and *mana*. The *manapu* is prepared from rice flour and milled grains, while *mana* is prepared from wheat flakes. *Manapu* starters are prepared in the traditional style using rice flour or millet flour and other ingredients as shown in Figure 18.7. The traditional method of *mana* preparation from wheat flakes is illustrated in Figure 18.8. *Poko* preparation is presented as a flow chart in Figure 18.9.

Although *poko* has been a popular traditional fermented product, it has not been the subject of detailed microbiological studies. Research studies on microbiological and biochemical characteristics of *murcha* starters and *poko* fermentation revealed that LAB and yeasts are the predominant microbial groups, while a few fungal organisms do occur. In a few samples analyzed, there was the presence of *Escherichia coli* and *S. aureus*, but the samples were devoid of *B. cereus*. *Poko* fermentation was the resultant of microbial succession with the predominant microorganisms identified being *Sacc. cerevisiae*, *Candida versastilis*, *Lactobacillus* spp., *Pediococcus* spp., and *Rhizopus* spp. A quality *poko* product with desirable attributes of pH, acidity, reducing and total sugars and alcohol could be obtained in a fermentation period of 3 d at 30°C (132).

Considering the natural fermentation involved in *poko,* fermentation due to the use of starter culture cakes with mixed microflora, attempts have been made to use defined microbial organisms as starter cakes. Defined starter cakes for *poko* fermentation were prepared using a mixed inoculum of *Sacc. cerevisiae*, *Rhizopus chinensis,* and *Pediococcus pentosaceus*. The product prepared with the defined starter was evaluated

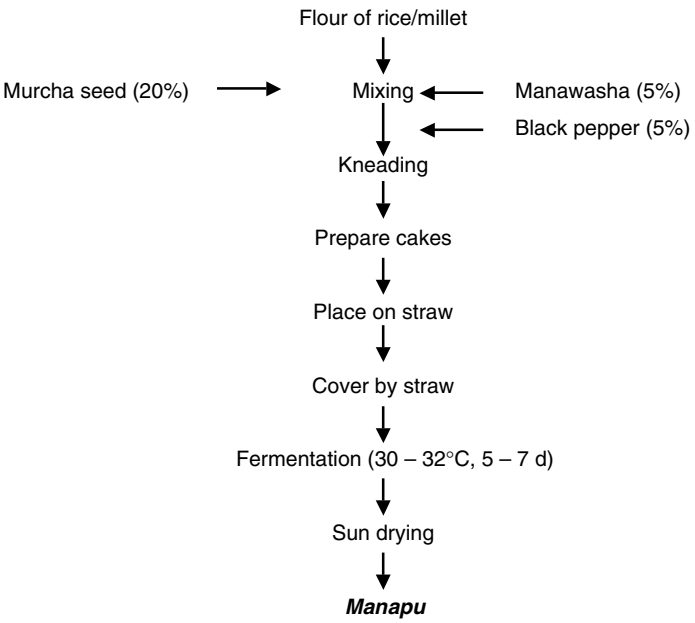

Figure 18.7 Traditional method of *manapu* preparation
Source: Shrestha, H., K. Nand, E.R. Rati., *Food Biotechnol*. 16:1–15, 2002.

Source: Shrestha, H., K. Nand, E.R. Rati., *Food Biotechnol*. 16:1–15, 2002.

for its performance against the traditional manapu starter. *Poko* prepared with the defined microbial starter had increased levels of vitamins including pyridoxine, thiamine, vitamin B_{12}, niacin, and folic acid. Additionally, the use of a defined starter ensured a better quality product with built in aspects of hygiene and safety (133).

18.3.3.7 Rabadi

Rabadi is a fermented beverage popular in north western parts of India, particularly the state of Rajasthan. The product is prepared from a mixture of pearl millet flour (*Pennisetum typhoideum*) or wheat flour and buttermilk, which is then placed in an earthen container and allowed to ferment for 4–6 h at ambient temperature. The fermented product is diluted with water, boiled and salted to taste. Due to the process of natural fermentation and lactic flora coming from buttermilk, lactobacilli count appears to increase (134).

Rabadi fermentation of freshly ground wheat millet flour brought about significant increase in HCl-extractability of calcium, iron, copper, zinc, manganese, and phosphorus (135). Consumption of such fermented foods may help to ameliorate the prevalent mineral deficiencies due to their limited bioavailability from such coarse grains and they may lead to better mineral status of the population (96–98).

18.3.3.8 Other Products

The diversified culture of the Indian subcontinent is well represented by the wide range of traditional fermented foods. The foods and their preparations previously discussed in this presentation have revealed the scientific knowledge and understanding of the

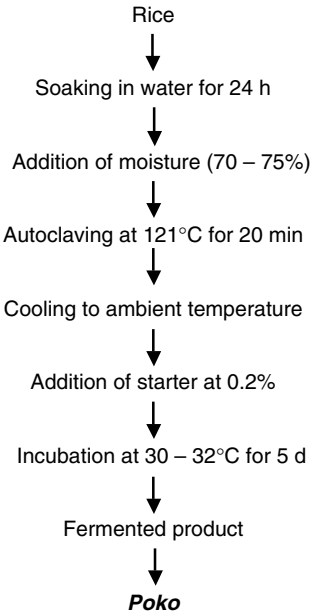

Figure 18.9 Traditional method of *poko* preparation
Source: Shrestha, H., K. Nand, E.R. Rati., *Food Biotechnol*. 16:1–15, 2002.

biotechnological aspects involved in the major cereal and legume based fermented foods. Other popular food items are consumed widely by the Indian population, but scientific studies involving these foods are lacking. A few of these foods follow:

1. *Papadam* is a spiced condiment prepared from fermented Blackgram dhal paste. The prepared dough is slightly spiced as that of *punjabi warries* and is rolled into wafer-like pieces of about 10–20 cm diameter and 0.5 mm thick, which are then subjected to drying under sunlight for 6–8 h allowing for the simultaneous processes of fermentation and drying. The dried product is then deep fried in oil and consumed more as a culinary food item.
2. *Kulcha* is a popular product consumed in Pakistan and Northern India. The product is prepared from white wheat flour mixed with milk, sugar, salt, curds, dry yeast, baking powder, and water, with the ingredients kneaded well into soft stiff dough. The dough is subjected to fermentation for a period of 6–8 h at ambient temperature. The fermented dough is divided into equal size balls which are then rolled or flattened by hand to thick round *kulchas* of about six inches in diameter. The smoothly flattened dough is baked in a *tandoor* (metallic baking tray or special oven made of clay) to obtain a golden brown color. *Kulchas* are served hot.
3. *Batura* is a leavened bread, deep fried in oil, widely consumed in Northern India as snack item along with *masala channa* (*Cicer arietinum*). The product is prepared from a mixture of white wheat flour, baking powder, salt, curds, sugar, and water. The dough is prepared with little oil and covered with a hot cloth and kept for 1–2 h at ambient temperature. Then the dough is divided into equal sized balls and each one of them is rolled out into discs of five inches in diameter. The rolled out discs are deep fried in oil over medium flame, until the *baturas* reach light brown in color on both sides. The product is served hot.

4. *Naan* is a leavened flat bread baked in a clay oven called the *tandoor* and is widely consumed by the people of Northern India and Pakistan. The product is prepared from a mixture of white wheat flour, milk, egg, baking powder, salt, sugar, and curds. The dough is allowed to ferment at ambient temperature for 1–2 h. Then the dough is divided into equal sized medium balls, which are then rolled out into oblong shapes on a lightly flattened surface. The flattened dough is put on a wet cloth and then transferred onto the inner wall of preheated *tandoor* (clay oven) oven wall. The final product — *naan* — when fully cooked is crisp and brown on both sides, which is removed using skewers and served hot, topped with butter.
5. *Jelaebie* is a sweet savory item widely consumed in almost all parts of India and Pakistan on occasions of festivals and other celebrations. The product is prepared from a batter of wheat flour and water, fermented for 8–10 h. The fermented batter is squeezed through a thin cloth with a hole of 3–5 mm diameter, deposited as spirals into boiling vegetable oil and then deep fried. The light brown and crispy spirals are removed from the oil with a perforated ladle and immediately immersed in 70% sugar syrup. The crispy spirals, known as *jelaebie,* are removed from the sugar syrup and served hot as a delicious sweet savory item.

18.4 COMMERCIALIZATION OF TRADITIONAL FERMENTED FOODS

The review presented in this chapter has brought into focus the entire scenario of traditional fermented foods of the Indian subcontinent. In the background of a diversified Indian culture, it is quite natural that a large number of these fermented foods have their base in India. Although these foods are consumed almost on a daily basis by one section of population or the other, the approach toward commercialization is at the infancy stage. This slow progress may be due to the fact that these foods are still in the domain of home scale or at the most cottage scale operations. However, in recent times, with the changing social pattern, the consumer driven market is moving toward convenience foods, or more so fast foods, which encompasses a wide range of traditional fermented foods.

In the changing scenario, attempts have been made at the Central Food Technological Research Institute, Mysore, India to develop process know how for certain popular products. A few of them are:

1. Ready to use *idli* and *dosa* batter in retail packs, which afford a great deal of convenience with a shelf stability of 3–5 days at ambient temperature.
2. Preparation of pickles and *chutneys* which give a wider market, as these two food items are the regular items of lunch and breakfast menus.

In the light of an exhaustive biotechnological information about traditional fermented foods, in the future, food suppliers should look at aspects that would make these fermented foods achieve commercial outreach with built in concepts of convenience, shelf stability, hygiene, and safety toward improvement of human health.

ACKNOWLEDGMENT

The authors are thankful to Dr. V. Prakash, Director, CFTRI, Mysore for the support and interest in the area of traditional fermented foods.

Fermentation Biotechnology of Plant Based Traditional Foods of the Middle East and Mediterranean Region

Parthena Kotzekidou and Effie Tsakalidou

CONTENTS

19.1 HISTORY

Fermented foods of plant origin are popular in the Mediterranean and Middle East region. Traditional fermentation processes give rise to foods that are prized for their palatability and wholesomeness, but also enriched with essential amino acids and vitamins. Vegetables and fruits are preserved by lactic acid fermentation, producing pickled vegetables and table olives, which can be consumed without cooking. Alcoholic fermentation by yeast is generally less common and prevails mainly in bread making (1).

The Mediterranean food culture, rich in foods from plant materials, is linked to health and is thought to be associated with longer life expectancy. Throughout the Mediterranean Basin, a lower incidence of cardiovascular and cerebrovascular diseases, and certain cancers such as colon, breast, and other hormone dependent cancers, occur less frequently than in Northern Europe (2).

The objective of this chapter is to provide a view of the present state of knowledge of the fermentation of plant derived products like fermented vegetables, table olives, and bread in the Mediterranean and Middle East countries.

19.2 FERMENTED VEGETABLES

19.2.1 Introduction

The preparation of vegetables by lactic acid fermentation (pickling) on a small scale in the home has been applied in the Mediterranean and the Middle East region since antiquity. Nowadays, fermented vegetables such as cucumbers, green tomatoes, peppers, eggplants, carrots, okra, and mixed vegetables (including carrots, cauliflower, celery, green tomatoes, and cucumbers) serve as appetizers and are usually produced in salt brine by commercial processors. Vegetables for pickling are harvested while still immature, as fully ripened vegetables are too soft for most commercial uses. The fermentation is due primarily to the lactic acid bacteria, although yeasts and other microorganisms may be involved depending on the salt concentration and other factors. Salt influences the type and extent of microbial activity and prevents softening of the vegetable tissue (3).

The conventional method of fermenting vegetables used by industry is natural fermentation carried out by the indigenous microbial flora of the product. The microbial load of the fresh vegetables can, however, be highly variable, influenced by the ambient temperature during harvesting and other factors which are hard to control. This has numerous drawbacks that limit the yield of the process and affect the quality of the final product, making it difficult to anticipate the course of fermentation. To prevent defective fermentations, brines with high salt concentrations are sometimes used in order to regulate the type and extent of microbial growth, as well as to prevent softening of the product. Increased salt concentrations slow down the process, as the growth of lactic acid bacteria is inhibited, and the product may turn soft due to the growth of molds. In addition, subsequent removal of the salt is needed, which can result in leaching and substantial losses in vitamins and other nutrients, and the handling of highly polluting saline effluents is involved (4). Recent research is focused on the application of starter cultures in controlled fermentations to obtain a high quality end product as well as to reduce the amount of waste brines which can result in a significant environmental pollution problem (5). This review deals with fermented vegetables (with the exception of sauerkraut which is not a typical product of the Mediterranean and the Middle East Region) produced either by small scale producers who shelf their products in bulk, using refrigeration to assure stability, or by large scale producers after pasteurization at low temperature (such as an internal product temperature

of 71°C with no holding time) to increase the shelf life. The microbiology of fresh pack pickles (pasteurized, unfermented pickles) is not included in the present review.

19.2.2 Microorganisms Involved in Fermentation

The microflora of fresh vegetables is mainly dominated by Gram-negative aerobic bacteria and yeasts, while lactic acid bacteria constitute a small portion in the initial population (6,7). Most vegetables, with the addition of salt brines (providing that salt concentration does not exceed 8%), under anaerobic conditions and appropriate temperature, undergo a spontaneous lactic acid fermentation during which lactic acid bacteria have a competitive advantage. The species of lactic acid bacteria most associated with the natural fermentation of vegetables are: *Pediococcus pentosaceus, Lactobacillus brevis,* and *Lactobacillus plantarum* (8). While *Pediococcus* species tolerate a minimum pH of 4.0 for growth, *Lactobacillus* species are the most acid tolerant, with a minimum pH of 3.8 (9). The growth of lactic acid bacteria depends on the available nutrients, salt concentration, pH value, and temperature of the environment. Changes of these parameters influence the dominant organisms. Organisms such as *Leuconostoc mesenteroides* are usually inhibited in the brine by the higher salt concentration, temperature, and rapid pH drop (5). The addition of salt and the rapid production of organic acid suppress the Gram-negative bacteria, which the lactic acid bacteria outnumber on the product. In addition, bacteriocins produced by lactic acid bacteria isolated from naturally fermented vegetables have a broad spectrum of activity and indicate that antimicrobial proteins have an important role in the ecology of fermented products (8,10–14).

Fermentation of vegetables occurs in four sequential stages (8). In the initial stage Gram-positive and Gram-negative microorganisms naturally present on the vegetables may grow. During the primary fermentation, growth of lactic acid bacteria occurs with or without fermentative yeasts. Secondary fermentation occurs if fermentable carbohydrates remain after the primary fermentation, which can be assimilated by fermentative yeasts while lactic acid bacteria are inhibited by low pH. Postfermentation is characterized by the depletion of fermentable carbohydrates and the absence of microbial growth under anaerobic conditions; while during the exposure of the brine to the atmosphere oxidative microorganisms grow on the surface. The proliferation of the naturally occurring lactic acid bacteria during initial and primary fermentation depends on their presence on the raw material and the physical and chemical conditions during fermentation.

During spontaneous fermentation of eggplants two stages appear: an initial stage (with a duration of 2 days) in which obligately heterofermentative *Lactobacillus fermentum* and *L. brevis* predominate, with a peak in the *L. fermentum* load on day 2; followed by a stage of vigorous sugar fermentation (with a duration of 5 days) dominated by *L. plantarum* (9). Similarly, during the spontaneous fermentation of okra, within the first 24 h of fermentation the heterofermentative *Lactobacillus cellobiosus* is dominant, while after 48 h of fermentation strains of *L. plantarum* predominate and the pH value of the brine is very low (pH 3.4) (15). *Lactobacillus plantarum* is the terminal organism in many natural lactic acid fermentations due to its high acid tolerance (16). Vegetables fermented with the homofermentative *L. plantarum* are microbiologically stable, provided all detectable sugars are removed, the pH is 3.8 or less, and they are stored in anaerobic conditions (17).

There have been only limited quantitative data obtained on the formation of products in vegetable fermentations by homofermentative or heterofermentative organisms (8). Carbon dioxide production is of major importance in the fermentation of vegetables. High levels of CO_2 are known to cause gassing or bloating of cucumber tissue, leading to undesirable defects (called "bloaters" or "floaters") (5). Although CO_2 is a major end product of heterolactic acid bacteria, CO_2 production by homofermentative lactic acid bacteria occurs

by decarboxylation of malic and citric acids present in many vegetables as well as amino acids (18,19). In green bean juice fermented by the homofermentative *L. plantarum* only lactic acid is obtained as a fermentation product, whereas *Leuconostoc mesenteroides* and *Lactobacillus brevis* strains form typical heterofermentative products, i.e., acetic acid, in addition to lactic acid, ethanol, and mannitol, as well as a large amount of CO_2, are formed (20). In okra juice fermented by strains of *L. plantarum*, although the majority of the strains produced only lactic acid, three strains produced acetic acid and ethanol in addition to lactic acid, and showed low lactate dehydrogenase (LDH) activity, whereas the strains of *Lactobacillus cellobiosus* and *L. brevis* carried out a typical heterolactic fermentation (21).

19.2.3 Controlled Fermentation

The main advantages of controlled fermentation are the use of brines with low salt concentrations, the substantial shortening of the fermentation time, and the improvement of the quality, achieved by uniform sensory and nutritional quality attributes in the final product.

Controlled fermentation is commercially used in cucumber fermentation in a process thoroughly described by Fleming (3). The acidification of the brine to 4.5 with acetic acid or vinegar serves to virtually eliminate growth of the natural microbial flora. The concentration of salt required to prevent softening is 5–8%. Addition of calcium acetate or calcium chloride results in firmness retention of cucumbers at relatively low concentrations of sodium chloride (1.4–4%). The brine is purged with nitrogen to maintain an anaerobic headspace at the top of the tank as well as to remove dissolved CO_2 and prevent bloater formation. A pilot study showed that temperature (17 and 26°C) affects the rate of fermentation, and in combination with purging strongly affects the incidence of bloater damage (22). A 24 h buffering of the brine with sodium acetate serves to eliminate secondary fermentation by yeasts. With the pH at 4.7, the brine is inoculated with *L. plantarum* or *P. pentosaceus* or a combination. At temperatures between 26 and 29°C rapid growth of these starter cultures is favored (23). The inoculation with starter cultures is undertaken in order to complete the controlled fermentation as rapidly as possible to reduce purging costs (8).

19.2.4 Starter Cultures

To avoid the drawbacks of natural fermentation, addition of starter cultures and maintenance of anaerobiosis under controlled fermentation conditions is achieved. Although there are very few commercial starter cultures designed for vegetable fermentations (24), their benefits in vegetable fermentations are important. Starter cultures help to standardize the fermentation by controlling the competitive microbiota, especially in the cases when treatments are undertaken to rid the raw product of the natural epiphytic microflora that interfere with fermentation. This can be achieved either by blanching using hot water (66–80°C), chlorination and subsequent acidification (5,8), or lye treatment (lye concentrations 1–2% NaOH) (25). When mixed starter cultures are applied to the raw material, their selection is based mainly on the competitiveness between the starter and the natural flora, as well as on the sensory properties of the fermented product.

The commercial culture "Vege-Start 60™" (Chr. Hansen's Laboratorium, Horsholm, Denmark), composed of a mixture of *Lactobacillus* sp., primarily *L. plantarum,* was used for the fermentation of blanched Almagro eggplants (Appellation of Origin of a pickled product manufactured using a native variety of eggplant) in brine with a salt concentration not exceeding 6%, while the temperature in the fermenter was 32°C. A shortening of the fermentation process was observed; the fermented product was of good quality, though somewhat bitter due to the starter culture (26). In an effort to overcome the bitter taste, starter cultures composed of lactic acid bacteria isolated from spontaneous fermentations

were used in order to select the most appropriate starter culture. By the combined action of the obligate heterofermentative species *L. brevis* and the facultative heterofermentative species *L. plantarum,* fermented eggplants with sensory characteristics preferred by panelists were obtained. Whereas *L. fermentum,* present in certain starter formulations tested, appeared to encounter difficulty growing during fermentation and exerted little influence on the sensory characteristics of the product (9,27).

During fermentation of okra a *Lactobacillus cellobiosus* strain (isolated from a spontaneous fermentation) could ferment okra mucilage, a polysaccharide composed of galacturonic acid, galactose, rhamnose, and glucose, lowering the pH and retaining the natural color of the product. When blanching preceded the fermentation improved quality characteristics of the fermented product in comparison to spontaneous fermentation were obtained. The commercial culture "Vege-Start" can antagonize the natural microbiota, lowering the pH of the raw product and improving the fermentation characteristics (28).

The addition of *L. plantarum* with pH control during fermentation of green beans, cucumbers, red and green bell peppers, and green tomatoes gives fermented products microbiological stablility during 12 months storage in hermetically sealed jars at approximately 24°C , providing all fermentable sugars are removed during fermentation and the product is stored at pH 3.8 or below (17). During fermentation of carrot, cabage, beet, and onion vegetable mixtures with cultures of *L. plantarum, Pediococcus acidilactici* and *L. mesenteroides* applied as a mixed starter culture, acceleration of the fermentation process and prevention of deterioration of the fermented product for up to 90 days is obtained. Although this mixed culture has a similar fermentation pattern to a spontaneous fermentation, the ethanol production is lower, and the acidification rate is faster, which helps to stabilize the final product as well as to reduce the production of gas during the fermentation and storage of the product (24). Peeled garlic blanched in hot water (90°C) for 15 min and fermented using a starter culture of *Lactobacillus plantarum* reaches a pH of 3.8 after 7 days, whereas the growth of the starter culture is inhibited in unblanched garlic. The blanched fermented garlic is microbiologically stable during storage at 30°C in acidified brine (containing 3% NaCl and pH 3.5 at equilibrium) and keeps the flavor (29).

19.3 TABLE OLIVES

19.3.1 Introduction

For centuries, the fruits of the cultivated olive tree *Olea europaea sativa*, a typical plant of the countries of the Mediterranean Basin, have been used for direct consumption and oil production. The first reference to the olive tree is reported in the Bible. In its first book, *Genesis*, the flight of the dove with the olive branch announcing the end of the flood is described. Nowadays, the cultivation of the olive tree is practiced in the Mediterranean area and the Middle East, as well as in parts of America and Australia. The Mediterranean region still serves as the major international olive growing area, accounting for almost 98% of the world's olive tree plantation (2). The main cultivars of table olives are presented in Table 19.1. Olive processing is the largest agroindustrial sector of the economy in some Mediterranean countries such as Spain, Italy, and Greece (32).

Table olives have been consumed since ancient times. For direct consumption, olives must first be processed in order to remove, at least partially, the natural bitterness of the fruit. As the bitterness is related to the stage of ripeness of the fruits, different processing methods have been used world wide. The methods of greatest importance are: Spanish

Table 19.1
Main table olive cultivars suitable for the preparation of green olives or black olives in brine in Mediterranean and Middle East region.

Country of Origin	Green Olives	Black Olives in Brine
Spain	Manzanilla	Holiblanca
	Sevillana or Gordal	Cacerena
		Lechin
Italy	Ascolana	Itrana
	Oliva di Spagna or Cerignola	Uovo di Piccione
	Sant' Agostino	
	Cucco	
Greece	Conservolea	Kalamon
	Chalkidiki	Conservolea
Turkey	Domat	Gemlik
	Memeli	Edencik
Morocco	Picholine	Picholine
	Zitoun	Zitoun
Algeria	Sigoise	Sigoise
	Azeradj	Azeradj
Tunisia	Meski	Meski

style green olives in brine; California style black olives in brine; and Greek style naturally black olives in brine (31). In the Spanish style and Californian style processes, bitterness is removed by an alkaline treatment, whereas in the case of the Greek style process, fruits are placed in brine and the debittering process is slow and sometimes partial.

Oleuropein, a secoiridoid glucoside that is commonly found in the leaves of the olive tree as well as in the fruits, is responsible for the natural bitterness. Hydrolysis of the oleuropein to more simpler, less bitter compounds, such as elenolic acid and β-3,4-dihydroxyphenyl ethyl alcohol (hydroxytyrosol), is obtained by olive processing in order to provide some form of debittering of the fruits (33,34). This can be achieved by alkaline hydrolysis (i.e., treatment of the olives with sodium hydroxide solutions before the fermentation; the product is referred to as treated olives in the international standards) and by further storage in brine or in dry salt. When there is no alkali treatment before fermentation and the olives are placed into brine or dry salted, bitterness may be also removed slowly and partially during the acid fermentation and the product is characterized as untreated. There are three main types of olives in brine according to the Unified Qualitative Standard Applying to Table Olives in the International Trade (35): green olives, turning color olives (untreated, as well as treated, including black olives; i.e., fruit harvested during the stage of turning color and blackened by oxidation in an alkaline medium), and naturally black olives.

There are numerous regional or national variations of the processing conditions applied (31) concerning:

1. The condition of the fruit (green color, naturally black color, turning color)
2. Treated or untreated (referred to the procedure applied to eliminate bitterness)
3. The preservation method (in brine or dry salting)

This review deals with table olive fermentation processing in the Mediterranean and the Middle East region; i.e., Spanish style green olives in brine (lye treated green olives in brine) and naturally black olives in brine (untreated naturally ripe black olives in brine).

The occurrence of biophenolic components in olives, and particularly oleuropein as well as compounds derived from the hydrolysis of the oleuropein (34), provides functional value to the Mediterranean food culture, owing to recognized antioxidant activities of these substances (36). Olive biophenols demonstrate antioxidant and free radical scavenger ability as well as antimicrobial activity, which are important for human health and well being (2). The natural bitter tasting oleuropein releases phytoalexins against pathogens. In vegetables, biophenols play an important role as the defense mechanism against pathogen and insect attack (37). In olives, the relevance of these bioactive molecules has been acknowledged for their contribution to flavor and to preventing rancidity (38). In the Spanish style green olives process oleuropein is completely degraded by the alkali treatment that is commonly used, yielding hydroxytyrosol and elenolic acid, with the consequence that lactic acid bacteria are the predominant microorganisms; whereas in undebittered olives phenolic substances inhibit *L. plantarum* strains (34,39) as well as mold growth and mycotoxin production (40). Although hydroxytyrosol has an inhibitory effect against *L. plantarum* ATCC 8014 inoculated in untreated olive brines, other *L. plantarum* strains are able to grow in alkali treated olive brines as a consequence of the different permeability of fruit for phenolic substances. It is suggested that proteins and amino acids of olives can mask the bactericidal effect by combining with the phenolic compounds, whereas in the case of untreated fruits the nutritional and neutralizing compounds take a long time to emerge from the fruits (39).

19.3.2 Microorganisms Involved in Fermentation

19.3.2.1 Spanish Style Green Olives in Brine

Spanish style green table olive processing consists of a treatment with NaOH solution (1.8–3.0%, w/v) in order to: hydrolyse the bitter glucoside oleuropein, promote alkaline hydrolysis of proteins in the flesh, and make the skin more permeable. In order to eliminate the lye inside the olives, one, two, or three washings follow. The lye treatment has the following consequences: the pH increases to values between 7.5 and 8.5 and the initial population of microorganisms is reduced, and during washing the nutrients and sugars from the olives are reduced. In order to partially neutralize the lye, food grade HCl or other strong acid can be added to the washing water, reducing the pH to approximately 6.0. The olives are then brined in a 10–12% w/v NaCl solution in which they undergo a typical lactic fermentation once a uniform NaCl concentration of 6–8% is reached. As a consequence of the alkaline treatment, brine pH values during the first days are well above neutrality; i.e., more than 10 in some cases. This has led to the recommendation of decreasing the pH artificially by bubbling CO_2, adding other acids, or waiting until the pH is around 6–7 as a result of natural microbial growth, with the risk of spoilage (41,42). Salt is added during the fermentation to maintain the NaCl concentration at 5–6%. The release

into the brine of olive cell constituents (sugars, B-complex vitamins, and amino acids) controls the fermentation rate, as their diffusion from olive flesh into the brine depends on the permeability of the skin, temperature, salt concentration, and ratio of olive to brine (31). Later on in the fermentation vitamins may be excreted by autolysis of Gram-negative bacteria or yeasts occurring in the microflora. At the end of the fermentation, in order to avoid the growth of spoilage microorganisms, the level of NaCl is increased to 7%. When the fermentation is completed a pH below 3.5 coupled with a NaCl concentration greater than 5% is sufficient to preserve the fruit anaerobically (5).

The olive fermentation is described as occurring in three stages, though a fourth spoilage stage is described (5,43): During the initial stage of the fermentation Gram negative aerobic bacteria of the genera *Aeromonas, Flavobacterium* and *Pseudomonas,* as well as some molds, are suppressed under the normally anaerobic fermentation conditions. The facultative organisms of the coliform aerogenes group (*Enterobacter cloacae, Citrobacter* species, *Klebsiella aerogenes,* and *Escherichia coli*) predominate during the first 2 days of the fermentation, and gradually disappear during the second stage of the fermentation, as the pH decreases due to the increasing population of lactic acid bacteria of the genera *Pediococcus, Leuconostoc,* and *Lactococcus.* Lactic acid producing cocci occurring during the first and second stage of fermentation provide a good degree of acidity. However, some of these are heterofermentative producing low amounts of lactic acid. Gram-positive sporulating bacteria and yeasts occuring as contaminants may develop. Whereas sporulating Gram-positive bacteria disappear from the fourth to the fifth day, the yeasts develop quickly as the pH decreases. When the pH reaches 6.0 the second stage of the fermentation begins, which lasts until the pH reaches 4.5 and takes 10–15 days. During this stage the Gram-negative bacteria disappear, while lactobacilli reach the maximum population. The third stage of the fermentation lasts until the fermentable carbohydrates are depleted. *Lactobacillus plantarum* is the dominant microorganism occurring with fermentative and oxidative yeasts in reasonably high levels during this stage of fermentation. The yeasts produce a number of vitamins that may encourage the growth of *L. plantarum* (44). Although the contribution of individual yeasts to the fermentation is unclear, it is believed that they play a role in the organoleptic characteristics of fermented olives. A yeast population consisted of *Hansenula anomala, Candida krusei, Saccharomyces chevalieri, Candida parapsilosis* and *Hansenula subpelliculosa* dominate in some fermentations (43). From spontaneous fermentations of olive brines at different sites in Portugal ascomycetous species dominate the yeast flora, and among them the asporogenous are less numerous than the ascosporogenous yeasts. In the layter group *Pichia anomala* and *P. membranaefaciens* as well as its anamorphic state *Candida valida* and *P. pseudocactophila* are the predominant species. The species *Saccharomyces cerevisiae, Debaryomyces hansenii, Kluyveromyces lactis,* and *Rhodotorula mucilaginosa* are also present (45). The oxidative yeasts can be harmful because they metabolize lactic acid and raise the pH, which can lead to spoilage (5). During the period of storage the salt concentration is increased to avoid the growth of *Propionibacterium* during the fourth stage and the corresponding depletion of lactic acid. When the concentration of NaCl is $\leq$5% *Propionibacterium* may metabolize lactic acid with a consequent rise in pH (to 5) and the possibility of the development of species of *Clostridium* which lead to an unpleasant odor called "zapatera" (43). A yeast population composed of strains of *Saccharomyces cerevisiae, Pichia anomala, Candida etchellsii, Candida versatilis,* and *Rhodotorula glutinis* is isolated from boaters of fermented green table olives during storage (46). *In vitro* inhibition of these yeast species is achieved using laboratory media containing essential oil of garlic (47).

19.3.2.2 Naturally Black Olives in Brine

The process is practiced traditionally in Greece. The olives are harvested when they are completely ripe; i.e., when the skin has a color between violet and black, but before they are overripe. They are put into tanks and covered with 6–10% brine. The maintenance of strict anaerobiosis by the addition of olive oil is important to avoid the growth of film forming yeasts and surface growth of molds causing removal of sugars and acids and increasing the brine pH. As the olives are not treated by alkali, the diffusion of the soluble components through the skin is slow. A mixed population of Gram-negative bacteria of the coliform aerogenes group, lactic acid bacteria (mainly *Lactobacillus* sp.) and yeasts are present if the NaCl concentration is $\leq 7\%$. The growth of lactic acid bacteria throughout fermentation depends on various factors such as olive cultivars, NaCl concentration, and initial pH correction of brines (48). If the concentration of salt in the brine stays at 10%, the presence of yeasts is dominant. In this case an acetic fermentation caused by acid forming, salt tolerant yeasts occurs. When fermentative yeasts predominate, the final product has pH values between 4.5 and 4.8. Although the contribution of individual yeasts to the fermentation is unclear, it is believed that they contribute to the organoleptic characteristics of fermented olives. Yeast strains isolated from spontaneous naturally black olive fermentations are mainly *Saccharomyces oleaginosus, Torulaspora delbruekii,* and *Debaryomyces hansenii* (31,49,50). The main species of yeasts involved in fermentation of naturally black olives in brine in different Mediterranean countries are presented in Table 19.2. Scanning electron microscopy shows a yeast rich biofilm development on the epicuticular wax of the olive skin during fermentation. Especially, yeasts predominate in the stomatal openings, whereas bacteria are more numerous in intracellular spaces in the substomatal flesh (51).

Spoilage results from the growth of clostridia, *Propionibacterium,* and sulphate reducing bacteria. Because of the great maturity of the raw material different genera of microorganisms and enzymes present in the fruit are implicated in spoilage affecting the texture and the flavor of the product (5,43). During the whole fermentation process it is important to achieve anaerobiosis in order to avoid mold growth, as mycotoxin production is reported

Table 19.2
Main species of yeasts involved in fermentation of naturally black olives in brine in Mediterranean region.

from molds isolated from black olives in dry salt (52,53). Yeasts are involved in soft stem end spoilage, and include oxidative pink yeasts of the genus *Rhodotorula* and fermenting yeasts belonging to the genus *Saccharomyces* (5). Yeasts identified as *S. oleaginosus, S. kluyveri,* and *Hansenula anomala* var. *anomala* spoil the olives by a combination of gas pocket formation and softening (54). Strains of the "pink yeasts" *R. glutinis* var. *glutinis, R. minuta* var. *minuta,* and *R. rubra* grow and form pellicles in olive brines and produce polygalacturonases which cause a softening of olives held in storage (55).

In order to improve the quality of the table olives, that is, reducing shriveling and the salty taste of processed fruits, fermentation of naturally black olives under reduced salt concentrations is achieved. In spontaneous fermentations, the predominant microorganisms are yeasts, whereas in reduced salt concentrations lactic acid fermentation occurs in addition. A more active role of lactic acid bacteria is desirable to limit the negative effects of yeasts on the product quality, as some yeasts are responsible for deterioration; i.e., gas pocket formation and softening of the fruit (56).

19.3.3 Improved Fermentation

19.3.3.1 Controlled Fermentation

In traditional producing areas, physicochemical characteristics of the brines concerning initial NaCl content, pH, and the type of added acid are used to control the fermentations. In this case the spontaneous microflora are associated with *L. plantarum* and *L. pentosus* (57,58). The development of these species is essential to provide the large amount of lactic acid needed for olive preservation. Early in the fermentation *L. plantarum* and *L. pentosus* constitute a small proportion of the bacterial population, but within one or two weeks of the olives being placed in brine, *L. plantarum* and *L. pentosus* become dominant over Gram-negative bacteria and other lactic acid bacteria, and they coexist with a yeast population up to 3 months, until the end of the fermentation process (57–59). *Lactobacillus plantarum* plays an essential role during the fermentation process of Spanish style green olives, providing the large amount of lactic acid needed for olive preservation (43). Therefore, during the fermentation, the olives are handled in order to favor the growth of the small population of *L. plantarum* present on the fruit. However, in some cases, *L. plantarum* fails to grow and the undesirable, competing natural microflora predominates leading to wide variations in the flavor and quality of fermented olives and often to spoilage by a variety of microorganisms. Therefore, control procedures in combination with the use of suitable *L. plantarum* starter cultures are necessary to prevent spoilage and to provide a product of consistently high quality (43). A complete lactic acid fermentation can be achieved by the addition of glucose to the brine together with a *L. plantarum* starter culture. In addition, the complete control of fermentation results in a profound improvement of texture, color and other sensory qualities of the finished product (60) eliminating the initial microflora consisting of other spontaneously occurring lactic acid bacteria, Enterobacteriaceae, *Pseudomonas* species and micrococci (61).

In an effort to obtain green table olives with a lower sodium content the traditional method of using brine containing NaCl only, has been replaced in some instances with brines containing $CaCl_2$ and KCl. In the alternative brines, normal lactic fermentation is carried out allowing the olives to lose their bitter taste. The product obtained has low sodium content and good organoleptic characteristics (62).

19.3.3.2 Starter Cultures

Olive processing remains an empirical process and is far from being controlled. However, interest in developing starter cultures to be used in table olive fermentation is increasing.

