Altruism and Duty

In his article "Professionalism and Humanism beyond the Academic Health Center," Swick (2007) suggests using the humanities to show our own personal humanity. Swick's article includes a list of selected works by physician authors that he believes convey the values of humanism and professionalism. Inui (2003) emphasizes the link between personal and professional growth and development that can be further enhanced through such mechanisms as ethics training and social medicine courses—history, medicine, health, and society.

There are two established professional development small groups to consider; Balint groups and "Literature & Medicine: Humanities at the Heart of Health Care." The aim of a Balint group is to help the doctors with the psychological aspect of their patients' problems—and their problems with their patients. The focus of the work is on the doctor-patient relationship. Additional information about Balint groups and workshops can be found on their Web site.

Literature and Medicine: Humanities at the Heart of Health Care was created by the Maine Humanities Council and is a workplace program that gives people involved in the delivery of health care an opportunity to come together and reflect on their roles as health care providers through the medium of literature. Detailed information of the program is available on their Web site.

Confront the Facts

In addition to all of the efforts medical schools make to include the elements of Professionalism in their curriculum, we must add one more—"Confront the Brutal Facts." In his book *Good to Great*, Jim Collins (2001) devoted an entire chapter titled "Confront the brutal

facts, yet never lose faith". Based on the author's extensive research, one of the elements that enables companies to become great is their ability to confront the most brutal facts of reality while maintaining faith that they will prevail regardless of difficulties. Based on Collin's guidance, the osteopathic profession needs to foster a "climate where the truth is heard." We must help our students and ourselves move through their grief process to find acceptance (Kübler-Ross, 2003); and to be forthright about the fact that the daily application of professionalism is a continuous struggle. The majority of physicians are high academic achievers striving for the "A" in all areas of medicine, including professionalism. The brutal truth about professionalism is that it is composed of a number of important elements that must be done the best that we can in the face of resource limitations and at times, conflicting priorities.

As a case in point, let's take compassion and medical knowledge, two fundamental qualities of professionalism. While a student might achieve an "A" in compassion by spending an extra 30 minutes with an upset family member; he/she sacrificed an obligation to pursue medical knowledge by missing noon lecture. Although this is admittedly a simplistic example, the message is absolutely crucial for creating an environment where the truth is heard. We must encourage acceptance of the struggle involved in balancing conflicting demands while attempting to embody the multiple elements of professionalism. We must also affirm that fact that in spite of the difficulties we face each day, on balance, professionalism prevails because of our devotion to it and our steadfast determination to keep trying to do the very best that we can at it.

Authenticity is the Heart of Professionalism

Professionalism comprises a set of expected behaviors. Institutions select the behaviors of professionalism that will be measured to determine competency (Cohen, 2007). There is another important element of professionalism—caring—which is harder to quantify. Caring, also described by Cohen as humanism, denotes an intrinsic set of "deep-seated convictions about one's obligations toward others." It is possible for physicians to "go through the motions" of professional behavior without actually believing in the virtues that support them (Cohen, 2007). The bond between the *behaviors* of professionalism and the *attribute* of caring is critical to the delivery of meaningful health care and is sustained by the osteopathic physician's ability to be authentic. "All humans have authenticity detectors... that psychic mechanism by which we can recognize the ring of truth that helps us determine if that person is trustworthy" (Spence, 1995). We fuel our authenticity by telling the truth about ourselves which in turn strengthens the trust in our relationships. For example, physicians are often reluctant to admit that "they don't know," concerned that this disclosure would undermine the patient's confidence in their care. However, the act of fabricating a diagnosis when the physician is unsure is readily picked up by the patient and could actually undermine the patient's trust and confidence in that physician. When we dare to tell the truth, all the elements of communications, physical and verbal, automatically come together to deepen our authenticity.

Professionalism is a Journey

The osteopathic physician does not become a professional but rather chooses to be professional daily. The truth about our days is that even when they are carefully planned with our very best "time-management" skills, circumstances will arise that are unplanned, competing, and all worthy of our full attention. What do we do? Employing the concept developed by the Covey team of "integrity

in the moment of choice" is one approach (Covey et al., 1994). Covey writes that we increase our ability to act with integrity when we "pause; ask with intent, listen without excuse and act with courage," it includes asking questions such as "What's the best use of my time right now?" It is important to avoid rationalizing your choices and to choose your actions based on enduring principles (Covey et al., 1994). Professionalism is processed based, and it demands daily effort and regular self-examination.

SUMMARY

Professionalism has been a cherished ideal since the foundation of osteopathic medicine. Although much has been done in recent years to better delineate the traits and behaviors associated with professionalism, it still remains a personal journey for each physician.

KEY CONCEPTS

- The experience of illness has a powerful effect on individuals, perhaps the determining factor in the eventual outcome.
- Personality factors have been shown to affect the development of certain illnesses.
- The biopsychosocial model of patient care correctly conceptualizes components of disorders, but may not differentiate the degree to which these factors are present in particular disorders.
- Disorders affecting relatively young, healthy people with little evidence of attendant increased mortality can be effectively treated using a purely psychological or “mind-body” approach.
- The unconscious mind can perpetuate physical symptoms that begin with a clear physical cause.

INTRODUCTION

As George Engel (1) pointed out in 1977, all patients with an illness have physical, psychological, and social components that interact in complex relationships to impact the onset, course, and outcome of their illness. The experience of illness has a powerful effect on individuals and, for some patients, may become the determining factor in the eventual outcome. In addition, factors such as social support, stable living situations, and personality factors have been shown to play important roles in health outcomes (2).

For example, the Canadian Health Study found that an individual's perception of health was more highly correlated with longevity than were other more objective measures of health, such as the number of chronic diagnoses (3). The Alameda longitudinal study found that individuals with higher levels of social support (defined as being married, being involved in religious or social groups, or having close friends) had 50% lower mortality over the course of 9 years (4). Conversely, depression is associated with increased mortality after a myocardial infarction (5).

Personality factors have also been shown to affect the development of certain illnesses. The longitudinal study of physicians and attorneys from the University of North Carolina showed that those who reported higher levels of hostility and anger during graduate school were more likely to develop myocardial infarctions and had higher mortality rates later in life (6). Hostility also appears to predict cardiovascular mortality among middle-aged men (7). Stress and emotional reactions to stress have been shown to alter a variety of markers that are associated with poor health outcomes, such as tissue necrosis factor, interleukin 6, and C-reactive protein (2,8).

When the biopsychosocial model of patient care was proposed, it provided physicians with a way to conceptualize illness and the relationship between the patient and the illness. In this model, there is an interaction between the physical disease process (pathologic changes in the body), the psychologic makeup of the individual, and the social milieu of the patient. A generation of physicians and psychologists has used this model in research and patient care to elucidate complex relationships between illness and disease. Although this model correctly points out that all disorders have components of biologic, psychologic, and social determinants, it may not differentiate the degree to which these factors are present in particular disorders.

Cancer and cardiovascular diseases comprise the major causes of mortality in the United States and have a clear age-related prevalence. Although there is significant literature documenting relationships between these diseases and psychological factors, there is little evidence that psychosocial interventions affect the course of the pathological disorder and virtually no evidence that these disorders can be cured by psychosocial treatments (9,10). It may be inferred that psychosocial treatments are best characterized as helping to cope with the effects of these primarily biologic processes.

A second group of disorders can be considered to have more equal balance between biologic and psychosocial factors. Disorders such as asthma, rheumatoid arthritis, and inflammatory bowel disease cause clear pathologic changes, but they also occur in younger individuals and can follow a course that is mild, moderate, or severe. There is some literature to suggest that psychosocial interventions can improve the symptoms in these disorders, but true cures appear to be less likely (11). Psychosocial interventions can be considered for these disorders to attempt to decrease exacerbations of the underlying process.

A third group of disorders is the subject of this chapter: disorders affecting relatively young, healthy people with little evidence of true pathologic changes in the body, nor evidence of increased mortality due to the disorders. These disorders comprise a wide range of syndromes but can be grouped into pain syndromes (including headaches, migraine, back pain, neck pain, whiplash, fibromyalgia, temporomandibular joint syndrome, and chronic abdominal and pelvic pain syndromes), autonomic nervous system (ANS)-related disorders (including irritable bowel syndrome, interstitial cystitis, postural orthostatic tachycardia syndrome, reflex sympathetic dystrophy, and functional dyspepsia), and neurologic-psychologic syndromes (including insomnia, fatigue, paresthesias, and tinnitus). These disorders are not generally considered to be psychosomatic disorders; however, there is ample evidence that these disorders are primarily caused by physiologic, rather than pathologic conditions within the body and that they can be effectively treated using a purely psychological or “mind body” approach (12,13).

Table 27.1 outlines the differences between these three categories of illness vis-à-vis psychological processes.

TABLE 27.1

Physical, Psychological, and Social Interactions

Group	Examples	Epidemiology	Role of Psychological Factors	Treatment Aim Biomedical/Psychological
1	Cancer CAD	Increases with age; mortality common	Associated but not causative	Rx disease/cope with stress
2	Asthma IBD RA	Young to middle age; morbidity common	May cause exacerbations	Rx disease/prevent exacerbations
3	HA, LBP, Fibromyalgia Whiplash	Young to middle age; no mortality; no tissue destruction	Causative of symptoms	Rx symptoms/control or cure

CAD, coronary artery disease; IBD, inflammatory bowel disease; RA, rheumatoid arthritis; HA, headaches; and LBP, low back pain.

HISTORICAL BACKGROUND

In 1934, Harriman reported a case of a former nun who secretly got married but suddenly developed paralysis of her right arm at the very moment at which she was going to convey this news to her family in a letter (14). This is an example of a conversion reaction caused by great conflict in the unconscious mind of this patient. In the 1600s and 1700s, common consequences of stressful events and strong unconscious emotions were so-called hysterical paralysis and hysterical seizures (15).

Changes in society and advances in medicine (e.g., discovery of deep tendon reflexes, which could quickly distinguish organic from psychogenic paralysis) caused these syndromes to greatly diminish in occurrence. When a medical condition is clearly viewed as being psychogenic by a culture (and by the medical profession), the unconscious mind will be less likely to produce that syndrome. However, humans continue to experience great stresses and strong emotions and these emotions are commonly manifest as physical (and psychological) symptom complexes. Therefore, paralysis and seizures have been replaced in the 21st century with chronic back pain, fibromyalgia, fatigue, irritable bowel syndrome, and other similar disorders (15).

In 1950, Hans Selye described the General Adaptation Syndrome in rats who had been subjected to stress in the laboratory. These rats showed signs of immune dysfunction (shrunken thymus glands) and ANS overactivity (peptic ulcers and enlarged adrenal glands) (16). Building on the prior work of Walter Cannon, who described the fight or flight response (17), this ushered in the era of understanding that stress and emotional disturbances could cause physical changes in the body. In 1975, Robert Ader found that rats given cyclophosphamide in bowls of saccharine (with its characteristic taste) developed immune suppression that was reproducible when they were later exposed simply to saccharine (18). These findings (which have been reproduced in humans) (19) confirmed that the mind can cause physical disorders via the sympathetic nervous system and that these pathways can be conditioned by classic behavioral techniques.

In the 1970s, Dr. John Sarno, a rehabilitation physician in New York City began to question the conventional wisdom of ascribing most chronic back and neck pain to musculoskeletal derangements in the spine (20). He noted that radiological imaging studies were often predictive of neither the level of pain or neurologic symptoms, nor the course of the illness. Since then, several studies have documented that MRI findings have little correlation with low back

pain (LBP). For example, in those without LBP, 64% were found to have disc bulging, protrusion, or extrusion (21). In follow-up studies, the development or persistence of back pain shows no correlation with MRI findings (22,23). Despite increased spending for surgery, injection therapies, and other modalities, disability for back pain has risen in the last decade (24). Noting the lack of efficacy for these therapies, Deyo and colleagues have suggested that invasive treatments be curtailed (25).

Dr. Sarno explored the theory that stressful situations, the response to stressful situations, and both conscious and unconscious emotions were the actual cause of the physical symptoms seen in many of his patients. He developed a psychoeducational approach for these patients and has found success in curing patients with chronic musculoskeletal symptoms. In addition, he has found that many patients had concomitant symptoms in other systems (such as GI and GU systems) and psychiatric symptoms (such as anxiety, depression, insomnia, fatigue) improved along with the musculoskeletal symptoms when some of the underlying psychological issues were identified and addressed. The key component of this approach however is not in the psychological treatment modalities, but in the recognition that while the physical symptoms are real, these symptoms are not due to a pathologic derangement in the body, but that they are caused by mental processes and therefore they can be cured with a purely psychological approach (26).

NEUROPSYCHOPHYSIOLOGIC MECHANISMS OF MIND-BODY SYNDROMES

The mechanisms for psychophysiological dysfunction producing psychosomatic syndromes have begun to surface in recent years. There are two distinct pathways involving the CNS, by which musculoskeletal pain can be amplified and/or reduced. The current prevailing paradigm for physiological pain modulation—the gate-control theory—acknowledges that an individual's emotional state can modulate the perception of pain (27).

An area of the brain known as the “rostral anterior cingulate cortex” (rACC; sometimes referred to as the “medial prefrontal cortex”) is known to modulate the intensity of pain that an individual perceives (28,29).

The psychological function of the rACC has been described as generating the emotional response to a perceived error (30).

In contrast to the rACC, the dorsolateral prefrontal cortex (DLPFC) is able to decrease the perceived intensity of pain, in part

by inhibiting the rACC (31). The role of the DLPFC in reducing perceived pain intensity is further supported by studies that show atrophy or neurodegeneration of this brain region in patients with persistent LBP, compared to controls (32–34). Among the many psychological functions of the DLPFC, the most pertinent to our discussion is its role in the interaction between cognitive and emotional processing. The DLPFC has been shown to be activated by praise and feelings of positive self-worth (35).

In addition to the above mechanisms, researchers have shown that stress causes increases not only in cortisol but also in inflammatory cytokines such as tissue necrosis factor- α and nuclear factor kappa-B (NF- κ B) which induces expression of proinflammatory cytokines such as TNF- α , interleukin-6, and interleukin-1 β (36). All of these cytokines are known to cause sensitization of peripheral nociceptors which lead to increased pain (37,38).

Figure 27.1 describes a hypothesis of the mechanisms that underlie psychosomatic syndromes. The process may start with an injury or significant conscious or unconscious stressors, but the syndrome may become perpetuated by sensitization of afferent nerve fibers, amplification of signals by the amygdala and the anterior cingulate cortex, and reinforcement of efferent signals in the ANS. These processes all occur in the unconscious part of the brain. Conscious and willful activity in the DLPFC can attenuate these processes as shown (39,40).

PSYCHOLOGICAL ISSUES

Numerous studies document the role of the unconscious mind in determining human behavior. For example, being presented with words such as old, wise, retired, and gray in a word experiment caused those participants to walk slower than a control group (41). People who were shown subliminal words related to assertiveness later were more likely to interrupt the investigator than those who were shown subliminal words related to politeness (42). People who briefly held an iced coffee drink in their hand rated a stranger as being less friendly than did people who held a warm cup of coffee (43). It is estimated that approximately 95% of our thoughts and feelings reside in the unconscious mind and while a human

brain can take in about 11 million bits of information each second, the conscious brain can only process about 40 bits of information in a second and that the vast majority of our thoughts and emotions occur in the unconscious mind (44).

The unconscious mind can perpetuate physical symptoms that begin with a clear physical cause, such as a car accident or an injury. In these cases, the mind may “use” the opportunity of the accident in order to develop pain that serves a function for the individual, such as relieve them from a difficult work situation. A study that created a sham (or placebo) car accident showed that 10% of the participants had neck pain 4 weeks after the “accident,” even though their necks did not move during the sham accident. Those who were most likely to develop neck pain were those who were under the most stress and emotional distress at the time of the accident (45). In contrast, demolition car drivers who have an average of over 150 crashes per race rarely develop chronic neck pain (46). And a study of people involved in motor vehicle accidents in Lithuania showed no difference in neck pain or headaches compared to a group of people who had not been in car accidents, suggesting that whiplash is potentially a “culture-bound syndrome” (47).

The unconscious mind is also more likely to produce symptoms that run in the family, for example, headaches and abdominal pain, or symptoms that are discussed in magazines and television shows or advertisements. Another mechanism for the “choice” of a particular symptom complex is due to prior learning. For example, someone who had an injury to a certain area is more likely to develop psychogenic pain in that area since the neurological pattern of pain and nerve sensitization has been produced in the past and is remembered by the brain.

Finally, some symptoms are symbolically representative of a clear psychological process, such as a man who develops groin pain after an extramarital affair. It appears that the unconscious mind is likely to produce physical symptoms at times of severe stress as an outlet or an escape mechanism for the buildup of unacceptable emotions that have no outlet. It is also possible that the unconscious mind is alerting the individual to what it perceives to be dangerous situations through the development of pain. For example, a woman who migrated to the United States from India developed

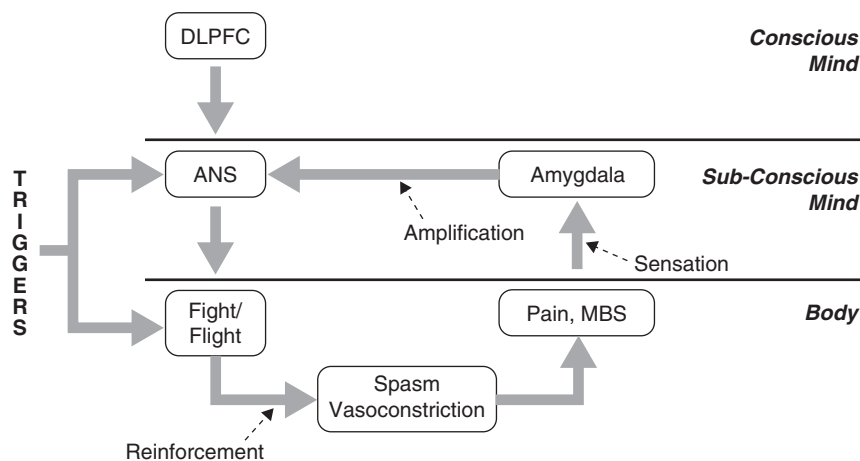

Figure 27-1 This figure represents the theorized pathways that produce and perpetuate the mind-body syndrome. These pathways can begin due to an injury or stressful events that produce strong unconscious emotions in the amygdala. Afferent sensory nerves develop sensitization over time and send signals to the amygdala. Signals in the brain get amplified by emotions and the ANS activates the fight or flight mechanisms, which produces muscle spasm, and vasoconstriction, which worsens the physical symptoms in the body. These pathways get reinforced over time and this creates a vicious cycle of pain and increased emotional responses. A variety of triggers (such as certain positions, places, weather changes, foods, or situations) can act as conditioned responses and add to the neurologic pathways that perpetuate pain. In the conscious portion of the brain, the DLPFC area can act to attenuate and break the cycle at the level of the ANS.

fibromyalgia at a time in her life when she was beginning to think of doing some more things for herself such as taking classes at a local college. However, her husband took an extra job, she had three adolescent children who required a great deal of attention, and then both her mother-in-law and her brother moved into the home. Being a dutiful person who was obligated to others before her own desires, she put aside her own desires and she sublimated her feelings of resentment. Her body reacted to this set of stressors and repressed emotion with a widespread painful process, which responded to the psychological intervention mentioned below.

Another example is that of a firefighter who developed neck pain after a fall in a burning building and was on disability from work due to severe neck pain. Although he had similar injuries in the past and had bounced back from them, this fire was different because it caused the death of one of his friends. Following the fire, in his conscious mind of course, he wanted to improve and return to work; however, his unconscious mind would not let him and found a way to create pain, which prevented him from returning to active duty. Once he understood that there was no significant pathological process in his neck and that the underlying cause of his pain was due to emotions triggering a pattern of nerve pathways creating pain, he completed the psychological interventions described below and had a dramatic resolution of his symptoms allowing him to return to work. Table 27.2 outlines conditions for which a psychosomatic etiology is common.

MANAGEMENT OF MIND-BODY SYNDROMES

Current treatment approaches to patients with these unexplained symptom complexes consist of pain medications, modulators of pain perception, such as pregabalin and gabapentin, exercise, osteopathic manipulation, and physical therapy. These modalities are all successful in many patients; however, certain patients do not respond and

appear to require alternative approaches. Psychological approaches typically consist of cognitive behavioral therapy and stress reduction. Studies using mindfulness meditation have shown a reduction in pain for patients with chronic musculoskeletal pain (48) and fibromyalgia (49,50). Cognitive-behavioral therapy, which works in part by reducing psychosocial stress, has also been shown to be effective in chronic musculoskeletal pain (51–54). Finally, studies using therapeutic writing techniques in fibromyalgia have shown reductions in pain comparable to standard pharmacological therapy (55,56).

A model for treatment of these “mind-body syndromes” consists of the following steps. First, each patient is asked to read *The Mindbody Prescription* by Dr. Sarno (26). This gives the patient a basic understanding of how physical symptoms, which are real, located in the body and often severe, can be caused by conscious and unconscious emotional turmoil.

Second, each patient has a 60 to 90 minute office visit to rule out any physical disorders that require conventional medical attention and to search for patterns of psychosomatic symptoms across their life span beginning in childhood. It is important to listen carefully to the patient’s life story and to help them uncover particular stressors and emotional reactions that have triggered such psychosomatic symptoms. It is useful to attempt to help the patient understand the role of conditioned responses that serve as stimuli triggering the neurologic pathways that have developed over time (e.g., certain positions, activities, weather changes, foods, locations).

It is necessary to explain the physiologic pathways between the emotional centers of the brain (amygdala) and the ANS, which creates the physiologic substrates of pain and other symptoms (e.g., sensitized nerve pathways) in order to help them understand the role of the unconscious mind in producing emotions that can produce significant physical symptoms despite being suppressed.

It is critical to normalize and destigmatize psychosomatic disorders and accept them as a part of being “human,” and to explain how simple psychological techniques can alter the vicious cycle of pain and offer hope that their symptoms are curable.

An important step in the treatment process is patient participation in a 4-week seminar. Participants receive a workbook and instructions for performing specific therapeutic writing exercises to help them express emotions and better cope with prior and current stressors, specific meditative exercises based on mindfulness meditation developed for this purpose, specific declarative and affirmative sentences that are spoken to oneself as a method for disrupting patterns of neurologic connections that promote symptoms, and exercises to develop and carry out activities that previously caused symptoms or are pleasurable and desirable.

Finally, follow-up is conducted to plan for the future depending on the response obtained to this program. Patients may require individual psychotherapy as an adjunct to the program. The program is also available on the internet (57) and in a self-help book (58).

In 1976, Ivan Illich warned of the potential iatrogenic consequences of a classification of disease that labels patients (59). When patients with psychosomatic disorders are labeled as having degenerative disc disease on the basis of an MRI or as having fibromyalgia on the basis of an arbitrary classification system, the stage is set for a vicious cycle of exacerbation of symptoms and of psychologic status. Eugene Carragee also warned of this process occurring in patients with back pain, “ill-considered attempts to make a diagnosis on the basis of imaging studies may reinforce the suspicion of serious disease, magnify the importance of nonspecific findings, and label patients with spurious diagnoses” (60).

The tremendous advances in biomedical technology over the past several decades have led to an overemphasis on the biologic, while ignoring the psychologic and the social causes of common symptoms.

TABLE 27.2

Conditions for Which a Psychosomatic Etiology is Common

Types of Disorders	Clinical Conditions
Chronic pain syndromes	Tension headaches Migraine headaches LBP Neck pain Whiplash Fibromyalgia Temporomandibular joint syndrome Chronic abdominal and pelvic pain syndromes Chronic pain syndromes
ANS-related disorders	Irritable bowel syndrome, interstitial cystitis, postural orthostatic tachycardia syndrome, reflex sympathetic dystrophy, functional dyspepsia
Neurologic syndromes	Insomnia Chronic fatigue Paresthesias Tinnitus

In addition, there has been a surge in expenditures for complementary and alternative treatments. An alternative nosology of disease has been created by this movement and includes labels such as chronic yeast infection, chronic food allergies and deficiencies of natural hormones, gastric acid or various nutritional supplements. Such “diagnoses” can have similar effects to medical labeling, that is, turning a person with functional symptoms due to stressors into a patient with a “disease.”

APPLICATION TO PATIENT CARE

Therefore, in the course of routine patient care, it is critical for physicians to be aware of the probability that psychosomatic disorders will occur in most people during the course of their lifetime. A careful history and physical examination should include investigation into the potential for both organic and functional disorders; that is, examining not only for signs of nerve root compression, tumor, or infection, but determining the psychological and social factors that may have led to this set of symptoms at this point in a person's life.

The most important question to ask is “What was happening in your life at the time these symptoms began?” For patients who present with the new onset of headaches, bowel or bladder symptoms, or painful conditions that are not determined to have a clear pathologic basis, some amount of probing regarding stressors and underlying emotions may be required to uncover feelings of guilt, fear, resentment, or anger. Careful listening is important to validate the suffering of the patient and to reassure the patient that you take their condition seriously. Listening for and probing to obtain the psychosocial context of this point in a patient's life will allow the physician to understand the potential contribution of psychosocial factors in the illness and will serve as starting point for understanding and potentially curing those ailments that are purely functional.

It is critical to inform the patient with a psychosomatic illness that they are “not crazy,” but that these conditions commonly occur in most people. If the patient feels they are being told, “It's all in your head,” they will be less likely to improve. It is better to tell patients that all symptoms have a cause and we have to get to the root cause of the symptoms in order to cure them. A careful psychosocial history with emphasis on their childhood stressors as well as their adult stressors is necessary in order to uncover potential root causes. Looking carefully for temporal relationships between stressors (even mild stressors can precipitate significant symptoms if they trigger an emotional response connected to childhood stressors) is important to confirm a psychosomatic etiology.

Once a psychosomatic condition is diagnosed, the management should consist of the following:

Avoid excessive rest and disability. Encourage routine activities and exercise as tolerated.

Reassure about the lack of serious disease and inform the patient that they do have a condition. One useful term is “mind-body syndrome.” Emphasize that mind-body syndrome is real and that their symptoms are very real, but they are curable.

Avoid excessive testing and excessive referral to specialists who may be likely to reinforce the suspicion of serious disease. Explain the results of nonspecific test findings (such as degenerative disc changes) as findings that are within the range of normal.

Explain how the mind-body syndrome causes real symptoms and how physiologic mechanisms in the brain and body create this vicious cycle (see Fig. 27.1).

Consider a referral to a physician or psychologist who specializes in this condition or to a counselor who can help the

patient understand and cope with their childhood and adult stressors.

Give them resources, such as books by Dr. John Sarno or web sites such as www.tarpityoga.com or www.unlearnyourpain.com.

A tremendous amount of money is spent on the diagnosis and treatment of psychosomatic disorders. The majority of people will have physical and psychological symptoms at some time in their life due to psychological states. If psychosomatic disorders were widely recognized by the lay public and medical professionals (both traditional and alternative), there would be increased potential for alleviation of common symptoms, decrease in medical costs, and prevention of chronic symptom complexes. The treatment of these disorders requires a careful history, judicious use of diagnostic tests to rule out serious pathologic processes, attention to past and current psychosocial stressors and reactions to these stressors, validation of the real nature of the symptoms (“It's not all in your head”), explanation of the psychophysiology basis of functional symptoms, and brief educational and psychologic interventions. In this way, patients are empowered to gain control over their symptoms, understand themselves better, and obtain tools to improve their psychological states.

KEY CONCEPTS

- Spirit defined as an “animating or vital principle” can be viewed from a broad range of perspectives. For the physician, the patient represents the primary focus.
- Many people seek to discern the degree to which their own lives are aligned with this animating principle. For the astute clinician, individual patients are often the best guides.
- The role of the physician is to enhance the patient in her/his quest, and not to promote the physician’s personal value system.
- The nature of the human condition is such that illness and disease do occur. Physicians can do much to promote understanding and provide comfort.

INTRODUCTION

The starting point and the first stumbling block to treating a person in terms of body–mind–spirit is to understand what is meant by each of these terms. In osteopathic medicine, we feel they have come to represent a comprehensive approach to an individual. Elsewhere, body–mind–spirit has become such an increasingly popular term that it has been applied as a catchphrase, a means to promote a product. Interested readers who would like to verify the extent to which this term has become a marketing slogan are invited to do an Internet search. Ironically, a match for “osteopathic medicine” does not emerge. Chapter 27 has addressed the topic of mind–body interactions. This chapter will address the spirit component.

DEFINING SPIRIT

Teresa of Avila (1515–82), mystic and founder of the reformed Carmelites, stated, “I can’t understand what the mind is, or how it differs from soul or spirit. They all seem the same to me.” (1) Tenzin Gyatso, the 14th Dalai Lama, citing the Buddhist principle of emptiness, remarks that Buddhism does not recognize spirit as an independent part of a person:

... if we examine our own conception of selfhood, we will find that we tend to believe in the presence of an essential core to our being, which characterizes our individuality and identity as a discreet ego, independent of the physical and mental elements that constitute our existence. The philosophy of emptiness reveals that this is not only a fundamental error but also the basis for attachment, clinging, and the development of our numerous prejudices (2).

Hazrat Inayat Khan, who introduced Sufism, the mystical component of Islam, to the western world, writes: “... If we define spirit, it cannot be spirit; the spirit that can be defined cannot be spirit. The best definition of spirit is ‘that which is not matter’” (3).

Given that the religious community itself has difficulty in defining a term that at least by appearances belongs in that domain, let’s turn to historical and secular approaches. In the tradition of the Abrahamic faiths, spirit, *ruah* has an original meaning of breath, wind. A similar semantic development is found in the Greek *pneuma*. The English word “spirit” is derived from the Latin

spiritus but contains the basic meaning of “breath,” “blow” (4). In one dictionary, spirit is described as an animating or vital principle in man (and animals); that which give life to the physical organism, in contrast to it purely material elements; the breath of life (5). Spirituality, in a narrow sense, concerns itself with matters of the spirit, which is closely tied to religious belief and faith. Especially in modern America, many are concerned that a distinction be drawn between spirituality and religion. Here’s one useful formulation: “Spirituality is the way you find meaning, hope, comfort and inner peace in your life. Many people find spirituality through religion. Some find it through music, art or a connection with nature. Others find it in their values and principles” (6).

Andrew Taylor Still had strong spiritual feelings that were intertwined with his osteopathic philosophy. He stated “God is the Father of osteopathy and I am not ashamed of the child that is of his mind” (7). On the other hand, throughout *Osteopathy, Research and Practice*, Still described the osteopathic physician as a mechanic (8). He reasoned that the good osteopathic physician should know the cause of the problem, but he was not to waste time on the reason for the cause. Of the tenets of osteopathic medicine, published in Kirksville in 1953 (9), the first was equally blunt: the body is a unit. It was expanded with the publication of the first edition of *Foundations of Osteopathic Medicine* (10):

The body is a unit; the person is a unit of body, mind and spirit.

In that textbook, Irvin M. Korr, Ph.D., develops further this expansion of the concept of unity:

Important and valid as is the concept of body unity, it is incomplete in that it is, by implication, limited to the physical realm. Physicians minister not to bodies but to individuals, each of whom is unique by virtue of his or her genetic endowment, personal history, and the variety of environments in which that history has been lived. The person, obviously, is more than a body, for the person has a mind, also the product of heredity and biography. Separation of body and mind, whether conceptually or in practice, is an anachronistic remnant of such dualistic thinking as that of the 17th century philosopher–scientist, René Descartes. It was his belief that body and mind are separate domains, one publicly visible and palpable, the other invisible, impalpable, and private. This

dualistic concept is anachronistic because, while it is almost universally rejected as a concept, it is still acted out in much of clinical practice and in biomedical research. Clinical and biomedical research (as well as everyday experience) has irrefutably shown that body and mind are so inseparable, so pervasive to each other, that they can be regarded and treated as a single entity. It is now widely recognized (whether or not it is demonstrated in practice) that what goes on (or goes wrong) in either body or mind has repercussions in the other. It is for reasons such as these that I prefer unity of the person to unity of the body, conveying totally integrated humanity and indivisibility (11).

SCIENCE AND RELIGION

Judging from what we know of present-day primitive cultures, religion, magic, and medical treatment were seen in prehistory as inseparable from each other. Primitive man apparently often distinguished between ordinary conditions (such as old age, cough, cold, and fatigue) and illnesses caused by spirits and evil forces that required the special services of a medicine man, shaman, or witch doctor (12).

Plato (circa 429–347 BCE), a contemporary of Hippocrates, a student of Socrates, and the teacher of Aristotle, was one of the most influential thinkers in the history of the western world. His interests were mainly in the nature of the soul and matter. His medical speculations were logical but without direct experimentation. Physicians who supported his doctrine, especially in the third century BCE and thereafter, were called dogmatists. For them, reasoning superseded observation.

Aristotle (384–322 BCE) was the son of a physician. He, along with Hippocrates before him, and Galen afterward, were the principal authorities of pagan, Christian, and Muslim medical thought until the Middle Ages.

During the Middle Ages, in Judaic thought, disease was equated with punishment for sin or with divine disfavor. Early Christian churches did little to change this popular viewpoint. In some respects, the attitude of the Islam toward the origin of disease was similar to the Judeo-Christian idea, in that Allah caused illness as punishment for a person's sins, or for reasons beyond human comprehension, but sickness was usually borne without moral stigma. While one might hope for miracles through prayer, one could also seek divine help through the agency of a physician (13).

In the 17th century, the Age of Reason represented a major turning point in the history of science. Instead of asking *why* things occur, scientists turned to *how* things happened. This represented a shift in emphasis from speculation to experimentation. Interpretations became mechanistic and the language of science became mathematical (14). René Descartes (1596–1650) promoted ideas that would become a transition between the earlier influences of Aristotle and Galen and the Age of Reason. The scientific approach gained momentum during the Industrial Revolution.

The medical profession stands at the door between science and religion, at times taking the role of arbitrator, and offering scientific explanation when the *how* clashed with religions interpretation of the *meaning* of the event. Remarkable advances of science in the last few decades have led to discoveries that were formerly in the exclusive realm of religion. This difference in perspective can be highlighted by the example of a sunrise. Gerard Manley Hopkins (1844–1889), English poet and Jesuit, practiced pantheism; that is, he saw God in everything. His famous poem *God's Grandeur* concludes with this description of a sunrise.

Oh, morning, at the brown brink eastward, springs—
Because the Holy Ghost over the bent
World broods with warm breast and with ah! bright wings.

In contrast, a scientist might point out that visible red light has a wavelength of about 650 nm. At sunrise and sunset, red or orange colors are present because the wave lengths associated with these colors are less efficiently scattered by the atmosphere than the shorter wave lengths of the colors blue and purple. If the blue and violet light has been removed as a result of scattering, red and orange are more readily seen. In this example, the sunrise is measurable, and a personal perspective determines the attribution of God's hand, or explanation by scientific facts. Much of what we deal with in medicine involves issues for which nothing can be measured, such as hope, faith, and out of body experiences, which engenders lively debate.

With the development of functional magnetic resonance imaging, diverse pharmacologic agents, improved understanding about epilepsy, and deep brain stimulation treatments, discreet brain regions are now identified that have been associated with language, art, and religion. At one end of the spectrum, Francis Collins, head of the Human Genome Project, states that molecular biology and brain function argue for the existence of a personal God (15). At the other end, British neurologist Michael Trimble proposes that some of the greatest religious figures in history had what were probably complex partial seizures (16).

Some individuals who have survived cardiac arrest report out-of-body experiences during the time of their resuscitation. Sometimes, this is reported by patients following surgery with general anesthetic. Experimentally, out-of-body experiences in the brain can be repeatedly elicited during stimulation of the posterior part of the superior temporal gyrus on the right side using electrodes that have been implanted to suppress tinnitus (17). Out-of-body experiences may also be reported by sufferers of migraine headaches or epilepsy. Recently, neuroscientists have developed methods to induce an out-of-body experience in healthy volunteers using head-mounted video displays that give people a different perspective on their own bodies. The sense of touch was used to enhance the illusion (18,19). So, when a person describes an out-of-body experience, did it actually happen, or did this just seem to happen, and can it be explained by firing of a few neurons? If you are taking care of the patient for whom this occurred, does it matter?

Francis Collins offers a conciliatory statement to resolve the battle between science and religion. "Science is the only reliable way to understand the natural world and its tools when properly utilized can generate profound insights into material existence. But science is powerless to answer questions such as "Why did the Universe come into being?" "What is the meaning of human existence?" "What happens after we die?" One of the strongest motivations of humankind is to seek answers to profound questions and we need to bring all of the power of both the scientific and spiritual perspectives to bear on understanding what is both seen and unseen" (20).

PRAYER, HEALING, AND MIRACLES

Prayer has long been used as a coping mechanism for illness. A survey of more than 31,000 adults indicated that 36% of U.S. adults use some form of alternative remedies. When prayer is included in the definition of complementary and alternative medicine (CAM), the number of U.S. adults using CAM rose to 62% (21).

Prospective randomized trials can be evaluated in terms of spirituality, worship service attendance, frequency of prayer/meditation, and intercessory prayer. In a study of 503 patients with acute myocardial infarction who had depression or low social support, there was no evidence that self-reported spirituality, frequency of church attendance, or frequency of prayer is associated with cardiac morbidity or all-cause mortality (22). Although measurable outcomes in terms of mortality or morbidity do not occur, prayer has been demonstrated to provide a coping mechanism for cardiac surgery patients, likely mediated through optimism (23). Jantos and Kiat (24) suggest four plausible mechanisms whereby there may be a benefit: (a) a relaxation response, (b) placebo, (c) expression of positive emotions, and (d) a channel for supernatural intervention. These authors conclude that spirituality has an impact on the health and well-being of individuals, and this needs to be reflected in patient care. Patients consider prayer and spiritual issues to be important, and they yearn for open dialogue with their caregivers concerning important spiritual beliefs and practices. Such information may be relevant to understand a patient's resources for coping with illness.

Intercessory prayer has been the subject of sufficient study that large-scale, multicenter randomized controlled trials are available now to assess intercessory prayer with other noetic interventions (healing practices that are not mediated by tangible elements).

The STEP study was a randomized controlled trial of 1,802 patients undergoing coronary artery bypass surgery at six U.S. medical centers (25). Two third of the patients were told they might receive prayer on their behalf; one half of these patients received intercessory prayer and half did not receive prayer. A third of the patients received prayer after being told they would receive it. Prayers were performed by members of three religious groups remote from the hospital. At 30-day follow-up, 1,201 patients did not know whether they had received prayer. Fifty-two percent of the people who actually received prayers suffered surgical complications. Fifty-one percent of the patients who did not receive prayer suffered complications. Six hundred and one patients knew they received prayers, and 59% of them suffered complications (relative risk 1.14, 95% CI: 0.02–1.28).

The MANTRA II study was a randomized trial of 748 patients undergoing percutaneous coronary intervention or catheterization at nine USA medical centers (26). Three hundred seventy one patients were assigned prayer and 377 patients no prayer. Three hundred seventy four were assigned music, imagery, and touch therapy (MIT) and 374 did not receive MIT. There were four study groups: (a) standard care only, (b) prayer only, (c) MIT only, and (d) prayer plus MIT. There were no differences in the primary composite end point of in-hospital major adverse cardiovascular events, 6-month readmission, or death. However, mortality at 6 months was lower in the MIT therapy than the group with no MIT therapy (hazard ratio: 0.35, 95% CI: 0.15–0.82, $p = 0.016$). Patients who received MIT also had a significant decrease in anxiety and emotional distress prior to the catheterization. MIT therapy was administered by practitioners certified in level 1 Healing Touch (27).

The outcomes for intercessory prayer were summarized in two systematic reviews. The Cochrane database summarized 10 studies ($N = 1,646$) (28). Individual studies did find some effects. Most data were equivocal. Evidence presented prompted the authors to say it was interesting enough to suggest that further study is warranted into the human aspects of the effects of prayer. The review concluded that it is impossible to improve or disprove in trials any supposed benefit that derives from God's response to prayer. The results of the review and meta-analysis of prayer and health by Masters and Spielmans (29) are presented in Figure 28.1.

Forest plots and confidence intervals for 15 trials are summarized. When the studies are combined, the effect does not reach statistical significance. In addition to evaluating distant intercessory prayer, they also considered the frequency of prayer, content of prayer, and prayer as a coping strategy. In these categories, not all evidence regarding prayer is positive. The authors conclude that a highly developed model of prayer as coping would include integration of other aspects of the individual's personality, cognitive abilities, physical skills, and socioenvironmental context.

The large-scale review by Jonas and Crawford, *Healing, Intention and Energy Medicine* (30) goes beyond intercessory prayer and healing prayer to include mind-matter interactions, qigong, and the therapeutic effects of music. No well-designed, well-conducted

Figure 28-1 The effects of distant intercessory prayer summarized for 15 individual studies. The effect size and confidence intervals for each individual study is shown. Open circles to the right of the zero identity line represent effect sizes that favor intercessory prayer, while those to the left favor control patients. The overall combined effect is shown in the solid circle at the bottom of the figure. From Masters and Spielmans (28).

randomized controlled trials demonstrated statistically significant beneficial effects of any of these interventions.

A PARADIGM SHIFT?

Readers are cautioned against drawing the conclusion that this discussion of science and religion lays out a simple conflict. Because science is expressed by humans, its implementation may reflect some unscientific behavior. One example demonstrates bias. Years ago, a delegation from Jehovah's Witness, a religious group that does not permit its members to receive blood transfusions, made a presentation to a hospital staff, indicating that the staff performed too many blood transfusions. The initial response from the staff was negative: all transfusions seemed appropriate and met standard scientific guidelines. The transfusion committee agreed. In turn, Jehovah's Witness representatives pointed out that preoperative preparation and intraoperative techniques, including use of cell savers, could eliminate many transfusions. In the end, everyone won. The staff adopted the recommendations, and surgery became safer for Jehovah's Witness patients, and other patients were spared unnecessary transfusions.

A more daunting example of how science may be reported to us comes from observations reported over the past few years from the National Institutes of Health, the Center for Disease Control, and other institutions that receive funding from the federal government. Recently, scientists have reported unprecedented pressure from governmental bodies to reconfigure scientific reports to conform to political viewpoints. Over the past decade, several national and international medical publications reported another troublesome problem: information presented as scientific fact may not be so, since drug companies concealed the degree to which information was selectively presented.

Religion may employ some values beneficial to science. Although science is morally neutral, the inventions of science, such as weapons of mass destruction and stem cell research, challenge our society because of the threat they pose without alignment to some moral or ethical context, which may be supplied by religion. At the same time, many religions would be well served by an attitude expressed by the Dalai Lama, "...certainly some specific aspects of Buddhist thought will have to be modified in the light of new scientific insights" (31).

The scientific study of prayer may lead to a paradigm shift, one that is likely to be more obvious to the nonbeliever. Multiple randomized, controlled trials show that intercessory prayer does not have measurable benefit in clinical outcomes. This should not be a challenge to religious faith. Research studies often start out with "hard" endpoints, such as death or length of survival; later they move to "soft" outcomes, some of which are more important to patients, such as quality of life. In this regard, future studies of noetic interventions might assess nonclinical outcomes, such as happiness, hope, and acceptance, in the face of adversity, at least some of which have been described as fruits of the spirit (32).

APPROACH TO SPIRITUALITY IN PATIENT CARE

Although health professionals may be uncomfortable taking a spiritual history and assessment of a patient, patients expect it and others may welcome it. Further, the Joint Commission for the Accreditation of Healthcare Organizations requires that spiritual assessment be made for each patient admitted to an acute care hospital or nursing home, or seen by a home health agency.

Spiritual assessment should, at a minimum, determine the patient's denomination, beliefs, and what spiritual practices are important to the patient. This information would assist in determining the impact of spirituality, if any, on the care/services being provided and will identify if any further assessment is needed. The standards require organizations to define the content and scope of spiritual and other assessments and the qualifications of the individual(s) performing the assessment (33).

The World Health Organization has established a quality of life instrument to assess facets of spirituality, religion, and personal beliefs (34).

Surveys of patients in an ambulatory setting indicate that many but not all patients welcome a carefully worded inquiry about their spiritual or religious belief in the event that they become gravely ill (35). As a general statement, patients who were more interested having their physician address this topic had a serious or life-threatening illness, and were in general not interested in this at a routine office visit (36). Writing on behalf of the Working Group on Religious and Spiritual Issues at the End of Life, Bernard Lo, M.D., et al. (37) offered a practical guide for physicians to discuss religious and spiritual issues at the end of life. They address four topics:

1. Some patients may explicitly base decisions about life-sustaining interventions on their spiritual or religious beliefs. Physicians need to explore those beliefs to help patients think through their preferences regarding specific interventions.
2. Other patients may not bring up spiritual or religious concerns but are troubled by them. Physicians should identify such concerns and listen to them empathetically, without trying to alleviate the patient's spiritual suffering by offering premature reassurance.
3. Some patients or families may have religious reasons for insisting on life-sustaining interventions that physicians advise against. The physician should listen and try to understand the patient's viewpoint. Listening respectfully does not require the physician to agree with the patient or misrepresent his or her own views.
4. By responding to patient's spiritual and religious concerns and needs, physicians may help them find comfort and closure near the end of life.

The question "Are you at peace?" has been suggested as one item that can be used to initiate a discussion of spiritual concerns at the end of life (38). Asking patients about the extent to which they are at peace is a starting point to assess spiritual concerns. It gives the patient the opportunity to indicate if they are at peace with God, at peace with their personal relationships, or at peace with themselves. In turn, the physician can then direct additional questions to the patient's response in terms of traditional and nontraditional definitions of spirituality, psychological concerns, or topics the patient might list as disturbances of peace, including financial and family issues, etc.

The spiritual needs of children have been less well evaluated. At least for those with complex health care needs in the hospital, there seems to be a need for health care professionals to recognize that children have spiritual needs that can include religious beliefs (39). A comprehensive text on spirituality and patient care has recently been published in its second edition (40) and is recommended to the interested reader who wishes to pursue this topic further. A summary of this discussion in the form of aphorisms is given in Box 28.1.

Aphorisms for Spirituality in Patient Care

1. Ask open-ended questions to initiate a discussion.
2. Ask the patient to say more.
3. Acknowledge and normalize the patient's concerns.
4. Use empathetic comments.
5. Ask about the patient's emotions.
6. The profound issues of spirituality offer a prime opportunity for patient-centered care.
7. The issue of spirituality may center on the *meaning* of the challenging illness. Avoid the temptation to supply that meaning to patients, especially to a locus external to the person who is living that meaning. (e.g., "This has meaning in God's plan for you" or, "Future patients will benefit from your battle with this disease.")
8. Spiritual issues at the end of life are a challenge for authenticity.
9. Live your life in such a manner that you develop the courage to be happy; take that happiness to the bedside for your patients.
10. Allow goodness, kindness, and love to be expressed.

The first five points are modified from Lo, et al. ref 37. The author is indebted to William A. Russell, M.D., for providing the last four points from his perspective as a pediatrician.

SUMMARY

A definition of spirit as "an animating or vital principle" is useful because it can be productively viewed from a broad range of perspectives. The scientist, the atheist, the existentialist, and the religious person can all use this as a starting point. While the physician will have his or her own perspective, the patient will represent a primary focus.

Many people choose to take an intentional or mindful approach to the life journey incorporating to some degree what Plato called "the examined life." They establish a process of discerning the degree to which their own life is aligned with this animating principle. A survey of poetry, art, music, religion, philosophy, and even "the school of hard knocks" makes clear the rich human experience in the pursuit of this path. For young people, preoccupied with the development of the ego, their question may be "Who am I?" Halfway through life, some people awake one day with the question "Is this all there is?" This characteristic of the midlife crisis may be approached in terms of alignment with the animating principle, or with renewed efforts in the materialistic quest (red sports car, floozy romantic love interest), in which case a second midlife crisis may later appear!

No matter what the person's age, serious, potentially fatal illness represents a threat to this animating principle that may call forth powerful personal responses: "What does it all mean?" "Will I ever get better?" "Has my life been worthwhile?" "What happens after I die?" Appropriately, many patients change their orientation in order to enhance this animating force, according to their understanding and the nature of their illness. For example, some will seek any and all forms of treatment that might extend their life, whether or not it is of proven value. Others, for example the young man or woman who has survived his or her first heart attack, may finally adopt the heart-healthy lifestyle they have been hearing so much about. Another may choose at this time to decline chemotherapy or dialysis and spend the rest of her or his time with family and friends.

The effective physician is likely to be one who spends some time focusing on these issues; personal growth is a component of professionalism. (See Chapter 26, Professionalism.) The astute clinician is likely to be a keen observer of how other people have pursued this basic question. Of the many examples extant (heroes, saints, parent figures), individual patients may be some of the best guides. Physicians should always be aware that their role is to enhance the patient in his or her quest and not to promote their own value system.

Many of the issues raised by patients represent profound questions, and our answers are not much better now than when they were first raised thousands of years ago. We can help with two of them. When the patient asks if they will get better or be cured, it is helpful to understand our role in healing and our contribution to health and wholeness. The nature of the human condition is such that illness and disease do occur. Physicians can do much to help patients move toward the understanding of wholeness and recognition that health includes our adaptation to the presence of some illness, whether it is a consequence of aging, or a disease process.

When the patient asks what happens when he or she dies, we cannot address what occurs after their death. We can speak to what happens *while* they die. And, there, we can always provide comfort. No physician should use the term "I have nothing more to offer." When patients reach the final stages in their life, the world of medicine has a wealth of resources to alleviate pain and provide psychological and emotional support. These include hospice care, hospital or outpatient spiritual support services, and pastoral care by clergy and laity (see Chapter 31).

KEY CONCEPTS

- Osteopathic principles and philosophy call for a patient-centered approach to the medical encounter.
- Patient-centered care is more than a set of definable communication skills; it is a value that endorses the importance of providing information and facilitating patient involvement.
- Medical encounters often fail to provide patient-centered care.
- Patient-centered skills can be learned; however, the influence of improving patient-centered communication on health outcomes is less clear.
- Patient perception that they have found common ground with their physician appears to be an essential aspect of the patient-centered method.

INTRODUCTION

Proposed tenets of osteopathic medicine and principles for patient care (Rogers et al., 2002) have put forth that “a person is the product of a dynamic interaction between body, mind and spirit,” and that “the patient is the focus for healthcare.” These tenets direct osteopathic students and practitioners to provide care to patients that may be described as “whole patient” care or “patient-centered care.”

The purpose of this chapter is to guide the student through a definition of patient-centered care from multiple perspectives and to review the evidence identifying the efficacy of such an approach. We will also review the striking evidence that it is common for patients in today’s health care system to experience care that is not patient centered. The clinical skills and system changes needed to ensure the delivery of a more patient-centered approach to care will also be discussed.

PATIENT-CENTERED CARE IN THE CONTEXT OF THE MEDICAL ENCOUNTER

Patient-centered care within the context of the medical encounter has been defined and described by many. Perhaps the earliest proponent of an expanded model of medical care in the United States was George Engel (1977, 1980). Dr. Engel articulated the limitations of applying a strict biomedical conceptualization to patients presenting with medical illness. He developed an approach to care that he defined as the biopsychosocial model. The application of this model to the medical encounter has been described as patient-centered care (Stewart, 2003, p. 123) or relationship-centered care (Tresolini and the Pew-Fetzer Task Force, 1994).