In order to achieve an improved and more predictable fermentation process, an appropriate starter culture has to fulfill the following requirements:

1. Ability to dominate the indigenous microflora
2. Accelerated growth under fermentation conditions; i.e., growth in table olive brines, low temperature
3. Homofermentative metabolism
4. Tolerance to salt, acid, and polyphenols
5. Composed of strains specifically adapted to possible water soluble B complex vitamins deficiency
6. Oleuropein splitting capability
7. Ability to produce bacteriocins, providing the producer strain with a selective advantage over the competing and spoilage microflora which develops during fermentation

The successful use of *L. plantarum* as a starter culture in olive fermentations, in which this species dominates the epiphytic microflora, is due to the ability of some strains to produce bacteriocins which are active against the natural competitors of *L. plantarum* as well as against bacteria that can cause spoilage (63,64). *Lactobacillus plantarum* LPCO10, a strain originally isolated from a Spanish style green olive fermentation, produces two bacteriocins: plantaricin S (pls), a two peptide bacteriocin, and plantaricin T (plt) (63). The genes plsA and plsB encoding for production of plantaricin S, are commonly distributed among wild-type *L. plantarum* strains isolated from olive fermentations from different olive processing plants in South Spain (65). When *L. plantarum* LPCO10 is used as a starter culture, it does not completely eliminate the development of the indigenous microflora but has a substantial effect without reducing the quality of the product. The presence of bacteriocin in the brines at the end of the fermentation is useful in preventing the growth of spoilage microorganisms such as clostridia or propionibacteria, as both are sensitive to the antimicrobial compounds produced by *L. plantarum* LPCO10, and both occur at the late stage of fermentation (59). Production of plantaricin S by wild-type *L. plantarum* strains is a constitutive trait, for once the appropriate genes are present, bacteriocin production takes place. As plantaricin S is active against many other lactic acid bacteria present in the olive fermentation, its constitutive production provides the producer strain with an ecological advantage in order to dominate the fermentation process (65). Thermostable antibacterial proteins isolated from *L. plantarum* LB17.2b are active against other *L. plantarum* strains occurred naturally in olive fermentation brines as well as against *Weissella* strains and *E. faecalis* (64). Enterocin 900 produced by *E. faecium* BFE 900 isolated from black olives is active at pH values ranging from 2 to 10 and has antagonistic action toward *L. sakei, C. butyricum,* enterococci, and *Listeria* species, including *L. monocytogenes* (14). In Table 19.3 are presented the main bacteriocins produced by strains isolated from fermented olives.

The amount of inoculum is of importance when starter cultures are applied in food fermentations. In the case of olives the minimum inoculum size for significant improvement of the fermentation process ranges from 10^5 cfu/mL to 10^7 cfu/mL (59,66). In some cases, i.e., fermentation at low temperature (12°C), a high inoculum (4×10^7 cfu/mL) is necessary to carry out a practically normal Spanish style green olive fermentation using 3% NaCl and pH correction with HCl to 5.0 by the addition of three strains of *Lactobacillus plantarum* (LPC1, LPC2, and LP33) (67). An inoculum size necessary to achieve an initial population of *L. plantarum* or *L. pentosus* close to 10^6 cfu/mL, is considered the minimum for significant results in the case of inoculation at alkaline pH (above 9) of lye treated

Table 19.3
Bacteriocins produced by strains isolated from fermented olives.

Bacteriocin	Strain/ Product Isolated	Inhibitory Spectrum	Ref.
Plantaricin S & Plantaricin T	*L. plantarum* LPCO10 Spanish-style green olives	strains of lactobacilli, leuconostocs, pediococci, streptococci, propionibacteria, clostridia	(63)

green olives. A marked decrease of viability is noticed as a result of the unfavorable conditions, the survivors can withstand this hostile environment, and eventually grow and initiate lactic acid fermentation. The inoculum lethality is, on average, two log cycles when applied at day 0 and 1 log cycle at day 2. A previous pH correction is therefore not required, nor is waiting for pH reduction by other microorganisms necessary (42).

Starter cultures added to Spanish style green table olives (conservolea variety) declined the population of *Escherichia coli* O157:H7 inoculated in the fermentation brine, but the pathogen did not die out during fermentation. The main factor that governs the behavior of this pathogen during fermentation is the amount of acids produced (61).

19.3.3.3 Microbial Degradation of Oleuropein

Oleuropein is labile in alkaline conditions, yielding hydroxytyrosol and elenolic acid. So, during Spanish style green olive processing sodium hydroxide treatment is used to remove most of the bitterness of the fruits. However, the lye treatment causes many chemical and physical changes in the fruit, leading to the loss of soluble constituents and nutrients of the fruit. In order to overcome the problems associated with the lye treatment, alternative microbiological procedures to debitter table olives have been untertaken.

Oleuropein can also be hydrolyzed enzymatically by bacterial β-glucosidase and esterase in a two step process. In the first step the glycosidic linkage of the oleuropein is hydrolysed by β-glucosidase to glucose plus oleuropein aglycone, and in the second step the amount of aglycone formed is converted to hydroxytyrosol and elenolic acid by esterase activity (68). Lactobacilli have an important role in the biological debittering process of naturally ripened olives. Oleuropeinolytic *L. plantarum* strains (*L. plantarum* B17, B20, B21) isolated from the brine of naturally ripe olives not treated by alkali, grow at a pH 3.5, and tolerate 1% oleuropein and 8% NaCl in the growth medium. They hydrolyze oleuropein via β-glucosidase production to its aglycone; after the β-glycosidic linkage is completely hydrolyzed, as deduced from the disappearance of oleuropein, other compounds originate due to esterase activity that hydrolyzes the ester to β-3,4-dihydroxyphenylethanol and elenolic acid. Therefore, the hydrolysis of oleuropein during the fermentation process of olives not treated with alkali is attributed to the acid pH and to β-glucosidase produced by oleuropeinolytic microorganisms (33,34). The determination of the conditions for bacterial growth in olive brines is of great importance for the development of a

new biotechnology for removing the bitter secoiridoid glucoside, oleuropein, from the olives replacing the traditional alkali treatment used for debittering of olives (68).

Oleuropein is also hydrolysed by β-glucosidase produced by *L. mesenteroides* DIP20 isolated from the brine of naturally ripened olives. The maximum amount of β-glucosidase is produced during the first 24 h of the exponential growth phase. The enzyme shows maximum catalytic activity at pH 8 and 55°C. In the presence of 20 U/mL of β-glucosidase extracted from the bacterium, fifty percent of the initial concentration of oleuropein (2.25 mM) is hydrolyzed in 6 h of incubation at pH 7 and 55°C (69).

19.4 BREAD MAKING

19.4.1 Introduction

Cereal based foods are a major source of inexpensive dietary energy and nutrients worldwide. Many cereal foods are made without any fermentation process, such as boiled or steamed rice, porridge, pasta, and cookies. When fermentation is applied it is often alcoholic fermentation by yeast that prevails, as in bread making and brewing. However, there are also a number of cereal based foods that are fermented by lactic acid bacteria, such as European sour rye bread, various Asian flat breads, and the numerous types of fermented sour porridges, dumplings, and nonalcoholic beers common in Africa and elsewhere. In these applications the lactic acid bacteria contribute technological and nutritional benefits, as well as affecting flavor and keeping properties of the products (70).

Addition of water to flour inevitably leads to acid and gas production in the resulting dough. This observation was made early in history and was exploited to produce leavened bread as a staple of the diet. Credit for the first technical innovation, the introduction of leavening, seems to belong to the Sumerians in Southern Mesopotamia and may date from approximately 6000 BC. At the very beginning, heated convex stones prepared the bread from flour or parched grain, with hot ashes sometimes thrown over the cake. In 3000–2000 BC the ancient Egyptians took over and carried this elementary art to high perfection. In the ancient world they were known as the "bread eaters". Bread was more than just food, it was a standard of social status; even salaries were paid in the form of bread. Herodotus says of them "they knead their dough with their feet, but their clay with their hands". A common shape for Egyptian bread revealed by ancient monuments or in excavated tombs in a small round loaf like a muffin or elongated roll, sprinkled on top with seeds. Ancient Greeks improved the taste of bread by adding other ingredients such as sesame, pieces of fruits and honey, and offering bread with a meal was an indication of hospitality. Bread making was initially a housewife's art, but in the fifth century BC the first public bake houses ("artopoieion") were established. Even then, in poor families the housewife continued to prepare bread. Bread was named according to the way of baking ("apopyrias" on charcoal, "esharitis" on grate), or the way of preparation ("zymitis" with yeast, "azymos" without yeast), or its shape (rectangular "vlomiaios", concave "mystili", flat "plakitis"). Rome continued the development of bread making. After the war with Perseus (171-168 BC) public bake houses came into use, although the Romans continued to regard bread making as a housewife's art. The ruins of Pompei reveal several home mills and ovens. About 100 AD, the Emperor Trajan founded the College of Pistores (bakers), leading Juvenal in his famous satire to make the remark that Romans only needed two things, "panem et circenses" (bread and circuses). The Romans built the first watermills, while windmills appeared in the middle ages. Even Leonardo Da Vinci worked on the improvement of mills, but the first iron made cylinder mills were constructed in the nineteenth century (71,72).

The superior palatability of yeast raised or leavened bread led to the almost universal adoption of the necessary bread making procedures in those countries where bread became the staple cereal based food. However, there were no further notable technological innovations for nearly 6000 years (73). Mechanization, which gradually took over toward the end of the nineteenth century, better wheat varieties, flour improvers taking over from atmospheric oxidation, and diastatic correctives ensuring satisfactory gas production during fermentation, all evolved the technology, but did not revolutionize it. On the other hand, it was not until the early twentieth century that the key role of yeasts and lactic acid bacteria in (sour)dough making was recognized (74,75). Wolffin in 1894 was the first to demonstrate the occurrence of lactic acid bacteria and yeasts in sourdough and to associate acidification with bacterial metabolism (76). However, the first defined starter culture for sourdough preparation, namely the San Francisco starter, was patented in the early 1970s (77). Recent research on sourdoughs has focused on the identification of the microflora, investigations of the carbohydrate and nitrogen metabolism of the yeasts and LAB involved, and of flavor generation during fermentation (78).

19.4.2 Microbiological and Technological Aspects

Conventionally, bread making starts with the preparation of dough, which is formed in the course of rapid kneading of flour, water, salt, and yeast. *Saccharomyces cerevisiae* is specialized for bread making, exhibiting maximal fermenting activity at about 30°C. The taste, aroma, and color of bread are the combined effect of substances that already exist in flour and those produced during fermentation and baking. During dough fermentation, yeasts ferment the free sugars of the flour (about 1%) to ethanol, carbon dioxide, and organic acids. During baking, the Maillard reaction and caramelization reaction that take place are responsible for the formation of aroma compounds such as aldehydes and (di)ketones. However, artisan bread production often employs sourdough processes or the use of preferments. This provides a wide, regional variety of breads and specialty products.

Sourdough is a mixture of wheat or rye flour and water that is fermented with lactic acid bacteria (LAB) and yeasts (79). Aeration of dough and bread probably was the principal reason for using sourdoughs from an historical perspective. Primarily fermenting yeasts causes the aeration occurring in a sourdough. Heterofermentative lactic acid bacteria may also have a significant leavening effect in sour rye dough. Sourdough fermentations improve dough properties, bread texture and flavor, retard the staling process, and prevent bread from mold and bacterial spoilage (80–82). Sourdough can be prepared in bakeries or obtained from commercial suppliers (83,84).

The benefits of lactic acid fermentation in bread making are more apparent in making rye bread. Sourness in white wheat bread induces a characteristic flavor not always acceptable. On the other hand, sour rye bread is favored over nonacidified rye bread. Acidification by the lactic fermentation also improves bread making properties of rye by suppressing the high endogenous activity of α-amylase and other enzymes (85,86). The water soluble rye flour proteins cannot form a proper network of hydrated gluten, which is crucial for retaining water as well as carbon dioxide during dough preparation and fermentation. In rye flour pentosans play the role of gluten and their action is enhanced when sourdough is used (87,88).

Due to their artisan and region dependent handling, sourdoughs are an immense source of diverse LAB and yeast species and strains. In sourdoughs the lactobacilli predominate although leuconostocs and pediococci have also occasionally been reported to be present. Yeasts are also present in sourdough unless the fermentation is carried out at an elevated temperature inhibiting yeast growth. In general, the spectrum of LAB involved in sourdough fermentations includes many different species of lactobacilli, in particular

L. sanfranciscensis and *L. brevis*. It seems, however, that the dominant microflora is mainly selected by the environmental conditions induced by the sourdough fermentation technology. Many researchers still report on the existence of nonidentifiable and perhaps new sourdough LAB species and strains (89). A precise identification of strains isolated from sourdoughs is often problematic because the properties of the isolated strains do not always fully comply with those of the model strains originating from other ecological environments. The use of modern identification methods shows earlier results in a new light (79,90,91). Molecular techniques including 16S rDNA sequencing, Randomly Amplified Polymorphic DNA (RAPD), and other polymerase chain reaction (PCR) based techniques are necessary for the taxonomic investigation of complex ecosystems (92). These polyphasic approaches have allowed the description of new species including *Lactobacillus pontis* (93), *Lactobacillus panis* (90), and *Lactobacillus frumenti* (94).

The yeasts present in sourdough are acid tolerant and form a stable combination of mutual benefit with the lactobacilli. The yeasts produce amino acids, vitamins, and other growth factors required by the lactic acid bacteria (95–97), whereas the acids produced by the lactic acid bacteria suppress the growth of other microbes. *Candida milleri* appears to be the most typical yeast species in sourdoughs, although baker's yeast *S. cerevisiae* and strains closely related to it are also commonly detected in sourdoughs. Many of the strains currently designated as *C. milleri* were earlier named as *Torulopsis holmii*, the asporogenous form of *Saccharomyces exiguous*. There is a peculiar symbiosis between *C. milleri* and *L. sanfrancisco* (identical to *L. brevis* var. *lindneri*), as was first described for the San Francisco sourdough French bread process by Kline and Sugihara (83). Later a corresponding relationship was also detected in sourdoughs from elsewhere, as in a German sourdough starter, a Sudanese Kirsa sourdough, and an Italian Panettone sourdough (98–100). An obvious key factor for this symbiosis and highly resistive relationship appears to be the strong preference of the lactobacilli for maltose, as clarified in details only recently (99–104). In these sourdoughs the *L. brevis* var. *lindneri* utilizes only maltose while releasing glucose that is used by the *C. milleri*, which is incapable of assimilating maltose.

According to the technology applied for their production, sourdoughs have been grouped into three types. Type I sourdoughs are traditional doughs sustained by continuous propagation at an ambient temperature of 20–30°C with a final pH of 3.9 (105). Mostly, traditional three stage fermentation processes are used. "Anstellgut" in Germany, "mother sponge" in San Francisco, "le chef" in France, "masa madre" in Spain, "madre" or "capolievito" in Italy and "prozimi" in Greece belong to this type (81,106). *Lactobacillus sanfranciscensis* and *L. pontis* are the predominant LAB in these doughs (107). Also, *Lactobacillus fructivorans*, *Lactobacillus fermentum*, *Lactobacillus brevis*, and *Lactobacillus farciminis* were found in some of these doughs (70,79). In contrast, leavening of type II sourdoughs is achieved by addition of bakers' yeast to the dough. This is essential, because type II doughs employ a less time consuming, one stage fermentation process at temperatures exceeding 30°C. Type II doughs are mostly used in industrial processes to produce bakery pre products. In most of the cases the fermentation broth is applied as a dough souring supplement and aroma carrier (104). Dominant LAB strains in these doughs are *L. panis*, *L. pontis*, *L. reuteri*, *L. johnsonii*, *L. sanfranciscensis*, *L. fermentum*, *L. delbruekii*, *L. acidophilus*, *L. brevis*, *L. amylovorus*, and *L. frumenti* (81,94). Type III doughs are dried preparations of doughs (81). They are made by (traditional) sourdough fermentation with subsequent water evaporation (86).

Most scientific literature on lactic acid bacteria in cereal based foods derives from studies on sour rye bread, which is typical for Central, Northern, and Eastern Europe. Much of this work was reviewed by Spicher and Stephan (108) in their book on sourdough technology. Recently, Loenner and Ahrne (109) reviewed applications of lactobacilli in

baking. Table 19.4 summarizes the existing literature data on the main microbial species found in traditional sourdoughs in Mediterranean and Middle East countries.

In Italy sourdough is used in more than 30% of bakery products (110), which include more than 200 types of sourdough breads (111). Most of these breads originate from very old traditions and differ in type of flour, other ingredients, type of sourdough, technology, and shelf life. These differences greatly influence the microbial composition of sourdoughs and, consequently, the characteristics of the baked end products. Ottogalli et al. (110) suggested two different microbial situations in Italian sourdoughs: the strict and the weak association. The strict association is characterized by the presence of microbial forms, one lactic rod, *L. sanfranciscensis* or *L. brevis* var. *linderi*, and one yeast, usually *S. exiguus* or *Candida holmii*. On the other hand, the weak association is characterized by a more heterogeneous microflora of yeasts, like *Saccharomyces, Candida, Hansenula, Pichia* and *Rhodotorula*, and lactic acid bacteria. The latter are rods belonging to obligately homofermentative, facultative heterofermentative, and obligately heterofermentative groups, and cocci belonging to the *Pediococcus*, *Leuconostoc,* and *Enterococcus* genera. For instance, Pugliese sourdoughs are composed of *L. plantarum*, *L. brevis*, *L. fermentum*, and *L. fructivorans*, and Foggia sourdoughs are composed of *L. brevis, L. sanfranciscensis, Leuconostoc citreum,* and *W. confusa* (110,112,113). *Lactobacillus sanfranciscensis* is the predominant bacterial species in Italian sourdoughs (110,112), and it is either associated with *L. plantarum* (112,114) or with *L. alimentarius* (113). The dominance of *L. paracasei* is rather uncommon, although this species has been found in pizza doughs (115).

Greek traditional wheat sourdoughs belong to type I and are prepared without the addition of baker's yeast. However, there is only very limited data on Greek sourdoughs. In a recent survey, it was found that the dominant yeast species were *Saccharomyces cerevisiae*, *Pichia membranaefaciens,* and *Yarrowia lipolytica*; it was actually the first time that the presence of *Y. lipolytica* in sourdough was reported (116). The isolated bacteria

were classified into the species *L. sanfranciscensis*, *L. brevis*, *L. paralimentarius*, and *Weissella cibaria*, the last one never being previously isolated from sourdough. This consortium seems to be unique for Greek traditional wheat sourdoughs, while no *L. pontis* or *L. panis* strains were found (106). From an ecological point of view, the presence of *W. cibaria* is interesting and new for sourdough fermentations. The only *Weissella* species detected in previous studies is *W. confusa* (107,113). It may be assumed that isolates assigned to the latter species are misidentified and actually belong to the very recently described species *W. cibaria*, a species which is both genomically and phenotypically highly similar to *W. confusa* (117). A common characteristic for both species that allows distinguishing them from the other *Weissella* species is the ability to grow at 45°C, which may be in favor of type II sourdough fermentation processes. Both taxa have been isolated from fermented foods (117). A misidentification may also have occurred for sourdough isolates previously assigned to the species *L. alimentarius*. Recently, two phylogenetically highly related species, *L. paralimentarius* and *L. kimchii*, were described (118,119). In the description of the most recently described species *L. kimchii*, the taxon *L. alimentarius* is included for comparison, but not *L. paralimentarius*. However, according to De Vuyst et al. (106), it is shown that *L. kimchii* and *L. paralimentarius* are genomically related at a binding level close to the borderline of species delineation (68%). The observed instability of some phenotypic features of, for instance, *L. alimentarius*, included as a reference strain in both studies, may raise the question whether there was enough evidence to create two distinct species for these taxa.

In rural areas of Portugal a special type of corn and rye bread is prepared using as starter dough carried over from a previous making. According to Almeida and Pais (120), *S. cerevisiae* is the dominant yeast species in these doughs, followed by *Issatchenkia orientalis, Pichia membranaefaciens,* and *Torulaspora delbruekii*. In a recent and extended survey, more than 400 strains were isolated from sourdough as well as maize and rye flours from several geographic locations in Portugal and in two different periods within the agricultural year. The dominant groups were yeasts and lactic acid bacteria (LAB). The most frequently isolated yeasts were *Saccharomyces cerevisiae* and *Candida pelliculosa*. The most frequently isolated LAB were (heterofermentative) *Leuconostoc* species and (homofermentative) *Lactobacillus* species. *Lactobacillus brevis, L. curvatus*, and *L. lactis* ssp. *lactis* were the dominant species for the *Lactobacillus* genus; *Lactococcus lactis* ssp. *lactis* for lactococci; *Enterococcus casseliflavus, E. durans*, and *E. faecium* for enterococci; and *Streptococcus constellantus* and *S. equinus* for streptococci (121).

In Arab countries, North Africa, the Middle East, and elsewhere flat breads made from wheat are the staple food. Dough for the flat bread is often fermented in process closely similar to that used for sourdough rye bread in Europe. Differences exist between the protein requirements of pan bread and Arabic bread. In contrast to the linear relationship between protein content and loaf volume in pan bread, a parabolic relationship has been reported for the Arabic bread, with an optimum between 10–12% protein, within a wheat cultivar (122). These differences could be partially attributed to the differences in the dough characteristics and the time temperature combinations employed in the baking of these bread types. Pan bread doughs have relatively lower surface area:volume ratios especially as Arabic bread is baked from dough sheets, which are often 1–3 mm thick (123). Furthermore, pan bread requires longer baking time as compared to Arabic bread, which is fully baked after 15 or 90 s in an oven at 650 or 400°C, respectively (124). There are numerous local varieties of these breads, such as lavash, injera, idli and others described by Steinkraus (125), Chambell-Platt (126), and Quail (124). It has been shown that the yeasts *C. milleri* and *S. cerevisiae* and the lactics *L. plantarum* and *L. brevis* are the dominant microflora in traditional Moroccan sourdough (127). It has been suggested

that the interactions between yeasts and lactic acid bacteria in spontaneously fermented sourdough constitute an important factor for the flavor and texture of Moroccan sourdough bread (128).

Many cereal based foods made by lactic acid fermentation are products other than sour bread. Such meals used to be staple foods in many countries, including many in the Mediterranean area, but nowadays they are common mainly in Africa, such as ogi and agidi in Nigeria, koko, akassa, and kenkey in Ghana, uji in East Africa, mawe in Benin, and mahewu in Southern Africa. These include beverages, gruels, and porridges, dumplings used in stews, and fried products. Maize, sorghum, millet, and other starchy materials are used for their preparation (126,129). Grains are first soaked in water for 1–3 days, usually at ambient temperature, softening for easy crushing or wet milling into slurry. Hulls, bran particles, and germ are removed by sieve procedures. During the soaking stage, mixed fermentations, including lactic acid fermentation, take place, and these go on in the slurry. This slurring stage has many similarities with the sourdough procedures used in traditional sourdough bread making. In the fully fermented slurry there may be up to 10^9 cfu/g of LAB, which equals cell densities found in a fermented sourdough. Mainly lactobacilli and leuconostocs are responsible for the souring process. When the fermentation is completed, the slurry is boiled with a necessary amount of water so that gelatinization of starch occurs and a product of desired consistency is obtained (130,131).

19.4.3 Biochemistry of the Fermentation Process

The main consideration on the effect of sourdough fermentation on the flavor and texture of wheat and rye bread is the carbohydrate metabolism by lactic acid bacteria (LAB) and yeasts. In the complex sourdough ecosystem, the metabolism of carbohydrates is affected either by the flour composition or by the LAB and yeast interactions. The concentration of soluble carbohydrates, namely maltose, sucrose, glucose, and fructose, of wheat flour varies with the type of flour from 1.55 to 1.85%, depending on the balance between starch hydrolysis by the flour and microbial enzymes, and microbial consumption (132). Maltose is the most abundant fermentable carbohydrate, and hence maltose catabolism is a key process during fermentation (133). The organic acids and ethanol produced contribute to the aroma of sourdoughs, whereas the production of acetic and lactic acid by sourdough LAB as well as specific inhibitors active against molds or rope forming bacilli, delay or prevent the growth of spoilage organisms during bread storage (80,134–136). Furthermore, they strongly affect the rheological properties of wheat doughs (87,137). Finally, biological acidification of the dough delays starch retrogradation effectively, and this effect is dependent on the selection of LAB used to initiate the fermentation (138).

In yeasts, carbohydrates enter the cell through facilitated diffusion by an either inducible or constitutive permease (139,140). Sucrose may be hydrolysed already outside the cell (141). Inside the cell, carbohydrates enter the glycolysis pathway to produce pyruvate. Under anaerobic conditions, pyruvate is decarboxylated to acetaldehyde, which is finally reduced to ethanol, serving in this way the necessary regeneration of NAD. Alternatively, NAD may be regenerated through the reduction of phosphodihydroxyacetone to 3-phospho-glycerol, which is finally dephosphorylated to glycerol (142,143). The formation of glycerol is essential for the recycling of the inorganic phosphate used in glycolysis (144,145), while accumulation of glycerol plays an important role in the swelling of doughs with high carbohydrate content (146,147). Among the by products of the alcoholic fermentation, trehalose, a storage disaccharide that is produced from 6-phosphoglucose, plays an important role in the protection of cell membranes (148,149). Its production is usually induced under stress conditions (150,151). Besides glycolysis, yeasts may also use the pentose phosphate pathway, which results in the production of

NADPH to be used in biosynthesis of fatty acids and amino acids. Depending on the stage of growth, *S. cerevisiae* may catabolize up to 20% of glucose via this pathway.

Regarding nitrogen source utilization, yeasts are able to use a wide range of inorganic and organic nitrogenous compounds, such as ammonium ions and amino acids, which are taken up by active transport systems (97,152,153). Most strains of *S. cerevisiae* use asparagine preferentially, then aspartate, glutamine, glutamate, and lysine, and to a much lower degree glycine, arginine, and proline (152,154,155).

Among lactic acid bacteria, those found in sourdough fermentations belong mainly to the heterofermentative species, which catabolize glucose via the pentose phosphate pathway. Lactic acid, ethanol, and carbon dioxide are the main end products of sourdough LAB cultivated under anaerobic conditions (85). Under microaerophilic conditions, both oxygen and fructose can be used as electron acceptors. This gives rise to the formation of additional metabolites such as acetate and mannitol (81). In sourdough, maltose is the most abundant fermentable carbohydrate, and hence maltose catabolism is a key process during fermentation. Microbial associations of maltose positive and maltose negative LAB strains are typical for sourdoughs dominated by *L. sanfranciscensis* (78). In *L. sanfranciscensis*, *L. reuteri* and *L. fermentum* a constitutive, intracellular maltose phosphorylase catalyses the phosphorolytic cleavage of maltose, yielding glucose-1-phosphate and glucose (93). Glucose-1-phosphate is then converted by phosphoglucomutase to glucose-6-phosphate, which is further metabolized via the pentose phosphate pathway (79,81). On the other hand, hexokinase activity, which catalyses the conversion of glucose to glucose-6-phosphate, is virtually absent in cells growing exponentially in maltose containing media, and thus the nonphosphorylated glucose is excreted in the medium in a molar ratio with maltose of about 1:1 (99,156). It has been shown, however, that no glucose accumulation occurred in the fermentation broth, and no maltose phosphorylase activity could be detected in cell extracts prepared from cells grown in the presence of both maltose and fructose, suggesting that in the presence of both maltose and fructose in the medium, induction of hexokinase activity does occur (106). Similarly, in experiments performed with growing cells of *L. sanfranciscensis*, no significant accumulation of glucose was observed in the medium as reported for resting cells of *L. sanfranciscensis*, *L. reuteri*, and *L. pontis* (101,103,157). It is also believed that hexokinase activity is induced in the presence of glucose or fructose in the medium (158).

Lactobacillus sanfranciscensis and *L. pontis* are able to use fructose as a carbon source; however, in the presence of maltose they use it mainly as an electron acceptor and fructose is reduced to mannitol (103,159,160). According to Röcken and Voysey, oxygen was proven to be the preferred hydrogen acceptor for the *L. sanfranciscensis* strains (86). When oxygen is depleted, fructose is used as an electron acceptor (102,103). Through the reduction of fructose to mannitol, extra ATP is produced via the acetate kinase reaction, and thus maltose fructose cometabolism yields a shorter lag phase and a higher growth rate and biomass production (161). It has been shown that at a molar ratio of 4:1 (fructose:maltose), acetic acid is the main product (102,103,162,163). *Lactobacillus sanfranciscensis* stoichiometrically converts fructose to mannitol, while *L. pontis* produces small amounts of lactic acid and ethanol (164).

It has been shown that several strains of *L. sanfranciscensis* are able to use citrate as an electron acceptor in the presence of maltose (103). On the other hand, cometabolism of maltose and citrate has not been observed for *L. pontis* (164). According to Gobbetti and Corsetti (165), during cometabolism of maltose and citrate, lactic acid and acetic acid are initially produced, but when citrate is exhausted lactic acid and ethanol are the main products. In all cases, maltose serves as a carbon source, while citrate as an electron acceptor. The production of small amounts of succinate from citrate has been also observed, indicating the presence of citrate lyase, malate dehydrogeanse, fumarase and succinate dehydrogenase.

During cometabolism of malate and maltose, higher amounts of lactic acid are produced by *L. sanfranciscensis*, and the lactic acid produced is stoichiometrically proportional to the malate consumed, indicating the presence of the malolactic enzyme (166). Fumarate is metabolized by *L. sanfranciscensis* to a lesser degree than malate. In *L. pontis*, it has been observed that malate and fumarate are converted to succinate via the reaction of succinate dehydrogenase and fumarase, while the presence of malate results in higher acetate production.

The acetate formed is of major importance for the development of flavor and the microbial stability of the bread. The molar ratio of lactate to acetate in bread is defined as the fermentation quotient (FQ), and it is considered optimum in the range 2.0 to 2.7 (81). The FQ of sourdough can be decreased by addition of fructose to the dough when using *L. brevis* as a starter culture, resulting in increased acetate titers (162,167).

Nitrogen is a limiting factor for lactic acid bacterial growth in various ecosystems. It has been shown that glutamate, isoleucine, and valine are essential amino acids for *L. brevis* subsp. *linderi* and *L. plantarum*. Arginine, methionine, and leucine enhance growth, while alanine, glycine, aspartate, lysine, histidine, cysteine, tyrosine, serine, threonine, and proline do not affect growth (97). In this context, the proteolytic system of lactic acid bacteria is very important. The proteolytic system of *Lactobacillus sanfranciscensis* has been studied (168,169), while the use of lactic acid bacteria able to assimilate arginine for the improvement of the organoleptic properties of bread is under examination (170–172).

The main issue during sourdough fermentation is the lack of balance between maltose consumption from the side of microorganisms and production of new maltose from the enzymatic hydrolysis of starch (173). This results in rapid exhaustion of soluble carbohydrates in wheat flour sourdough. This is not the case for rye flour sourdough due to the higher amylolytic activities (86). Generally, yeasts and lactic acid bacteria have a different carbohydrate uptake rate. Most yeasts take up hexoses and maltose via high affinity systems, while with lactic acid bacteria the uptake depends on the carbohydrate concentration and it is thus less efficient (78).

The competition for the main carbon sources is eventually the main prerequisite for the symbiosis of yeasts and lactic acid bacteria in sourdough. The lack of this competition between *L. sanfranciscensis* and *S. exiguous* for maltose is of essential importance for the traditional San Francisco sourdough (78). The glucose secreted by certain strains of *L. sanfranciscensis* during maltose fermentation can be used by yeasts such as *S. exiguous*, which cannot metabolize maltose, or it may restrain competitors such as *S. cerevisiae* via catabolite repression (101,156). When sucrose is used as carbon source, *L. plantarum* growth and lactic acid production is higher in the presence of *S. cerevisiae* and *S. exiguous* (156). Yeasts hydrolyze sucrose to fructose and glucose, which are used by *L. plantarum* more rapidly than sucrose itself. Sucrose hydrolysis by yeasts is by a factor of 200 more rapid than the consumption of the monosaccharides produced, leading this way to fast exhaustion of sucrose in the medium (132).

Concerning nitrogen source availability, coculture of *L. brevis* subsp. *linderi*, *L. plantarum, S. cerevisiae* and *S. exiguous* in a medium containing adequate amounts of carbon sources and vitamins promoted the growth of lactic acid bacteria due to the lack of competition over nitrogen sources (97). Yeasts prefer the uptake of ammonium salts compared to amino acids, and at the same time they release amino acids and small peptides during their growth or due to autolysis (97,174). In sourdough, *S. cerevisiae* releases mainly γ-aminobutyrate, proline, valine, sioleucine, glycine, and alanine, while lactic acid bacteria release glycine and alanine (175). The release of amino acids by the yeasts promotes the growth of *L. sanfranciscensis* even in media which did not initially contain the essential amino acids (valine and isoleucine) (78).

With respect to the production of aroma compounds, the heterofermentative lactic acid bacteria produce mainly ethylacetate and some alcohols and aldehydes, the homofermentative LAB produce mainly diacetyl and other carbonyl compounds, while yeasts produce various isoalcohols (176). The production of aroma compounds depends on strains and strain combinations. There are strain combinations which virtually did not affect the profile of aroma compounds of sourdough (177), while others yield a profile of high quality (78). Coculture of *L. sanfranciscensis* with other homofermentatative or heterofermentative lactic acid bacteria results in a balanced aromatic profile. Homofermentative lactic acid bacteria and *L. sanfranciscensis* promote yeasts metabolism, which are mainly responsible for the improvement of the organoleptic quality of the final product (178,179).

Special attention has been paid in recent years to the effect of the final metabolic products on the growth of sourdough microorganisms. Ethanol diffuses through the cytoplasmic membrane and accumulates intracellularly, independently the growth phase of yeast (180,181). The accumulation is species or even strain dependent (182). Medium ethanol concentrations (2–6% vol/vol) inhibit maltose phosphorylase inactivation due to catabolite repression in the presence of other fermentable carbohydrates (183). Higher ethanol concentrations limit growth and metabolic activity. Although the exact mechanism is not fully understood (184), experimental data indicate that this inhibition is mainly due to decreased water availability (185). Ethanol has also an impact on membrane structure and on enzymes, and it has been shown to inhibit glycolytic enzymes by *in vitro* experiments (186–188).

Lactic and acetic acid produced by lactic acid bacteria may inhibit yeast growth (189). At the pH of sourdough (3.6–3.9) both acids are in their undissociated form and thus can diffuse through the cytoplasmic membrane (190,191). Acetic acid is considered more important and its impact on yeast growth has been studied in more detail (192–195). Ethanol produced by yeasts and the heterofermentative lactic acid enhances the diffusion of acetic acid into the cytoplasm of yeasts (196,197). Inside the cell, acetic acid dissociates and inhibits several glycolytic enzymes (198,199).

19.4.4 Effect of Fermentation on the Nutritional Quality

Cereal grains are an important dietary source for the world's population, especially in the developing counties. They are estimated to directly provide 50% of human calories in the world and 70–80% of all food calories consumed in China and India. Worldwide, cereals are the direct or indirect source of about 75% of our dietary protein. At the same time, they are a significant source of some of the B group vitamins and minerals. Cereals contribute to 33.6% of thiamine, 22.7% of niacin, and 14.2% of riboflavin consumption in the U.S. diet. Wheat, which is mainly used for bread making, contains per 100 g fresh weight 454 mg potassium, 433 mg phosphorus, 183 mg magnesium, and 45 mg calcium. Furthermore, cereal based foods are a major source of dietary fiber in most diets (200).

Many cereal based foods, such as pasta and cookies, are made without any fermentation process. On the other hand, there are many others that are prepared through alcoholic and or lactic acid fermentation. These include bread, beer, and sour porridges. In these applications the microflora involved contribute to the improvement of the organoleptic properties, the shelf life of the final products and their nutritional profile. The reader may be reminded that phytic acid (myoinositol hexaphosphate) is considered an undesirable constituent of many cereal products as it may bind essential minerals (Zn, Fe, and Ca) and render them nutritionally unavailable. Furthermore, phytic acid seems to reduce protein nutritional quality in high protein wheat bran flour (201). It has been shown, however, that bread raised by yeast fermentation contains less phytic acid than "flat" bread. This destruction of phytic acid has been attributed to the indigenous flour phytase but also to the yeast phytase (202,203). However, some authors suggest that phytic acid may partially contribute

to the beneficial effects attributed earlier exclusively to dietary fibers, such protective role in carcinogenesis and beneficial effects in heart disease (195,205).

The organic acids produced during sourdough fermentation enhance the perception of the other aroma compounds in bread, improve its physicochemical characteristics, and prolong its shelf life. Acetic acid at a concentration of 100–200 ppm increases the intensity of other aroma components in wheat bread, while at a fermentation quotient (FQ = the molar ratio of lactate to acetate) of 2.0–2.7 the taste and aroma of rye bread is more intense. It has been shown that acidification due to fermentation delays starch retrogradation more efficiently than chemical acidification (206,207). Lactic acid bacteria strains producing amylases and proteases but not pentosanases enhance that impact of biological acidification, although the exact mechanism is not understood (208–210).

Mold growth is the most frequent cause of bread spoilage. In unpreserved bread a shelf life of 3–4 days may be expected, especially if the hygiene during production is not sufficiently high. Besides the repelling sight of visible growth, molds are responsible for off flavor formation and production of mycotoxins and allergenic compounds, which may be formed even before growth is visible. In wheat bread *Penicillium commune*, *P. solium, P. corylophilum* and *Aspergillus flavis* dominates, whereas *P. roqueforti, P. corylophilum* and to some extend also *Euroticum* species are dominant in rye bread (211). The yeasts commonly known as chalk molds are also important spoilers of bread. The most important of these species is *Endomyces fibuliger* (212). The shelf life of bread inoculated with conidia of typical bread molds such as *Aspergillus niger*, *Cladosporium herbarum* and *Penicilium verrucosum* has been extended by increasing the amount of sourdough used. The fungistatic effect of sourdough has been attributed to lactic acid and, especially to acetic acid produced by heterofermentative lactic acid bacteria (213). However, other organic acids produced during sourdough fermentation such as caproic acid produced by *L. sanfranciscencis* (214), or phenyl lactate and p-hydroxyphenyl lactate produced by *L. plantarum* (136) seem also to play an important role in the prolongation of the shelf life of bread. Ropiness is the second most important spoilage of bread after molding and occurs particularly in summer when the climatic conditions favor growth of bacteria. Initially it is noticed as an unpleasant odor, followed by discolored, sticky and soft bread crumb, caused by the breakdown of starch and proteins and the production of extracellular slimy polysaccharides. It is mainly caused by *Bacillus subtilis*, but *B. licheniformis*, *B. megaterium,* and *B. cereus* have also been associated (215). The inhibition of *Bacillus* growth in sourdough bread has been attributed to the enhancement of spore thermal inactivation during baking by the presence of acetic acid (86), and the production of bacteriocins by the lactic acid bacteria involved in the fermentation (134,216–218).

It should be noticed, however, that most fermented cereal based foods are heat treated after fermentation, and thus the microflora are killed. However, in recent years there is an increased interest in cereal based functional foods that contain live probiotic bacteria. Fuller (219) and Havenaar and Huis in't Veld (220) provided earlier definitions for probiotic organisms, while Guarner and Shaafsman (221) refined the term to "living microorganisms, which upon ingestion in certain numbers, exert health benefits beyond inherent basic nutrition". In order for probiotic strains to exert their beneficial effect on the host, they have to be able to survive passage through the host's digestive tract, and colonize and metabolize in the lower intestine or colon. It was soon realized that in the presence of suitable dietary polysaccharides probiotic bacteria may be more effective. This has led to the prebiotic concept. Prebiotcs are nondigestible food ingredients that selectively increase the relative proportion of beneficial bacteria in the colon.

Carbohydrates of cereal origin and their hydrolysates are a potential source of prebiotics. Such polysaccharides must escape digestion in the upper gastrointestinal tract and

they must be hydrolysable and fermentable by the gut flora. In cereal grains the most typical indigestible polysaccharides and dietary fiber components are cellulose, resistant starch, oligosaccharides, and polysaccharides, such as araboxylans or pentosans present predominantly in the cell wall of wheat and rye, and mixed linked β-glucans found in the cell walls of oats and barley (222–224). It has been shown that oligosaccharides isolated from wheat bran are selectively used by bifidobacteria (225), while cereal β-glucans were mostly converted to butyrate and probably metabolized by the colonic epithelial cells (226). The main end products of the intestinal fermentation of dietary fibers are short chain fatty acids (SCFA), such as acetate, propionate and butyrate, and gases such as H_2, CO_2, H_2S, and CH_4. The gases are either metabolized or excreted in breath and flatus (227). Fermentation intermediates like lactic acid are further converted by the colonic microflora to propionate. The SCFAs are readily metabolized and may contribute to many physiological beneficial effects. Butyrate is taken up and used as an energy source by colonic epithelial cells, while acetate and propionate enter the portal blood supply (227). There is a hypothesis that propionate and acetate present in the enterohepatic circulation may inhibit hepatic synthesis of cholesterol; however, this still needs to be confirmed (228). Although a lot of work has to be done in order to fully clarify the interactions between probiotic bacteria and prebiotic food components, some cereal based functional foods have recently entered the market (229–231).

3.20

Fermentation Biotechnology of Animal Based Traditional Foods of the Middle East and Mediterranean Region

Effie Tsakalidou and Parthena Kotzekidou

CONTENTS

20.1 HISTORY

Fermented dairy and meat products have been known in the Mediterranean and Middle East region since ancient times. Fermentation is of great importance, as it contributes to the preservation of vast quantities of nutritious foods without significant fuel requirements, providing a wide diversity of flavors, aromas, and textures, and enriches food with vitamins and essential amino acids (1).

Lactic acid fermentation induced by lactic acid bacteria, which convert fermentable sugars primarily to lactic acid, are responsible for processing and preserving milk, producing sour milks, yogurts, and cheeses. Mixtures of yogurt and wheat undergoing lactic acid fermentation give rise to highly nutritional foods like Greek trahanas. These foods were originally developed empirically. Later, it was found that under certain treatments lactic acid bacteria occurring in raw materials improved keeping quality and safety as well as sensory characteristics of the fermented product, inhibiting the growth and survival of spoilage microorganisms and pathogens. Although acidity and the presence of undissociated organic acids are the most important inhibitory agents, other antimicrobial factors associated with lactic acid bacteria, such as bacteriocins, carbon dioxide, hydrogen peroxide, ethanol, and diacetyl are responsible for the inhibition of food spoilage and pathogenic bacteria (2).

Because of the recognition that fermentation plays an important, beneficial role in human nutrition and health as well as in food safety, the production of fermented products has shown a steady increase over recent years (3). Food fermentations that improve the balance of essential amino acids or their availability influence the nutritional value of fermented foods. In a similar way, fermentations that increase the content or availability of vitamins such as thiamine, riboflavin, niacin, or folic acid can have profound effects on the health of the consumers of such foods (1).

Mediterranean foods are produced through fermentation and other natural processes according to ancient recipes used locally. In the last few years there has been a tremendous back to nature emphasis, demanding a change in the market to naturally processed, additive free, and healthy products. The nutritional, sensory, and functional enhancement of traditional foods offer the potential for improving human health and wellbeing within the context of the Mediterranean diet (4).

The objective of this chapter is to provide food scientists, microbiologists, and nutritionists with a comprehensive and solid view of the present state of knowledge of the indigenous fermented foods of animal origin in the Mediterranean and Middle East countries, which since ancient times have played a vital role in feeding humans with nutritious and flavorsome foods in the context of a significant component of their cultural heritage.

20.2 DAIRY PRODUCTS

20.2.1 Introduction

Cheese making and fermented milk production are some of the oldest methods practiced by man for the conversion of a highly perishable and nutritional foodstuff (milk) into products with extended shelf life. It is commonly believed that cheese was developed in the Fertile Crescent between the Tigris and Euphrates some 8000 years ago. The Agricultural Revolution occurred here with the domestication of plants and animals. Cheese manufacture accompanied the spread of civilization throughout the Middle East, Greece, and Rome. There are several references to cheese in the Old Testament, such as Job (1520 BC) and Samuel (1170–1017 BC); in the tombs of Ancient Egypt; and in classical Greek literature, such as Homer (1184 BC), Herodotus (484–408 BC), and Aristotle (384–322 BC).

Movements of Roman armies spread the consumption of cheese throughout the known world of that time. After the fall of the Roman Empire, the great migrations of people throughout Europe promoted the further spread of cheese manufacture (5).

There are no records available regarding the origin of yogurt. However, the belief in its beneficial influence on human health and nutrition has existed in many civilizations for a long time. According to a Persian tradition, Abraham owed his fecundity and longevity to yogurt, while in more recent times Emperor Francis I of France was supposed to have been cured of a debilitating illness by consuming yogurt made out of goat's milk. It is likely, however, that the origin of yogurt was the Middle East. The evolution of this fermented product through the ages can be attributed to the culinary skills of the nomadic people living in that part of the world (6).

The first fermented dairy products were produced by an accidental combination of events: the ability of a group of bacteria, now known as lactic acid bacteria, to grow in milk and to produce just enough acid to reduce the pH of the milk to the isoelectric point of the caseins, at which these proteins coagulate. While lactic acid produced *in situ* is believed to have been the original milk coagulant, an alternative mechanism was also recognized from an early date. Many proteolytic enzymes can modify milk proteins, causing them to coagulate under certain circumstances. Before the development of pottery (ca. 5000 BC), the stomachs of slaughtered animals provided ready made, easily sealed containers. Stored in such containers, milk would extract coagulating enzymes from the stomach tissue, leading to its coagulation during storage.

Although the history of cheese and fermented milks can be traced back for thousands of years, cheese and yogurt making remained an art rather than a science until relatively recently. It is only since the turn of the twentieth century that serious attempts have been made to understand the associated microbiology. The result of this interest has been that many products are now manufactured with well defined starter cultures. Microbiological aspects of bovine cheeses manufactured worldwide, especially on an industrial scale and almost exclusively from pasteurized milk (e.g., Cheddar cheese), have been studied for decades. Not until recently have in depth studies focused on artisanal cheese manufactured in Mediterranean countries. Such studies deal with the characterization of those microbial groups related to ripening aspects and sanitary issues. It has always to be borne in mind that the production of fermented milks is a biological process, and the organisms involved are subject to the same variability as any other life form. Obviously, the selection pressure put upon a given species in a factory situation may be better defined than for species found in other environments. Even so, variation is still an active component of the system.

20.2.2 Microbiological and Technological Aspects

20.2.2.1 Cheese

Cheese is one of the most diverse food groups. According to Burkhalter (7) around 500 varieties are produced from cow's milk, while Kalantzopoulos (8) listed 500 more produced from sheep's or goat's milk. The variety of cheeses produced in the countries of the Mediterranean basin is probably the highest in the world. A major source of variation in the characteristics of cheese resides in the species from which the milk was produced. Although milk from several species is used in cheese manufacture, the cow is worldwide by far the most important, while sheep, goat, and buffalo are commercially important in certain areas. This is the case in the Mediterranean and Middle East countries, where herds of sheep are abundant and widely distributed, and the most representative cheese varieties are manufactured from ewe's milk. Mediterranean countries undoubtedly account for production of most ewe's and goat's milk worldwide. Almost all such milk, usually in raw

form, is converted into cheese. Many of these cheeses are protected by Appellation d'Origin Protégée (AOP) (8).

The majority of the Mediterranean cheeses are produced using animal rennet as the coagulant. However, several cheeses in the Iberian Peninsula are traditionally produced with the use of plant rennet, namely an aqueous extract from the cardoon flowers (*Cyanara cadunuculus*). These include Serpa and Serra da Estrella in Portugal, and Casar de Caceres and La Serena in Spain. All these cheese varieties are produced from ewe's milk. Ewe's and goat's milk are used for the production of many other traditional varieties of cheeses in the Iberian Peninsula using animal rennet as coagulant. Although plant coagulants and chymosin have similar specificities in the cleavage sites, as they hydrolyse between hydrophobic amino acids, plant coagulants are considered more proteolytic than chymosin, and thus casein hydrolysis may result in lower gel firmness (9,10). In general, artisanal ewe's and goat's cheeses in the Iberian peninsula can be divided into four groups based on milk source and rennet type: (1) cheeses manufactured with raw ewe's milk and coagulated with plant rennet (e.g., Azetiao, Castelo Branco, Evora, Nisa, Serpa, Serra da Estrella, and La Serena), (2) cheeses made from raw ewe's milk and coagulated with animal rennet (e.g., Terrinco, Idiazabal, Manchego, Roncal and Zamorano), (3) cheeses manufactured with raw goat's milk and coagulated with animal rennet (e.g., Cabra Transmontano and Majorero), and (4) cheeses made from mixtures of raw ewe's and goat's milk and coagulated with animal rennet (e.g., Amarelo da Beira Baixa, Picante da Beira Baixa, and Rabacal). Most of these varieties are semihard or hard cheeses, apart from Sepra, Serra da Estrella, and La Serena, which are soft cheeses. A thorough review on the microbiology and biochemistry of these cheese varieties has been recently published by Freitas and Casalta (11). On the other hand, many important cheese varieties in Portugal and Spain are manufactured from cow's milk with animal rennet as coagulant. These include Pico (soft) and Sao Jorge (semihard) in Portugal, as well as Cabrales and Picon Bejes-Tresviso (blue veined), Cantabria and Cebreiro (soft), Mahon and Penamellera (semi hard) in Spain (12). Serra da Estrella is the most traditional cheese in Portugal, while Manchego is the most typical Spanish cheese. Traditionally, Serra da Estrella is produced without deliberately added starter cultures. At the end of ripening the cheese has a flat cylindrical shape; the rind is thin, uniform, smooth, and straw yellow; the cheese has no eyes; its color varies from ivory to white; and it exhibits a buttery texture, strong aroma and a clean, smooth and slightly acid flavor (13). Lactic acid bacteria, mainly *Lactococcus lactis*, *Enterococcus faecium* and *Leuconostoc mesenteroides*, and *Enterobacteriaceae* are the dominant fermentation organisms, while a large spectrum of yeasts, mainly *Sporobolomyces roseus* are also found (14,15). Although Manchego cheese is named after the La Mancha region, where the original product was traditionally made from raw ewe's milk, nowadays the manufacture of Manchego type cheeses is spread throughout Spain. When produced at industrial scale, *Lactococcus lactis* and *Lactococcus cremoris* are used as starters. Animal rennet is used for coagulation and the curd is heated to 37°C. The cheese must be ripened for at least 2 months after molding at 12–15°C and 75–86% RH. Mesophilic homofermentative lactobacilli, mainly *Lactobacillus plantarum* and *L. casei*; enterococci, mainly *E. durans*; *Leuconostoc* species, mainly *L. mesenteroides* spp. *dextranicum* and *L. paramesenteroides*; and *Pediococcus species*, mainly *P. pentosaceus,* are the most important groups (16,17,18). The most frequently isolated yeasts belong to the *Debaryomyces* and *Candida* genera, followed by *Yarrowia, Pichia, Saccharomyces* and *Tolusporosa* (19).

Many Mediterranean cheese varieties belong to the surface ripened cheeses. These include both the bacterial smear surface ripened and the mold surface ripened cheeses. The bacterial smear surface ripened cheeses can be broadly defined as those cheeses in which bacteria are present in large numbers on the surface of the cheese and play a significant role

in determining the final characteristics and attributes of the cheese (20,21). French cheeses such as Beaufort, Comte, Gruyere, Saint Paulin, and Munster, and the Italian cheese Taleggio can be classified in this group. The pH on the surface of the cheese is about 5.0 and the cheese is generally ripened at temperatures of 12–16°C at a relative humidity of greater than 90%. These conditions result in rapid development of the smear. The microbiology of the smear is complex and its role in the ripening of the cheese is poorly understood. It is generally believed that yeasts grow during the first few days of ripening, oxidizing lactate fully to CO_2 and H_2O, and deaminating amino acids to the corresponding ketoacid and NH_3, thus leading to pH increase where the bacteria can grow (22). Yeasts of the genera *Candida*, *Debaryomyces*, *Kluyveromyces,* and *Rhodotorula* develop initially on the surface of Gruyere and Beaufort cheeses up to 10^9 cfu/g and then decrease to 10^5 for the rest of the ripening period (23). At the end of the ripening period, *Brevibacteria* species (mainly *B. linens*), coryneform bacteria, micrococci, and staphylococci are the dominant microorganisms (24,25,26). Compared with other types of cheese, the smear cheeses are characterized by a more rapid ripening process and by a more intense flavor due to a particular method of curing that involves the creation of conditions favorable for the optimal development of a complex microbiological community on the smear (27).

The mold surface ripened cheeses are mainly represented by the French varieties Camembert and Brie. Although during the initial stages of ripening their surface microflora may be similar to those of bacterial smear surface ripened cheeses, at the end of the ripening period, molds such as *Penicillium camemberti* are the dominant microorganisms (28). The composition and evolution of the microflora in these cheeses are complex, especially when raw milk is used, while the high biochemical activities of molds on the surface give these cheeses a very typical aroma and taste. In Camembert cheese, the starters used, mainly *Lactococcus lactis* spp. *lactis* and *Lactococcus lactis* spp. *cremoris*, dominate in the 24 h curd. At that point yeasts, mainly *Kluyveromyces lactis*, *Sacharomyces cerevisiae* and *Debaryomyces hansensi* grow on the surface. The mold *Geotrichum candidum* appears together with the yeasts, but its growth is limited by salting. A white felt of *P. camemberti* develops on the surface of Camembert cheese 6–7 days postmanufacture (29,30). *Penicillium camemberti* converts lactate to CO_2 and H_2O, and the surface is deacidified; and thus an aerophilic acid sensitive bacterial flora, consisting mainly of coryneform bacteria (*B. linens*) and micrococci becomes established (28). The French semihard cheeses Saint-Nectaire and Tome de Savoie are also white mold cheeses produced, however, in limited quantities. The sequential appearance of microorganisms on the rind and the curd of a Saint-Necatir type cheese has been documented (31).

Blue veined cheeses belong to the mold ripened cheeses. As the mold surface ripened cheeses, they are characterized by extensive proteolysis and lipolysis. However, in this case *Penicillium roqueforti* is grown not on the surface of the cheese but within the curd. The French Roquefort, the Italian Gorgonzolla and the Spanish Cabrales, Picon Bejes Tresviso and Valdeon belong to this group of cheeses. For the production of Roquefort cheese a water suspension of *P. roqueforti* spores is added to the milk just prior to setting, or spores are dusted onto the curd. In addition to *P. roqueforti* and lactic acid bacteria, the flora of Roquefort cheese, made from raw ewe's milk, also contains yeasts, micrococci, staphylococci and coliforms. *Lactococcus* species are always clearly dominant inside the cheese. *Lactobacillus* species, mainly *L. casei* and *L. plantarum*, reach a maximum just before salting, while yeasts and *Leuconostoc* species are also present from the beginning of the ripening (32–37). Cabrales is produced in Northern Spain from mixed raw cow's, ewe's, and goat's milk, with neither lactic starter nor *P. roqueforti* added. Its microflora during ripening has been investigated by Nunez (38). In the interior of the cheese, lactic streptococci, mainly *S. lactis*, predominate before and during salting (0–4 d).

Streptococcus lactis and lactic acid utilizing yeasts prevail during drying room ripening (5–15 d), while during cave ripening (16–120 d), molds, mainly *P. roqueforti*, and lactobacilli, mainly, *L. plantarum*, are the dominant species. On the cheese surface, *S. lactis* comprises the major flora before and during salting. *Streptococcus lactis*, micrococci, and *Leuconostoc* species are the main microbial groups during drying room ripening, and micrococci throughout cave ripening. Coliforms and coagulase positive staphylococci die off during the first month of maturation. Picon Bejes Tresviso is the second most important blue veined cheese in Spain after Cabrales. It is made primarily from cow's milk, which is sometimes mixed with small quantities of ewe's and goat's milk. The cheese is pierced on the 4th day after production and the growth of *P. roqueforti* is very abundant throughout the mass. In the first few days hardly any microbial growth on the surface is observed, but as the ripening process advances, a surface slime containing yeast and bacteria, which are very perceptible at the end of the ripening, develops on the cheeses. Once the ripening process is finished, and before covering the cheeses with *Acer pseudoplatanus* leaves, the cheeses are washed and the surface slime eliminated (39). Valdeon is a blue veined cheese produced in Spain from goat's milk. Nearly 95% of the aerophilic mesophiles on the cheese are lactic acid bacteria. *Enterococcus* and *Lactococcus* species are the dominant genera during the first stages of ripening, while *Lactobacillus* and *Leuconostoc* species replace the lactococci with proceeding ripening (40). Gorgonzolla is an Italian blue veined cheese produced from cow's milk. The use of natural lactic acid bacteria starters has been, in part, discontinued and selected strains of *L. delbruekii* spp. *bulgaricus* and *S. thermophilus*, along with *P. roqueforti*, have been introduced. According to Gobbetti et al. (41), *S. thermophilus*, *P. roqueforti*, lactococci, and surface grown micrococci, yeasts, and molds are present in the ripened cheese. As for other blue cheeses, the interactions between lactic acid bacteria and mold starters have been reviewed and a positive influence of the thermophilic lactic acid bacteria on the growth and the proteolytic activity of *P. roqueforti* has been reported (42). Due to the complex microflora and technology used to produce Gorgonzolla cheese, several studies also investigated the causes of some cheese defects, such as swelling by yeasts due to starter failure caused by phage (43). Kopanisti, a traditional Greek soft cheese prepared from cow's, ewe's, and goat's milk or mixtures of them has a strong flavor similar to that of blue veined cheeses. The procedure of manufacture and ripening promotes an abundant growth of a great variety of microorganisms, such as streptococci and lactobacilli, as well as yeasts. Kaminarides and Anifantakis (44) isolated and identified *Trichosporon cutaneum*, *Kluyveromyces lactis*, *Saccharomyces exiguus*, *Saccharomyces cerevisiae*, *Rhodotoula rubra*, *Trichosporon penicillium*, *Candida lusitanie* and *Debaryomyces hansenii*.

The French Emmental, Gruyere and Beaufort, and the Greek Graviera cheese belong to the so called Swiss-type cheeses (45,46). They are usually made with thermophilic starters (*S. thermophilus*, *L. helveticus* and *L. delbruekii* spp. *lactis*) and sometimes mesophilic lactic acid bacteria (*Lactococcus lactis* spp. *lactis*). The curd and whey mixture is always cooked between 50–56°C and the ripening time varies from 2 to 18 months. Often eyes are present due to the fermentation by propionic acid bacteria (*P. freudenreichii* spp. *shermani*) of lactate to propionate, acetate, and CO_2. The texture is slightly elastic and the flavor mild and slightly sweet, with intensity increasing with aging (47). However, these characteristics are not typical for all Swiss-type cheeses. For instance in Comte and Graviera, propionic acid bacteria are not intentionally added, and Beaufort has no openness. Some of these characteristics are found in other cheeses, like the high cooking temperature in Parmegiano-Regiano, in which no propionic acid fermentation occurs. The interactions between the different microbial groups of the Swiss-type cheeses microflora, as well as the genetic diversity within certain groups, have received much attention in

recent years (48–51). The heterofermentative lactic acid fermentation provokes abundant eye formation but is of minor importance. Mixed acid fermentation may occur due to the growth of *Enterobacteriaceae* leading to an excess of eye formation. Butyric acid fermentation by *Clostridium butyricum* and *Clostridium tyrobutyricum* is undesirable, because lactate is converted to butyric and acetic acids, CO_2, and hydrogen, which causes the cheese loaf to blow (46). Some Swiss-type cheeses, such as Gruyere and Beaufort, undergo a smear ripening process. The surface of the cheese is first deacidified by yeasts, which provokes various salt tolerant microorganisms to develop, such as micrococci and *Brevibacteria* species, which then degrade the lactic acid and influence the flora and the color of the surface of cheese.

The grana cheeses, e.g., Parmigiano-Regiano and Grana Padano, are one of the most important characteristic groups of Italian cheeses from the technological point of view. The other characteristic groups are Pasta Filata and Pecorino Romano. They are prepared from partially skimmed cow's milk, using natural whey starters, while high scalding temperatures (54–55°C) and long ripening times (greater than 12 months) are applied. They are classified as extra hard because of the low moisture content (52). Lactic starters used in the production of grana cheeses are whey cultured mixed strains of homofermentative thermophilic lactobacilli and a small number of heterofermentative lactobacilli (53,54). Using randomly amplified polymorphic DNA (RAPD) fingerprinting, interactions between *L. helveticus*, *L. delbruekii* spp. *lactis* and *L. delbruekii* spp. *bulgaricus* were shown, and this was confirmed by comparison of growth kinetics and pH behavior in mixed and single strain cultures (55). The differences seen in bacterial species and strain composition between the whey starters and the curd and cheese are in agreement with the different biochemical and biophysical characteristics of the two ecosystems (56,57). A comprehensive study on the microbiological characteristics of milk, natural whey starter, and cheese during the first months of aging of Parmigiano Regiano showed that the thermophilic lactobacilli (between *L. helveticus*, *L. delbruekii* spp. *lactis* and *L. delbruekii* spp. *bulgaricus*) were derived from the natural whey starter, while S. *thermophilus* originated from the raw milk. Natural whey starter was also the source for *L. rhamnosus*, which was present throughout the entire period of cheese aging. The other components of the nonstarter microflora, mainly mesophilic lactobacilli and pediococci, were derived from the raw milk (58). The monitoring of propionibacteria, enterococci, coliforms, anaerobes and staphylococci has been also reported (59). In Grana cheese a key role is played by *L. helveticus,* which is the prevalent species in the natural whey starter cultures and in cheese in the early stages of ripening (54,60). Using polymerase chain reaction (PCR) fingerprinting it was shown that the community of *L. helveticus* dominating in Grana cheese is composed of different biotypes (61).

Pasta Filata cheeses are very popular in the Mediterranean countries. They include soft or semisoft varieties, typically consumed fresh or after only a brief period of aging (e.g., the Italian Mozzarella) and semihard or hard varieties, which are subjected to considerable aging before being consumed (e.g., the Italian Provolone and Caciocavallo). Similar to Caciocavallo is the Balkan variety Kashkaval, as well as Kasseri in Greece, Kasar peynir in Turkey and Romy in Egypt. Typical for the production of Pasta Filata cheeses is that after renneting, the curd is first cooked at 48–52°C and at a later stage it is kneaded in hot water (85–90°C) until it can be stretched (52,62). For cheese making, either natural whey starters, resulting from the incubation of cheese whey from the previous manufacture, or natural milk starters, obtained by incubation of heat treated raw milk, are used, in which thermophilic rods, like *L. delbruekii* spp. *lactis*, *L. delbruekii* spp. *bulgaricus* and *L. helveticus*, in addition to thermophilic cocci, like *S. thermophilis*, and mesophilic cocci, like *Lactococcus lactis* dominate. *Enterococcus* species, *Leuconostoc* species, and yeasts can also reach high numbers, while they are often contaminated by coliforms (63–67). Yeasts, in particular

Kluyveromyces and *Saccharomyces*, seem to affect the functional and sensory properties of Mozzarella cheese (68). RAPD-PCR and 16S rRNA analysis are presently widely applied to determine the genetic diversity and to differentiate the biotypes in the microflora of Pasta Filata cheeses (67,69). A new *Streptococcus* species, *S. macedonicus*, has been recently isolated from traditional Greek Kasseri cheese (70). *Streptococcus macedonicus* seems to be also part of the microflora on hard Italian, semicooked (44–49°C) cheeses like Asiago d'Allevo, Fontina, Montasio, and Monte Veronese (71).

The subtropical climate in most of the Mediterranean countries imposed the production of white brined cheeses (white pickled cheeses). Brined cheeses share the practice of storage in brine (pickle), usually salted whey, for extended periods. They are of great importance for warm climates, because under these conditions the shelf life of milk is short and cheese deteriorates before it ripens. Possibly, these cheese varieties share the same origin, with various modifications to suit local conditions and needs, and they are therefore quite different in several aspects including the type of milk used and the manufacturing and storage conditions. The most well known cheeses of this class are Feta in Greece, Domiati in Egypt, Beyaz peynir in Turkey, and Halloumi in Cyprus (72,73). Feta is a soft white cheese made from ewe's milk, but goat's milk may be used as well, or mixtures of both. *Streptococcus thermophilus*, *L. bulgaricus* and *L. lactis* spp. *lactis* are commonly used as starters. Dry salting of the curd and slime formation are essential for the development of the characteristic flavor during ripening. In fresh Feta cheese, the predominant natural lactic microflora consists of the starter cultures, which are gradually replaced by salt resistant nonstarter lactic acid bacteria (NSLAB), consisting of mesophilic lactobacilli (mainly *L. plantarum*), pediococci (mainly *P. pentosaceus*), *Leuconostoc* species, and enterococci (mainly *E. faecium* and *E. durans*). The presence of yeasts (mainly *S. cerevisiae*), micrococci and coliforms in low numbers has also been reported (74–81). Domiati cheese is mainly made from buffalo's milk, cow's milk, or both, but also from ewe's and goat's milk. Large quantities of NaCl (8–15%) are added to milk before salting. This results in the need for more rennet and a longer coagulation time than for other cheeses, while the curd is usually weak. It is made either without or with the addition of starters, which are usually mixed cultures of lactococci, streptococci and lactobacilli (82). Enterococci (*E. faecium, E. faecalis* and *E. durans*), lactococci (*L. lactis* spp. *lactis* and *L. lactis* spp. *cremoris*), lactobacilli (*L. casei*, *L. plantarum*, *L. brevis* and *L. fermentum*) and streptococci are the most common microorganisms isolated from Domiati cheese, however enterococci are predominant among them. Lactococci dominate during the early stages of pickling and later lactobacilli (83,84). Several nonlactic acid bacteria have also been isolated, especially micrococci (*M. luteus*), yeasts (*Trichosporon, Saccharomyces, Pichia, Debaryomyces, Hansula, Torulopsis, Endomycopsis*, and *Cryptococcus*), and molds (*Aspergillus, Penicillium, Cladosporium* and *Geotricum*) (85–87). Turkish white cheese (Beyaz peynir) was manufactured initially from ewe's or goat's milk, but cow's milk or a combination of milks is now generally used for its production. In the traditional manufacture no starter cultures are used, and the milk may or may not be pasteurized, while today different mixed starters including thermophilic and mesophilic bacteria are used (88). At the beginning of ripening, *L. lactis* spp. *lactis* is the predominant species, while enterococci (*E. faecalis* and *E. faecium*) are the second most important group. *L. casei, L. plantarum, L. fermentum* and *L. brevis*, *Leuconostoc lactis* and *Leuconostoc mesenteroides* are also present. Lactoccoci decline during ripening, lactobacilli increase, and enterococci remain relatively constant, while staphylococci, micrococci and coliforms decrease (89,90). Halloumi, the traditional cheese of Cyprus, which appears to be a hybrid between the high salted Feta and the Pasta Filata varieties common in the Middle East, has received little attention to date. It is a semihard cheese preserved in brine and made from ewe's milk or mixtures of ewe's and

goat's milk (91). In mature Halloumi cheese made either from bovine or ewe's milk, *E. faecium*, which dominated the microflora of the fresh ewe's cheese, was replaced by lactobacilli, including a new species, *Lactobacillus cypricasei* that was not found in the bovine samples. Yeasts counts in mature ewe's and bovine cheeses reached $2.3 - 2.8\ 10^5$ cfu/g. Some of the yeasts were proteolytic or lipolytic and it was assumed that they were having a positive impact on the flavor of cheese (92).

Whey cheeses are produced from whey by coagulation via acidification or a combination of acid and heat. They are soft, unripened cheeses, ready for consumption once the manufacturing operations are complete (93). Ricotta in Italy, Mizithra, Anthotyro, and Manouri in Greece, Anari in Cyprus, and Karichee in Lebanon belong to this type of cheese. Most are produced on a small scale and enjoy a limited market, and published data on these cheese varieties are scarce.

20.2.2.2 Fermented Milks

According to Robinson and Tamime (94) fermented milks can be divided into three main categories based on the metabolic products: lactic fermentations (such as Yogurt, Laban, and Bulgarian buttermilk); yeast lactic fermentations (Kefir and Koumiss); and mold lactic fermentations (Villi). Closely related products are manufactured from fermented milks by dewheying to concentrate the product, which could resemble soft cheese (Labneh); drying of cereal fermented milk mixture (Kishk or Trahana); and freezing fermented milk to resemble ice cream (95,96). The organoleptic qualities of the fermented milks result from the multiple fermentations of milk constituents that take place. Bacteria, yeasts, and molds or combinations of these carry out fermentations. The main fermentation product is lactic acid from lactose. This is responsible for the sharp, refreshing taste of all fermented milks. It also serves as a background for the most distinctive flavors and aromas characteristic for each product. Fermented milks dominating in the Mediterranean basin are the lactic acid fermented milks, while cereal fermented milk mixtures are very popular in the Eastern part of the Mediterranean Sea.

Yogurt is the most important lactic acid fermented milk. Yogurt and yogurtlike products that appear in the Mediterranean basin include Cieddu, Mezzoradu, and Gioddu in Italy; Jiaourti in Greece; Jugurt and Ayran in Turkey; Leban or Laban in Lebanon; and Zabady in Egypt (97). Besides cow's milk, ewe's, goat's and buffalo's milk have also been used for the manufacture of yogurt. The fermentation of milk takes place at 40–45°C. The souring of milk results from the paradigmatic cooperation between *Lactobacillus delbruekii* spp. *bulgaricus* and *Streptococcus thermophilus*, two thermophilic lactic acid bacteria, which traditionally comprise the typical microflora of yogurt (96). Initially, production was confined to natural yogurt, and the market was limited to those who believed that yogurt is beneficial to health. Gradually however, attitudes towards yogurt changed and the advent of fruit yogurts during the 1950s gave the product an entirely fresh image, and it became a popular and inexpensive snack food or dessert. The method of producing yogurt has in essence changed little over the years. The fact that all commercial yogurts share a common core has lead to the word yogurt being applied to a whole range of products, such as Dried Yogurt, Frozen Yogurt and even Pasteurized Yogurt. The inclusion of these varieties under the banner of yogurt offends some people, because yogurt per se must by virtue of the process contain an abundance of viable bacteria originating from the starter culture. Presently, other lactic acid bacteria, mainly *Lactobacillus* spp. such as *L. casei*, *L. acidophilus* and *L. rhamnosus*, as well as *Bifidobacterium* species, such as *B. bifidum*, *B. infantis* and *B. longum*, or combinations of these two groups are widely used for the production of the so called probiotic yogurts.

Natural yogurt is prone to spoilage during storage, especially at ambient temperatures, because of the high content of water (85%). Traditional and advanced methods have been used to remove yogurt whey for the manufacture of strained yogurt. Traditionally, yogurt is strained in a special cloth bag, while modern methods include ultrafiltration and centrifugation (98,99). In the Middle East countries simple techniques are traditionally applied. Concentrated yogurt is produced either by the daily addition of milk to the yogurt hanging in goat's or sheep's skin, or by the addition of various quantities of salt. In Turkey it is called Torba, Kurut or Tulum, while in the Arab countries Labneh or Lebneh. In Egypt, yogurt is placed in earthenware vessels and condenses to Leben Zeer. In Lebanon, salted yogurt is made into small balls, placed in the sun to dry and then kept in either glazed earthenware pots or glass jars and covered with olive oil (Labneh Anbaris). Chanklichis similar to Labneh Anbaris, but it is enriched with herbs and spices, presumably to assist preservation. Both are consumed with bread and olive oil as appetizers. Production of smoked yogurt involves the heating of yogurt for a few hours over low fires of a special type of wood; the yogurt is then preserved over the winter months in jars covered either with olive oil or tallow (97,100). Drinking yogurt is also very popular in the Middle East countries. Yogurt is stirred, cooled, and finally diluted with an equal volume of water. Sometimes, it is flavored with salt or even flavoring extracts such as mint. In Turkey the product is called Ayran (97).