In its essence, patient-centered care may be viewed as a core value implemented through a set of clinical skills. Information and involvement are at the heart of the patient-centered model. Patients are encouraged to express their values and preferences prior to the implementation of diagnostic or therapeutic interventions. The physician uses a cluster of communication skills with the specific intent of (a) identifying and responding to patients’ ideas and emotions regarding their illness and (b) reaching common ground about the illness, its treatment, and the roles that the physician and the patient will assume (Epstein, 2000). This is consistent

with the practice and application of evidence-based medicine, one component of which is the assessment of patient values. (Sackett et al., 2000, p. 1)

Patient-centered care is in contrast to a more prevalent model in health care that may be best described as benevolent paternalism: an approach to care where the well-meaning physician determines what is best for the patient and applies diagnostic and therapeutic interventions with little or no dialogue between the patient and physician (Braddock et al., 1999; Coulter, 1999). Benevolent paternalism is recognized when clinicians make statements to patients such as, “It is time for your mammogram,” or “You need to have a colonoscopy,” or “Your hemoglobin A1C should be below 7.5%.” These statements represent possible choices that patients can make in their care, each with its own potential for benefit and harm. A patient-centered approach would engage patients in the evaluation of these choices, identifying the opportunity for benefit and risk juxtaposed against the relative value or importance of the choice given the overall state of the patient’s life at the time (Austoker, 1999). Although difficult for many physicians to grasp, now is not always the right time for a patient to quit smoking, reduce their drinking, start a diet, begin exercising, start a new blood pressure medication, engage in screening, or practice stress reduction techniques (Rollnick et al., 1999, pp. 34–36).

The patient-centered approach encourages physicians to cultivate healing relationships based on who the patient is rather than who the physician would have him be (Epstein, 2000). This method, however, is not a simple passive acceptance of each patient, but a skilled and directive approach to the doctor–patient relationship based on respect, empathy, and a shift toward power sharing with the goal of enhancing and optimizing patient health.

Stewart (2003) has described six interactive components of the patient-centered method:

1. Exploring both the disease and the illness experience
2. Understanding the whole person
3. Finding common ground
4. Incorporating prevention and health promotion
5. Enhancing the patient–doctor relationship
6. Being realistic

Specific communication skills are utilized to facilitate the implementation of these components.

PATIENT-CENTERED CARE IN THE BROADER CONTEXT OF SYSTEMS OF CARE

There is increasing concern that our current system of health care fails to deliver consistently safe and effective patient-centered care. Perhaps the most visible light focused on this problem came with the publication of Institute of Medicine's (IOM) report, *To Err Is Human* (Kohn et al., 2000). This report described a dysfunctional and disintegrated health care system where the risk for harm to patients is real and often not appropriately addressed. In the follow-up publication, *Crossing the Quality Chasm: A New Health System for the 21st Century*, the IOM called for reform to ensure safe, effective, patient-centered, timely, efficient, and equitable health care delivery. Patient-centered care was defined as, "providing care that is respectful of and responsive to individual patient preferences, needs, and values and ensuring that patient values guide all clinical decisions" (Committee on Quality Health Care in America, Institute of Medicine, 2001, pp. 39–40).

Other national organizations have joined in the call for a more patient-centered health care system. The Institute for Healthcare Improvement has defined "ten simple rules" to guide reform (Institute for Health Care Improvement, 2008). The first four of these rules identify components that are recognized as the foundations of a patient-centered model of medical care: (1) care is based on continuous healing relationships, (2) care is customized according to the patient needs and values, (3) the patient is the source of control, and (4) knowledge is shared and information flows freely.

The American Osteopathic Organization, in collaboration with other professional societies, is calling for the development of new model of primary care delivery known as The Patient-Centered Medical Home (PC-MH) (American Academy of Family Physicians, American Academy of Pediatrics, American College of Physicians, and American Osteopathic Association, 2007). The PC-MH is based on seven guiding principles, one of which is a "whole person orientation." In this model, the primary care physician is placed at the center of a system designed to provide coordinated and integrated comprehensive care for patients of all ages.

Other proposed changes to enhance patient-centered care at a system level include allowing patients to schedule their own appointments and providing open access to their electronic medical record. New models for chronic disease management that include group visits and coaching patients to become more engaged and active in the medical encounter are also being implemented (Bergeson and Dean, 2006).

THE CURRENT STATE OF DOCTOR-PATIENT COMMUNICATION

When one begins to look inside the medical encounter for evidence of patient-centered communication, a concerning picture starts to arise. For example, investigators have studied how well physicians assess the reasons why patients present for medical care in different clinical settings. This task, which should occur early in a medical encounter, is known as assessing the patient's agenda and is a basic component of patient-centered care.

Agenda setting in primary care visits was assessed by Marvel et al. (1999). The investigators evaluated 264 medical encounters performed by 29 board-certified family physicians. The physicians in this sample failed to elicit the patient's initial statement of concern in 25% of the encounters. In the 75% of encounters where the agenda was assessed, physicians allowed patients to complete their initial statement of concern only 28% of the time, with the remaining patients being interrupted and redirected after a mean of

23.1 seconds. The patients in the sample who were allowed to complete their initial statement of concern took an average of only 6 more seconds to do so. In addition, interrupting patients increased the risk of late arising concerns by more than twofold (the patient who at the end of a visit states, "Doctor, did I tell you that I am also having chest pains?"), resulting in an inefficient and potentially dissatisfying encounter for both the patient and the physician.

Agenda setting and other communication skills were evaluated in emergency room encounters by Rhodes et al. (2004). These investigators analyzed 93 emergency department encounters performed by 24 emergency medicine residents and 8 nurses. The physicians in this sample failed to introduce themselves in one third of the encounters and indicated their level of training in only 8%. Only 20% of patients were allowed to complete their presenting complaint without interruption; the remaining 80% patients were interrupted in a mean of 12 seconds. Discharge instructions, an important component of emergent and urgent medical encounters, lasted 76 seconds on average (7 to 202 seconds). Only 16% of patients were asked if they had any further questions and clinicians never confirmed patient understanding.

The exploration of the emotional aspects of illness, known as empathic communication is another important component of the patient-centered method. Suchman et al. (1997) evaluated empathic communication in 23 encounters performed by generalist physicians in outpatient settings. The investigators found that patients rarely expressed emotions directly, but tended to offer indirect clues to the emotional impact of their illness. Physicians commonly ignored the emotional content offered by patients, often diverting the conversation back to the exploration of the biomedical aspects of the encounter. Physician failure to acknowledge emotional content frequently resulted in patients engaging in repeated attempts at emotional expression, often with increasing intensity, placing efficiency and satisfaction within the encounter at risk.

In a similar study, Levinson et al. (2000) found that physician failure to respond to emotional clues presented by patients in primary care and surgical settings resulted in encounters that tended to last longer compared to encounters where emotional expression was acknowledged and facilitated. Taken together, these observations suggest that the expression of emotion appears to be an important and perhaps essential aspect of the medical encounter for many patients. These results should challenge the common assumption that allowing patients to express emotions will cause physicians to lose control of the direction and duration of the medical encounter.

Involving patients in medical decision making is another communication element at the heart of the patient-centered approach. Braddock et al. (1999) evaluated the nature and completeness of informed decision making in 1,057 routine medical encounters with 59 primary care physicians (family practice and general internal medicine) and 65 general and orthopedic surgeons. The investigators developed a taxonomy of decision making, recognizing that medical decisions vary in terms of complexity and uncertainty. Seven elements of informed decision making were identified. Through a consensus process, the authors determined which of these elements should be included for decisions of varying complexity. A medical decision was defined as "complete" if all of the required elements were present. Basic decisions, such as checking a TSH level in patients on thyroid replacement therapy or electrolytes in patients on antihypertensive therapy, were considered complete if only two of the seven elements were present: discussing the nature of the decision and asking the patient to voice a preference. Complex decisions, such as prostate cancer screening or genetic testing for breast cancer risk, should include all seven of the elements.

The 1,057 encounters included 3,552 decisions, 1,857 of which were basic, 1,478 were intermediate, and 217 were complex. About one in five (17.2%) of the “basic decisions” contained the two required elements for completeness and only one of the “complex decisions” in the entire sample contained the required seven elements.

In a type of secondary analysis, the investigators asked how often the two essential elements required for basic decisions were present in any decision, regardless of complexity. For this analysis, any decision making was defined as complete if the physician simply discussed the nature of the decision and asked the patient to voice a preference. An example of complete decision making at the most basic level might be, “Because of your age, we should probably check a PSA level. Is that OK with you?” Although two component basic decision making could be viewed as the moral minimum for any decision, only one in five decisions (20.4%) in the entire cohort, regardless of the level of complexity, met this very basic level of completeness. Surgeons tended to outperform primary care physicians (21.8% vs. 18.9% complete, respectively), but results for both groups were shockingly low. If patient-centered care is performed on a platform of information and involvement, this evidence suggests that current medical care frequently falls short of the ideal.

On perhaps a more positive note, some evidence suggests that osteopathic physicians might be more patient-centered compared to our allopathic counterparts. Carey et al. (2003) evaluated audiotapes of 54 medical encounters with 11 osteopathic and 7 allopathic physicians to determine if osteopathic and allopathic primary care physicians differed in a communication style. In a blinded analysis, osteopathic physicians were more likely to discuss preventive measures, health issues in relation to family life and social activities, and the patient’s emotional state compared to allopathic physicians. These results suggest that osteopathic principles and training are congruent with the patient-centered approach.

EVALUATING THE EFFECT OF PATIENT-CENTERED COMMUNICATION ON MEDICAL AND HEALTH OUTCOMES

Although it is clear that communication problems in the medical encounter are common, it may be less clear if educational interventions can improve physician communication behavior or if improved communication will result in improved health outcomes. Before one can suggest wide-ranging changes in the structure of the doctor-patient encounter, some evidence of feasibility and benefit should exist.

Rao et al. (2007) performed a systematic review to evaluate the effectiveness of communication interventions on subsequent communication behaviors in the medical encounter. The authors identified 36 randomized controlled trials that met their inclusion criteria. Educational interventions varied and focused on physicians only, patients only, or a combination of both and may have utilized one or more educational strategies of varying intensity. In general, physicians exposed to the various interventions tended to exhibit more patient-centered behaviors and receive higher global ratings of their communication. When patients were the target of the interventions, they tended to be more involved during the encounter and obtain more information compared to control patients. However, the investigators noted that many of the effective interventions required fairly intense educational efforts and recognized that easy integration into a busy practice setting may not be feasible.

Perhaps the most important and effective educational approaches will be achieved through the integration of comprehensive communication curriculum into medical school curriculum when students are still forming their professional identity (Kalet et al., 2004; Yedidia et al., 2003). Indeed, most if not all medical schools have formal communication skills curriculum and methods to assess the acquisition of these skills. Whether these skills can be maintained when students are placed into the “real world” of clinical medicine is not entirely clear.

Although it is apparent that educational interventions are able to change physician and patient communication in the medical encounter, it remains less clear if these changes actually result in measurable differences in medical outcomes. In an attempt to answer this question, Griffin et al. (2004) conducted a systematic review of randomized controlled trials evaluating the impact of communication interventions on changes in measurable health outcomes or satisfaction. Communication interventions were directed at patients, practitioners, or both. Measurements of changes in the communication process evaluated either patient participation in the encounter, such as question asking or information seeking, or changes in physician communication style, such as addressing psychosocial issues or attending to patient emotion. A range of outcome measures were evaluated with some studies including more than one assessment. Changes in health outcomes included the evaluation of objective measures of disease processes such as change in blood pressure or glucose control, or changes in subjective measures of illness experiences such as self-reported symptoms of anxiety, depression, functional status, well-being, and quality of life. Other health-related outcome measures included changes in cost, patient knowledge, and adherence to treatment. Changes in satisfaction usually involved measurements of patient satisfaction with the process and outcomes of care.

The authors screened more than 21,200 reports and performed a full assessment of 148 of these to identify 35 trials that met their inclusion criteria. The quality of the reviewed and included trials varied considerably and rigorous outcome measurements were lacking in many of the studies. Most of the trials occurred in primary care settings and included patients with common chronic medical problems. Median follow-up time was only 4 weeks. Only four of the trials that utilized objective measures of health outcomes met all of the prespecified quality criteria.

Communication process improved to a significant degree in 22 of 30 (73%) of the trials that evaluated these measures. However, in six trials, at least one measurement of communication process deteriorated. Objective measures of health outcomes, including HBA1c levels, blood pressure control, and cholesterol levels, favored the intervention group in five of six trials (83%). Subjective measures of health outcomes, including pain ratings, functional status, well-being, and other psychological symptoms such as depression and anxiety, favored the intervention group in 21 of 25 trials (84%). Neither of the two studies that measured medication adherence favored the intervention group. Patient satisfaction with the process of care was higher in the intervention group in 17 of the 27 (63%) trials that assessed this outcome. In contrast, satisfaction increased in control group in 7 of the 27 trials (23%).

The authors concluded that although there is significant evidence to support the concept that interventions directed at changing the process of communication between doctors and patients can lead to a more patient-centered style, the influence of these changes on health-related outcomes is variable and less certain. It is clear from this review that there remains a significant need for more and higher quality research before one can state with a degree

of certainty that patient-centered communication will consistently lead to improved health outcomes.

Our understanding of what constitutes the essential components of the patient-centered method was deepened by a well-designed observational cohort study performed by Stewart et al. (2000). Medical encounters between 39 family physicians and 319 of their patients were evaluated to determine the influence of both objective measures of physician-patient communication and subjective measures of patient perception of patient centeredness on health-related outcomes and the subsequent utilization of medical resources. Audiotapes of the medical encounters were scored for the degree of patient-centered communication in the following three domains: physician exploration of the disease and illness experience, understanding the illness in the context of the whole person, and finding common ground. Immediate postencounter interviews were conducted with the patients to determine their perception of the patient centeredness of the visit. The investigators developed a total patient-centeredness score and two subscores rating the exploration of the disease and illness, and the finding of common ground. The utilization of medical care resources during the subsequent 2-month period was assessed by determining the use of diagnostic testing and referrals related to the main complaint of the visit and the number of return visits to the physician. Health outcomes included patient ratings of symptom severity and level of concern immediately postvisit and in telephone interviews conducted 2 months later.

In a somewhat surprising finding, objective ratings of patient-centered communication from audiotape analysis failed to correlate with either subsequent resource utilization or patient-reported health outcomes. However, subjective measures of the patient's perception of patient centeredness were associated with decreased postvisit levels of discomfort and concern about symptoms and improved mental health scores at two months. Subsequent health care utilization was also influenced by the perception of patient centeredness. Patients who perceived the encounter to be more patient centered were 40% less likely to receive diagnostic tests and 50% less likely to be referred. This relationship was even stronger for the subscore of reaching common ground where there was an 80% reduction in diagnostic testing and 60% reduction in referrals.

This study seems to indicate that patient perception may be far more important than objective counts of the occurrence of specific communication skills. It appears that the physician striving to improve health outcomes through a more patient-centered approach should continually ask themselves and the patient, "Are we achieving common ground in this encounter?"

IMPROVING THE PATIENT-CENTERED APPROACH

There are several well-accepted models designed to help students and physicians conceptualize and learn the essential communication tasks and skills of a more patient-centered medical encounter. Most medical schools have identified one of the accepted models and have developed structured curriculum based on essential texts and readings. It is beyond the scope of this chapter to discuss these models in depth; rather, each medical student must engage in the curriculum at his or her school. The following suggestions have been derived from the synthesis of several models, as well as clinical experience.

The first step in any encounter, for new or return patients, and regardless of the setting, is to invest in the beginning. This is accomplished by assessing the patient's agenda early with the use of open-ended questions. An example for a new patient might

be (after you have introduced yourself to the patient), "How were you hoping that I can help you?" Facilitative comments are used to ensure that the patient has given you a complete statement of their concerns. For example, a patient may be presenting with a complaint of headaches. After you have heard a bit about the nature of the initial problem, it is important to stop the patient and check for additional concerns. The physician might say, "So it sounds like the main reason for your visit today is headaches. Before I learn more about them, it's helpful for me to know if there are other concerns that you may have. What else is on your mind?" For return appointments, it is appropriate to acknowledge that you may have requested the follow-up visit, while still being sure to assess the patient's agenda for new concerns or complaints. An example might be, "The reason I asked you to come back was to see how you were doing with the adjustment in your insulin dose. But before we start, how about you, what do you want to be sure we accomplish in today's visit?" Or, "In addition to checking on your diabetes, what other issues are on your mind that we may need to talk about today?" I also find it helpful to check with the patient later in the encounter to be sure we are meeting our mutual agenda. "So, if we accomplish these three things today, will that meet your needs?"

Even when the reason for the visit is quite clear and focused, such as in an emergency department, it may still be appropriate to initiate the encounter with an open-ended question. An example might be, "The nurse tells me that you have a pretty bad injury to your hand. Before I take a look, how are you holding up?" The question, "How are you holding up?" is particularly useful in emergency room settings because it actively encourages patients to disclose emotional aspects of their illness and will create opportunities for the physician to offer brief moments of support and empathy in what is often an emotionally charged environment of care. While examining the laceration, the physician can efficiently assess the patient's complete agenda by stating, "It's clear this laceration is the main reason you came in. However, it's helpful for me to know if there are any other concerns that you may want to tell me about while we get you fixed up. What else is going on?"

As the studies described earlier point out, patients often fail to directly verbalize the emotional content of their illness. It is therefore important to be alert to and acknowledge nonverbal expressions of emotion and create opportunities for patients to talk about their feelings. These conversations do not need to be long or dominate the discussion of medical topics. Brief comments like, "you seem uncomfortable" or "you have been suffering a lot with these headaches" gives the patient permission to describe the more complicated and frightening aspects of their illness. As mentioned earlier, failure to acknowledge the emotional domains of illness may prolong the encounter and harm satisfaction. Remember, there is a human relationship embedded within every doctor-patient relationship.

Education and the involvement of patients in medical decision making is another essential and moderately complex task. An in-depth discussion of this area is beyond the scope of this chapter. However, a few comments may be helpful. As physicians offer diagnostic and therapeutic options and advice to patients, it is important to recognize that it is perhaps the norm for patients to feel some degree of ambivalence about many of these decisions, particularly more complex decisions. Simply reflecting this ambivalence can be very helpful to patients. An example might be, "On the one hand you can see your blood pressure is remaining elevated and that is concerning to you. You worry about having a stroke like your father and you would like to keep that from happening to you. And yet on the other hand you do not really like taking medication.

It's expensive and it seems that it makes you feel tired and not like yourself. You don't like the thought of adding a new pill to the two that you are already taking. Do I have that right?" You can then ask patients. "What do you see as your options?" or "How can I help you with this decision?"

It can also be helpful to present a menu of choices while creating space for the patient to decide. An example might be, "I see three options for your blood pressure that all seem reasonable and safe in the short run, and maybe there are some that I haven't thought about. The first would be to keep things the same and watch what happens to your blood pressure readings. A second approach might be to work a bit harder on diet and exercise and to really be sure that you are taking all of your pills as prescribed. A third would be to add a new pill. What are your thoughts? Do any of these options sound reasonable, or do you see others we may not have talked about?"

An approach that may be helpful and efficient when discussing higher complexity decisions, such as the acceptance of screening, is to talk to patients about groups of people and then ask the patient to decide which, if any, group they see themselves most likely to fit into. An example might be, "There are some patients who value doing all they can to lower their risk of dying from a cancer like colon cancer. These patients see the benefits of screening and are willing to undergo these tests even in the face of some uncertainty about the benefits and acknowledging the small, but real potential for harm. They, for the most part, choose to undergo screening. And then there are other patients who do not feel so strongly. They tend to be more concerned about the potential risks for harm and tend to want to avoid undergoing tests and medical procedures. They are willing to accept the small but real risk that some day they may develop a cancer that might have been helped or even cured by screening. These patients, for the most part, choose not to undergo screening. How about you? What group do you see yourself fitting into? And is there more information that you might need to help you decide?"

All medical encounters should conclude with some review of what has transpired and the plans for ongoing and follow-up care. It may be helpful to have patients summarize their understanding prior to leaving. At a minimum, it is clearly helpful to check with patients by asking, "Does today's plan make sense?" followed by the more open-ended question, "What other questions do you have?" Asking the patient about any concerns regarding the treatment plan can be very enlightening. It actively pulls for the emotional content of the patient's illness and may provide insight to important issues that could hinder compliance. It will again offer brief opportunities to provide empathy and support to patients.

And lastly, the task of understanding the whole person in the context of a medical encounter is greatly facilitated by asking the simple question, "What would you like me to know about you as a person?" This question appears to be best asked early in the encounter after the patient's initial agenda has been assessed. I will often structure the question in the following manner: "So it seems that the main issues that bring you here today are your blood pressure, your diabetes, and the back pain that has been troubling you. Do I have that right? Before we explore these medical topics in more depth, I am wondering if I could learn a bit about you as a person. What would you like me to know about you?" This question can be both refreshing to patients and at times unsettling. Patients who have never been asked such a question by a physician may respond with some defensiveness by asking, "What do you mean? What do you want to know?" I gently stay with the question by reflecting, "Anything. Anything you would like me to know?" Sometimes I ask patients, "What do you love to do?" These discussions do not

need to last long, but the simple process of a doctor actually being curious about a patient beyond their symptoms and illness can facilitate patient engagement in the encounter and the perception of being on common ground. It is this kind of information that allows a doctor to really know their patient.

SUMMARY

The time-pressured world of modern medical practice, defined by product lines, revenue generated per case, physician relative value units, corporate pressures on throughput, decreasing physician reimbursement, and the application of clinical guidelines to patients with little or no dialogue conspire against a more collaborative approach to the medical encounter. It is clear that with appropriate effort patient-centered communication skills can be defined and learned. However, the effect of these changes on measurable outcomes is less certain. There are many factors that influence health outcomes, only one of which is communication within the context of a medical encounter. Social economic status, job stress, social isolation, education status, and mental health factors are just a few of the known determinates of health that are not easily influenced within the confines of a professional medical encounter.

Patient-centered care appears to be more than a set of skills to be learned and applied; it is, perhaps, a way of being with patients. A patient-centered approach will require that physicians affirm a deep personal value that believes in the capacity of each patient to be a meaningful partner in their own health care, capable of making choices that fit with their values and broader life circumstances. It will also require a commitment to finding common ground with patients in the medical encounter. As Stewart et al. (2000, p. 800) state, "Physicians may learn to go through the motions of patient-centered interviewing without understanding what it means to be a truly attentive and responsive listener" (Stewart et al., 2000, p. 800). Our presence and how patients perceive us matters. Perhaps for no other reason, efforts to improve patient centeredness may be justifiable on moral and ethical grounds alone. After all, is this not the care that you hope one day to receive from your physician?

KEY CONCEPTS

- Decrease of overall mortality is due to effective public health measures for disease prevention aimed at large populations.
- Many of the most common noncommunicable diseases are strongly linked to lifestyle and behavior.
- Research into human nutrition continues to identify significant problems in the “western diet,” with significant overlap in consensus of the constitution of a healthy diet.
- Physical activity is inversely correlated with morbidity as well as mortality.
- Tobacco and alcohol are readily available, relatively inexpensive, and legal substances that cause more human misery than all illegal substances combined.
- Ill health, disability, and death from unhealthy sexual practices are almost completely preventable.

INTRODUCTION

Historians of medicine and public health have described in detail the dramatic changes that have taken place in medical education, practice, and research in the 20th century. Most of these changes are the result of more effective and expansive technology that has enabled us to trade short-term mortality for long-term morbidity. Disability and death, especially from acute infectious disease, have been increasingly replaced by the chronic illnesses that make their appearance in middle age and late life.

In 1900, the average life expectancy at birth was 46.3 years for men and 48.3 for women. By 2005, however, life expectancy dramatically increased to 75.2 years for men and 80.4 years for women (1). The sweeping epidemiology study, *The Global Burden of Disease (GBD)*, based upon more sophisticated analyses and egalitarian principles, sets life expectancy standards at birth to be 80 years for men and 82.5 years for women (2). These increases are mostly attributable to the decrease in infant mortality.

Overall mortality has decreased more due to research and technology developed toward more effective public health measures for disease prevention aimed at large populations than medical procedures aimed at individuals. These fundamental strides include the increasing promotion of clean air and water standards; high-quality, safe, affordable food; and safer living and work environments. This increased survival expectancy also includes a generally well-regulated pharmaceutical industry providing immunizations to prevent most common acute infectious diseases occurring early in life and effective antimicrobials to treat infectious diseases we fail to prevent.

These positive strides are now facing serious challenges due to increasing social and lifestyle changes, especially in Western societies. Further advancements in improving the long-term health of our patients depend, for the foreseeable future, upon our understanding the major impact of behavior on health and illness. This involves continuously educating our patients, encouraging their active participation in and cooperation with health maintenance, and motivating them to make choices that will promote the healthiest, most enriched, vigorously productive, and enjoyable lives possible. Growing old remains inevitable but fortunately for most, ill health is not.

Assisting our patients to live long and live well certainly does not mean emphasizing prevention and health maintenance to

the neglect of research into increasingly effective technological interventions. New technologies will always be a vital component of the continuum of health care. The promise of effective genetic therapies is especially exciting and represents our most probable next revolution in eradicating chronic as well as acute illnesses (3). In the interim, however, preventive research in the form of improved screening, health maintenance, and positive health-related behavioral changes must be given at least equal emphasis. New strategies to promote positive behavioral change in our patients must be an enduring and vital component of osteopathic medical education, practice, and research if the profession is to make a significant improvement in the overall health of the population.

ADDRESSING THE BURDEN OF DISEASE

The *GBD* continues to represent the most current and profound ongoing study surveying health, injury, and illness worldwide. This investigation, which is a collaborative effort by the Harvard School of Public Health (HSPH), the World Health Organization (WHO), and the World Bank, has changed our understanding of the emerging patterns of illness and provided new methods to calculate its impact on the individual and society.

Looking at mortality is important but an incomplete method of measuring the impact of disease. The level of illness morbidity is increasing and is the more difficult health problem to measure. The *GBD* has assisted health policy planners and medical educators by developing and elaborating the concept of “Disability Adjusted Life Years” (DALY). This method is a means to more accurately determine and quantify the manner in which illnesses rob people of fulfilling and productive lives.

The *GBD* continues to confirm a number of startling shifts in the patterns of disease in countries with developed market economies and developing countries. Since the *GBD*'s data sets begin in 1990 and project out to 2020, and since its most recent data are so accurate, it provides a virtual road map to the changing face of global illness. One of the clearest trends continues to show that the disease patterns of developing nations are beginning to approximate those of the developed ones today. Noncommunicable diseases such as depressive disorders and heart disease are eclipsing the threats of the past, like infectious disease and malnutrition.

The use of the DALY method also continues to demonstrate the formerly drastically underestimated burden of mental illness.

Even in the original 1990 data, the *GBD* indicated that unipolar depressive disorder, bipolar disorder, schizophrenia, obsessive compulsive disorder, and alcoholism accounted for five of the top 10 leading causes of disability worldwide. The burden of psychiatric disorders is highest in the developed nations and this trend continues in an alarming direction. If osteopathic medicine is to make any significant strides in reversing this trend, the profession must pay much more attention to screening, early diagnosis, and expeditious interventions.

The *GBD* also highlights the striking and complex interlocking nature of behavioral risk factors and illness. The most common behaviors most closely associated with disease and ill health include tobacco use, alcohol abuse, and unsafe sexual practices. Given present behavioral trends, tobacco use alone will outweigh the burden of any single illness by 2020. Western nations have instituted preventive measures to lower tobacco use, but the developing countries are becoming the new emerging tobacco market, much to their detriment. Complicating things further is the manner in which some diseases aggravate and predispose to others causing further disability (e.g., hypertension and diabetes increase the risk for heart disease, stroke, and peripheral vascular disease) (4).

Many of the most common noncommunicable diseases are strongly linked to lifestyle and behavior. Osteopathic physicians committed to the most effective comprehensive care simply must place more emphasis upon promoting positive behavioral changes for their patients. We should remain excited about emerging “procedure-oriented” technological interventions but must immediately place more focus upon “the basic building blocks” of health to improve the care we provide. Attention to increasingly customizing comprehensive care in every patient encounter will heighten the efficacy of our treatment and most likely decrease health care costs. Awareness of the leading causes of death, as shown in Table 30.1, certainly emphasizes the value of comprehensive osteopathic care.

TABLE 30.1

Leading Causes of Death in the United States

Causes of Death	Number of Deaths in Thousands
1. Heart disease	652
2. Cancer	559
3. Stroke	144
4. Chronic respiratory disease	131
5. Accidents	118
6. Diabetes mellitus	75
7. Alzheimer’s disease	72
8. Pneumonia and influenza	63
9. Inflammatory kidney disease	44
10. Suicide	33

IMPACT OF ILLNESS ON THE INDIVIDUAL AND SOCIETY

Nutrition

Nutritional sciences continue to reaffirm the aphorism by Oscar Wilde: “You are what you eat.” Research into human nutrition has continued to identify significant problems in the “Western Diet,” with the United States being the most striking example. Nutritionists acknowledge significant overlap in the general consensus of what constitutes a healthy diet. Within the past 7 years, however, the controversies about specific foods and especially the proportions of those foods have begun to escalate.

Pick Your Pyramid

More than a decade ago, the United States Department of Agriculture (USDA) created the “Food Guide Pyramid” as a useful model to illustrate to the general public what constitutes a healthy diet. In its first iteration, it received almost universal approval from nutritionists who agreed it was a major positive step. Disagreement was limited to “arguing around the margins” about types of foods and proportions, but the discourse was more relevant to research than practice. The USDA Pyramid has since been revised twice with the last major revision being in 2005 (Fig. 30.1). Since collection and review of nutritional research is ongoing, it is anticipated that the next revision might occur in 2010.

Controversy began after the second revision when nutritional researchers, especially those within the HSPH, openly questioned the influence of food industry on the final product. Because the USDA Guidelines determines the standards for all federal food programs, including school lunch programs, and influences the food shopping choices of many of the general public, even minor recommendations could affect sections of the food industry. The HSPH argued that the revision was not based solely upon the best nutritional science but reflected undue influence by lobbying efforts. The controversy spilled over from the scientific literature to health-related literature for the general public.

The HSPH responded with its own “Healthy Eating Pyramid” (HEP) within the next year and it was been updated in 2008. The Harvard Guidelines stress their version is based only on the best-available science and is easier for the general public to grasp. One major difference includes the HEP suggesting eating more protein from fish, especially those species containing high levels of omega 3 fatty acids and significantly limiting red meat. The HEP also stresses less dairy products and the use of a daily multivitamin, calcium, and vitamin D supplementation. It also emphasizes limiting salt, refined grains, and sugary drinks and, optionally, alcohol in moderation (5,6).

Increasing numbers of people, for reasons of health, spiritual faith, and/or concerns about the moral treatment of animals, are becoming strict vegetarians. For those people, both the USDA and the Harvard Pyramids are only partially useful. To ensure that these people get sufficient protein and vitamin coverage, the “Vegan Food Pyramid” was created (7) (Fig. 30.2).

All three pyramids are featured as charts for use in discussing and customizing prescriptive nutritional advice for patients. Simple readjustments tailored for the individual patient offer significant protection from developing some of the most disabling chronic problems including cardiovascular disease, stroke, hypertension, obesity, osteoporosis, and certain forms of neoplastic disease (8,9).

Figure 30-1 The USDA MyPyramid.

Physical Activity

Modern scientific research continues to affirm that a healthy life is also an active life. Becoming increasingly fit through a range of physical exercises provides many correlative health benefits. Stories in popular media about people who harm their health by compulsively exercising teach us nothing beyond the obvious consequences of extremes in any endeavor. Exercise and health scientists have much more to offer, and here there is more agreement than controversy in the benefits of increasing levels of physical fitness.

Nearly all systematic studies show that high levels of physical activity delay all-cause mortality but mostly due to lower rates of cardiovascular disease. These studies show also that physical activity is inversely correlated with morbidity as well as mortality.

One of the hallmark prospective studies of physical activity and its relationship to health and specific illnesses demonstrates that the risk of all-cause and cause-specific mortality declines across physical fitness quintile from the least fit to the most fit in both sexes (10).

EXERCISE PYRAMIDS

Like nutrition, the basic principles of exercise are fairly straightforward and easy to understand for most people. A number of research exercise programs, however, have taken their cues from nutritional science research and have developed their own “Exercise Pyramids.” Also like eating a healthier diet, increasing levels of fitness offer additional protection from developing many diseases, including

Figure 30-2 Vegan Food Pyramid
(Courtesy of Joshua Wold and VeganFoodPyramid.com).

cardiovascular disease, stroke, obesity, non-insulin-dependent diabetes, and osteoporosis. Moreover, a regular comprehensive exercise program has benefits of better emotional and mental health, especially a reduction in feelings of anxiety and depression. Exercise has also been demonstrated to improve immune responses (11,12).

Exercise Pyramids have been created to assist with discussions about prescriptive exercise with patients; these models stress being active in ways that emphasize fun and enjoyment. The extent to which physical activity is paired with enjoyment is the extent to which it will probably be incorporated into a healthier lifestyle. Most people find exercise much more enjoyable when paired with a social activity. Physical activities shared with friends and family (including the four-legged kind) are more likely to become a life-enriching and ordinary activity of daily living.

Extremely important and most often left out of discussions about promoting health by physicians is the issue of role modeling. Osteopathic medicine embraces a comprehensive approach to health, and this includes the physician acting as a role model for vitality and fitness. Patients are much more likely to hear and accept prescriptive advice about health from a physician whose lifestyle exemplifies the behaviors being suggested. Almost regardless of prior levels of fitness, patients can be motivated to begin by first taking steps to increase their levels of activity in their daily lives.

The Exercise Pyramids give examples of this at their bases. Total fitness involves a balanced program consisting of preferably daily aerobic exercise, resistance exercise, and gentle stretching. Aerobics develop stamina, resistance training develops strength, and stretching increases flexibility and helps prevent injury. Patients should be encouraged to begin slowly, consistent with age and current fitness, and gradually increase their level of exercise to prescriptive goals. The levels of fitness they ultimately attain will involve many factors, especially their improved health status and the enjoyment and pride they derive from their efforts. Special attention must be taken with patients for whom exercise represents risk. For these patients, consultation with physical medicine and rehabilitation and/or physical therapy will greatly assist with the therapeutic effects of an exercise program (13). Development of an active lifestyle should

begin early and consistent with physicians being role models for patients; parents can become the most important role models for their children to develop good health habits early.

Americans now spend over \$12 billion yearly on health-related activities, mostly belonging to health clubs, spas, and/or buying expensive exercise equipment and clothing. While these amenities might add to the social enjoyment of exercise, fitness need not be expensive. Most important expenses should be to promote safety. (Shoes appropriate for the activity, helmets for bicycling, wrist braces and knee pads for in-line skating and skate boarding, etc.) Attention to proper clothing is especially important for young children and the elderly. Clothing should attend to function first with style and fashion being optional. For the increasingly active and fun lifestyles, other protective gear and measures should be taken including sun glasses and adequate sun screen. Adequate hydration is also extremely important. For exercise lasting under 1 hour, cool water is usually sufficient. For exercise lasting longer, especially if in hot, humid conditions, a favorite "sports drink" will provide additional glucose and electrolyte replacement, preventing excess fatigue, dehydration, and speed postexercise recovery. The old coach's advice is still valid: "Take frequent small drinks, if you wait until you feel thirsty, it's already too late."

Obesity

It is ironic that with both the current emphasis by many on health and fitness and the near-universal Western stigma toward people who are overweight, that obesity is now epidemic.

The good news is that the prevalence of obesity in adults has stabilized since 2003 but remains still at 34%. Worse news, however, is that the prevalence of obesity in children has continued to rise from 4.5% in 1970 to 16.3% in 2006. Researchers continue to debate the health risks of being mildly or even moderately overweight. They are in near complete agreement however about the health risks as body mass index (BMI) exceeds 30. The most recent list of health problems associated with obesity is listed for adults and children in Box 30-1, from the Centers for Disease Control (14).

Health Risks Associated With Obesity

- Coronary heart disease
- Type II diabetes
- Cancers (endometrial, breast, and colon)
- Hypertension (high blood pressure)
- Dyslipidemia (e.g., high total cholesterol or high levels of triglycerides)
- Stroke
- Liver and gallbladder disease
- Sleep apnea and respiratory problems
- Osteoarthritis (a degeneration of cartilage and its underlying bone within a joint)
- Gynecological problems (abnormal menses, infertility)

Health promotion researchers have conclusively demonstrated that simple caloric restriction alone does not produce long-term positive results for people who are overweight or obese. Moreover, unsupervised very-low-calorie-diets involve serious health risks (15). For most patients, de-emphasizing weight and emphasizing fitness is the best place to start. Educating, encouraging, and motivating patients to follow the recommendations of the Food and Exercise Pyramids can improve outcomes for both adults and children.

The best guides to monitor progress include the BMI and waist circumference at the navel. The measurement of waist circumference adds an important parameter because the presence of circumferential fat has been demonstrated to pose additional health risks. The ideal trajectory is a gradual weight loss of between 1 and 2 lb per week until the patients' goals are reached. The maintenance of health and fitness requires life-long attention. If former habits of unhealthy eating and sedentary lifestyle return, health risks will predictably again rise. Comprehensive management also requires confronting social pressures and misinformation about weight and the variation among somatotypes. The fashion and advertising industries create completely unrealistic standards of beauty. Even the photographs of fashion models are computer retouched to the point where the finished product represents an aesthetic ideal that does not exist in the natural world. Exciting research into the genetic control of hunger, satiety, and metabolism continues, but these treatments are still far into the future.

For some patients, the course of their weight problem has progressed to a point to where they are at imminent risk. It is here where more vigorous and even invasive surgical procedures are life saving. Medications and bariatric surgery are indicated in these circumstances, and these treatments are beginning to show increasing success. Patients still need to be educated beforehand that decreased health risks, even after successful acute treatment, require life-long behavioral changes. Literature written by physicians and exercise scientists for the lay public are many times very helpful and can easily be incorporated as a component of patients' overall fitness plans (16).

Substance Use and Abuse

Illegal substance abuse continues to be an ongoing social scourge and a significant public health problem. It is ironic however that the two substances that cause more human misery than all illegal substances combined are readily available, relatively inexpensive, and legal. Focusing upon the hazards of these legal substances to our patients is essential to the practice of osteopathic medicine.

Tobacco

Since the release of the first "Surgeon General's Report on Smoking" in 1964, the United States has made impressive strides in lowering the prevalence of smoking. Tobacco companies have been rightfully taken to task for the damage to public health for which they are responsible. As stated earlier though, these companies have merely shifted their markets outside the United States especially targeting developing countries. The strong statement from the *GBD* merits repeating here: "By 2020 tobacco is expected to kill more people than any single disease, surpassing even the HIV epidemic." The most recent Surgeon General's Report, while indicating clear successes, continues to stress that we have still much more room for improvement. The report expands the list of diseases that are directly related to smoking including acute myeloid leukemia, cataracts, abdominal aortic aneurysm, periodontitis, and cancers of the cervix, kidney, pancreas, and stomach (17,18). Most shocking is the more current report on the health consequences of second-hand smoke. Public health research now demonstrates clearly that involuntary exposure to tobacco smoke poses more serious health risks than expected, especially for infants and children. The report does not equivocate: "There is no risk-free level of exposure to second hand smoke." The evidence is now conclusive that second-hand smoke increases the risk for nonsmokers for heart disease, lung cancer, sudden infant death syndrome, respiratory infections, and asthma. The total costs of smoking are estimated at over \$100 billion today. The negative effects of smoking on productivity are likewise staggering. The Office of Technology Assessment estimates the costs of lost productivity to be over \$47 billion for smokers and lost productivity to second-hand smoke at over \$8.6 billion. The message to our patients needs to be loud, firm, clear, and persistent: "If you don't smoke, don't ever start and if you do smoke, quit!"

Smoking cessation literature continues to show that most people who do smoke would prefer to quit and have made efforts to do so. Many smokers are able to quit on their own, but many go to their family physicians for help. The following are some very useful methods physicians can suggest that will increase the likelihood of success:

- Publicly declare a date to stop. Compose a written statement that includes a request of support from family, friends, and co-workers. Some programs even recommend announcing the intent to stop smoking in the local paper.
- Prepare by making efforts to minimize stress, eat a healthier diet, and begin a program of physical fitness.
- Attend to nicotine withdrawal by gradually smoking fewer cigarettes each day.
- Get rid of the "stash" and begin to buy cigarettes one pack at a time.
- Break up learned patterns of smoking by waiting at least 10 minutes before lighting up when craving begins. Smoke with the cigarette in the nondominant hand. Smoke only while standing. Any strategy that makes smoking more inconvenient will help.
- Maintain a positive attitude as the cessation date approaches. A helpful "cognitive restructuring" approach is to de-emphasize the idea of "giving something up," replacing it with a list of all that will be gained from your efforts.

On the quitting date and thereafter:

- Make sure all cigarettes are gone.
- Prepare for times of craving by substituting healthy alternatives: fresh fruit, carrot or celery sticks, xylitol chewing gum.

Many report brushing your teeth at times of craving to be a very helpful strategy:

- Increase fluid intake, especially drink water.
- Record progress in a diary or calendar.
- Financially reward yourself. Open an exclusive savings account and regularly deposit the money formerly spent on cigarettes. Be fair to yourself and also bank the spin-off savings from smoking damage to clothing, furniture, automobile interior, etc. Also save the cost of at least one visit to the doctor's office. Enjoy watching your savings grow!

Even with physician advice and coaching, some patients will have increased success with over-the-counter or prescription medications. Nicotine replacement products in all their delivery forms will attenuate withdrawal symptoms. Low-dose antidepressant medications have been demonstrated to be helpful, especially doxepin and bupropion. Also, low-dose clonidine has been shown in the literature to be helpful. Finally, a new medication for smoking cessation (varenicline) has been marketed so successfully that patients will request it by its brand name.

Forms of alternative/complementary medicine may have a place in a comprehensive smoking cessation program depending upon the knowledge base of the physician and the level of acceptance of the patient. One of the most common complementary treatment methods is acupuncture, but the clinical literature about its efficacy is quite mixed (19). When provided by a qualified therapist, acupuncture has demonstrated such a mild side effect profile that it could be included as adjunctive treatment.

An analysis of the literature on smoking cessation reveals the most successful smoking cessation programs use multimodal approaches sharing the commonalities of education, positive motivational encouragement by physicians and other health care professionals, face-to-face contact with a therapist, group therapy emphasizing mutual support, the offer of traditional and complementary treatment, and long-term follow-up (20,21).

Finally, patients who continue to experience relapse should be strongly encouraged to "never quit trying to quit." Helping patients to stop smoking may just be the physician's single most effective preventive effort. WAKE UP CALL: According to the WHO, 45 more people have died worldwide from smoking-related illnesses in the time it has taken you to read this section on tobacco (22).

Alcohol

Although the benefits of moderated alcohol intake have received increasing attention in the medical and popular literature, the abuse of alcohol accounts for a wide spectrum of health and social problems. Alcohol abuse plays a causal or contributing role in injury and deaths from accidents, homicides, and suicides.

Personal Safety

Attending to personal and family safety is a major component of a preventive health program. Educating patients by providing the best and most current information is key. Addressing personal safety issues can be incorporated into new patient screening and provided for current patients in the form of pamphlets. Some safety videos are also available.

AUTOMOBILES

Approximately 50,000 people in the United States die every year in automobile accidents. The automotive industry has made

significant strides in making cars safer with the advent of air bags and antilock brakes. Laws that make the use of seat belts mandatory and call for infants and small children to be secured in the rear seats in protective seating have also helped reduce deaths from automobile accidents. Physicians can help patients better understand automobile safety issues by encouraging patients to:

- Purchase vehicles with the latest safety devices (i.e., air bags, antilock brakes)
- Keep automobiles safer through proper maintenance, especially of brakes and tires
- Obey speed limits and all traffic regulations
- Follow all regulations when operating recreational vehicles
- Wear an approved helmet and protective clothing when operating a bicycle, moped, or motorcycle
- Avoid driving while taking sedative medications
- *Never* drink alcohol before driving

HOME

Provide patients with information on how to maintain a safe environment in their home. The following list is not inclusive of all issues; rather it represents significant areas where simple attention can make a major difference in household safety. The general nature of these recommendations does not minimize their importance for the health of patients:

- Keep medicines, harmful chemicals, and cleaning products secure and especially out of reach of children.
- Prevent fires by judicious use of auxiliary home heating devices and by proper use of electrical appliances and outlets.
- If fire should occur, minimize danger and damage by the use of smoke detectors and fire extinguishers.
- Develop and practice an escape plan from the home in the event of fire or other disaster (i.e., earthquake, hurricane, tornado). Most local fire departments and electric companies will inspect your home and make safety recommendations at little or no cost.
- Patients who choose to own guns should keep them in a secure place, unloaded, with appropriate locking mechanisms on the triggers. Likewise, ammunition should be kept in a secure place, separate from the weapons.
- Keep power tools and lawn care equipment in good repair, especially their safety guards, and wear safety glasses and ear plus during their operation.
- Falls are a major cause of injury to older adults. Keep bathrooms and stairways free of obstacles and install appropriate lighting, handles, and banisters. Secure the edges of throw rugs to minimize trips and falls.
- In winter, keep sidewalks and outdoor stairs clear of snow and ice. This can be a component of a family's fitness plan.

SEXUALITY

Sexual behavior is a central component of healthy human functioning and a source of pleasure, comfort, and intimacy. Unfortunately, lack of knowledge about human sexuality can result in more than an unwanted pregnancy; it can result in illness and death. As well as providing the best possible counsel and information about contraception and family planning, physicians must also inform sexually active patients about safe-sex practices. Female patients suffer far more than male patients in the area of sexually transmitted diseases (STDs) due to their more complicated and lengthy reproductive roles. Again, ironically, ill health, disability,

and death from unhealthy sexual practices are almost completely preventable. High-risk practices should immediately be curtailed. These include:

- Sex with an intravenous substance abuser
- Sex with a prostitute, stranger, or person whose sexual history is unknown
- Sex without the use of a condom
- Sex with any person who engages in any of the above behaviors

Further, patients should be advised that abstinence or maintaining a mutually monogamous relationship with one partner is the best method for preventing all types of STDs. For many people, however, this advice is not acceptable. In such cases, the physician should instruct patients to minimize high-risk behaviors. Although not 100% effective, consistent, and correct, use of condoms and other barrier contraceptives decrease risk of pregnancy and STDs and should be encouraged. Studies reveal that using contraceptives containing the spermicide nonoxynol-9 with condoms offers further protection if the barrier should fail.

FAMILY AND WORK

A healthy family life has long been known to be a source of comfort, joy, and inspiration. The family is the basic unit of society and needs the support of all. Fragmented, blended, or single-parent families need even more support. Families experiencing problems or who are in turmoil should be encouraged to seek help, whether it be support from caring relatives and friends, support groups, or professional family therapy. The primary care osteopathic physician should engage patients in constructive discussions about family health. Five general qualities shared by healthy families include:

- A clear understanding of each member's role and responsibilities
- An equitable distribution of power
- Support and encouragement
- Effective communication
- A shared system of values or beliefs

It should become routine in osteopathic, family-oriented health care to inquire about these characteristics in medical history taking and to promote them at every therapeutic opportunity (23,24).

Doing work that one finds meaningful is a source of pride and personal fulfillment. The most tragic work situation is for one to feel trapped in a work circumstance one despises. Many people, however, fail to take the steps necessary to make their work more meaningful or to prepare themselves to change jobs or careers. If patients find that, despite their best efforts, they are unhappy in their work, they should be encouraged to survey their situation and develop a plan of change. Opportunities for alternative education and training are more abundant and accessible now than ever before. Even in the most difficult economic circumstances, education is the best investment a person can make.

Many people unhappy with their work never take full advantage of what the situation offers. Most large employers have tuition-reimbursement plans for educational courses that go unused by employees. Patients should also be encouraged to cultivate friendships at work. If a workplace does not provide activities, patients can become agents of change who organize and develop work-related social or sports activities. Work need not be daily tedium and loathing, and even planning for a change can be the activity that lifts a patient's spirits and gives them hope and comfort. Work should not be a constant endeavor of joyless striving but rather an undertaking that provides meaning and satisfaction.

DOCTOR-PATIENT RELATIONSHIP

The doctor-patient relationship remains the single most powerful healing tool of the physician. Technology is obviously important, but the power of the doctor-patient relationship allows "high-tech" medicine to be used most wisely and to the greatest benefit. Primary and secondary prevention are two of the most important goals of the osteopathic physician, especially those in primary care practice. Physicians can do the most to encourage patients to become partners in their health care by using the power inherent in the doctor-patient relationship.

Most physicians agree that counseling is one of their most important tasks; paradoxically, most feel ineffective in this role. Many physicians feel generally pessimistic about their ability to motivate patients toward positive change. This pessimism exists partly due to a lack of effective training about behavioral change during medical school and in postgraduate medical education. Physicians generally underestimate the difficulty in changing behavior, even their own. Most wrongly believe their only duty is to provide information and end up preaching to or lecturing their patients, rather than informing them. Because this approach alone usually fails, physicians can become discouraged and stop trying to change patient behavior or begin to provide information in a cursory manner, never really expecting patients to cooperate.

Behavioral scientists investigating change as a process have proposed both general and specific approaches that are realistic, practical, and broadly applicable in health care settings. One of the most helpful models is that proposed by Prochaska and DiClemente (25,26). This model divides the process of change into stages. The duty of osteopathic physicians is then to assist their patients to identify the stage they are in and to move successfully into the next. This approach is useful in three important ways because it:

1. Acknowledges that change is difficult and requires planning.
2. Minimizes discouragement on the part of patient and physician.
3. Continually encourages positive work toward lasting or permanent change.

The stages of change include:

1. *Precontemplation*: In this first stage, patients are unaware of or perhaps deny the negative consequences of their behavior. This can include, for example, rationalizations like "I know lots of people who smoke who are healthy." The task of the physician in this stage is to make patients aware of the fallacy of such rationalizations by providing good information and/or by introducing therapeutic tension into the patient's belief systems.
2. *Contemplation*: At this stage, patients spend variable lengths of time reflecting on their behaviors and assessing both negative consequences of continuing a behavior and the probable benefits of positive change.
3. *Preparation*: Patients acknowledge that change is desirable. The physician's task is to negotiate a plan aimed at the higher likelihood of success.
4. *Action*: The patient and physician implement the plan for behavioral change with clear outcome measures to monitor progress.
5. *Maintenance*: Patients have experienced the reinforcing effects of their action plan to the point where the change becomes an ordinary part of their life.

The Prochaska/DiClemente model allows for the possibility and probability of relapse, especially with difficult changes like smoking

cessation. If or when relapse occurs, rather than abandoning the process, the physician and patient move back to a prior stage to troubleshoot the problem before moving ahead again. Continuous attention and incremental improvement are far superior in the long run to giving up in frustration or demoralization.