Dry forms of yogurt and cereal mixtures, known mainly as Kishk in the Arab countries and Trahana in Greece and Turkey, are very popular in the East Mediterranean countries. The methods employed for manufacture may differ from one region to another, because they are based on tradition. Milk from different species (cow, sheep, goat, buffalo, and camel) may be used for production of natural yogurt. The cereal fraction is crushed wheat, wheat flour, semolina, or parboiled wheat, known locally as bourghol (Arab countries) or bligur (Greece and Turkey). Natural or concentrated yogurt is mixed with the cereal fraction and the mixture is shaped into small rolls and placed in the sun to dry. It is sold either as rolls or in a ground form as flour. Kishk and Trahana as dishes are prepared by reconstituting the yogurt and cereal mixture with water and then simmering the mix gently over a fire. The consistency of this product, which is normally consumed with bread, is rather similar to porridge (97,101). There is no information in the literature on the starter cultures used in the preparation of Kishk or Trahana. It may be assumed that *L. bulgaricus* and *S. thermophilus* used for the production of yogurt constitute the major part of this microflora, while the indigenous microflora of milk and cereals may also play a significant role, depending on the technology applied. No improvement of the quality of Kishk was observed when *L. acidophilus* and *L. casei* were added to the yogurt starter culture (102). El-Sadek et al. (103) determined spore formers (*B. licheniformis, B. subtilis* and *B. megatherium*) to be the major part of the microflora in Egyptian Kishk, followed by lactic acid bacteria. Proteolytic and salt tolerant microorganisms were detected in appreciable numbers (3.9×10^6 cfu/g) in samples of Egyptian Kishk, along with *Bacillus subtilis*, *B. polymyxa*, *B. coagulans* and *B. cereus*, while yeasts and molds were also present ($9.0 \times 10^1 - 2.5 \times 10^3$ cfu/g) (104). Lactic acid bacteria isolated from Trahana were found to belong to the genera *Lactobacillus*, *Leuconostoc*, *Pediococcus* and *Enterococcus*. *Lactobacillus plantarum* was the most frequently found species, followed by *S. faecalis*, *L. mesenteroides* and *Lactobacillus brevis* (105).

20.2.2.3 Biochemistry of the Fermentation Process

The first essential step in milk fermentations is the catabolism of milk lactose by the lactic acid bacteria. Lactic acid bacteria as a group exhibit an enormous capacity to degrade different carbohydrates and related compounds. The main end product is lactic acid (more than 50% of sugar carbon). It should be noticed, however, that lactic acid bacteria adapt to various

conditions and change their metabolism accordingly. This may lead to significantly different end product patterns.

Lactose fermentation is by far the most studied disaccharide metabolism in lactic acid bacteria. As shown for *Lactococcus lactis* and *Lactobacillus casei*, lactose is taken up via the phosphoenolpyruvate dependent phosphotransefase system (PTS) and enters the cytoplasm as lactose phosphate (106,107). Lactose phosphate is cleaved by phospho-β-D-galactosidase (P-β-gal) to yield glucose and galactose-6-phosphate, which are further catabolized. The enzyme systems of lactose PTS and P-β-gal are generally inducible, and repressed by glucose (108). An equally common way for lactic acid bacteria to metabolise lactose is by means of a lactose carrier (permease) and subsequent cleavage by β-galactosidase (β-gal) to yield glucose and galactose, which may again enter the major pathways (109,110).

For glucose fermentation two major pathways occur in lactic acid bacteria. The Embden-Meyerhof-Parnas pathway (glycolysis) is used by all lactic acid bacteria except leuconostocs, group III lactobacilli, oenococci, and weisellas. It is characterized by the formation of fructose-1,6-diphosphate (FDP), which is split by the FDP aldolase into dihydroxyacetone phosphate (DHAP) and glycerinaldehyde-3-phosphate (GAP). GAP (and DHAP via GAP) is then converted to pyruvate in a metabolic sequence including substrate level phosphorylation. One mole of glucose results in 2 moles of lactic acid and a net gain of 2 moles of ATP. The glycolysis pathway is used by the homofermentative lactic acid bacteria. The other main fermentation pathway is the pentose phosphate pathway. The key step is the phosphoketolase split of xylulose-5-phoshate to GAP and acetyl phosphate. GAP is then converted to lactate, while acetyl phosphate is converted to acetate and ethanol. This pathway is used by the heterofermentative lactic acid bacteria. The heterolactic fermentation gives 1 mole each of lactic acid, ethanol, and CO_2 and 1 mole of ATP per mole of glucose. It should be noted that glycolysis may lead to a heterolactic fermentation (meaning significant amounts of other end products besides lactic acid) under certain conditions, and some LAB, regarded as homofermentative, use the pentose phosphate pathway when metabolizing certain substrates (111). Regarding galactose, the galactose-6-phosphate formed by PTS is metabolized through the tagatose-6-phosphate pathway (112). The Leloir pathway is used by galactose fermenting LAB, which transport galactose with a permease and lack of galactose PTS (113).

Citrate, which is present in milk in concentrations around 9 mM, can also serve as an energy source for lactic acid bacteria. It is generally accepted that next to lactose, citrate metabolism plays an important role in milk fermentations. The ability of lactic acid bacteria to metabolize citrate is invariably linked to an endogenous plasmid that contains the gene encoding the transporter, which is responsible for citrate uptake from the medium (114). Within the cell, citrate is initially converted by the citrate lyase to acetate and oxaloacetate. Oxaloacetate in then decarboxylated into pyruvate. With involvement of the intracellular enzyme pool, pyruvate may be then converted to acetyl CoA (via the pyruvate dehydrogenase complex), which leads to acetate (via acetate kinase) and acetaldehyde or ethanol formation (via alcohol dehydrogenase); to formate (via pyruvate formate lyase); to α-acetolactate (via acetolactate synthase), which leads to acetoin (via acetolactate decarboxylate), and diacetyl and 2,3-butanediol (via diacetyl/acetoin reductase); and finally to lactate (via lactate dehydrogenase). The energy is mostly generated from the conversion of acetyl CoA to acetate, meaning that citrate acts as an electron acceptor, resulting in a higher production of acetate and ATP, probably via the acetate kinase pathway. Additional energy is produced during the initial breakdown of citrate into pyruvate (115). Furthermore, recent studies performed with *L. lactis* ssp. *lactis* var *diacetylactis* (114,116) and *Leuconostoc oenos* (117) indicated that the uptake of citrate is coupled to the generation of a proton motive force, which was shown to be strong enough to drive the additional ATP synthesis.

Some of the products of citrate catabolism, such as diacetyl, acetaldehyde, and acetoin, have very distinct aroma properties and influence significantly the quality of fermented foods. For instance, diacetyl determines the aromatic properties of fresh cheese, fermented milk, cream, and butter (118). The breakdown of citrate results as well in the production of carbon dioxide, which can add to the texture of some fermented dairy products (119). Not all lactic acid bacteria are able to metabolize citrate (120). Strains of *Lactococcus lactis* and *Leuconostoc* species have been extensively studied in respect to citrate metabolism and production of aroma compounds (119,121,122). Data also exist on citrate metabolism by *Enterococcus* strains (123–126). In many dairy products originated form the Mediterranean area enterococci comprise a major part of the fresh cheese microflora, and in some cases they are the predominant microorganisms in the fully ripened product.

The metabolism of lactate and sugars by propionic acid bacteria has been recently reviewed by Piveteau (127). Dairy propionic acid bacteria have the ability to utilize a variety of substrates for energy. Lactate, produced by lactic acid bacteria, is the main energy source for propionic acid bacteria in cheese. As early as the nineteenth century, the stoichiometry of the reaction resulting in the production of propionate from lactate was established by Fitz: 3 lactate = 2 propionate + 1 acetate + 1 CO_2 and 1 H_2O. However, in Swiss type cheeses, these theoretical equations are rarely found and the relative concentrations of propionate, acetate, and CO2 may be significantly different from the expected molar ration of 2:1:1 (128,129).

Proteolysis is considered the most complex of the three primary events during cheese ripening, the other two being lactose fermentation and lipolysis. It is important for flavor and texture development, and has therefore been a popular research subject. The main proteolytic agents in cheese manufacture are the rennet, the indigenous milk protease, and the proteolytic enzymes of starter and nonstarter microflora. The role of animal rennet, which consists of chymosin and pepsin, in milk clotting is well documented. The split of κ-casein at the Phe105 - Met106 bond to para-κ-casein and the glycomacropeptide is the first step for destabilizing casein micelles and subsequent milk coagulation. The specificity of calf chymosin on α_{s1}-, α_{s2}- and β-caseins has been established and the results can, largely, be extended to cheese (130,131). Gastric proteinases from calves, kids and lambs have been used traditionally as rennet. However, plant proteinases appear to have been used as rennet for hundreds of years as well. Extracts from dried flowers of *Cyanara cardunculus* have been employed successfully for many centuries in Portugal and in some regions in Spain for the production of cheeses like Serra da Estrella and La Serena. A few experiments have also been carried out pertaining to the manufacture of French cheeses like Camembert and Gruyere (132), and Italian cheeses like Grana, Provolone, and Bel Paese (133) using plant rennet. However, problems have been encountered, such as slightly more acid and bitter flavors and softer curd, with concomitant increased tendencies for loss of shape. *Cyanara cardunculus* proteinases acting upon casein show preference for bonds between bulky regions. They are claimed to be similar to chymosin in terms of specificity and kinetic parameters, but they produce higher levels of the ripening index than commercial animal rennet (10). Plasmin is the indigenous milk proteinase, and it is a trypsin like serine proteinase. Its complex consists of the active enzyme (plasmin), its zymogen (plasminogen) and plasminogen activators, all associated with the casein micelles, while the enzyme inhibitors are in the serum phase. The enzyme is active on all caseins, especially α_{s2}- and β-, but it shows very low activity on κ-casein. Plasmin activity in cheese is clearly indicated by the formation of γ-caseins from β-casein during ripening (130). Pasteurization increases plasmin activity in milk, probably because of the inactivation of plasmin inhibitors or by increasing the rate of plasminogen activation (134). In hard cooked cheeses like Swiss-type cheeses or the Italian grana cheeses, plasmin is mainly

responsible for the primary hydrolysis of caseins, because rennet is almost completely inactivated during cooking and has only a weak action on caseins (135).

It is a general belief that lactic acid bacteria have limited abilities to synthesize amino acids, which are essential for their growth, and milk contains insufficient amounts of free amino acids and low molecular mass peptides to sustain growth (136,137). Although they are considered as weak proteolytic bacteria compared to other groups of microorganisms, it has been shown that lactic acid bacteria posses a complex proteolytic system capable of hydrolysing milk proteins to peptides and amino acids (138,139). Furthermore, it is generally accepted that their proteolytic system contributes to the degradation of milk proteins and hence to the texture, taste, and aroma of dairy fermented products (140–142). The most extensively studied proteolytic system is that of *Lactococcus lactis*, and it serves as a model for all lactic acid bacteria. An extracellular, membrane anchored serine proteinase (PrtP) is an essential component of this system. PrtP exists in at least two variants in lactococci with somewhat different specificities in the degradation of milk casein. The products of this initial casein degradation (amino acids and peptides) are transported into the cell by transport systems specific for amino acids (113), two di- and tripeptides (DtpT and DtpP) (143) and an oligopeptide transport system (Opp) accepting four to eight residue peptides (144). Inside the cell, several peptidases with a wide range of specificity complete the degradation (145). By analysing the peptide fraction in milk during growth, it was calculated that oligopeptides small enough to be accepted by the Opp system represent 98% of the nitrogen source for growth of lactococci in milk (146). Proteolytic activity by LAB is quite common, but only in a few cases has the system been thoroughly analysed (147). The gene for the PrtP-type proteinase of *Lactobacillus paracasei* has been cloned and sequenced (148). The derived amino acid sequence showed a very high degree of similarity to the lactococcal counterpart, indicating that the system in this species might be similar.

In recent years, it has become clear that a number of enzymes are involved in the conversion of amino acids to flavor components. These enzymes may catalyze reactions such as deamination, transamination, decarboxylation, and cleavage of the amino acid side chain. Branched chain amino acids can be transaminated to keto acids, which then undergo either spontaneous degradation or are enzymatically converted to the corresponding aldehydes or carboxylic acids (149–151). Most of these activities have been demonstrated *in vitro* for lactic acid bacteria, but how and whether they proceed *in vivo* is not always easy to establish. For instance, 3-methyl butanal originating from leucine has been characterized as an important volatile compound formed during the ripening of Parmesan cheese, which is responsible for a spicy cocoa flavor (152). It may have positive as well as negative effects on the sensory perception of cheese. Its contribution to the overall perception of cheese probably depends on the other volatiles present and the composition of the matrix.

The proteinases of propionic acid bacteria have been recently reviewed by Langsrud et al. (153), and they appear to be of modest importance in the breakdown of milk caseins. Their growth in cheese seems to depend on the primary hydrolysis of caseins by lactic acid bacteria. However, dairy propionibacteria have high peptidase activities, especially proline specific activities, which may be involved in the hydrolysis of the peptides produced from the initial breakdown of caseins (154–156).

Penicillium spp. play a major proteolytic role in mold ripened cheeses. Both *P. camemberti* and *P. roqueforti* synthesize a metalloproteinase, an aspartate proteinase as well as an acid carboxypeptidase and an alkaline aminopetidase. Moreover, *P. roqueforti* synthesizes one or more alkaline carboxypeptidases and some strains also produce an alkaline proteinase (28).

Yeasts are involved both directly and indirectly in the ripening of cheese (157,158). Assimilation of lactate, formation of alkaline metabolites, liberation of bacterial growth

factors, fermentation of lactose, lipolysis, proteolysis, and formation of aroma compounds are some of the yeast activities which are considered important for the typical characteristics of the smear surface ripened cheeses (27,157,159).

Geotrichum candidum has properties of both yeast and molds and presently is considered to be a yeast. It is generally believed that *G. candidum* is found in all smear and mold ripened cheeses, although recent literature does not support this conclusion (22,160). The precise role of *B. linens* in the ripening of smear surface ripened cheeses is not known but the organism certainly makes a major contribution. *Brevibacterium linens* has an active proteolytic system, especially with respect to peptidase activity (161).

Lipolysis is among the principal events occurring during cheese ripening. The free fatty chain length can vary considerably depending on the type of milk fat and the hydrolytic agent present. Free fatty acids can be further converted to methyl ketones, lactones, thioesters, keto acids, and hydroxy acids, which contribute along with the free fatty acids to the flavor of the ripened product, while the volatile short chain fatty acids are responsible for the rancid flavor of milk (162). The main lipolytic agents in cheese include the indigenous milk lipoprotein lipase, lipases, and esterases produced by the starter and nonstarter bacteria, and depending on the cheese variety, enzyme preparations added during manufacturing. Milk lipase causes significant lipolysis in raw milk cheese, but it is inactivated during pasteurization at 76°C for 10 sec. It is selective for fatty acids at the sn-3 position, where most of the butyric acid in milk fat is esterified, explaining thus the unbalanced concentration of free butyric acid in cheese (161). In most cheese varieties relatively little lipolysis occurs, with the exception of mold ripened cheeses. The lipases produced by *P. roqueforti* and *P. camemberti* are the main contributors, while lipolytic yeasts and micrococci also play a role. Despite the interstrain variations, both *Penicillium* species produce very active extracellular lipases, which have been isolated and well characterized. Lipolysis in these cheeses does not, however, result in rancidity possibly due to the neutralization of the pH during ripening (21,28). The aroma and flavor of blue veined cheeses is dominated by methyl ketones, the main ones being 2-heptanone and 2-nonanone. They are formed via the β-oxidation pathway, and their concentration is proportional to lipolysis. Reduction of methyl ketones leads to the formation of the respective alcohols, which are present in appreciable concentrations, especially 2-pentanol, 2-heptanol, and 2-nonanol, in the blue veined cheeses (163). Another lipolytic agent used is the pregastric esterase (PGE), which is present in the rennet used for the production of some Italian cheeses (e.g., Provolone). It also shows high specificity for the short chain fatty acids esterified in the sn3 position and it is responsible for the characteristic piquant flavor of these cheeses (164). Lactic acid bacteria are generally considered low in lipolytic activity. It is true that their lipolytic system has not been extensively studied compared to the proteolytic system, although there are several reports on lipases and esterases produced by lactic acid bacteria (165–170). Esterases and lipases have been also been isolated and characterized from the cheese surface bacteria *B. linens* (171) and *Anthracobacter nicotiniae* (172), as well as from propionibacteria (173,174). Vital information on the cellular location of all these enzymes, their specificity, and their overall role during ripening remains to be determined.

20.2.2.4 Effect of Fermentation on Nutritional Quality

Milk and fermented dairy products are considered as foods of high nutritional value. The nutritional importance of dairy products arises from their high content of biologically valuable proteins. In cheese manufacture, the milk casein is incorporated in the cheese curd, while most whey proteins pass into the whey. Because the whey proteins are nutritionally superior to casein, which is deficient in sulfur amino acids, the biological value of the

proteins in cheese is therefore lower than that of the total milk proteins. Concerning fat content, in recent years there has been worldwide a tendency for low fat milk and cheese, because they are perceived as healthy due to their low fat content. However, many consumers prefer high fat cheese because a high fat content contributes significantly to the flavor characteristics. However, the cholesterol content of cheese is rather low (up to 100 mg/100 g depending on cheese variety), and thus cheese cholesterol contributes only 3–4% to total cholesterol intake. Compared to milk, fermented products are superior for diets of persons suffering from lactose intolerance and diabetes. During cheese manufacture most of the milk lactose passes to the whey, and that retained in the cheese curd is partially or fully converted to lactic acid during cheese ripening. Cheese usually contains both lactic acid isomers, L(+) and D(-), depending on the type of starter used. During storage, L (+) lactate can be converted to D (-) by the nonstarter lactic acid bacteria. Humans can metabolize D (-) lactate only to a certain extent by the nonspecific mitochondrial enzyme D-2-hydroxy acid dehydrogenase. The World Health Organization (WHO) recommends D (-) lactic acid free diet for infants up to one year old, while there is no limit for adolescents or adults. Finally, milk and its products frequently comprise for humans the major source of minerals like calcium and phosphorus, and they are important sources for some vitamins of group B, especially riboflavin (vitamin B_2), while the fat soluble concentrated vitamins depend on the fat content (175,176).

Besides this classical positive impact of dairy products on human diet and thus health, presently a big discussion is taking place on the therapeutic properties of fermented milks. Lactic acid bacteria involved in dairy fermentations are known to contribute various desirable factors in addition to the physicochemical and organoleptic properties of the final product. These food grade and safe microorganisms have been used in food and feed preservation for centuries because they can produce a variety of antimicrobial agents, including organic acids like lactic, acetic and formic acid, and ethanol, carbon dioxide, diacetyl, and hydrogen peroxide (177). Additionally, several strains of lactic acid bacteria produce bacteriocins, which are peptides or proteins with an antibacterial activity against bacteria closely related to the producer strain. Furthermore, some of them inhibit spoilage bacteria and food borne pathogens including *Listeria monocytogenes*, *Staphylococcus aureus*, and *Clostridium botulinum*, and thus may be of great interest to the food industry as natural food preservatives (178,179). Problems concerning low production levels and instability of bacteriocins in certain food environments still need to be addressed. However, it is generally accepted that the use of bacteriocin producing cultures in food is of considerable advantage over using purified bacteriocin preparations. The latter application requires extensive and costly purification schemes, toxicology tests, and may suggest a nonnatural image of the additives, for instance with respect to the applied concentrations (180). No bacteriocin activity was detected during ripening of Feta cheese made with the antilisterial *E. faecium* FAIR-E 198 as adjunct starter (181). When crude enterocin CRL35 was added in goat's milk cheese deliberately inoculated with *L. monocytogenes,* the presence of the enterocin could not be detected in cheese during ripening; however, the growth of the pathogen was drastically inhibited (182). On the other hand, when a nisin producing *L. lactis* strain was used as starter in Camembert cheese contaminated with *L. monocytogenes*, the population of the latter increased upon prolonged ripening, especially on the surface (183). This was attributed to the probable nisin adsorption to fat and proteins, the lower nisin solubility at high pH values and the breakdown of the molecule by fungal proteases. It has also been reported that the use of a bactericinogenic *L. lactis* starter for Mozzarella cheese preparation resulted in the apparent death of *L. monocytogenes* after 24 h of storage, but after 7 days of storage revival and growth of this pathogen was observed (184). However, some successful examples of *in situ* bacteriocin production during cheese making have been described.

Giraffa et al. (185) showed that enterococci were suitable for producing bacteriocins in milk, in the presence of rennet, during an incubation period that simulated the first 55 h of Taleggio cheese making (186) and concluded that *E. faecalis* INIA 4 was able to produce enterocin in competition with a milk native microflora during the manufacture of Manchego cheese. Furthermore, an increase in enterocin activity was recorded in the cheese during the first week. During Taleggio cheese manufacture and ripening, Giraffa et al. (187) showed that bacteriocin production by *E. faecium* 7C5 started during whey drainage and generally reached a maximum amount just after cheese salting. The stability of the enterocin during ripening was not affected, although the heterogeneous microflora present in raw milk, as well as the enzymatic activity of rennet, were capable of inactivating the inhibitor. Furthermore, *E. faecium* 7C5 inhibited the growth *of L. monocytogenes* on the surface of Taleggio cheese (188).

The decarboxylation of free amino acids during cheese ripening produces amines. Biogenic amines, such as tyramine and histamine, exhibit biological activity, and the consumption of food containing high concentrations of these compounds may cause toxic effects for susceptible individuals. Biogenic amines are also of concern in relation to food spoilage. After fish, cheese is the next most commonly implicated food associated with histamine poisoning (189,190). The concentrations of individual amines in cheese show great variation and depend on the quality of the initial milk, the ripening period, the storage conditions, the level of proteolysis, the pH, the salt content, the microbial flora, and the synergistic effects between microorganisms (189,191–193). Among decarboxylase positive microorganisms, many strains of *Enterobacteriaceae* and certain lactobacilli, pediococci, and enterococci are particularly active (194).

Among biogenic amines, the predominant presence of tyramine has been reported for Idiazabal cheese (195), for Feta cheese (196), and for Beyaz peynir (197). Tyramine has also been found in Camembert, Parmesan, Romano, Roquefort, and Swiss-type cheeses (189). In Feta cheese, it appeared that the low pH and the high salt content did not create favorable conditions for amino acid decarboxylation, keeping the total level of biogenic amines relatively low (617 mg/kg in the 120 days mature cheese) (196). Storage of Azeitao cheese at 25°C promoted a significant increase in the tyramine and putrescine levels (198). In a survey of commercially available processed cheeses in Egypt, tyramine was detected in 70% of the samples at an average concentration of 58.7 mg/Kg, while no histamine was detected in any of the samples (199), but Ras cheese may contain appreciable amounts of biogenic amines (200,201).

In recent years, there has been much interest in the use of various strains of lactic acid bacteria as probiotics. Probiotics are broadly defined as "living microorganisms, which upon ingestion in certain numbers, exert health effects beyond inherent basic nutrition" (202). Most of the facts on probiotic bacteria are based on anecdotal reports and poorly controlled studies, which make the work inconclusive and recommendations difficult. However, evidence is currently accumulating from well designed, randomized and placebo controlled double blind studies indicating that a few well characterized lactic acid bacterial strains have documented health promoting effects when defined doses are administered. It should be noticed, however, that each probiotic strain should be tested on its own merit, because even closely related strains may behave differently in the human intestine (203).

Lactobacillus species (mainly *L. acidophilus* and *L. casei*), *Bifidobacterium* (*B. longum* and *B. infantis*) and *Enterococcus* (mainly *E. faecalis*) comprise the main genera to which the most commonly used probiotic bacteria belong. This is probably due to the perception that they are desirable members of the intestinal flora (204), while at the same time these bacteria have been traditionally used in the production of fermented dairy products and have the GRAS (generally regarded as safe) status (205). However, many

probiotic organisms currently employed in the dairy food industry are not of human origin and, therefore, do not meet the criteria for the selection of probiotic microbes acceptable for human consumption (206).

Several publications have reviewed the area of physiological activity, mechanisms, and clinical studies (206–208). It seems that the key points of accepted and potential benefits are: aid in lactose intolerance, resistance to enteric pathogens, anticolon cancer effect, small bowel bacterial overgrowth, immune system modulation, allergy, blood lipids and heart disease, antihypertensive effects, and protection from urogenital infections, infections caused by *Helicobacter pylori,* and hepatic encephalopathy (206–208). Probiotic containing products appear in a variety of formats: conventional foods (probiotic containing yogurts, fluid milk, and cottage cheese, consumed primarily for nutritional purposes, but also for their probiotic benefits), food supplements or fermented milks [food formulations whose primary purpose is as a delivery vehicle for probiotic bacteria and their fermentation end products, consumed for health effects, in monoculture (Yakult, Japan) or mixed cultures (LC1, Nestle, CH; Actimel, Danone, F and others)], and dietary supplements (capsules and other formats designed to be taken by healthy individuals looking to enhance health) (209).

In the last two decades a number of studies have been performed on bioactive peptides present in the amino acid sequence of milk proteins. Although other animal and plant proteins contain potential bioactive sequences, milk proteins are currently the main source of a range of biologically active peptides. The structures of biologically active sequences were obtained from *in vitro* enzymatic and by *in vivo* gastrointestinal digestion of the appropriate precursor proteins (210,211). Bioactive peptides produced from milk proteins, especially from β-casein (β-casomorphins) are potential modulators of various regulatory processes in the body: Opioid peptides are opioid receptor ligands, which can modulate absorption processes in the intestinal tract, angiotensin-I-converting enzyme (ACE) inhibitory peptides are hemodynamic regulators and exert an antihypertensive effect; immunomodulating casein peptides stimulate the activities of cells of the immune system; antimicrobial peptides kill sensitive microorganisms; antithrombotic peptides inhibit aggregation of platelets; and caseinophosphopeptides may function as carriers for different minerals, especially calcium. Bioactive peptides can interact with target sites at the luminal side of the intestinal tract. Furthermore, they can be absorbed and then reach peripheral organs. Food derived bioactive peptides are claimed to be health enhancing components that can be used for functional food and pharmaceutical preparations (212). Recently, peptides inhibitory to ACE and endopeptidases and aminopetidases of lactic acid bacteria and *P. fluorescens* were isolated from Italian cheeses such as Mozzarella, Italico, Crescenza, and Gorgonzola (213).

20.3 FERMENTED MEATS

20.3.1 Introduction

Fermentation and drying of meat products are the most ancient ways of food preservation in the Middle East and Mediterranean region. The two processes are mentioned together, because in practice they are impossible to separate (214). The production of fermented meats is thought to have originated in the countries surrounding the Mediterranean Sea, as the climate, especially during the winter months, with fairly low temperatures and low relative humidities, is suitable.

We find proof of ancient sausage production in verse 43 of the eighteenth Rhapsody from Homer's The Odyssey. Sausages, described as "…goatpaunches…filled with blood

and fat," were offered by Antinoos, son of Eupeithes, to the bravest suitors. Although the historical origin of fermented sausage still remains unknown, the Mediterranean sausage manufacturers were among the first to fill fresh meat into intestines and preserve the product by adding salt and drying. The Romans knew that ground meat with added salt, sugar, and spices turns into a palatable product with a long shelf life if prepared and ripened properly (215). Etymological investigations have shown that there are many linguistic modifications of the word sausage. The word salami may be derived either from the Greek island Salamis or the ancient city Salamis on the east coast of Cyprus; or it may be originated from the Italian word for salt, *sale* (216–218).

In early times people became aware of the preserving effects of salt and drying, and therefore over the centuries were able to develop many cured products. The term "curing" in the Mediterranean region means a long ripening (ageing) process, where complicated biochemical, proteolytic, and lipolytic modifications take place that are responsible for the distinctive flavor of the products (219,220). Fermented sausages are usually made from comminuted meat and fat mixed with salt, curing agents, sugar, and spices and filled into casings (215). Although there are too many variants, some characteristic examples are the Italian salami with all its variations, the French saucisson sec, the Spanish chorizo and salchichon, the Greek fermented sausage, the Turkish dry sausage (soudjuk or sucuk) and similar products in most Middle Eastern Countries. In most Mediterranean countries fermented sausages are produced with pork and beef, while Italian salamis are manufactured from pork only, and Turkish sucuk from cow and sheep meat. The products are often heavily spiced as in the case of sucuk, which contains various seasonings, i.e., garlic, black and red pepper, cumin, and cinnamon (221).

Dry cured ham is another cured meat product. The production of uncooked ham and similar cured products is confronted with a variety of extraordinary handicaps, which make it difficult to obtain a uniform quality product. There are national and local specialties as a consequence of variations in the use of raw materials, formulations, and manufacturing processes, which come from habits and customs of the different countries and regions (219). Some characteristic products are the Italian Parma and San Daniele hams, Spanish Iberian and Serrano hams, and French Bayonne and Corsican hams. A typical Mediterranean dry cured product made of beef is the Greek and Armenian Basturma or Turkish Pastirma or Pasterma; the meat is covered with a layer of a paste (3–5 mm thick) consisting of helba, garlic, salt, paprika, and pepper (222). Presently, in an effort to improve the safety and quality characteristics of the products, starter cultures are used.

Traditional intermediate moisture meat products are produced in the Middle East and Mediterranean region by salting and drying. The preservation of meat by salting and sun drying, a practice dating back several centuries in the Middle East, results in a product called kaddid. The successful preservation of this product is the result of lowering the water activity (a_w), salting, and spice flavoring (adding coriander, garlic, and pepper). The product is characterized by a strong flavor due to fat lipolysis and probably free fatty acid oxidation. Proteolysis may also help in flavor development by releasing amines and amino acids, which may have an influence on the organoleptic characteristics. Microbial populations of coliforms, enterococci, and staphylococci are reduced during processing, but staphylococci survive in the product, and the possibility of a foodborne outbreak exists (223).

20.3.2 Biochemical and Microbiological Changes in Fermented Meats

20.3.2.1 Fermented Sausage

The production of fermented meats is based on the enzymatic activity of certain microorganisms resulting in transformation and modification of the raw meat. Historically, the

responsible microflora are accidentally introduced from the environment. Essentially two bacterial groups are responsible for the desired meat fermentations that lead to safe and stable products: the lactic acid bacteria and the catalase positive cocci (*Micrococcaceae*) (224). Gram-negative bacteria are usually present only in small numbers, which rapidly decline over time. Lactobacilli usually dominate the lactic acid bacteria microflora in naturally fermented sausages. The growth and metabolism of lactic acid bacteria is affected by the presence of oxygen. Usually the carbohydrates are metabolized via glycolysis. However, under certain conditions, the heterofermentative pathway is activated, resulting in undesirable flavor components, such as acetate (218). In the presence of oxygen, metabolites other than those found in anaerobic conditions may be observed. In addition to the formation of hydrogen peroxide, which may be formed during the aerobic metabolism of glucose, the yields of lactic acid, acetic acid, acetoin, and ethanol are also affected. *Lactobacillus plantarum,* which under anaerobic conditions mainly forms lactic acid from glucose, shows a dramatic increase in the production of acetic acid under aerobic conditions, together with small amounts of acetoin (224). Manganese is also required by lactic acid bacteria for various enzyme activities, including those of the Embden-Meyerhof pathway (225). In addition, some spices, such as red pepper, stimulate the rate of lactic acid formation by supplying manganese. Lactic acid bacteria also use manganese as a superoxide scavenger (which is presumed to be an intermediate in hydrogen peroxide formation) (108), which may explain the very high manganese requirements. During ripening of fermented sausage the main microbiological reactions that occur are the production of nitric oxide by nitrate and nitrite reducing bacteria, which is crucial for red color formation as a result of nitrosomyoglobin formed; and a decrease in the pH of the sausage emulsion via glycolysis by acidogenic microorganisms. When nitrate is used, it must first be reduced enzymatically to nitrite; the pH of the meat should be in the range of 6.0–5.4, because a stronger degree of acidity would prevent bacterial enzymatic activities. The competition of the microorganisms for the available nutrients and the pH dependent reduction of nitrate to nitrite are the two factors influencing these reactions. Nitric oxide formation and a decrease in pH are therefore the crucial points of sausage fermentation as the rate of nitric oxide myoglobin formation increases with falling pH and is therefore accelerated by the activity of the lactic acid bacteria in fermeted sausages. During nitrite inhibition, many homofermentative lactobacilli are found to release CO_2 as a result of the manganese increase in the cells and stimulation of the heterofermentative pathway (226). Under anaerobic conditions nitrates and nitrites serve as oxidizing agents for bacteria; catalase positive cocci occurring naturally in meat reduce nitrates into nitrites, affecting the formation of curing color in fermented sausages. However, peroxides formed by lactic acid bacteria in the presence of oxygen and peroxide groups present in fatty tissue can, at low pH values, attack the iron moiety in nitric oxide myochromogen resulting in discolorations (215). The nitrate reducing organisms, usually catalase positive cocci, make an important contribution to the flavor of the products and also produce catalase, which removes H_2O_2 produced by the lactobacilli that can cause color problems (227); and play an important role in forming and stabilizing the desired sensory properties of fermented sausages (215).

Relative humidity and air velocity in the drying chamber may affect the rate and intensity of acidification. With higher relative humidities and lower air velocities, rapid acidification may produce important defects because drying of the surface reduces the amount of free water available for bacterial growth. Good raw material and appropriate regulation of environmental conditions (temperature, relative humidity, and air velocity) are important factors affecting product quality. The fermentation of traditional meat products is based on the natural climatic conditions, and therefore the risk of faulty fermentations is rather high (218).

Typical Mediterranean-type products involve longer ripening periods, often without clear separation between fermentation and ageing. Smoke is not applied and acidulation to final pH values above 5 is slower (228). A slow curing process (up to 2 or 3 months) is given where nitrite is not usually used. Nitrate is added as sodium or potassium salts, which is transformed to nitrite by bacteria, with nitrate reductase activity naturally occurring in meat or added as starter cultures. Their flavor is directly related to the biochemical, proteolytic, and lipolytic mechanisms which take place during ripening (229). Shelf life is mainly determined by drying and lowered water activity (228).

The most important dry cured sausages in Spain are chorizo and salchichon (229). The fermentation process may be slow or fast, depending on the temperature used during ripening and the raw material. In the slow fermentation, temperatures of 15–16°C and nitrate for nitrification are used; nitrate is reduced to nitrite by bacterial nitrate reductase activity. The fast method involves the use of nitrite and exposure to high temperatures, between 22 and 25°C for 2 to 3 days depending on the diameter of the sausage, which favors development of the bacterial flora responsible for fermentation, consisting mainly of lactobacilli and micrococci in the case of chorizo (230). In modern industrial production of traditional products, an alteration of the traditional process using fast curing techniques results in a gradual loss of the typical sensory characteristics. The final result is a very intense acid taste, which is not acceptable to consumers (229).

20.3.2.2 Dry Cured Ham

A variety of processing practices have been developed throughout centuries for production of ham and similar cured products using different raw materials, ageing times, and manufacturing techniques, which have been adopted locally through individual experience and tradition. Traditional dry cured ham is produced by the rubbing on of salt, whereas the accelerated production processes include brine salting or brine injection pumping with the simultaneous addition of starter cultures (218). The main difference between these methods is the varying concentration of salt, the presence or absence of nitrate or nitrite, and the varying amounts of sugar and types of spices. Other distinctions are based on the degree to which the ham is smoked, aged, and dried in order to provide aroma and to ensure shelf life. In the long processed dry cured ham (the ripening period is 12 or more months, characterized as "slow process") the typical dry cured flavor is fully developed, whereas in the short processed dry cured ham (the ripening period has a minimum of 6 months, "rapid process") it is not (231). The lipolytic and oxidative degradation joined with the catabolism of amino acids produce volatile compounds which are responsible for the typical aroma of dry cured hams (220). The muscle aminopeptidases are the main contributors to the generation of free amino acids during the processing and contribute to flavor development (232). A common feature of Mediterranean raw ham manufacturing is a dry salting phase at low temperature (2–4°C) with a duration of 8 to 10 days followed by a post salting stage, during which the temperature is kept below 4°C for a period between 20 days and 2 months. The inhibition of spoilage microflora during the curing process makes limited storage possible (217). During the last ripening and drying stage, which has a duration from 6 to 24 months (for Serrano ham this stage takes about 9–12 months, while for Iberian ham it can be extended up to 18–24 months), the temperature is held between 14 and 20°C with the relative humidity decreasing from 90 to 70% (233). These temperatures set a limit to fermentation and the employment of starter cultures. During the last curing period the ham is frequently covered with lard in order to prevent excessive drying, whereas a natural mold covering can be developed (218).

The microbiological stability of dry cured ham is due to salt, curing agents, and the action of tissue enzymes with little contribution from microorganisms. In order to overcome

the risk of growth of pathogens during the salting process, it is important to select meat pieces of normal pH ($\leq$ 5.8), otherwise injection of psychrotrophic lactic acid bacteria together with fermentable sugar is recommended (234). The large sizes of meat particles and the high salt concentrations have negative effects on growth and physiological activities of the microorganisms, but microorganisms play an important role in curing processes as they contribute to the appearance and flavor of raw hams by reducing nitrate and forming aroma precursors. *Micrococcaceae,* which comprise the predominant extrinsic flora, penetrate into hams, as do chlorides, during postsalting stages, and the technological characteristics of the process favor the development of *Micrococcaceae* on the deep muscular tissues of hams (235). Lactic acid bacteria, along with fermentable sugars, may be added to the injection brine in order to lower the pH value of the meat and to accelerate the salting process (236).