A review of doctor–patient relationship literature proposes four specific sequential strategies for motivating patient cooperation and encouraging patients to take more personal responsibility for their health. These strategies are grounded in the patient compliance literature and have been expanded and integrated to include relevant social influences and psychotherapy research. A major contribution of this research has been the identification of the patient’s health beliefs as a powerful predictor of cooperation with treatment. The review focuses on the critical importance of the doctor–patient relationship and interaction and then expands to the patient’s relationship with the entire integrated primary care health team.

Patients who are not clear about what they are expected to do are unlikely to follow recommendations. A number of studies show major patient dissatisfaction with not receiving enough information from physicians. Dissatisfied patients are less likely to cooperate and may not ever return.

STRATEGY 1: INFORMING THE PATIENT

The physician should never make assumptions about a patient’s knowledge and understanding, regardless of socioeconomic class or level of education. A confident level of baseline knowledge should first be established. The physician can implement this by allowing the patient time to explain their understanding of health problems and then identify any incorrect or idiosyncratic perceptions. The cultural belief system of patients should also be explored. Verbal instructions should be clear and can be supplemented with pictures and printed materials if necessary. The physician should avoid jargon whenever possible. The physician can check the patient’s level of understanding by asking the patient to repeat instructions or demonstrate how they might share the instructions with a third party. This area of the doctor–patient relationship has been receiving more recent attention than any other aspect (27,28).

STRATEGY 2: OBTAINING COMMITMENT FROM THE PATIENT

This strategy involves the use of referent power, social power bestowed on a significant figure whose acceptance and approval are highly regarded and desired. The use of this referent power involves making direct and clear statements about a desired behavior change and eliciting the patient’s commitment to cooperate. Using the example of smoking, this would involve stating in a non-judgmental but direct and authoritative manner the detrimental effects of smoking, and then asking the patient directly for a commitment to stop. Physicians’ success in eliciting this commitment is revealed in higher patient smoking cessation rates.

STRATEGY 3: NEGOTIATING AND TAILORING A REGIMEN

All treatment recommendations require a change from the patient’s ordinary lifestyle (Box 30-2). The more complex the changes recommended, the more difficult it is for the patient to cooperate. The goal of negotiation is to arrive at an agreement. Through negotiation

History Taking and Behavior Change

1. Standard Osteopathic Examination
2. Review of five osteopathic domains (see Chapter 1)
3. Behavioral lifestyle choices
 - (a) nutrition, body weight
 - (b) physical activity
 - (c) tobacco and alcohol use
 - (d) personal safety, high-risk behaviors
 - (e) sexual behaviors
 - (f) family and work stress
4. Treatment recommendations
5. Health Promotion Counseling and strategies for behavioral change
6. Relapse Prevention Counseling and follow-up planning
7. Continuous reinforcement of self-management and patient responsibility throughout the examination and treatment

and exploration of lifestyle and belief system issues, a regimen can be tailored to the individual life circumstance of each patient. When the negotiated agreement is written up as a mutually binding contract, it is more likely to be kept. A verbal agreement may also suffice.

STRATEGY 4: ATTENDING TO THE PATIENT’S EMOTIONAL RESPONSES

The quality of the doctor–patient relationship is crucial at this point. Patients often complain, even bitterly so, about not being listened to or not having the opportunity to tell their story. Stories abound about technically competent but cold and aloof physicians. Research into doctor–patient relationships has shown that patients’ judgments about physicians are made on the basis of the physician’s ability to recognize and respond to emotional concerns. Positive behavior change occurs more often in the presence of a high-quality doctor–patient relationship. Patients in distress and suffering anxiety are not in the best condition to attend to the cognitive components of their instructions. When physicians attend to a patient’s emotions and set the patient at ease, they facilitate routine history taking understanding and cooperation.

Physicians also need to communicate their interest and concern for their patients nonverbally. Several tactics communicate care and interest including smiling, sitting down, using appropriate eye contact, and not appearing to be rushed.

The osteopathic physician in the patient encounter has a distinct advantage over other health care professionals through the medium of touch and “the laying on of hands.” Through the integrated verbal and nonverbal communication of care, trust is promoted, cooperation is maximized, and the doctor–patient relationship is further strengthened.

The use of the integrated primary care team in this process is summarized in Table 30.2. The primary care team encounter is *individualized* with active patient participation. Treatment is customized, flexible, and based on both physical examination and ongoing biopsychosocial findings. It is a collaborative, cooperative alliance between the health care team and the patient with the goal of facilitating the patient’s own capacity to restore health and maintain optimal function of mind, body, and spirit. This is the true art and science of osteopathic care.

TABLE 30.2

Primary Care–Based Patient Encounter

Activity	Outcome	Agent	Adjunct
Screening	Identification of risky behavior	Physician Nurses Other staff	Questionnaires Interactive Computer
Informing	Knowledge	Physician Nurse Health educator	Written materials Video station

SUMMARY

During the last century, the leading causes of death were diseases such as influenza, tuberculosis, pneumonia, diphtheria, and gastrointestinal infections. “Since then, the yearly death rate from these diseases per 100,000 people has been reduced from 580 to 30!” (1). Today, the major causes of premature death and disability result from behavioral factors, such as accidents and violence, or long-standing habits, such as smoking, high-fat diets, lack of routine exercise, stress, and alcohol abuse (2). Both the WHO and the HSPH predict that by 2020, in the developing countries where four fifths of our planet’s people will live, seven out of ten deaths will be traced to lifestyle factors setting the stage for ischemic heart disease, depression, and chronic obstructive pulmonary diseases. In fact, by 2020, tobacco alone is expected to cause more premature death and disability than any single disease (22). Future improvements in health will come from managing the effects of unhealthy behaviors.

Most of the task of providing the highest quality, cost-effective care involves teaching and motivating patients. The place to begin in creating the desired behavior we wish to see in our patients is to make them clearly reflected in our own. Many physicians have been successful in altering their personal health behavior habits for the better, but there is always room for improvement. Doctor means teacher, and the old maxim remains sound: “Example isn’t the best way to teach, ultimately it is the only way to teach.”

KEY CONCEPTS

- The challenges of patient care at end of life are daunting.
- A significant opportunity is presented for offering each patient the most complete expression of osteopathic medicine's philosophy and practice.
- Physicians must respect and accommodate patient needs in communicating prognosis.
- Physicians must also respect family members' needs in order to understand the dying process and process grief.
- Student–physician interaction with the dying may be the ideal training ground for young doctors.

INTRODUCTION

The opportunity and ability to employ all the facets of being an osteopathic physician is never more needed than at the end of a patient's life. When there is no more surgical intervention possible or advisable, when there are no more tests and studies to conduct, when there is no more medication that can turn the tide of the inevitable decline, then the physician moves fully into utilizing her and his most important tool, the physician–patient relationship for psychological support.

End-of-life care is filled with demands and challenges that all physicians must deal with at some point. No discipline in medicine—except perhaps pathology—escapes the issues of end-of-life care. Ironically and unfortunately for their patients, physicians in those disciplines that are perceived as relatively immune to routinely dealing with end-of-life issues find themselves least prepared when these issues inevitably arise. Further, a very interesting phenomenon that occurs not infrequently is that the student physician who has taken the time to establish a rapport through caring may be the first physician the patient will turn to with questions and concerns at end of life. The wise medical student will learn the principles of end-of-life care to be able to assist all patients.

PRINCIPLES OF END-OF-LIFE CARE

To clarify the requirements for proper care, The Milbank Memorial Fund published a set of “Principles for Care of Patients at the End of Life: An Emerging Consensus among the Specialties of Medicine.” (1) The American Osteopathic Association End-Of-Life Care Advisory Council prepared an osteopathic version of these principles, which were approved by the American Osteopathic Association (AOA) House of Delegates in 2000 (2,6).

RESEARCH INTO END-OF-LIFE CARE

The landmark study—“A controlled trial to improve care for seriously ill hospitalized patients: The study to understand prognoses and preferences for outcomes and risks of treatments (SUPPORT)”—gave the first clear understanding of how patients and families viewed their end-of-life care experiences (3). The phase I observation stage documented shortcomings in communication, frequency of aggressive treatment, and the characteristics of hospital death. It documented a strong indictment of the medical care system discovering that only 47% of physicians knew when

their patients preferred to avoid cardiopulmonary resuscitation, 46% of do-not-resuscitate (DNR) orders were written within 2 days of death, 38% of patients who died spent at least 10 days in an intensive care unit, and for 50% of conscious patients who died in the hospital, family members reported moderate-to-severe pain at least half of the time. Unfortunately, the Phase II intervention part of the study did not demonstrate any improvement in care or patient outcomes. The study's conclusions recommended greater individual and society commitment and more proactive and forceful measures to fill the gaps identified (3).

Many subsequent studies have sought to study the quality of end-of-life care and to understand the perception of both physicians and patients/families about expectations and knowledge of end-of-life care issues. The persistent lack of patients' knowledge of options at the end of life was studied by Silveira et al. (4). Of the 1,000 patients surveyed, there were 728 respondents. Only 23% to 46% of those responding demonstrated an appropriate awareness of four areas relevant to end-of-life care (4). All research points to the importance of more education of physicians and patients about end-of-life care issues.

GOALS OF CARE

The most important issue that needs to be addressed in dealing with patients at end of life is to determine their goals of care. What does the patient perceive as appropriate care at the end of his or her life? How does the patient wish to see himself or herself living out their final days? What does the patient see as the acceptable limits of his or her existence given the constraints of the current medical condition? These questions take the emphasis from “which procedure to perform” and move it to “how do you want to spend your final days?” The patient who states that he or she wants every measure employed to keep himself or herself alive every possible minute regardless of being aware of the surroundings leads the physician to create a very different care plan than one for the patient who states that he or she wants to spend the final days at home out of pain surrounded by loved ones. End-of-life decisions should be the result of the collaboration and mutual informing of the patient, the patient's family and the physicians, each sharing his or her own expertise to help the patient make the best possible decision, often in the worst possible circumstances.

Patients and families also need to understand that the goals of care can and should change as the disease progresses. “Initially,

patients might hope that the cancer responds to chemotherapy or surgery. When disease control is no longer possible, patients might hope to live pain free, achieve closure on personal issues or die surrounded by friends and family” (5).

Adults with decision-making capacity should be informed of their choices, and they have the legal and ethical right to make their own decisions about their life, including the right to refuse recommended life-sustaining medical treatment. This position honors the patient’s autonomy and liberty as guaranteed in the U.S. Constitution. This right exists even when the physician disagrees with the patient’s decision (6).

Patients without decision-making capacity can have their choices adhered to by physicians who follow a previously executed advance directive described below. The principle of “best interests” (what would the reasonable and informed patient select) is invoked if the individual’s wishes are not known. Quality of life should be viewed from the patient’s perspective in all these decisions because quality of life can only be self-determined. Extreme caution must be exercised when trying to determine what constitutes quality of life for another person as research has shown that patients consistently assess their quality of life to be better than their caregivers think their patients do (6).

The over-riding issue is not what the family or friends want for the patient at end of life, but rather what would the patient want for him/herself. If the noncognitive patient were to awaken for only 15 minutes and be able to fully understand the circumstances, what decisions would the patient make? If the answer is unclear, society should err on the side of life. If the answer is clear, then refusal to follow the patient’s wishes is unethical and illegal (6).

ADVANCE CARE PLANNING

Ideally, every person who comes to the hospital or care setting would have completed some type of document that falls under the category of “advance care planning.” This approach was the impetus for the “Patient Self-determination Act of 1991,” which requires that every person entering a facility that receives Medicare/Medicaid funding must be asked whether they have executed such a document or wish to do so. Provision of care is not predicated upon existence or absence of such a document, the only requirement is that the patient or family is aware that such information is available and that such a document could be created. Advance care planning documents generally include living wills or durable medical powers of attorney for health care affairs (proxy designation for health care affairs) and can be self-executed with or without the aid of an attorney. This medical power of attorney is separate and distinct from the legal power of attorney and neither one implies the presence or intent of the other. Such documents are available from many organizations and are also online. These documents carry the weight of law but can be superseded by the patient at any time. Living wills document the desired treatments but leave much room for interpretation when the situation doesn’t match the directives, so a combination of a living will and a durable medical power of attorney may be best. When the physician, patient, and family have had these conversations earlier and are in agreement, there is little need for such documentation. However, when that is not the case, these documents can assist in settling disagreements. Ultimately, if agreement cannot be reached, the hospital ethics committee can also be called upon to assist these deliberations.

Sample living wills and durable medical powers of attorney can be downloaded from several Internet sites, search term: living will form.

WHOLE PATIENT ASSESSMENT

Nowhere is the principle of assessing the whole patient more important than at end of life. However, whole patient assessment does not imply that the physician will be employing futile treatment. Whole patient assessment implies that the patient at end of life is to be accorded the same well thought out evaluation and care as any other patient. A fever in a patient dying from heart failure is not caused by the heart failure and may be an indication of an easily treatable problem. Pedal edema in a patient with respiratory failure without cor pulmonale cannot be assumed to be due to the respiratory failure. More than one patient at end of life has had incorrect assumptions made about symptoms and has been denied simple and appropriate care just because he or she is “dying anyway.” A proper patient assessment does not have to be painful, costly, onerous, or futile. It just has to be thoughtful and appropriate.

SYMPTOM MANAGEMENT

Closely tied to the approach of whole patient assessment is the requirement to provide proper symptom management. When whole patient assessment does not reveal a treatable cause for a specific symptom, there are appropriate interventions for those symptoms. The types of symptoms most frequently encountered as part of the end-of-life process that may not be indicative of another medical cause include dyspnea, nausea, vomiting, constipation, diarrhea, anorexia, cachexia, fatigue, weakness, fluid balance problems, edema, skin integrity, decubitus ulcers, odors, and insomnia. The physician caring for the patient with such symptoms at end of life is referred to the American College of Physician (ACP) Clinical Practice Guidelines (11) and Education for Physicians on End of Life Care (EPEC) (7) www.EPEC.org and to the Osteopathic EPEC (12) for best practices. www.osteopathic.org (search term “palliative care”)

PAIN MANAGEMENT

Another aspect of patient care at end of life, which bears special mention, is that of proper pain management. The key concept about how much medication to provide to control pain is “it takes as much as it takes.” All the restrictions and guidelines about dosing of pain medication do not apply at end of life for anyone other than the narcotic-naive patient. The principle of “go low and go slow” applies to every patient until the appropriate level of pain relief has been achieved. The other key concept of pain management is that pain medication should never be administered on a “prn” basis but as a continuous infusion to maintain a baseline of pain control. This level of control may have to be supplemented at times of unavoidable painful processes, or if the level of pain steadily escalates, but the patient should never be allowed to experience unrelieved pain. There is no need to fear addiction at end of life, although medication tolerance may be seen, expected, and properly managed with increased dosing. The proper usage of narcotics at the end of life in a person who is or was addicted to narcotics prior to acquiring the terminal illness requires more thoughtful planning, but no such person should ever be denied narcotics for the purposes of providing adequate pain relief.

DOUBLE EFFECT OR SECONDARY EFFECT AND TERMINATION SEDATION

Subtopics under pain management are the related principles of double effect or secondary effect and the issue of terminal sedation.

It is possible that a patient can be in so much pain at end of life, particularly with such diagnoses such as bone metastasis after the patient has passed the limits of radiation, that the patient's pain may be uncontrolled by any current measure. At that point, it is appropriate to present the option of controlling that pain by medicating the patient into a coma. This is called "terminal sedation." The patient is kept comfortable even though not cognizant of the surroundings. The appropriate level of pain medication dosing is determined by monitoring the patient's native blood pressure, respiratory rate, and heart rate to see the response of the body to the effects of the pain medication. Another natural response to uncontrolled pain that can be helpful in this assessment is grimacing. Monitoring how the body naturally responds to the relief of pain allows for appropriate adjustments in dosage, increasing to control the pain, and decreasing the dosage if the current medication level appears to be too strong for the body's present pain level. Such a required level of pain medication may result in the patient dying sooner than without that level of pain medication. The sheer anxiety of unrelieved pain can trigger the counter-regulatory hormones that can act to prolong life. Relief of that level of pain may decrease those same counter-regulatory hormones to the level that the life processes are no longer stimulated and the patient may die. The concept of double effect or secondary effect indicates that the primary and intended effect was to ease pain, and not to kill the patient. A well-designed study in a hospice population found no association between percentage of change in dose of opioids and time until death (13). The primacy of the intent of maintaining pain control is evident by the proper monitoring as described above.

HOSPICE AND PALLIATIVE CARE

The hospice concept of providing comfort when cure is no longer possible was initiated in England and quickly spread to the United States beginning in the 1970s. Although the number of patients who die while being cared for by hospice has been rising slowly, patients generally do not spend enough time in these programs to experience all the potential benefits. Such benefits include provision of medications and durable medical equipment, a major focus on aggressive pain management, counseling services both before and up to a year following death for the family, out patient medical support and in patient care for extremely demanding situations. More recently, palliative care programs have been developing across the United States to provide the expertise and standards of practice developed by hospice to patients who have needs for symptom control and supportive care earlier in their illness. All hospice programs fall under the umbrella of palliative care; however, palliative care is indicated beyond the specific time limits of and criteria for hospice, generally anticipated to apply to the specific diagnoses and limited to the last six months of life. The focus of hospice is to work toward death with dignity employing an entire team of professionals bringing the needed expertise to the entire galaxy of end of life. According to anecdotal experience, while designed to improve the quality of patients' lives as they fight their disease, good palliative care may help to increase life expectancy in certain diagnoses (7).

TRANSITIONS OF LIFE

There exists another aspect of assisting patients as they move toward the end of their lives that may be one of the most challenging, as Thomas Finucane, M.D., eloquently points out in an editorial in the November 3, 1999 issue of *JAMA* (8). It is the process of "moving through the transition from gravely ill and fighting death to terminally ill and seeking peace, shifting the goals of

treatment from cure or longer survival to preservation of comfort and dignity."

Two conflicting issues clash here. The dying patient desperately wants to live as long as possible, as healthy as possible, able to enjoy life and people, without pain. When this is no longer possible, the patient also wants death to come swiftly, peacefully, and painlessly at the last possible minute. The physician also wants this scenario for every patient. The problem is medicine does not have the ability to predict the future and give patients a precise, reliable date and time when death will come. Ironically, many chronically ill patients never experience a time during which they are clearly dying of their disease; "the sickest patients are not necessarily the ones who die first" (8).

The result is the patient chooses to accept a less and less "ideal" quality of life, adjusting to more and more incapacitation and pain in exchange for one more day, and yearning for this day not to be the last. Some patients seem to accept death's coming easily, accepting the future, even choosing not to eat and drink. For many others, however, hope (no matter how faint) persists so strongly that surrender to the inevitable end of life is more excruciating than the pain and the struggle. Openly discussing this struggle to shift goals may be the only way to avoid a time where "do everything you can, doctor," in life becomes "why did this have to drag on so long?" after death (8).

This point is confirmed by a significant study of prognosis from George Washington University and the Department of Veterans Affairs published in *JAMA* (9). The study looked at seriously ill hospitalized patients with advanced chronic obstructive pulmonary disease, congestive heart failure, or end-stage liver disease. It found that the recommended clinical prediction criteria are not effective in identifying a population with a prognosis for survival of 6 months or less (9).

While we may not be able to predict the exact day of demise, we can predict that all indications point to the fact that the time is so short that hospice and palliative care is the best way to proceed, even though the patient and family may not be eager to hear that recommendation. The following words from the attending physician may be useful in the discussion: "Do you think it is time to consider a different type of treatment that focuses on your symptoms? I'll be here with you no matter what you decide." Another approach might be "I want to provide intense, coordinated care with a team of professionals who will treat your symptoms and help you stay comfortable" (5).

LEGAL MYTHS AND REALITIES

A significant barrier to proper care is lack of understanding on the part of the physician about legal issues at the end of life. Many physicians are not aware of the underlying principles vis-à-vis actual legal concerns. The body of law known as right-to-die cases extends ordinary treatment refusal doctrine to end-of-life decisions. The courts have affirmed a right to refuse life-sustaining treatment. Making a distinction between what treatment is life sustaining and what is not, is the difficulty. Meisel, Snyder, and Quill published a well-written set of "Seven legal barriers to end-of-life care: myths, realities and grains of truth," for the ACP—American Society of Internal Medicine End-of-Life Care Consensus Panel (10).

COMMUNICATING BAD NEWS

One of the major challenges at end of life is that of telling a patient that he/she is at the end of life. Every physician has to communicate uncomfortable information or to give the family/patient bad

news at some time in the process of providing medical care. It is important to develop the skill of delivering this type of information. Most people want to know such information and delivering it well actually strengthens the patient–physician relationship. The patient/family not only learns the information but also learns that the physician who doesn't shy away from the hard issues can be trusted to tell the truth. Delivering such information thoughtfully fosters collaboration between the physician and the patient/family as they then have time to plan and cope.

COMMUNICATION PROTOCOL

There is a seven-step protocol that has been developed as part of the program “Education for Physicians on End of Life Care (EPEC)” that is recommended as an effective approach to communicating bad news (7). All these steps may need to be modified by the urgency of the situation. The emergency department setting with an elderly demented patient quickly approaching his or her final minutes dictates a different pace than in the office setting talking to an alert patient who needs to be advised of a condition with a long prognosis:

1. Know yourself. Whether they know it or not, physicians communicate their own emotional responses in the most subtle ways, so it is important to be aware of your own responses.
2. Create a plan. Allot adequate time without interruption. Plan what to say after confirming the medical facts. Don't delegate this job. Create an environment that is conducive to conversation.
3. Establish what the patient already knows. The patient may already have suspected the worst.
4. How much does the patient want to know? There can be various patient preferences, either declining to know the details or choosing to designate someone else to communicate on his or her behalf. This varies with race, ethnicity, culture, religion, socioeconomic status, age, and developmental level.
5. Say the information and stop to allow the patient/family time to process. Avoid a monologue, jargon, and euphemisms, and pause frequently.
6. Be prepared for emotions. Some may respond with tears, anger, and anxiety, and others may experience denial, blame, guilt, fear, and shame.
7. Plan for the next steps in the process of the disease and approach.

FAMILY REQUESTS TO WITHHOLD INFORMATION

If the family anticipates the worst and requests that information not be told to the patient, the physician still has a legal obligation to tell the patient. The family needs to discuss the reason for their fears of the information being shared. It is always the physician's responsibility to tell the truth to the patient, but it may be necessary to assist the family in working through their issues so that they see the importance of telling the truth and understand why it is not fair to the patient not to have this information. It may be appropriate to talk to the family and the patient at the same time.

LANGUAGE BARRIERS

When language is a barrier, the best approach is to obtain a translator as the family members who may be able to translate may have difficulty with the medical terms and concepts or may feel compelled to modify the news to protect the patient. A family

translator may also not want to be the one to actually be the first to have to utter the words that will bring such dismay.

COMMUNICATING PROGNOSIS

When the physician is asked about prognosis and timing of death, it is helpful to find out why the patient wants to know. There may be a specific event coming up that the patient wishes to plan for, or the reasons for asking may be very ill-defined. The “planner” patient will want more details. Avoiding precise answers is appropriate indicating that the prognosis is either in hours instead of days, days instead of weeks, weeks instead of month, or in months instead of years. Precise answers can be perceived as a guarantee that no physician is able to provide.

THE TIME TO WITHDRAW INTERVENTIONS

Another aspect of communication that can be unexpectedly challenging is when the time comes for the invoking of the patient's wishes to withdraw interventions. It is unkind and unwise to ask the family “do you want us to take your family member off the ventilator now?” This approach puts the family member in the position of having to “make the decision to let Mom die,” and actually having to say those words, when in reality that decision was already made by the patient some time ago. The better approach is to tell the family, “as we have discussed repeatedly, your mother indicated in her living will that when we got to this point she did not want life support continued, so we think it is time to take her off the ventilator, which we can do at 6 P.M. tomorrow.” Allowing plenty of time for that information to sink in and for the family to respond, guides the rest of the treatment plan and timing.

WITHHOLDING AND WITHDRAWING TREATMENT

As was indicated in the “legal myths and realities” section, there is much misinformation about the difference between withholding and withdrawing treatment. In my experience in seminar after seminar that I have personally presented on end-of-life care topics, when I have polled physicians about which choice seems to be “harder” for the physician to perform, the results always indicate that physicians feel that choosing to withdraw treatment is more difficult to handle psychologically than withholding treatment. Nevertheless, all sources agree that there is no difference legally, morally, or ethically as the end result is the same, death of the patient (7). If the treatment is initially withheld, there is no possibility of determining whether or not it may have been successful.

On the other hand, if the specific treatment is instituted and is determined not to be successful, there is often significant reluctance to remove that treatment. In my opinion, this reluctance is based upon the fact that when the treatment is removed, the patient will likely die sooner than if the treatment had been continued, so the appearance is created that removing the treatment was the event that killed the patient. On the contrary, the disease process kills the patient. The treatment was shown to be ineffective in reversing the disease process and therefore was futile. The best approach to this difficult situation is to explain prospectively that a specific treatment will be instituted as a time-limited trial, with the time specified. At the appointed time, depending upon the natural course of the disease process and the chosen treatment, the issue is then revisited. Either the treatment is successful and is no longer needed, or the treatment is achieving desired results and a new time-limited plan is created, or the treatment is unsuccessful with no reason to continue

and a plan to remove the treatment is created. The time-limited trial combines the advantages and avoids as much as possible the disadvantages of these two approaches to patient treatment.

ARTIFICIAL NUTRITION AND HYDRATION

Providing such support at end of life may at times be beneficial; however, sometimes this intervention may be excessively burdensome and may actually prolong the dying process. The use of artificial nutrition and hydration involves a medical procedure with potential side effects and complications. That fact is also the reason that the proper terminology is to use the technical medical phrase “artificial nutrition and hydration,” not “providing food and water.” A decision to not provide or to discontinue this intervention may pose some significant challenges particularly to families. Physicians need to assist patients and families to understand the role of artificial nutrition and hydration at the end of life, which is to provide temporary support to allow time for other interventions to have a chance to work. Families also need to understand that as body processes shut down, loss of the sensations of hunger and thirst are part of the dying process. Research has shown that discontinuing such support doesn’t contribute to suffering, but those concerns may persist (6).

DO NOT (ATTEMPT) RESUSCITATE STATUS

This status is indicated for most patients when it is anticipated that there is only a short length of life remaining. It means that the physician continues to provide all comfort care and when the patient slips into the final minutes of life, nothing is done to stop that process. Sometimes physicians who have been reluctant to write an actual DNR order will indicate that any code procedure should be “slow” (when full resuscitative efforts are not expended with the pretense that they are). This is not appropriate as it represents an attempt to deceive, which is an ethical violation (6). Even in optimal circumstances, code procedures are not successful in the majority of patients, so any “restricted” code order (chemical code, do not intubate, no compressions) is even less likely to be successful, therefore seldom indicated.

Obtaining patient/family permission for a DNR status order can be very challenging. Following the principles in the paragraph “communicating bad news” will be helpful. A suggested sequence of discussion can be:

1. Gently introduce the topic of end of life, such as “it looks like your disease isn’t really responding to treatment.”
2. Let the patient/family respond about their thoughts, feelings, and impressions.
3. Introduce the next statement such as “we have all been working to meet your needs and want to be sure we follow your wishes in the event your time is near.”
4. Again, let the patient/family respond.
5. Ask the question, “have you thought about what is most important to you in how you want to spend your final hours?”
6. If there is no clear direction from the patient/family, another question could be “in the event your heart stops, do you want to be kept alive on machines?”
7. It is always best to focus on the patient’s goals of care. Having the patient explain his or her last-hour wishes can also lead to the question, “so it sounds like you want your last hours to be quiet and peaceful and free of pain, with no machines to prolong the inevitable?”
8. The best approach is to be osteopathic and focus on the whole person, letting the dialogue flow from your human-to-human relationship. It is important never to take away hope and also to

acknowledge that if the clinical situation improves, a change in DNR status can be made.

Families have specific needs at this time, as well as the patient (i.e.,) the need to understand the dying process, the need to have cultural and religious differences understood and honored, the need to process grief. The osteopathic physician understands the important contribution of the family to the patient’s overall well-being.

SUDDEN ILLNESS

A particularly difficult aspect of end-of-life care arises when the terminal illness/trauma has occurred suddenly without warning and especially in an otherwise healthy and/or young person. All the principles of good communication apply. The physician must be aware that the level of understanding about the terminal illness including the options and pathway ahead will likely be minimal. Determining the approach to care will be a delayed “process” and may be much more contentious as the terminal nature of the illness is complicated by the unexpected nature of the situation. The grief and anger that result from the sudden and unplanned nature of the illness are almost inevitable. Frequently, the physician has never met that new patient and/or family until this event; so this fact further complicates patient care as there is no basis for trust in the physician–patient relationship. The best approach is always to be as open as possible, provide as much information as possible, and never withhold partial information waiting for more definitive testing. It is also appropriate to err on the side of life to allow families time to process the grief. The assistance of social workers and other support staff as well as any of the patient’s or family’s personal trusted advisors, especially including spiritual advisors, is never more valuable than in this situation.

MEDICAL FUTILITY

A further aspect of sudden illness but also of other terminal illnesses is the issue of medical futility. Present-day medical care has not been well served by the media where every illness is solved at the conclusion of the movie or the TV show. There is a very high expectation by the American public that with sufficient consultations, testing, and interventions, every patient can be saved, for the present day. Also, the lack of medical knowledge in the general population complicates this issue, as there is often little understanding of basic anatomic and physiologic principles. The physician is often faced with a demand/expectation that a particular intervention should be instituted, when there is no possibility that the intervention is appropriate or indicated for the diagnosis. An excellent example is that of the individual who has suffered a severe crush injury to the chest in a motor vehicle accident, which has created a diminished cardiac output that has prevented adequate perfusion of the kidneys resulting in kidney failure. The demand for a kidney transplant in this situation is a request for a medically futile procedure. While technically feasible, a kidney transplanted into this setting of inadequate perfusion is also doomed to fail. The best approach is a thorough explanation, assistance from social workers, and a willingness to understand, acknowledge, and tolerate the frustration of the person requesting the futile intervention.

PHYSICIAN-ASSISTED SUICIDE AND PHYSICIAN-ASSISTED DEATH

Currently in flux is the issue of physician-assisted suicide (PAS). While Oregon is the only state that currently allows the full legal

provision of PAS, other state legislatures are also addressing this issue in various forms. The general provisions of the Oregon law require verification of terminal status without depression, a waiting period between a repeated request for PAS, and the ability to swallow the specified prescribed barbiturate in liquid form.

The U.S. attorney general filed a law suit against the state of Oregon opposing PAS and lost the case. In an interesting turn of events, although both the AOA and the American Medical Association officially oppose PAS, both organizations opposed the attorney general's lawsuit. This opposition was based on the premise of the lawsuit, which was that physicians should not be allowed to prescribe medication for an off-label use. Therefore, the implication was that since no medication is approved by the Food and Drug Administration for assisting a patient to commit suicide, that practice would have been judged illegal if the lawsuit had prevailed. Taking this outcome to the next step runs afoul of the fact that included in most state medical licensure statutes is the prerogative of physicians to use best judgment to prescribe medication for off-label purposes, so if this lawsuit had been successful, the unintended consequence would have set a chilling precedent leading to restriction of the lawful practice of medicine in every setting.

The AOA opposes the practice of PAS. Such a practice puts the physician in the position of making a determination as to whether to be on the side of working to save a patient or on the side of working to kill a patient. No physician should have to make that decision and no patient should wonder if the physician is weighing that option. In a survey of 988 terminally ill patients by Emanuel and associates in 2000, identified factors associated with a patient being less likely to consider euthanasia or PAS which were "feeling appreciated, being aged 65 years or older, and being African American." Factors associated with being more likely to consider euthanasia or PAS were "depressive symptoms, substantial care giving needs, and pain" (14). Foley (15) makes the strong point that competent care for the dying can relieve the concern of those patients considering PAS, and this approach should be advocated in preference to PAS.

There is also a move to change the descriptive title of this practice from PAS to physician-assisted death. This proposed change would appear to be an attempt to camouflage the fact that when the patient takes the prescribed medication for its intended purpose, the patient is committing suicide and the physician assisted that suicide by providing the means. PAS (where the physician provides the means and the patient acts) is also clearly differentiated from euthanasia (where the physician provides the means and completes the act for the patient).

There is no question this is a highly emotionally charged issue with no lack of strength of opinions on both sides. The perspective of proponents of physician-assisted suicide is PAS is the best alternative to other methods of ending one's life when the burdens of that life have become untenable from the patient's perspective. Only a small percentage of those patients in Oregon who have invoked the provision of this law, have actually consummated this method of ending their life, indicating that making this request was as much to provide the option for control of the dying process as to actually use that option.

STUDENTS AND END-OF-LIFE CARE

To what degree should students be involved in this process? Should students restrict participation to information gathering? If so, are there key elements to determine? How do they record their findings (this information doesn't exactly fit in the SOAP note)? Should students ever introduce discussion in this area? If so, are there limits to how they advance the information that they gain? Who is the recipient of the information they gather: attending,

case worker, hospital chaplain, or potential hospice person? This is a most provocative series of questions to which the answer is yes, no, maybe, sometimes, and even "I don't know." After learning how to diagnose and treat disease, the student on clinical rotation starts to experience the biggest challenge to being a physician, how to translate all that knowledge into real patient care. The patient who can't understand, refuses to listen, chooses not to follow the instructions, or hides the true problem out of fear is still the patient who needs care. The physician has to learn that he or she is frequently part of the trigger or reason the patient acts and responds in the way he or she does. The physician-patient relationship is ultimately the strongest tool the physician has to help the patient. The student physician cannot wait to learn to work in this relationship until after completion of residency.

On the other hand, the student physician is still a student working under the attending physician's license. The best guidance I can provide is to include the following question in every history and physical, "have you made anyone aware of your wishes for the end of your life through some tool like a living will?" The answer is to be precisely documented as stated by the patient, in the notes section of the chart in the appropriate manner with the rest of the history and physical information such as "last tetanus shot, last mammogram, last colonoscopy, etc." This simple question opens the door for the patient to walk through if desired. If the patient is not ready to discuss this topic, the answer will indicate it is time to move to the next topic. The student is not expected to probe any further, to answer questions, or to counsel the patient. The student is expected to bring to the attention of the attending physician (or designee such as a resident) if the patient requests further discussion or information. The student should function like a conduit to carry information and concerns from the patient to the attending physician who can assess the situation and decide what orders are appropriate, including a possible DNR status. The patient will set the tone, indicate the depth and length of the conversation, indicate whether further questions are appropriate, or whether the patient just wants a willing listener. Many times, the patient has been waiting for a physician to broach this topic. Two leaders in end-of-life care, Dr. Susan Block and Dr. J. Andrew Billings, have studied the student-physician interaction with the dying and suggest that end-of-life care may be the ideal training ground for young doctors (16).

SUMMARY

Although the challenges of patient care at end of life are daunting, it is a truly rewarding time to care for patients. Every one of our patients and each of us will pass through this experience. It can be handled well or be given short shrift. It may be the only opportunity to bring to bear all the best that osteopathic medicine has to offer, honoring the patient as a whole person and calling upon each osteopathic physician to create the milieu for the use of everything we have learned. To share this time with a patient and make his or her last days comfortable and meaningful is a true gift, a reciprocal gift that the patient and physician give each other. The physician who welcomes and embraces the interaction at end of life is touched in ways that won't be forgotten by the patient, the family, or the physician.

KEY CONCEPTS

- Evidence-based medicine (EBM) builds upon a framework of valid patient-oriented information dispensed within the time constraints of a typical practice.
- The EBM approach of today is, in effect, an elaboration of osteopathic medicine's break away from the harmful effects of 19th century medical treatments in pharmacotherapy and surgery.
- In the practice of EBM, an easily grasped series of steps allows physicians to utilize the best-available research in caring for their patients.
- The focus of EBM is the appraising of individual research studies of therapy, diagnosis, harm, and prognosis.
- EBM functions as a tool for the practicing physician. Repetition and practice are the key to becoming comfortable and efficient with the concepts and steps, allowing physicians to stay informed and to properly inform the patient.

INTRODUCTION

Physicians of today are confronted with an insurmountable amount of medical information from a variety of sources (1,2), much of which has the potential to change the way we practice medicine and care for our patients. Many medications or treatment modalities, which were formerly considered to be the standard of care, have now been shown to either be of questionable benefit or even to cause harm to our patients. Thousands of health care research articles are published each month (3)—far beyond the capacity of any physician to read. This knowledge explosion is primarily a result of electronic resources such as the Internet and has forced physicians to be selective in what they use to stay updated, thus making valid information, and the ability to assess for validity, more important than ever.

The concept of **Evidence-Based Medicine (EBM)** evolved in 1992 by the Evidence-Based Medicine Working Group (4). EBM is intended to provide a method for practicing physicians to efficiently utilize published research to improve the care they provide in their clinical practice. EBM builds upon a framework that allows physicians to provide the most valid patient-oriented information to patients within the time constraints of a typical practice (5).

Why is EBM important to osteopathic physicians? Andrew Taylor Still originally broke from traditional medicine as a result of his observation that the allopathic medicine of the time was often more harmful to the patient than no treatment at all, violating one of the key tenets of modern medicine—"first do no harm" (6). Osteopathic medicine was founded upon an ideology that the body can heal itself and that the physician's role was to assist it in this process. As scientifically valid treatments became available in pharmacotherapy and surgery, Still and other osteopathic physicians began to embrace and utilize them. For today's osteopathic physicians, it is important to use scientifically valid methods of treatment and diagnosis to care for our patients. EBM provides us with a framework to do this.

STEPS IN PRACTICING EVIDENCE-BASED MEDICINE

The practice of EBM is based upon a series of steps that allows physicians to utilize the best available research in caring for their patients (5). These **fundamental steps** are:

1. Ask an answerable question.
2. Search the available evidence.
3. Critically appraise the evidence for its validity, impact, and applicability.
4. Integrate this critical appraisal with the physician's clinical expertise and the patient's unique biology, values, and circumstances.
5. Evaluate and improve how one performed the first four steps.

Step 1: Ask an Answerable Question

There are two types of questions that one can ask: background questions and foreground questions. Background questions are those that ask for general knowledge or background about a certain condition, illness, or some aspect of health status and are commonly asked by learners early in their career. Foreground questions ask for specific information in order to perform clinical decisions or actions (5). Foreground questions have four components, also known as the "**PICO**" format: (a) patient and/or problem; (b) intervention or exposure; (c) comparison (if relevant); and (d) clinical outcome (including time if relevant) (5). An example of a foreground question is "In adults with diabetes mellitus, would the use of metformin lower the risk of having a cardiovascular event compared to taking a sulfonylurea?" Well-formulated questions create a basis for a well-defined literature search and appraisal process.

Step 2: Search the Available Evidence

Once an answerable question is formulated, the next step is to search the available evidence for an appropriate answer. It is important

to realize that not all evidence is of equal value. Systematic reviews, randomized controlled trials, observational studies, and secondary publications are resources of evidence of varying degrees of reliability. The most reliable information comes from homogeneous systematic reviews (with or without meta-analyses) comprising multiple randomized controlled trials. The next most reliable information comes from individual randomized controlled trials followed by observational studies. Although this list represents a hierarchy, caution is advised since the best study design is determined by the study question. Moreover, a systematic review is only as good as the individual studies that are summarized in the review. Clinical guidelines are a source of evidence that must also be critically appraised since the development of a guideline may be based on expert opinion (low quality) or independent well-designed trials (high quality). Another valuable source of evidence for practicing physicians is secondary publications, such as *Journal of Evidence-Based Medicine*, which is a collection of articles from various journals that are already appraised for the reader with summary recommendations.

Step 3: Assess the Evidence for Validity, Impact, and Applicability

Physicians spend a considerable amount of time making therapeutic decisions, performing and ordering diagnostic tests, understanding the potential risks of their and the patients' actions, and assessing potential long-term outcomes of medical decisions. Hence, the focus of this introductory EBM chapter is on appraising individual research studies of therapy, diagnosis, harm, and prognosis. It should be noted that there are methods to appraise other types of articles such as decision prediction rules, cost-effective analyses, clinical guidelines, and so on. However, these are beyond the scope of this chapter and readers are encouraged to seek other valuable resources on these topics.

Shared Concepts Impacting a Study's Validity

When assessing the validity of therapeutic, diagnostic, harm, and prognostic articles, there are some core concepts that they all share. These concepts include blinding, accounting for all study participants at the end of the study, treating each study participant equally throughout the study, and ensuring the participants are similar to some extent. These concepts are discussed in more detail below and then followed by additional validity questions that are specific to the article type.

Blinding

In therapeutic and harm studies, study participants, clinicians, and investigators should not know who is allocated to the intervention group or control group. Unblinded studies have the potential to introduce significant bias into the study since participants, and researchers alike, may respond differently or intentionally (or unintentionally) alter the study's protocol. **Double-blinding** refers to keeping the participants and investigators (including clinicians) blinded to avoid conscious or unconscious actions that may jeopardize the integrity of the study.

In diagnostic studies, the test of interest is normally compared to a reference standard. Comparing a rapid streptococcal test to a throat culture is such an example. The testers should be blinded to the diagnostic test results (i.e., rapid streptococcal test) when performing and interpreting the reference standard test (i.e., throat culture).

Accounting for all Study Participants

All patients who started the study must be accounted for at the end of the study since a large loss of participants to follow-up may lead

to biased results. For example, if very sick patients do not complete a study or drop out of the study early because of death or unacceptable side effects, the outcome may appear falsely favorable if they are not accounted for. Furthermore, study participants should be analyzed in their original group assignment. This principle is called "**intention-to-treat analysis**" (7). A crude "**5 and 20 rule**" can guide readers in determining the completeness of the study (8). If less than 5% of the study population is lost to follow-up, one can be reassured that the loss to follow-up minimally impacts the results. However, if more than 20% of the study population is lost to follow-up, caution is advised. One must weigh the strengths and weakness of the study itself, such as the study's sample size and the length of the study, when there is a 5% to 19% loss to follow-up.

Treating all Participants Equally

Keeping study groups blinded would prove to be difficult if the intervention and the control groups were treated differently. For example, if study participants in the intervention group had more frequent follow-up visits or if the study pill looked and tasted differently than the placebo pill, participants may develop the suspicion that they were receiving the intervention or the placebo.

Ensuring Study Groups are Similar

The description of a study population is usually found in the first table of an article. Since there are always some established risk factors that may affect the outcome, it is important to determine whether these factors are equally balanced between study groups. Another important consideration is that the study's population should be relatively similar to the physician's practice population. This increases the likelihood that the study's results can be **generalized** to a specific patient population.

Additional Validity Criteria for Therapeutic Studies

Randomization is the most important factor that impacts the validity of a therapeutic study (9). It ensures that each person has the same probability of being chosen and assigned to a specific study group. Nonrandomized studies may consciously or unconsciously cause an imbalance of important factors that can potentially impact the study's final results.

Additional Validity Criteria for Diagnostic Test Studies

Both the diagnostic test and the **reference standard** test must be performed and compared to one another. This should not be an issue if the study is truly blinded. The reference standard establishes whether the disease of interest is present or not (10), allowing the diagnostic test's characteristics to be calculated (i.e., sensitivity, specificity, etc.).

Additional Validity Criteria for Harm Studies

The follow-up period in a valid harm study should be sufficiently long since short follow-up periods may allow too little time for the disease (outcome) to manifest. The length of the study is determined by the study question, intervention, outcomes of interest, and limiting circumstances (i.e., funding). Phase IV clinical trials represent the study period in which participants are followed over extended periods of time. Recent FDA actions, such as pulling certain medications off the market, highlight the importance of having sufficiently long follow-up periods to monitor potential adverse events.

Additional Validity Criteria for Prognostic Studies

Prognostic studies usually stratify the study group into cohorts based on comorbid conditions or factors that influence the outcome (11).

TABLE 32.1

Hypothetical Example for Calculating EER and CER

Study Plan	Received Beta-blocker	Received Placebo
Number of patients in each group	100	100
Died within 2 y since initial myocardial infarction	5	15

$EER = 5/100 = 0.05 = 5\%$
 $CER = 15/100 = 0.15 = 15\%$
 $RRR = 0.15 - 0.05/0.15 = 0.67$ or 67%
 $ARR = 0.15 - 0.05 = 0.10$ or 10%
 $NNT = 1/0.10 = 10$

These factors can include the stage of disease or other diseases that may impact the outcome of interest. Demographic factors (i.e., age, sex) and environmental risk factors must also be considered. These potential “**confounding**” factors can be addressed using statistical techniques or participants can be matched (i.e., paired up) at the start of the study.

Assessing the Importance of Studies

Once the validity of a specific article is established, the next step is to assess the magnitude of its treatment effects.

The Magnitude of Effects of Therapeutic Studies

Most studies report their outcome in a dichotomous fashion. For example, one may evaluate whether or not daily use of a beta-blocker prolongs life after an initial myocardial infarction (Table 32.1). One can then compare the event of interest (i.e., death rates) among those who received a beta-blocker and those who received nothing (or placebo). The proportion of those who died in the

placebo group is the “**control event rate**” (CER), also considered the baseline risk.

The proportion of those who died in the intervention group (received beta-blocker) is called the “**experimental event rate**” (EER). The **relative risk reduction** (RRR; $RRR = CER - EER/CER$) is common term that is used to explain the magnitude of a treatment effect. However, the RRR conveys limited information to the clinician because it does not take the baseline risk into account, not giving the clinician the ability to discriminate large treatment effects from small ones. The **absolute risk reduction** (ARR; $ARR = CER - EER$) takes the baseline risk into account (12). By taking the reciprocal of the ARR, the **number needed to treat** (NNT; $NNT = 1/ARR$) can be calculated (5). The NNT corresponds to the number of patients who need to take the therapy (i.e., beta-blocker) to prevent one outcome (i.e., death) over a certain period of time.

The Magnitude of Diagnostic Test Characteristics

The characteristics of a diagnostic test can be calculated by using a 2×2 table, as depicted in Table 32.2. The columns often refer to the presence or absence of the disease of interest as determined by a standard reference. The rows of the table are the “positive” or “negative” results of the diagnostic test of interest.

Based on Table 32.2, the **prevalence** of the disease (i.e., congestive heart failure) in the study population is 10.7%. A patient’s **pretest probability** (the probability that a patient has the disease before the diagnostic test is performed) can be estimated by the prevalence if the patient is relatively similar to the study population. The **positive predictive value** is the probability that a patient has the disease if the diagnostic test is positive, whereas the **negative predictive value** is the probability that they do not have the disease if the test result is negative. **Sensitivity** is another characteristic of a diagnostic test that is commonly reported, which is defined as probability of a positive test given that the target disease is present. **Specificity** is defined as the probability of a negative result given that the target disease is not present. These parameters are then used to calculate the **positive (LR+) and negative (LR-) likelihood ratios** of diagnostic tests. The LR+ is the ratio of the true-positive rate to the false-positive rate. In the example in Table 32.2, a positive test result would be 9.77 times as likely in someone with

TABLE 32.2

Example of a 2×2 Table

		Target Disorder		
		CHF	No CHF	Totals
Diagnostic test result	BNP \geq 100	138 (a)	118 (b)	256 (a + b)
	BNP < 100	19 (c)	1196 (d)	1215 (c + d)
Totals		157 (a + c)	1,314 (b + d)	1,471 (a + b + c + d)

Prevalence = $(a + c)/(a + b + c + d) = 157/1,471 = 10.7\%$
 Positive predictive-value = $a/(a + b) = 138/256 = 53.9\%$
 Negative predictive-value = $d/(c + d) = 1,196/1,215 = 98.4\%$
 Sensitivity = $a/(a + c) = 138/157 = 87.9\%$
 Specificity = $d/(b + d) = 1,196/1,314 = 91.0\%$
 $LR+ = sensitivity/(1 - specificity) = 0.879/1 - 0.91 = 9.77$
 $LR- = (1 - sensitivity)/specificity = 0.25/0.88 = 0.28$ ($(1 - 0.879)/0.91 = 0.13$)
 BNP, B-type natriuretic peptide; CHF, congestive heart failure.

the disease as in someone without the disease. Likewise, the LR is defined as the ratio of the false-negative rate to true-negative rate. There are two mnemonics that are used in remembering the clinical applicability of specificity and sensitivity: (a) for a test with a high *Specificity*, a *Positive result rules-in* the diagnosis (**SpPin**) (5) and (b) for a test with a high *Sensitivity*, a *Negative result rules-out* the diagnosis (**SnNout**) (5).

The Magnitude of Effects from Harm Studies

The magnitude of association in retrospective studies is reported as an **odds ratio** where a value of less than one confers a protective effect of the intervention and a value of greater than one confers a detrimental effect of the intervention. A sample calculation is shown in Table 32.3.

Prospective studies (i.e., clinical trials and cohort studies) report the magnitude of an association by using a **“Relative risk”** which is defined as “the ratio of the risk in the treated group (EER) to the risk in the control group (CER)” (5,13). Interpretation of the relative risk is the same as the odds ratio and a sample of a relative risk calculation is also shown in Table 32.3. The odds ratio and the relative risk are difficult to conceptualize for patients and physicians, and thus can be reported as the **Number needed to harm** (NNH). The NNH is defined as the number of patients who need to be exposed to the causative agent to produce one additional harmful event over a specified period of time (5,14). The calculation is shown in Table 32.3 but can only be utilized for clinical trials and cohort studies.

The Magnitude of Prognostic Study Results

The outcome of prognostic studies provides information about survival over time. A **survival curve** is one of the most common ways prognostic data are presented. It provides the proportion of individuals who are alive (i.e., have not had the outcome, such as death) at any given time point. Prognostic information can also be presented as the probability of being alive at a particular point in time, usually at 1- or 5-year time points. In addition, **median survival** is used to describe the amount of time in which 50% of patients have died. At times, all three measures are required to be fully informed about the prognosis of certain diseases.

Step 4: Applying the Evidence to the Patient

One of the strongest links between osteopathic medicine and EBM practice is the need to consider the whole patient in terms of

cultural, economic, religious, and other special circumstances that impact the applicability of evidence to the specific patient. In fact, many physicians, especially osteopathic physicians, start the application of EBM at this step. A physician should take into account the patient’s beliefs and wishes, such as lifestyle modification over taking a medication. Although the physician should be knowledgeable of the current guidelines and evidence, patient-centered decision making should be at the core of the patient–physician relationship (15). Social and economic factors regularly impact what the patient is willing to do regardless of what the evidence shows. High medication costs and copayments are common reasons why patients fail to take prescribed medications (16). These barriers must be considered at the clinical encounter in order to keep the best interest of the patients in mind. Patient-centered care involves offering and discussing alternative options for the patient to consider. Moreover, it involves listening, assessing, assimilating, and delivering a shared treatment plan with the individual patient. Without this, EBM truly becomes “textbook medicine.”

As discussed earlier in the chapter, one can only apply the evidence of a study to a patient if the study population is similar to that patient. This applies to the demographic characteristics of the study population and also the factors that may have impacted the study’s results. For example, a study assessing a medication’s efficacy on heart failure symptomatology may have excluded diabetics or patients with a history of a myocardial infarction. The question becomes, “Can these results be applied to a patient who is a diabetic and had two previous myocardial infarctions?”

Step 5: Evaluate and Improve on Performance of Steps 1 to 4

This chapter is the first of many steps to becoming proficient in practicing EBM. This chapter outlined some of the basic EBM principles to allow physicians, residents, and medical students to begin understanding its importance. Repetition and practice are the key to becoming comfortable and efficient with the concepts and steps required to appraise different articles. EBM functions as a tool for the practicing physician, allowing them to stay informed and able to properly inform the patient. The systematic approach to appraising articles is only one part of EBM mastery. Failing to utilize personal expertise and consider patient values and expectations gives credit to those who criticize EBM as “textbook medicine.” So what’s next? Continue reading articles on EBM, attend sessions at conferences, and start appraising one article a week. As a guide to appraising articles, PowerPoint presentations and worksheets are available at no cost at <http://www.hsc.unt.edu/departments/cebm/lectures.htm>.

TABLE 32.3

Calculating an Odds Ratio (OR) and Relative Risk (RR)

	Adverse Outcome	No Adverse Outcome
Exposure to treatment	(a)	(b)
No exposure to treatment	(c)	(d)

Calculations:

$$OR = (a) \times (d) / (b) \times (c)$$

$$RR = [a/a + b] / [c/c + d]$$

$$EER = a / (a + b)$$

$$CER = c / (c + d)$$

$$\text{Absolute risk increase (ARI): } EER - CER$$

$$NNH = 1/ARI$$

Palpatory Examination

WALTER C. EHRENFEUCHTER AND ROBERT E. KAPPLER

KEY CONCEPTS

- No known device has been developed that exceeds the tactile sensitivity of the human hand.
- The development of palpation can be accomplished through various exercises.
- Familiarization with determination of layers of the body is the outcome of progressive developmental exercises.
- The learning process for the physician never stops.
- The development of a high level of palpatory skill is ongoing, requiring patience and practice.

INTRODUCTION

The scanning evaluation is carried out in all body regions indicated by abnormalities found in the screening exam. Therefore, findings of asymmetry, spinal curve abnormalities and abnormalities of body posturing, combined with regional range of motion testing, guide the physician in choosing the location(s) to perform layer-by-layer palpation. In the case of more than one area of abnormality being identified, typically it is the region of greatest motion loss that is evaluated first, that is where the key lesion is most likely located.

PALPATION DEFINED

The *Glossary of Osteopathic Terminology* defines palpation as the application of variable manual pressure to the surface of the body for the purpose of determining the shape, size, consistency, position, inherent motility, and health of the tissues beneath (1). Another definition is Palpation is the lightly placing of hands or fingers on the patient's body to discover changes from the normal condition of soft tissues, bones or organs beneath the surface of the skin, as well as the skin itself (2). The reality is that there has been no device developed that comes close to mimicking, let alone exceeding the tactile sensitivity of the human hand.

When performing palpation in a given region of the body, it is best to apply a layer-by-layer approach. This consists of:

- Observation
- Temperature
- Skin topography and texture
- Superficial fascia
- Muscle
- Tendons
- Ligaments
- Bone
- Erythema friction rub

Palpation always includes notation of any areas of tenderness, which is defined medically as the presence of pain elicited by palpation. How hard does one need to press to accomplish these various layers? Light surface palpation requires only a few grams of pressure. Deep bony palpation requires about 1,500 g of pressure or about 3.33 lb (8).

OBSERVATION

Visual observation of the skin surface must precede any palpatory examination (Fig. 33.1). Observation is made of the skin color, and any adnexal changes such as the presence of pimples, dry or scaly skin, folliculitis, and pigmentary changes. The spinal segments or body surface associated with any findings are noted for further review during the examination. These reflect local sympathetic nervous system changes and neural trophism that can be segmentally associated with somatic dysfunction.

TEMPERATURE

Skin temperature has been observed since the time of Hippocrates. He observed the patient for hot spots by having an assistant smear the patient with a thin layer of mud. Areas that dried first were warmer than those that did not.

Today the osteopathic physician evaluates the skin temperature by using the volar aspect of the wrist, or the dorsal surface of the hypothenar eminence of the hand. The physician does this by placing the wrists or hands a few centimeters above the area to be tested and using both hands to evaluate the paraspinal areas bilaterally simultaneously, searches for areas of thermal asymmetry (Fig. 33.2).

Heat radiation may be palpated in many other areas of the body (e.g., the abdomen or extremities). If the physician is unable to discern a temperature difference while off the skin surface, then he or she may at this point make very light contact with area to be examined. The hands are then lifted off, not dragged along the surface, and then replaced gently on the next levels to be examined. Again, the spinal segments or body regions of abnormality are noted.

Changes in temperature reflect a change in local blood flow that may be due to inflammation, or to the changes in sympathetic tone associated with segmental somatic dysfunction.

SKIN TOPOGRAPHY AND TEXTURE

A very light touch is used. Generally, the palmar surface of the fingertips is used for this type of palpation. This pressure will permit the finger pads to glide smoothly over the skin surface without excessive friction.

The skin is evaluated for sweat gland activity, greasiness (sebaceous gland activity), thickening, or roughness. The spinal segments or body regions of abnormality are noted. Gently pressing the fingers into the skin surface will allow the physician to evaluate for

Figure 33-1 Observation.

changes in skin turgor and tension. These changes reflect a change in local sympathetic nervous system activity associated with segmental somatic dysfunction.

SUPERFICIAL FASCIA

The physician now makes a broader contact with the skin surface and presses gently with the palm of the hand to engage the fascia. The amount of pressure necessary typically causes slight reddening of the physician's nail beds (Fig. 33.3). The physician gently moves the hands cephalad and caudad, side to side, and clockwise and counterclockwise to elicit motion tensions and directions of ease and bind in the superficial fascia.

Gradually applying more pressure will allow the physician to evaluate deeper and deeper layers of fascia right down to the muscular investing fascia. The segmental levels or body regions associated with asymmetric bind of the fascias are noted, as well as the depth of penetration necessary to elicit that alteration. Any areas of tenderness are likewise noted.

MUSCLE

Deep palpation is defined as pressure sufficient to contact the peri-axial tissues of the spinal column. Muscle is the next layer of tissue to be palpated, and additional pressure is required to feel through the superficial tissues to get to the musculature. The amount of pressure varies from patient to patient depending on the thickness of the subcutaneous fat layers. The thicker the fat, the more difficult it is to palpate changes in the deeper tissues.

Typically, the pads of the fingers are aligned perpendicular to the direction of the muscle fibers and firmly pressed into the muscle then rolled across the fiber bundles (Fig. 33.4). Sufficient pressure is

typically necessary to blanch the physician's nail beds. An irritable muscle will twitch in response to this "plucking" of the muscle.

The physician evaluates muscle turgor, tension, thickness, shape, and irritability. Many terms are used to describe the changes that are felt in abnormal musculature: ropiness, stringiness, fibrotic, dense, and so on. The segmental location of any of these changes is noted as well as the character of the muscle tissue at that location. While muscle hypertonicity may extend for a number of levels (e.g., T4-9 left paraspinal), the physician also notes the level of peak muscular change (T6 left PVM). The location of any tenderness elicited or trigger points discovered is also noted.

TENDONS

Although tendons are not readily palpable in the paraspinal tissues, in the periphery tendons should be traced to their bony attachments as well as their continuity with the muscle. Any fibrous thickening, change in elasticity, or tenderness should be noted. Tenderness at the muscle attachment to bone is termed an enthesopathy. Trigger points are commonly located in the myotendinous junction.

LIGAMENTS

The ligaments accessible to palpation vary with location in the spine. Palpation of the ligaments should include a search for the presence of the ligament (absence indicating a traumatic rupture or congenital absence), tension in the ligament (normal, excessive, or lax), and elicited tenderness.

BONE

Even deeper pressure will allow the physician to palpate the bony structures beneath the musculature. The bone is palpated for evaluation of normal contour, tenderness, and for motion.

ERYTHEMA FRICTION RUB

In erythema friction rub, the pads of the physician's second and third fingers are placed paraspinally and then in two or three quick strokes drawn cephalad to caudad down the spine (Fig. 33.5). The normal tissue response is initial blanching followed by reddening of the skin surface, followed by a slow fading of the redness back to normal skin color.

Any deviation from this by tissues remaining pale, remaining red, or becoming red initially instead of pale, is abnormal and the spinal levels and laterality of the findings are noted.

Most of us use fine palpation on a daily basis without realizing it. We do such things as picking coins out of a pocket or purse by touch. We readily differentiate between dimes, nickels, pennies, and quarters, based on the known characteristics of each coin (10).

Figure 33-2 Temperature.

Figure 33-3 Palpating fascia.

There is no substitute for experience. Inexperienced examiners have been shown to be able to palpate motions as small as 1 mm in excursion. Experienced examiners have been shown to palpate motion as small as 0.0846 mm (3/100").

The diagnosis of somatic dysfunction requires at least two of the following:

- Tenderness
- Asymmetry
- Range of motion changes
- Tissue texture changes

The scanning examination, applied to areas of previously discovered screening abnormalities, provides further information on asymmetry, tenderness, and tissue texture changes associated with the somatic dysfunction. It also provides an opportunity for segmental localization.

There are three basic phases to kinesthetic observation (palpation):

1. Detection
2. Internal amplification and magnification (eyes closed)
3. Combining Nos. 1 and 2 with the physician's three-dimensional knowledge of anatomy yields analysis and interpretation (4).

What remains now is for the physician to interpret the results of the palpatory examination on a level-by-level basis. Table 33.1

Figure 33-4 Palpating muscle.

outlines the changes one would expect in the presence of either acute or chronic somatic dysfunction. This would allow an examiner to ascertain whether a somatic dysfunction is new (acute) or old (chronic) or perhaps a combination of the two (acute exacerbation of a chronic condition). This determination is critical in choosing the correct manipulative techniques to apply to a given individual.

PALPATORY EXERCISES

Learning Palpatory Technique

To accomplish this task, it is necessary to teach the fingers to feel, think, see, and know. One feels through the palpating fingers on the patient; one sees the structures under the palpating fingers through a visual image based on knowledge of anatomy; one thinks what is normal or abnormal; and one knows with a confidence acquired by practice that what is felt is real and accurate.

Through complex peripheral and central processing, the smallest sensory perception can be amplified to the point of conscious recognition and analysis.

Exercise 1: Palpating Inanimate Objects

Purpose

To perceive slight tactile differences of tissue texture and motion. Exercises on inanimate objects serve to sharpen tactile concentration and attention. Concentration is essential. Close the eyes to eliminate extraneous stimuli. Pay attention to kinesthetic sensations received through the fingers.

Procedure

1. Put a mixture of coins in a pocket or purse. By touch, distinguish between heads and tails, and between pennies, dimes, nickels, and quarters. Identify date lines on the coins.
2. Locate a hair that has been placed under a sheet of paper; attempt to estimate its length. Add sheets of paper until you can no longer palpate the hair.
3. Palpate several types of human bones. Identify the bones and their component parts, envisioning the tissue that normally surrounds them.
4. Palpate a human bone and a solid plastic imitation of the same bone. Identify the characteristics of the human bone that distinguish it from the replica.

Mitchell (3) calls palpation a two-way communication system in which the patient's tissues react to the presence of the palpator's hand. This is more likely to occur when palpation has been practiced over a period of time.

Three steps define the process. The first is detection, the second is internal amplification or magnification, and the third is analysis and interpretation. This last step translates palpatory findings into meaningful anatomic, physiologic, or pathologic states (V. Frymann. Syllabus for workshop on palpation, 1990). Familiarity with osteopathic terminology permits description of palpatory findings in consistent terms.

Effective palpatory technique cannot be learned by observation. Watching another physician palpate a patient indicates where the hands are placed but gives little or no indication of the feel of tissues being palpated.

Many individuals have a dominant hand with which they prefer to palpate or motion test. This may or may not be the hand with which they write. Recognition of a dominant hand will allow the individual to develop a compensatory mechanism to obtain accurate information when using both hands.

Figure 33-5 Demonstration of erythema friction rub.

Exercise 2: The Dominant Hand

Purpose

The purpose of this exercise is to determine the dominant hand. It is believed that when a person does not consciously think about it, he or she will put his or her dominant hand on top when the hands are clasped.

Position

This exercise can be done in a standing or sitting position.

Procedure

Without consciously thinking about it, clasp your hand together in front of you, with one hand on top of the other.

Results

The hand that *is* on top will most likely be your dominant hand. It is also believed that palpatory results are more consistent if the examiner has the dominant eye over the area that is being palpated.

For example, if one hand is stronger than the other, practice in applying equal pressure over equivalent structures can result in accurate interpretation of such manual information.

Interpretation of dominant and nondominant proprioceptive feedback from each hand is also a response that the individual can adjust.

Exercise 3: The Dominant Eye

Purpose

The purpose of this exercise is to determine the dominant eye. Some believe that palpation and the interpretation of palpatory findings are more accurate if palpation is performed with the dominant eye over the area being palpated.

Position

This exercise can be performed standing or sitting with a distant clock or visible object to look at.

Procedure

1. Look at the distant object with both eyes open (Fig. 33.6).
2. Extend your dominant hand and make a circle with your thumb and index finger that encircles your view of the distant object.
3. Now, close one eye, then open it and close the other eye.

Result

The eye that saw the object encircled with the fingers of your dominant hand is generally your dominant eye (6). Recognition of dominance, if it exists, and development of a compensatory mechanism is the main issue here; in time, apparent palpatory ambidexterity may result.

There are more touch (kinesthetic) nerve endings in the pads of the fingers than elsewhere in the hand. It is generally agreed that the thumb and/or the first two finger pads, rather than the fingertips, are the most sensitive part of the hand to train and use for palpation (V. Frymann. Syllabus for workshop on palpation, 1990).

Some physicians find that variations in skin temperature are best perceived by the dorsum of the hand, especially the dorsum of the middle phalanges of fingers two, three, and four; others use the palmar surface. Try both and see which is more effective for you. The coordinated use of the palms and the fingers around an object is best suited for obtaining a stereognostic sense of contour (4).

Flexibility of the joints of the elbows, wrists, hands, and fingers is important. Relaxation is also important to eliminate any muscle tension that would block perception. Strength of hands and fingers can be increased by using a finger exerciser, squeezing a ball, or playing a musical instrument that requires fingering. Because the hands are so important to a physician, they should be carefully protected and cared for. They are sensitive diagnostic instruments.

Light touch is thought by many persons experienced in palpation to be the most useful and easy to use. Very light touch, or light touch, consists of laying the hands passively on the skin or moving the hands lightly over the skin. Such light touch can be used to determine skin temperature, texture, moistness, oiliness, resistance, tone, and elasticity. It may be possible to determine skin temperature

TABLE 33.1

Palpatory Signs of Acute or Chronic Somatic Dysfunction

Signs	Manifestations
Pain	
Acute	Severe, cutting, or sharp
Chronic	Dull, achy with paresthesias.
Skin changes	
Acute	Warm, moist, red, inflamed
Chronic	Cool, pale
Vasculature	
Acute	Vessel injury with resultant release of endogenous peptides, chemical vasodilation, inflammation, and edema
Chronic	Vessels constricted due to increased sympathetic tone
Sympathetic activity	
Acute	Systemically increased sympathetic activity, but the local effect of this increased activity is overpowered by bradykinins released, so there is local vasodilation due to chemical effect
Chronic	Local vasoconstriction due to hypersympathetic tone; systemic tone has returned toward normal.
Musculature	
Acute	Locally increased muscle tonus, muscle contraction, spasm, ropiness, mediated via the muscle spindle. Minimal somatosomatic reflex effects.
Chronic	Decreased muscle tone, flaccid, mushy, limited range of motion likely due to fascial contracture. Common somatosomatic reflex effects.
Mobility	
Acute	Range of motion is often normal, but the quality is sluggish.
Chronic	Range of motion is diminished, but quality of remaining motion is normal.
Soft tissues	
Acute	Boggy edema, acute congestion, fluids from vascular leakage, and chemical reactions in the tissues.
Chronic	Congestion, doughy, stringy, fibrotic, thickened, exhibits increased resistance to penetration, contracted, contractured.
Adnexa	
Acute	Moist skin, no trophic changes
Chronic	Scaly, dry skin, pimples, folliculitis altered pigmentation (trophic changes).
Visceral	
Acute	Minimal somatovisceral reflex effects.
Chronic	Common somatovisceral reflex effects (5).

Paresthesias—crawling, tingling, itching, burning, or gnawing sensations (10).

sensation by passing the hand just above the skin. Firmer pressure communicates with the deeper cutaneous layers and fascial sheaths. It explores superficial muscles to determine their tone and mobility. Firm pressure and compression explore deeper muscle, fascia, and bony relationships.

Exercise 4: Layer Palpation**Purpose**

The goal of this exercise is to palpate your own tissues and concentrate and perceive various layers and structures of the body by varying the pressure of palpation.

Position

The position for this exercise is seated comfortably beside a table with your nondominant arm resting on the table.

Procedure

1. Close your eyes and relax. Concentrate your attention through the palpating fingers of your dominant hand.
2. Lightly palpate the dorsum of the nondominant hand using the fingers of your dominant hand. Scarcely touching the surface, feel the contour of the hand.
3. Test palpation with the dorsal and palmar aspects of the palpating fingers to determine which is most sensitive to temperature.

Figure 33-6 Right eye dominance. **A.** Both eyes open. **B.** Right eye closed; left eye open. **C.** Left eye closed; right eye open. (Modified from WA Kuchera, with permission.)

4. Using very light touch, palpate and describe skin texture, moisture, and thickness.
5. Gently pinch the skin on the back of the hand. Elevate it and release it. How long did it take for the skin to resume its normal configuration?
6. Evaluate skin drag on both the palm and dorsum of the hand. Skin drag is the estimation of the amount of resistance experienced when the pads of the fingers are lightly applied and moved (dragged) over the skin surface. On which aspect of the hand do the palpating fingers move most easily? Why? Describe any increase in skin drag that is due to excessive dryness, slight perspiration, or edema. Describe any decrease in drag resulting from excessive perspiration, oiliness, or atrophy.
7. Locate the veins and note their size and texture. Make a fist several times to engorge the veins and then describe the differences observed.
8. Locate the radial artery and describe the differences between it and a vein.

9. Increase the contact between your palpating fingers and the skin of your hand so that you create a shearing stress in the subcutaneous tissues. Shearing in this context refers to movement of tissues between layers. Note that with this palpation one can shear only so far before the palpating fingers slide on the skin. Shear across the hand in various directions describing what you feel. Does the skin move equally and easily in all directions?
10. Palpate the extensor tendon of the ring finger. Place two fingers along the length of the tendon; flex the ring finger, and palpate the sense of the linear movement along the tendon.
11. Palpate the tendon of the biceps at the elbow. How does it feel? It should be ropelike, smooth, and firm.
12. Place the thumb and index finger of the palpating hand on either side of the mid-phalangeal articulation of a finger on the opposite hand. Note the quality and range of various elements during flexion and extension. Now lighten your touch while performing the same movements. Notice how little contact is needed to distinguish flexion and extension.
13. Place your palpating fingers on the anterior surface of the proximal third of your other forearm. Using slightly more pressure than that used for skin, palpate the muscles used to flex the middle finger. Now maintain palpatory contact during flexion of the middle finger. Describe the feel of these flexor muscles and fascia during the maneuver.

When you are examining a patient, tell the patient in general terms about the procedure as it goes along. This is especially important if significant tenderness might be elicited during deep palpation. Take the necessary time, moving gently and deliberately. Initially it is common to apply too much pressure in an attempt to feel the tissue. Avoid poking, prodding, tickling, or stirring the tissue. These actions can cause reflex irritation (4).

Louisa Burns, a noted early osteopathic researcher, made the following suggestions to those beginning to develop palpatory skills:

- Palpate the objects with the lightest possible touch, scarcely touching the surface.
- Be aware of surface elevations and temperature differences.
- Using slightly more contact, palpate the surface.
- Try to ascertain the qualities or characteristics of the substance of the object.
- Describe perceptions as accurately as possible.

Exercise 5: Palpate Your Partner's Forearm

Purpose

The goal of this exercise is to determine the characteristics of different structures in the forearm of another person.

Position

You are seated comfortably, facing your partner, who is seated, facing you from across a narrow table.

Procedure

1. Grasp your partner's left forearm with your nondominant hand.
2. Lightly place the palm and fingers of your dominant hand over the dorsal forearm of your partner, just distal to the elbow. Close your eyes, relax, and concentrate your attention through the palmar surface of your fingers.
3. Without moving your hand, think skin. Try to perceive and describe skin temperature, texture, thickness, and moisture.

4. Next, compare the dorsal and palmar aspects of the forearm, and describe the differences. Which aspect is smoother? Thicker? Warmer? Drier?
5. Now, with a slightly firmer touch, concentrate on the second layer, the subcutaneous fascia. Gently move the skin of the forearm longitudinally and horizontally. How thick is it? How loose? Many of the tissue texture changes associated with somatic dysfunction are within this layer.
6. Gently and slowly increase the depth of touch until you feel the deep fascial layer that forms a sheath around the underlying structures. Think deep fascia. Is it smooth? Continuous? Firm?
7. While palpating the deep fascial layer; slowly move the hand horizontally across the forearm to identify areas of thickening that form fascial compartments between bundles of muscles. Identifying enveloping layers of deep fascia is often helpful in separating one muscle from another; use it to work with even deeper structures.
8. Palpating through the deep fascia, concentrate on the underlying muscle. Is it soft and compliant? How is its elasticity? Pay attention to individual muscle fibers and the directions in which they run.
9. Have your partner slowly open and close his or her hand as you note the quality and range of movement created by the contracting and relaxing muscle. Describe the difference. Palpate the forearm muscles as the hand is clenched. This sensation simulates the feel of the most common tissue texture abnormality (TTA) at the level of muscle or in areas of somatic dysfunction.
10. Still palpating at the level of muscle, move your hand slowly down your partner's forearm until you feel the musculotendinous junction, an area or region where the muscle is vulnerable to injury.
11. Move past the musculotendinous junction toward the wrist. Note the transition from muscle to musculotendinous junction to the smooth, round, firm feel of tendons.
12. Follow the tendons distally until you feel a structure that binds them at the wrist. This is the transverse carpal ligament (flexor retinaculum) and palmar carpal ligament (a thickening of the deeper anterolateral fascia). Note fiber direction, thickness, and firmness. How does it feel in comparison with the tendon? Compare the palpatory sensation over this area with that over tendons that are more superficially located.
13. Now place your index finger over the proximal radiohumeral joint at the dimple of the elbow. Place your thumb opposite your index finger, on the ventral side over the lateral side of the humeroulnar attachments. You should now be palpating the head of the radius. Describe the characteristics. Compare the feel of this living bone with a plastic model or with your memory of bone from a cadaver.
14. Move your thumb and index finger proximally until you locate the joint space. Your finger and thumb fall into it. You should not be able to feel the joint capsule. The joint capsule is not palpable because palpable joint capsules signal pathologic changes.

Palpatory skill involves more than a mechanism for finely tuned sensory perception. A more significant component is to be able to focus on the mass of information being perceived, paying close attention to those qualities associated with TTA, and bypassing many of the other palpatory clues not relevant at the time. These skills might be enhanced by trying to palpate a hair through several pages of a telephone directory.

Exercise 6: Palpatory Sensitivity

Purpose

The goal of this exercise is to determine and improve your sensory awareness.

Position

For this exercise, sit comfortably in front of a table with a phone book and objects of various thicknesses, including a human hair.

Procedure

1. Starting with the thickest object, place them, one at a time, under a page in the phone book and see if you can palpate their edges and dimensions.
2. Then add pages and palpate until you can no longer determine the objects' dimensions. How many pages were between your fingers and each object before you could no longer palpate it? Can you palpate the human hair through a single page from the phone book?

Palpatory sensitivity involves a process of developing mental filters. Consider an analogy in music, where the orchestra conductor focuses on the violins. The conductor is aware of the entire orchestra playing, but is diverting attention to a specific portion of sound that he or she perceives. The brain cannot process everything at once. By concentrating only on the portion you want, it becomes easy and fast to detect areas of significant TTA. In a comparison of student musculoskeletal examinations with experienced examiners, Kappler et al. (5) observed that the experienced examiners recorded fewer findings than student examiners, but the experienced examiner's findings were more significant. This shows that experienced physicians apply a filtering process to their palpatory data, rejecting insignificant findings without being consciously aware that they are doing this. The student is overwhelmed with the mass of palpatory data and has not yet developed this filtering process to reduce the data to a manageable component.

MOTION PERCEPTION

If any motion is present, describe the sensations transmitted through the fingers. Also, estimate the weight of objects, the amount of pressure needed to move them, and the resistance or force exerted against your pressure.

Perception of motion is an essential component of palpation. A major difference in palpation of living tissue is this sensed motion. Motion of the body is described as passive, active, and inherent (6).

Passive motion is brought about by the physician; it is movement done to the subject. Active motion is performed by the subject; it is deliberate, conscious muscular activity. Inherent motion is activity unconsciously generated within the body (J. Goodridge. Michigan State University College of Osteopathic Medicine. Biomechanics syllabus, 1986), such as respiratory motion or peristalsis. Inherent motion is postulated to occur in any of several ways:

- Biochemically, at the cellular or subcellular level
- As part of multiple electrical patterns
- As a combination of a number of circulatory and electrical patterns
- As some periodic pattern not yet understood

Experts agree that individuals can perceive tissue movement as minute as 1 mm (6). With practice and patience, inherent motion may be palpated.

By varying the palpation pressure, successive layers of tissue can be palpated. In palpating superficial tissue, use the lightest effective touch. To palpate successively deeper layers, apply only as much additional pressure as necessary. As a general rule, this means palpating to the depth of the tissue or structure to be examined, that is, down to but not through the structure being examined. The use of various depths of touch differs from physician to physician, usually depending on the model of diagnosis and treatment chosen.

Exercise 7: Palpating Spinal Motion and Paravertebral Tissues

Purpose

The goals of this exercise are to learn how to palpate living tissue in the classroom situation with an instructor available to demonstrate and interpret as needed and to be able to palpate the thoracic and lumbar spinal areas, testing for and finding any regions with relative resistance of the vertebrae and their spinous processes when passive flexion is introduced.

Position

Your partner sits on the table and you stand behind your partner.

Procedure

1. Using your finger pads, place the first three fingers of your dominant hand between the spinous processes of T1 and T2, T2 and T3, and T3 and T4. Remember to use the pads of your fingers. Place your other hand on the top of your partner's head.
2. Locate the spinous processes and interspinous ligaments, noting how they feel. Compare differences between the feel of the bone and the feel of the ligament.
3. Passively flex the head and neck while sensing for increasing tension of the interspinous ligaments. Note: One spinous process may move more easily than another (Fig. 33.7).
4. Using the fingers of both hands, palpate for temperature differences along the paravertebral thoracic and lumbar spine. Use either the palmar or dorsal surface of your fingers, depending on which you find to be more sensitive.
5. Using both hands simultaneously, stroke the back from C7 to L5. Which areas are warmer? Try to find a segment within the thoracic area that is either warmer or cooler than another segment. Compare left with right sides, and superior with inferior.

Figure 33-7 Palpating upper thoracic flexion-extension.

Stroking of this type is useful in identifying changes in contour, as well as identifying areas of edema and increased tissue tension.

6. Palpate for moisture differences, noting stickiness, dryness, wetness, waxiness, and slipperiness.
7. Proceeding from T2 to L5, lightly compress the paravertebral soft tissues. Then use deeper pressure, but less pressure than that required to palpate bone. You may notice that in some areas, tissues compress more easily; while in others, there is more resistance. Significant resistance indicates an area of TTA (1), which bears further investigation.
8. Lightly palpate the skin and subcutaneous tissue over the resistant site. This helps you identify the outer limits of tissue texture involved.

Developing Advanced Skills in Palpation of Tissue Texture Abnormality

Advanced palpatory skills require practice and experience. We try to define or describe what the tissues feel like. The important factor is an imprint in the brain of the sensation that is perceived. Attempting to translate this sensation into words is inadequate. It must be perceived. Comparing an area of tissue texture abnormally with an adjacent area without this tissue texture is essential. Experiences that involve **COMPARISON** are far more valuable than experiences palpating an abstract area.

Think of evaluating hot or cold water. If a hand is in warm water (e.g., 90°F) and this hand is used to evaluate a test beaker of water at 70°F, this beaker will seem cold. Now the hand is placed in water at 50°F, and then evaluate the temperature of 70°F water. The water in the test beaker will seem warm. Perceiving difference between water temperature or difference between tissue texture is best achieved by comparing one against the other.

A skilled osteopathic physician has developed a store of information in the brain about what tissues feel like, and especially the tissue texture change of somatic dysfunction. When the skilled examiner palpates an area, he or she can compare the current palpatory sensation with the store of information in the brain. This is a different type of comparison. To the novice, it appears to be evaluating the abstract but it is really a matter of comparing what is perceived with the palpation with prior experiences stored in the brain.

Once the osteopathic has developed this advanced skill in palpating, the skill is never lost. The author has experienced older osteopathic physicians who were almost frail, yet when they laid their hands on a patient, they immediately detected areas of tissue texture change.

The author's theory about this type of learning is that this is cerebellar learning. Cerebral learning is subject to the curve of forgetting. Cerebellar learning is never forgotten.

SUMMARY

Position your dominant eye over the structure being palpated. Place thumbs or finger pads over the area to be palpated. To ensure greater accuracy, mentally transfer your thoughts to the interface of your hand with the patient's body. Realize that resiliency or resistance to motion can be sensed in the initial movement during motion testing. You can miss these subtle findings and get hung up on gross motion restrictions, for example, how far a vertebral joint or tissue moves rather than the quality of the movement. Avoid the following common errors in palpation:

- Lack of concentration
- Too much pressure
- Excessive movement

These palpatory skills provide a method of obtaining practical experience in developing the art of palpation. There are many other exercises. Initially, palpation is practiced on a partner in the skills laboratory. During clinical clerkships, one gains additional experience by examining attending physicians' patients. Ultimately, palpatory experience is gained from palpatory examination of the physician's own patients. The physician continues to learn and never stops gaining experience. The preceding section shows how to get started in the process of obtaining palpatory data from the patient.

Remember that development of a high level of palpatory skill is an ongoing process, requiring patience and practice. "Osteopathy cannot be imparted by books. Neither can it be taught to a person intelligently who does not fully understand anatomy" A T Still (7).

Screening Osteopathic Structural Examination

WALTER C. EHRENFEUCHTER

KEY CONCEPTS

- Screening osteopathic structural examination involves a comprehensive assessment of motion characteristics, static, and dynamic.
- The ability to accurately locate anatomical landmarks is mandatory in preparation for initiating motion challenge.
- The proper interpretation of response to motion challenge is referred to the patient's mid-gravity line.

INTRODUCTION

The screening examination is designed to determine rapidly where in the body the most significant somatic dysfunctions reside. It is designed simultaneously to find larger orthopedic structural abnormalities that may be responsible for generating these dysfunctions.

The nature of the screening examination is that it is sensitive to the discovery of the presence of dysfunction, but not specific as to the spinal segments or structures involved, or for the tissues responsible for creating and maintaining the dysfunction.

The screen consists of two portions, a static postural examination and a dynamic part, which includes regional range-of-motion testing and observation of gait (1).

Static Postural Examination

Observation

The patient should be undressed enough to be able to accurately observe the overall configuration of the body without it being obscured by clothing. This also allows you to observe the patient for evidence of other serious diseases. One common finding is the presence of pigmented nevi with the possibility of malignant melanoma. The reality is that people do not get to see their backs. Skin tumors can grow quite large here prior to discovery. Patients sustain burns from heating pads, develop erythema ab igne from chronic heating pad use and develop discoloration of the skin, abrasions, and even ulceration in skin overlying points of chronic pressure.

Body Symmetry

Assessment of body symmetry constitutes the first portion of the overall structural examination. Some minor asymmetry is present in virtually all human beings. The goal of the examination is to determine what abnormal asymmetries are present in a given individual. Figure 34.1 shows examination for symmetry of posterior landmarks of the body. The posterior landmarks commonly used in the screening structural examination are in **bold** type in the following discussion.

Ankles and Feet

Arches—Observe the height of the arches on each foot. Most important is the fact that they are symmetric, not whether they are both flat or not.

Achilles Tendons—Observe the medial and lateral surfaces of the tendon. The curve of the tendon should be symmetric. Flattening of the normal curve on the medial side of the Achilles tendon indicates the likely presence of a

valgus hindfoot deformity. The valgus hindfoot accompanies longitudinal arch collapse in the foot. Again, asymmetry becomes the most significant finding.

Significance—Unilateral arch collapse with valgus hindfoot can occur to assist the body in compensating for an anatomically long leg on the ipsilateral side, and dysfunctions of the pelvis that create a functionally long leg on the ipsilateral side (anterior rotation of the innominate, inferior innominate shear, etc.)

Legs

Observe the size and symmetry of the gastrosoleus muscles. If asymmetric try to determine if one is enlarged, or if one is smaller. A large calf can be due to deep venous insufficiency in the ipsilateral leg, a small calf may indicate muscle atrophy due to chronic entrapment of the S1 or S2 nerve roots, or even the sciatic nerve itself.

Knees

Observe the popliteal creases. If unlevel in the presence of normal ankles and feet, they indicate the presence of a short tibia and fibula on the ipsilateral side.

Observe the shape of the popliteal fossa. If flattened or exhibiting a genu recurvatum, it indicates hyperextension of the knee and the presence of laxity of the posterior cruciate ligament. Again, if unilateral, it may represent a compensatory change for an anatomic or a functional long leg on the ipsilateral side.

Observe any medial or lateral deviation of the leg at the knee (genu valgus (knock kneed) or genu varus (bow legged)). Typically, these are congenital or developmental deformities, although they can occur with advanced unilateral compartment arthritis of the knee. The presence of a unilateral varus or valgus deformity may shorten the ipsilateral leg and affect the rest of the body above. If bilateral, asymmetry may indicate a worsening of the condition again as a result of an anatomic or functional long leg.

Thigh

Observe the posterior thigh muscle mass. If enlarged, it may be due to venous insufficiency or thrombosis, or there is also the possibility of an underlying tumor. This author has personally had a patient present with low back pain and asymptomatic enlargement of one thigh. Further examination, imaging, and ultimately surgery resulted in the removal of a football-sized liposarcoma from the patient's thigh. Again, decreased size of the muscle mass unilaterally may indicate a chronic entrapment of the L5, S1, or S2 nerve roots, or the sciatic nerve's tibial division.

On examination note:

- Midgravitational line
- Achilles tendon: straight, curved?
- Position of feet
- Relation of spine to midline (curves, etc.)
- Prominence of sacrospinalis muscle mass
- Symmetry of calves
- Symmetry of thighs (including any folds)
- Symmetry of buttocks
- Lateral body lines
- Levelness of greater trochanters
- Prominence of posterior superior iliac spines
- Levelness of posterior superior iliac spines
- Levelness of iliac crests (supine, prone, sitting, standing)
- Fullness over iliac crests
- Prominence of scapula
- Position of scapula and its parts
- Levelness and relation of fingertips to body
- Arms (relations)
- Levelness of shoulder
- Neck-shoulder angles
- Level earlobes
- Level of mastoid processes
- Position of body relative to a straight vertical line through the midspinal line
- Posterior cervical muscle mass (more prominent, equal, etc.)
- Head position: lateral inclination

Figure 34-1 Examination for symmetry of posterior landmarks of the body. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 2.8.)

Gluteal Region

The gluteal folds should be symmetric; again, asymmetry may indicate a leg-length inequality. The **greater trochanters** should be palpated and assessed for levelness, again as a check for leg-length inequality. The gluteal muscle mass should be assessed for asymmetry. Enlargement may indicate the presence of a buttock tumor (lipoma is the most common), whereas atrophy may indicate chronic entrapment of the S1 nerve root or entrapment of the superior and inferior gluteal nerves in the greater sciatic foramen due to hypertrophy of the piriformis muscle.

Iliac Crests

The iliac crests should be assessed for symmetric height over their lateral aspect. Asymmetry could indicate the presence of an anatomic or functional leg-length inequality. If the legs have been symmetric all the way up to the gluteal folds and greater trochanters, asymmetry of the iliac crest height can indicate the presence of a short hemipelvis.

POSTERIOR SUPERIOR ILIAC SPINES

Again, the assessment is for symmetric localization relative to vertical displacement and anterior-posterior displacement. A low

posterior superior iliac spines (PSIS) can be caused by an anatomic or functional leg-length inequality, a short hemipelvis, and by innominate somatic dysfunction. Low PSIS results from posteriorly rotated innominate, or inferior innominate shear. High PSIS can result from anteriorly rotated innominate, or superior innominate shear. A posterior displacement of the PSIS indicates the possible presence of a posteriorly rotated innominate; anterior displacement an anteriorly rotated innominate. Posterior rotation or superior shear of the innominate is a common compensatory mechanism for an anatomic long leg.

Thoracic and Lumbar Spine

The spinous processes should all be in a vertical straight line. Large side-to-side deviations indicate the presence of a scoliosis. If there is leg-length inequality present, observe the scoliosis for its “fit” with the unlevel sacral base. This is done to determine whether the scoliosis is due to the leg-length inequality, or the patient has two separate conditions (2). Figure 34.2 shows lumbar scoliosis due to a 2-inch sacral base unleveling from an anatomic short left leg.

Mild scoliosis may be produced by segmental or group somatic dysfunction. The direction of the curve gives a general indication

Figure 34-2 Lumbar Scoliosis due to 2-in sacral base unleveling from an anatomic short left leg. (Original photograph: Walter C. Ehrenfeuchter, D.O., F.A.A.O., with permission.)

of the sidebending component of the segmental dysfunctions. If the curve is due to a single segmental dysfunction, the dysfunction may be located at the bottom of the curve, the top of the curve, or right in the middle. If there is a group of dysfunctional segments, they are likely all sidebending and rotating in opposite directions.

The presence of a thoracic scoliosis can indicate a primary thoracic curvature, a secondary thoracic curvature compensating for a primary lumbar curve, or a secondary thoracic curvature compensating for an unleveling of the cranial base. The unlevel cranial base may be due to cervical spine abnormalities (e.g., Klippel Feil Syndrome), a head tilt due to asymmetric cervical muscle tone (Torticollis), or even somatic dysfunction of the cranial base.

Excessive prominence of a spinous process may indicate the presence of an angulate Kyphosis, which can be due to a congenital anomaly of the vertebral body, or possibly compression fracture.

Exaggeration of the kyphotic thoracic curve can occur due to flexed segmental dysfunctions, flattening of the kyphotic curve from extended segmental dysfunction. Exaggeration of the thoracic Kyphosis can occur in some conditions of the spine such as Scheuermann disease or diffuse idiopathic skeletal hyperostosis (DISH). DISH occurs more frequently in patients with type II diabetes mellitus.

Exaggeration of the lumbar lordotic curve can be due to an extended segmental dysfunction or a flexed or anteriorly rotated sacrum. Flattening of the lumbar lordotic curve can be due to a flexed segmental dysfunction or an extended or posteriorly rotated sacrum. It can also be flattened by muscle spasm or the presence of ankylosing spondylitis.

Observe the lumbosacral junction for the presence of skin anomalies including a hairy patch, pigmented nevus, port-wine stain, pilonidal sinus, pilonidal cyst, or lipoma. The presence of a

skin lesion has a strong correlation with presence of an underlying congenital bony abnormality including many forms of occult spinal dysraphism.

Paravertebral Muscle Mass

Observe for symmetry. Prominence of the paravertebral muscle mass can indicate the presence of vertebral rotation to the ipsilateral side. It may also represent hypertrophy or hypertonicity of the larger muscle mass. Uncommonly, it can be the result of a tumor or an abscess in the musculature.

Lateral Body Line

The lateral body line is the silhouette of the contour of the sides of the trunk below the rib cage. These become especially useful in obese patients where the condition of the lumbar vertebrae and the paravertebral muscles is harder to assess. For example, flattening of the left lateral body line and exaggeration of the curvature of the right lateral body line suggest the presence of a scoliosis in the lumbar region convex to the left. In the severely obese, the left lateral body line in this case could exhibit two skin folds, and the right lateral body line three skin folds, indicating the presence of the same sidebending curve.

SCAPULAR LANDMARKS

The position of the scapulas is under numerous muscular and postural influences. The landmarks that are of the greatest importance here are the **acromion process, the inferior angle, spine of the scapula,** and the medial scapular border.

A line across the shoulders should be perpendicular to the spinal column, regardless of what the spinal column is doing in the upper thoracic region. If the spinal column is vertical, the shoulders should be symmetrically horizontal. If a scoliosis has the spinal column sidebent right in this region, the right scapular landmarks will be lower than the left.

The medial border of the scapula should roughly parallel the spine, regardless of the position of the spine at this site. Forward carriage of one shoulder will result in the medial scapular border being farther from the spinous processes than its normal mate. Normally, the medial scapular border is approximately 2 to 3 inches. Rotation of the scapula due to shoulder muscle imbalances will result in a loss of the parallel relationship between the spine and the medial border of the scapula.

If the spine is vertically straight, and the scapulas are unlevel, it indicates a problem with the shoulder girdle. Typically, the spine of the scapula is even with the spinous process of T3, whereas the inferior angle of the scapula is even with the spinous process of T7 (transverse processes of T8). If one scapula is higher than this in position, scapula alta, it implies the presence of hypertonic or contracted musculature involving the shoulder elevators (upper trapezius, the rhomboids, and levator scapulae). If sufficiently high and present from birth, it represents a congenital Sprengel deformity. On the other hand, a scapula positioned lower than normal, scapula infra, can represent weakness of the shoulder elevators vs. hypertonicity of the shoulder depressors (latissimus dorsi, lower trapezius, lower serratus anterior).

Arm Position and Length

Viewing the position of the arms in relation to the trunk can give you further insight into dysfunctions of the shoulder girdle musculature by revealing rotations of the entire extremity. The distance

of the arms from the torso also informs you as to the possibility of scoliosis decompensation or pelvic side shift. The length of the arms from acromion to fingertip should be observed. Just as you can have a patient with a short leg, you can also have a patient with a short arm. This becomes significant for work and sport activities involving the upper extremities.

Slope of the Shoulder

Observe the slope of the shoulder where it meets the neck. These two surfaces should be symmetric. They should meet the vertical muscle mass of the cervical spine in the mid-cervical region. Asymmetry must be interpreted in light of all the preceding data regarding scapular position. If a fold of skin attaches to the neck higher than the mid-cervical region, this constitutes a web neck, or pterygium colli. It may even attach as high as the mastoid process. This is associated with congenital disorders such as Klippel-Feil syndrome or Turner syndrome.

Cervical Spine

The cervical spinous processes should be vertically oriented. Slight deviations from this are the norm, since the mid-cervical spinous processes are bifid and it is not unusual for one to be longer than the other, giving one the impression that a cervical vertebra is out of line with the rest of the neck. This is a normal finding.

The paravertebral muscle masses should be symmetric. Prominence of a muscle mass unilaterally may indicate the presence of unilateral facet dislocation with overriding, enlarged facet joints due to arthritic changes, local muscle hypertonicity, or a hematoma within the musculature.

Head

The head should sit level on top of the cervical spine. A tilt of the head atop the neck indicates the presence of either asymmetric suboccipital muscle tone or the presence of hypertonicity or spasm of one of the larger muscles that attach to the cranium (torticollis). It can also represent the sidebending component of an occipitoatlantal somatic dysfunction. In rare cases, it represents head positioning to reduce the impact of some forms of diplopia.

The **mastoid processes** should be level and theinion positioned in the midline. Asymmetry of the mastoid processes in the presence of a head positioned symmetrically atop the neck should lead you to think of the possibility of cranial somatic dysfunction with involvement of the temporal bones. Likewise, the position of the pinnae of the ears should be observed. Asymmetry again suggests the presence of cranial somatic dysfunction involving the temporal bones.

Patient Seated

The same landmarks of the torso, shoulders, neck, and head are again examined with the patient in the seated position (Fig. 34.3). Any changes in pattern from what was previously observed indicate a strong influence from problems in the lower extremity from the hip joints and hip girdle musculature (including the psoas muscles) down to the feet. These problems would need to be identified and addressed before any clear conclusions can be made regarding the presence of somatic dysfunction from the pelvis on up.

Some structural and postural abnormalities of the body are more obvious when viewed from the anterior perspective.

Feet

Apparent in-toeing (pigeon toed) and out-toeing (duck footed) positions of the feet can be due to local foot deformities like metatarsus adductus, lower leg abnormalities like tibial torsion, of femoral abnormalities such as anteversion or retroversion of the femoral neck. They may also represent the position of the entire lower extremity under the influence of a shortened piriformis muscle (out-toeing) or iliopsoas muscle (in-toeing).

Knees

Observe again for varus, valgus, and recurvatum or flexion contracture deformities of the knees. Observe the tibial tuberosities for prominence as this may represent a case of Osgood-Schlatter disease.

Observe the height of the patellas relative to the tibial tuberosities. Search for the presence of patella alta (high-riding patella) or patella baja (low-riding patella).

Thighs

Observe the symmetry of the thigh muscle mass. Atrophy of these muscles can occur as a result of long-standing knee disorders such as osteoarthritis, or from entrapment of the femoral nerve or L2, L3, or L4 nerve roots.

Pelvis

Observe the position of the anterior superior iliac spines (ASIS) and pubic bones. They are supposed to reside in the same anterior coronal plane. If not, it tells you there is either an anterior or a posterior pelvic tilt that can cause changes in the lumbar lordotic curve (anterior tilt—increased lordosis; posterior tilt—flattening of lordosis). Likewise, changes in the lumbar curve can force changes in the tilt of the pelvis. Pelvic tilt is also under the influence of the hip girdle musculature. Anterior tilt may be caused by hypertonic or contracted iliopsoas muscles, posterior tilt by hypertonic or contracted hamstrings.

Pelvic rotation about a vertical axis is also readily viewed from the anterior aspect, with shifting of the ASIS anteriorly or posteriorly in response to positioning of the entire pelvis.

Observe the pelvis for evidence of pelvic side shift. This can again be compensation for a leg-length discrepancy, or it can be due to a leg-length discrepancy depending on the individual. Side shift will increase the prominence of the greater trochanter on the side to which the pelvis has shifted and will increase the tension in the iliotibial band.

The symmetry of the ASIS may also be altered by the presence of virtually any of the innominate dysfunctions.

Abdomen

The prominence of the abdomen is often in response to the shape of the lumbar lordosis. If the lordosis is flattened, it will tend to flatten the abdomen. If the lordosis is increased, it will make the abdomen more protuberant. This author has seen a case of lordosis due to paralytic polio that was so severe that the anterior portion of the lumbar spine could be seen pressing against the abdominal wall and the vertebrae and anterior discs readily palpable just beneath.

Protuberance of the lower abdomen is common in the presence of an increased Kyphosis or from flattening of the diaphragm due to respiratory conditions such as emphysema or asthma.

Figure 34-3 Examination for symmetry of anterior landmarks of the body. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 2.7.)

On examination note:

- Midgravitational line
- Lateral body line
- Position of feet
 - Pronation
 - Supination
 - Levelness of tibial tuberosities
- Levelness of patellae
- Anterior superior iliac spines
 - Level?
 - Anteroposterior: rotational prominence
- Prominence of hips
- Iliac crests, levelness
- Fullness over iliac crest
- Relation of forearms to iliac crests
 - One longer
 - Anteroposterior relation
 - Nearness to body
- Prominence of costal arches
- Thoracic symmetry or asymmetry
- Prominence of sternal angle
- Position of shoulders
 - Level or unlevel
 - Anteroposterior relations
- Prominence of sternal end of clavicle
- Prominence of sternocleidomastoid muscles
- Direction of symphysis menti
- Symmetry of face (any scoliosis capitis)
- Nasal deviation
- Angles of mouth
- Level of eyes
- Level of supraciliary arches (eyebrows)
- Head position relative to shoulders and body

If the spinal curves are normal and no respiratory condition exists, the protuberant abdomen provides evidence of visceroptosis and the patient should be evaluated for the same.

Normally, there is about three or four finger-breadths of space between the top of the iliac crest and the lower costal margin. This can be decreased by the presence of scoliosis. In severe or decompensated scoliosis, one side of the costal cage can literally be sitting on top of the iliac crest. At times, this can shift far enough laterally to put pressure on the liver or the upper left abdominal viscera. Elevation of liver or pancreatic enzymes can be the result.

Rib Cage

The prominence of the xiphoid process should be noted. It is not uncommon for the xiphoid to become more prominent as one ages. Then, due to clothing pressure or sleeping prone, it becomes tender to touch and the patient presents with “midepigastric pain” with the resultant unnecessary work-up. Palpation of the xiphoid will reproduce the patient’s pain and render a diagnosis of xiphalgia.

Observe the patient for any deformities of the sternum. The pectus excavatum (funnel breast) is the most common (Fig. 34.4), pectus carinatum (pigeon breast) less so. Any deformity of the

sternum should prompt an examination for occult congenital heart defects. While not a 100% correlation, heart defects are more common in patients with sternal abnormalities than in the general population.

Observe the prominence or lack thereof of the two halves of the rib cage. An anterior prominence of the rib cage on one side of the spine is frequently due to the rotational component of scoliosis. It is the analogue of the rib hump on the posterior side of the body.

Observe the costal cartilages for any deformity or swelling. Congenital abnormalities in the structure of the lower 4 or 5 costal cartilages are quite common. The normal rib cage is shaped something like an apple. A common abnormality is the presence of an outflaring of the lower rib cage. The resultant lateral sulci formed are called Harrison Grooves. These are most often familial, but can come about from any condition (such as very young pregnancy, large Wilms tumors) that bows out the growing costal cartilages. After skeletal maturity, the position of the cartilages is relatively fixed.

A visible or palpable ridge at one or more costochondral joints can indicate the presence of a “separated rib.” When deformity is present at the time of injury, the articulation will often heal with

Figure 34-4 Pectus excavatum. (Original photograph Walter C. Ehrenfeuchter, D.O., F.A.A.O., with permission.)

a slight anteroposterior deformity. This is not amenable to correction after this injury has already healed.

Swelling of one or more costal cartilages (typically the second or the third) indicates the likelihood of Tietze syndrome, believed to be a viral infection of costal cartilage. This must be differentiated from the more common costochondritis that does not cause swelling of the cartilage, just tenderness.

Shoulders

Observe and palpate the clavicles for symmetry. Rarely will you see cases of congenital absence of the clavicles. A clavicle can be misshapen due to congenital anomaly, fracture during birth, or subsequent fracture at a later date. The length of the clavicle from sternum to acromion in part determines the position of the entire shoulder. The clavicle is the upper extremity's only bony connection to the axial skeleton. A shortened clavicle often causes anterior shoulder carriage, pulling the scapula farther away from the spinal column than its mate on the uninjured side. Figure 34.5 shows a deformed clavicle due to old fracture with malunion.

Cervical Region

Observe the patient for prominence of the sternocleidomastoid muscles and scalene muscles. Hypertonicity, contracture, and hematoma will shorten all of these commonly injured muscles. This will in turn alter neck and head carriage in response.

Head

Observe the carriage of the head atop the neck. Some dysfunctions in this region will be more obvious from an anterior view than the posterior.

Figure 34-5 Deformed clavicle due to old fracture with malunion. (Original photograph Walter C. Ehrenfeuchter, D.O., F.A.A.O., with permission.)