20.3.3 Starter Cultures

Although excellent fermented meat products can be produced without use of starter cultures (218), starters consisting of one (single starter) or several (mixed starter) strains are used today when manufacturing on a large industrial scale in order to standardize the product process and the quality of the product. Starter cultures are mixtures of lactic acid bacteria (*Lactobacillus*, *Pediococcus*), catalase positive cocci (*Staphylococcus, Kocuria* [formerly *Micrococcus*]), yeasts (*Debaryomyces*) and molds (*Penicillium*), depending on the final characteristics required, as they normally bring about and stabilize the desired sensory properties (237). Lactic acid bacteria are used less in Mediterranean countries because consumers reject the acid flavor and aroma (238); usually, they are used as mixed cultures in combination with catalase positive cocci. There are starter preparations for inoculating dry sausage emulsions as well as microorganisms for inoculating curing brines used for cured ham manufacture; and also for the surface inoculation of dry sausage and cured ham.

Metabolic activities of the microorganisms used as starters are essential for the desirable changes determining the particular characteristics of the fermented meat product. Lactic acid bacteria represent the most important group of starter organisms, as they are well adapted to the meat environment and are involved in all changes occurring during fermentation and ripening. The acidogenic bacteria transform carbohydrates into lactic acid through homofermentation. Lactic acid affects nitrate and nitrite reduction, which in turn influences meat color. Bacterial activity enhances gel formation, lending to a firmer consistency of the product as well as the development of aromatic compounds. Catalase positive cocci play an important role in sausage ripening by contributing to the development of the typical flavor as a consequence of their proteolytic and lipolytic activities. Catalase protects from color changes and rancidity, whereas nitrate and nitrite reductases aid in reddening and reduce residual nitrite content. The proteolytic activity of starter cultures affects the biogenic amine content of the product. Use of starter cultures guarantees safety (by control of pathogens or spoilage microorganisms), and is necessary to standardize product properties (consistent flavor and color, and improved texture).

Enterococcus strains isolated from different nonmeat origins and used as starter cultures in Spanish style dry fermented sausages improved the organoleptic properties of the product; so the enterococci may be suitable for addition to meat as cocultures to improve safety (239). *Enterococcus* strains may enhance sausage aroma and taste by their proteolytic activities, but may also compromise safety if opportunistic pathogenic strains proliferate. *Enterococcus* strains have recently assumed major importance in clinical microbiologigy as well, concerning their antibiotic resistance and their possible involvement in food borne illnesses due to the presence of virulence factors, such as the production of adhesins and aggregation substances (240).

Staphylococcus equorum is used in starter preparations with application in curing of raw ham, as the strains of this species grow well at temperatures below 10°C (241,242). *Halomonas elongata,* a psychrophilic and halophilic species that strongly reduces nitrate and nitrite, may be favorable in ensuring low nitrate concentration and in improving the sensory quality of ham (243).

Yeasts and molds traditionally play an important role in sausage fermentation, as well as maturation of hams, having an important role in the flavor of the product due to the enzymatic attack on the proteins and fats. The mycelial coat reduces moisture loss and facilitates uniform drying (244). Furthermore, mold protects the sausage from damage by intense light and high oxygen concentrations, and prevents rancidity by synthesizing catalase. Commercially available starter cultures of *Penicillium nalgiovense, P. chrysogenum, P. camemberti* may be used. The surface of the sausages is usually inoculated by dipping in a suspension of mold spores or by spraying. The cultivated molds avoid colonization by undesirable molds causing faults in the appearance and aroma of the products. Yeast starters such as *Debaryomyces hansenii* and *Candida famata* are used to produce a powdery surface or a fruity or alcoholic aroma (244). Strains of *Penicillium aurantiogriseum* and *P. camemberti* isolated from the surface of Spanish hams can give high quality characteristics to traditional meat products and can serve as a base for the production of starter cultures (245).

20.3.4 Microorganisms Occurring in Traditional Meat Products

20.3.4.1 Fermented Sausage

The microflora of naturally fermented sausages is usually dominated by lactobacilli (Table 20.1) and *Micrococcaceae* (Table 20.2). The microflora of Soppressata molisana, a traditional dry sausage produced in Southern Italy, is composed of lactobacilli and catalase positive cocci. The large majority of the lactobacilli isolated are *L. sake,* whereas a few strains are obligate heterofermentators belonging to *L. brevis.* Several isolates are hydrogen peroxide and acetoin producers (246). Among the catalase positive cocci occurring in the product during ripening, a predominance of micrococci (42%) and coagulase negative

Table 20.1
Main lactic acid bacteria involved in fermentation of traditional Mediterranean and Middle East meat products

Country of Origin Type of Sausage	Species	Ref.
Italy

Greece		
Greek-type sausage	*S. saprophyticus, S. xylosus*	(261)
Greek-type sausage	*S. saprophyticus, S. carnosus, S. xylosus*	(263)

staphylococci (58%) is observed, with a prevalence of *Staphylococcus xylosus* and *Micrococcus kristinae* (247). Nine percent of staphylococci were coagulase positive and thermonuclease negative, but no strains of *Staphylococcus aureus* were isolated (247). Quite variable biochemical behavior is observed in the natural *Micrococcaceae* of the product. All strains are able to grow in the presence of 10% NaCl and a large majority are able to reduce nitrates to nitrites. Forty one percent of the micrococci and 16% of the staphylococci are able to hydrolyze pork fat, but only 2% of micrococci hydrolyze Tween 80. Micrococci showed a higher proteolytic activity in skim milk than staphylococci, whereas acetoin production was a strain specific trait (247). A natural fermentation therefore does not guarantee a consistently flavored product.

In Naples-type salami, manufactured without starter cultures, homofermentative lactobacilli constitute the predominant flora. Approximately 60% are identified as *L.sakei,* whereas 40% are *L. bavaricus* (248). *Micrococcaceae* constitute a fairly homogeneous group, which represents an intermediate variety between *S. xylosus* and *S. saprophyticus* and is isolated during the whole ripening process (248). Using a molecular method consisting of polymerase chain reaction amplification and denaturing gradient gel electrophoresis, *S. xylosus* proved to be the main species of the *Micrococcaceae* isolated during ripening of naturally fermented Italian sausages (249). The yeast population isolated from Naples-type salami mainly comprises *Debaryomyces* strains (248).

The dominant microflora in Spanish style dry cured sausage Chorizo Gallego is composed of lactic acid bacteria, but *Micrococcaceae,* enterococci, and bacilli also comprise a large portion of the total microflora of the product (250). The lactic acid bacterial microflora in different varieties of chorizo is composed of *L. sakei* (68.8%), *L. curvatus* (16.47%) and *Pediococcus* species (8.52%). Strains of *L. sakei* and *L. curvatus,* which ferment maltose but not lactose, are more dominant at the beginning and in the middle of the process, whereas lactose (or lactose and maltose) fermenting *L. sakei* and *L. curvatus* occur in higher numbers in the final product (251). The main lactobacilli isolated from dry fermented sausages in Spain are *Lactobacillus sakei* (55%), *L. curvatus* (26%), *L. bavaricus* (11%) and *L. plantarum* (8%); from the strains isolated, the most aciduric is *L. plantarum*. Although all *L. sakei* strains produce ammonia from arginine, in some strains the arginine deaminase pathway is induced only at a low oxygen level (252). *Staphylococcus xylosus* is the most predominant species among *Micrococcaceae* isolated from chorizo (95% of the strains isolated). Among such isolates, 38% are suitable as a starter culture as

they show nitrate reductase and urease activity, low and moderate proteolytic and lipolytic activities, and do not produce acetoin (253).

The characteristics of the specific strains of lactobacilli isolated from meat origin have to be taken into account in order to select starter cultures in the manufacture of dry fermented sausages. From the evaluation as a starter culture of a mixture of *L. sakei, L. curvatus, L. bavaricus,* and *L. plantarum* strains isolated from naturally fermented Spanish sausages in comparison to a control (noninoculated batch) the following observations were made: a faster drop in pH was recorded in *L. curvatus* and *L. bavaricus* lots and correlated with a higher amount of nitrates. Some *L. sakei* strains gave rise to a product with the best sensory evaluation. *Lactobacillus plantarum* lots showed a high acidity, which was not well accepted by the panelists and was related to the highest amount of lactic acid. Especially dry sausages with a high D-lactate content had a very sour taste. One *L. curvatus* strain showed some important sensorial descriptors, in particular aged flavor, odor intensity, and typical flavor. The control lot showed suitable nitrate reduction, but the hydrogen sulfide odor detected, related to the higher content of *Enterobacteriaceae*, diminished its overall sensory acceptability (254).

Lactobacillus sakei CL 35 is a starter culture isolated from chorizo, which is able to inhibit Gram-positive and Gram-negative bacteria with the exception of the genus *Micrococcus.* When it is applied in combination with different concentrations of nitrite the microbiological quality of the product is improved (255). By use of the *Lactobacillus sakei* CL 35 as starter culture, a domination of the lactic acid bacteria (10^8–10^9 cfu/g) in the microflora is observed during ripening, followed by Micrococcaceae in high populations (10^5–10^6 cfu/g) and a decrease of the *Enterobacteriaceae.* This starter culture has a high acidifying capability and excretes antibioticlike substances ensuring the safety of the product (256).

In salchichon the bacterial flora is composed mainly of lactic acid bacteria and plays an important role in acidification. *Streptococcus, Microbacterium* and *Enterobacteriaceae* species are also involved, but only during exposure at high temperatures because their action is reduced as a consequence of growth of lactobacilli (257). During the fermentation stage of salchichon using a commercial mixture of *P. pentosaceus* and *Micrococcus varians,* proteolysis and lipolysis phenomena derived from high counts of lactic acid bacteria and *Micrococcaceae* occurred. The organoleptic characteristics of the final product are affected by an increase in the total free amino acid content, the peroxide index and the carbonyl compound content, as well as a decrease in protein solubility and the percentage of polyunsaturated free fatty acids (258).

In naturally fermented traditional Greek salami, the lactic acid bacterial species found are mainly *L. sakei* and *L. curvatus* followed by *L. plantarum* (259,260). *Carnobacterium* species are the second most frequent type of lactic isolates (about 10% of the isolated strains), identified as *C. piscicola* (261). Gas forming lactic acid bacteria of the genus *Weissella,* belonging to the species *W. hellenica, W. paramesenteroides, W. minor, W. halotolerans and W. viridescens,* occur as meat contaminants, due to poor hygienic precautions (262). The enterococci population, consisting mainly of *Enterococcus faecium* (259), increases during early fermentation and competes well in the fermented product comprising 4% of the isolated lactic acid bacteria (260). *Micrococcaceae* populations are poor competitors in the presence of actively growing aciduric bacteria, and their population is low consisting mainly of *Staphylococcus saprophyticus, S. carnosus* and *S. xylosus* (261,263). Although the role of *S. saprophyticus* in sausage aromatization is minor, *S. xylosus* is an important organism for dry sausage manufacture and is included in commercial starter culture preparations when a very aromatic product is intended (261).

In the microflora of Turkish sucuk, which is commonly fermented without starter culture, the predominant lactic acid organisms are *L. sakei, L. curvatus, L. alimentarius, L. plantarum* and *L. brevis* (264).

Although the role of lactobacilli in the production of traditional fermented meat products is well documented, there is little information available concerning lipases from *Lactobacillus* species. This is a consequence of a comparatively low production of lipase by these microorganisms, especially when compared with *Staphylococcus* species and *Micrococcus* species. Lactic acid bacteria lipases are involved in the development of flavor and aroma in fermented food products. A *L. plantarum* strain isolated from chourico, a traditional Portuguese dry fermented sausage, produces a highly thermostable extracellular lipase, which can be helpful for industrial utilization of lipases (265).

20.3.4.2 Dry Cured Ham

The natural microflora of lactic acid bacteria in dry cured hams is normally not very numerous (10–10^4 cfu/g) consisting of *Pediococcus pentosaceus,* the homofermentative lactobacilli *L. alimentarius* (43%), *L. curvatus* (16%) and *L. casei* var. *rhamnosus* (5%), and the heterofermentative *L. divergens* and atypical streptobacteria (266). Coagulase negative staphylococci are predominant in Spanish dry cured ham, probably because of their high salt tolerance, comprising 90% of the catalase positive cocci (267). *Staphylococcus xylosus* and *S. sciuri* are the main coagulase negative staphylococci growing in the product (267,268). In Spanish dry cured ham processed by both the slow and the fast process *S. xylosus* was the predominant microorganism among Gram-positive, catalase positive cocci isolated (269,270). A decrease in the number of *Enterobacteriaceae* species identified was observed as curing progressed during the two dry curing processes. At the end of the fast curing process, *Leclercia adecarboxylata* is the only species present, whereas at the end of the slow curing process, it is the most prevalent species, accompanied by *Klebsiella pneumoniae* and *Enterobacter agglomerans* (271). In Iberian dry cured ham, even after 16 months of maturing *S. xylosus* and *S. equorum* are the predominant organisms among the *Micrococcaceae* present in the product, and their metabolic activities contribute to the characteristics of the final product (241).

The Spanish hams are salted with marine salt alone or in combination with nitrate or nitrite. During the salting stage the microorganisms present in the salt develop several actions in the brine formed (reduction of nitrates to nitrites, proteolysis, and lipolysis) or penetrate the ham contributing to the sensorial properties. The salt during salting process of dry cured hams offers an ecosystem consisting of catalase positive cocci. Among 369 isolates, 60% belonged to the genus *Staphylococcus,* 25% to *Micrococcus,* 6% to *Kocuria,* 5.4% to *Dermacoccus* and 0.5% to *Stomatococcus.* The species most often isolated are *Staphylococcus xylosus, M. lylae, S. equorum* and *D. nishinomiyaensis* (272).

The good preservation of traditional Middle East and Mediterranean dry cured meat products like basturma is a result of lowering the water activity, salting, and spice flavoring (mainly the bactericidal effect of garlic) (273). The normal microflora of the product consists mainly of lactobacilli, staphylococci, and enterococci; whereas *Enterobacteriaceae* and sulfite reducing clostridia are present in low counts (222). From the 120 catalase positive cocci isolated, 42% were identified as *S. epidermidis,* 32% as *S. saprophyticus,* 12% as *S. simulans,* 4% as *S. carnosus,* 2% as *S. hyicus* subsp. *hyicus* and 7.5% as *K. varians* (274).

20.3.5 Quality Characteristics

20.3.5.1 Flavor Development

The typical flavor of fermented meat is a result of the interaction of numerous compounds resulting from the microbial and muscle enzyme metabolism of carbohydrates, proteins, and lipids which, in combination with spices and seasonings, create the specific profile for each product (219,275). In products where only curing agents are used, the flavor differs

noticeably according to the use of nitrate or nitrite. Acidification plays a major part in these reactions, influencing not only the products produced but also the enzyme mechanisms of curing. With Mediterranean area products, curing with nitrate is considered indispensable because, among other factors, it directs the microbial development toward the growth of favorable microorganisms, especially lactic acid bacteria and catalase positive cocci that produce oxidized derivatives, aldehydes, and ketones, which together with nitrated and nitrosed compounds contribute decisively to the flavor (219). Acids derived from carbohydrate fermentation by staphylococci induce an acid taste (D-lactate) or aroma (acetic acid), whereas diacetyl and acetoin impart a buttery flavor (276). Because smoking is very seldom used in the Mediterranean area (277), the flavor of the products is directly related to the biochemical, proteolytic, and lipolytic mechanisms which take place during ripening (229). Although results are published indicating the importance of bacterial proteinases, the endogenous enzymes in meat play a crucial role in the development of flavor in fermented sausages (243). Bacterial metabolism of L-leucine, mainly by staphylococci, and to a less extent by *Lactobacilli,* is generally held responsible for the production of 3-methyl butanal, an important component of the dry sausage aroma (228). Bacterial lipases show very low activity under conditions found in fermented sausages, but lipid oxidation reflected in hexanal concentration and associated with a rancid aroma is important in Mediterranean sausages (276).

The flavor in the case of mold ripened dry sausages, which are normally ripened for a long time, is due to the surface flora consisting of molds and yeasts (219). Molds have an important role on the flavor of sausages as a consequence of proteolysis and lipolysis. A common type of enzymatic attack on amino acids is the oxidative deamination to ammonia and the corresponding alpha keto acid (278). The liberation of ammonia raises the pH of the sausages, which coincides with the abundant appearance of molds. The sausages produced have a mild flavor, which allows meaty notes to dominate the overall flavor profile (227). In dry cured Iberian ham proteolysis by *P. chrysogenum* contributes to the ripening and flavor of the product (279).

In salchichon the acid aroma is correlated with the acetic acid content, whereas the bitter flavor is correlated with the concentration of free amino acids: aspartic acid, glutamic acid, serine, glycine, asparagine, and threonine (280). It seems possible that controlling the level of free amino acids is a prospect of controlling the level of some aroma compounds important to dry sausage flavor.

20.3.5.2 Microbial Safety

20.3.5.2.1 Inhibition of Bacteria The most important mechanisms to ensure microbial safety of fermented meats are the formation of lactic acid, acetic acid, and possibly bacteriocins. Other metabolites of lactic acid bacteria, such as diacetyl and hydrogen peroxide, interfere with the sensory properties. Although the main acid formed is lactic acid, the antimicrobial effect of acetic acid should not be neglected, because at the same concentration and pH, it is more effective than lactic acid. The sensitivity of the different bacteria to acids depends on the action of other factors such as a_w and nitrite concentration. As a result, even small differences in acid concentrations have a major effect on acid sensitive microorganisms (237).

Bacteriocinogenic starter cultures are used to improve the competitiveness of the starter strains and to prevent the growth of food pathogens (243). Bacteriocin producing cultures of *L. curvatus, L. sakei,* and *L. plantarum* may control the meat microflora and inhibit foodborne pathogens during the production of fermented meat products (281). The levels of *Listeria monocytogenes,* particularly, can be reduced by one or two log cycles

compared to nonbacteriocin producing cultures. The effect of bacteriocins on the safety of meat products is limited because of the resistance of Gram-negative bacteria to them, their inactivation in the meat, and the possibility of resistance development in the target organisms (237).

All genera of lactic acid bacteria found in fermented meats produce bacteriocins, which act against bacteria closely related to the producer organisms. Many of them also inhibit *Listeria* but only few are effective against *Bacillus, Clostridium,* and *Staphylococcus.* Bacteriocin resistant mutants are developed from sensitive bacteria. For instance, nisin and sakacin resistant mutants of *L. monocytogenes* have been reported, but nisin resistant variants of *L. monocytogenes* were sensitive to sakacin formed *in situ*; thus, combinations of bacteriocins may be more effective against *Listeria* than single bacteriocins (237). Gram-negative bacteria are sensitized to bacteriocins by treatment with chelating agents, and strains of lactic acid bacteria have been constructed that form and export colicin, but it is not known if such combinations are effective in meat systems (282).

The main factors affecting the effectiveness of bacteriocins in meat systems are the reduction of bacteriocin activity by the binding of bacteriocin molecules to food components, by the destabilizing action of proteases and other enzymes, and by an uneven distribution in the food matrix (283). The low carbohydrate content and low ripening temperature of fermented meat products may be responsible for a low bacteriocinogenic activity. Furthermore, *Listeria* inhibition is dependent on ecological factors prevailing in sausage fermentation such as pH and the concentration of sodium chloride, nitrite, and nitrate (284).

During Spanish style dry sausage fermentation, bacteriocin producing *Enterococcus* strains (CCM 4231, RZS C13) used as starter cultures strongly inhibited the growth of *Listeria* species (239). Enterocin P, produced by *E. faecium* P13, inhibited most of the tested spoilage and foodborne Gram-positive pathogenic bacteria, such as *L. monocytogenes, S. aureus, Clostridium perfringens,* and *Clostridium botulinum* (285). A different strain, *E. faecium* P21, produces two bacteriocins identical to enterocin A and enterocin B, which show a narrow antimicrobial activity against closely related lactic acid bacteria and strong antimicrobial activity against spoilage and foodborne Gram-positive bacteria, including *L. monocytogenes, S. aureus, C. perfringens,* and *C. botulinum* (286). A *Pediococcus acidilactici* strain isolated from commercial starter cultures used in the Spanish meat industry shows an inhibitory action against a wide range of Gram-positive bacteria including. *L. monocytogenes, E. faecalis, S. aureus,* and *C. perfringens* (287). Leucocin F10, a bacteriocin produced by a strain of *Leuconostoc carnosum* isolated from fermented sausages manufactured in Southern Italy, is inhibitory to *Listeria* species, *Leuconostoc* species, *E. faecalis,* and *L. sakei* (288). From Spanish fermented sausages the following bacteriocins were detected: plantaricin D, produced by *L. plantarum* CTC305 and active against different lactic acid bacteria and Gram-positive pathogens like *L. monocytogenes;* sakasin T, isolated from *L. sakei* CTC372 and active against *L. monocytogenes* and *S. aureus*; sakacin K, a heat stable proteinaceous antagonistic compound active against *L. monocytogenes* and isolated from *L. sakei* CTC494 (the first 30 amino acid residues from the N-terminus of sakacin K are identical to those of curvacin A in *L. curvatus* LTH1174 and sakacin A in *L. sakei* Lb706) (289). Sakacin B (with molecular weight estimated to 6.3 kDa) produced by *L. sakei* 251, a strain isolated from naturally fermented Greek dry sausage, is inhibitory toward various lactic acid bacteria of meat origin, but it is not effective against Gram-positive pathogenic bacteria. Thus, this bacteriocin is useful to control adventitious lactic flora in natural meat fermentations (290). The main bacteriocins produced by traditional fermented meat products of Mediterranean and Middle East region are presented in Table 20.3.

Bacteriocins produced *in situ* may contribute to the dominance of the producing strains over other lactic acid bacteria during fermentation as well as to the reduction of the levels of

Table 20.3
Bacteriocins produced by strains isolated from traditional fermented meat products of Mediterranean and Middle East region

Bacteriocin	Strain Isolated	Inhibitory Spectrum	Ref.
Enterocin P	*E. faecium* P13	*L. monocytogenes, S. aureus,*	(285, 286)
Enterocin A & Enterocin B	*E. faecium* P21	*C. perfringens* & *C. botulinum*	
Leucocin F10	*L. carnosum* F10	*Listeria* spp., *Leuconostoc* spp., *E. faecalis* & *L. sakei*	(288)
Plantaricin D	*L. plantarum CTC305*	*L. monocytogenes* & Lactic acid bacteria	(289)
Sakacin B	*L. sakei* 251	$Gram^+$ pathogens	(290)
Sakacin K	*L. sakei* CTC494	*L. monocytogenes*	(289)
Sakacin T	*L. sakei* CTC372	*L. monocytogenes* & *S. aureus*	(289)

the affected food pathogens. The use of *L. sake* is an adequate safety factor in chorizo, having a significant inhibitory effect on *Enterobacteriaceae* counts (256). Another strain of the same microorganism (*L. sakei* 121) proved to ensure safety in Soppressata Molisana (291).

Greek dry salami produced without starter cultures is free of *Salmonella* after formulation, while very low numbers of sulfite reducing clostridia and no coagulase positive staphylococci are present. *Listeria* species, including *L. monocytogenes,* occurring in raw meat are detected until the fourth day of fermentation, but disappear by the end of fermentation (261). Culture filtrates of *L. sake, L. curvatus* and *L. plantarum* strains isolated from Greek fermented sausage have antimicrobial activity against *L. monocytogenes* and *S. aureus* strains in well diffusion assays, whereas all isolated *S. xylosus* strains and a large majority of *S. carnosus* and *K. varians* strains exhibited antilisterial activity (260,263). Good hygienic conditions of the raw materials, a balanced amount of quickly and slowly fermentable carbohydrates, and a reasonably adjusted ripening program result in production of salamis of desired quality and safe. The addition of starter cultures is, however, of virtal importance in eliminating health risks (259,261). Strains selected as starter cultures can be followed during fermentation by rapid identification according to their enzymatic pattern (260,263).

In Turkish sucuk the probability of contamination with *L. monocytogenes* is deemed high (292); bacteriocinlike metabolites produced by lactic acid bacteria isolated from the product showed inhibitory activity against *L. monocytogenes* strains tested with agar spot tests and well diffusion assays (293). In laboratory scale the addition of 10^6–10^7 cfu/g of each one of *L. sake* ATCC 15521 and *P. acidilactici,* improved fermentation and controlled inoculated *Yersinia enterocolitica* O:3 (approximately 10^5 cfu/g), mainly due to lactic acid produced, whereas the inoculated foodborne pathogen is not eliminated in a natural fermentation (294). Starter cultures composed of *L. plantarum* with *S. carnosus* and *P. acidilactici* with *S. carnosus* improve the microbial safety and hygienic quality of sucuk (295,296).

In dry cured ham *Enterobacteriaceae* growing during the first nonrefrigerated steps of the curing process before the decrease of a_w can cause deep putrefaction of the product. Therefore, *Enterobacteriaceae* ought to be considered a microbial quality related hazard in the development of hazard analysis critical control point (HACCP) systems for dry cured hams (297). In general, spoiled hams have higher moisture content, and a lower content of sodium chloride, nitrates, and nitrites than the unspoiled product. Insufficient salt concentration during curing causes deep spoilage by *Serratia liquefaciens, Enterobacter*

cloacae and *Proteus vulgaris.* These strains can grow in 7% NaCl at 5 °C, but the reduction of temperature to 2°C reduces the NaCl tolerance significantly (298). The most frequently isolated species in the spoiled hams during the fast dry curing process is *Serratia liquefaciens*, whereas in the slow dry curing process it is *Leclercia adecarboxylata.* In addition, strains of *S. aureus* were isolated from spoiled product with both processes (299).

In traditional Middle East and Mediterranean dry cured meat products like basturma, modifications of the original process or formula, such as increase of the final moisture content or decrease of the level of garlic or salt, introduced major safety hazards which caused an outbreak of salmonellosis in California in 1982 (300). Contamination of the product during processing with *Salmonella* species or *S. aureus* results in survival of the contaminating pathogens in the product for an extended period of time, and the occurence of a foodborne outbreak depends on the extent of initial contamination (222). In an effort to improve the quality characteristics and safety of the product, inoculation by starter culture combinations of *L. sakei, L. pentosus, L. curvatus, S. carnosus, S. xylosus and K. varians* has been used (301–303). In this case the inoculated bacteria are not spread evenly in the meat tissue and multiply in small groups (301) showing that a selection of starter cultures and the inoculation techniques is needed, because a homogeneous distribution of added microorganisms is important for their effect (304).

20.3.5.2.2 Biogenic Amines In long ripened meat products significant amounts of biogenic amines may be formed by the action of microbial decarboxylases on free amino acids, resulting from the proteolytic process that normally takes place during the ripening of fermented sausages. The microorganisms responsible for the decarboxylation reactions may be introduced as starter cultures in sausages or may be part of the natural microflora. Thus, *Enterobacteriaceae* are involved in the production of putrescine, histamine, and cadaverine, and *Pseudomonas* in the production of putrescine (305). From the lactic acid bacteria, all strains of *Carnobacterium* found in meat products and some strains of *L. curvatus* and *L. plantarum,* used as starter cultures, produce tyramine (306). *Micrococcaceae* and enterococci have been also involved in the production of biogenic amines (307). Spontaneous nonstarter lactic acid bacteria and *Enterococci* are indicated as responsible for tyramine formation during ripening in Italian sausages (305). Furthermore, wide variations have been observed in the amine content of different batches of the same commercial brand of fermented products. The presence of biogenic amines in foods is the consequence of a complex equilibrium between the physicochemical characteristics of the product (pH, a_w, and nutrients), the technological conditions (temperature, starter mediated fermentation, and use of raw materials with good hygienic quality) and the enzymatic activities of the microorganisms present. Especially, the availability of free amino acids, and the presence of microorganisms that can decarboxylate the amino acids, as well as the incidence of favorable conditions for their growth, affect the formation of amines (308). In sausages, histamine is often detected at low level, but can be occasionally produced in high amounts (309). The main amine found in Mediterranean sausages is tyramine, which is formed by tyramine forming lactic acid bacteria by decarboxylation of tyrosine (228). The amines putrescine and cadaverine can also be used as indicators of the microbial quality and safety of fermented meat products (308). In Turkish style sausage (sucuk) high concentrations of histamine and tyramine were observed in some samples and the addition of a commercial starter culture and high concentrations of additives reduced their formation (296). In fermented sausage produced in Egypt using *L. plantarum* and *P. acidilactici* as starter cultures, however, tyramine development was continued during ageing, although potassium sorbate was added at up to 0.06% (310). Two *Lactobacillus* strains, *L. curvatus* and *L. homohiochii,* isolated from a Portuguese traditional dry fermented sausage, showed increased proteolytic activity and were able to decarboxylate tyrosine to tyramine and, to

a lesser extent, ornithine into putrescine (308). On the other hand, the use of *S. xylosus* S81, which can be isolated from fermented sausage in Southern Italy, as a starter culture influences the amount of histamine and other biogenic amines during ripening by influencing the level of the microbial amino oxidases and the amino acid decarboxylases (311). Starters (composed of *Micrococcus carnosus,* and *L. plantarum* or *P. pentosaceus*) seem to decrease biogenic amine formation but do not prevent it. The high background flora naturally present on the raw meat and pork lard seems to have a strong influence on biogenic amine formation during ripening (312). The use of a mixed starter culture composed of a tyramine producing *L. curvatus* and a proteolytic *S. xylosus* yielded lower amounts of tyramine than those produced by the wild microflora in the control batch, whereas the accumulation of the diamines putrescine and cadaverine in sausages was efficiently reduced (313).

Formation of carcinogenic nitrosamines constitutes an additional toxicological risk related to biogenic amines, especially in meat products that contain nitrite and nitrate as curing salts. It is important for the meat industry to produce fermented products with a high degree of safety with respect to biogenic amines, because of their possible involvement in various diseases such as migraines, headaches, gastric and intestinal ulcers, and allergic responses (314). Therefore, before being selected as starter cultures, strains should be screened for their proteolytic and decarboxylase activities. Biogenic amines in foods are of health concern, especially for people with low monoamine oxidase or diamine oxidase activities, due to medical treatment (311). Thus, the use of starter cultures exhibiting amine oxidase activity is of importance to prevent or reduce the accumulation of biogenic amines (311,315). In fact, biogenic amines are physiologically inactivated by amine oxidases, which are found in bacteria, fungi, plant, and animal cells and are able to catalyze the oxidative deamination of amines producing aldehydes, hydrogen peroxide, and ammonia (316).

20.3.5.3 Probiotic Properties

There is a world wide trend toward new probiotic functional foods, and meats may be another application area. The development of new probiotic functional foods, such as fermented meat products, presupposes the application of probiotic lactic acid bacteria with the following characteristics: resistance to sodium chloride and sodium nitrite; growth and activity during fermentation and ripening; resistance to acid environment; resistance to lysozyme; resistance to bile salts; and ability to colonize the human intestinal tract by means of some mechanisms for adhering or binding to the intestinal cells (317,318). There exists a need to select strains of lactic acid bacteria originating from the indigenous microflora of traditional products on the basis of these properties in order to obtain strains which are well adapted to the microenvironment which could dominate the microflora of the fermented meat product. *Lactobacillus curvatus* strains originating from commercial meat starter cultures have the capacity to survive 0.3% bile salts at pH 5 (319). Bile salts affect the cell membranes of the microorganisms, as they are composed of lipids and fatty acids. Some lactobacilli are able to hydrolyze bile salts with a bile salt hydrolase enzyme, weakening their detergent effect (319). The resistance to bile salts varies considerably between the *Lactobacillus* strains, and the mechanism is still unknown (319). A large majority of *L. sakei, L. curvatus* and *L. plantarum* strains isolated from Greek-style fermented sausage tolerate 0.3% bile salts (260). The probiotic properties of desirable bacteria are dependent on their ability to remain viable and to colonize the surface of human intestinal cells; a viable cell population of 10^7–10^9 cells per day is necessary in order for any beneficial effects to develop in humans (317). The application of probiotic cultures in fermented meats in conjunction with low fat and low salt content might have health promoting effects.

3.21

Anaerobic Processes for the Treatment of Food Processing Wastes

Roger A. Korus

CONTENTS

21.1 INTRODUCTION

The effective treatment of wastewaters is crucial to the operation of food processing plants. Whereas aerobic processes effectively treat low strength wastes, anaerobic processes more effectively treat high strength wastes. These high strength wastes have chemical oxygen demand (COD) levels greater than 2,000 mg/L or biological oxygen demand (BOD) levels greater than 1,000 mg/L. However, these thresholds can be lowered by biomass retention and proper nutrient supplementation, and if the wastewater is warm and contains adequate alkalinity. Anaerobic processes treat high strength wastes without the high energy requirements

and biomass production of aerobic processes. In addition methane rich biogas is produced as a renewable energy source. Up to 0.395 liters of methane (measured at 35°C and 1 atm) can be produced per gram of COD removed.

Anaerobic treatment is often a pretreatment method where effluent BOD is typically 100–500 mg/L and may be followed by aerobic treatment to achieve treatment objectives. However, there are examples of anaerobic treatment to less than 20 mg/l BOD (1). Anaerobic processes are typically conducted at approximately 35°C in the pH range of 6.8–7.4 and convert soluble organic carbon into carbon dioxide and methane. Toxic compounds can adversely affect anaerobic treatment, but toxins are not usually a major problem in food processing wastes. In order to assess the anaerobic treatability of a wastewater, a laboratory or pilot plant study is generally advisable. Especially with wastewaters that contain compounds of low solubility such as fats, oils, or greases (FOG) or complex carbohydrates, a treatability study is essential. Also, there is a wide range of anaerobic technologies to choose from. Fortunately, there are hundreds of anaerobic treatment facilities in operation and even more published research studies that guide in the selection of treatment options and feasibility determinations.

Over the past thirty years, the popularity of anaerobic wastewater treatment has greatly increased. In large part this has resulted from the development of high rate systems that overcome the slow growth rate of anaerobic microorganisms by retaining these organisms within the anaerobic reactor. With an increase in anaerobic biomass, much higher rates of anaerobic digestion can be obtained. Also, these systems are less susceptible to operational upsets, and start up can be accomplished within a few weeks using highly active anaerobic sludge from an existing facility.

21.2 TREATABILITY ASSESSMENTS

Initial laboratory tests can be used to determine the appropriateness of anaerobic treatment for a particular wastewater. These tests can determine alkalinity, rate of COD/BOD removal, waste toxicity, and supplemental nutrient requirements. Additional pilot plant tests can determine operational parameters. It is important in these tests to assess the need for acclimation of the anaerobic biomass to unfamiliar substrates and toxins. This acclimation period is not required if anaerobic biomass is obtained from a process treating a similar wastewater. If not, an acclimation period of 30–60 days may be required before treatability conclusions can be made.

The characterization of waste streams should not be neglected. Nearly always, some wastewater streams in a food processing plant will be more amenable to anaerobic treatment. The BOD and COD levels, pH, temperatures, and flow rates of the principal streams should be determined. Often the high level waste streams can be segregated, and treatment of these streams can achieve most of the treatment objectives. Once the wastewater streams to be treated are identified, representative samples can be taken for laboratory anaerobic tests. It is crucial that these samples be representative or time averaged samples that truly reflect the wastewaters to be treated.

Laboratory tests are conducted in well mixed batch reactors containing 50 mL to several liters of wastewater with a 10–20% inoculum. This inoculum can be obtained from an operating anaerobic reactor or a municipal anaerobic sludge digestor. The key measurement is the methane production rate. In this measurement it is important to measure only methane and not simply biogas production. The carbon dioxide can be removed by bubbling through a NaOH solution or can be determined by gas chromatography. This test should be run until the cessation of gas production, typically requiring 30–90 days with

longer times required for acclimation to toxic or wastewaters of composition much different than the inoculum.

In laboratory tests temperature is typically held at 32–35°C. Alkalinity and pH are also measured during the test. The pH should not drop below 6, and if the alkalinity drops below 500 mg/L the dissolved CO_2 will cause the pH to drop below 6. Bicarbonate (HCO_3^-) will neutralize acid generated during anaerobic treatment by the following reaction:

$$HCO_3^- + H + \rightarrow H_2O + CO_2$$

As bicarbonate alkalinity is consumed by this reaction, there is reduced buffering. Supplemental alkalinity must be supplied often as Na_2CO_3 whenever tests indicate that alkalinity might be less than 2500–3000 mg/L during anaerobic treatment. Several titration methods are available for the determination of alkalinity and volatile acid concentrations (2,3). An alternative spectrophotometric method has recently been described (4). Alkalinity supplementation can be a major cost and can exceed in cost the value of methane produced.