Observe the position of the symphysis menti relative to the midline of the body and to the midline of the face. Observe the jaw for symmetry relative to the rest of the head. Lateral deviation of the jaw can signify a shortened portion of the mandible, with resultant dental abnormalities and the potential for temporomandibular dysfunction syndrome and pain. Asymmetry of the jaw can also be generated by somatic dysfunction of the temporal bones.

Observe the face for symmetry. Facial asymmetry can occur due to congenital malformation of the skull, as a result of birth trauma to the sphenobasilar synchondrosis, or acquired sphenobasilar somatic dysfunction as a result of head trauma or dental work. It can also occur as a result of facial bone somatic dysfunction as a result of trauma to the face. Facial asymmetry is often most evident in the shape of the orbits or entire face. Often, a visual determination of the cranial dysfunctions present can be made before palpating the motion of the head.

Figure 34.6 is a lateral view of normal posture with midgravitational line.

Knees

This may be the easiest way to observe genu recurvatum or flexion contracture of the knee. Again, symmetry may be more important than the mere presence of one deformity or the other.

Thighs

The lateral thigh surface should be smooth. If a deep groove is present running from the greater trochanter of the femur to the knee, it suggests shortening and contracture of the iliotibial band.

Pelvis

Anterior or posterior pelvic tilt is readily seen from the lateral aspect.

Lumbar Lordosis

Observe for a normal lumbar lordotic curve.

Figure 34-6 Lateral view of normal posture with midgravitational line. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 2.9.)

On examination note:

- Lateral midgravitational line
 - a External auditory canal
 - b Lateral head of the humerus
 - c Third lumbar vertebra
 - d Anterior third of the sacrum
 - e Greater trochanter of the femur
 - f Lateral condyle of the knee
 - g Lateral malleolus
- Anterior and posterior body line
- Feet: degree of arching or flatness
- Knees: degree of flexion or extension
- Spinal curves: increase, decreased, or normal
 - Cervical lordosis: posterior concavity
 - Thoracic kyphosis: posterior convexity
 - Lumbar lordosis: posterior concavity
 - Sacrum, lumbosacral angle
- Arms: position relative to body
- Abdomen: prominence or flatness
- Sternal angle
- Thorax: prominence or flatness
- Head: relation to shoulder and body

Thoracic Kyphosis

Observe for a normal thoracic kyphotic curve.

Cervical Lordosis

Observe for a normal cervical lordotic curve.

Shoulders

Anterior shoulder carriage is readily apparent from the lateral view as is posterior carriage or a military-type posture. Anterior shoulder carriage with the scapula shifting superiorly and laterally will cause the acromion process to impinge upon the supraspinatus tendon. This can result in subacromial bursitis, rotator cuff tendonitis, frozen shoulder (fibrous adhesive capsulitis), and partial or total rupture of the supraspinatus portion of the rotator cuff.

Head Carriage

Note the position of the head relative to the rest of the trunk.

MID-GRAVITY LINES

Components of the posterior mid-gravity, anterior mid-gravity, and lateral mid-gravity lines are shown in Table 34.1.

Posterior Mid-Gravity Line

The posterior mid-gravity line (see Fig. 34.1) begins at a mid heel point, passes directly through the gluteal crease; the spinous processes of the sacral, lumbar, thoracic and cervical vertebrae; and the inion.

Assessment of body symmetry about this line makes readily apparent any pelvic side shift, any minor scoliotic curves, and head tilt.

If the line is reversed and begun at the inion passing down through the spine, other information can be gathered. In the presence of a scoliosis, no matter how severe, if it is a compensated curve, this plumb line will fall through the spinous process of S1. If decompensated, the plumb line will fall laterally to one side or the other.

If the body as a whole has compensated for a decompensated or traumatic spinal curve, even when the plumb line does not fall mid-sacrum, it may still fall normally at the mid heel point.

If the body is unable to compensate for any deformity above the feet, the plumb line will fall off of the mid heel point to one side or the other.

Posturing, which relieves or minimizes pain in any part of the body, can also shift this plumb line off of the mid heel point.

Anterior Mid-Gravity Line

The anterior mid-gravity line (see Fig. 34.3) again originates at the mid heel point, passes upward through the pubic symphysis, the

TABLE 34.1

Mid-Gravity Lines and Their Components

Mid-Gravity Line	Components
Posterior	<ul style="list-style-type: none"> • mid heel point • gluteal crease • spinous processes of the sacral, lumbar, thoracic, and cervical vertebrae • inion
Anterior	<ul style="list-style-type: none"> • mid heel point • pubic symphysis • umbilicus • xiphoid process • midsternum • episternal notch • symphysis menti • glabella
Lateral	<ul style="list-style-type: none"> • lateral malleolus • patella • greater trochanter of the femur • sacral promontory • midbody of L3 • greater tuberosity of the humerus • odontoid process of C2 • external auditory meatus

umbilicus, xiphoid process, midsternum, episternal notch, symphysis menti, and glabella.

Again, some truncal asymmetries and deformities are most visible from an anterior perspective, especially those involving the rib cage, jaw, and face.

A plumb line hung from the glabella can be used in much the same way that a plumb line from the inion is used.

Lateral Mid-Gravity Line

The normal lateral mid-gravity line (see Fig. 34.6) passes just anterior to the lateral malleolus, just posterior to the patella, through the greater trochanter of the femur, the sacral promontory, the midbody of L3, the greater tuberosity of the humerus, the odontoid process of C2, and the external auditory meatus.

Most of the anteroposterior deformities that can occur will cause pain in one part of the body or another and become a pathological state in their own right.

An extreme abnormality of this weight bearing line is the situation where only the lateral malleolus is on the line. The rest of the points are anterior to this plane. Patients appear to be on the verge of falling forward and are in fact contracting every posterior truncal muscle they have to fight this gravitational tendency. Often, such patients have had their sense of normal posture disrupted by some trauma and have come to accept this distorted posture as correct. In addition to manipulative treatment, this type of patient will frequently require postural reeducation.

If the lateral malleolus is on the line as is the greater trochanter, but the knee is not, it demonstrates the presence of knee flexion contracture or genu recurvatum.

An increased lumbar lordosis will carry the points on L3 and the sacral promontory forward, but leave all other points on the line. This is often due to a bilaterally flexed sacrum or other anterior going sacral dysfunctions, or an extended dysfunction of the one or more of the lower lumbar vertebrae. It can also be due to weak lower abdominal musculature.

The “sway back” posture places the malleolar point on the mid-gravity line, but the only other point typically on the line is the greater tuberosity of the humerus. All other points fall anterior to the line. This posture commonly results from pregnancy. After the birth of the child, the body maintains this posture as it has learned this to be the normal. Abdominal strengthening exercises, osteopathic manipulative treatment, and postural re-education can all be used to correct this postural deformity.

Increased thoracic kyphosis tends to shift all points below the shoulder posterior to the weight bearing line except the malleolar reference point. Often, the head is carried anterior to the line for balance.

To a lesser degree, this is the same posture assumed by students while studying in a seated position. For every inch that the external auditory meatus is shifted anterior to the ideal mid-gravity line, an additional ten pounds of load is placed on the posterior cervical musculature. The solution is to relearn to sit upright. This can be assisted by raising the materials being read and propping them on something akin to a music stand. There are commercial devices that will do this. Artists and draftsmen have long used tilt top tables that take the strain off the neck and shoulders and allow the person to sit upright. So, put those heavy text books to good use and make them into a support for the notes you are studying from.

Some authorities prefer to reference the lateral mid-gravity line to the external auditory meatus, rather than the lateral malleolus. This changes the relative position of the landmarks for all the conditions listed above; it does not change the diagnoses (3–5).

REGIONAL RANGE-OF-MOTION TESTING

Regional range-of-motion testing is the last part of the screening structural examination. There are three things of note when performing these tests. First, any region with diminished range of motion is abnormal. Second, any region with increased range of motion is abnormal and may be compensating for an adjacent area that is hypomobile. Third, for the paired motions of sidebending and rotation, any left-to-right asymmetry is abnormal, even if the overall range of motion is normal.

The following screening range-of-motion exam will not pick every possible somatic dysfunction, but most will be discovered through it. In addition to measuring the ranges of motion, when possible, regional motion will be examined both actively and passively. The loss of active range of motion has many causes; the loss of the additional passive range of motion is most commonly associated with somatic dysfunction. The quality of that motion will also be assessed, as will any associated special tests.

Screening Ranges of Motion**Cervical Region**

The normal range of motion for flexion is 45 to 90 degrees, and for extension is 45 to 90 degrees. The procedure for screening range of motion in the cervical region is:

1. The physician palpates between the spinous processes of C7 and T1 (Fig. 34.7).

Figure 34-7 The physician palpates between the spinous processes of C7 and T1. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.1.)

Figure 34-9 Passive forward bending. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.9.)

2. Instruct the patient to bend the head forward as far as he or she can go without pain. Normal range of motion is 45 to 90 degrees (Fig. 34.8).
3. After the patient has reached full active flexion, passively carry the head farther forward until motion is palpated at C7/T1 (Fig. 34.9).
4. Instruct the patient to return to the neutral position (Fig. 34.10).
5. Instruct the patient to bend the head backward as far as he or she can go without pain (Fig. 34.11).
6. Once the end of the active range of motion has been reached, the physician passively carries the head into further extension until motion is again palpated. (Fig. 34.12).

For sidebending, the normal range of motion is 30 to 45 degrees. The procedure for screening sidebending in the cervical region is:

1. The physician palpates over the Intertransverse spaces bilaterally between C7 and T1 (Fig. 34.13).
2. The patient is instructed to actively sidebend the head to the right to the pain-free limit of motion. Normal is 30 to 45 degrees (Fig. 34.14).

Figure 34-8 Instruct the patient to bend the head forward as far as he or she can go without pain. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.4.)

3. At the end of active right sidebending, the physician passively sidebends the patient's neck to the right while palpating for motion at C7/T1 (Fig. 34.15).
4. The patient is instructed to return his or her head to the neutral position (Fig. 34.16).
5. The patient is instructed to actively sidebend the head to the left as far as it will go without pain (Fig. 34.17).
6. At the end of the range of motion, the physician passively moves the patient's head into further left sidebending while palpating for motion at C7/T1 (Fig. 34.18).

The normal range for rotation in the cervical region is 70 to 90 degrees. The procedure for screening is:

1. The physician palpates over the Intertransverse space between C7 and T1 (Fig. 34.19).
2. The patient is instructed to actively turn his or her head to the right as far as it will go without pain. Normal range is 70 to 90 degrees (Fig. 34.20).
3. At the end of active right rotation, the physician passively turns the head farther while palpating for motion at C7/T1 (Fig. 34.21).

4. The patient is instructed to return his or her head to the neutral position (Fig. 34.22).
5. The patient is instructed to actively turn the head to the left as far as it will go without pain (Fig. 34.23).
6. At the end of active left rotation, the physician passively turns the head farther to the left while palpating for motion at C7/T1 (Fig. 34.24).

A loss of approximately 50% of rotation in the cervical spine can have several types of dysfunction associated with it. First, since approximately 50% of cervical rotation occurs at C1 on C2, it could indicate a dysfunction at this level. It could also indicate the presence of hypertonicity or spasm of a long restrictor muscle such as levator scapulae or sternocleidomastoid. Lastly, it could indicate a group dysfunction of everything from C2 to C7. Less severe motion losses are typically due to one or more segmental dysfunctions from C2 to C7.

Thoracic Region

The procedure for screening sidebending T1 to T4 is:

1. The patient is seated on the side of the treatment table. The physician stands behind and at the side of the patient on the side to be tested. The physician palpates of the transverse processes of T4 (Fig. 34.25).

Figure 34-22 Neutral. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.16.)

Figure 34-25 The physician palpates over the transverse processes of T4. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.21.)

Figure 34-23 Active rotation—left. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.18.)

Figure 34-26 Palpating first rib—springing force. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.22.)

Figure 34-24 Passive rotation—left. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.20.)

2. The physician places his first metacarpal-phalangeal joint over the first rib at the base of the neck. The physician's elbow is held high above the shoulder to deliver a springing force toward the spinous process of T4 (Fig. 34.26).
3. This produces passive sidebending of T1 to T4. Normal range of motion is 5 to 25 degrees. There is no active motion test for this range.
4. Steps 1 to 3 are repeated on the opposite side of the body.

The procedure for screening sidebending T5 to T8 is:

1. The patient is seated on the side of the treatment table. The physician stands behind and to the side of the patient on the side to be tested.
2. The physician palpates over the transverse processes of T8 (Fig. 34.27).
3. The physician places his first metacarpal-phalangeal joint over the midpoint of the shoulder. The physician's elbow is held high above the shoulder to deliver a springing force toward the spinous process of T8 (Fig. 34.28).
4. This produces passive sidebending of the thoracic spine from T5 to T8. Normal range of motion is 10 to 30 degrees. There is no active motion test for this range.
5. Steps one through four are repeated for the opposite side.

Figure 34-27 The physician palpates over the transverse processes of T8. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.25.)

Figure 34-30 Springing over the acromioclavicular joint. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.30.)

Figure 34-28 Springing over midpoint of shoulder. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.26.)

Figure 34-29 The physician palpates over the transverse processes of T12. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.29.)

The procedure for screening sidebending T9-12 is:

1. The patient is seated on the side of the table. The physician stands behind and to the side of the patient on the side to be tested. The physician palpates over the transverse processes of T12 (Fig. 34.29).

2. The physician places his first metacarpal-phalangeal joint over the acromioclavicular joint. The physician's elbow is held high above the shoulder to deliver a force toward the spinous process of T12 (Fig. 34.30).
3. This produces passive sidebending from T9 to T12. The normal range of motion is 20 to 40 degrees. There is no active motion test for this region.
4. Steps 1 through 3 are repeated for the opposite side of the body.

The procedure for screening rotation T9-12 is:

1. The patient is seated on the side of the treatment table with the arms crossed, holding on to his or her own shoulders.
2. The physician stands behind and to the side of the patient on the side to be tested and palpates over the transverse processes of T12 (Fig. 34.31).
3. The patient is instructed to turn his or her body as far as possible to the ipsilateral side. This is the active range of motion. Normal is 70 to 90 degrees (Fig. 34.32).
4. Once this has been accomplished, the physician grasps the patient's contralateral arm and attempts to rotate them farther in the same direction. This is the passive range of motion (Fig. 34.33).
5. Steps 1 to 4 are repeated for the opposite side of the body.

Rib Motion

Screening for rib motion involves palpating for pump handle motion (Fig. 34.34) in the upper ribs and for bucket handle motion (Fig. 34.35) in the lower ribs.

The procedure for screening ribs 1 and 2 is:

1. The patient is supine on the treatment table. The physician is positioned at the head of the table and palpates over ribs 1 and 2. The thumbs are placed on the angles of rib 1. The index fingers are placed posterior to the clavicle over the anterior aspect of rib 1. The middle or ring fingers are placed over the anterior aspect of rib 2 (Fig. 34.36).
2. The patient is instructed to inhale and exhale deeply. The physician palpates the range and quality of motion of the first two ribs noting any asymmetry that may exist. The principal motion in this location is designated as pump handle. There is no passive motion test for this range (Fig. 34.37).

Figure 34-31 The physician palpates over the transverse processes of T12. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.33.)

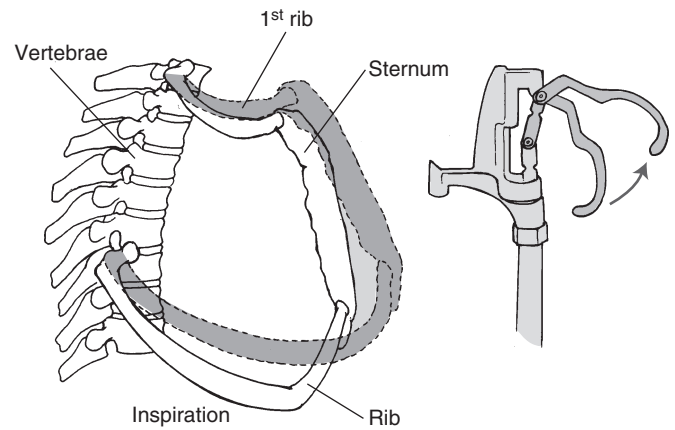

Figure 34-34 Pump handle motion. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.60.)

Figure 34-32 Active range of motion. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.34.)

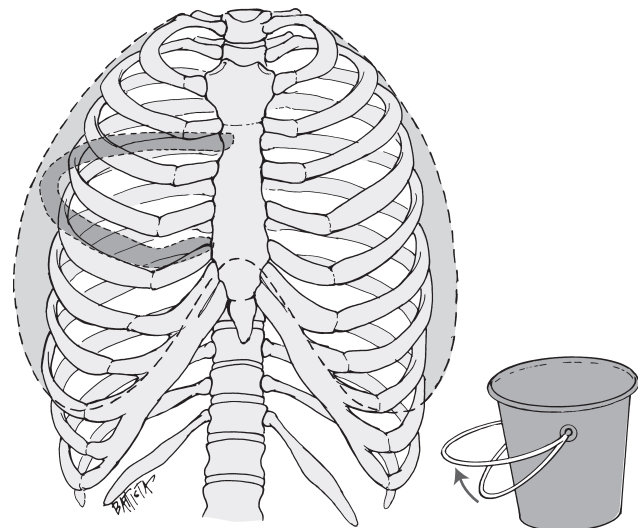

Figure 34-35 Bucket handle motion. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.61.)

Figure 34-33 Passive range of motion. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.36.)

Figure 34-36 Palpating over anterior ribs 1 and 2. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.62.)

Figure 34-37 Palpating over anterior ribs 1 and 2—on skin. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.63.)

Figure 34-40 The physician palpates the lateral aspects of ribs 6 to 10. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.74.)

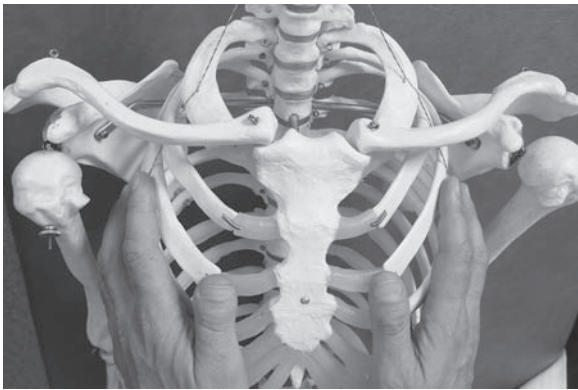

Figure 34-38 The physician palpates over the anterolateral aspect of ribs 3 to 5. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.70.)

Figure 34-41 The physician palpates the lateral aspects of ribs 6 to 10—on skin. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.75.)

Figure 34-39 The physician palpates over the anterolateral aspect of ribs 3 to 5—on skin. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.71.)

The procedure for screening ribs 3 through 5 is:

1. The patient is supine on the treatment table. The physician palpates over the anterolateral aspect of ribs 3 to 5. This is done with the physician standing at about the level of the patient's waist (Fig. 34.38).
2. The patient is instructed to inhale and exhale deeply. The physician palpates the range and quality of motion of ribs 3 through 5 noting any asymmetry that exists. The principal motion in this location is described as combined pump handle and bucket handle. There is no passive motion test for this range (Fig. 34.39).

The procedure for screening ribs 6 to 10 is:

1. The patient lies supine. The physician stands at the side of the patient at the level of the patient's pelvis. The physician palpates the lateral aspects of ribs 6 to 10 (Fig. 34.40).
2. The patient is instructed to inhale and exhale deeply. The physician palpates the range and quality of motion of ribs 6 through 10 noting any asymmetry that exists. The principal motion at this location is described as bucket handle. There is no passive motion test for this range (Fig. 34.41).

The procedure for screening ribs 11 and 12 is:

1. The patient is prone. The physician stands at the side of the table and palpates ribs 11 and 12. The thumbs go on the

inferior aspect of rib 12 with fingers over the tips of rib 11 (Fig. 34.42).

2. The patient is instructed to inhale and exhale deeply. The physician palpates the range and quality of motion of ribs 11 and 12 noting any asymmetry that exists. The typical motion for these ribs is described as caliper motion. There is no passive motion test for this range (Fig. 34.43).

Restriction of motion and motion direction of these lower ribs is under the strong influence of the quadratus lumborum muscle. Any restriction must be interpreted in light of this influence.

Lumbar Region

The procedure for screening flexion in the lumbar region is:

1. The angle created by lumbar flexion is formed using lines joining the lateral malleolus to the greater trochanter and the greater trochanter to the acromion process (Fig. 34.44).
2. The patient is instructed to slowly bend forward as if he or she is going to touch the toes. They should bend forward as far as possible. The normal range of active motion here is 70 to 90 degrees (Fig. 34.45).
3. Note to see that there is a normal reversal of the lumbar lordosis. Persistence of the lordosis indicates immobility of the

Figure 34-42 The physician palpates ribs 11 and 12. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.78.)

Figure 34-43 The physician palpates ribs 11 and 12—on skin. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.79.)

Figure 34-44 Patient in sagittal plane. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.34.)

Figure 34-45 Active forward bending. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 3.39.)

spine despite hypermobile hip joints and a normal range of motion.

4. If it is uncertain whether normal lumbar motion is occurring or not, the modified Shober test is used.

In this test, a mark is made on the skin midway between the PSIS. Measure down 5 cm and make another mark. Measure up 10 cm from the initial point and make another mark. The total distance in the erect position should measure 15 cm. With the trunk flexed, this distance should stretch to 20 cm. Less than this indicates a significant restriction of lumbar motion (Fig. 34.46).

Note: When Shober first described this test, he made only two marks, one midway between the PSIS and another 10 cm above. Early efforts to confirm the validity of this test with x-rays discovered that a significant number of times, the first mark was above the L5/S1 motion segment, so it was modified to include the downward measurement of 5 cm. Radiographic validation of the test came in the 1960s using metallic skin markers and lumbar x-rays (6–8).

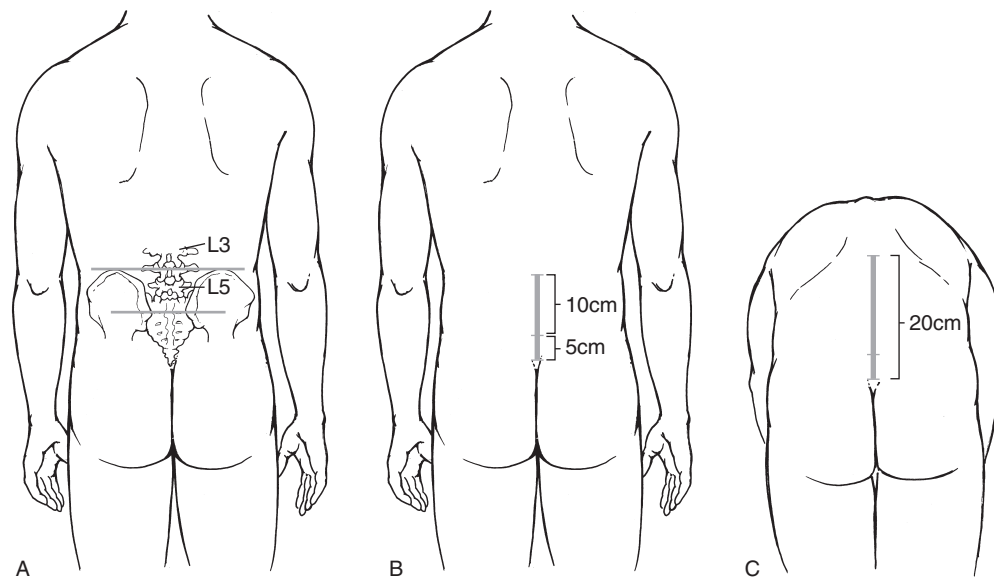

Figure 34-46 Modified shober test.

The procedure for screening extension in the lumbar region is:

1. The angle created by lumbar flexion is formed using lines joining the lateral malleolus to the greater trochanter and the greater trochanter to the acromion process (see Fig. 34.44).
2. The patient is instructed to place the arms out in front for balance and then bend backward as far as possible while keeping the knees straight.

The normal range for lumbar extension is 30 to 45 degrees (Fig. 34.47).

To screen sidebending/active range of motion in the lumbar region:

1. The posterior landmarks used for this measurement are a line from the mid heel point to the spinous process of S-1, and from S-1 to the spinous process of T1 (Fig. 34.48).
2. The patient is instructed to slide her hand down the lateral thigh toward the knee reaching as far as she can go (Fig. 34.49).

Figure 34-47 Lumbar extension (backward bending). (Original photograph: Walter C. Ehrenfeuchter, D.O., F.A.A.O., with permission.)

3. Note where the sidebending occurs. Is the arc of motion smooth or does the back “hinge” at a certain level?
4. Repeat the same motion to the opposite side.
5. Note any asymmetry in both the quantity and the quality of motion. Normal range of motion for this range is 25 to 30 degrees (9–11).

The Hip Drop Test

The hip drop test is performed to screen for sidebending/passive range of motion in the lumbar region. This test is interpreted as passive motion as the lumbar spine spontaneously responds to an artificially produced sacral base declination:

1. The patient is instructed to flex one knee, allowing the pelvis to drop on that side of the body. (Fig. 34.50).
2. Observe for symmetry of range and quality of motion. Many lower extremity conditions can interfere with this test: bad knees, tight iliotibial band, inability to dorsiflex the ankle, etc. (12).

Figure 34-52 Negative standing flexion test. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.107.)

Iliosacral Motion

The screening test for innominate dysfunction is the standing flexion test:

1. The patient stands erect with the feet a shoulder width apart.
2. The physician stands or kneels behind the patient with his eyes at the level of the PSIS.
3. The physician's thumbs are placed on the inferior slope of the patient's PSISs. The physician maintains a firm pressure on the PSISs to ride with the bony landmarks, not shift due to skin or fascial drag (Fig. 34.51).
4. The patient is instructed to actively bend forward and try to touch her toes (Fig. 34.52).
5. The test is positive when asymmetry of the thumbs occurs. The side of a positive test is the one where the thumb on the PSIS moves at least one thumb breadth more cephalad at the end range of motion. (Fig. 34.53).
6. A positive standing flexion test indicates the side of likely iliosacral dysfunction. A false-positive test can be created by a leg-length discrepancy $>1/2$ in, contralateral tight hamstring,

Figure 34-53 Positive standing flexion test—right. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.108.)

Figure 34-54 Seated flexion test—start position. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.109).

Figure 34-55 Negative seated flexion test. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.110.)

Figure 34-56 Positive seated flexion test—right. (From Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott Williams & Wilkins; Figure 5.111.)

contralateral tight iliopsoas muscle, or the presence of a unilateral sacral dysfunction. If this test is negative, the presence of an iliosacral dysfunction is highly unlikely (13).

Sacroiliac Motion

The screening test for unilateral sacral dysfunction is the seated flexion test:

1. The patient is seated on a low stool or side of a treatment table with the feet touching the floor.
2. The physician stands or kneels behind the patient with his eyes at the level of the patient's PSISs.
3. The physician's thumbs are positioned on the inferior slopes of the PSISs (Fig. 34.54).
4. The patient is instructed to bend forward as far as possible (Fig. 34.55).
5. A positive test is one where the PSIS moves more cephalad by at least one thumb breadth at the end of the range of motion (Fig. 34.56).
6. Potential dysfunctions here include anterior and posterior torsions, and unilateral flexed and extended sacra (14).

An additional test for sacroiliac motion is the pelvic side shift test:

1. The patient stands erect with the feet shoulder width apart.
2. The physician stands behind the patient with one of the physician's hands contacting the patient's iliac crest and the other on the opposite deltoid/shoulder area.
3. The physician gently pushes the iliac crest/pelvis laterally (translates) to the opposite side utilizing the hand on the deltoid/shoulder to stabilize the thoracic spinal segments. The ease and amount of motion is noted.
4. The physician next switches hand positions and introduces motion to the opposite direction. Motion in each direction is now compared.
5. A positive pelvic side shift reveals freer translation to the side of the side shift and named for that direction. A positive pelvic side shift means that the sacrum (base of support) is positioned on the side of the freer motion and may indicate a possible long leg to the side of and/or a tight psoas muscle to the opposite side of the pelvic side shift.

Sacral Motion

The screening test for bilateral sacral dysfunction is the sacral rock test:

1. The patient is prone on the treatment table.
2. The physician stands at the side of the treatment table at the level of the patient's pelvis.
3. The physician places his cephalad hand on the sacrum with the heel of the hand at the sacral base, fingers pointing toward the coccyx (Fig. 34.57).
4. The physician's caudad hand reinforces the cephalad hand with the thumb and the index finger creating a space for the cephalad hand's wrist (Fig. 34.58).
5. The physician presses straight down into the sacrum so that any body movement is imparted to the sacrum.
6. The physician attempts to rock the sacrum through flexion (Fig. 34.59) and extension (Fig. 34.60). Bilateral sacral dysfunction feels exceptionally rigid—a so-called concrete pelvis (15).

Symptom Exacerbation or Remission

One of the important accompaniments of range-of-motion testing is the exacerbation or remission of patient symptoms. Table 34.2 includes a partial list of structures and conditions that would be

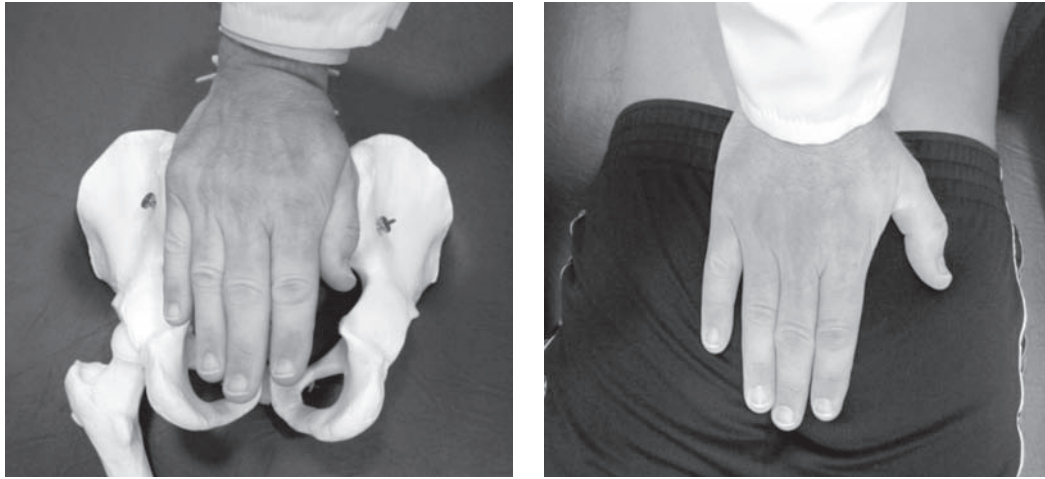

Figure 34-57 Sacral rock test—step 3. (Original photos: Walter C. Ehrenfeuchter, D.O., F.A.A.O., with permission.)

TABLE 34.2

Structures and Conditions Exacerbated by Spinal Range of Motion

Structure	Motion	Condition
Cervical Spine	Flexion	Disc Herniation Posterior Muscles
	Extension	Facet Joint Disease Anterior Muscle
	Sidebending	Trapezius muscle Levator Scapulae muscle
	Rotation	Splenius capitis and cervicis muscles Sternocleidomastoid muscle
Thoracic Spine	Flexion	Paraspinal muscles Posterior shoulder girdle muscles Disc Herniation
	Extension	Facet Joint Disease
	Sidebending	Intercostal muscles Serratus Anterior muscle
	Rotation	Abdominal Oblique muscles
Lumbar Spine	Flexion	Disc Herniation Lumbar Paravertebral muscles Lumbosacral Ligaments
	Extension	Spondylolisthesis Facet Syndrome Spinal Stenosis Psoas Spasm
	Sidebending	Lateral Abdominal Wall muscles Iliotibial Band Syndrome
	Rotation	Abdominal oblique muscles Iliolumbar ligaments Piriformis Syndrome (16)

exacerbated by spinal range of motion. Listed muscle pains apply to both injury and muscle hypertonicity or spasm. The diagnosis of somatic dysfunction requires at least two of the following:

- Tenderness
- Asymmetry
- Range-of-motion changes
- Tissue texture changes

The screening evaluation will at least provide you with regional data as to asymmetry and range-of-motion changes. “We know that if we are ever to know the whole, we must first know the parts.” A.T. Still.

Segmental Motion Testing

WALTER C. EHRENFEUCHTER

KEY CONCEPTS

- Understanding of the characteristics of vertebral unit position and motion is essential to accurate segmental definition.
- Accurate segmental definition enhances recognition of somatic dysfunctions responsible for symptomatology or disordered physiology.
- Osteopathic manipulative treatment is directed to correction of dysfunctions that maintain symptomatology or disordered physiology.
- The goal of osteopathic diagnosis and treatment is to facilitate change for the better in the patient's overall body physiology.

INTRODUCTION

The final portion of the osteopathic structural examination is segmental definition. This is carried out guided by the findings in the screening examination and the scanning evaluation (layer-by-layer palpation). If there are no findings on the scanning exam for a given segment, it is unlikely that any significant somatic dysfunction exists at that segment and segmental definition is unnecessary.

VERTEBRAL UNIT

The vertebral unit is defined as two adjacent vertebrae with their associated intervertebral disc, arthrodial, ligamentous, muscular, vascular, neural, and lymphatic elements (Fig. 35.1).

Conventionally, when referring to motion of a single vertebra, we are in fact referring to that segment's vertebral unit. For example, when referring to the motion of L3, we are in reality referring to the motion of L3 in reference to L4.

Potential Segmental Motions

Using a Cartesian coordinate system, the position or motion of any vertebra can be described in space as a combination of rotation about any of the three axes and translation along any of the three axes. This system, while useful for biomechanical research purposes, is clinically cumbersome. For simplicity, the movements of the individual vertebrae are broken down into three components: flexion or extension, rotation, and sidebending (Table 35.1).

When referencing the position or motion of a vertebra, the position of a point on the superior endplate at the anterior most part of that endplate is used (Fig. 35.2).

Conventionally, the diagnosis of a segmental dysfunction may be described in one of two ways:

1. That vertebra's position relative to the vertebra below.
2. The directions of motion restriction of that vertebra relative to the vertebra below.

For example:

- Positional diagnosis—L5 flexed, sidebent right, rotated right
- Motion restriction diagnosis—L5 restricted in extension, left sidebending, and left rotation.

The two examples describe exactly the same segment, just from two different points of view.

In positional language, words end in -ed and -ent, as in flexed, extended, rotated, and sidebent. In motion restriction language, words end in -ing and -ion, as in flexion, extension, rotation, and sidebending.

When diagnosing somatic dysfunction, the positional diagnosis is determined and named for what the vertebra does most easily. In other words, the direction of freest motion, the direction of ease, is identified.

Physiologic Laws of Spinal Motion: Fryette's Principles

Fryette's principles regarding the physiologic laws of spinal motion include:

- I—In the neutral range, sidebending and rotation are coupled in opposite directions
- II—In sufficient flexion or extension, sidebending and rotation are coupled in the same direction (4)
- III—Initiating movement of a vertebral segment in any plane of motion will modify the movement of that segment in other planes of motion.

Figure 35-1 The vertebral unit.

TABLE 35.1

Vertebral Movements

Movement	Definition
Rotation	Movement in a transverse plane about a vertical axis
Sidebending	Movement in a coronal plane about an anterior-posterior axis
Flexion	Anterior movement in a sagittal plane about a transverse axis
Extension	Posterior movement in a sagittal plane about a transverse axis.

Laws I and II apply to thoracic and lumbar motion only. Sidebending and rotation are considered coupled motions (i.e., you cannot have one without the other). They were described by Harrison H. Fryette, D.O., in 1918. All of his observations regarding vertebral mechanics were made without benefit of x-rays; he used palpation only. Law III was described by C. R. Nelson, D.O., in 1948.

Neutral is a Range

Neutral in the world of spinal mechanics is not a single point, but rather a range in which the weight of the trunk is borne on the vertebral bodies and discs, and the facets are “idling” (3) (Fig. 35.3).

In this range, Law I applies. That is, when one or the other is introduced, sidebending and rotation will be coupled in opposite directions; the motion segment will sidebend right and rotate left or it can sidebend left and rotate right. This is referred to as Type I mechanics (Fig. 35.4). A dysfunctional segment held in this position is referred to as a Type I dysfunction.

NonNeutral Mechanics

In the thoracic and lumbar spine when sufficient flexion or extension beyond the neutral range occurs, sidebending and rotation will be coupled to the same side. The segment is flexed or extended and sidebent right, rotated right or sidebent left, rotated left. This is referred to as Type II mechanics (Fig. 35.5). A dysfunctional segment held in this position is referred to as a Type II dysfunction.

Figure 35-2 Point of reference for vertebral motion.

Figure 35-3 Neutral range. (From the Kimberly Manual Outline of Osteopathic Manipulative Procedures. Marceline, MO: Walsworth Publishing Company, 2000:10.)

Law III has been interpreted to mean that if motion is restricted in any one direction (e.g., rotation), then motion will also be restricted in sidebending and flexion/extension. If motion is improved in any one direction (e.g., flexion/extension), it will be found to have improved in rotation and sidebending as well.

Due to the cumbersomeness of the longhand descriptions of vertebral position, shorthand abbreviations and notations have been developed, as shown in Box 35.1.

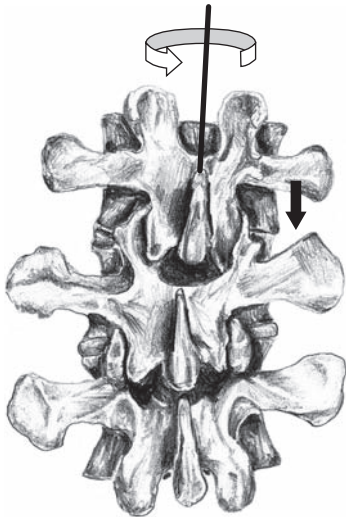

Figure 35-4 Fryette Type I mechanics. (Courtesy of Adam Ehrenfeuchter, San Francisco, CA.)

Figure 35-5 Fryette Type II mechanics.

Characteristics of Type I Dysfunctions

Type I dysfunctions tend to occur in groups (7), for example, T1-7 NR_RS_L. This constitutes typical scoliosis mechanics. This does not preclude their occurring singly, for example, T5 NR_RS_L.

Groups of Type I dysfunctions tend to compensate for a single Type II dysfunction. When present, the Type II dysfunction is typically at the apex of the group dysfunction, or at either end of the group.

Characteristics of Type II Dysfunctions

Type II dysfunctions tend to occur singly, although you may have two Type II dysfunctions adjacent to each other (7). More than that is rare. Extended Type II dysfunctions are frequently the product of the segmental muscle contraction that results from a viscerosomatic reflex and should prompt the search for visceral disease and dysfunction.

Shorthand Abbreviations and Notations for Segmental Dysfunctions

Abbreviations

- N—Neutral
- F—Flexed
- E—Extended
- L—Left
- R—Rotated
- R—Right
- S—Sidebent

Notations

Type I dysfunction:

L5 Neutral, rotated left, sidebent right

Classic Spinal Mechanics

Classic Fryette mechanics is exhibited by the typical thoracic and lumbar vertebrae. The motion pattern in these regions is determined by patterns of force generated by the discs, ligaments, and musculature. Motion patterns in the cervical spine are largely determined by the shape of the facet joints, independent of the discs, ligaments, and musculature.

Motion in the cervical region is often described in terms of Fryette “Like” mechanics. It is not Fryette mechanics in that it is independent of sagittal plane position.

The occiput on C-1 always follows Type I **Like** mechanics in that sidebending and rotation are always coupled to opposite sides, whether the occiput is flexed, extended, or neutral (6).

C1 on C2 is considered to only rotate, even though considerable (20 degrees) sagittal plane motion is possible. That is because dysfunctions typically are discovered only in the rotational component of C-1 motion (6).

C2-6 always follow Type II **Like** mechanics in that sidebending and rotation are always coupled to the same side, whether these segments are flexed, extended, or neutral (6).

C7 has inferior facet joints that are more thoracic in configuration and thus tends to follow classical Fryette mechanics (2,5).

Exceptions to the Laws of Spinal Mechanics

Single plane dysfunctions are quite possible and involve restriction of motion on both facet joints, for example, T10 flexed or L5 extended.

Compressive Dysfunctions are also possible and also involve restriction of motion of both facet joints, for example, Occiput compressed on C1.

Trauma to the supporting ligaments and/or discs can generate segmental instability and any direction of dysfunction is possible. These dysfunctions do not occur as a result of exaggerated physiologic motion of the spine, but are caused by external traumatic forces.

Advanced degenerative disc disease and degenerative facet joint disease lead to segmental instability and, again, any direction of dysfunction is possible. This can also lead to neural entrapment

due to a phenomenon called dynamic lateral stenosis. Figure 35.6 shows a detailed view of lumbar vertebral column showing large osteophytes.

Congenital anomalies of the vertebrae or facet joints will also alter the motion characteristics of those segments. Facet tropism, a turning of the facet joints from their usual orientation, can dramatically alter the motion characteristics of a segment and may present with bony asymmetry and thus congenital asymmetric vertebral motion. Figure 35.7 shows a transitional lumbosacral segment causing atypical lumbosacral mechanics.

Categorizing Somatic Dysfunction

Somatic Dysfunction can be categorized by the tissue or structure most responsible for the motion restriction at that segment (8). Most dysfunctions are a combination of types, but it is helpful for the purpose of technique selection to consider searching

Figure 35-6 Detailed view of lumbar vertebral column showing large osteophytes.

Figure 35-7 Transitional Lumbosacral Segment causing atypical lumbosacral mechanics. (Photograph courtesy of Walter C. Ehrenfeuchter, D.O., FAAO.)

for the reason for segmental restriction to exist. Types of somatic dysfunction include:

- Arthrodistal restriction
- Muscular restriction
- Fascial and ligamentous restriction
- Edema-causing restriction

ARTHRODISTAL RESTRICTION

This type of somatic dysfunction is maintained by the facet joint structure itself. The articular restriction is often accompanied by a reflex muscle guarding response that will not relax until the articular “lock” is released. When acquired by acute injury, these dysfunctions can be quite painful. Despite the level of pain and guarding, the patients often derive instantaneous relief when these dysfunctions are properly treated.

Articular restrictions may be generated by acute trauma, sustained muscle hypertonicity, repetitive motion injuries (microtrauma), fascial or ligamentous contracture, or poor posture.

The articular restrictions are maintained by a combination of thin layer adherence and muscle guarding response. If the dysfunction becomes chronic, it will lead to fascial contracture and desiccation of the facet joint.

Thin layer adherence is a process where two congruent surfaces are “glued” together by a typically lubricating substance when the said substance is spread thinly enough. For thin layer adherence to occur, one needs to have congruent surfaces and a lubricating substance.

In a congruent joint, all joint surfaces are in complete contact with each other in the anatomic position. The spinal facet joints are congruent joints.

Synovial fluid when present in normal amounts is an exceptionally effective lubricant. It has been estimated that it makes the joint surfaces 10 times slipperier than ice on ice. It is very viscous and possesses a high surface tension (a single drop of normal synovial fluid can be strung out to a length of several feet without breaking).

So if you combine the congruent facet surfaces with the viscous synovial fluid and add a force that compresses the facet surfaces together, you get thin layer adherence and an articular dysfunction.

In the acute, traumatically induced articular dysfunction, where does the synovial fluid go? Some is squeezed out of the joint space and distends the capsule, one source of the pain. Over time, the synovial fluid is both adsorbed into the surface of the cartilage and removed from the capsule and surrounding tissues by the lymphatics.

MUSCULAR RESTRICTION

One very common cause of asymmetric and restricted segmental motion is the attached musculature. A detailed analysis of the influence of all the various muscles which attach to axial skeleton is beyond the scope of this book; however, some broad generalizations may be made.

Short restrictor muscles are those muscles that only cross one vertebral segment or cross one joint in the peripheral skeleton. When hypertonic, they will alter the positional and motion characteristics of just a single vertebral segment. Long restrictor muscles are those muscles that cross more than one vertebral segment on more than one joint in the peripheral skeleton. When hypertonic, they will alter the positional and motion characteristics of groups of vertebrae.

Deep Segmental Spinal Muscles

These muscles run only a segment or two adjacent to the spinal column and rib cage, and include such muscles as Rotatores Brevis, Levator Costorum Brevis, Interspinalis, Lateral Intertransverse, Rectus Capitis Posterior Minor, and a number of others. These muscles are short restrictors. They are also totally involuntary in their action. One cannot consciously think, "I want to sidebend L4 on L5, let me just contract the Lateral Intertransverse muscle at that segment." Nothing will happen. These muscles serve to balance the spinal column in response to larger movements of the trunk and long restrictor muscles. More importantly, they respond rapidly and in predictable patterns to facilitation of spinal cord segmental influences. They are believed to be the muscles that produce and maintain the extended Fryette Type II dysfunctions in response to viscerosomatic and somatosomatic reflexes. Their actions as a group in truncal posturing and locomotion are so complex that very little is known about how they function together.

Intermediate Spinal Muscles

These muscles run parallel to the spinal column and cross anywhere from two to eight or more segments and include such muscles as Multifidus, Semispinalis, Longissimus, Iliocostalis, Quadratus Lumborum, and Psoas Major to name but a few. These muscles are long restrictors. They are voluntary, motor muscles that move the trunk under the direction of volitional thought. They also function unconsciously in large truncal movements like those necessary to maintain balance and propulsion in the gait cycle. When these muscles are hypertonic, they produce sidebending of the spinal

column and group curves usually composed of vertebrae engaged in Fryette Type I mechanics.

Superficial Back Muscles

These are muscles that are incidentally involved in spinal motion owing to their attachment to the spinal column or ribs. They are actually used to brace or move the extremities. These muscles include Trapezius, Latissimus Dorsi, Rhomboideus Major and Minor, Serratus Anterior, Pectoralis Minor, and more.

When hypertonic, they influence both motion of an extremity, but also spinal motion as well. An example of this would be hypertonicity of the Rhomboid Minor m. This would tend to draw the scapula medially and superiorly. If the Scapula is anchored by its other attached musculature, its attachment to the spinous processes of C7 and T1 would tend to rotate these vertebrae away from the side of the hypertonic Rhomboid (remember the reference point for vertebral rotation is on the front of the vertebra).

When these muscles go into a true spasm, they produce significant pain and will grossly distort the normal curves of the spine and body posturing. Additionally, this produces a host of adaptational responses that can be body wide in scope.

FASCIAL AND LIGAMENTOUS RESTRICTION

The ligaments of the spine can shorten due to fibrosis resulting from trauma, or due to inflammatory diseases of the spine. Which ligaments shorten or lose elasticity the most will determine which directions a vertebral segment can and cannot move.

Likewise, the fascial envelope in which the contractile elements of the muscles reside can shorten due to a host of causes (congenital, developmental, disuse, injury, inflammatory diseases of muscle). Again when shortened, they produce patterns of restriction that are identical to those that would occur if that same muscle were hypertonic. However, even with the contractile elements of the musculature relaxed, the more static investing fascia of the muscle remains shortened.

EDEMA-CAUSING RESTRICTION

The presence of fluid in the interstices of any region of the body will create motion restriction. Part of this is due to the presence of pain from fascial stretching and compartmental distention. Part of this is due to the actual presence of the fluid itself, distending fascial compartments, stretching tissues and thus taking some of the "slack" out of the fascia or joint capsules themselves. While no set pattern of dysfunction has been ascribed to segmental or regional edema, its importance has long been acknowledged by the Osteopathic profession.

END FEEL

The concept of end feel is one in which the characteristics of how the tissue feels at the end of range of motion testing for large joint motions, or for segmental motion testing has significant implications for the Osteopathic physician. The quality of the end feel is used to determine the most likely etiology of the motion restriction (articular, muscular, fascial, edema). Once this is determined, it is used by the physician to guide in the selection of which Osteopathic manipulative technique would be most useful in addressing that particular region or dysfunction.

Each etiologic agent of somatic dysfunction produces its one distinct end feel. Edema tends to produce a mushy or fluid-filled sponge kind of end feel. Muscle hypertonicity has a somewhat stretchy or rubbery end feel. Articular dysfunctions tend to have a more solid end feel with loss of the elasticity usually palpated in muscular or edematous restrictions. Ligamentous and fascial restrictions often have a very hard, abrupt end feel with near total loss of tissue elasticity.

It is not uncommon for a patient to exhibit several types of restriction in a single dysfunction, especially when these dysfunctions are chronic in nature. So one could apply a muscle energy technique to a segmental dysfunction and, on retesting, discover that now that the contractile elements of the muscle have relaxed, that the segment now exhibits a more fascial restriction type of end feel calling for the application of a direct myofascial release technique. Another example would be where edema is present, and after applying indirect myofascial release, or lymphatic approaches, the end-feel changes to one of articular restriction calling for an articular or high-velocity, low-amplitude thrust technique. Likewise, the failure of a technique to work for a given dysfunction may arise from a misinterpretation of the end feel by the inexperienced physician, not a poor application of a given technique. The technique may be applied perfectly, but if applied for the wrong tissue etiology of the restriction, it would be unsuccessful.

Primary and Secondary Somatic Dysfunction

A primary dysfunction is one that is caused by a trauma, or repetitive microtrauma. It serves as the initiating event for the generation of a variety of symptoms and events such as local pain, somatosensory referred pain, local muscle guarding responses, initiation of somatosomatic and somatovisceral reflexes, and creation of secondary somatic dysfunctions (10).

Secondary somatic dysfunction can arise secondary to a variety of other conditions. The following list of causes is not exhaustive, but contains many of the more common causes:

- Local diseases of the spine such as degenerative disc disease or facet joint osteoarthritis
- Mechanical effects of larger deformities such as Kyphosis or scoliosis
- Compensatory for primary or other secondary somatic dysfunctions
 - Viscero-somatic reflex-generated dysfunctions
 - Somato-somatic reflex-generated dysfunctions (11)

The Key Lesion

The key lesion is defined as that somatic dysfunction that causes and maintains a whole pattern of dysfunction including secondary somatic dysfunctions.

The key lesion frequently represents, on a percentage basis, the *most* restricted structure in a patient's body. A great deal of time and effort is often expended searching for the key lesion, as it is this dysfunction, that when corrected, will result in the greatest change for the better in the patient's overall body physiology (9).

SUMMARY

So what is it that the overall osteopathic structural exam is searching for? It is searching for larger deformities that give rise to secondary somatic dysfunctions. It is searching for evidence of musculoskeletal diseases that give rise to somatic dysfunction. It is searching for somatic dysfunctions that may be responsible for the patient's symptomatology or dysfunctional physiology. It is searching for the location of the key lesion. It is searching for the tissue responsible for maintaining the key lesion. It is searching for normal tissue behaving badly. It is in short the search for a 100% reversible entity. It is the search for somatic dysfunction. "When you know the difference between normal and abnormal you have learned the all absorbing first question.....you must take your abnormal case to the normal, lay it down, and be satisfied to leave it" (1).

Postural Considerations in Osteopathic Diagnosis and Treatment

MICHAEL L. KUCHERA

KEY CONCEPTS

- Alteration of postural alignment and recurrent somatic dysfunction are key manifestations of gravitational strain.
- Postural compensation is best understood as an integrated homeostatic process.
- Postural decompensation is associated with various pathophysiological states of gravitational strain.
- Patient education is a primary source of initiating the means to a successful management plan for issues of gravitational strain.
- The osteopathic medical profession has contributed many strategies to address issues of gravitational strain.

INTRODUCTION

The osteopathic postural-biomechanical model provides one of five major approaches to structuring osteopathic manipulative care. Viewing clinical findings through the “lens” of this model and interpreting those findings with the benefit of the growing evidence base can provide remarkable insights into multiple systems, structures, and functions.

The osteopathic postural assessment evaluates more than upright symmetry; it considers the homeostatic capability of integrated components of the neuromusculoskeletal system to resist constant gravitational stress and to adapt to ever-changing situations. In the incorporation of “body unity” principles, the osteopathic postural model interprets the physical body as a *tensegrity system* within which even minor changes in one body region may affect significant biomechanical, tensile, and ergonomic changes elsewhere. This interpretation expands an osteopathic practitioner’s understanding of both etiology and treatment intervention. It also accepts that postural patterns are capable of providing a cogent glimpse of that patient’s unique interrelationship of body, mind, and spirit. Carefully exploring the specific pattern of the “body unit’s” homeostatic response provides clues to both the function and the dysfunction of key anatomical, physiological, and psychological structures.

Applying this model, the osteopathic physician seeks to achieve each patient’s maximum function and to prepare that patient’s neuromusculoskeletal system to respond optimally to postural realignment. To achieve this requires accessing and sometimes “reeducating” peripheral and central interactions that are biomechanically, physiologically, and psychologically linked. Conservative modalities available to the osteopathic physician for this purpose include osteopathic manipulative treatment (OMT), functional orthotics and orthopedic braces, exercise protocols, and patient education. These treatment modalities typically precede or accompany less conservative options ranging from prolotherapy to surgery.

The discussion in this chapter will make the case for considering the postural gravitational strain model whenever evaluating the health status of a patient. It will further describe how to implement the osteopathic postural care model in planning effective treatment strategies whenever a postural pattern for group spinal curves or recurrent skeletal, arthrodiol, or myofascial dysfunction is diagnosed.

Nearly 2,500 years ago, Hippocrates said, “*The regimen I adopt will be for the benefit of my patients according to my abilities and judgment.*” The guidelines in this chapter lay out principles intended to enhance your ability to understand postural mechanisms as dynamic

processes affecting interrelated structures throughout the body. With understanding and practice, your judgment in prescribing individualized postural treatment regimens will evolve and improve.

History and Unique Postural Contributions by the Osteopathic Profession

Neither the clinical observation of postural imbalance nor the use of radiographic assessment is unique to the osteopathic profession. However, osteopathic physicians integrated the two almost ninety years ago to better study structure and function.

In 1895, the discovery of the roentgen ray permitted visualization of structures inside the body. By 1898, the American School of Osteopathy in Kirksville, Missouri, had acquired the second machine west of the Mississippi and was producing the earliest roentgenologic studies of circulation (1). Hoskins and Schwab (2) introduced the standing postural x-ray series in 1921, opening the field for clinical interpretation and integration. Martin Beilke in 1936 acknowledged the value of the technique by observing, “The osteopathic profession can lay claim to these contributions as being strictly original and especially applicable to our approach in finding etiological factors in a given pathological process and in applying corrective measures” (3).

For many years, lack of standardization for postural radiographic procedures prevented the profession from combining important multicenter data needed to develop a common set of guidelines to interpret postural studies and formulate care. J. Stedman Denslow and his coworkers called for standardization in 1955 (4), although even today relatively few academic healthcare institutions outside of the osteopathic profession have adopted that recommendation.

Standard protocols provided measurable, accurate, and reproducible data to correlate with the osteopathic palpatory structural examinations. Published for decades thereafter in osteopathic literature, the profession documented the natural history of postural changes and also the consistency of radiographic postural findings (5,6). A compilation of many of the classic osteopathic articles discussing diagnosis, clinical impact, and treatment of postural subjects can be found in the *1983 Yearbook of the American Academy of Osteopathy, Postural Balance and Imbalance* (5). This compilation and a 1983 research study published in *Spine* (7) (itself based upon the osteopathic contribution to the importance of postural imbalance) would spark a second renaissance of osteopathic postural research that lasted nearly 2 decades.

Definitions and Basic Postural Principles

If we regard posture as the result of the dynamic interaction of two groups of forces—the environmental force of gravity on one hand, and the strength of the individual on the other—then posture is but the formal expression of the balance of power existing at any time between these two groups of forces. Thus, any deterioration of posture indicates that the individual is losing ground in his contest with the environmental force of gravity (8).

Analysis of a patient's posture provides an enormous amount of information about that individual. If and how the patient compensates or decompensates under gravity's continuous stress speaks volumes about that patient's homeostatic reserves. The pattern and degree of antigravity (postural) muscle dysfunction, the presence and type of group spinal curves, and the locations of the resultant postural spinal crossovers offer clinically relevant insight into physical structure–function relationships. Observation of posture may also offer the clinician the first clues to the underlying emotional, spiritual, and psychological elements of a patient. Conversely, it may also suggest a source of physical pain and energy depletion that precipitates or perpetuates nonphysical dysfunctions within that individual.

The postural model encompasses a range of treatment strategies designed to impact general health status or to treat the underlying cause of specific problems. Such strategies play a central role in the management of certain spinal conditions such as scoliosis or spondylolisthesis that are associated with postural decompensation. In addition, such strategies may significantly improve symptoms associated with a wide range of neuromusculoskeletal conditions. Postural improvement can reduce and potentially eliminate gravity strain's constant precipitation and perpetuation of myofascial trigger points and other recurrent somatic dysfunction. Amelioration of gravity strain has been postulated to support homeostatic mechanisms by reducing nociception and segmental facilitation and by supporting the clinical goals defined by the osteopathic respiratory-circulatory model.

Base of Support and Center of Gravity

Posture is defined as the distribution of body mass in relation to gravity over a base of support. As an adult shifts from a standing to seated posture, this *base of support* shifts from the feet alone to a base that includes the pelvis. Theoretically, a center of mass for the entire body could be mathematically approximated using force plates or computer-assisted summation of horizontal cross-sectional measurements for any given posture. By definition, however, in the living human, the *center of gravity* must remain a *theoretical* point representing the weight center of the body for the given posture; the point about which the body balances in every direction moment to moment. For simplicity, osteopathic practitioners accept that the generic clinical center of gravity in an adult's passive upright standard posture lies approximately in the middle of the third lumbar vertebral body (9).

Balancing against gravity over a base of support is not a passive process. For example while standing, moving your arms from your sides to a horizontal position in front of your body shifts your body mass and, therefore, the center of gravity anteriorly. To keep from falling forward, dynamic homeostatic mechanisms are activated to alter total body posture from the toes to the head. The resulting posture will often be observed to increase regional spinal curves and requires energy from multiple muscles to maintain it.

Functional postural demands will also alter structure, usually first at the sites where structural anatomy changes. For example,

consider the compensatory response to gravity that begins as soon as an infant attempts to assume an upright position and continues throughout life (Fig. 36.1). In order to stand upright with the least amount of effort, the infant learns to balance the center of gravity by positioning various segments of the spine over the base of support formed by the region of anatomy immediately underneath. The “toddler” learning to walk then exercises postural control to adjust for falling forward as the mass of a lower extremity is moved forward.

These evolving regional changes typically take place at the so-called anatomical transition zones where anatomical “blocks” interface with anatomical spinal “rods.” The transitional zones include the:

- *Lumbopelvic region* where the pelvis joins the lumbar spine
- *Thoracolumbar region* (or inferior thoracic outlet) where the lumbar spine joins the thoracic cage
- *Cervicothoracic region* (or superior thoracic inlet) where the thoracic cage joins the cervical spine
- *Craniocervical region* where the cervical spine joins the head

In this fashion, two secondary lordotic curves normally develop in the cervical and lumbar regions to counterbalance the primary thoracic curve present at birth. These three spinal curves together will resist gravity much better than one single sagittal plane curve. They allow a person to function in an upright position; however, they result in human specific problems that affect both structure and function. These problems are characterized by coordinated compensation occurring in multiple regions and planes.

Optimal Posture

Postural homeostatic mechanisms automatically integrate a number of systems whose goal is to provide balance and stability during activities of daily living in the most energy-efficient manner possible. The musculoskeletal system contributes innately to postural homeostasis as a *tensegrity system* and is discussed later in this

Figure 36-1 Changes in sagittal plane spinal curves from day 1 through age 10 years. (From Kapandji IA. *The Physiology of the Joints*. Vol 3. New York, NY: Churchill-Livingstone, 1974:17, with permission.)

chapter. (In architecture, tensegrity is defined as “the property of skeletal structures that employ continuous tension members and discontinuous compression members in such a way that each member operates with the maximum efficiency and economy.”) (10) The neurological system contributes through its antigravity and balance functions to insure the body’s “best attempt” at an upright position and orientation; it involves multisensory pathways to provide the visual, vestibular, and somatosensory data from proprioceptor and cutaneous receptors required to optimize these functions (11) The central nervous system (CNS) then integrates this sensory information to create an internal frame of reference that regulates the center of gravity and creates the optimal posture for that individual.

This best attempt by the body is *an optimal posture* for a given individual; a balanced configuration of the body with respect to gravity. Optimal standing postural alignment involves the total body and depends, in part, on balancing regional structures including cervical, lumbar, and thoracic curves under gravity’s influence; it depends also on normal arches of the feet, vertical alignment of the ankles, and horizontal orientation (in the coronal plane) of the sacral base. The presence of *the optimal or ideal posture* suggests that there is a perfect distribution of the body mass around the center of gravity; the compressive force on spinal disks is balanced by ligamentous tension; and there is minimal energy expenditure from postural muscles (12,13). Structural or functional factors, however, frequently prevent achievement and maintenance of optimal or ideal posture. When this occurs, homeostatic mechanisms manifest compensatory patterns in an effort to provide maximum postural function within the existing structure of the individual. *Compensation* is the counterbalancing of any defect of structure or function (14).

An optimally balanced standing postural alignment in the coronal plane normally divides the body into two equal parts (Fig. 36.2A and B). The center of gravity line, or “weight-bearing

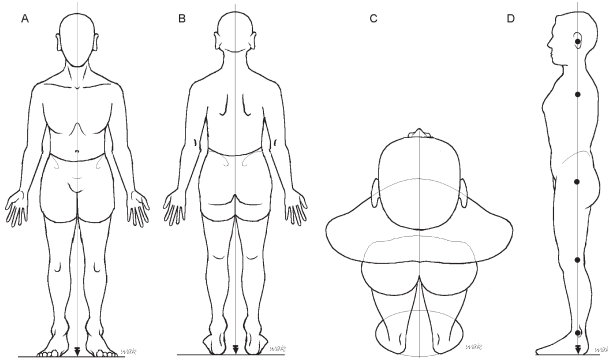

Figure 36-2 An optimally balanced standing postural alignment in the coronal plane (A,B) normally divides the body into two equal parts. The center of gravity line, or “weight-bearing line,” runs midway between the feet, through the pubic symphysis, along the midline of the vertebral column, and bisects the center of the suprasternal notch and glabella. Ideally, there would be no rotation in the horizontal plane of any body region (C) and no coronal plane side-bending asymmetry. Optimal postural alignment in the sagittal plane (D) has been characterized by a weight-bearing line that passes through the lateral malleolus, midknee, femoral head, anterior third of the sacral base, middle of the body of the L3 vertebra, humeral head, and external auditory meatus. (Courtesy of William Kuchera, D.O., F.A.A.O.)

line,” runs midway between the feet, through the pubic symphysis, along the midline of the vertebral column, and bisects the center of the suprasternal notch and glabella. Ideally, there would be no rotation in the horizontal plane of any body region (Fig. 36.2C) and no coronal plane side-bending asymmetry.

Optimal postural alignment in the sagittal plane (Fig. 36.2D) has been characterized by a weight-bearing line that passes through the lateral malleolus, midknee, femoral head, anterior third of the sacral base, middle of the body of the L3 vertebra, humeral head, and external auditory meatus.

Failure of the body to align optimally with respect to its center of gravity functionally stresses pain-sensitive soft tissues and joint facets that were not adapted for direct, sustained weight-bearing function. Thus, structural change, increased energy demands, and pain are the results of postural decompensation (15).

Common Postural Clinical Conditions

Postural Types: Body Unity Issues

Clearly, posture is not just a stack of spinal curves with musculoligamentous connectors. Posture is influenced by the patient’s triune emotional, spiritual, and psychological sense of self and by their inner energy reserves. It has been astutely observed that posture, to a large degree, can be a somatic depiction of one’s inner emotions; what has been termed a *somatization of the psyche* (16). In emotionally depressed patients, for example, the somatic posture is also often termed *depressed*. Sagittal plane curves are typically accentuated and patients seemingly hang from their soft tissues without the apparent energy to stand tall. (See Table 36.1 for other postural types associated with the psyche.) In some chronic conditions where both physical and psychoemotional dysfunction exist, it is often difficult to know whether the psychoemotional state or the posture is the primary factor maintaining the cycle.

Sometimes, the primary psychological issue does not directly manifest in the posture; instead, for example, it may lead to fluctuations in weight, such as obesity. Such changes may, in turn, cause secondary changes in posture by requiring a redistribution of body mass or the use of medications that affect postural homeostatic mechanisms. Some health professionals generalize certain body types (endomorph, mesomorph, or ectomorph) as being “linked” to a corresponding personality; regardless, there are mass and distribution of mass issues that affect both posture and the energy demands required to implement postural change.

Even when body unity issues do not directly impact the manifestation of posture, they can subvert a well-planned treatment program. In particular, compliance, vanity, and patient education are body unity issues that must be addressed in a complete postural treatment regimen. Patients’ philosophies toward illness, their way of life, their appearance, their education, and the environment in which they function all can affect their compliance, which in turn affects the outcome of the treatment program.

Spinal Biomechanics

“Biomechanics from the osteopathic perspective has evolved into a dual study of the adaptive responses of the body to gravitational force and the effects of alterations in joint mechanics that result from injury or impaired function” (17).

Spinal joints are designed to provide the motion in our activities of daily living and to permit the body unit to adopt the optimal dynamic posture in order to remain upright while doing so. Most ordinary and compensatory spinal motions involve a group of vertebral segments. In thoracic and lumbar group curves, such spinal motions follow Fryette’s first principle of physiological motion and are necessary to allow for positional changes of the body. This

TABLE 36.1

Examples of Relationships Between Psyche and Posture

Psychological Tendency or Psyche	Posture	Implications
Healthy individuals who are open and ready internally to meet all external environment has to offer	Gentle, firm back curves; flexible body, pelvis-hips-knees	Capable of adaptation and homeostasis; maximal function within triune body
Depression; defeated individuals; downcast attitude; Those who feel, "I can't"	Posture is also "depressed." Head droops forward Trunk bends downward Shoulders project forward "Limp posture" resembles a very tired person	Tendency toward cervical and lumbar lordosis coupled with thoracic kyphosis. Posture leads to an abnormal stretch of ligaments and to pain. Bioenergetically a fatiguing posture, as keeping this position causes overload on the extensor muscles. Posture adds physiological tiredness to the preexisting psychological feeling. Decreases depth of inhalation and compromises the respiratory-circulatory model.
Hyperkinetic individuals; aggressive individuals; anxiety; anger	Postural position very unbalanced Shoulders are carried anteriorly Pelvis is flexed Muscles are in a constant state of supported contraction	Postural muscles especially psoas prone to triggerpoints. Muscles of jaw, posterior neck, and shoulders especially tight
Individuals ashamed of body maturity (common in some girls reaching growth spurt earlier than boys of same age; development of breast tissue)	Posture is slumped with shoulders rolled inward	Prone for thoracic outlet symptoms from increased lordosis in neck and trigger points in pectoralis muscles
Proud, outgoing	Chest leads ("throw chest out")	Often a hard, rigid back
Threatened; fearful individual	Forward neck; prominent buttocks; protruding collapsed abdomen	Tightened buttocks, hamstrings and sphincters Tight thoracoabdominopelvic diaphragms
Shame, sorrow, sadness	Head hangs ("hang your head in shame")	
Obstinate or determined	Chin leads ("stick your neck out")	

Source: Some thoughts extracted from "psycho-orthopedics" by Sypher FF. Pain in the back: a general theory. *J Int College Surgeons*, 1960;33:6 and reported in Irvine WG. New concepts in the body expression of stress. *Can Fam Physician* 1973;38-42.

means that when the spine is in its neutral position (an absence of marked flexion or extension) and side bending is introduced, the vertebrae rotate into the produced convexity (18). (Rotation is to the opposite side of side bending.)

These types of dynamic spinal curves may be produced in the coronal plane by unilateral muscle contraction. Tension originating from this muscle creates a concavity, which results in a lateral curve. The involved thoracic and lumbar vertebrae rotate into the convexity. These Type I curves disappear when the muscle relaxes. Type I curves become a biomechanical problem when restriction occurs and the spine no longer straightens.

The total somatic body reaction that manifested as postural changes in response to less than ideal conditions is better understood by applying knowledge of spinal biomechanics. For example, the *bottom-up* spinal response to unleveling the sacral base in the coronal plane or an anatomically short lower extremity is guided

by spinal biomechanical principles. To keep the eyes level at the opposite end of the body, the lumbar vertebrae located above the sacrum start to side bend away from the low sacral base thereby creating a scoliotic curve. As this Type I lumbar group curve forms, all other spinal regions capable of adjusting their alignment attempt to accommodate the new postural balance. Similarly, spinal biomechanics largely direct the postural response in a *top-down* spinal response to certain craniocervical dysfunctions or deformations.

Early postural compensation is associated with the development of a longer single lumbar or lumbothoracic scoliotic curve—convex on the side of the low sacral base. In this *C-shaped scoliotic curve*, the horizontal cephalad planes are typically depressed on the side opposite the depressed pelvic horizontal plane. Later, the compensatory mechanisms redistribute postural responsibilities resulting in the formation of several lateral curves. In this more *chronic*

postural compensation (an *S-shaped scoliotic curve*), the shoulders and the greater trochanteric planes are typically depressed on the same side as the depressed sacral base. (The typical biomechanical response to sacral base unleveling is shown in Fig. 36.3.)

Postural patterns can be classified according to their capacity to be lessened by employing specific functional maneuvers that are appropriate for the regions' spinal biomechanics. If some spinal motion such as side bending can reduce a lateral curve, it is known as a *functional* or *secondary* curve. If it is unable to be reduced, it is known as a *structural*, *fixed*, or *primary* curve. A functional scoliotic, for example, is reversible; a structural scoliotic curve is nonreversible. Because structure and function are interrelated, many scoliotic curves are a mixture of these two classifications. This phenomenon is also seen with postural patterns in other planes.

Postures Seen in Pathology

Rational, conservative management of the postural components of patients with certain orthopedic disorders or structural pathology presupposes early and accurate diagnosis and a thorough

understanding of the biomechanics involved. While the underlying cause is important for prognosis, knowing the static and dynamic effects of the pathology on spinal mechanics and on the homeostatic reserve required for compensation is central to the treatment design. For example and as discussed later in this chapter, management of patients with spondylolisthesis typically emphasizes sagittal plane strategies; management of scoliosis patients typically emphasizes coronal plane strategies. Table 36.2 lists examples of other pathological conditions in which the application of the osteopathic postural model is useful.

Postural Compensation: An Integrated Homeostatic Process

Genetic, traumatic, and habitual processes that require compensation accumulate and create an environment where few patients have ideal posture. Compensated postures are not ideal postures; they are, however, the result of several integrated homeostatic mechanisms working through the entire body unit to maximize

Figure 36-3 Typical postural compensation for short-leg syndrome. (Courtesy of William Kuchera, D.O., F.A.A.O.)

TABLE 36.2

Examples of Pathology and Posture

Pathology	Primary Plane(s) of Postural Involvement	Postural Effect
Cervical disk disease	Coronal and sagittal	Aggravating radiculopathy; Side bending toward can compromise nerve root; Decreased lordosis can move disk material posteriorly
Cervical osteoarthritis	Sagittal and coronal	Aggravating radiculopathy; Increased lordosis can close foraminal opening; Side bending toward can compromise nerve root
Lumbar disk disease	Horizontal, coronal and sagittal	Rotational stresses poorly tolerated by lumbar disks; flattened lordosis can move disk material posteriorly; side bending towards can compromise nerve root
Lumbar osteoarthritis	Sagittal and coronal	Aggravating radiculopathy; Increased lordosis can close foraminal opening; Side bending toward can compromise nerve root
Lumbar L5-S1 spondylolisthesis	Sagittal	Shifts weight bearing anteriorly to increase strain on posterior spinal elements; may aggravate back pain or nerve roots; increased iliolumbar ligament strain
Visceroptosis	Sagittal	Aggravates fascial drag on abdominal and pelvic organs
Osteoporosis	Sagittal	Osteoporosis typically first affects the anterior portion of the thoracic spine; increased kyphosis may increase pressure on anterior thoracic vertebral bodies; thoracic compression fractures may increase thoracic kyphotic curves
Uterine prolapse	Sagittal	Studies reported in the <i>Am J of Obstetrics and Gynecology</i> (1996 and 2000) demonstrated correlation of increased uterine prolapse in women with loss of lumbar lordosis and in increased thoracic kyphosis (risk increased 3.2x)
DJD of the hip	Coronal	Increased DJD of the hip seen on the long-leg side
Lumbar facet arthritis	Sagittal	Posterior weight-bearing mechanics transfer functional demand to lumbar facets
Any pathology where there is a congestive component	Sagittal especially but any plane	Postural decompensation affects the respiratory-circulatory model by decreasing the efficacy of the thoracoabdominopelvic pump
Any pathology worsened by hypersympathetic tone	Any plane where the postural crossover occurs at the common site of autonomic to the organs or tissues involved	Postural decompensation increases segmental facilitation (especially at crossover sites and secondarily at apices of postural curves); this typically will decrease blood flow, alter glandular functions, and/or increase pain
Any pathology that significantly compromises energy use (e.g., congestive heart failure or severe chronic obstructive pulmonary disease)	Any plane that significantly increases the energy demands of maintaining posture or effecting gait	Postural demands may take energy needed to maintain functional activities of daily living in severely compromised individuals

function. If not overly stressed, many compensated postures will remain relatively asymptomatic.

Postural compensation is coordinated by the CNS with continuous feedback provided by visual information, vestibular information from the semicircular canals, and kinesthetic/proprioceptive information from tendons and muscles (19). The resultant posture is manifested throughout the entire body to minimize energy requirements and to distribute and balance somatic stress, while keeping the eyes and semicircular canals as level as possible.

Postural homeostatic lessons are gradually “learned” by the evolving peripheral-CNS interrelationship. Influences begin with forces *in utero*; then from birth, throughout the growth process, and into senescence, soft tissue structures and functions both influence, and are influenced by, the cumulative functional demand placed upon them by postural compensation. As a result:

- Each person will progressively compensate in a different way depending, in part, on his or her unique intrinsic and extrinsic risk factors
- Postural preferences and patterns will conform within the resultant connective tissue structure
- Neuromusculoskeletal structures will remodel to reflect the functional demands placed upon them
- Functional capability will be limited by less than ideal structure.

These progressive and interactive neuromusculoskeletal compensatory processes impact postural diagnostic and treatment protocols. With regard to diagnosis, an osteopathic examination of selective soft tissue tensions and dynamic posture and segmental motion testing should be added to static postural alignment in the upright weight-bearing position. This combination illuminates structure-function interrelationships and provides clinical clues about the inherent capability of the patient’s neuromusculoskeletal system to balance and maintain biomechanical alignment. Radiographic analysis of bony postural relationships (discussed later) adds further insight. With regard to therapeutics, recognition of the long-term nature of postural compensation suggests that a reversal toward ideal posture should be equally progressive and consistent if it is to succeed.

Potential Impact

Postural mechanisms acting from moment to moment may have only a transient negative impact on an individual. Persistent demands however lead to adaptations; in certain individuals, intrinsic or extrinsic factors may overtax one or more of the homeostatic processes that could lead to the manifestation of symptoms and eventually to postural decompensation.

Understanding how either postural compensation with adaptation or postural decompensation might negatively impact health requires a closer look at how each impacts tensegrity, group curves, and spinal mechanics. In this fashion, it becomes possible to predict and/or assess whether an individual’s posture is contributing to negative functional or structural conditions.

Tensegrity

The *tensegrity model* plays a significant role in understanding the effects of postural stress, compensation, adaptation, or decompensation. Introduced by architect Buckminster Fuller in 1929 from the terms *tension* and *integrity*, tensegrity modeling has been successfully applied to biological systems. The model helps explain how most of the integrated structure-function arrangements in living systems require such little energy for their maintenance (*postural integrity*). The way in which bony tension elements are held together by connecting elastic elements (ligaments and antigravity muscles) helps create/maintain the balance between stability and

strength; it also explains how forces are dispersed through the body diffusely. The tensegrity model helps explain the predictable total structural response to tension change anywhere in the body.

In this model, it is recognized that:

- Areas of hypomobile somatic dysfunction may cause compensatory hypermobility elsewhere
- Hypermobility in one or more regions may affect compensatory hypomobility elsewhere
- Fascial patterning and musculoligamentous tensions take on primary importance as the model’s connecting elements

It also helps to explain why certain global or local host factors adversely affect the capability of some individuals to successfully resist the effect of gravity strain or why injury to local sites (e.g., a foot or knee) may lead to secondary symptoms like back pain or headaches. For these reasons, a number of clinical models including osteopathic and orthopedic medicine cite tensegrity principles (16,20,21) when discussing the importance of postural balance and treatment.

Group Curves

Postural terminology applied to group curves is apparent in some situations and requires a thorough understanding of clinical medicine for others. Normal postural curves in the sagittal plane for example are termed *kyphotic* (forward bending) or *lordotic* (backward bending) *curves*; when they are pathological they are termed *kyphosis* and *lordosis*, respectively. Similarly, when pathological, coronal side bending (or *scoliotic curves*) of more than 5 degrees is termed *scoliosis*. Scoliosis is sometimes referred to as *rotoscoliosis* because rotation and side bending are inseparably linked. The pathology may be called a *kyphorotoscoliosis* if all three planes are significantly involved.

The terminology reflects the presence of an underlying continuum of responses to dynamic postural processes. Examples of this include the spine that is initially in a curved position to compensate for an anatomic short leg or certain structural deformities, postural balance adaptation, or even long-term positional change (such as may be required for a certain occupation) that becomes a pattern. In response to functional demands, the tissues associated with this curve change. Tissue texture changes become palpable and over time, tissues on the convex side become lengthened; those on the concave side become shortened. Bony remodeling in response to stress within the scoliotic group curve takes place, and the result is structural deformation of the vertebral body with lateral wedging and scoliosis (22). Longstanding curves with this type of anatomical adaptation resist change. Eventually, the curved position becomes the neutral position and is readily apparent in the analysis of standardized static postures.

In the process of postural compensation and adaptation, group curves in a given plane typically assume certain patterns. The most common patterns have group curves occurring in one direction in one region and in the opposite direction in the adjacent spinal regions, alternating so that the body can maintain some type of postural balance. Most commonly, these changes occur within the so-called transitional regions—areas where anatomic structure changes create the potential for the greatest functional change (Fig. 36.4).

Describing the pattern (23–25) of the group curves in various patient populations along with the location and direction of the major group curve provides a convenient way of summarizing common postural prototypes. Postural patterns or *patterning*, therefore, refers to useful and classifiable combinations of regional compensatory changes:

- Naming the anatomical locations of the postural *crossover* site provides clinical clues to potential somatovisceral sequelae or to sites at risk of arthritic change. Crossover sites are named

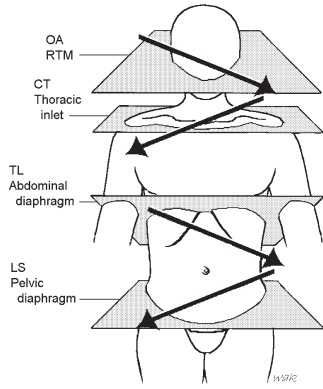

Figure 36-4 Compensation in the horizontal planes: Alternating pattern of rotation at transition zones. (Courtesy of William Kuchera, D.O., F.A.A.O.)

for the vertebral level where group curves change direction and crossover the ideal gravity line.

- Naming the apices of group curves is also clinically helpful.
- By international convention, group curves in scoliotic patterns are named for their convex side. For example, rotoscoliosis right means a postural curve that is convex to the right by being side bent to the left by more than 5 degrees.

Mechanics and Patterning

The biomechanical principles in postural compensation lead to fairly predictable response patterns to disturbances in one or more regional postural curve.

The systemic fascial or regional compensatory pattern will consist of an alternating directional pattern in one or multiple planes occurring at the transitional regions of the body (25) (Fig. 36.5A or its less common mirror image). (See the discussion of compensated fascial patterns in Chapter 51 and recognize the relationship this pattern has relative to the Postural and Respiratory-Circulatory models as a consequence):

- In group postural curves, spinal side bending and rotation are biomechanically linked with each other (18) with the thoracic

Figure 36-5 The systemic fascial or regional compensatory pattern will consist of an alternating directional pattern in one or multiple planes occurring at the transitional regions of the body. (Courtesy of William Kuchera, D.O., F.A.A.O.)

and lumbar regions for example, typically manifesting curves that side bend in one direction and rotate in the opposite direction.

- In sagittal plane postural curves, the degree of flexion or extension may manifest alone or in conjunction with all three cardinal planes.

With respect to the spinal mechanical compensatory pattern, gravity-induced changes in each plane of motion in the lumbopelvic region are particularly predictable because of this region’s proximity to the L3 vertebral center of gravity.

- In the sagittal plane, gravity encourages the sacral base to rotate anteriorly and encourages innominates to rotate posteriorly (Fig. 36.6) (26,27). This occurs because the L3 weight-bearing gravitational line falls anterior to the middle transverse sacral axis and behind the femoral axis. Homeostatic mechanisms that resist this counter-rotation are provided by muscular tone and by pelvic and lumbosacral ligaments (28). The anterior rotation of the sacrum in turn tends to increase all lordotic and kyphotic curves.
- Compensatory changes in the coronal plane (as occurs with leg-length inequality) can also be generalized. As shown in Figure 36.3, the lumbar spine side bends away from and rotates toward the low sacral base. The pelvis as a unit typically side shifts and rotates around a vertical axis toward the long leg side. The innominate may attempt to compensate for the “short leg” by rotating anteriorly on the short leg side. This functionally lengthens that extremity. The innominate on the side of the apparent long leg may rotate posteriorly to functionally shorten that extremity. Often, on the long leg side, the foot assumes a pronated position, and the lower extremity internally rotates. The lumbosacral angle (LSA) increases 2 to 3 degrees. The increased LSA and pelvic rotation often mask the presence of an unlevel sacral base (29). The vertebrae of the most caudal scoliotic curve usually side bend away from and rotate toward the side of the apparent short leg.
- Pelvic rotation in the horizontal plane occurs concomitantly with biomechanical stresses in the coronal plane (such as the short-leg syndrome) (30). This can present a therapeutic

Figure 36-6 In the sagittal plane, gravity encourages the sacral base to rotate anteriorly and encourages innominates to rotate posteriorly. (Courtesy of William Kuchera, D.O., F.A.A.O.)

challenge when prescribing foot orthotics in an attempt to treat leg length or to level the sacral base. Strategies helpful in addressing this clinical challenge are described later in this chapter.

Relationship to Somatic Dysfunction

The consequences of postural compensation are most commonly asymptomatic; however, they may predispose an individual to prolonged or recurrent positions or adaptations that are less than ideal. As such, the postural element becomes a precipitator or perpetuator of certain somatic dysfunctions that may elicit symptoms. For example, it is widely quoted that posture is the most common precipitating and perpetuating factor for Travell myofascial trigger points (31). It contributes in the same fashion to recurrent dysfunctional muscle imbalance between the antigravity postural muscles and their antagonists.

In the thoracic and lumbar spine, somatic dysfunction secondary to postural compensation typically carries the freedom pattern of the neutral Type I spinal group curve mechanics that predominate in that patient; the restriction being in the opposite direction. If and when symptoms occur from Type I somatic dysfunctions, any pain or segmental facilitation generated is likely to be focused at the postural crossover sites where the most “work” is allowed or at the apices of the curves where the most restriction often exists. Should postural compensation in the sagittal plane predispose for somatic dysfunction that remains either flexed or extended outside the neutral range, the most symptomatic area may also be a single segment at the center of the sagittal postural curve. That segment is almost always symptomatic and may demonstrate somatic dysfunction that is either uniplanar (flexion or extension) or triplanar (Type II dysfunction).

Postural compensation or adaptation may also predispose and perpetuate fascial dysfunction at all four transitional zones. The directional pattern of compensatory regional fascial function and dysfunction is also an alternating one.

Postural compensation requires the work of muscles and, even prior to postural decompensation (discussed later), may predispose an individual to patterns of muscular somatic dysfunction. This is particularly true in patients who complain that their symptoms began after a particularly “long day on their feet.” In these patients, look for muscular somatic dysfunction in their over-worked antigravity muscles and, if identified, in those of the same myotatic unit (muscles sharing the same function). Such muscular dysfunction symptomatology may range from achiness and hyperirritability to local crampy pain to the distantly referred pain and entrapments resulting from the development of myofascial trigger points. Antigra-vity/postural muscles are discussed further in this chapter.

Characteristically for this etiological cause, even after successful initial treatment of the individual arthro-dial or myofascial somatic dysfunctions, the same pattern initially seen will often gradually recur until the primary postural element is addressed. Such recurrence should therefore trigger suspicion that postural compensation mechanisms underlay this diagnosis. It is important here to point out that the locations of somatic dysfunction in a primary postural pattern may be significantly different from a primary viscerosomatic pattern even though in both a pattern of recurrence is seen.

Some osteopathic physicians question the value of treating secondary group curve and regional fascial somatic dysfunctions; in treating posturally related somatic dysfunction they might focus only on any nonneutral Type II single segmental dysfunctions present. Others emphasize the importance of treating group curves when they are symptomatic or when the dysfunction might interfere with the success of implementing one of the osteopathic models of care. The correct answer to the question (of whether to treat or not) probably depends on asking another question about the patient involved.

“What is the functional significance of a group curve for the patient?” If the group curve contributes to dysfunction of the patient or prevents success in applying another treatment, then it should be treated.

Gravitational Strain Pathophysiology and Postural Decompensation

Gravitational force is universal, a systemic stressor, and an often underestimated and potentially progressive disruptor of postural homeostasis. Although it exerts a constant force on all structures, some individuals appear to be less capable of resisting gravitational effects than others. Possessing certain intrinsic (host) or extrinsic risk factors, these individuals may have weakened support mechanisms, increased functional demand on postural structures, and/or biomechanical disadvantages that challenge their ability to compensate for gravity’s effect on their body systems (15,32–35). Considered in this fashion, posture is a secondary finding.

Of the many signature manifestations of pathophysiology resulting from the individual’s chronic attempt to stave off the effects of gravity (15), altered postural alignment and recurrent somatic dysfunction are the most prominent. Other signs and symptoms indicative of *gravitational strain pathophysiology (GSP)* include low back pain, pain referred to the extremities, headache, somatovisceral manifestations, fatigue, and weakness will escalate in frequency and severity as key host compensatory mechanisms are progressively taxed.

Postural decompensation occurs when an individual’s functional homeostatic mechanisms are overwhelmed (36) or when the degree of pathological change becomes structurally incapable of resisting gravitational force.

Predisposing Factors

The presence of a number of anatomic, congenital, and acquired conditions can stress postural compensatory mechanisms or accelerate the signs and symptoms of GSP and postural decompensation. In return, chronic postural functional demands will initiate and accelerate structural changes. This is a classic example of the reciprocity of structure–function interrelationships.

Patients with predisposing intrinsic or extrinsic factors will be at the highest risk of postural decompensation. Identifying these predisposing factors with an appropriate history and physical examination is an important diagnostic goal in the osteopathic postural model.

Intrinsic Factors

A number of host (intrinsic) factors decrease the ability to adequately resist gravity and create a predisposition towards postural decompensation. Examples include:

- Age (intrinsic factors related to muscle weakness, fascial elasticity, bone mass, etc.)
- Altered integrity or response from antigravity soft tissues (systemic hypermobility syndrome, various connective tissue disorders, muscular dystrophy, etc.)
- Incompetent bony antigravity structures (spondylolysis or spondylolisthesis, etc.)
- Poor tissue health (related to poor nutrition, inactivity with subsequent deconditioning, metabolic diseases, etc.)

Examples of host factors that increase asymmetry within the body and thereby magnify demands on postural compensatory mechanisms include:

- Altered base of support (unilateral pes planus [flat foot]), wearing shoes with high or worn heels, dysfunctional gait following ankle sprains or strains, anatomically short leg, etc.)

- Changes of body habitus (pregnancy, obesity, etc.)
- Congenital bony asymmetries (small hemipelvis, wedge vertebrae, etc.)
- Ergonomic factors associated with poor sitting or standing habits
- Strenuous posturing required by certain work environments or recreational activities such as gymnastics or carrying heavy rucksacks.

This chapter has already discussed a number of disorders which have known postural changes often due to each compromising one or more postural homeostatic mechanisms that result in a less efficient or defective host response (see pathologies or body unit issues related to posture).

Extrinsic Factors

Traumatic postural decompensation occurs when macrotrauma or recurrent microtraumas disrupt muscular, ligamentous, or bony stability of the spine. Such decompensation may occur more frequently in patients with a history of automobile accidents or surgical laminectomies (macrotraumas); or of carrying heavy loads for significant distances or certain high-level sport activities, as exist in gymnastics, weight-lifting, golf, or football (35) (microtrauma). Fractures of the spine, pelvis, or lower extremity may produce sacral base unleveling or the need for other compensatory changes above the area of the trauma. In addition, a few occupations actually increase extrinsic gravitational stress, for example, certain military pilots who experience multiple G-forces.

Responses of Tissues

Skeletal-Arthrodial Response

According to Wolff Law, bone remodels over time in response to the stress placed upon it (37). In this fashion, the vertebrae of patients with exaggerated or lateral postural curves will develop wedging of the vertebral body and exostoses (spurs). Posterior weight-bearing mechanics transfers weight onto the spinal facets, which results in modified function, increased calcium deposition that may appear on radiographs, and pain.

Degenerative change in spinal and other major weight-bearing joints (such as the hip) also occurs when there is accentuated functional demand and asymmetry. Degenerative arthritis of the hip joint that is accompanied by tenderness over the greater trochanter often develops on the long leg side (38).

One third of the sample population studied in a long-term radiographic postural study documented a chronic, progressive postural decline with spinal postural patterns which continued to evolve with age (6). The likelihood of several lateral curves evolving is higher when the leg-length inequality is >10 mm (39). The stereotypic posture of the geriatric patient depicts a decrease in total height as their kyphotic and lordotic curves are accentuated. In addition, the radiographic measurements of such patients show a height diminution (an increased pelvic index [PI] ratio) within the pelvis (32,40).

Regional (Transition Zone) Fascial Response

Postural patterning influences and is influenced by the fascias and related structures. J. Gordon Zink described patterns (25) that are clinically relevant to the diagnosis and treatment of fascial compensation and decompensation. Based on the palpatory fascial preference to motion, these fascial patterns may be classified as *ideal*, *compensated*, or *uncompensated* (Fig. 36.5A is one of two compensated—meaning directionally alternating—regional patterns). The postural influence on *fascial patterning* is important for understanding the effect that postural management has in improving the respiratory-circulatory model (41). Conversely, fascial preference

influences tissues and skeletal structures of each region and produces the dynamic postural characteristics of that body region.

Muscular Response

Gravitational stress placed on musculoligamentous structures is constant and is amplified in patients with less than ideal postural alignment. When the viscoelastic deformation properties of a muscle are unable to resist an imposed stress, predictable pathophysiological changes occur (15). These changes are both functional and structural. The *elastic* component represents the transient functional change in connective tissue length occurring in response to stress. The viscous component, on the other hand, is responsible for the more permanent (*plastic*) deformation of connective tissue that occurs with static postural change.

Stressed myofascial structures undergo sustained changes in length and deleterious change is most pronounced in shortened muscles (42). New collagen, with a half-life of 10 to 12 months, realigns the connective tissues in response to vectors of stress, perpetuating postural problems and maintaining the biomechanical amplification of gravitational stress. Postural patterns that are compensated are more likely to decompensate.

The structure of the muscle and its function are related; both playing a major role in the muscle patterns commonly seen in posture-initiated pain and dysfunction. In GSP, stressed antigravity muscles develop chronic, recurrent trigger points (43), consistent myotomal and sclerotomal pain patterns (44), and predictable functional changes. While postural (antigravity) muscles are structurally adapted to resist fatigue and function in the presence of prolonged gravitational exposure, when their capacity to resist stress is overwhelmed, they become irritable, tight, and shortened (45). Many muscles that are antagonists of these postural muscles, react when stressed by becoming weak or pseudoparetic (45). Therefore, GSP manifests as dysfunction in a *postural pattern* of tight and weak muscles or of myofascial trigger points (Fig. 36.7) (45–47). Recognizing such predictable patterns involving multiple muscles (Tables 36.3 and 36.4) should suggest GSP as a possible underlying

Figure 36-7 A postural pattern of tight and weak muscles or of myofascial trigger points. (Courtesy of William Kuchera, D.O., F.A.A.O.)

TABLE 36.3

Examples of Postural (Hypertonic-Prone) Muscles and Symptoms

Lower Body Muscle(s)	Symptoms
Iliopsoas	Inability to stand straight (psoas posturing); knees flexed; recurrent L1 or L2 NN somatic dysfunction; pain referred to back and anterior groin; positive Thomas test; may falsely increase PI measurements and decrease LS angle unless treated
Quadratus lumborum	Low back pain referred to the groin and hip; may be misdiagnosed as gr. trochanteric bursal disorder; exhalation 12th rib somatic dysfunction; diaphragm restriction
Thoracolumbar erector spinae	Low back pain; recurrent thoracolumbar somatic dysfunction; segmental facilitation
Hamstrings	Pain sitting or walking; pain disturbs sleep; pain referred to posterior thigh; straight leg raising limited mechanically; the combination of tight hamstrings on one side and tight rectus femoris on the other usually suggests postural strain seen with pelvic rotation in the horizontal plane; may cause false positive straight leg raising test
Rectus femoris	Pain deep inside the knee; the combination of tight hamstrings on one side and tight rectus femoris on the other usually suggests postural strain seen with pelvic rotation in the horizontal plane
Piriformis	Pain down posterior thigh; may entrap peroneal portion of sciatic nerve; perpetuated by (and perpetuates) sacroiliac dysfunction; associated with pelvic floor dysfunction, dyspareunia or prostatodynia
Thigh adductor (short)	Pain referral to the inguinal ligament, inner thigh, and upper medial knee
Gastroc-Soleus complex	Nocturnal leg cramps; pain referral to upper posterior calf, instep, and heel

The **“Lower Cross Syndrome”** (or **“Pelvic Cross Syndrome”**) reflects the **pattern** of lower body postural-phasic muscles in Tables 36.3 and 36.4 affecting the lower kinetic chain (lumbopelvic hip complex, knee, and ankle). The patient usually presents with anterior pelvic tilt, increased lumbar lordosis (swayback), and weak abdominals; they usually experience chronic low back pain, piriformis syndrome and anterior knee pain. This syndrome was popularized by Czech neurologists and manual medicine specialists, Vladimir Janda, M.D. and Karel Lewit, M.D.

Upper Body Muscles	Symptoms
Upper trapezius	Most likely muscle in body to develop TrPs; headache pain refers to occiput and/or to side of head near temple
Sternocleidomastoid	The SCM clavicular head is rich in proprioceptors (informs CNS where head is with respect to body), so dysfunction leads to postural instability & spatial disorientation; may veer off to one side while walking; refers pain to forehead bilaterally and ear. Sternal head may cause visual and ANS symptoms
Levator scapulae	Stiff neck (especially with rotation); pain to base of neck, vertebral border of the scapula and posterior shoulder
Pectoralis major (upper)	May cause chest wall pain with radiation down arm in anginal pattern (if on left) and intense nipple hypersensitivity
Pectoralis minor	Prominent in slumped postures with rolled in shoulders, increased kyphosis, and anterior neck carriage; May entrap brachial nerve and/or axillary artery leading to radial sided dysesthesias and possible loss of the radial pulse
Cervical erector spinae	Headache and neck pain; recurrent cervical somatic dysfunction
Scalenes	The entrappers—may entrap neurovascular bundle (esp lower trunk of the brachial plexus and/or subclavian vein) with dysesthesias to 5th digit and/or puffy hands; may also reflexly limit thoracic duct return leading to upper extremity swelling; TrPs may cause dysesthesia into thumb and index finger side of hand. May lead to recurrent elevated rib 1–2 somatic dysfunction

Janda’s and Lewit’s **“Upper Cross Syndrome”** reflects the **pattern** of lower body postural-phasic muscles in Tables 36.3 and 36.4 affecting the upper kinetic chain (neck, shoulder, upper chest). The patient usually presents with headaches, upper thoracic pain, and various Thoracic Outlet Syndrome signs and/or symptoms.

TABLE 36.4

Examples of Phasic (Pseudoparesis-Prone) Muscles and Symptoms

Lower Body Muscle(s)	Symptoms
Gluteus minimus	Pain characteristic when arising from chair; pain referral to buttock, lateral and posterior thigh; “pseudosciatica”; antalgic gait; positive Trendelenburg test
Gluteus medius	Pain aggravated by walking; pain referral to posterior iliac crest and sacroiliac joint; positive Trendelenburg test
Gluteus maximus	Restlessness; pain sitting or walking up hill; antalgic gait
Three Vasti (but not rectus femoris)	Buckling knee syndrome; weakness going up stairs; thigh and knee pain; patellar tracking imbalance; chondromalacia patellae
Rectus abdominis	Increased lordosis; constipation
Tibialis anterior	Pain referred to great toe and anteromedial ankle; may drag foot or trip when tired
Upper Body Muscle(s)	Symptoms
Mid/lower trapezius	Refers pain and tenderness to the region of the upper trapezius
Latissimus dorsi	Causes chronic midthoracic back pain but with the slack muscle, no particular position offers relief
Rhomboids	Ache between shoulder blades; cracking or scrunching sounds when move shoulder
Deep cervical flexors	Longus colli and longus capitis muscles leading to recurrent cervical somatic dysfunction; loss of neck stability

cause. In these patients, treatment of the dysfunctional postural alignment yields more lasting results than treatment of the secondary recurrent myofascial trigger points or muscle imbalances in isolation.

Finally, GSP and postural decompensation may also involve a loss of energy because of the increased active muscle contraction (48) needed to counteract gravity or to ambulate.

Ligamentous Response

Stabilizing ligaments are stressed in individuals with postural imbalance or diminished homeostatic abilities to resist gravity—in particular, the iliolumbar, sacrotuberous (ST), and long dorsal (posterior) sacroiliac ligaments; each having its own predictable sclerotomal pain pattern.

The iliolumbar ligaments (ILL) are critical for stabilizing the lumbar vertebrae with respect to the pelvis (28). They are usually the first structures to be involved with GSP and are also affected by both sacral and innominate rotations (Fig. 36.8). The attachments of these ligaments become tender to palpation when stressed—unilaterally in coronal plane postural strain and bilaterally in sagittal plane strain conditions. ILL calcification may occur with long-standing postural strain because calcium is laid down along lines of stress (Wolff law) (37). Functional changes include tenderness, edema, and pain referred to the lower extremity (Fig. 36.9); these findings disappear with treatment.

ST ligament and long dorsal sacroiliac (LDSI) ligaments resist anterior and posterior rotation of the sacrum respectively (Fig. 36.10) (49). The LDSI ligament connects the sacrum and the posterior superior iliac spine (PSIS), whereas the main part of the ST ligament connects the sacrum and ischial tuberosity.

Postural stress involves a more complex biomechanical interaction than is depicted in Figures 36.8 and 36.10. It involves interaction between these ligaments, the sacroiliac joint, the thoracolumbar fascia, and a variety of muscles including the multifidi, biceps femoris, and glutei (49). The pelvic girdle as a foundation for function and support must therefore be interpreted in its relationship to other areas of the spine and all four extremities.

Response of Related Neural, Vascular, Lymphatic, and Visceral Elements

The postural model overlaps with the respiratory-circulatory and neurological models of patient assessment and treatment. Each of these models looks to transition zones as key areas for identifying and treating somatic dysfunction.

The transition zones are closely linked to transverse diaphragms; dysfunction in these areas often results in reduction of venous and lymphatic return. Reduction of postural decompensation frequently improves respiratory homeostasis and reduces circulatory impediment. Additional symptoms originate at the individual's postural crossover sites, where the spinal curve crosses from side to side or anterior to posterior across the weight-bearing line (Fig. 36.11) and may secondarily occur at postural curve apical sites. These sites often manifest local subjective joint and myofascial tissue symptoms. The resultant nociception frequently links the postural model to the autonomic model through resultant facilitated segments (50,51) producing inappropriate increases in sympathetic activity. Posturally mediated facilitation, in turn, results in dysfunction of segmentally related vascular and lymphatic structures, somatovisceral reflex change, and subsequent related organ dysfunction.