Laboratory tests can determine whether supplemental nutrients can improve anaerobic treatment. Nitrogen and phosphorus are the major elements that might be limiting. For every 1000 parts BOD, 6–10 parts nitrogen and 1–2 parts phosphorus are required, much less than for aerobic treatment where the biomass production is much greater. Therefore, in anaerobic treatment nitrogen and phosphorus are seldom limiting. More likely it is trace metals that can be limiting. Speece recommends that a cocktail of 1 mg/L $FeCl_2$, 0.1 mg/L $CoCl_2$, and 0.1 mg/L $NiCl_2$ be added if high volatile acids persist in the effluent (1). There are many examples of iron, cobalt, and nickel supplementation increasing the rate and extent of anaerobic treatment (1). In addition, zinc, copper, manganese, molybdenum, selenium, tungsten, and boron have been reported to stimulate anaerobic activity (1). These trace elements can be quickly tested in laboratory assays where equal aliquots of biomass are placed in flasks and then supplemented with trace metals. Gas production can be used to determine if metal supplementation enhances the rate of gas production relative to the control. If methane yields are much less than the theoretical 0.395 liters per gram of COD, and if volatile fatty acid concentrations remain high after trace element additions, then the reasons for low methanogen activity should be investigated. Possible reasons are toxicity of the wastewater, or the washout, or low inoculum activity of the methanogens.

21.3 MONITORING AND PROCESS CONTROL

Monitoring and control are crucial to the successful operation of anaerobic process. The principal operational variables that must be controlled include flow rate of wastewater, pH and alkalinity, temperature, and foaming. Monitoring is essential to provide reliable indicators of operational problems and as the basis for control strategies that will maintain stable and efficient operation.

Volumetric loading rates of 1–25 kg BOD/m^3-day can be obtained in anaerobic digesters, but the higher loading rates require highly active, acclimated biomass concentrations of 10–50 g/L. These high biomass levels require either a high inoculum of acclimated biomass, or a long start up time, with proportionally low feed rates until the active biomass reaches a high concentration. These high biomass levels can only be reached in digesters that retain or recycle biomass. During startup and steady state operation, gas production, pH, alkalinity, volatile acid concentration, COD/BOD, and loading rate should be measured. These diagnostic tools will determine whether the digester is overloaded or if toxicity, nutrient limitations, or other reactor conditions are limiting performance.

The best monitoring gives the earliest indication of operational problems. The most common and serious problems usually result in a drop in pH preceded by a reduction in alkalinity. This can occur during startup if the digester is overloaded and during continuous operation if the methanogen activity is inadequate. Alkalinity is generally expressed as $CaCO_3$ equivalents. Given that the molecular weight of $CaCO_3$ is 100, 200 mM/L would correspond to an alkalinity of 2000 mg/L. Alkalinity measurements typically measure both partial alkalinity, a measure of bicarbonate concentration, and volatile fatty acid concentration. Partial alkalinity is a measure of buffering capacity, or the ability to maintain pH, as the concentrations of the volatile fatty acids increases or influent pH changes. Partial alkalinity or bicarbonate concentration has been found to be the most sensitive indicator for digestor pH upsets (2).

Poor digester performance is often attributed to a low concentration of methanogens. Of the two main groups of bacteria involved, acidogens and methanogens, the methanogens are slower growing and more susceptible to toxins. The most common biomass measurement, volatile suspended solids (VSS), gives no indication of the acidogen or methanogen populations. A characteristic of methanogens is their UV induced autofluorescence that permits counting by autofluorescence microscopy. A high correlation was evident between methane production and methanogenic population (5).

21.4 PROCESS TECHNOLOGIES

Many anaerobic processes and process configurations have been used for wastewater treatment. Several comparative studies have been conducted on high strength food processing wastewater. This review will focus on the anaerobic technologies most commonly used commercially, the Upflow Anaerobic Sludge Blanket (UASB), the anaerobic contact process, and the anaerobic filter, and will briefly discuss new hybrid and low rate technologies. There are approximately 800 UASB systems installed worldwide, nearly half in the food processing industries (6). Other technologies, which in total have fewer commercial installations than UASB installations, will be discussed in less detail.

21.4.1 Upflow Anaerobic Sludge Blanket (UASB) Process

The two leading companies in terms of the number of full scale anaerobic systems installed, are Paques and the Biothane Corporation, both with over 300 anaerobic installations. Paques and USFilter signed an exclusive license agreement in 2003 under which USFilter will design and supply Paques UASB anaerobic technologies for all industrial applications in the United States and Canada. Aerobic technologies often complement anaerobic treatment enabling treated water to be discharged directly into the environment.

The concept of UASB reactor design is simple (Figure 21.1). There are no moving parts within the UASB reactor. Pretreatment steps to remove suspended solids, fats, oils, and greases are required. Also, flow equalization is necessary for biomass retention. With such pretreatment in place, the UASB can convert achieve 70–95% BOD conversions. Wastewater is distributed into the tank through spaced inlets. The wastewater passes upward through a sludge bed composed of 0.5–2 mm microbial pellets. A high rate of anaerobic treatment results from retention of the anaerobic sludge bed within the reactor. The upward motion of gas bubbles causes hydraulic turbulence which provides reactor mixing. Baffles deflect the gas bubbles into a gas cap with a solid settling region above the gas outlet. The gas–liquid–solid three phase separator at the top of the UASB reactor is critical to effective operation. The UASB concept was first described in 1980 (7). The first pilot plant was installed at a beet sugar refinery in The Netherlands. Soon after, several full

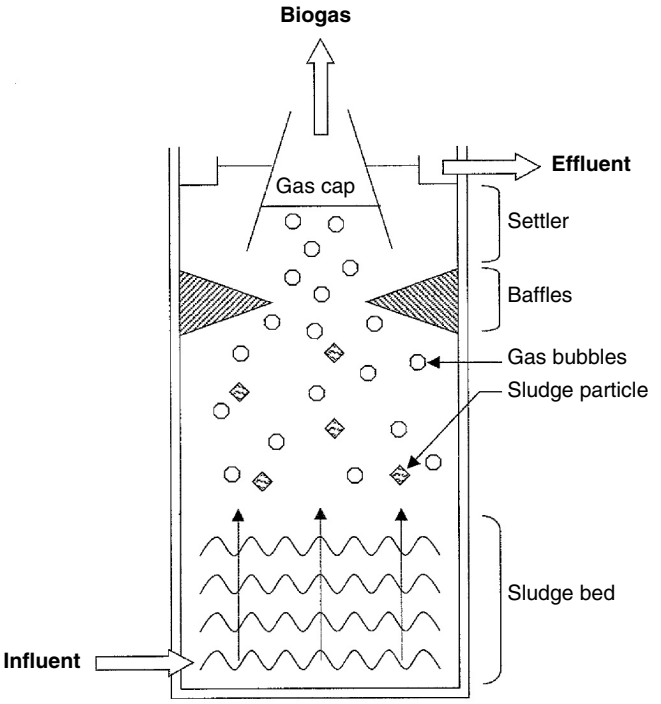

Figure 21.1 The upflow anaerobic sludge blanket (UASB) reactor

scale plants were installed at sugar refineries, recycle paper plants, potato starch plants, and other food industries.

UASB systems have a high organic loading capacity, 10–15 kg COD/m^3-day. A variation on the UASB concept, the expanded granular sludge bed (EGSB), uses a higher upward flow velocity that partially expands the granular sludge bed (8). This improves wastewater–sludge contact and allows higher organic loading in the range 15–35 kg COD/m^3-day. However, taller reactors or effluent recyclers must be used to achieve adequate wastewater treatment. The EGSB design is most appropriate for low strength wastewaters (less than 2000 mg COD/L) or for wastewaters that contain inert or poorly biodegradable suspended particles that should not be allowed to accumulate in the sludge bed.

The major consideration in UASB or EGSB operation is the development and maintenance of sludge granules. With the large number of existing UASB installations, large quantities of highly active anaerobic sludge are available, and start up of new installations can be made within a few weeks, sometimes within a few days. The maintenance and enhancement of biomass granulation is common to other high rate anaerobic systems where the retention of biomass within the reactor is crucial to efficient operation. The relatively large particle size granules have a higher settling velocity and higher specific activity than flocculent biomass.

Various forms of microbial conglomerates have been used in the form of flocs, pellets, and granules. Flocs have a loose structure and form a homogeneous layer after settling. Pellets and granules have a denser structure and a heterogeneous, well defined appearance after settling. UASB granules typically have a spherical form with diameters from 0.14–5 mm (9). Brewery-grown granules were observed to have a narrow size distribution of 1–2 mm, with a few 2–8 mm (10). However, only the outer 200–300 μm may be active because

of diffusional limitations. Granules cultivated on acidified substrates, such as acetate, are generally smaller than granules grown on acidogenic substrates, such as glucose. Reported settling rates for UASB granules are in the range of 18–100 m/h (9). Densities of granules are 1.03–1.08 g/mL, but values up to 1.4 g/mL have been reported. The internal composition and organization of the granules varies with wastewater composition. Extracellular protein and polysaccharides in the granules are important for the structure and maintenance of the granules. This extracellular polymer content varies between 0.6–20% (9).

The UASB reactor operation is characterized by three zones (1). Granules grow mostly in the lower zone where volatile acid and hydrogen concentrations are high. Total COD is reduced to less than half its initial value, and total alkalinity decreases to a minimum as pH declines. In the middle zone total alkalinity and pH increase to stable values as the volatile acids are converted to methane and carbon dioxide. The upper zone is a settling zone where concentrations of soluble components are constant. The overall effect is an alkalinity requirement of 1.2–1.6 g alkalinity as $CaCO_3$/g COD for carbohydrate wastewaters. The function of alkalinity is primarily to control the pH decline in the lower zone.

Well developed, active granules with high physical strength and settling velocity are required for optimal operation of UASB reactors. The major advantages of granular sludge in high rate anaerobic reactors (11) are:

1. The superior settling characteristics of granular sludge. Settling velocities are commonly about 60 m/h in UASB reactors where upflow velocities are usually below 2 m/h. Solid retention times of over 200 days can be achieved with hydraulic retention times as low as 6 hours.
2. The high methanogenic activities of granular sludge. High volumetric rates in excess of 50 kg COD/m^3-day can be achieved with specific methanogenic activities of more than 2 kg COD/kg VSS.

Recent studies of UASB granules from fruit and vegetable cannery, two brewery, and slaughterhouse effluents illustrate the variations of granule structure on wastewater composition (10,12). Previous studies indicated that inferior granules were produced in UASB reactors treating protein-based, slaughterhouse wastewater. These recent studies verified that granule properties, including composition, size distribution, density, settling velocity, shear strength, and extra cellular polymeric substances (EPS), depend more on wastewater type than on reactor design or operating conditions such as pre acidification level. While the cannery and brewery-fed reactors had excellent shear strength, settling distribution, and density, the slaughterhouse granules had poor strength and settling velocity. Protein (slaughterhouse) wastewater was modeled using a biofilm model, and granules were predicted to have slow growth rates, low microbial density, and no trophic layers (12). The primary cause of this structure was the particulate nature of the wastewater rather than the presence of proteins. Some advantages of a well formed granular sludge are syntrophic associations with optimum distances between microbial partners, capability to withstand high gas and liquid shear rates, and resilience to shocks and toxins. As an example, an internal circulation (IC) reactor generates high levels of shear and requires rapid settling velocities but allows rapid reaction. Therefore, it would be ideal for treatment of cannery wastewater but would probably operate poorly when treating the wastewater from a complex protein source (10).

In efforts to improve granule formation, structure and activity, trace metal ion supplementation, especially iron, nickel, cobalt, and manganese, has been used to enhance UASB performance. Trace metal addition has promoted an increase in UASB specific

activity to 2.6 g COD/g VSS-day (1). In a comparison study of pea and French fries wastewater, Fe, Co, and Ni supplementation increased the volatile suspended solids (VSS) form 3kg/m^3 to 100 kg/m^3 and achieved COD reduction in excess of 95% at an organic loading rate of 10 kg/m^3-day.

Thickening agents have been used to enhance granule formation and to stabilize larger granules. This is especially important during the start up period of UASB reactors. Chitosan was shown to enhance the growth rate of granules from 19 μm/day in a control reactor to 56 μm/day with an ethanol–sucrose feed (13). Chitosan is a cationic natural polysaccharide polymer that was injected weekly at 25 mg/g suspended solids (SS) during a five week reactor operation. Synthetic cationic polymers have shown similar effects.

UASB reactors should be operated much differently during the start up period as opposed to the stable steady-state operation. Start up time can vary from less than a month to about a year. Reduced organic loading and monitoring of the sludge biomass are essential during start up. Sludge loading rates (SLR = g COD/g VSS-day) during start up have been proposed for several classes of wastewaters (14). For example, with a sugar molasses wastewater the proposed SLR during start up was 0.065–0.14 g COD/g VSS-day, while during stable operation SLR could be in the range of 0.30–0.78. At higher loading rates granules would not be retained in the UASB reactor. Also, higher levels of alkalinity and nutrients can improve start up performance. For example, by maintaining alkalinity:COD, N:COD, and P:COD at 1.06, 0.018 and 0.0028 during startup, granulation was observed after thirty days, and an average of 3.1 mm granules were obtained after ninety days of UASB operation (15). After this size granules were formed, addition of nutrients could be suspended and the alkalinity:COD ratio could be reduced to 0.4 without degrading process performance. Additionally, a high concentration of methanogens is advantageous. The inner core of granules typically consists of rod-shaped bacteria resembling *Methanosaeta* spp. The middle layer consists has a high content of syntrophic bacteria capable of producing and utilizing hydrogen, and the outer layer contains mostly acidogenic bacteria but also *Methanosarcina* spp. Granules were observed to grow at rates of 31, 21, 18, and 7µm/day in UASB reactors inoculated with syntrophic methanogenic consortia, *Methanosaeta* nuclei, *Methanosarcina* nuclei, and acidogenic floc, respectively (16).

Multivalent cations have been shown to enhance sludge granulation and reduce the time required for UASB start up (17). An optimum calcium concentration of 150–300 mg/L enhances biomass accumulation and granulation. The addition of Al^{3+} at a concentration of 300 mg/L reduced sludge granulation time in UASB reactors by approximately one month and produced larger granules compared to a control reactor.

Many of the operational considerations for UASB systems are valid for other high rate anaerobic processes. The formation of active granules with a high settling velocity is crucial to the retention of biomass and the operation with high VSS and organic loading rate.

21.4.2 Internal Circulation Reactor

The internal circulation (IC) process is based on the UASB concept of biomass granulation and the use of three phase separators. Its unique feature is the separation of produced biogas in two stages within a reactor with a large height–diameter ratio (Figure 21.2). The ratio of height–diameter is typically 4–8 with the reactor height up to 16–25m. The gas collected in the first stage is used to generate a gas lift that forces water up through a riser into the gas–liquid separator at the top of the reactor. Through this separator, the biogas leaves the reactor, while the water–sludge mixture returns through the downcomer back to the bottom of the system. The effluent from the first, lower reactor compartment is given additional treatment in the upper compartment. The upper level three phase separator collects the biogas formed in the upper compartment and the final effluent leaves the reactor

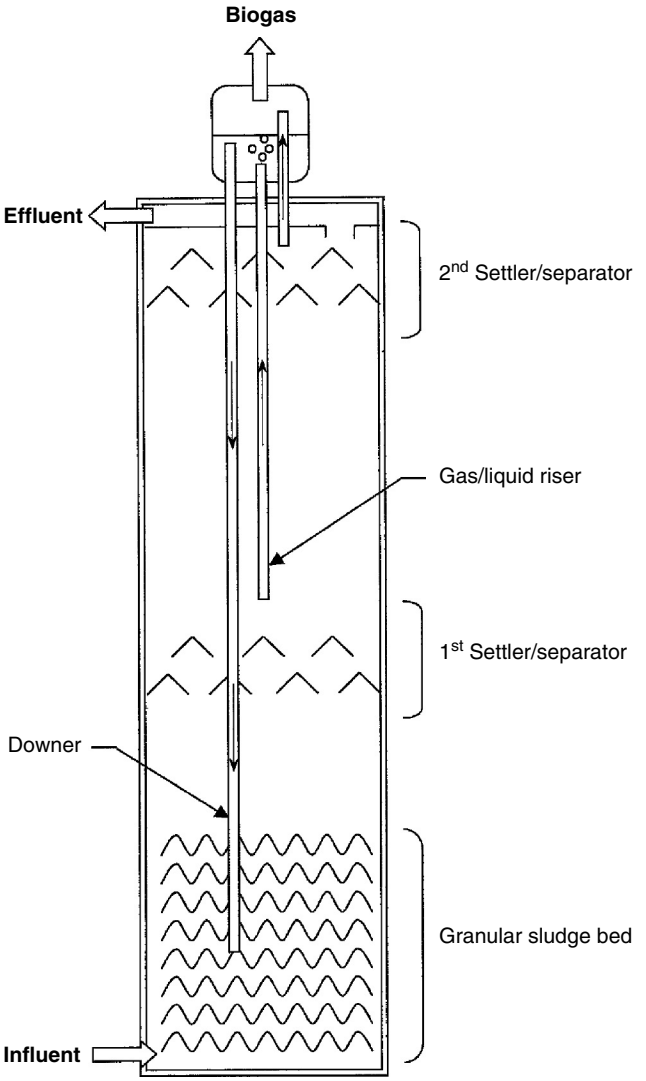

Figure 21.2 The internal circulation (IC) reactor

at the top. In the upper polishing section, there is a relatively long hydraulic retention time in a plug flow regime. This low superficial velocity and lower biomass concentration avoids solids loss especially during high peak loads.

The two stage design of the IC reactor allows up to three times higher volumetric loading rates and less than half the hydraulic retention times when compared to conventional UASB reactors (18). Hence the IC process is termed an ultra high rate process. A commercial IC process is offered by Paques as the BioPAQ IC system. This IC process is advertised to treat BOD in excess of 1000 mg/L with organic loading rates (OLR) in the range 20–35 kgCOD/m^3-day. Comparison tests showed that sludge granules from IC reactors have about two times higher methanogenic activities than UASB granules (18). Another advantage of the IC system is its very small footprint. The slim BioPAW IC systems are especially popular in densely populated areas such as South East Asia. More than 70 IC plants are being operated worldwide. Brewery and other food processing industries are the major users.

21.4.3 Anaerobic Contact and Anaerobic Filter Processes

After UASB systems, the anaerobic contact process and the anaerobic filter are the next most common anaerobic treatment systems with over 100 installations each (6). Historically, the first high rate anaerobic process, the anaerobic contact process, was developed in the 1950s. The anaerobic contact process consists of a completely well mixed digester and an external clarifier to separate and return the active biomass (Figure 21.3). The clarifier is required because of poor biomass retention within the digester. This problem is most acute during system start up. Mixing in the digester is achieved by mechanical stirrers or through the production and injection of biogas. The basis of this process is the maintenance of high sludge content in the digester for high rate organic removal and stable operation. The COD removal efficiency ranges from 65–98% depending on the type of wastewater. For efficient process control sludge loading in the digester and in the clarifier must not exceed capacity.

Anaerobic filters are usually operated in the upflow mode to minimize plugging (Figure 21.4). A major problem is clogging of the packing material. As with all high rate anaerobic processes, the limiting factor for efficient operation is the amount of active biomass that can be retained under high loading conditions. In anaerobic filters the space occupied by the packing material diminishes the overall sludge retention, but the high surface area provided by the packing encourages biofilm growth and biomass retention.

21.4.4 Hybrid Anaerobic Processes

There are several hybrid anaerobic processes that combine aspects of UASB, anaerobic filter, and other filtration processes. An example is the NewBio reactor that utilizes down flow with an intermittently backwashed sand filter to retain biomass and solids within the reactor (Figure 21.5). A major advantage of this hybrid technology is the capability of treating wastewaters containing high levels of solids, fats, oils, and greases. These wastewater components are difficult to treat with upflow processes as these components either wash out of the reactor or collect at the surface. The sand filter allows biomass and other water insoluble materials to be retained within the reactor. Clogging of the sand filter is prevented by periodically backwashing the filter bed to restore flow through the sand filter. The key to backwashing is a mixing blade that slowly rotates through the sand bed when pressure drop through the sand bed becomes excessive. Water is injected through nozzles in the front of the mixing blade to fluidize sand immediately in front of the blade. Water

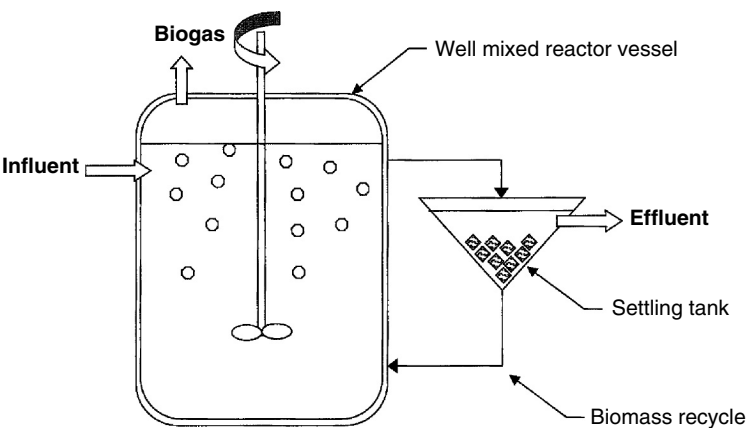

Figure 21.3 The anaerobic contact process

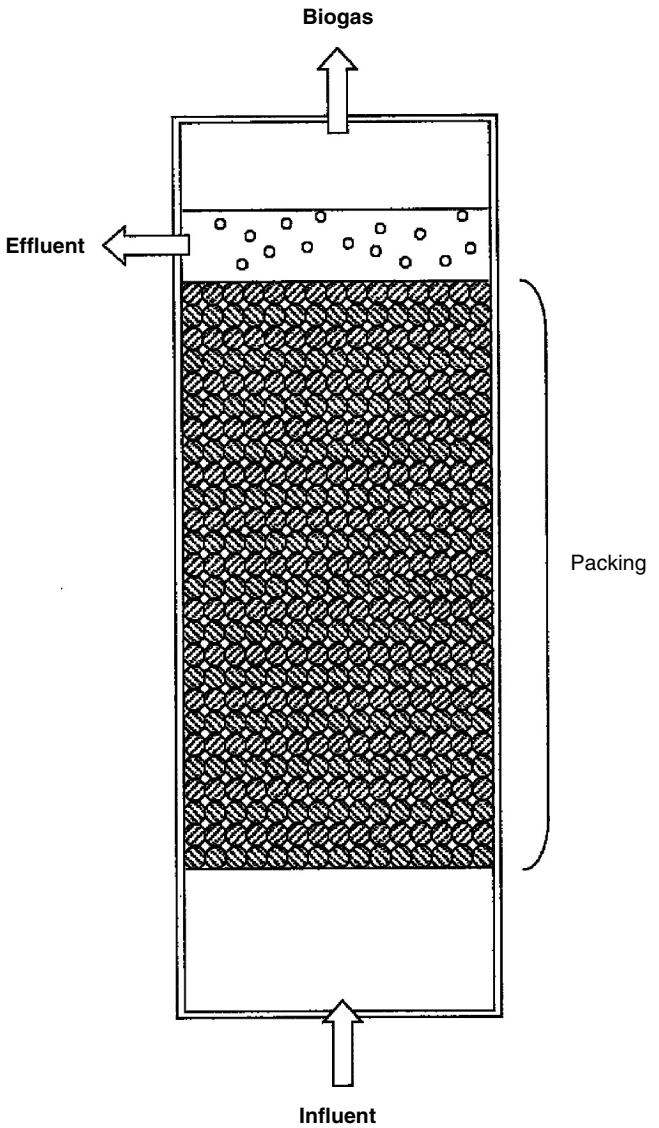

Figure 21.4 The anaerobic filter

pumped through nozzles in the rear of the blade provides a slow rotation of the mixing blade through the sand bed.

A series of pilot scale tests of the NewBio hybrid anaerobic process have been conducted with wastewater generated at two salad dressing production facilities (19). Operating at a hydraulic retention time of 12 days the system provided 98–99% BOD and total suspended solids (TSS) removals. Similar results were obtained in a full scale system shortly after startup at one of the salad dressing facilities. In addition, the computer controlled operation of these systems allows remote data acquisition and control.

In cases where granules cannot be formed from the wastewater treated and a fully packed anaerobic filter is too costly, an upflow hybrid reactor may be considered. This reactor contains an open section at the bottom and a packed section above. This packed

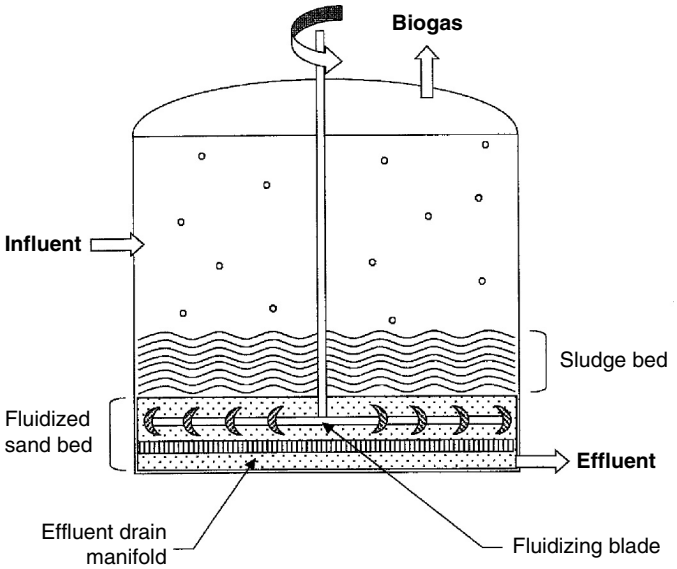

Figure 21.5 The NewBio hybrid anaerobic reactor

section improves the capture of the poor quality flocs escaping from the lower section. A column hybrid reactor with the bottom two thirds occupied by a sludge blanket and the upper one third by submerged clay rings was evaluated using slaughterhouse wastewater (20). COD removal was over 96% with loading rates up to 25 kg COD/m^3-day. The filter element of the reactor was highly efficient in retaining biomass; leading to a biomass accumulation yield coefficient of 0.029 g VSS/g COD higher than reported previously for either UASB or anaerobic filters operating independently. An example of a commercial system is the ADI-HYBRID reactor. Its major stated advantage is its stability and resilience against shock loadings. This system does not need a granular sludge because the overlying media intercepts solids, promotes flocculation, and returns solids to the sludge bed below. Loading rates of 10–20 kg COD/m^3-day are claimed.

21.4.5 Low Rate Process

An example of a low rate hybrid anaerobic process is the ADI bulk volume fermenter (BVF) process (Figure 21.6). This system combines features of the anaerobic contact process with intermittent mixing and sludge recycle. The reactor has two zones with a reaction zone at the inlet end and a clarification zone at the outlet end. The reactor can be an aboveground tank or a lined earthen basin with a floating insulated membrane cover for gas recovery and temperature and odor control (21). ADI-BVF systems have been installed at dairies, breweries, potato processing plants, corn processors, and meat and seafood processors. Over 80 BVF reactor installations worldwide are treating high strength organic wastewaters (22). These systems have the ability to digest high influent concentrations of fat, oil, and grease (FOG) and suspended solids (SS). An example is a 1.1 million gallon steel tank with a floating membrane, designed to treat 126,000 gal/day ice cream plant wastewaters, with 4,400 mg COD/L. COD and BOD are reduced by 85% and the effluent is discharged to the city sewer system.

The roof of the BVF reactor is typically a floating, insulated geomembrane cover that operates under a slight vacuum to collect and prevent escape of biogas into the environment (22). This low rate reactor has a relatively long retention time, typically seven

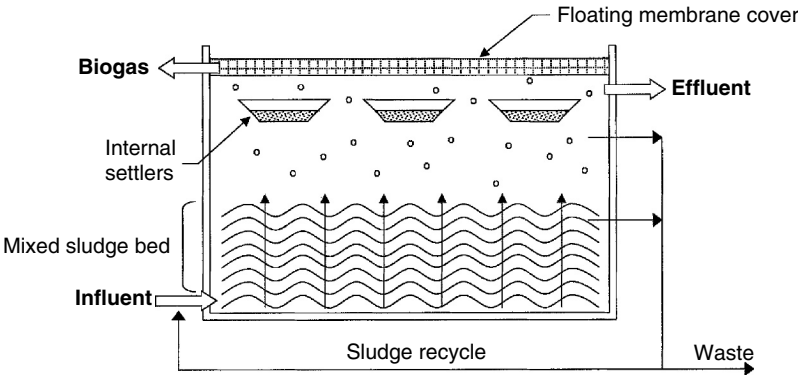

Figure 21.6 The ADI low rate bulk volume fermenter (BVF) process

days or more. The relatively large reactor size can serve to equalize flow from downstream processes as the floating membrane cover allows for expansion of the liquid within the reactor. When treating slow-degrading FOG or suspended solids, a scum layer can form at the liquid surface below the floating cover where it can gradually degrade without adversely affecting reactor operation. With the low upflow velocities and gas production rates, a low rate process can better retain sludge solids and maintain low effluent suspended solids concentrations. Internal settlers mounted in the upper portion of the BVF reactors enhance the liquid–solid separation.

21.4.6 Comparative Studies

Comparative studies illustrate the difficulty of ranking different high rate system performance. Performance is dependent on many factors such as properties of the inoculum, wastewater characteristics, and detailed design variables for each system. In a comparative study of an anaerobic filter, contact process, UASB system, and fluidized bed pilot plants each operating on ice cream wastewater, the upflow anaerobic filter gave the best results, and a full scale anaerobic filter was subsequently installed (23). However, poor biomass retention was observed in all reactors, possibly due to the high fat content of the wastewater. The UASB reactor gave the poorest performance because granulation of the biomass was not achieved. Several attempts at seeding the UASB with sewage sludge and sludge from an anaerobic digester treating creamery effluent were unsuccessful.

Laboratory scale anaerobic filter and fluidized bed with porous packing were compared for treating distillery wastewater (24). The highest organic loading rate, 32 kg COD/m^3-day, and a 96% COD removal at 5.88 kg COD/m^3-day was possible with the fluidized bed using SIRAN packing, an open pore sintered glass packing.

There are few comparative studies, and most food processors must make a comparison by visiting wastewater treatment facilities of different vendors and, if possible, conducting pilot plant studies with their wastewater. An example is Roger Sugar Ltd., which has been investigating options for treating sugarbeet-processing wastewater (25). An anaerobic–aerobic process was required to remove in excess of 99% of incoming BOD and to nitrify–denitrify the wastewater. At sugarbeet facilities the dominant anaerobic technologies are UASB and anaerobic contact systems. In addition, one German anaerobic fluidized bed process was reviewed. All processes operated with good stability. The anaerobic contact process found favor in the treatment of sugarbeet wastewaters where calcium concentrations can be greater than 600 mg/L, and calcium carbonate fouling is of less concern than with anaerobic fluidized bed or UASB processes. All exhibit good

organic loading capacities, from 3–10 for anaerobic contact, 15 for UASB, and 25 kg/m^3-day for anaerobic fluidized bed systems. A major disadvantage of the fluidized bed is the need to discharge expensive carrier material. Differences among installed UASB systems were noted including shape, size, and concrete vs. steel materials, designs for distributing influent and recirculated flow, and separator designs at the top of the reactors. Generally phosphoric acid was fed to provide nutrient balance, antifoam, antiscalants, and weak acids, or chlorine to control foaming, calcium carbonate precipitation and to maintain clean heat exchange surfaces. A UASB system was selected after reviewing bids with performance specifications, performance guarantees, and material standards provided in the specification package.

21.5 APPLICATIONS

Food processing industries are usually situated in rural areas and provide a significant enhancement to the economies of many rural areas. These dairies, breweries, potato processors, corn processors, sugar factories, beverage industries, and many others are increasing limited by waste disposal requirements. Often these rural industries are forced to pay high disposal fees, and often their wastewater treatment requirements overwhelm the small local wastewater treatment facilities.

The anaerobic treatment of food processing wastes developed rapidly in European countries with a rapid growth in commercial installations during the late 1970s and 1980s, and more recently has developed in the United States. By 1990 there were over 600 anaerobic plants in Europe, most situated in the northern European countries where waste disposal costs were highest (26). By 1996, 106 anaerobic treatment plants had been installed at food processing plants in Germany (27). More than 850 agricultural biogas plants were reported in Germany in 2000 with volumes between 100 and 4,000 m^3, and 150 plants were planned for 2001 (28). The German government supported these plants by refunds based on electrical capacities. Government goals are to reduce the disposal of organic wastes, promote the recycling and utilization of wastes as a renewable energy source, and to decrease CO_2 emissions. The treatment of fat containing wastes from slaughterhouses or food industries has the highest biogas potential with gas yields up to 800 m^3 per ton of waste (28).

Anaerobic treatment produces 12×10^6 BTU as CH_4 per 1,000 kg of COD converted to CH_4 (1). Approximately 10,000 BTU are consumed in the generation of 1 kWhr of electricity. However, the biogas produced is 60–65% methane, with the remainder mostly CO_2. Methane, at standard temperature and pressure (0°C and 1 atm), has a heating value of 35,800 kJ/m^3 (960 Btu/ft^3). Natural gas has a heat content of 1,000 Btu/ft^3 because of small amounts of higher molecular weight hydrocarbons. Biogas will have proportionally less energy content than methane depending on the methane fraction.

Biogas from municipal anaerobic sludge digesters is routinely used for space heating and heating the digester. In larger plants, digester gas may be used as boiler fuel or for internal combustion engines, which can be used for generating electricity of operating pumps or blowers. A significant portion of the energy necessary to operate a wastewater treatment plant can be derived from the methane produced by anaerobic digestion. However, the conversion process requires expensive equipment and costly operation and maintenance. Most plants simply flare the excess methane.

The application of anaerobic treatment to food-processing waste management can best be discussed by focusing on specific food-processing industries. This review will focus on dominant food-processing industries where anaerobic treatment has been successfully

applied in the treatment of wastewaters. Despite the differences among industries, many of the problems and solutions are common to all areas of food processing.

21.5.1 Fermentation and Beverage Industries

An area with increasing demand for high strength wastewater treatment has been the winery and microbrewery industries. Much of the research supporting anaerobic treatment of these wastewaters has been conducted in Europe and Australia. Very high organic loads characterize these fermentation wastewaters with additional problems associated with high suspended solids and phenolics and other byproducts of the fermentation processes that may be difficult to degrade. Before the introduction of high rate anaerobic reactors, aerobic processes or anaerobic sludge blanket systems treated these wastewaters.

Anaerobic processes have been widely applied for the treatment of brewery wastewaters. The ADI-BVD reactor has been used to treat this high carbohydrate, nutrient deficient wastewater. The high rate UASB and more recently IC reactors have been popular systems for treating brewery wastewaters. An anaerobic–aerobic wastewater treatment plant at a German brewery using a UASB first stage consistently removed greater than 80% COD at a loading rate of 8–10 COD/m^3-day (29). Using a large inoculum shortened start up time, and the recommended amount of inoculum was 10–20 kg volatile suspended solids (VSS)/m^3. No problems occurred when the UASB was restarted after standstill periods of several days or even weeks. Excessive scum layer problems have been observed in a field scale UASB, requiring shut down of the system for physical removal of the scum (30). Reducing the total suspended solids in the influent reduced, but did not eliminate, the scum layer accumulation.

An excellent case study for the application of the UASB process to the treatment of brewery wastewater is the seven year experience of Oriental Breweries in Korea (31). At the relatively low influent concentrations, averaging 1,620 mg COD/L, removal rates of approximately 80% were obtained, but at long hydraulic retention times. Gas produced by the digester was used to reduce operating costs by 30–45% to about \$.10/m^3. Good granule formation was difficult with this under loaded reactor, and this was attributed to excessive pre acidification. Later tests showed that a critical loading rate of 34–39 kg COD/m^3 total sludge bed volume-day (14–16 kg COD/m^3 reactor volume-day) was required to achieve 80% COD reduction, and the use of an upflow acidification reactor in series with a methanogenic UASB did not improve system performance (32). Field results (31) were only 20% of this critical rate.

Research and applications for winery wastewater treatment has largely focused on extensions of those anaerobic and aerobic methods successfully applied to the treatment of brewery wastewater. Little attention has been paid to the development of methods that successfully remove recalcitrant compounds that plague winery wastewaters such as phenols, tannins, and lignins. Tannins are the most common and crucial to the winemaking process, and tannins are most abundant in red wines. Tannins have been shown to inhibit microbial digestion (33).

UASB processes are most often described for winery wastewater treatment. UASB treatment of winery and cannery wastewaters has been used as the first step treatment followed by oxidation with ozone and ozone with hydrogen peroxide and granular activated carbon (34). With a hydraulic retention time of 24 hours, over 90% COD reduction was achieved. However, anaerobic treatment alone could not achieve the target COD effluent concentration of 75 mg/L, and the additional oxidations steps were required. Laboratory UASB reactors treated winery wastewater removed greater than 85% of the COD from wastewaters containing 1,000–17,000 mg COD/L at organic loading rates of 6.5–12.5 kg COD/m^3-day and hydraulic retention times of less than one day (35). There was a substantial decolorization of the wastewater with 45–67% reduction of polyphenol content.

An anaerobic sequencing batch reactor treated winery wastewater with a COD removal efficiency of greater than 98% operating at an organic loading rate of 8.6 kg COD/m^3-day and a hydraulic retention time of 2.2 days (36). Also, fluidized bed anaerobic reactors have been successfully used to treat winery wastewaters (37). Both laboratory and full scale of immobilized film technology reactors have successfully removed high percentages of COD. These reactors utilize carrier particles with a high surface area and low energy requirements for fluidization so that fluidization can be achieved at low upward flow rates.

Anaerobic processes have also been used to treat distillery wastewaters. For example, in whiskey production COD and suspended solids concentrations range between 10–60 and approximately 10 g/L, respectively. UASB granular bed anaerobic baffled reactor (GRABR), upflow anaerobic filter, and hybrid reactors have all been used to treat distillery wastewaters (38,39). Using the GRABR 90–96% COD reductions were obtained with the best performance at a hydraulic retention time of 4 days and a loading rate of 2.37 kg COD/m^3-day. The anaerobic filter with a support medium consisting of multi layer plates had a COD removal efficiency of 76% at 20 kg COD/m^3-day loading, removed approximately 70% of the total nitrogen by biological nitrification and denitrification, and converted approximately 70% of the organic phosphorus into soluble phosphate. A sequential anaerobic–aerobic laboratory system could achieve 99.5% COD removal with loadings as high as 39 kg COD/m^3-day in a two stage UASB (39). Nutrient supplementation had little effect on system performance.

An analysis of wastewater treatment at eleven Korean distilleries showed that barley, rice, tapioca, sweet potato, potato, and corn are used as raw materials (38). Difficulties in anaerobic treatment were reported only with the use of naked barley as the raw material. A thermophilic anaerobic reactor containing both a lower and an upper zone with modular blocks of cross flow media with a specific surface area of 102 m^2/m^3 was used to treat the naked barley wastewater with a soluble COD removal efficiency of 85–91% at loading rates of 5.45–11.52 kg/m^3-day.

Other applications of anaerobic wastewater treatment in the beverage industries include bottling plants and fruit juice processors. These are in general readily degradable wastewaters and high efficiencies of COD and BOD removal can be obtained. As with most food processing wastewaters, beverage wastewaters generally have low toxicity to anaerobic organisms and contain few refractory organic compounds. An exception is coffee, which is one of the most complex to degrade of the commonly encountered food commodities containing a high amount of lipids, 7.4 g/L tannin, and lignin (1). Also, in the roasting process a number of complex heterocyclic compounds are formed. Mesophilic anaerobic treatment of instant coffee wastewater has been difficult, but thermophilic operation has successfully treated the wastewater over a four month period.

21.5.2 Dairy Industries

High concentrations of fats are characteristic of wastewaters from dairy industries. These wastewaters are often very high strength, 40–80 g COD/L, and often contain high concentrations of proteins and lipids. Fat, oil, and grease (FOG) concentrations are typically in the 200–2000 mg/L range and can be even higher. Also, potentially inhibitory cleaning chemicals are often present due to the need to ensure continued disinfection of the production equipment. Because of the high organic content of these wastewaters, anaerobic digestion is essentially the only viable treatment method.

UASB reactors are very successful for wastewaters containing high concentrations of carbohydrates, but granule formation is more problematic with high fat wastewaters. When growing on these hydrophobic substrates, some bacteria produce extracellular polysaccharides that exhibit surface active properties that may inhibit granulation. After seeding a UASB reactor treating high strength ice cream wastewater with granular sludge,

deterioration of granules can be observed within a short period of time (40). Also, emulsified triglycerides can cause severe flotation and washout of granular anaerobic sludge, and fat can agglomerate and float to the surface as a scum layer. For these reasons, packed bed reactors such as the anaerobic filter and hybrid reactors are more common for treating these wastewaters because these packed-bed reactors more effectively retain biomass.

An operational problem that must be considered when treating wastewaters high in protein and oil content is the tendency for foam formation. These substrates can lower the surface tension, and sudden bursts of gas production associated with increased loading can cause foam formation. Severe foaming can carry the biomass out of the reactor. Foam sensors can indicate when foam begins to form. Addition of an antifoam agent or a reduction in loading rate can reduce the potential for foaming.

A wide range of anaerobic reactors has successfully treated dairy wastewaters including low rate BVF reactors, UASB and hybrid UASB reactors, expanded granular sludge bed reactors, anaerobic filters, and other hybrid reactors. Operation at COD concentrations between 3–5 kg COD/m^3 is recommended to ensure high levels of biodegradation and to avoid flotation problems (41). Sludge flotation and washout in a UASB reactor was reported with a lipid loading rate exceeding 2 g COD/L-day.

There are approximately one dozen ADI-BVF reactors treating wastewaters from dairy and cheese processing facilities (22). This low rate technology is well suited for treating these high FOG and TSS-containing wastewaters. For six BVF reactors operating at cheese and multiproduct dairy plants, 87–94% COD removal rates were obtained for flows of 74,000–193,000 gpd, influent COD in the range 3,730–15,450 mg/L, FOG up to 1,470 mg/L, and TSS up to 4,170 mg/L (22). At a multiproduct cheese plant a 6.4 L Plexiglas reactor was used for bench scale testing. With a COD loading of 1.44 kg/m^3-day and an average hydraulic retention time of 10.6 days, 94% COD and 99.5% FOG removals were obtained. Based on the pilot testing no supplemental alkalinity, micronutrients, or macronutrients were required for the full scale system, and it was demonstrated that peak COD loadings of 3.36 kg/m^3-day would have little effect on digester performance. Also, tests showed that no primary treatment to remove solids or FOG was needed.

In many cases, alkalinity chemical addition is not required for low rate anaerobic systems treating dairy wastewaters, because there is often sufficient natural alkalinity present as a result of caustic cleaning chemicals used in the plant, and due to the digestion of protein in the anaerobic process which generates alkalinity (22). However, in the case of a multiproduct dairy that also produces nondairy products such as imitation sour cream and nondairy creamers, magnesium hydroxide addition was used to maintain alkalinity (22).

Addition of trace metals has been shown to enhance the anaerobic treatment of whey and other food processing wastewaters (1). Elevated levels (over 500 mg/L) of volatile acids in the reactor effluent indicate a need for supplemental metals. The addition of Co, Fe, and Ni can significantly enhance the COD removal rate. Whey can be difficult to treat with its high COD concentration, lack of alkalinity, foaming tendency, and the difficulty in obtaining granulation, and tendency for biomass washout (42, 46). Biochemical methane potential experiments showed that nutrient and trace metal supplementation is vial for the anaerobic treatment of cheese whey (42). With such supplementation, UASB reactors could treat undiluted cheese whey at hydraulic retention times of 2–3 days with COD removal efficiencies of 95–97% for influent COD concentrations of 42,700–55,100 mg/L. Similar results were obtained in a laboratory scale upflow hybrid reactor (43). Hydraulic retention times as low as two days were used to treat whey with influent concentrations of approximately 20 g/L. At COD loading rates up to 11.3 kg/m^3-day, removal efficiencies more than 95% were obtained when the alkalinity in the reactor was stabilized by controlling the influent pH.

To improve the retention of granular anaerobic sludge when treating cheese whey, a multiplate, compartmentalized reactor was designed (44). This 450m^3 reactor consists of four compartments with gas collected and evacuated through side outlets below each plate. With influent COD concentrations of 20–37 g/L, loading rates up to 14.7 kg COD/m^3-day, and hydraulic retention times of 55–68 hours, COD removal efficiencies of approximately 92% were obtained.

Ice cream wastewater is another challenge for anaerobic treatment. Ice cream wastewater is a complex mixture that includes high concentrations of milk proteins, lipids, and carbohydrates. High rate anaerobic processes are difficult to apply because granulation conditions may not be achieved. UASB reactors have been operated for three-year periods without granule production (1). Although granulation on ice cream wastewater was not achieved, commercially available UASB granules from a dairy reactor allowed stable operation of a laboratory UASB reactor for over a year (23). However, of four pilot scale digesters, the anaerobic filter operated at the highest loading rate of approximately 6 kg COD/m^3-day. The anaerobic filter was selected for full scale installation over UASB, fluidized bed and contact process designs. Poor biomass retention was observed in all reactors, possibly related to the fat content of the wastewater, and was the limiting factor in performance. For example, during shock loading experiments, where loading was increased to 14 kg COD/m^3-day, undegraded fat accumulated within the anaerobic filter bed (23).

A four compartment anaerobic baffled reactor removed 99% of the COD from ice cream wastewater at a loading rate of 15 kg COD/m^3-day, the highest loading rate examined (40). This compartment reactor could be classified as a series of UASB reactors with internal baffles retaining biomass in each compartment. The partial degradation of the fatty components of the ice cream wastewater in the first compartment may allow good granule development in subsequent compartments. Granulation was achieved in anaerobic baffled reactors within three months. With the addition of a cationic polyamide-epichlorohydrin polymer as a granulating agent, granules formed earlier and were larger and more compact (40).

Although the focus of this review has been on the removal of organics, often classified as COD, from food processing wastewaters, the removal of macronutrients such as nitrogen and phosphorus is of increasing concern. Increasingly, wastewater treatment processes will need to be designed for specific nutrient removals. As an example, three compartment pilot scale reactors, with anaerobic–anoxic–oxic zones, were used to treat dairy processing wastewater (45). Effluent was sent to a clarifier, and settled biomass was returned to the reactor. In the anaerobic phase, readily degradable carbon sources, such as volatile fatty acids, induce phosphate removing bacteria to take up the acids and release phosphate into solution. In the aerobic phase, luxury P uptake occurs with phosphorus removal at 75–98%. In the anoxic phase, both nitrogen and phosphate are removed. With hydraulic retention times of 1.2 days and inlet concentrations of 1,757 mg COD/L, 62 mg NH_4-n/L, and 57 mg P/L, removal efficiencies of 94%, 97% and 75% were obtained for COD, NH_4-N and P, respectively (45). A phosphate removal efficiency of 98% was obtained with a higher biomass recycle rate and longer retention time.

21.5.3 Meatpacking and Slaughterhouse Industries

Meat processing plants and slaughterhouses generate large volumes of high protein, high fat wastewaters with 0.4–3.1 m^3 wastewater produced per slaughtered animal (46). Nitrogen, phosphorus, and sulfur compounds are present in significant quantities. There is a large insoluble fraction consisting of colloidal and suspended matter in the form of fats, proteins, and cellulose, which degrade slowly in anaerobic reactors.

Wastewater COD levels vary with the difficult slaughterhouse processing and recovery methods. When blood and viscera are recovered, and pretreatment to recover fats and

suspended matter is effectively used, COD can be approximately 1000 mg/L. Otherwise, COD levels can be as high as 12,000 mg/L. BOD levels are usually in the 1000–2400 mg/L range with the soluble fraction between 40–60% (46).

Anaerobic ponds have been used to reduce the BOD/COD levels of slaughterhouse wastewaters. However, these ponds degrade wastewaters at a low rate often with unpleasant odor generation. Performance is improved with effective pretreatment including screening and dissolved air flotation for the removal of fats and suspended solids. Covered anaerobic ponds reduce odor release and permit the capture of biogas. Retention times are typically 12–14 days and BOD loadings are approximately 0.33 kg/m^3-day (47). The biogas contains 0.2–0.7% H_2S that must be removed, for example by iron sponge filters, before use. BOD removals are typically 85–90%.

High rate anaerobic processes can be used to treat lagoon effluent or used independently. Sequencing batch, UASB, anaerobic contact, hybrid, and anaerobic filter reactors have been used to treat slaughterhouse wastewaters. Ultraviolet disinfection may be advantageous as a post treatment operation. Slaughterhouse wastewaters present two major problems for high rate anaerobic treatment:

1. The high fat and protein content of the wastewaters are much more resistant to anaerobic degradation than carbohydrates. The fats are sparingly soluble and tend to form scums, coat surfaces, and adsorb on biomass flocs and granules. Together with the high suspended solids content of the wastewater, granule formation is inhibited. The small flocs or granules that do form have a low settling rate.
2. The BOD/COD concentrations in the wastewater are relatively low for the successful operation of a high rate anaerobic process. These high rate processes operate better with BOD concentrations of 10,000 mg/L or more (47).

Because of the slow granule development, packed bed anaerobic reactors, such as the hybrid or filter reactors, and the anaerobic contact and sequencing batch reactors appear more suitable for these wastewaters. Pretreatment to remove fats and suspended solids is essential for optimum performance in all cases. The anaerobic contact process has been relatively popular for the treatment of slaughterhouse wastewaters with removal efficiencies of more than 84% BOD, 93% COD, and 75 % TSS in at a large plant with a COD loading of 3 kg/m^3-day (47). However, floating sludge problems that forced a plant in the UK to shut down has plagued other plants.

Large scale anaerobic filters have been installed in Europe, but little data concerning their performance is available (47). Reports list COD removals of 80–85% at COD loadings of 2–3 kg/m^3-day. Higher COD loadings appear to lead to poorer performance. Also, ineffective pretreatment resulting in a high fat and grease content of the wastewater caused unstable operation of an anaerobic filter treating slaughterhouse wastewater. A laboratory scale anaerobic filter was successfully used to treat wastewater from a fish meal factory (48). Fish meal processing wastewaters are characterized by a very high organic content (30–120 g COD/L) consisting of up to 70% protein. A reactor packed with PVC rings operating at a loading rate of 5 kg COD/m^3-day with a high recycle rate consistently operated at a COD removal rate of over 80%.

Other biofilm anaerobic reactors have been applied to the treatment of slaughterhouse wastewaters. A hybrid reactor was used to treat wastewater from a pig slaughterhouse at a loading rate of 2.7 kg COD/m^3-day. The main operating problems were carryout of granular sludge and fines, and loss of sludge during periods with high influent fat levels. The granular sludge required approximately two years to develop (12). A laboratory hybrid in which the bottom two thirds was occupied by a sludge blanket and the upper one third

by clay rings operated with a 96% COD removal rate with slaughterhouse wastewater loading rates up to 25 kg COD/m^3-day (20).

The application of UASB reactors for the treatment of meat processing wastewaters is problematic because of the accumulation of suspended solids and floating fats and the poor quality of the granular sludge. This leads to biomass washout and low methanogenic activity. Large scale UASB reactors have been installed at slaughterhouses, but loss of sludge and lowered rates of BOD removal occurred because of the high fat concentrations (47). The key operating issue for UASB reactors is adequate pretreatment to remove suspended solids and fat to prevent their accumulation and subsequent loss of active sludge. UASB reactors often are forced to operating at low COD loading rates (0.3–1 kg/m^3-day), long hydraulic retention times (10–15 days), and poor COD removal (72–87%) (47). However, under optimum pretreatment conditions, UASB reactors can operate with COD loadings up to 11 kg/m^3-day with COD removal efficiencies of 80% or better (46,47).

Problems associated with granule formation in wastewaters high in protein and fat content have been examined in several studies. Anaerobic sequencing batch reactors were used to investigate the effects of pork fat particles on the rate of anaerobic digestion (49). The fat particle degradation was mainly controlled by the rate of free long chain fatty acid oxidation rather than the rate of fat hydrolysis. Also, these fatty acids adsorb on the biomass giving misleadingly low soluble COD values. Methane production was inhibited during the early phase of fat digestion. Low hydrogen partial pressure was required in order to favor fat oxidation, and high methanogen activity was essential for utilizing the hydrogen produced during fat oxidation. The particulate nature of slaughterhouse wastewater was predicted, and observed, to adversely affect granule formation (12). With high concentrations of sugar, a layered granule structure is predicted with fermenters in the outer layer, hydrogen utilizers and producers in the middle layer, and acetate utilizers in the center. High rate UASB processes treating slaughterhouse wastewater lack this structure and the resulting flocs have a low density of microorganisms. The tendency to form weak flocs is amplified at low substrate concentrations and low loading rates, which may be necessary in treating particulate wastewater.

In summary, the key requirements for the high rate anaerobic treatment of slaughterhouse wastewater are pretreatment to remove fats and suspended solids and to dampen flow fluctuations, and relatively low COD loadings (2–11 kg/m^3-day) (47).

3.22

International Aspects of the Quality and Safety Assessment of Foods Derived by Modern Biotechnology

John R. Lupien

CONTENTS

22.1 INTRODUCTION

Agriculture (including crops, fishery, forestry, and animal husbandry) must feed an increasing world population, forecast to reach 8000 million by 2020, of which 6700 million will be in developing countries (1). Although population growth rate is steadily decreasing, the increase in absolute numbers to be fed will require steady increased gains in productivity, often in countries where environmental degradation threatens decreased productivity.

To meet future needs and to be able to sustain agricultural production, agricultural research will have to use all available technologies, including the rapidly developing modern biotechnologies. The Food and Agriculture Organization of the United Nations (FAO) has recognized that the new techniques of biotechnology are powerful tools in agricultural

development, and have great potential to benefit agriculture. At the same time, FAO has pointed out that there are a number of uncertainties and possible risks associated with their use (2) (Annex 1, FAO Statement on Biotechnology).

New technologies, such as modern biotechnologies, if properly focused, should provide solutions for some of the problems hindering sustainable rural development and the achievement of food security. Biotechnology may also offer a tool to resolve certain environmental problems, some of which derive from unsustainable agricultural and industrial practices.

22.2 BIOTECHNOLOGY IN FOOD

Biotechnology has a long history of use in food production and processing. It represents both traditional breeding techniques and the latest techniques based on molecular biology. Modern biotechnological techniques, in particular, open up very great possibilities of rapidly improving the quantity and quality of food available.

The 1992 United Nations Convention on Biological Diversity (CBD) defined biotechnology as "any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use (3)." In agriculture, biotechnology includes the application of tissue culture, immunological techniques, molecular genetics and recombinant DNA techniques in all facets of agricultural production and agro-industry.

Within the past few years, a variety of foods produced using biotechnology have been approved in many countries. Examples are crops such as maize, potatoes, soybeans, tomatoes, and oilseeds. The benefits of biotechnology are many and include providing resistance to crop pests to improve production and reduce chemical pesticide usage, thereby making major improvements in both food quality and nutrition. Biotechnology is also being used in a wide range of applications in fermentation techniques and in animals and plants for the production of food additives and pharmaceuticals.

It is important to consider any potential human health or environmental risks when foods are developed using biotechnology. It is vitally important to encourage worldwide efforts to develop and apply appropriate strategies and safety assessment criteria for food biotechnology research and to ensure the wholesomeness and safety of the food supply.

The increasing development of genetically modified organisms is accompanied by the need for all necessary controls related to their testing, release, use, and cross border movements. Adequate national legislation is necessary to protect the environment, biodiversity, and human health. There is also the need to consider how to carry out adequate levels of risk assessment and risk management of genetically modified organisms and their products and mechanisms and instruments for the application and control of biotechnology.

The Resumed Extraordinary Conference of the Parties to the Convention on Biological Diversity held in Montreal, Canada in l998 adopted the Cartagena Protocol on Biosafety (4). The objective of the Protocol is to contribute to ensuring an adequate level of protection in the field of the safe transfer, handling and use of living modified organisms[1] (LMO) resulting from modern biotechnology[2] that may have adverse effects on the

[1] Cartagena Protocol on Biosafety definition: LMO means any living organism that possesses a novel combination of genetic material obtained through the use of modern biotechnology;

[2] Cartagena Protocol on Biosafety definition; "Modern Biotechnology" means the application of: (I) *In vitro* nucleic acid techniques, including recombinant deoxyribonucleic acid (DNA) and direct injection of nucleic acid into cells or organelles, or (ii) Fusion of cells beyond the taxonomic family that overcome natural physiological reproductive or recombination barriers and that are not techniques used in traditional breeding and selection

conservation and sustainable use of biological diversity, taking into account risks to human health, and specifically focussing on transboundary movements.

While there are a number of contradictions and imprecise statements in this new Protocol, the key concept seems to be the notion of advance informed agreement (AIA), which should be given by the country of import prior to the transboundary movement of an LMO. Many of the provisions of the Protocol need further discussion before they can be implemented and the Protocol contains provisions for such discussions. For example, it appears that the advance informed agreement procedure in the Protocol might not apply to LMOs intended for direct use as food or feed, or for processing. At the same time, the Protocol contains an article on the handling, transport, and identification of LMOs intended for "food, feed, or processing" (LMO/FFPs). Such contradictions require further discussion, preferably based on sound science.

The Protocol promotes a "precautionary approach" in assessing the usefulness and safety of LMOs and LMO/FFPs. The Protocol provides that risk assessments shall be carried out in a scientifically sound manner taking also into account risks to human health. The Protocol does not imply a change in the rights and obligations of a Party under any existing international agreement including WTO, SPS, and TBT Agreements. It is understood that the Protocol and trade agreements should be mutually supportive and none of them should be subordinated to the other.

This paper describes an overview of relevant instruments in the field of biotechnology that deal directly or indirectly with issues related to biotechnology, with particular reference to FAO and relevant bodies and ongoing processes within FAO, and outlines international mandates and capacity to advise UN member governments on matters and international regulations relevant to biotechnology and food and agriculture. Cooperation between FAO, the World Health Organization (WHO) and the World Trade Organization, and among other concerned UN agencies, is necessary to effectively carry out international work on biotechnology. To facilitate the quality and safety assessment of foods derived by means of modern biotechnology, action at the international level has been necessary to provide timely expert advice in this matter to all Member States.

22.3 INTERNATIONAL WORK ON BIOTECHNOLOGY

The United Nations and FAO have been involved for many years in biotechnology in order to advise and assist its Member Countries to adopt useful methodologies and monitor development in the area. In 1984, an FAO/International Atomic Energy Agency (IAEA) meeting discussed the role of relevant international organizations in biotechnology, and since then numerous sectoral and general meetings called by UN agencies have included specific aspects of biotechnology.

In 1991, the member countries of the FAO Council endorsed a draft "Code of Conduct for Biotechnology as It Affects the Conservation and Use of Plant Genetic Resources (5)." A draft was prepared, following a survey among 400 experts worldwide, requested by the Commission on Genetic Resources for Food and Agriculture (CGRFA). Its aim is to minimize possible negative effects of biotechnology on the overall conservation of plant genetic resources. Noting that CBD was considering the development of a biosafety protocol,[3] the Commission recommended that FAO participate in this work in

[3] The CBD definition of Biosafety "the safe and environmentally sustainable use of all biological products and applications for human health, biodiversity and environmental sustainability in support of improved global food security"

order to ensure that aspects of biosafety in relation to genetic resources for food and agriculture be appropriately covered.

A number of FAO publications — both meeting reports and technical bulletins — have addressed aspects of biotechnology, as mean of assisting member governments to acquire the technology, implications for agriculture, and trade-related issues, and many of these can be found on the FAO website (www.fao.org).

Particular biotechnology-related issues have been considered by a series of FAO/WHO expert consultations and workshops such as two Joint FAO/WHO Expert Consultations in 1990 and 1996 which addressed safety assessments of food derived by modern technology and outlined the procedures to be followed in establishing the quality and safety of such food.

The first Joint FAO/WHO Consultation on the Assessment of Biotechnology in Food Production and Processing as Related to Food Safety (November 1990) (6) reviewed the status of biotechnology as used in food production and processing and discussed foods derived from plant, animal and microbial sources. The consultation proposed safety assessment paradigms for each food source and recommended that safety assessment strategies should be based on the molecular, biological and chemical characteristics of the food to be assessed. It noted that traditional food safety assessment techniques, based on toxicological testing as used for food additives, for example, may not always apply to foods or food components produced by biotechnology.

A fundamental conclusion of the 1990 consultation concerning modern biotechnology was that "The use of these techniques does not result in food which is inherently less safe than that produced by conventional ones."

Another Joint FAO/WHO Consultation on Biotechnology and Food Safety held in 1996 recommended international guidelines for safety assessment of foods and food components which have been produced by techniques that change the heritable traits of an organism, such as recombinant DNA (rDNA) technology (7).

The 1996 Joint FAO/WHO Consultation established the concept of substantial equivalence, which is a dynamic, analytical exercise in the assessment of the safety of a new food relative to an existing food. This comparative approach was based on the possibilities that it may be possible to demonstrate that a genetically modified organism, or a food or food component derived from it, is substantially equivalent to a conventional counterpart already available in the food supply. Substantially equivalent in this context refers to both conventional nutritional equivalencies and to safety considerations.

If it is not possible to demonstrate substantial equivalence, it may be possible to demonstrate that a genetically modified organism, or food component derived from it, is substantially equivalent to its conventional counterpart apart from certain defined differences. It may not be possible to demonstrate substantial equivalence between the genetically modified organism or food component derived there from and a conventional counterpart, either because differences are not sufficiently well defined or because there is no appropriate counterpart with which to make a comparison.

While recognizing there may be limitations to the application of the substantial equivalence approach to safety assessment, the Consultation recommended that safety assessment based upon this concept be applied in establishing the safety of food products derived from genetically modified organisms to provide comparable or increased assurance of the safety of food products derived from biotechnology.

Three expert consultations, designed to provide expert advice to the Codex Ad Hoc Task Force and to FAO and WHO Member Countries, followed, in 2000 and 2001. In June 2000, FAO/WHO convened an Expert Consultation on Foods Derived from Biotechnology (8) that reviewed previous FAO/WHO recommendations and strongly

reendorsed the concept of "substantial equivalence" as the best method of assessing the safety and suitability of foods derived from biotechnology.

In January 2001, FAO/WHO held a further Expert Consultation on Foods Derived from Biotechnology (9), concentrating on the possible allergenicity of food derived from biotechnology. This meeting pointed out that no problems with allergenicity have yet occurred with foods derived from biotechnology, mentioned that some food allergens might be removed from foods by future biotechnology developments, devised some suggested methods for testing new foods for possible allergenicity, and again endorsed the concept of "substantial equivalence."

In September 2001, FAO/WHO held a third Expert Consultation on Food Derived From Biotechnology (10), to consider safety and suitability aspects of genetically modified microorganisms. The report of this session has been published on the FAO website, as have been most of the previous reports. The meeting confirmed, in general, the recommendations of previous expert consultations, and pointed out some of the special features of genetically modified microorganisms in the human gut. It did not find any causes for immediate concern, recommended a system for evaluating genetically modified microorganisms, and again endorsed the concept of "substantial equivalence."

22.4 QUALITY AND SAFETY ASSESSMENT

The use of biotechnological processes, particularly genetic modification, is extremely important in devising new ways to increase food production, increase pesticide resistance and reduce use of pesticides, improve nutrient content, and provide better processing or storage characteristics. It follows that when new foods or food components are developed using biotechnology, there are both national legal requirements and consumer expectations for effective systems and procedures to assess the safety of the food and food component for consumption.

With regard to these needs, there is a series of instruments and international regulations in the field of food and agriculture in FAO that deal directly or indirectly with biosafety and biotechnology related issues which would be of relevance to the quality and safety assessment of foods derived by modern biotechnology.

22.5 FAO PROGRAMS ON FOOD QUALITY AND SAFETY

The Food Quality and Standards Service is a service within the Food and Nutrition Division of the Food and Agriculture Organization of the United Nations (FAO), located in Rome. The Secretariat of the Codex Alimentarius Commission is also located here. The Regular Program of the Food Quality and Standards Service provides the technical and scientific basis for FAO for all food quality matters, including food safety. This includes providing the secretariat for the Joint Expert Committee on Food Additives (JECFA) and participation in both the Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Expert Group on Pesticide Residues (JMPR).

The Food Quality and Standards Service of FAO develops and publishes guidelines and manuals (including the FAO Food and Nutrition Series, Manuals of Food Quality Control), arranges expert consultations and conferences (examples of recent consultations include the Joint FAO/WHO Expert Consultation on Biotechnology and Food Safety, 30 September – 4 October 1996; the Joint FAO/WHO Expert Consultation on the Application of Risk Management to Food Safety Matters, 27–31 January 1997; the Joint FAO/WHO

Consultation on Food Consumption and Exposure Assessment to Chemicals, 10–14 February 1997; the FAO Consultation on Animal Feeding and Food Safety, 10–14 March 1997; the Joint FAO/WHO Expert Consultation on Risk Communication to Food Standards and Safety Matters, February 1998; and the Joint FAO/WHO Expert Consultation on Risk Assessment of Microbiological Hazards in Foods, March 1999) and has a major and continuing program of providing technical assistance related to food standards and food control to member countries, particularly developing countries and countries in transition from a centrally planned to a market economy.

JECFA and JMPR are expert committees that provide the independent scientific advice that forms the basis for the development of food quality and safety recommendations used in international trade. These committees are forums in which independent, invited experts assess the state of scientific knowledge of food additives, pesticide and veterinary drug residues in food, mycotoxins and other chemical contaminants in food, and make recommendations to member governments and to Codex on such matters.

FAO's Food Quality and Standards Service also develops and publishes Manuals of Food Quality Control which provide recommendations for the development and operation of food quality and safety systems. While aimed primarily at providing advice to developing countries, they document modern approaches including the development of quality control programmes throughout the food chain that are applicable to all countries. Such an approach is instrumental in facilitating international trade in food. Key titles in the series include Food Inspection, Food for Export, Management of Food Control Programmes, Imported Food Inspection and Quality Assurance in the Food Control Laboratory (see website www.fao.org.nutrition for entire list of these publications and source for ordering).

The program of technical assistance projects undertaken by FAO's Food Quality and Standards Service includes assistance in food quality control including safety and such projects have established or strengthened the food control systems in a number of developing countries. Typically, they assist in establishing the infrastructure for an enhanced food control programme, assessing laboratory service requirements, providing guidance to develop legislation and procedural manuals, setting up reputable inspection and certification systems and providing training and staff development. In these assistance projects, the standards established by the Codex Alimentarius Commission are basic guides to international requirements.

22.6 CODEX ALIMENTARIUS

The Codex Alimentarius Commission (CAC) was formed by FAO and WHO in 1962 to implement the Joint FAO/WHO Food Standards Program. The objectives of the Program are to ensure consumers health and fair practices in the food trade. The CAC is an intergovernmental statutory body of FAO and WHO. Its current membership is 165 countries and the Commission member countries are empowered by the CAC statutes and rules to adopt and recommend for approval to the governing bodies of FAO and WHO standards, guidelines and recommendations related to the protection of health and the promotion of fair international trade of foods (11,12).

The scope of Codex Standards includes all food safety considerations, description of essential food hygiene and quality characteristics, labelling, methods of analysis and sampling, and systems for inspection and certification. Codex Standards, guidelines and recommendations are based on current scientific knowledge including assessments of risk to human health. As mentioned, risk assessments are carried out by FAO/WHO expert panels of independent scientists selected on a worldwide basis, and the results of their review and

deliberations are provided to Codex for use in Codex work, and to FAO/WHO Member Countries. The range of standards developed by the CAC covers all foods whether processed, semi processed or raw, intended for sale to the consumer or for intermediate processing. Over 200 standards, 45 Codes of Practice and 2,000 Maximum Limits for residues of agricultural and veterinary chemicals have been established.

In 1999, the Codex Alimentarius Commission established the Ad Hoc Intergovernmental Codex Task Force on Foods Derived from Biotechnology to develop standards, guidelines, or other recommendations on foods derived from biotechnology. The first Session of the Ad Hoc Intergovernmental Codex Task Force was held in Chiba, Japan from 14 to 17 March, 2000. The second Session was held in Chiba from 26–30 March 2001.

This Task Force is elaborating standards, guidelines, or recommendations, as appropriate, for foods derived from biotechnology or traits introduced into foods by biotechnology, on the basis of scientific evidence, risk analysis and having regard, where appropriate, to other legitimate factors relevant to the health of consumers and the promotion of fair trade practices. It must take full account of existing work carried out by national authorities, FAO, WHO, other international organizations and other relevant international for a, with close coordination and collaboration with appropriate Codex Committees within their mandate as relates to foods derived from biotechnology.

In its second meeting in 2001 the Task Force prepared "Proposed Draft Principles for the Risk Analysis of Foods Derived from Modern Biotechnology" and a "Proposed Draft Guideline for the Conduct of Food Safety Assessment of Foods Derived from Recombinant DNA Plants." Both of these documents were discussed and adopted by Codex at Step 5, of the 8 Step, Codex procedure at the July 2001 24th Session of the Codex Alimentarius Commission.

A further discussion of these documents of the 3rd Session of the Task Force in 2002 resulted in agreement on all aspects of the texts. The Task Force recommended final approval at Step 8 of the Codex procedures at the next Commission Session. The final texts adopted by the Task Force can be found in Annex 2 and Annex 3 to this Chapter. A Codex Draft Annex on the Assessment of Possible Allergenicity, Annex 4, was also recommended for Step 8 final Commission approval and a proposed Draft Guideline for the Conduct of Food Safety Assessment of Food Produced using Recombinant DNA Microorganisms, Annex 5, was approved by the Task Force and advanced to Step 5 of the Codex process (13–16).

Other Codex Committees such as the Codex Committee on Food Labeling, and the Codex Committee on Food Import Certification and Inspection Systems, are discussing biotechnology related topics such as voluntary or mandatory labeling systems, and means of assuring "Traceability" of foods and ingredients for foods (and feeds) derived from modern biotechnology. All of this Codex work, when applied at the national level by FAO/WHO member countries should assist greatly in assuring that harmonized procedures are used in the assessment and regulatory control of food derived from biotechnology.

The Uruguay Round of Multilateral Trade Negotiations established a new World Trade Organization (WTO) and included negotiations on reducing non tariff barriers to international trade in agricultural products and included Agreements on the Application of Sanitary and Phytosanitary Measures (the SPS Agreement) and on Technical Barriers to Trade (the TBT Agreement) (17). Both Agreements have implications for the work of the Codex Alimentarius Commission.

The SPS Agreement confirms the right of WTO Member countries to apply measures necessary to protect human, animal and plant life and health provided that "such measures are not applied in a manner which would constitute a means of arbitrary or unjustifiable discrimination between countries where the same conditions prevail, or a disguised restriction on international trade."

With respect to food safety, the SPS references the standards, guidelines and recommendations established by the Codex Alimentarius Commission relating to food additives, residues of veterinary drugs and pesticides, contaminants, methods of sampling and analysis, and codes and guidelines of hygienic practice.

Therefore, measures need to be taken with respect to foods to ensure to the Codex maximum levels or guidelines levels for contaminants, and to the Codex maximum residue limits (MRLs) for pesticide and veterinary drugs. Measures also need to be taken to ensure that the appropriate hygienic practices are followed at all stages of the animal feeding chain to prevent, eliminate, or reduce potential hazards in the food.

The objective of the TBT Agreement is to prevent the use of national or regional technical requirements, or standards in general, as unjustified technical barriers to trade. It covers all types of standards, including all aspects of food standards, other than those related to SPS measures, and includes a very large number of measures designed to protect the consumer against deception and economic fraud. The aspects of food standards it covers relate specifically to quality provisions, nutritional requirements, labelling, and methods of analysis. The TBT Agreement basically provides that all technical requirements and regulations must have a legitimate purpose and that the impact or cost of implementing the measure must be proportional to the purpose of the measure. It also places emphasis on international standards.

Codex standards, guidelines and other recommendations are not binding on Member States, but are a point of reference in international law (General Assembly Resolution 39/248; Agreement on the Application of Sanitary and Phytosanitary Measures; Agreement on Technical Barriers to Trade).

However, increased scientific, legal and political demands are being made on the standards, guidelines and recommendations elaborated by Codex. This is in part due to increased consumer interest in food safety, the WTO's SPS and TBT Agreements, harmonization initiatives, calls for increased scientific rigor, the need for transparency, and shrinking national regulatory resources.

The CAC is considering the development of a general standard that would apply basic food safety and food control disciplines to foods derived from biotechnology. The advice of prior FAO/WHO expert consultations in this area will be used as guidance for the conditions required for foods prepared from biotechnology.

22.7 OTHER FAO INSTRUMENTS THAT DEAL WITH ISSUES PERTAINING TO BIOSAFETY

22.7.1 The Commission on Genetic Resources for Food and Agriculture

The Commission on Plant Genetic Resources was established by the FAO Conference in 1983 (18). The mandate of the Commission was broadened to include all genetic resources that pertain to food and agriculture in 1995. The current Membership of the Commission on Genetic Resources for Food and Agriculture is 158 countries and the European Community.