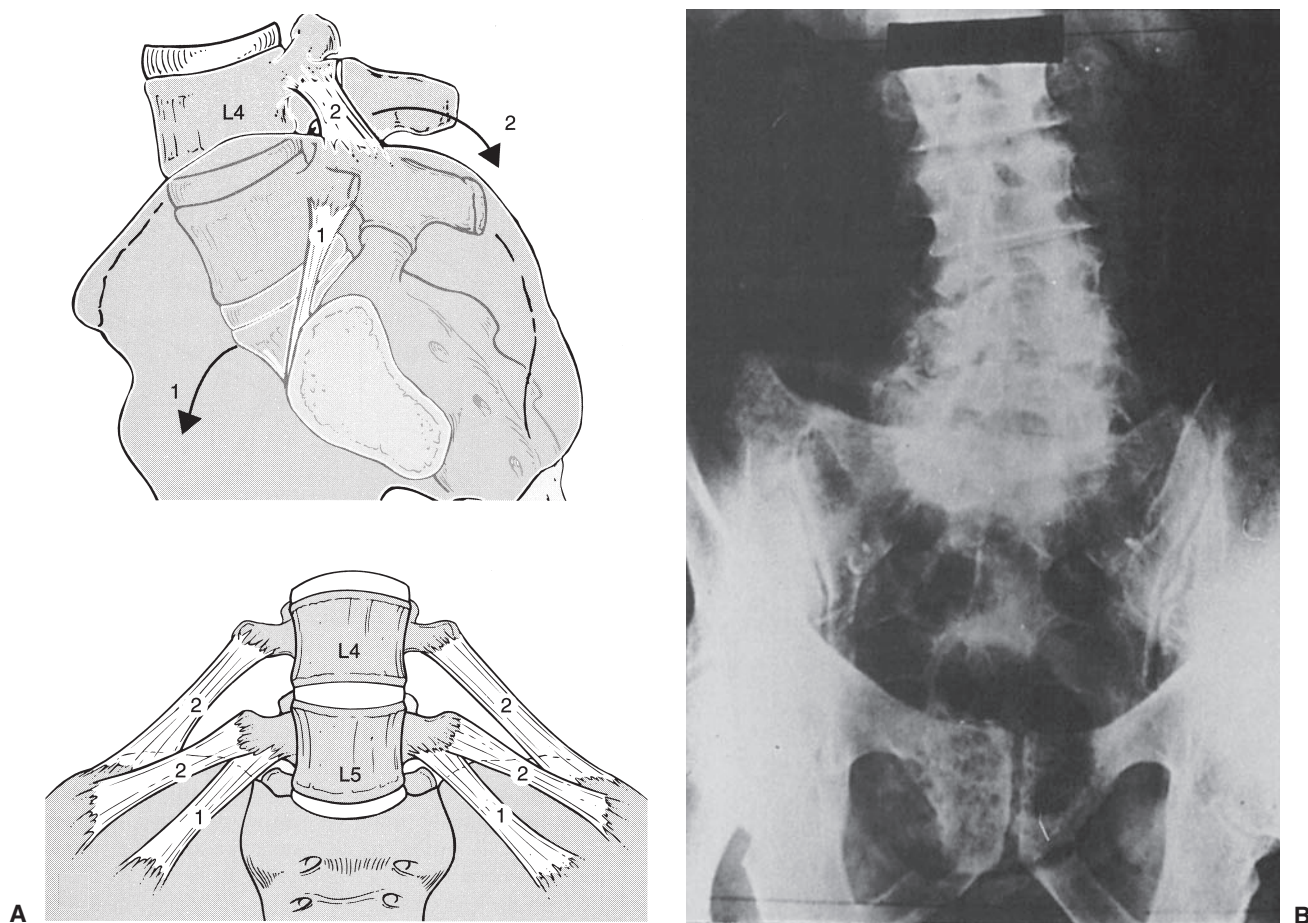

Figure 36-8 A. Anterior rotation of sacrum bilaterally stresses fibers labeled 1. Posterior rotation of innominates bilaterally stress fibers labeled 2. B. Calcification of iliolumbar ligament is an excellent example of structural change resulting from excess functional demand. (Radiograph from the Institute for Gravitational Strain Pathology Inc., with permission.)

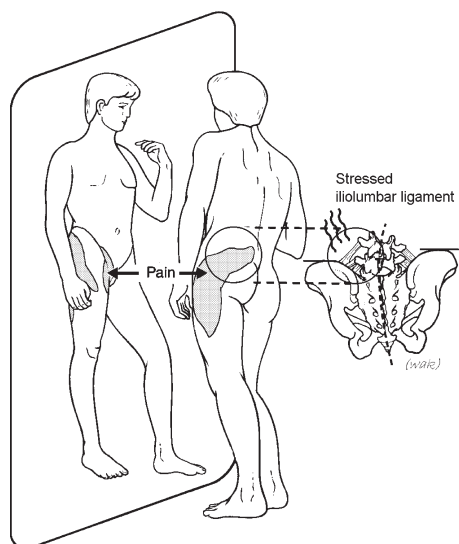

Figure 36-9 Iliolumbar ligament pain pattern from postural imbalance. (Courtesy of William Kuchera, D.O., F.A.A.O.)

Furthermore, in the coexistent presence of intervertebral foraminal compromise by cervical or lumbar degenerative disease (figure-of-eight deformities), increasing postural curves may further reduce homeostatic abilities to counter irritation or swelling in the area, resulting in altered axoplasmic flow, so-called double-crush phenomena, or radicular symptoms neurological model); each of these can also result in secondary myofascial trigger points (52–54).

In considering the postural model then, related neural, vascular, lymphatic, and visceral information should always be sought and an attempt should be made to correlate the site of GSP with local, visceral, or referred symptoms.

General Diagnostic Considerations

Observation and palpation of postural muscles, their antagonists, and regional or group spinal curves should be performed if possible with the patient in an upright, weight-bearing position. In this upright position, the patient is asked to move into various positions to determine whether any observed thoracic or lumbar rotoscoliotic group curve asymmetry can be functionally reduced or eliminated. The structural component in the coronal and horizontal planes is represented by the spinal asymmetry that is not modified by active or passive motion.

Figure 36-10 A. Sacrum rotating anteriorly winds up ST ligament. B. Sacrum rotating posteriorly winds up the LDSI ligament. (From Vleeming A, Snijders CJ, Stoeckart R, et al. The role of the sacroiliac joints in coupling between the spine, pelvis, legs, and arms. In: Vleeming A, Mooney V, Dorman T, et al., eds. *Movement, Stability, and Low Back Pain: The Essential Role of the Pelvis*. New York, NY: Churchill-Livingstone, 1997, with permission.)

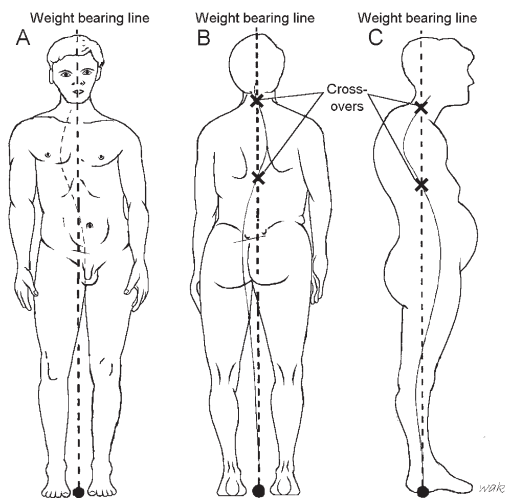

Figure 36-11 Postural crossover sites. (Courtesy of William Kuchera, D.O., F.A.A.O.)

Sagittal plane decompensation is associated with alteration of the anteroposterior (AP) regional curves of the body and specific palpable somatic patterns. In addition to myofascial and ligamentous clues, anterior sacral base and lumbar hyperlordosis, craniosacral extension mechanics often accompanies this condition. The extension phase of the craniosacral mechanism is often accompanied by fatigue, loss of energy, and/or psychological depression.

Asymptomatic postural compensation is of no concern in many individuals but constitutes a degree of risk for others. For individuals seeking patient care, recurrent symptoms may be eventually traced to the predisposition toward somatic dysfunction, nociception, facilitation, or stress within the tensegrity unit; each commonly engendered by postural decompensation. Furthermore, functional demands imposed by maintaining posture over long periods of time may induce structural changes; those which, although sometimes asymptomatic, are increasingly likely to become symptomatic when further stressors are added. Eventually, if postural compensation mechanisms are overwhelmed, the result is highly symptomatic postural decompensation (discussed in the next section).

The purpose of postural diagnosis therefore is to determine where in the continuum a given patient is and whether the osteopathic postural model could or should be integrated into that patient's healthcare regimen. To this end, the diagnostic process should answer at least four specific questions:

1. Does the patient's posture play a role in a patient's given complaint?
2. Does the patient's posture detract or limit the patient's ability for self-healing?
3. Does the patient's posture present a significant risk factor for pain, dysfunction, or pathology in the future?
4. Is the patient able to respond positively to a postural treatment regimen in a time- and cost-effective manner?

The postural diagnostic approach to answering these questions relies heavily on observation and palpation. It attempts to correlate other findings from the patient's history and physical examination in order to determine if any pertinent signs or symptoms exist. It may also bring in radiological or biomechanical tests to help quantify the extent and type of postural change.

Observation

Posture may be assessed statically or dynamically. Combining static and dynamic testing is a common postural assessment strategy to determine if a given postural compensation is functional or structural.

Observation of static posture in the upright position permits comparison of the patient's posture to the presumed ideal posture in each of the cardinal planes (see Fig. 36.2). In such a screening examination, postural curves that affect the neutral position become apparent and become the focus of further diagnostic testing. In the static postural screening examination, the levelness and alignment of key landmarks as well as the space around the body is observed. Analysis of static posture may be enhanced by using a grid or a hanging reference wire (plumb bob line) to obtain valuable information with or without radiographic assistance. Static postures such as sitting or standing should remain still; if they do not, this may indicate a problem with the postural control mechanisms associated with balance.

Suspicious regions identified in static testing may be further screened using dynamic positioning to determine if the postural

curve is *functional* (with flexibility) or *structural* (with no change permitted with motion), or *mixed* (with some combination of both). Dynamic postural testing not only adds insight into the flexibility of obvious spinal curves that were apparent in static screening, it may also uncover minor or overlooked functional curves. Dynamic postural testing frequently provides information on the spinal biomechanics of the region being tested and can uncover areas of somatic dysfunction. Dynamic postural analysis looks at how postural elements react to particular motions and can be quantified using manual or electronic goniometers to measure the magnitude and symmetry of total or regional motion in the three cardinal planes.

Coronal and Horizontal Plane Observations

Coronal and horizontal plane postural disorders are anticipated with certain combinations of static and dynamic observations. To diagnose coronal plane problems, first stand behind the upright patient and observe (using simultaneous palpatory assistance) to assess the following key static anatomical landmarks (Fig. 36.12) for asymmetry from the horizontal plane:

- Mastoid processes
- Acromioclavicular joints
- Inferior scapula

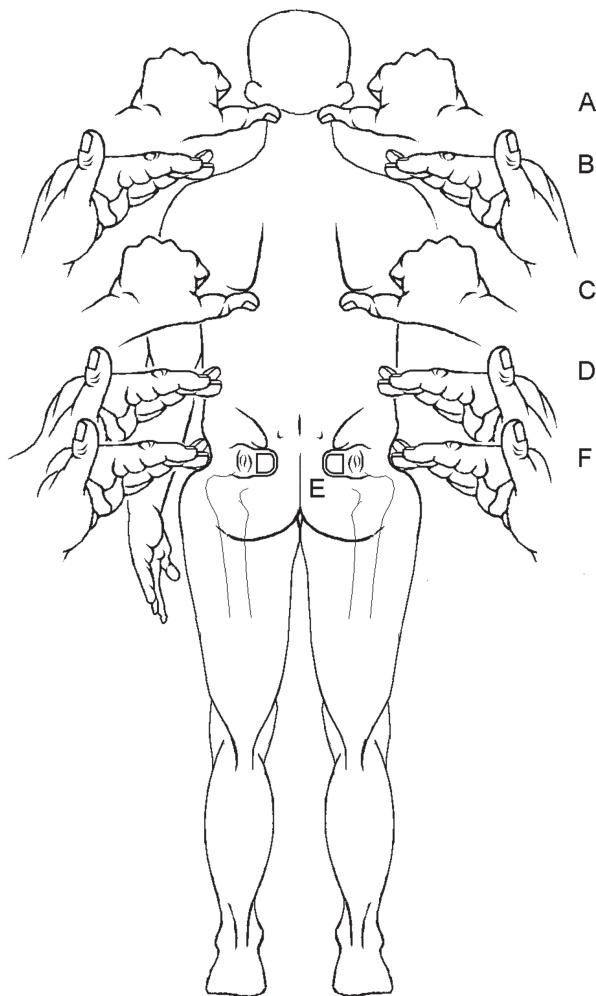

Figure 36-12 Levelness of horizontal planes. **A.** Occipital plane. **B.** Shoulder plane. **C.** Scapular plane. (inferior) **D.** Iliac crest plane. **E.** PSIS plane. **F.** Greater trochanteric plane. (Courtesy of William Kuchera, D.O., F.A.A.O.)

- Fingertips
- Iliac crests
- PSIS
- Greater trochanters
- Knee creases

In addition, observe the coronal plane for evidence of scoliotic curves and note the spinal level at which point the curve crosses an imagined midline (crossover sites). Sometimes, asymmetry due to shoulder muscle bulk arising from a *handedness pattern* may mislead the physician to think there is a scoliotic curve; in these cases, it may be helpful to observe the patient from the front as well. Lateral spinal curves in the back are often reflected in the front and are particularly easy to see in the chest hair pattern of some men. Look at the space around the body; is the space between one arm and the body greater on one side than the other?

Observation from the front of the body can also alert the doctor to horizontal plane problems. In the static postural diagnosis of this plane, an imaginary or actual plumb-bob line should equally bisect the body. Observations should include:

- Are midline structures like the nose and xiphoid process centered or not?
- Is the face turned with one ear more visible than the other?
- Is one humeral head, costal margin, or anterior superior iliac spine (ASIS) anterior to the other?

After static observation, add one or more dynamic tests. Two commonly used observational test combinations in postural analysis examples are shown in the adjacent Figure 36.13.

- Interpretation of the shape of the lumbar curve during a dynamic hip drop test in a patient with a lumbar Type I side-bending curve (Fig. 36.13A)
- Interpretation of static and dynamic postures in a patient with thoracic Type I double balanced side-bending curve (Fig. 36.13B and C)

The Adams forward-bending test is the most commonly used dynamic screening test for rotoscoliosis. It works because side bending and rotation in group curves are normally coupled Fryette Type I motions. The test involves standing behind the patient and observing for a “rib hump” as the patient slowly bends forward. Any

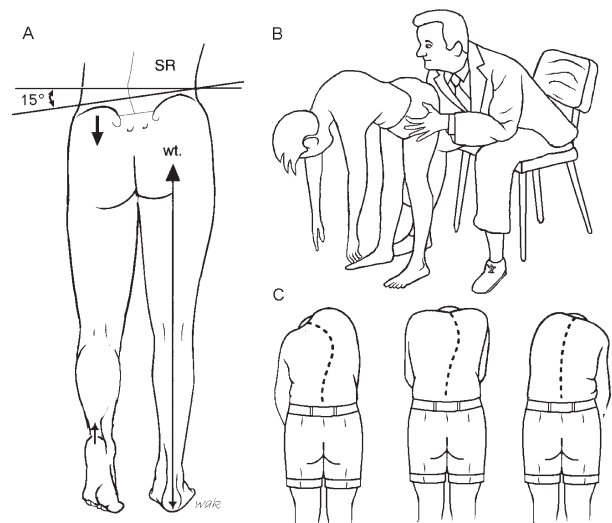

Figure 36-13 Assessment of structural or functional scoliosis. (Courtesy of William Kuchera, D.O., F.A.A.O.)

costal asymmetry should then be analyzed by having the patient (still flexed to the site of the asymmetry) try to side bend toward the high rib to see if levelness can be restored (Fig. 36.13C). Performed with care, this method should allow detection of scoliotic curves measuring as small as 10 degrees; when performed without focused attention, physicians have been documented to miss curves as large as 35 degrees. The forward-bending test has a sensitivity of only about 84% (less than Moire topography or scoliometer) but a specificity greater than both of those; it is most effective in thoracic scoliosis but has a high false-negative rate in the lumbar spine (55).

Sagittal Plane Observations

Viewing the static posture of patients from the side, the osteopathic physician should look for exaggerated or flattened kyphotic or lordotic curves. The clinician should also assess whether key anatomical landmarks are aligned from bottom to top along an imaginary ideal (Fig. 36.2D) or actual plumb bob line:

- Just anterior part to the lateral malleolus
- Just behind the midknee
- Femoral head
- Anterior one third of sacral base (radiographic observation only)
- Middle of the body of L3 (radiographic observation only)
- Humeral head
- External auditory meatus

Dynamic testing can be done while standing with the patient flexing and extending to determine the relative flexibility of the sagittal plane curves. Alternatively, in a functional lumbar lordosis, having the patient supine with bent knees as shown (Fig. 36.14) should permit the spinal curve to flatten onto the table (or floor). Inability to flatten this curve either actively or passively represents a sagittal plane structural component or pathology. When evaluating this element, be sure to simultaneously “observe with palpation” the lumbar spine as excessive or hypertrophied soft tissues in the adjacent flanks may mask the lordotic curve.

Palpatory Tissue Assessment

Musculoligamentous and fascial structures are affected early in patients with postural stress and somatic dysfunction here can be easily recognized with palpation.

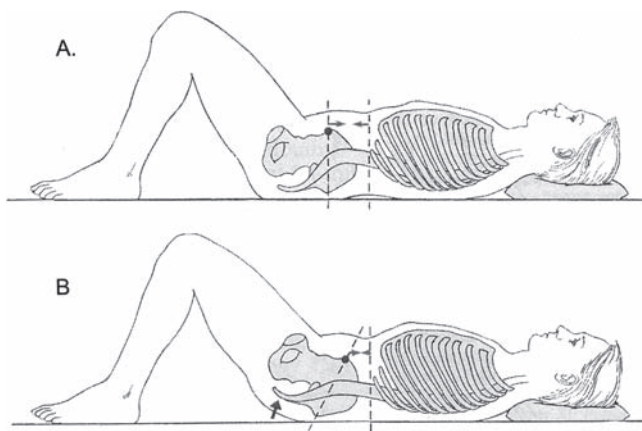

Figure 36-14 Lumbar lordosis, with patient actively attempting to flatten spine to table. **A.** Structural component (no reduction of lordotic curve). **B.** Flattening indicative of functional lordotic curve. (From Simon DG, Travell JG, Simons LS. *Myofascial Pain and Dysfunction: The Trigger Point Manual*. Vol I. Baltimore, MD: Williams & Wilkins, 1999, with permission.)

The symptoms arising from the resultant pathophysiological condition have associated palpable *tissue texture changes* that include the following:

- Muscle spasm in postural (antigravity) muscles
- Subtle weakness to muscle testing in postural antagonist (phasic) muscles
- Tenderness over ligamentous and osseotendonous attachments involved in postural stability
- Myofascial trigger points
- Edema or bogginess

Palpation identifies structural *asymmetries* of key landmarks and gathers information about the functional characteristics of the body unit. It is also the best tool for uncovering patterns of *restricted motion, tenderness, pain, strain, or adaptations* characteristic of postural disorders. Palpation of the postural response to certain movements helps to differentiate the degree to which a given postural curve is structural or functional (i.e., does it stay the same or increase or does it reduce or disappear?).

It is important not to miss these palpable changes or postural pattern clues, which are relatively early signs that postural compensation mechanisms are starting to be overwhelmed. If not recognized and addressed upon discovery, it is possible that the last step in the continuum of man's battle against gravity will be postural decompensation.

Postural Radiographic Series

As mentioned, posture and postural diagnoses involve the understanding of both static (structural) and dynamic (functional) characteristics; x-ray images primarily visualize the static or structural aspect of posture. Therefore, postural radiographs are typically performed after first using OMT to correct concomitant somatic *dysfunction*—especially preradiographic goals include normalizing lumbopelvic mechanics (56), and treating the larger postural muscles affecting the lower extremities and pelvis such as the quadratus lumborum (57), and iliopsoas (46) that are known to particularly distort static postural interpretation. Performed in this manner, an osteopathic postural series will document “repeatable findings when the state of the patient is unchanged and provide valid information concerning improvements or regressions in skeletal structure which are associated with changes in the patient's condition” (4).

These radiographs also contain information pertinent to assessing skeletal maturity (Fig. 36.15) and aid in identifying congenital anomalies and other structural deficiencies (see Fig. 36.16 and Table 36.5) that can enhance the potential for gravitational and other functional strain to overwhelm the body's homeostatic mechanisms or prevent their reversal through the employment of certain treatment strategies. Finally, postural radiographs may be used to quantify static postural distortion or decompensation from the ideal and to document improvement with treatment.

Protocol

While many radiologists are not trained to do postural studies specifically for osteopathic analysis, most will conduct them for referring physicians if informed of the protocol and necessary materials needed (such as is depicted in Fig. 36.17A and B) (58). The protocol involves two postural views, AP and lateral, which are captured in order to assess coronal, horizontal, and sagittal plane static postures (Figs. 36.18 and 36.19). These AP and lateral films are typically performed with the patient's shoes off to determine intrinsic postural discrepancies. At times, films may also be obtained with

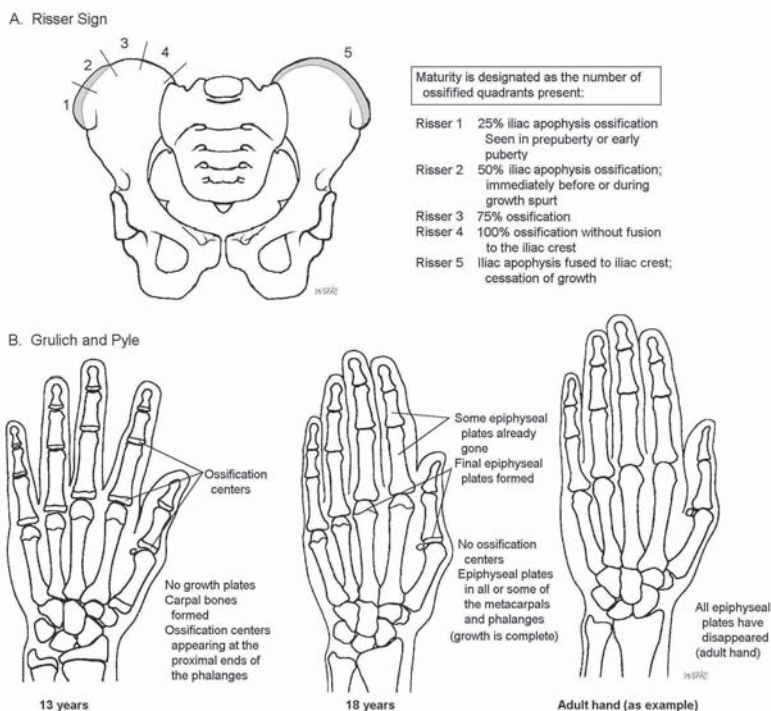

Figure 36-15 Skeletal maturity using Risser. (Courtesy of William Kuchera, D.O., F.A.A.O.)

the patient wearing their shoes, with a therapeutic lift or orthotic in place, to determine the amount of sacral base unleveling that still remains to be corrected (i.e.). The exposure of the patient to ionizing radiation in this study is minimal. For example, this protocol is calculated to expose the patient to 0.12 rad for the AP postural view but could be reduced even further with only 0.011 rad to the gonads using a lead gonadal shield (57). Known pregnancy would nonetheless be a contraindication to performing a postural radiographic series.

Postural x-ray views taken according to a standardized protocol (with precise foot placement, locked knees, and consistent arm positions) can be accurately and consistently measured for static postural information by radiologists or attending nonradiologist

physicians (59). Such a protocol is amenable to rapid adjustment and placement, making it practical even in busy radiology departments. Each time the patient is positioned in a reproducible weight-bearing posture and recorded with an independent vertical reference line (RL) on the film. The RL is unrelated to the position of the cassette, yet it is perpendicular to the line of the horizon. Measurements taken from the edge of the film may be inaccurate because of the variable position of the film within the cassette and therefore would produce misleading or nonreproducible results (57).

Lack of a standard protocol would render many measurements meaningless for the purposes of postural diagnosis, patient follow-up, or research. However, using standard protocols for taking and marking the films for postural measurements have been

TABLE 36.5

Radiological Findings on Postural Films

Radiological Finding and Appearance	Best X-ray View	Implications/Comments
Congenital		
Bat-wing deformity	A-P lumbosacral	Clinically: May alter joint mechanics, pain and inflammation possible if rudimentary L5-iliac joint, alters sacral base level Radiographically: May be unable to accurately measure sacral base unleveling
Sacralization of L5 Partial Sacralization = Bertolotti syndrome	A-P and lateral lumbosacral (both help)	Clinically: Short lumbar curve ($n = 4$) leading to more functional demand per segment and increased likelihood of developing degenerative L4 spondylolisthesis Radiographically: Unable to measure PI or lumbosacral lordotic angle
Lumbarization of S1	A-P and lateral lumbosacral (both help)	Clinically: Long lumbar lever arm ($n = 6$) leading to less stability and increased incidence of low back pain Radiographically: Unable to measure PI
Spina bifida occulta	A-P lumbosacral	Clinically: May not mean anything however may be harbinger of other posterior spinal congenital anomalies; muscles may attach and therefore function differently; often externally small tuft of hair at vertebral site
Facet tropism	A-P and lateral lumbosacral (both help visualize)	So common that most radiologists do not even report its presence ("most commonly occurring congenital spinal anomaly"); asymmetric function; may
Horizontal L5-S1 facets with— listhesis (see Table 36.7, Type I)	Lateral lumbosacral	Clinically: Drop-off sign is at level lower than isthmic type because spine remains attached to
Small hemipelvis	A-P pelvis	Clinically: May be associated with smaller extremity and/or face on same side; may lead to functional scoliosis in seated position (and similar symptoms)
Wedge vertebrae	A-P thoracolumbar	Radiographically: Impact on Cobb Angle process
Acquired		
Spondylolysis	Oblique lumbosacral	Clinically: May be asymptomatic but usually associated with increased sagittal plane stress and decompensation; called <i>prespondylolisthesis</i>
L5-S1 isthmic spondylolisthesis (see Table 36.7, Type IIA-B)	Lateral and oblique lumbosacral	Clinically: Loss of bony continuity coupled with typical postural anterior weight-bearing mechanics causes stress and strain on posterior support tissues and postural muscles generally; over Meyerding gr II, often very tight hamstrings Radiographically: Look also for other signs of calcified show "Scotty dog" deformity at site of spondylolysis
L4-5 degenerative spondylolisthesis (see Table 36.7, Type III)	Lateral lumbosacral	Clinically: often very flexible hamstrings
(Roto)scoliosis	A-P thoracolumbar	Clinically: See text discussion Radiographically: May distort traditional view (e.g., A-P view may become spinal oblique view)
Disk thinning	Lateral lumbosacral	Clinically: Decreases homeostatic reserve to swelling in area of neural foramina and may lead to increased radiculopathy or instability of vertebral unit Radiographically: May wish to do functional flexion-extension to look for low level secondary degenerative spondylolisthesis or retrolisthesis

(continued)

TABLE 36.5 (Continued)

Facet arthritis	AP and lateral	Seen in especially in posterior weight-bearing mechanics
Unlevel sacral base	A-P lumbosacral	Often a cause of functional scoliotic change above; coronal changes often linked to visual rotational change as well
DJD spurs, figure-of-eight vertebral foraminal changes; calcification of ligaments (e.g., iliolumbar)	Oblique as well as other views	Clinically: Structural signs of long-term functional demand (Wolff law) but themselves may be totally asymptomatic Radiographically: Should raise suspicion of postural stress warranting postural measurements
Fracture(s)	Multiple views; oblique view for optimal view of the pars interarticularis	Clinically: May cause reflect straightening of the spinal curve due to muscle spasm Radiographically: May not be able to accurately assess underlying lordotic angles due to straightening

Figure 36-17 X-ray set-up. **A.** Vertical Bucky diaphragm and piano wire reference. **B.** Rectangular metal base plate with RLs. 1, posterior line; 2, midheel line.

studied extensively for reproducibility, validity, and clinical relevance (60,61). In such studies (Fig. 36.20), interexaminer standard measurements of error are acceptably small and have been remarkably consistent in multiple studies (7,62,63). These might best be summarized as a mean error of <1.0 mm and a maximum error of 2.0 mm for linear measures and 2 degrees for angular measures. These were also the conclusions obtained when manual and computer-assisted measurements by different practitioners (radiologist, primary care physicians, and osteopathic medical students) (59) were compared.

General interpretation of postural radiographs

Postural measurements obtained in this way can be interpreted using the osteopathic postural model. This model presumes that static findings from postural radiographs will be correlated with various dynamic aspects of the clinical examination, including palpation, and can be used to uncover relevant structure–function and postural–biomechanical insights. To maximize the interpretation of the static information provided by postural x-rays, the osteopathic postural model also presumes that somatic dysfunction is corrected as much as possible *prior* to sending the patient for a postural radiographic series (56). The somatic dysfunctions that are most likely to create significant transient postural asymmetry on these films are:

- Sacral shear (unilateral sacral flexion)
- Innominate shear (e.g., superior or up-slipped innominate)
- Iliopsoas muscle spasm (46)
- Quadratus lumborum spasm (57)
- Innominate rotation

In interpreting these radiographs, a number of findings that may or may not be clinically relevant, including those listed in Table 36.5, are considered.

Examples of common lumbosacral anomalies appearing radiographically and having potentially significant impact when implementing the postural model are depicted in Figure 36.16 and Table 36.5. Several of these anomalies complicate the selection of landmarks used in postural measurements or in the interpretation of postural radiographic data. A few are recognized to cause low back pain or instability in a percentage of patients; others are widely believed to be incidental insignificant anomalies, but may be viewed as “risk factors,” others potentially complicate the findings in those patients who are diagnosed as having regional instability.

Interpreting AP thoracolumbar postural radiographs

The standing AP film of the thoracic and lumbar regions contains both qualitative and quantitative information about posture in the coronal and horizontal planes.

By noting the relative positions of the two pedicles and the spinous process, thoracic or lumbar vertebral rotation can be qualitatively assessed in AP radiographic views (see Fig. 36.18B). In the absence of vertebral rotation, the spinous process is located equidistant from each pedicle. With right vertebral rotation (named in relation to the direction of movement of a reference point on the anterior portion of the vertebral body), the spinous process visualized on the x-ray film appears closer to the left pedicle. With left vertebral rotation, the spinous process appears closer to the right pedicle on the x-ray film.

Vertebral side bending is easily observed on the AP radiographic view and can be qualitatively reported. Quantitative measurements of group curves are often more formally reported by using scoliosis nomenclature. Scoliosis, by convention, is reported in reference to the convexity of the curve. A right scoliosis is side bent left (convex right). The Cobb method is commonly used to measure scoliotic curves (see Fig. 36.18A) and with care is accurate

Figure 36-19 Measurements for a postural x-ray view. **A.** AP postural measurements. **B.** Landmark options for measuring sacral base unleveling. **C.** Lateral postural measurements. (Figs. 36.19A and C adapted from Kuchera WA, Kuchera ML. *Osteopathic Principles and Practice*. 2nd Ed. Rev. Columbus, OH: Greyden Press, 1994:63. Fig 36.19B adapted from Irvin RE, *Suboptimal posture: the origin of the majority of idiopathic pain of the musculoskeletal system*. In: Vleeming A, Mooney V, Dorman T, et al., eds. *Movement, Stability, and Low Back Pain: The Essential Role of the Pelvis*. New York, NY: Churchill-Livingstone, 1997:133–155.)

to within 3 degrees (64). Lines are constructed across the top of the superior vertebral segment and across the bottom of the inferior vertebral segment of a spinal scoliotic curve. Perpendicular lines are then constructed from these lines that intersect to form an angle—the Cobb angle measurement.

Interpreting AP lumbopelvic postural radiographs

The standing AP radiograph of the pelvis contains coronal and horizontal plane postural data. This film is especially important in evaluating the degree of sacral base unleveling, structural leg lengths, and pelvic rotation with the patient in a weight-bearing position; measures that are the central values influencing lift therapy in the osteopathic postural model. Roughening of the iliac crest where the iliolumbar ligament attaches or calcification of the iliolumbar ligament (see Fig. 36.8) (65) should be noted, as these are markers for postural stress.

Common measurements associated with coronal plane posture include the relatively straightforward iliac crest and femoral head

lines; horizontal lines quantifying any height asymmetry to these landmarks. The sacral base line used to report sacral base unleveling is determined in a less intuitive manner (see Fig. 36.19A and B). For clinically relevant reasons, this line is extended to the vertical lines extending from the femoral heads (4,59). The amount of sacral base unleveling is reported as the measured height difference of a line drawn across the top of the sacral base as extrapolated to its intersection with the femoral head lines. The margin of error in measuring sacral base unleveling, using this radiographic protocol, has been reported to be ± 0.75 mm (57). Measurements using the different choices for landmarks (line of eburation [see Fig. 36.19B] or the juncture of the sacral ala with either the iliac crests or the articular pillars) for identifying the sacral base are reported to have a variability of up to 2 mm (59,57). Therefore, the alternative selected should be that which has the least ambiguity or in which the set of reference points are most easily and accurately identified (34,56,66).

Because the osteopathic physician is more interested in leveling the sacral base than making the leg lengths equal, the sacral base

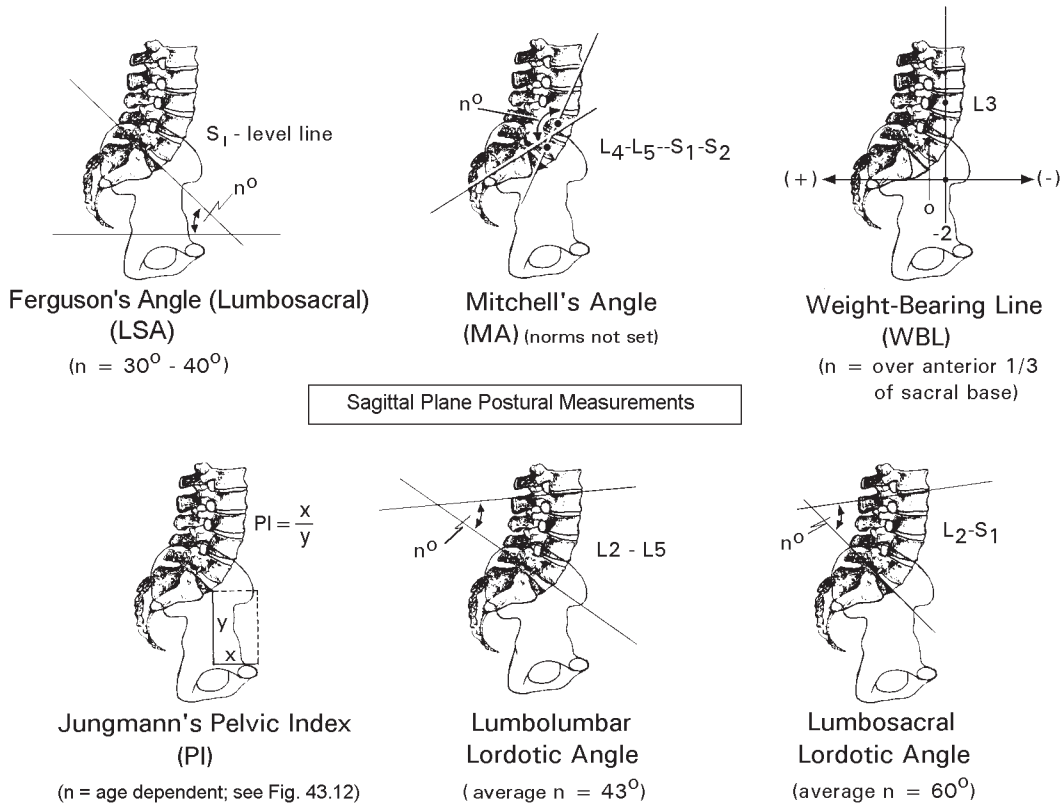

Figure 36-20 Sagittal plane standing postural radiographic measurements and their normal ranges.

unevening is usually of more clinical significance than comparison of anatomic leg lengths. In the presence of sacral base unevening, the direction of the lumbar side-bending component is also clinically relevant. In most cases without concomitant pelvic shear dysfunction, the iliac crest, femoral head, and sacral base unevening measurements will be roughly equal. In larger discrepancies, however, it would appear that intrapelvic homeostatic adaptations are inadequate or overwhelmed leading to sacral base height unevening that surpasses the difference in the femoral head heights (67).

Pelvic rotation is recognized qualitatively by observing asymmetry of the obturator foramina. It can be quantified by measuring the distance between the pubic symphysis and either the dark line representing the air in the gluteal crease or the median sacral crest (36). The pelvis is denoted to rotate in the direction in which the anterior portion of the pelvis (pubic symphysis) moves. In Fig. 36.19A, the pelvis is rotated to the left.

Interpreting lateral lumbopelvic postural radiographs

The standing lateral film of the pelvis provides a means for determining several sagittal plane postural measurements. (see Figs. 36.19C and 36.20) These include the angle of the sacral base (Ferguson angle), the weight-bearing line (WBL) from L3 relative to the sacral base, lumbar lordotic angles, and the PI. Normal values for these objective measures are summarized in Figure 36.20.

The ideal line of weight bearing (see Fig. 36.2D), previously described as running just anterior to the lateral malleolus, will be represented by a radiolucent line produced by the image of the metallic reference wire on the x-ray film. This *RL* can also be used to evaluate the approximate position of the center of gravity (body of L3) relative to the lateral malleolus of the ankle, the sacral base, and the femoral heads. The L3 WBL should ideally fall through the anterior one third of the sacral base. If this line falls posterior

to the sacral base, the lumbar facets are subject to an increased load. Especially in the case where significant stress is longstanding, the involved facets on the radiograph will exhibit arthritic change, seen as eburation (increased density) of these articulations.

The PI is a calculated ratio that quantitatively reflects the relative position of the innominates to the sacrum (Fig. 36.21). Normal PI values are age related (40) and are typically less than 1.00. As the patient ages, this postural intrapelvic ratio approaches (or, in the same conditions, may exceed) the value of 1.00. PI has been documented to be increased in some patient populations, including athletes with high functional demand in the sagittal plane (35), patients with chronic low back pain (40), and those with L5-S1 isthmic spondylolisthesis (46). In the latter group, patients with an extremely high PI for their age should be examined for spondylolysis or spondylolisthesis. Conversely, PI has been shown to be very low for age in patient populations with L4-5 degenerative spondylolisthesis (68).

Lordotic angles are objective measurements of lumbar lordosis (Fig. 36.22) (69). The observation of hyperlordosis is significant in the evaluation of patients with sagittal plane postural problems. Some of these measurements may eventually prove to be relevant, whereas others may never add any clinical relevance. Radiographically, lumbar lordosis is often only qualitatively assessed as normal, increased, or decreased. It can be quantified however by measuring the angle created by lines along the top of L2 and S1 (*lumbosacral lordotic angle*), or the top of L2 and the bottom of L5 (*lumbolumbar lordotic angle*) (69). These angles average 60 and 43 degrees, respectively (70). A modification of the Cobb method can also be used to quantify other sagittal plane curves.

Postural radiographic summary

Abnormal static postural measurements can be viewed as being biomechanical (or functional) risk factors for a patient. Using the

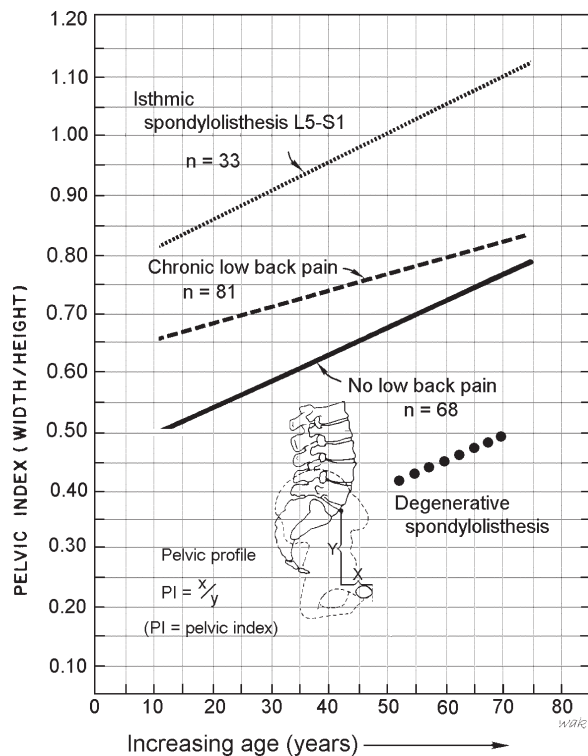

Figure 36-21 Pelvic index. (Courtesy of William Kuchera, D.O., F.A.A.O.)

standard radiographic protocol summarized in this chapter (58), measurements outside the normative range suggest a biomechanical disadvantage that increases functional demand. As the number of biomechanical risk factors increases, homeostatic maintenance of posture is more likely to fail. These factors not only strain musculoligamentous structures but also predispose the patient to the development of scoliosis, spondylolysis, or spondylolisthesis (71), or other postural diagnoses.

Balance Plates and Other Functional Postural Measures

Balance plates, computerized calculations of changing centers of mass during a particular activity, or even dynamic imaging procedures may also be additional quantitative measures used to understand the postural impact on structure and function. Some of these instruments can measure intersegmental as well as regional motions and are used to reinforce the palpatory determination of areas requiring manipulative treatment (hypomobile areas) and those that need strengthening exercise, prolotherapy, or extrinsic stabilization (hypermobile areas).

Correlation of static-dynamic diagnostic information within the structural-functional continuum will play a significant role in postural treatment regimens and in providing patient education concerning prognosis. Observation and palpation form the cornerstones of postural evaluation. Radiographic and computerized range-of-motion analyses provide additional or supportive information.

General Treatment Strategies

Properly designed postural care for patients with signs of GSP is often effective in ameliorating recurrent, predictable patterns of pain and dysfunction as well as relieving a wide range of secondary complaints (46,72). This is true for GSP with or without postural

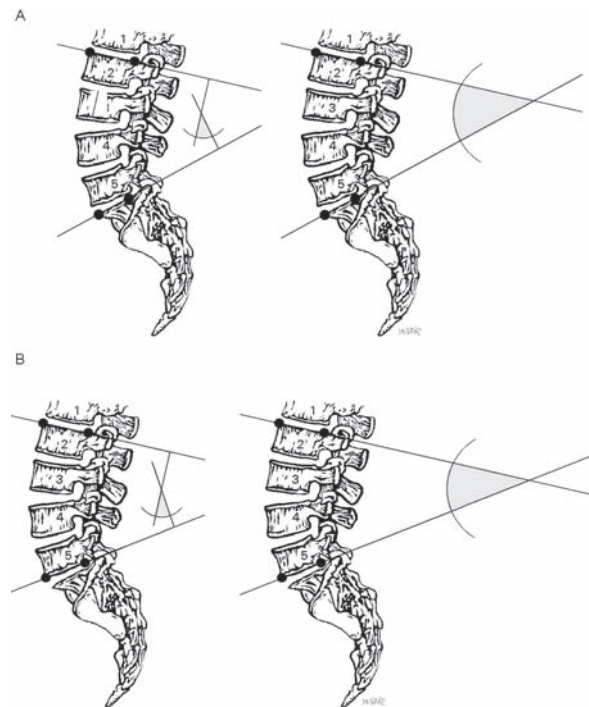

Figure 36-22 Lordotic angles of the lumbar A-P curve. **A.** Lumbar-sacral lordotic angle using L2 and S1 (average 60 degrees). **B.** Lumbolumbar lordotic angle using L2 and the bottom of L5 (average 43 degrees). (Courtesy of William Kuchera, D.O., F.A.A.O.)

decompensation, and principles used to prescribe individualized treatment plans do not vary significantly regardless of which plane of posture is primarily involved.

Treating a patient with postural decompensation clearly requires appropriate diagnosis of postural structures and their functional capabilities, and the treatment plan benefits from an estimate of overall homeostatic reserves. Knowing the duration of any functional imbalance or adaptation and the amount of any postural decompensation influences both the scope of the treatment regimen and prognostic expectations. Identifying significant muscle imbalance or joint somatic dysfunction in the absence of structural group curves may prompt corresponding “functional” treatment goals that promote freer motion within an optimally balanced posture. Such imbalance and dysfunction in the presence of significant structural group curve involvement suggests adopting “structural” treatment approaches. In both cases, improved results are more likely when cumulative strategies decrease functional demand on postural structures, modify biomechanical risk factors, and allow postural homeostatic mechanisms to operate under more optimal conditions.

The prognosis for many functional care regimens is likely to be a significant reversal or resolution of signs and symptoms. Expectations for structural care, in some cases, may need to be limited to maximization of function within existing structural constraints. Likewise, realistic goals should involve attempting to slow or halt further postural decompensation in advancing curves.

Recalcitrant dysfunctions, or those that only respond transiently to traditional postural strategies, might require adjunctive treatment modalities to accomplish the goals set for care. These additional adjuncts are particularly indicated for patients who have reduced intrinsic homeostatic compensatory mechanisms; structural change due to GSP and postural decompensation (reducing

the ability of the body to respond to otherwise successful treatment strategies); or those chronic back pain patients whose histories of failed surgical or medical management of concomitant arthritic, spondylolytic or disc disease suggest that their structural conditions will make it more difficult for the patient to functionally resist gravity.

If compensatory mechanisms remain overwhelmed, the following adjuncts could be combined with other conservative treatment of postural decompensation:

1. Postural education and compliance
2. OMT generally and to transitional zones
3. Postural exercise
4. Static postural bracing
5. Functional postural orthotics
6. Other miscellaneous approaches.

Postural Education and Compliance

Effective postural treatment regimens should emphasize education and compliance, especially in the initial phases of the reeducation program. Compliance is enhanced when the patient understands all components of the treatment protocol and their rationale.

In addition to other protocol components, provide to the patient sound *biomechanical and ergonomic education* emphasizing the choice of appropriate footwear, reduction of high heels, promotion of functional arches, and correction of pronation. Other useful education includes proper lifting technique and, when necessary to accomplish appropriate weight distribution, dietary counseling.

Counseling may also be helpful in modifying patients' *self-images* regarding their bodies or the choices they make affecting compliance. This is often required for successful treatment of the myofascial system. Teenage girls, for example, may slump severely because they are embarrassed about the development of their breasts. They may also not want to look taller than teenage boys who chronologically mature later. The personal attitude many teenage girls have toward their body must be changed through education about normal growth and development. Other patients need treatment of their primary psychological depression that results in a secondary postural slump. Proper postural education for the work site and other activities of daily living is also beneficial.

OMT Generally and to Transitional Zones

OMT is an integral part of care when applying the osteopathic postural model. It addresses predictable patterns of somatic dysfunction that consistently and recurrently accompany postural problems. It helps prepare the soma (muscles, joints, ligaments, and other supportive soft tissue) to better accept the positive postural change sought by postural care regimens. It addresses tensegrity issues by reducing tension and hypomobility that, if left alone, may prevent reversal of functional group curves physically or create pain in these sites (73).

In managing group curves affected by GSP or postural decompensation, several considerations exist concerning treatment of somatic dysfunction with OMT:

- The physician needs to identify and treat the cause of the curve. If the cause is functional, OMT might be used to remove that cause. Leveling the base of support by treating a unilateral pronated foot or a sacral shear somatic dysfunction in such a case would decrease the curve. If focal muscle hypertonicity has produced a curve, the muscle hypertonicity that produces the curve must be found. Causes of muscle hypertonicity are varied but if discovered and removed, the curve disappears.

- The concavity of a curve is typically on the tight or restricted side, while the convexity is on the unstable side. OMT involves stretching or mobilizing the concavity while strengthening the convex side. This should be followed by an exercise prescription to maintain the effect of the OMT.
- Postural change (both decompensation and "recompensation") often occurs first at the transition zones. Therefore, these regions should be diagnosed and dysfunction treated when found. The same system, to accomplish the first step in the respiratory-circulatory model, can be used effectively and efficiently in the postural model.
- As a patient adjusts to treatment for postural rebalancing, the spine must remain mobile to compensate for the change. Accomplishing such a primary goal while employing OMT or exercise in general postural treatment protocols may require regular OMT and carefully titrated exercise plans until the patient reaches that stage of healing in which their homeostatic mechanisms are no longer overwhelmed.
- If a curve has been present for some time, treatment of the curve improves motion within the curve. However, the curve itself or some asymmetry within the spine may remain or recur. Long-term anatomical (structural) change should not be expected to disappear with manipulation alone.

The particular OMT method selected should improve structure-function relationships where there is posture-induced pathophysiological change and do so with a minimum of side effects. In hypermobile areas, indirect method OMT is particularly useful for treating somatic dysfunction. It should be recognized that hypermobile areas may represent either primary traumatized tissue or regions of secondary compensation for other regions of restricted motion. In regions of longstanding hypomobility, direct methods, physical modalities, and stretching exercises are particularly useful. The percussion hammer technique (Fig. 36.23), as was taught by Robert Fulford, D.O., is clinically helpful in the treatment of

Figure 36-23 Percussion hammer technique. (Courtesy of William Kuchera, D.O., F.A.A.O.)

Figure 36-24 Seated OMT for postural transitional zones. (Courtesy of William Kuchera, D.O., F.A.A.O.)

some chronic postural problems (74). Examples of focused postural OMT to the transition zones are provided in Fig. 36.24 (seated) and Chapter 74 (supine).

Postural Exercise

Exercise is an often misunderstood and misused activity. The patient needs to be given a precise and realistic prescription for the goal, the dose, the frequency, and the duration of physical activities. In this manner, an exercise prescription can help the patient achieve rest, flexibility, strength, and endurance, depending on the desired goal. Specific *exercise* in postural decompensation cases should be designed first to rest, then to functionally enhance ineffective soft tissue structures, and finally to reintegrate the peripheral structures with their CNS controls.

Always consider the present status of the muscles and their ability to respond to a desired goal. In general, a person with decompensated posture requires a period of rest before exercise and compensation are effective; overly or continuously stressed or strained muscles cannot effectively be exercised until they have first

recovered (75). Thus, rest, medication, indirect OMT, and certain physical modalities may be necessary before beginning an individually designed exercise program; the appropriate exercise prescription for a patient with postural decompensation may be to *decrease* activities of daily living.

The bioenergetic cycle (76) (Fig. 36.25) describes the requirement of resting the body until it is physiologically capable of resuming its postural fight against gravity. Energy expenditure throughout each day is cyclical; sequencing is important for the efficacy of the process. Postural strain increases the expenditure in the early stages of the cycle and delays or even subverts later stages. When a person whose homeostatic reserves have been exceeded first lies down at night, it may take 30 minutes (or more) before the erector spinae and quadratus lumborum muscles relax and allow comfort in the supine position. These muscles, therefore, need to be monitored. Furthermore, reduction in both iliolumbar ligament tenderness and edema is an indicator that active postural exercises may then be effectively introduced to achieve strength, stability, and proprioceptive reeducation.

When the muscles are sufficiently recovered, certain exercise regimens are helpful for certain postural conditions. Pelvic coil exercises (77) are often beneficial for sagittal plane postural problems (Fig. 36.26). In patients with coronal plane postural decompensation, the exercises used in Konstantin, Poland, were shown to significantly improve postural alignment, but exercise in the United States was often deemed ineffective. More recently, many protocols for

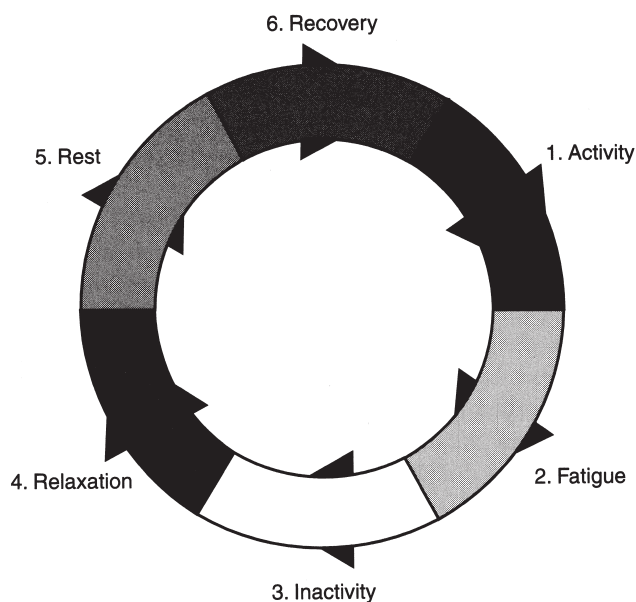

Figure 36-25 Bioenergetic model. (Modified from Jungmann M. *The Jungmann Concept and Technique of Antigravity Leverage*. Rangely, ME: Institute for Gravitational Strain Pathology, Inc., 1982. Courtesy of William Kuchera, D.O., F.A.A.O.)

trunk-specific exercises combined with correcting behavioral patterns have shown the benefits of including specific exercise in the regimens of all degrees of scoliosis (78–81). Optimally, effective postural exercise protocols include the goal of proprioceptive reeducation. Promotion of flexibility for realignment and selective strengthening for stability in hypomobile areas are goals for postural exercise.