The Commission has developed the following international agreements relevant to the biosafety protocol and to CBD:

1. The International Undertaking on Plant Genetic Resources, adopted by the FAO Conference in 1983. There are 113 countries that have adhered to the Undertaking. The revision of the Undertaking in harmony with the Convention on Biological Diversity is currently being negotiated by countries through the Commission.

2. The international Code of Conduct for Plant Germplasm Collecting and Transfer, which was adopted by the FAO Conference in 1993.

In 1989 and 1991 the Commission considered reports on technical and policy issues regarding Biosafety, within the context of biotechnology in general as explained previously.

22.7.2 Code of Conduct for Responsible Fisheries

The FAO Code of Conduct for Responsible Fisheries was adopted in 1995 by the 28th Session of the FAO Conference and provides a framework for the sustainable use and conservation of aquatic biodiversity (19). The code was created through negotiations with member Countries, NGOs and IGOs and contains articles on:

1. General Principles
2. Fisheries Management
3. Fishing Operations
4. Aquaculture Development
5. Integration of Fisheries into Coastal Area management
6. Post harvest Practices and Trade
7. Fisheries Research

Although the Code is voluntary, parts of it are based on relevant rules of international law, including those reflected in the United Nations Convention on the Law of the Sea.

Aquaculture is a primary means for the purposeful introduction of aquatic alien species, as well as the main motivation for the use of living modified aquatic organisms. Therefore, Article 9 on Aquaculture Development deals with these topics, specifically: Article 9.2 on the "responsible development of aquaculture including culture based fisheries within transboundary aquatic ecosystems" and Article 9.3 on the "use of aquatic genetic resources for the purpose of aquaculture, including culture-based fisheries."

22.7.3 The International Plant Protection Convention (IPPC)

Some of the potential environmental risks concern plant pests. The inclusion of pest resistance in plants should be carefully evaluated for potential development of resistance in pests and possible side effects on beneficiary organisms.

The IPPC is an international treaty for cooperation in plant protection, deposited with FAO and administered by FAO through the Secretariat for the IPPC. The purpose of the Convention is "*to secure common and effective action to prevent the spread and introduction of pests of plants and plant products, and to promote appropriate measures for their control.*"

The Convention had its beginnings in 1951 and came into force in 1952. It is recognized as the primary instrument for international cooperation in the protection of plant resources from harmful pests.[4] There are currently 106 governments that are contracting parties to the IPPC.

The role of the Convention with respect to trade has changed significantly as a result of the SPS Agreement. This is reflected in substantial amendments found in the New Revised Text approved by FAO Conference in 1997 (20).

[4] "Pests" are defined in the IPPC to be "any species, strain, or biotype of plant, animal or pathogenic agent injurious to plants or plant products"

The IPPC calls for phytosanitary measures to be based on a pest risk analysis, which covers both economic and environmental factors including possible detrimental effects on natural vegetation. The Convention also allows for the prohibition or restriction of the movement of biological control agents and other organisms of phytosanitary concern claimed to be beneficial into the territories parties.

22.8 CONCLUDING REMARKS

Adequate biosafety regulations, risk assessment of quality and safety of foods derived from biotechnology, mechanisms and instruments for monitoring use, and compliance are necessary to ensure that there will be no harmful effects on the environment and the health of people.

International organizations such as FAO, WHO, IAEA at the service of Member States by assisting in building capacities and providing technical advice and assistance in priority assignment, resource allocation, and international regulations.

Patenting Inventions in Food Biotechnology

R. Stephen Crespi

CONTENTS

23.1 INTRODUCTION

Patent law is a system for recognizing technological innovation and protecting the inventor for a limited period against the unauthorized use of the patented invention by others. It has existed for centuries and, despite criticism, it survives as the most useful type of intellectual property for protecting technological advance. Patent law has to respond continually to the needs of new and rapidly developing technologies and among these none has made more demands on it than biotechnology.

Patent law is based on the bargain theory of providing legal protection in return for full disclosure of inventions, as the alternative to a policy of industrial and trade secrecy. Open disclosure will appeal to researchers in academic and similar institutions, who will usually seek scientific publication in parallel with patenting. Some of the pitfalls to be avoided by inventors of this kind have been outlined previously (1). For industry, the choice between these alternatives will always be made, case by case, as matters of commercial judgement. Coca cola and Chartreuse are the most cited successful examples of products made by secret processes. From limited experience in the food industry, I well remember the panels of tasters who tried to divine the process by which our competitors managed to make their chocolate taste so good. But for a novel food product which can be analysed and the manufacturing process reverse engineered, patenting might be the preferred option. In the past, the alcoholic beverage and food industries have tended to avoid using the patent system and have preferred to rely on secrecy. The same can be said for the microbial strain improvement programs followed by industry for the production of antibiotics and other useful metabolites. However, considerable use has been made of patents where it is possible to protect key intermediates and final products of a fermentation process.

23.2 BASIC PRELIMINARIES

23.2.1 The Nature of Patents

A patent is a property right granted by state authority which excludes others from the use or benefit of the patented invention without the consent of the patent holder. A patent does

not confer a positive right to use an invention because freedom of use may be dependent on prior rights. For example a patent for an improvement on a basic product or process will often be subject to a prior patent for the basic product or process.

23.2.2 The Patent Application

To obtain a patent, an application must be filed with the relevant national authority (patent office) and will be examined for compliance with legal requirements. Separate patent applications are usually necessary in each country where protection is required but a single application in the European Patent Office (EPO) can cover any selection, or all, of the 30 European countries which are member states of the European Patent Convention (EPC) up to the point at which rights are granted.

There is no such thing as a world patent, although a so-called "international patent application" can be filed as a single patent application under an international convention (the Patent Cooperation Treaty, PCT) to which 126 member states are signatories. The early stages of a PCT application are managed by the World Intellectual Property Organization (WIPO), based in Geneva, and the specifications of these pending applications are published by WIPO. Eventually a PCT application splits into separate national applications for those countries which the applicant has designated for protection and these are then handled by the national patent offices of the designated states.

23.2.3 Patentability

The principal legal requirements for patentability are that the invention is new, involves an inventive step, and has an industrial or other useful capability. Also the patent application must include a specification of the invention which contains adequate instruction to enable the skilled person to produce or perform the invention. The invention is defined in the "claims" which are listed at the end of the patent document. A claim is a verbal formula which sets out what the patent protects (the scope of the patent), and it is therefore usual to include a series of claims directed to the various aspects of the invention. Common forms of claim are those directed to an apparatus or device, a process or product of manufacture, and a method of treatment, testing, or use.

23.2.4 Official Examination

The Patent Office will carry out a search of previously published documents including the scientific and patent literature to determine what is already known that may be relevant to the invention (the "prior art"). The application will then be examined in the light of the search results and the Examiner will raise objections if appropriate. Examination of the application usually involves extended argument about the specification, especially the scope of the claims, and may take considerable time to settle.

23.2.5 Opposition or Reexamination

Even after acceptance by the patent office, a patent application or patent can, in most countries, be opposed by third parties who may raise objections and prior art similar to or additional to those already overcome by the applicant. This is usually termed Opposition and involves argument between the applicant or patentee and an opponent, who have equal status as contending parties. U.S. patent law does not provide for opposition in this sense but allows a third party to request official reexamination of the patent in the light of prior art which has not already been considered. The third party can also participate up to a point in the reexamination procedure.

23.2.6 Special Features of U.S. Patent Applications

U.S. patent practice is unique in allowing an initial patent application to be refiled in the form of a "continuation" application which reproduces the text of the original application and retains its original priority date. In effect, this attractive facility extends the time to complete the process of argument with the Examiner over objections which may prove difficult to resolve speedily. A series of such continuing applications may be filed if desired and, provided the identical original text is adhered to in the refiled application, it will be possible subsequently to employ further arguments or scientific evidence to support the applicant's case. It will also be possible to make changes in the claims to improve the chances of reaching agreement with the Examiner as to their form and scope. This practice is used extensively by applicants for U.S. patents.

If any added data or other matter is added on refiling, the application is then designated as a "continuation-in-part" application (CIP) and, for this, the original priority date will be preserved only for what was originally present; the added matter will only be entitled, for priority, to the date of filing the CIP. Any intervening publications may therefore be citable as prior art against claims based on the added matter. This may also have consequences for disputes over priority, as will be apparent from the next section.

23.2.7 Conflicting Patent Applications

When two or more inventors are independently seeking a patent for the same invention, i.e., their claims cover the same ground, the U.S. Patent and Trade Mark Office (USPTO) has to decide which application has priority over the other(s). Provided the dates of filing of their respective applications are close to one another, the USPTO will declare "Interference." This is a procedure (too complex to attempt a summary here) based on examining laboratory notebook records and other evidence to determine the dates on which each party made the invention. This reflects the fact that U.S. patent law is a "first-to-invent" system. Other countries operate a "first-to-file" system, according to which the application with the earliest filing date will usually prevail, assuming that it is effective as a proper "enabling disclosure" of the invention.

23.2.8 Duration of a Patent

The term of a patent differs from country to country. In the U.S. and most European countries, the term is 20 years from the application date. The payment of annual official renewal fees is required in most countries to maintain a patent in force.

23.2.9 Enforcing Patents

A patent gives the patent holder no positive right to do anything except seek from a court a remedy against unauthorized use of the invention by others. A patent holder who takes such action has to face the possibility that the defendant will counterclaim that the patent is invalid and should therefore be revoked. Instead of going to law, a patent holder will often choose to regulate the situation by licensing the patent to the other party on reasonable terms.

23.2.10 Licensing Patents

The patent holder may wish to be the sole provider of the product or service covered by the patent and, subject to certain safeguards, this is permitted. Alternatively, the patent holder may license the patent to others for appropriate payment, either to one other party only (an exclusive license) or to more than one party (nonexclusive licenses). Where the patent holder is not an industrial or commercial organization, and does not wish to create

a start up company to commercialize the invention, licensing to the established industry is the most effective way of securing a financial return on the investment in research.

23.3 MAIN TYPES OF BIOTECHNOLOGY PATENTS

To be patentable, all biological materials, including biopharmaceuticals, agrobiotechnology products, food products, and their methods of manufacture or application, have to meet the same three legal tests of novelty, inventiveness, and practical utility as do the simpler chemical compounds and preparative methods of synthetic chemistry. Biotechnology inventions must also be capable of adequate description and definition in the patent specification, the all important document upon which rest all questions of patent scope (how much the patent covers) and patent validity (whether it is enforceable).

23.3.1 Food Products

In the past, the patent laws of many countries refused patents on food products as a matter of principle, although claims to inventive processes for producing them were allowable. The same applied to chemical products and medicines. In some countries, while food products were not automatically excluded from patentability, it was not possible to patent mere mixtures of known ingredients unless some special effect was involved. The underlying basis for this was that, if the properties of the mixture were simply the additive effect of the ingredients, no inventiveness was involved in "putting two and two together." In the parallel rule for medical products, evidence of a synergistic effect was often sufficient to overcome the objection. This type of exclusion persists in a few countries as, for example, Australia, which refuses patents for "Substances capable of being used as foods or medicines (whether for human beings or animals…), which are a mere mixture of known ingredients, and processes of producing such substances by mere admixture." However, in most other countries, this is dealt with under the heading of lack of inventiveness.

Novel food additives such as antioxidants, flavor enhancers, enzymes, and preservatives would be patentable as products in their own right.

23.3.2 Biological Products

23.3.2.1 Naturally Occurring Substances

Substances present as components of complex mixtures of natural origin, can in principle be patented where they are isolated, identified, and made practically available for the first time, and a process is developed for producing them so that they can be put to a useful purpose. This applies to inanimate substances and also to living matter. In appropriate circumstances such substances are not ruled out as mere "discoveries" but are considered as inventions by the legal authorities. For example, it is legitimate to isolate the true causative agents of folk remedies so that these may perhaps be synthesized and used in a more scientific way in therapy or for nutritional purposes, and there are many examples of patents based on this kind of research.

23.3.2.2 Microorganism Patents

These are now obtainable in most industrially developed countries, following the landmark decision of the U.S. Supreme court in 1980 that the living nature of microorganisms does not preclude them from patentability.

23.3.2.3 Plant Patents

These are also obtainable in U.S., Europe, Japan, Australia, and some other countries. Patent rights must be distinguished from the separate legal system of Plant Variety rights (also called plant breeders' rights). From the early 1960s, new plant varieties have been afforded protection under national laws of Plant Variety rights and an International Convention (UPOV). To avoid legal confusion, patent law in Europe excluded plant varieties from patentability, e.g., in the prototype provision of the European Patent Convention (EPC) Article 53(b) which excludes patents for "plant and animal varieties" and "essentially biological processes for the production" of plants and animals.

It is incorrect and confusing to refer to plant variety rights as "plant patents." The U.S. law provides for a special form of "plant patent" for asexually propagated plants, e.g., rose trees, but the normal U.S. "utility" patent can be used to protect other types of plant innovation, especially genetically modified plants. The U.S. has a Plant Variety Protection Act for sexually propagated plants and this corresponds to the plant variety rights system in other countries. These topics are more fully covered in specialist works on IPR in Agricultural Biotechnology (2).

Plant genetic improvement is more suitably protected under patent law especially if the invention is generically applicable, i.e., not limited to use with a single variety. The European Union Directive 98/44/EC makes this clear for the European Community. Also, the enabling methodology for this type of improvement can only be protected under patent law. Resolution of the apparent problem of interface between patent law and plant variety right law in Europe has been outlined previously (2).

23.3.2.4 Animal Breeds

Animal breeding by traditional methods has no legal system for protection comparable to plant breeder's rights. U.S. patents may in principle be obtained for nonnaturally occurring nonhuman multi cellular living organisms including animals. The first transgenic animal patent issued in 1988 to Harvard University with claims covering the "onco-mouse," one in which an onco-gene has been introduced to make the animal more susceptible to cancer and therefore more sensitive in testing possible carcinogens. Transgenic animal patents are available in European countries also. A European patent was granted for the onco-mouse but was formally opposed by animal rights groups.

23.3.2.5 DNA and RNA Sequences

Patents for nucleic acids may also be obtained in industrially developed countries. "Gene patents" are controversial and require more discussion than is feasible in this brief summary. The patent authorities in countries where such patents have been challenged consider that the gene in its natural state is unpatentable but that a patent can be granted when the gene is isolated and made available for a practical industrial or other useful purpose. Genes therefore constitute a special case of the general rule for naturally occurring substances. The common objections to gene patents have been discussed previously (3).

23.4 PATENTING IN BIOTECHNOLOGY

The special problems of biotechnology patents began to emerge with the development, after the Second World War, of microbiological processes for producing antibiotics, amino acids, enzymes, and other microbial products of industrial importance. To approach these problems it was inevitable that inventors and patent experts would draw upon a century or more of

experience in the patenting of chemical inventions and apply the established principles to the new situations. On the whole this has been successful, due to the fair degree of parallelism that exists between the two technologies. But the significant differences between living cells and the more manageable inanimate molecules have brought about a reexamination of traditional ideas of patent law to adapt it to deal effectively with biological systems and so stimulate innovation in this new field as it has done for older technologies.

23.4.1 Microbiological Inventions

Microbiological inventions follow the chemical pattern to a large extent, and the usual categories are shown in Table 23.1.

The microbiological equivalents of chemical products will be microbially produced products, or new microorganisms themselves or some other type of biological material including cell lines and plant or animal cells.

The early difficulties which appeared to be an obstacle to the granting of patents for living organisms have now been overcome intellectually and there is a clear trend toward the allowance of such patents at least in the major industrialized countries. Undoubtedly the decision of the U.S. Supreme Court in 1980, in the Chakrabarty case, to allow the following claim to a microorganism, was of prime influence in this connection.

"A bacterium from the genus *Pseudomonas* containing therein at least two stable energy-generating plasmids, each of said plasmids providing a separate hydrocarbon degradative pathway."

23.4.2 The Enabling Description of Microorganisms

It is a fundamental requirement of patent law that in return for legal protection, an inventor must disclose his invention in a manner sufficiently clear and complete to enable others of ordinary skill in the art to repeat or reproduce the process or product for which the patent is granted. Where the invention consists of or depends on a specific microorganism or other kind of biological material, this must be identified in the patent application to provide the "enabling disclosure" the law requires.

As compared with the chemical case, where a written description of the process is usually adequate, the requirement to provide a description which is reliably repeatable presents greater difficulty when living material is involved. Living material does not admit of a total description. But, more importantly, a total description would not by itself guarantee the means of producing the material. Where the microorganism is known and already available to the

Table 23.1
Categories of microbiological inventions

MICROBIOLOGICAL INVENTIONS
Production of microorganism (PROCESS)

End Products of biosynthesis (PRODUCT)
Formulations of microorganism (COMPOSITION)
Use of microorganism (PROCESS) to produce
biomass
by-product of microbial growth
an extracted product
an improved substrate
a biotransformation product.

skilled person and the invention resides, for example, in the discovery of some new property or use of practical value, it is usually sufficient to refer to the microorganism by name. But for a new microorganism, say a newly isolated or developed strain of a known species, the skilled person who attempts to repeat the procedure described in the patent specification will in most cases need not only a description of the organism but also a means of access to it.

Now if the patent application gives reliable instructions how to reisolate, rediscover, or reconstruct the new organism, this will be a sufficient disclosure. However, in most cases this cannot be achieved with certainty. Patent law has solved this problem by making use of the Culture Collection deposit system which the scientific community had created much earlier for its own needs. The practice has developed internationally, both through case law and in the express obligations written into modern patent laws, in many countries. The International Convention dealing with this requirement is *The Budapest Treaty on the International Recognition of the Deposit of Microorganisms for the Purposes of Patent Procedure*. It came into force at the end of 1980 and now has 60 Member States. The Treaty provides for the recognition of culture collections as International Depositary Authorities (IDAs) in any one of which a new strain of microorganism (or other type of biological material) can be deposited for the purposes of a patent application in any member state. At present there are 36 IDAs distributed among 21 of the Member States.

The maxim that what cannot be fully described must be deposited has therefore become part of patent law. This development has added a new dimension to patent law and practice for which no parallel exists in chemistry or other fields of technological innovation. Thus, the deposit of the organism supplements the written description and fulfils other important functions. First, it provides a reference material for resolving any dispute over the alleged novelty of the organism. Secondly, its reference function may be called upon to decide whether any third party is infringing the patent by using the same organism without a licence from the patentee. Finally, the deposit provides an available source material to enable others to make use of it when they are legally free to do so, i.e., when the patent is allowed to lapse or expires at the end of its normal term.

23.4.3 Availability of the Deposit

As to when a deposited culture can become available to the applicant's competitors and other third parties there is a difference between both the U.S. and Japanese patent systems, which allow access to the deposited culture only after an enforceable right has been granted, and the corresponding laws in European countries which allow access to the deposited culture upon first publication of the European or National Patent application (at 18 months after the filing date or priority date).

Loss of control of the new strain, at least for competitive research purposes, is mitigated under European patent practice by the option to elect for the so-called independent expert solution in the interim period between publication of the application and eventual grant of the patent. The function of the independent expert is to act for other persons or firms, e.g., the applicant's competitors, and to test, experiment with, and generally evaluate the invention on their behalf. The independent expert, though acting for third parties, must not pass the strain on to them. Under this alternative a measure of control on the use of the organism is provided for the applicant before he obtains an enforceable right.

Eventually, there must be full disclosure to the public and the skilled person must be put in a position of reproducing the inventive process or product, including access to deposited biological material. From then on policing problems vary with the nature of the patent protection obtained. When the microbiological invention leads to new products which can be the subject of product patents then detection of infringement is relatively straightforward. Where the products are not new, however, and novelty lies only

in the strain used or in some other parameter of the new microbiological process, then policing becomes more difficult. These factors can usually be fully anticipated before the decision to proceed by the patent route is first taken. One crumb of comfort may lie in the fact that the laws of some countries allow infringement actions to proceed on the basis of a strong *prima facie* case that the defendant is using the patented process. If the record shows that the defendant has obtained a sample of the patentee's deposited strain from the culture collection this might be sufficient to put the burden of proof of nonuse on the defendant.

23.4.4 Recombinant DNA Patents

In a recombinant DNA patent it will be common to have claims of various types, as shown in Table 23.2. For example, a possible claim might involve diagnostic methods and kits. Novel diagnostic methodology and reagents (or reagent combinations) for testing for contaminants, in food and other products, provide a growth area for patenting. Such patents usually have general application to products of many kinds in which microbial contaminants may be found but those specific for food products are also possible.

23.5 PRACTICAL EXAMPLES

Some remarks on selected patents in food biotechnology are given as illustrative of these principles. Being a random selection, it cannot be comprehensive as to the topics covered. Patents of interest are identified by patent numbers, from which copies can be obtained from the respective patent offices. Many will have lapsed by now either through nonpayment of renewal fees or by expiry at the end of their normal term.

23.5.1 Mycoprotein (*Fusarium* Strains)

The patenting of certain strains of *Fusarium graminearum* and foodstuffs based thereon began in mid 1970, at which time patents on living organisms were controversial in some countries. In Great Britain, two patents were obtained on this early work without much difficulty. UK patent 1,346,061 covered the various strains, a typical claim being "*Fusarium graminearum* Schwabe deposited with the Commonwealth Mycological Institute and assigned the number IMI 145425 and variants and mutants thereof".

Separate claims were also included for "fungal cultures" of these organisms and various aspects of the methodology.

For commercial reasons, and in view of the uncertainty as to the validity of microorganism per se patents at this date, the cultivation process for producing the edible mycelial protein was covered separately in UK patent 1,346,062. This also contained claims to the end product of the defined process, the "edible protein-containing substance" itself.

Table 23.2
Recombinant DNA patent claims

(1)	Recombinant protein products (and alleles, variants, derivatives)
(2)	DNA sequences coding for the products of (1)
(3)	Vectors containing the DNA sequences of (2)
(4)	Microorganisms, cell lines, and other organisms transformed with vectors (3)
(5)	Processes of producing products as in (1) by expression of DNA sequences (2) in a recombinant host organism

In the USA, protection for the strains by means of the ordinary "utility patent" was not acceptable to the U.S. Patent Office, so the applicants resorted to the unusual measure of protecting them under the plant patent law, which extends to fungi. Plant patent 4,347 covers the commercially important isolate. Three U.S. patents were apparently necessary to protect all aspects of this development, including the basic process (U.S. 3,937,654), the fungal cultures (U.S. 4,294,929) and the "Article of Manufacture" claims (U.S. 4,061,781). Distribution of the various claims to the technology over separate patents is usually required by official search and examination criteria but is sometimes done tactically by the applicant for licensing and other business reasons.

All these early patents have expired but later patents may still be in force covering subsequent developments of this commercially successful product (QUORN, Registered Trade Mark).

23.5.2 Mushroom (Mutant Strains)

In view of the Chakrabarty decision in 1980 it was no longer possible for the U.S. Patent Office to refuse patents for novel microorganisms, although in many instances it was necessary to restrict the claim to a "biologically pure culture" of the novel strain, newly isolated from nature or obtained by a mutagenic and selection process. U.S. patent 4,608,775 is a good example of a claim to certain fungicide resistant strains of *Agaricus Bisporus* produced by irradiation of commercially available strains followed by a special selection procedure. The derived strains were deposited at the Commonwealth Mycological Institute (England) and the patent claims refer to their accession numbers, this being a common practice for mutants.

23.5.3 Yeast Strains

Novel yeast strains were among the first types of microorganism to be patented. The earliest known patent of this kind is U.S. 141,072, granted to Louis Pasteur in 1873 for "yeast free from organic germs of disease, as an article of manufacture." Nowadays this would be claimed as "a biologically pure culture" in U.S. patent practice.

In the UK, patents were frequently obtained for brewers' and bakers' yeasts developed by breeders for some special advantage. As clearly useful in food or beverage manufacture, these aroused no controversy.

In more recent times, yeasts have been patented in terms of their possession of specific properties, as meeting some manufacturing requirement. For example, in UK patent 1,539,211, the yeast is claimed in terms of the volumes of gas released in certain established tests (A'3 and A'4), these being the criteria discovered by the patentee as indicative of suitability for fermenting sweetened dough. This patent was upheld in Litigation.

In European patent 8554, a similar approach to claim drafting succeeded. The claim defines the strains by reference to the amounts of gas released in four specified tests, A'1 to A'4. In the patent description these strains were produced by derivation from a parent strain α 1217, itself on deposit with two Culture Collections. The patent was opposed on the ground that the claim was too broad because no instructions were given for deriving the yeasts from any other strain than the deposited strain. This argument failed and the patent was maintained without limitation.

23.5.4 Trehalose

The disaccharide trehalose is an attractive food sweetener and has other useful properties for use in foods. It is produced by fermentation or enzymatic conversion methods.

U.S. patent 5,858,735 is directed to producing trehalose in high yields by cultivation of *Pleurotus eryngii*. The claims as originally filed also covered the use of some other

named species of *Pleurotus*, but the finally allowed claims were limited to use of *P. eryngii* in view of the unexpectedly high yields obtained with this species.

Genetic modification of various organisms to produce increased yields of trehalose and to benefit transformed organisms also in other ways is described in U.S. patent 5,422,254. Genes encoding the long and short chains of yeast trehalose synthase were isolated, sequenced, cloned, and used to transform yeast. This patent also indicates how the methodology can be extended to transform crop plants. The patent claims the isolated DNA fragments defined by nucleotide sequence, vectors containing the DNA, transformed yeasts, and the corresponding fermentation process technology. It was necessary to distinguish this invention from an earlier published European patent application 0451896 which had referred to a trehalose 6-phosphate synthase gene but without disclosing its isolation or sequence. This lack of "enabling disclosure" in a cited prior reference frequently provides a way of discounting any relevance it might be thought to have as prior art.

23.5.5 Extracted Proteins

23.5.5.1 Chocolate Flavor

Two patents have been granted in the U.S., Europe, and UK for proteins extracted from cocoa beans (*Theobroma cacao*) which are in part responsible for chocolate flavor. These claim, respectively, an extracted (or extractable) 23kD protein and a 67kD protein, both of defined amino acid sequence or partial sequence. The 67kD protein is thought to be the primary translation product which is processed *in vivo* to produce 47kD and 31kD polypeptides.

These patents also claim the isolated or recombinant nucleic acid encoding these proteins, and the chemical synthesis or microbial biosynthesis of the proteins by which large amounts of product are obtainable. The ultimate commercial purpose of this technology is at present uncertain. The patents are:

23kD
- U.S. 5,668,007
- GB 2,260,327
- EP 586372

67kD
- U.S. 5,770,433
- GB 2,260,328
- EP 535053.

23.5.5.2 Brazzein Sweetener

Heat resistant protein sweeteners, with long lasting taste, isolated from *Pentadiplandra brazzeana Baillon,* or produced recombinantly from the DNA of defined sequence, are covered in U.S. patents 5,326,580, 5,346,998, and 5,527,555. Patents of this type give rise to debates over bioprospecting (termed by some as "biopiracy").

23.5.6 Flavorsavor Tomato

The basic principle of antisense regulation of gene expression in plants was covered by U.S. patent 5,107,065 (Calgene Inc.) which has a broad claim to inserting DNA into a plant cell which is transcribed into RNA complementary to indigenous RNA for the gene concerned. This covers application to all plants. A specific claim to the use of the method

for tomatoes, by reducing expression of the polygalacturonase gene, is covered in Calgene's U.S. 5,453,566; this also has product claims to the resulting tomato plant cells and plants. An interference between Calgene and ICI on this development was settled out of court. In Europe, ICI obtained EP patent 0271988 for the use of those parts of the gene for which they had the earlier priority date. This patent is also relevant for use with processed tomatoes and the production of tomato puree.

For various reasons, these technologies are not currently in commercial use.

A later patent for achieving ethylene mediated response in the tomato by targeting the E8 gene is covered in U.S. 5,545,815 (Regents of the University of California).

23.5.7 Soybean Cultivar

New plant varieties produced by traditional plant breeding methods, e.g., involving crossing parental varieties and backcrossing to one of the parents, are unpatentable in Europe. Such methods are categorized as essentially biological and are excluded on this ground. The U.S. patent law is more generous and allows for patents for varieties of this type provided the method or product is assessed as inventive in some respect.

One example is U.S. patent 5,750,856 for a soybean cultivar having resistance to Roundup™ herbicide and high yield potential. The variety is designated 93149194423034 and seeds have been deposited with the American Type Culture Collection (ATCC) under Accession No. 209546. The patent claims seeds, plants, pollen, ovules, tissue cultures, and regenerated plants of the claimed variety, as well as the methodology to produce hybrids of this and other varieties. This type of claim structure is usual in such cases.

It appears that no corresponding patents have been applied for in other countries. This is not unexpected for reasons given earlier.

23.5.8 Golden Rice™

Technology has been developed (4) to raise levels of Vitamin A or the Vitamin A precursor, beta-carotene, in rice, and thereby to respond to the nutritional needs of peoples for whom rice is the most basic food crop.

This strategy, initiated by I. Potrykus and P. Beyer, is described in published International Patent Application WO 00/53768. It entails the insertion of 3 genes into the rice plant to complete the beta-carotene biosynthetic pathway. This application has not yet matured into granted patents in the many countries designated in the application, but the claims contemplated by the applicants can be seen in the published application.

One of the claims in WO 00/53768 is directed to:

> An isolated DNA molecule comprising a nucleotide sequence providing one or more expression cassettes capable of directing production of one or more enzymes specific for the carotenoid biosynthesis pathway selected from the group consisting of: 1) phytoene synthase derived from plants, fungi, or bacteria, 2) phytoene desaturase derived from plants, fungi, or bacteria, 3) carotene desaturase derived from plants, and 4) lycopene cyclase derived from plants, fungi, or bacteria, under the proviso that an expression cassette capable of directing production of phytoene synthase alone is excluded.

Additional claims cover vector systems containing the DNA and transgenic plants containing the DNA.

To achieve this strategy, and in addition to the proprietary genes, the methodology involves the use of a number of plant transformation vectors, promoters, and antibiotic resistance markers which are the subject of previous patent applications and granted

patents held by various owners or covered by material transfer agreements. These are listed in the ISAAA Brief. ISAAA refrained from recording conclusions as to the relevance of each and every one of these prior rights, but they point to alternative strategies for international organizations concerned with facilitating the introduction of the genetically improved rice varieties into developing country agriculture.

This case is a striking example of the complications sometimes encountered in achieving the desired objective. But, as pointed out by ISAAA, patents are territorially restricted. Not all of these prior patents may be granted (or may have even been applied for) in the rice-growing countries, in which case public research bodies would be able to exploit the technology without undue restriction in these countries. One of the relevant patent holders (Monsanto, 35S promoter) has been reported as willing to make its technology freely available to those wishing to promote gm rice (*Science*, Vol. 289, 11 August 2000).

23.5.9 Bovine Somatotrophin

For more than 50 years it has been known that the administration of bovine somatotropin to dairy cows will increase milk yield and cause other desirable effects. Possible commercial exploitation of this finding came under active consideration in the late 1970s but appeared prohibitively costly at that time. A perfunctory patent search carried out for the purposes of this chapter shows that it was not until the 1980s, when recombinant DNA technology came into its own and was being applied to human growth hormone that work began seriously on the use of BST in beef and dairy farming. Some perspective on the development of this technology may be obtained by a study of selected examples from the extensive patent literature on this subject, listed in roughly chronological order.

The increase in the mammary parenchyma caused by administration of growth hormone between the onset of puberty and the first parturition was disclosed in U.S. patent 4,521,409, applied for in October 1983 (Cornell Research Foundation). Although very brief in terms of detail, it mentions the possibility of using the recombinant hormone, by then "known in the art." Ensuring the proper conformation of the protein by treatment with 2-amino-2-methyl 1-propanol is the subject of U.S. 4,975,529 (Monsanto Co).

Subsequent patents issued for specific formulations of the hormone which gave improvements of various kinds. For example, U.S. patent 4,977,140 first applied for in August 1985 (Eli Lilly & Co) refers to somatotropin produced in various genetically modified organisms and formulated with a carrier composed of wax and oil. U.S. patent 5,004,728 is directed to obtaining an improvement in milk yield by the coterminous administration of the hormone and a long chain fatty acid.

A major advance came with the work of the Monsanto Co. in the development of an oil-based formulation designed for prolonged release of the hormone. This is represented by a series of patent applications originating as far back as October 1984, and prosecuted as continuation applications, maturing into patents granted from 1991 onward. Thus U.S. 5,013,713 contains method claims directed to the use of a nonaqueous composition comprising from 10% or more of BST in a continuous phase of a biocompatible oil. A later patent issuing from this series in 1997 is U.S. 5,595,971, with product claims directed to the composition itself, in which BST, which may be in metal-associated form, is dispersed in a biocompatible oil containing an antihydration agent which retards penetration of the oil by aqueous body fluids after injection. These two significant patents are especially relevant to the commercial product produced by the patent owner.

An interesting diagnostic test for animals that have been treated with BST is disclosed in U.S. patent 5,135,401, based on the fact that treated cows have lower levels of phosphorylation of fatty acid binding protein in milk fat globules.

According to U.S. 5,106,631, improved cheese quality is obtained from milk in which the BST concentration is maintained less than 0.2 mg/l in order to regulate the plasmin level.

As might be expected, patents soon began to issue on variant forms of somatotropin made possible by protein engineering. Thus, U.S. 5,089,473 applied for in August 1988 (Monsanto Co), is directed to the use of site-specific mutagenesis of the starting gene to replace asparagine by glutamine in the region of residues 95–101 thus improving the stability, and hence recovery, of the recombinant product. Related to this (but separate from it) is U.S. 5,130,422 which covers the corresponding encoding DNA. Another patent of this type is U.S. 5,631,227 (The Upjohn Co) filed in June 1985 but, again, stemming from a series of more than ten earlier related applications. This specifies a replacement of Asparagine 99 by aspartic or glutamic acid. On the front page of this patent, where prior scientific literature and prior patents are cited as "prior art" the list includes the preceding example (U.S. 5,130,422).

Stabilization of BST to minimize aggregation by reacting the 183 and 191 cysteine SH groups with ethyleneoxy-type derivatizing reagents is covered by U.S. 5,951,972. A similar approach is found in U.S. 6,010,999. In U.S. 5,891,840, stability is enhanced by altering or eliminating at least one of the 4 cysteine residues by replacement, modification, deletion, or chemical derivatization.

23.5.10 Detecting Microbial Contaminants

A considerable body of patent literature exists on methods of detecting pathogenic microorganisms in clinical samples, water systems, foods and other materials. Molecular biological methods utilize nucleic acid probes specific for many bacterial species and presented in various forms to hybridize to products obtained after performing polymerase chain reaction (PCR) or other methods of amplification of DNA or RNA in the test sample. Method claims are common in this field but novel probes can be patented as products where appropriate, as well as the ingenious ways in which probes are displayed on support structures.

One method of detection, designed to identify a number of different species in a single test, is described in International patent application WO 00/52203. The method targets a specific segment of 23 S ribosomal DNA common to a wide variety of bacteria and uses defined "universal" primers to amplify this sequence, following which the resulting mixture of amplicons is probed with a set of organism specific oligonucleotide probes immobilized on a hybridization membrane. Although originally invented in a hospital context, the method has many other possible applications.

U.S. patent 5,498,525 makes use of bacteriophage, specific to target organisms, and is said to enable organisms such as Salmonella and Listeria to be assayed in hours rather than days. Phage added to the test sample is taken up by the specific bacteria, if present, following which any nonabsorbed phage is inactivated or destroyed. Incubation is continued and phage is released from the bacteria and can be assayed. A convenient assay makes use of reporter bacteria which have been genetically modified to express a suitable signal when triggered by phage infection, e.g., luciferase. This invention is distinguished from the previously known and allegedly less convenient use of phage which has itself been genetically modified to express the signal directly.

23.6 CONCLUDING REMARKS

The documents cited are exemplary of the wide variety of subject matter that can be protected by patents and they have been selected from an extensive patent literature in their respective fields. It is common in many such areas of research to find that only a minority

of the patents granted are key patents in terms of commercial importance, and only a minority of patent holders are in sustained commercial development. In the early stages of any project it is often not clear what will prove essential to the technology finally adopted for commercial exploitation and so, in the interim, a fairly deep purse may be needed to maintain all the likely candidate patent applications and patents in force. Fortunately, patent costs are not all upfront costs and the major burden can be spread over extended periods during which the value of specific items can be assessed. Continual review of patent portfolios against agreed budgets will therefore be essential to all who make use of the potential of patent law to promote their interests, be they industry or public research organisations.