As noted, exercise prescriptions should promote the healing of strained and injured tissues before striving to accomplish any other postural goal. Two basic rules of exercise are thereby advocated for these patients (82):

1. Avoid exercising to the point of fatigue.
2. Discontinue any exercise that causes pain until a reason for the pain is discovered.

Static Postural Bracing

Nonfunctional *braces* or *corsets* may be used as adjuncts to short-term treatment. Under certain conditions, they may be used for longer periods.

Static structural bracing has both positive and negative aspects. On the positive side, static braces promote rest and healing in a region of acute strain; they support the structure and initially reduce ligamentous and muscular functional stress. On the negative side, the muscles soon become dependent on the support provided. The longer the brace is worn, the weaker the patient's own muscles become. Static braces are therefore better for providing rest in an acute condition rather than for treating a chronic postural one.

Use of static bracing in chronic situations requires both care designed to prevent muscle atrophy and the patient's dependence on the static brace. It is therefore imperative that the physician links the patient's brace treatment with an ongoing exercise program. Ideally, to prevent weakness and physical dependency, a physician should rarely introduce a static brace without having a plan to replace it (83).

Functional Postural Orthotics

Functional postural *orthotics* are more appropriate choices than static braces for patients with chronic GSP and postural decompensation. Such devices serve to direct, guide, and/or reeducate the body, as opposed to directly taking over support. They are capable of influencing physiological parameters and reducing associated low back pain. With respect to postural realignment, this class of treatment modalities includes several specific orthotics. Functional postural orthotics discussed in this chapter include over-the-counter flexible foot supports, graduated incremental heel or sole lifts, and a custom-fitted pelvic orthotic device.

A functional orthotic device may be added to a patient's treatment regimen to enhance homeostatic postural mechanisms, prevent GSP, or increase efficacy of a postural treatment regimen. It is indicated for those patients exhibiting chronic or recurrent conditions resulting from, or aggravated by, postural strain or decompensation. Its use can realistically be expected to improve the body's ability to resist strain and decompensation by altering biomechanical alignment or assisting soft tissue structures. Concomitant symptoms such as back pain, headache, fatigue, muscle imbalance, and functional visceral complaints may be relieved in a program that incorporates a functional postural orthotic, OMT, and patient education. These symptoms alone (in the absence of the underlying postural cause) are not a sufficient indication for the use of adjunctive orthotic devices.

A foot orthotic that incorporates a unilateral heel lift adds length to one of the two lower extremities thereby leveling that base of support. This shifts the balance from side to side and affects

posture primarily within the *coronal plane*. The direct mechanical impact of any such lift placed under the foot or heel is measured at the midcalcaneal line. In some ways, placing a unilateral shoe lift is similar to placing a shim under a table leg to balance the structure above it; in this case, in an attempt to level the top of the sacrum as a base of support.

A foot orthotic incorporating a unilateral anterior sole lift (usually placed under the metatarsal heads) will maximally affect posture in the *horizontal plane*. Located biomechanically anterior to the individual's WBL, an anterior sole lift will typically tip the structures above the feet backward. In this fashion, such a lift on the right will rotate the pelvis to the right.

A pelvic orthotic device, such as the Levitor (Fig. 36.27), has its greatest effect within the sagittal plane. This pelvic orthotic has been used in the United States since 1939 and is the only prescription, custom-fitted device for the pelvic base of support that is available for long-term use with chronic GSP or postural decompensation in the sagittal plane. It weighs 6 oz and is made of a high-test aluminum alloy that transfers pressure to cushioned pads; one over the superior portion of the pubic symphysis and the other on the posterior part of the sacral apex below the S2 middle transverse axis. This orthotic device was specifically designed to resist the counter-rotation of the sacrum and innominates that occur under the influence of the strain of gravity. It aids but does not replace the function of postural muscles, thereby avoiding the dependency caused by the prolonged use of static bracing.

While the mechanical design of each orthotic primarily affects one plane of motion, linked musculoskeletal biomechanics insure that all three of these examples affect postural change in all cardinal planes simultaneously (29). Treatment outcomes include improved balance mechanisms as demonstrated by changing graphic center-of-gravity plots and the reduction or reversal of lordosis, kyphosis, and scoliosis on postural radiographs (46). They also decrease low back pain, other musculoskeletal symptoms, energy demands, segmental dysfunction, and they appear to improve respiratory-circulatory functions.

Other Miscellaneous Approaches

Electrical stimulation of paraspinal muscles has been used in some centers. Electrodes are placed in the muscles on the side of the spinal convexity and are connected to a direct current from a

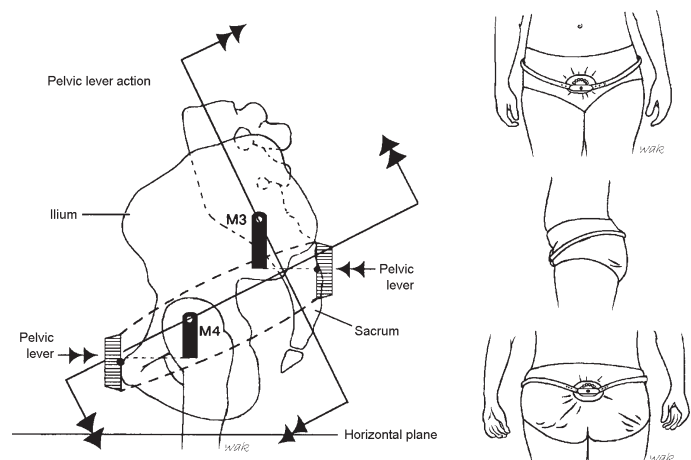

Figure 36-27 Pelvic lever action and Levitor. (From Jungmann M *The Jungmann Concept and Technique of Antigravity Leverage*. Rangel, ME: Institute for Gravitational Strain Pathology, Inc., 1982; with permission. Courtesy of William Kuchera, D.O., F.A.A.O.)

control box. An electrical current causes contraction of the muscles on the side of the convexity and is postulated to help reduce scoliotic curvature. Research suggests that, used alone, this modality is not effective in reversing scoliosis; but it is recommended by some centers as part of a unified treatment regimen to assist in muscle strengthening or pain relief.

Injection techniques using proliferative medication (*prolotherapy*) for ligamentous laxity may be employed if other conservative modalities alone fail to restore stability. Prolotherapy (sclerotherapy) consists of proliferant solution injected at a ligamentous attachment (44). When postural strain biomechanically overwhelms structural integrity, ligamentous laxity can result. Injection of a proliferant solution (such as 50% glucose) into the ligament at its fibro-osseous insertion can increase stability. Combined with exercise, OMT, and postural realignment to prevent return of musculoligamentous strain, this protocol can be an effective and conservative approach to hypermobility and ligamentous laxity (84).

When an insurmountable problem is primarily a structural one, so too is its treatment. In unstable situations, or in situations that have not responded to conservative care, surgery is a viable option to consider. In the case of severe scoliosis or highly symptomatic spondylolisthesis, this could consist of fusing vertebrae. Surgical implantation of orthopedic rods or other stabilizing apparatuses may also be required. Surgical techniques have even been successfully used to lengthen anatomically short legs.

In summary, numerous modalities are used to assist the body's postural response to gravity. An individually designed conservative program includes a carefully selected combination of patient education, OMT, exercise, and functional orthotics. All of these are aimed at modifying the structure-function relationship and enhancing the body's ability to self-heal. Therefore, postural balancing requires an understanding of the biomechanical nature and functional anatomy of each patient and a full understanding of osteopathic philosophy.

3-PLANAR POSTURAL CONSIDERATIONS: INTEGRATED POSTURAL TREATMENT OF SPECIFIC CLINICAL CONDITIONS

Coronal Plane Decompensation

Unleveling of the sacral base or a deformed vertebra resulting from a fracture or congenital deformation often leads to a compensation or adaptation that most predominantly affects the coronal plane curvatures of the spine. Motion (or lack thereof) in the coronal plane, however, is physiologically linked to that in the horizontal plane and lordosis (sagittal plane) has been specifically implicated as a destabilizing factor in the development and progression of scoliosis (85).

Occasionally, an unlevel sacral base is observed in a postural x-ray image with a straight spine above it. This requires muscular effort, resulting in spinal musculoligamentous strain that may manifest as back pain or headache. As the person grows older and the muscular compensation becomes inadequate, functional scoliosis manifests and structural scoliosis eventually develops (22).

Adaptation or decompensation in the coronal plane as measured in postural radiographic series also correlates with degenerative osteoarthritis of the hip (38), lumbar osteophytes (22,86), lumbar vertebral wedging (22), scoliotic patterns (especially where sacral base unleveling measures >10 mm) (67), and a variety of somatovisceral symptoms (34,87). This chapter will discuss the so-called short-leg syndrome as an example of a coronal plane

predominant functional condition and scoliosis as a predominantly structural condition.

Functional Considerations: "Short-Leg Syndrome"

References that attest to the existence of leg-length inequality in approximately 90% of the population have appeared in the medical literature since the latter half of the 1800s (88–90). John Hilton specifically mentioned lift therapy as a treatment for this problem in 1863: *Thus I have seen many patients wearing spinal supports, in order to correct a lateral curvature when the deformity might have and has been subsequently, corrected by placing within the shoe or boot a piece of cork thick enough to compensate for the shortness of the less well developed limb* (91).

Within the osteopathic profession, the term *short-leg syndrome* is a recognized misnomer. This text, however, will continue to refer to short-leg syndrome because of historical precedence. Regardless of the name, the cause of the condition may not be related to the actual length of the legs at all. It is called a syndrome because it is associated with a variety of related biomechanical findings and symptoms.

In the osteopathic postural model, an unlevel sacral base is the clinically relevant element in this syndrome even when the actual cause might extend all the way down to the arch of the foot or up to the cranium. Because a structural or a functional short lower extremity usually results in an unlevel sacral base, the spine that sits on that base compensates by changing its spinal curvatures. Subsequently, the person must often stand or walk differently. If the sacral base is unlevel for any reason, the innominates often rotate to compensate. This creates the appearance of a functionally short lower extremity. In either case, the most common spinal response is the development of a rotoscoliosis in which side bending of the most caudal curve is away from the side of the low sacral base, and usually on the side of the short leg. An atypical pattern in which the low sacral base is opposite the side of the low femoral head rarely does occur (67), however, and is clinically challenging to manage (Fig. 36.28).

Clinical Presentation

Compensatory measures are sometimes so good that any single landmark measurement may fail to provide a true and accurate

Figure 36-28 Frequency distribution of lumbosacral relationships to unlevel femoral head heights. $N = 738$. (From Kirksville College of Osteopathic Medicine, Kirksville, MO, with permission.)

diagnosis. Neither the alignment of spinous processes nor the level of the iliac crests (92) is a good single indicator of sacral base unleveling or short-leg syndrome. ASIS or hip-to-ankle measurements using a tape measure are also inaccurate (57,93–95). Comparison of the levels of the medial malleoli in the supine position is similarly inaccurate and potentially misleading (96,97). The greater trochanters in the standing position are somewhat more helpful clinically but can be in error when unilateral coxa varus or coxa valgus is present (98). Prevalence data and radiographic measurements definitely correlate much better than any of these clinical estimates of postural asymmetry. In one study of standing patients with known radiographic leg-length inequality, the wrong extremity was identified as being short in 13% of the clinical observations; more than half of the 196 clinical estimates of leg length were incorrect by more than 3/16 of an inch (97).

Recurrent patterns of somatic dysfunction of the pelvis, spine, cranium, or myofascial structures may also be a clue that the sacral base is unlevel or that a short leg is present. Soft tissue involvement with respect to the compensation occurring in the short-leg syndrome is particularly common throughout the entire body (tensegidity) and is a cause of many patient complaints. Tissues on the concavity shorten and demonstrate increased electromyographic activity (99,48). Tissues on the convex side lengthen. Patients with coronal plane postural imbalance develop tight abductors on one side of the pelvic sideshift and tight thigh adductors on the contralateral side. Associated horizontal plane imbalance often results in tight hamstrings on one side and tight rectus femoris muscle on the other thigh.

Coronal plane postural disorders are expected with certain combinations of static and dynamic findings such as constellations of asymmetry, recurrent somatic dysfunction, and tissue texture change. When this diagnosis is the result of leg length inequality, the standing trochanteric plane, the plane of the PSIS, and the iliac crests are usually depressed on the side of the depressed sacral base. Usually the more horizontal cephalad planes (shoulders, occipital) are also depressed to compensate for the unlevelness of the sacral base (39). The number of curvatures between the pelvis and the upper body will determine on which side the more horizontal cephalad planes are depressed in relation to the sacral base.

The iliolumbar ligament on the side of the convexity of the lumbopelvic curve is often the first structure to react to added stress in the lumbosacral area and the point of maximal tenderness to palpation is typically located over the attachments of the iliolumbar ligament at the iliac or L4 or L5 transverse processes. When stressed, it often refers pain around the ipsilateral side to the groin, and sometimes into the testicle or the labia and the upper medial thigh (Fig. 36.9) (100). The pain may be mistaken for arthritis of the hip, greater trochanteric bursitis, or even an inguinal hernia.

The sacroiliac ligaments on the side of the convexity may also become stressed and tender to palpation and may refer pain down the lateral side of the leg. Unilateral sciatica and hip pain, as well as pain over the greater trochanter, however, are more often expressed on the long leg side. Numerous postural muscles are strained and significant physiological changes related to segmental facilitation have been documented. Subsequently, there may be visceral dysfunction related to an increased sympathetic hyperactivity originating in spinal crossover areas located between T1 and L2.

Before definitive diagnosis of a patient's posture, OMT should be directed to all somatic dysfunction with particular care to correct dysfunctions of the sacrum, innominate, and quadratus lumborum. After OMT, the demonstration of a positive standing flexion test coexisting with a negative seated flexion test should raise the suspicion that lower extremity influences, such as a short lower

extremity, are affecting the function of the sacroiliac joint and the patient's posture (101).

In problematic cases, it may be helpful to obtain a standard standing postural x-ray series. After first removing the patient's somatic dysfunction, this x-ray series primarily portrays structural data associated with the best homeostatic compensation possible by the patient at the time. These standardized standing postural x-ray images can then be used to measure coronal plane values accurately, including the heights of the iliac crest, femoral heads, and sacral base as extrapolated over the femoral heads. The radiographic series will also provide quantitative measures of the degree, location, and type of scoliotic compensatory curvatures as well as any congenital or acquired bony anomalies.

When reading the x-ray image (Fig. 36.29) obtained by standard methods, remember that there is still potentially a 2-mm human error in measurement. This can occur even with flawless technique by the radiologic technician and perfect patient cooperation. The further from the exposed radiographic film, the greater the x-ray diversion meaning there can be up to a 25% bony magnification (distortion) for structures furthest away from the film (39,102). Nonetheless, repeat studies on leg length inequality of 108 subjects found 85% with less than a 1.5-mm difference in measurement and 10% with less than a 3-mm difference; in only three subjects did the repeat study differ as much as 5 mm (38).

Compensatory changes such as innominate rotations, pelvic rotation, and changes in the LSA might alter the x-ray appearance, which can misrepresent the extent of the patient's actual problem. For these reasons, a leg length difference of <5 mm might not be treated unless the patient has other clinically relevant complaints and risk factors. Conversely, the desire to attain "peak physical performance" or to prevent long-term sequelae such as osteoarthritis of the hip (107) might be an indication to treat a patient in this case. Patterns of imbalance recorded along the spine may be caused by as little as a 1/16 of an inch (1.5 mm) difference in leg length. Clinical symptoms can occur in these cases, including low back pain (103,104).

Treatment Considerations

Typically, treatment of the so-called short-leg syndrome involves lifting the heel of the leg on the side of the depressed sacral base. This is especially true if there is a compensatory curvature that side bends to the side opposite the short leg. In the rare situation where the curve has its concavity toward the side of the short leg, it may be necessary to begin by lifting the side of the long leg. This first effects a change in the lumbar scoliosis and also relieves some of the pelvic and lumbar strain (105). The lift on the long leg side is later reduced to begin lifting the depressed side of the unlevel sacral base.

Heel lift treatment using the osteopathic postural model is always combined with OMT and is usually not attempted until after an appropriate OMT trial. The rationale for both was clearly implied by Harrison Fryette: *In the average case I do not attempt a correction until I have mobilized the lumbar joints and established rotation in them; furthermore, if this region cannot be rotated toward the midline, the lift will not do what it is intended of it, for the correction will not take place in the lumbar region—the spine higher up will compensate by increasing its curve and only more trouble will result* (106).

OMT may alleviate a functional condition that manifests as an apparent short-leg syndrome. In the situation in which lift therapy is indicated, OMT prepares the somatic tissues to accept the realignment needed to respond to the newly established sacral base level.

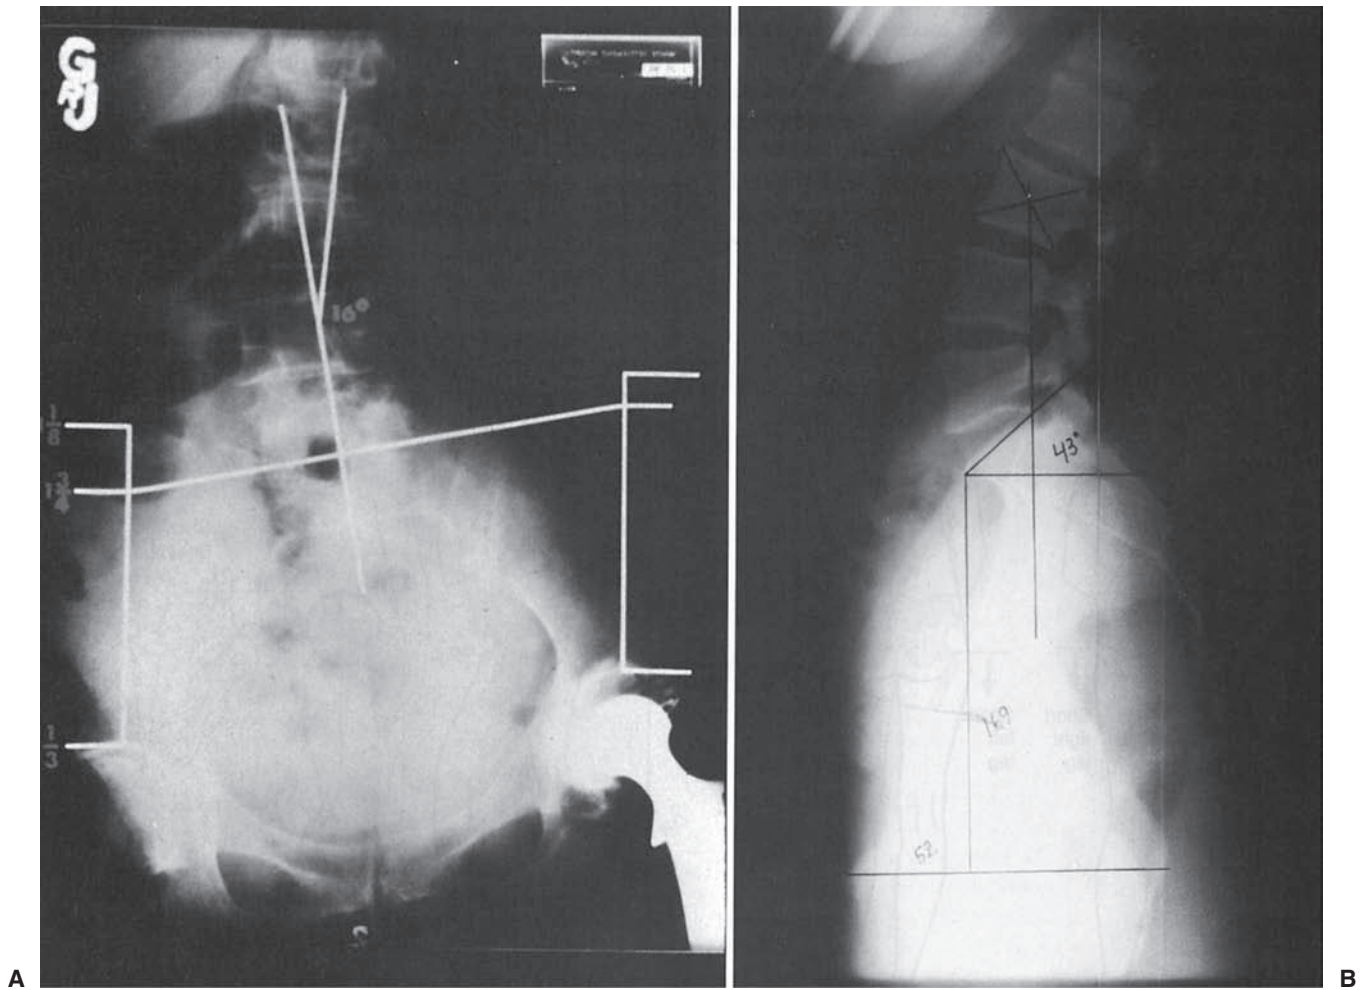

Figure 36-29 X-ray image marked for coronal (A) and horizontal (B) plane measurements. Ideal values would be no side-to-side unleveling of any of these landmarks and no pelvic rotation.

Whenever lift therapy is initiated, consider the implications of postural realignment and reeducation that must take place throughout the entire body. For many reasons, the initial amount of lift selected is rarely the full amount needed. In most cases, compensation, adaptation, and decompensation have occurred over a period of time, leading to shortening and fibrosis of soft tissues, bony remodeling, and regional somatic dysfunction. The easiest but least sensitive guideline used by clinicians is to select an initial lift that is one third to one half of the measured sacral base difference.

Attempts to formulate specific guidelines to better quantify the amount of lift are best appreciated by studying the writings of David Heilig, D.O., F.A.A.O. (107). Heilig found that one third to one half of the measured sacral base unleveling was too much initial lift in selected clinical situations. He developed a formula (Table 36.6) that considered the amount of lift to be directly proportional to the measured sacral base unleveling and inversely proportional to host factors such as the age, duration of the condition, and amount of compensation or adaptation acquired by the body. Heilig offered examples of patients who all had a 1/2-in sacral base unleveling but who, based on the formula, would receive different initial lifts.

One of the safest protocols taught at many of the colleges of osteopathic medicine is less complicated than the Heilig formula

yet sensitive to individual host factors. It employs a conservative “rule of thumb” that can later be modified by clinical experience and judgment. This protocol is designed to avoid any unexpected flare-ups of pain or somatic dysfunction that can occur if lift therapy is introduced too rapidly or if it exceeds the capability of the body to realign in response to the changes occurring in the sacral base level.

The following are only guidelines for the application of conservative lift treatment and must be adapted to each patient according to their individual evaluation and response (108):

- If lift therapy is required and if the patient is considered to be a “fragile” patient (arthritic, osteoporotic, elderly, having significant acute pain, etc.), begin with a 1/16-in lift and lift no faster than 1/16 of an inch every 2 weeks.
- If the spine is flexible and no more than mild-to-moderate strain is noted in the myofascial system, begin with a 1/8-in lift and lift at a rate no faster than 1/16 of an inch per week, or 1/8 of an inch every 2 weeks.
- If there was a recent and sudden loss of leg length on one side, as might occur following fracture or a recent hip prosthesis, and the patient had a level sacral base before the fracture or surgery, lift the full amount that was lost.

TABLE 36.6

The Heilig Formula and Patients with Same Sacral Base Leveling but Receiving Different Lifts

The Heilig formula suggests that the initial lift can be calculated as follows:

$$L < [\text{SBU}]/[\text{D} + \text{C}]$$

L, lift required; SBU, sacral base unleveling; D, duration; C, compensation.

Duration allotted as: (D = 1), 0–10 y; (D = 2), 10–30 y; (D = 3), 30+ y. Compensation allotted as: (C = 0), none observed; (C = 1), rotation of lumbar vertebrae into convexity of compensatory side bending; (C = 2), wedging of the vertebrae, altered size of facets, horizontal osseous developments from endplates, and/or spurring.

Patients With Same Sacral Base Leveling But Receiving Different Lifts

Case 1: Following fracture, minimal duration, no compensatory changes

$$L = [\text{SBU}]/[\text{D} + \text{C}] = 1/2"/[0 + 1] = 1/2"$$

Case 2: Patient age 35, injured in early youth, minimal compensation

$$L = [\text{SBU}]/[\text{D} + \text{C}] = 1/2"/[2 + 1] = 1/2"/3 = 1/6"$$

Case 3: Patient age 75, injured in youth, spurring, horizontal endplate development, rotation is marked

$$L = [\text{SBU}]/[\text{D} + \text{C}] = 1/2"/[3 + 2] = 1/2"/5 = 1/10"$$

Case 4: Patient age 26, polio affecting right leg in youth, minimal compensatory change

$$L = [\text{SBU}]/[\text{D} + \text{C}] = 1/2"/[2 + 0] = 1/2"/2 = 1/4"$$

Regardless of the method used to select the amount of the initial lift, certain other guidelines should be followed for optimum clinical results:

- Because of magnification, measurement error, and compensatory changes, the final lift height in a chronic short-leg syndrome may only be one half to three fourths of the shortness in that leg measured by the standard standing x-ray method.
- When a proper lift has eventually been reached and there are no pelvic or lower extremity somatic dysfunctions, the former positive standing flexion test should become negative. If a repeat x-ray image is desired, it should be taken using the same radiographic protocol and parameters that were used in the initial x-ray series, but with the shoes on and the lift in place.

Guidelines used in lift treatment are not absolute rules. One aspect of the art of medicine is an appreciation of the concerns that patients have about cost, cosmetic appearance, and convenience. Ideally, the shoe is rebuilt with every increment of lift to prevent alteration of foot mechanics and introduction of unwanted pelvic rotation. Few patients, however, would agree with this approach. The following guidelines, which emphasize clinical tolerances, can be pragmatically used in lift treatment. If problems arise, reducing the tolerances or insisting on continuing to the ideal lift may be necessary:

- The true height of a lift is measured from the bottom of the lift to a point where the calcaneal bone strikes the lift; it is not measured at the posterior edge of the lift.
- Up to and including 1/4-in of replaceable lift can be used inside of the shoe before the shoe no longer fits well.
- Up to and including a total of a 1/2-in lift can be placed between the heel of the patient's foot and the floor before foot mechanics are significantly disturbed.
- As a heel is progressively lifted, there is an increased tendency toward pelvic rotation, muscle imbalance, and alteration of foot mechanics.

Application of these principles to change the relative leg length by 1/2 in may result in:

- 1/4-in lift being placed inside the shoe and 1/4 in added to the heel of that shoe
- 1/2 in added to the heel of one shoe
- 1/4 in added to one sole and 1/4 in removed from the opposite sole (108,109).

Many other combinations exist within these general guidelines, permitting the osteopathic practitioner the latitude to balance nonphysical factors (such as vanity and cost) with those related to posture.

Any increase in height beyond the 1/2-inch heel lift must be added to the heel and also to the anterior half-sole of the shoe (Fig. 36.30). This principle preserves the relationship of the heel to the forefoot by maintaining a certain normal angle.

Studies (34,104) indicate that an 80% reduction in subjective pain and other posture-related symptoms (including the degree of functional scoliosis) could be expected as a result of properly balancing the sacral base with lift therapy to within 1 mm of levelness.

Balancing the weight of both shoes might be desirable, especially if large lifts are required. If a big lift is needed, placing cork material between the shoe and the heel might be necessary to reduce the weight being added to one side. In some cases, small lead weights might be added to the other shoe to help maintain balance.

OMT helps the patient's spine to adapt to the functional changes required by the new postures as seen in progressive lift therapy for a short leg.

Compressive force makes bone grow faster. A lift under a growing child's foot may be expected to stimulate faster growth in the epiphyseal plates of that lower extremity. The physician must therefore closely monitor leg lengths when using lift therapy for a child. The height of the lift must be adjusted according to clinical responses and the results observed on follow-up x-ray studies.

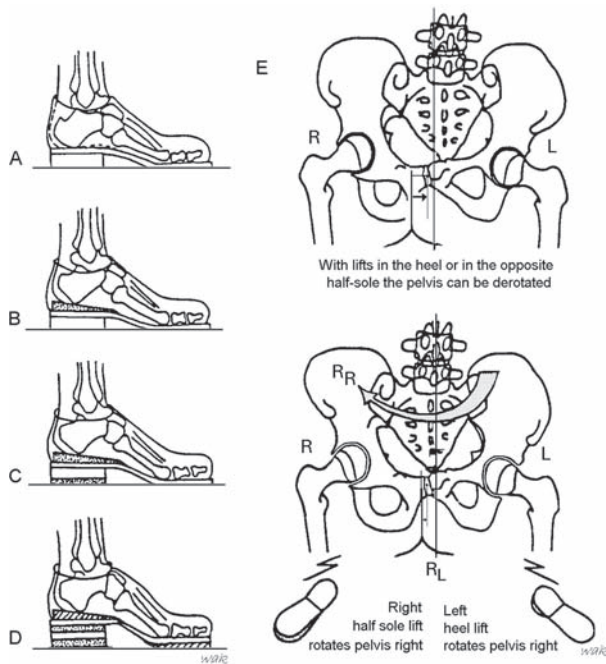

Figure 36-30 Principles of lift therapy. Heel lift measurements made at midcalcaneal line. **A.** Foot in a typical shoe. **B.** Heel lift in place. Maximum lift in shoe is 1/4 in. **C.** If more lift is needed, add to outside heel. **D.** If more than 1/2 in is required, or to create minimal disturbance of foot mechanics, the entire sole can be lifted. (Courtesy of William Kuchera, D.O., F.A.A.O.)

In growing athletes, alternating lower extremity growth parameters have been reported (107), and have prompted the clinical recommendation to check the pelvic and extremity levels at regular intervals. Fryette even remarked: “*In the last 15 years I have added lifts to the short side in many cases under the age of fourteen and in every case that I have kept under my observation for some time I have been astonished to find that the legs grew to the same length*” (110).

Structural/Pathological Considerations: Scoliosis

Scoliosis and rotoscoliosis are postural diagnoses with origins dating back to ancient Greece. Today, ten in every 200 children (10:200) develop scoliosis by the age of 10 to 15 years; 1 in every 200 (1:200) has clinical symptoms related to the curvatures. Boys and girls are equally affected, but the curvatures in girls are three to five times more likely to progress and produce subjective symptoms.

Curvatures are more likely to progress during times of rapid bone growth. Therefore, most cases (75% to 90%) of scoliosis in children are discovered—in part because of widespread screening programs—between the ages of 10 and 15 years.

Clinical Presentation

Scoliosis primarily affects the coronal plane. It is officially named according to the direction of the convexity of its curve. A curve that is side bent to the left is called a *right scoliosis* because the convexity of the curve is toward the right.

Symptoms and Screening

Children and adolescents with scoliosis are often asymptomatic and their scoliosis can go undiscovered. They, or a parent, may

have only noticed that clothing does not fit properly. Therefore, school children and teens should be routinely screened for scoliosis between the ages of 10 to 15 years when they are experiencing rapid bone growth.

As the person gets older, several symptoms may bring the scoliotic patient to the physician. These include:

- Arthritic symptoms
- Backaches
- Chest pains
- Neck aches
- Headaches
- Symptoms of organ dysfunction

Physicians only casually looking for scoliosis may miss a curve of up to 35 degrees; careful screening with a physical examination alone however should pick up the majority of scoliosis more than 10 degrees.

As previously described, in the standing position, the space around the patient’s body is analyzed, especially in the arm and waist area. Observe whether one hand hangs lower than the other or whether one hangs by the side while the other hand lies on or over the thigh. Look at the levelness of the occipital, shoulder, iliac crest, PSIS, and trochanteric planes (see Fig. 36.12). Run your fingers along the spinous processes from top to bottom. Have the patient forward bend and observe for an asymmetric “hump” along the horizon of vision. Its presence would indicate rotoscoliotic deformity with rotation to that side and side bending of the spine to the side opposite the hump.

If spinal curvature is found, have the patient bend over to that area of the spine and determine if the asymmetry goes away with side bending toward the side of the rib hump (see Fig. 36.13). Check the patient for conditions that could give the appearance of a short leg, such as sacral shear somatic dysfunction on that side. If you find somatic dysfunction, it can be corrected with manipulation. Recheck following OMT for lower extremity induced postural problems.

If the scoliotic curve remains, provide OMT until there is an adequate mobilization of the spine and then obtain a standardized standing postural x-ray image. The x-ray image provides the quantitative data to determine:

- Bony pathology
- Type and severity of spinal curvatures
- Amount of sacral base unleveling
- Femoral head and iliac crest levelness

Scoliosis may be classified by its reversibility, severity, cause, or location.

Classification: Reversibility

Scoliosis can be functional or structural. A simple physical examination technique used to assess the proportion of functional to structural scoliosis can be accomplished by standing behind a patient (Fig. 36.13B). The patient bends forward until maximal rib hump appears on horizon. With that much of the body forward bending, the patient swings the upper body, first left and then right, while the clinician observes the functional ability of the rib hump to lessen in degree. The amount of rib hump remaining during this maneuver indicates the associated structural scoliotic component. Functional scoliotic curves go away with side bending, rotation, or forward bending. If functional curves remain in the body too long, they may become structural (111). Structural scoliotic curves are fixed curves that do not reduce with side bending, rotation, or lift therapy.

Classification: Severity

Scoliotic curvatures are commonly and accurately measured from postural radiographs using the Cobb method (64) (see Fig. 36.18). The same vertebrae used to define the top and the bottom of the curve are used for future Cobb measurements to see if the curve is progressing. Scoliosis often increases rapidly during the growth spurt of adolescence. Take an x-ray image of the hands, iliac crests, or other epiphyses and obtain a bone age for those patients who have significant scoliotic progression. For females, the scoliosis is more likely to undergo a rapid progression. Significant progression of the curve is considered to be occurring if, on a second standardized postural x-ray taken within 5 months of the first one, there is a 5-degree or greater increase in the curvature.

The Cobb method is used to classify scoliosis as mild, modest, or severe (Fig. 36.31). The normal case shows no scoliosis. A curve of 5 to 15 degrees is assigned a mild severity classification. Moderate scoliosis curves measure 20 to 45 degrees. Severe scoliosis has a curve of more than 50 degrees and can be expected to affect both structure and systemic function. A thoracic curve of more than 50 degrees significantly compromises respiratory function; more than 75 degrees seriously compromises cardiovascular function. The effect on these two systems is inversely proportional to the degree of scoliosis and even mild curves impact exercise capacity (80).

Classification: Etiology

The following causes are listed according to decreasing frequency.

Idiopathic

This diagnosis accounts for 70% to 90% of scoliotic curves. By definition, the term *idiopathic* implies that there is no known reason for this type of scoliosis to occur. Osteopathic physicians believe that some of these may be explained as being compensatory curves that manifest as a response to an unlevel sacral (105) or cranial base (106). In cases where a biomechanical basis exists for the development of scoliosis, a diagnosis of an idiopathic scoliosis is erroneous. Other clinicians have implicated sagittal plane biomechanics in the

genesis and progression of different types of idiopathic scoliotic patterns (107). Better understanding of scoliosis might further reduce the number of cases classified as idiopathic.

Congenital

Congenital cases, of which 75% are progressive, are the second most common associated cause of scoliosis.

Acquired

Acquired scoliosis may result from the following conditions:

- Osteomalacia
- Response to inflammation or irradiation
- Sciatic irritability
- Psoas syndrome
- Healed leg fracture
- Following a hip prosthesis

Obviously, if a short-leg syndrome is documented as the reason for the patient's scoliosis, this should be reclassified as an acquired scoliosis.

Classification: Location

Various locations of scoliosis are reported below according to decreasing frequency (Fig. 36.32). Regions involved in scoliosis may be balanced or unbalanced. Unbalanced curves are more likely to decompensate, while balanced curves are subject to degeneration at crossovers.

Double major scoliosis

These are balanced curves but they are subject to degeneration at the crossover regions of the spine (see Glossary at the end of the textbook). This is the most common scoliosis, with a thoracic and lumbar combination being the most frequent.

Single thoracic scoliosis

Cosmetically, this curve is rather noticeable. It is usually side bent right and rotated left, producing a left paraspinous rib hump.

Figure 36-31 Curve patterns in idiopathic scoliosis. **A.** Mild (14 and 15 degrees). **B.** Moderate (38 degrees). **C.** Severe (59 and 85 degrees). Assessment of scoliotic severity defined by Cobb angle measurements for each portion of coronal plane curve. Classification system quoted allows a 5-degree gray zone between severity classes.

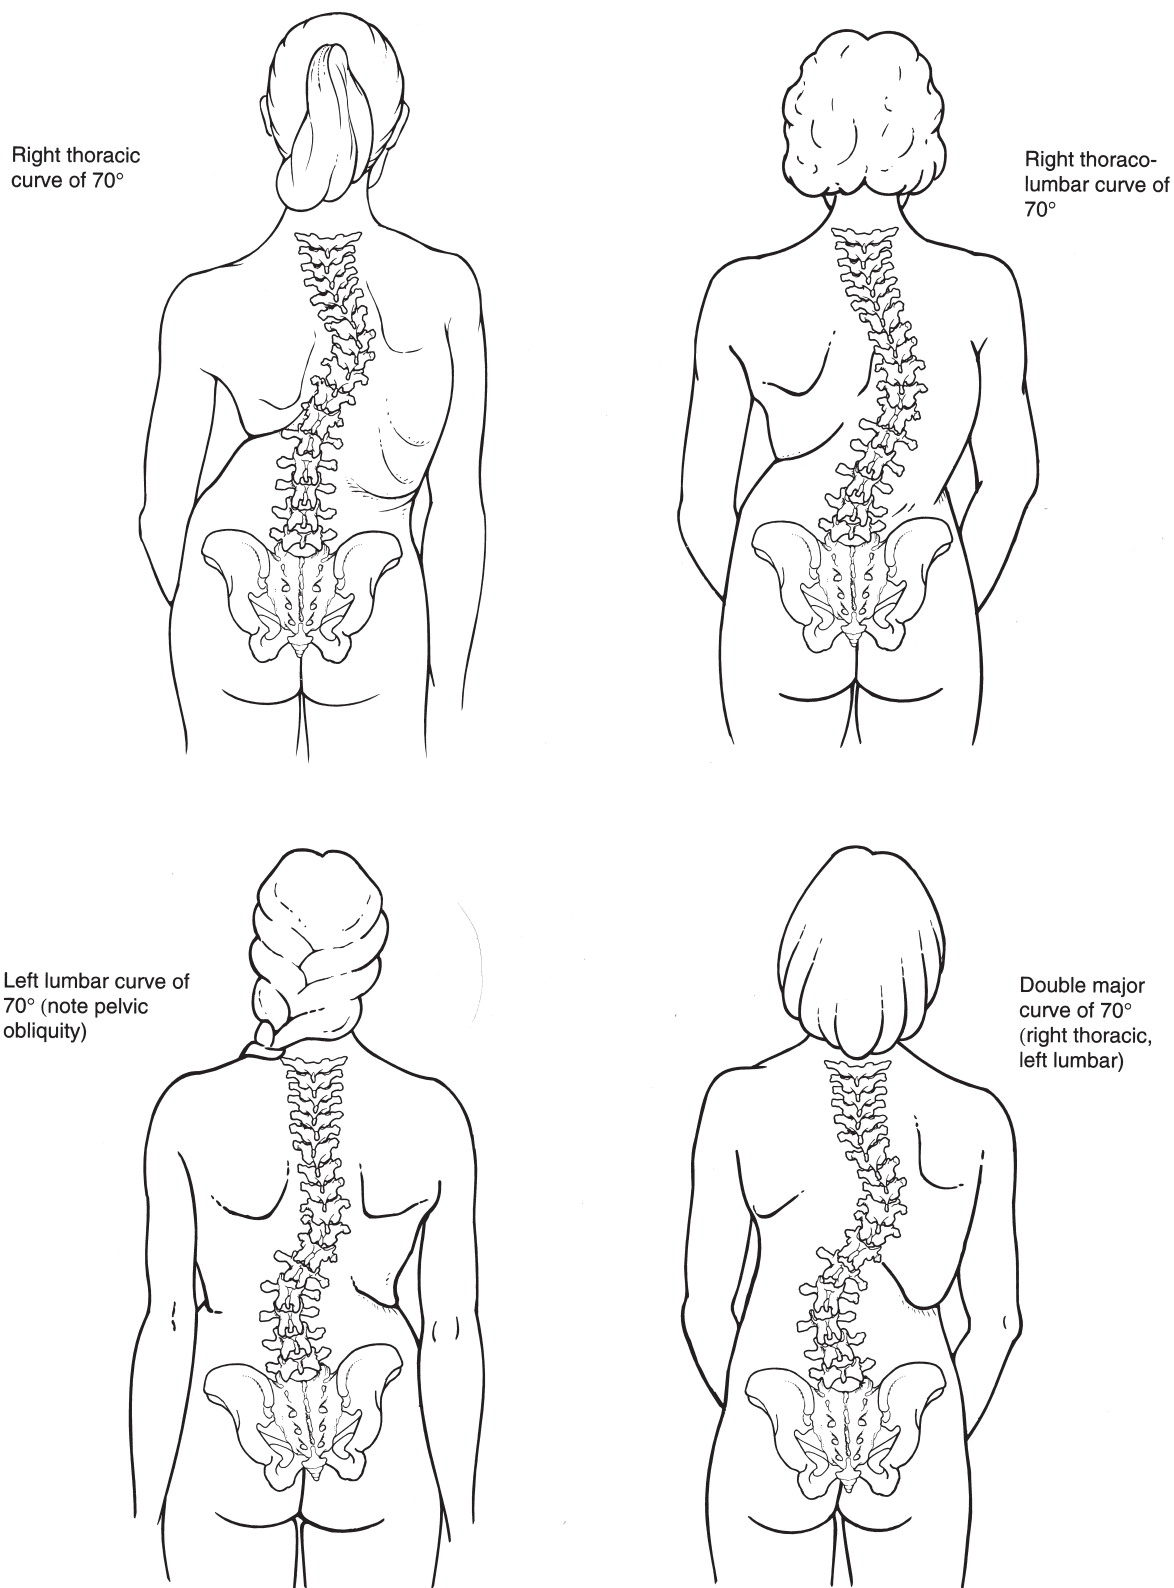

Figure 36-32 Curve patterns in idiopathic types of scoliosis classified by location.

If this type of curve should progress, it could compromise the function of the heart or lungs. It is the second most common scoliosis.

Single lumbar scoliosis

This curve is associated with arthritic change. It is the third most common scoliosis.

Junctional thoracolumbar scoliosis

This single curve scoliosis often results in structural (arthritic) change because it tends to be a longer curve that functionally over-stresses the spine. It is not a common scoliosis.

Junctional cervicothoracic scoliosis

This scoliosis is very uncommon.

General Treatment Principles Including Bracing

Appropriate treatment protocols are based on classification of the scoliosis and take into consideration factors affecting an individual's compliance.

While a systematic review of the limited number of clinical trials concludes that the "effectiveness of bracing and exercises is not yet established, but might be promising" (112), osteopathic treatment considerations for scoliosis according to its severity follows these general guidelines (108).

For **mild scoliosis**, use:

- OMT
- Konstantin exercises
- Functional orthotics
- Patient and family education

For **moderate scoliosis**, use:

- OMT
- Konstantin exercises
- Patient and family education
- Bracing
- (Electrical stimulation—debatable efficacy)

For **severe scoliosis**, consider surgery and adjunctive measures, including those listed for moderate scoliosis. Adjunctively adding patient-specific exercises to a bracing regimen, for example, may help reduce the degree that the spine returns to prebrace levels after discontinuing the bracing procedure (113).

Anyone with scoliosis of more than 15 to 20 degrees, a progressive curvature, or an intractable low back pain that is irresponsive of conservative treatment measures, should be referred to a physician who specializes in the treatment of this condition.

The goals of treatment are to obtain flexibility and improved balance of the spine. Decide what can be improved and then correct the primary cause or at least prevent the scoliosis from progressing. Postpone fusions as long as possible without endangering function or the patient's life. Osteopathic manipulation is a definite part of the management of a patient with scoliosis. The person with scoliosis must be able to compensate for the new posture that is introduced by the treatment methods used to prevent progression or reduce the severity of the curvatures.

Osteopathic Manipulative Treatment

When structural scoliosis is present, the goal of direct manipulation is to optimize the function of the existing structure. It is not primarily intended to straighten the curvatures. OMT should remove joint somatic dysfunction but should also include soft tissue, fascial releases, and indirect treatments designed to improve the body's general range of motion. Stretch the lumbosacral tissues and institute exercises to reduce the LSA and strengthen the psoas and abdominal muscles. After structural strains are allowed to heal, introduce a formal set of scoliosis exercises (such as Konstantin [64]) and self-treatment strategies for the soft tissues.

Orthopedic appliances, orthotics, or braces may also be used in conjunction with OMT. These adjunctive modalities were conceived to support, align, or prevent deformity and may stabilize function of a hypermobile part of the body. Braces are more effective if the scoliosis is moderate, if the spine is mobile, and if the spine still has not fully matured.

Braces

The Milwaukee brace (Fig. 36.33A) was introduced in 1945 and has been the standard for scoliosis bracing for many years. It is individually fitted and easy to prescribe, but it is also hard to wear

and is costly. It is worn 23 hours a day with only 1 hour allowed out of the brace for applying skin care. This brace is used in a growing patient with 20- to 40-degree curves. It works to control the scoliotic (lateral) curves until the spine matures, which is generally around age 21.

It is necessary to exercise the muscles that are supported by static braces or appliances. Studies suggest that, even for patients with a good reduction in the Cobb measurements, after a few years their curves return to approximately the extent present at the time that the brace was introduced.

An alternative brace for some patients with scoliosis is the Boston brace (Fig. 36.33B). This brace is made of plastic and is designed to work on deformities such as lordosis and rotation as well as scoliosis. The Boston brace can be used only if the apex of the curve is below T10. In these particular patients, it is helpful in addressing postural curves in all three cardinal planes.

Electrical Stimulation

Electrical stimulation was introduced as a treatment option in the 1970s. It was originally applied to the convexity of the curve and may be considered when the curve is in the thoracic region, measures 10 to 40 degrees, and the spine is flexible. This concept enjoyed some degree of popularity but is not often used today; its efficacy being up for debate. If electrical stimulation is applied to a patient's lumbar curve, it increases the lumbar lordosis.

Surgery

Surgical fusion is performed only in one out of every 1,000 scoliosis cases. It is usually considered for scoliosis patients with progressive 45 to 50 degree curves in order to prevent the heart and lung complications that accompany curvatures >50 degrees. The placement of stainless steel Harrington rods (Fig. 36.34) and spinal fusion is an extensive surgery. The mechanical power of the body is dramatically demonstrated by the propensity of the rods to become stressed and break, requiring another extensive surgery to replace them.

Horizontal Plane Decomensation

Clinical Presentation

Patients with horizontal plane problems often present with muscle imbalance. For example, frequently the rectus femoris muscle is tight on one side and the hamstrings are tight on the other. In this situation, they may complain more of knee than back pain. Such muscle imbalance, however, leads to a similarly wide range of symptoms as with postural disturbance in any other postural plane.

As these patients stand in front of you with their feet aligned, one or more of the following may seem to be more anterior than the other:

- ASIS
- Lower rib cage
- Hand
- Shoulder at the acromioclavicular joint
- Mastoid process

In compensated patients, the anterior component will alternate in sequential transition zones. Those with decompensation are more likely to be symptomatic because as they walk they are less capable of positioning one region of the body in line with the region above or below.

Posture in the horizontal plane is linked directly to that in the coronal plane. Interestingly, in use of orthotic devices to modify the

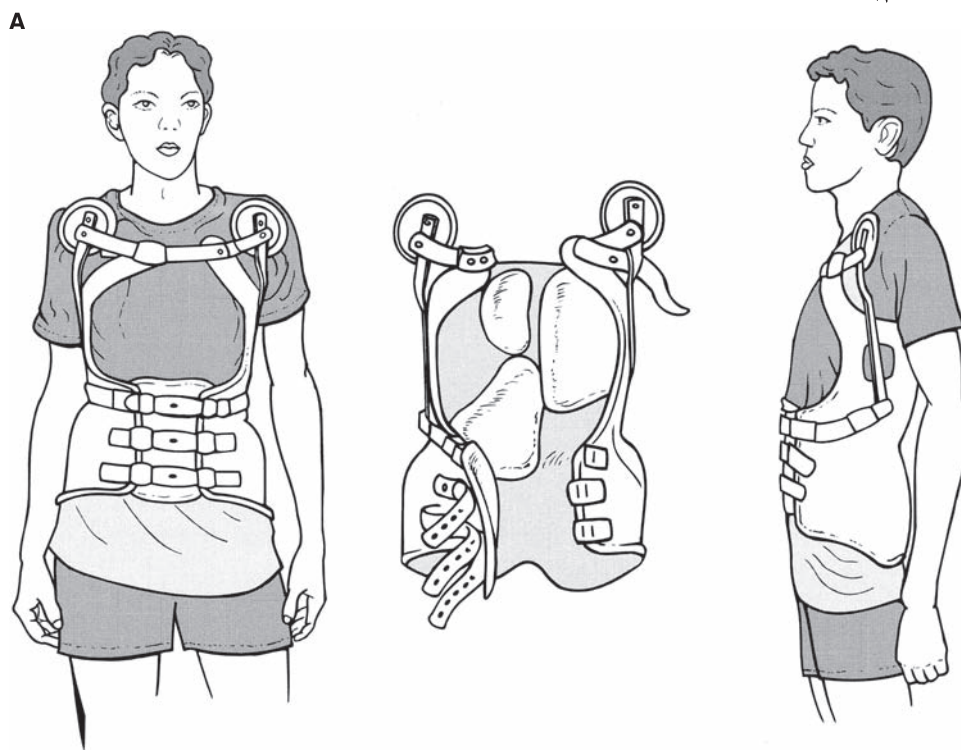

Figure 36-33 A. Milwaukee brace.
B. Boston brace.

other cardinal planes, the horizontal plane seems to be the second most affected. For example:

- Heel lift effects: coronal → horizontal → sagittal
- Levitor effects: sagittal → horizontal → coronal

Treatment Considerations—Functional Conditions

The functional orthotic best suited to modify posture in the horizontal plane is the anterior sole lift. The clinical use of anterior

sole lifts (in distinction from heel lifts) or the combination of an anterior lift in one shoe and/or a heel lift in the opposite shoe to affect posture in the horizontal plane has largely been explored by osteopathic physicians, Ross Pope and James Carlson (114). An increase in the sole height of a shoe encourages rotation of the pelvis toward that same side. A unilateral heel lift rotates the pelvis to a lesser degree and rotates it away from the lifted side (108). Because this method is relatively new, few clinical trials have been performed. The predominance of clinical experience, however,

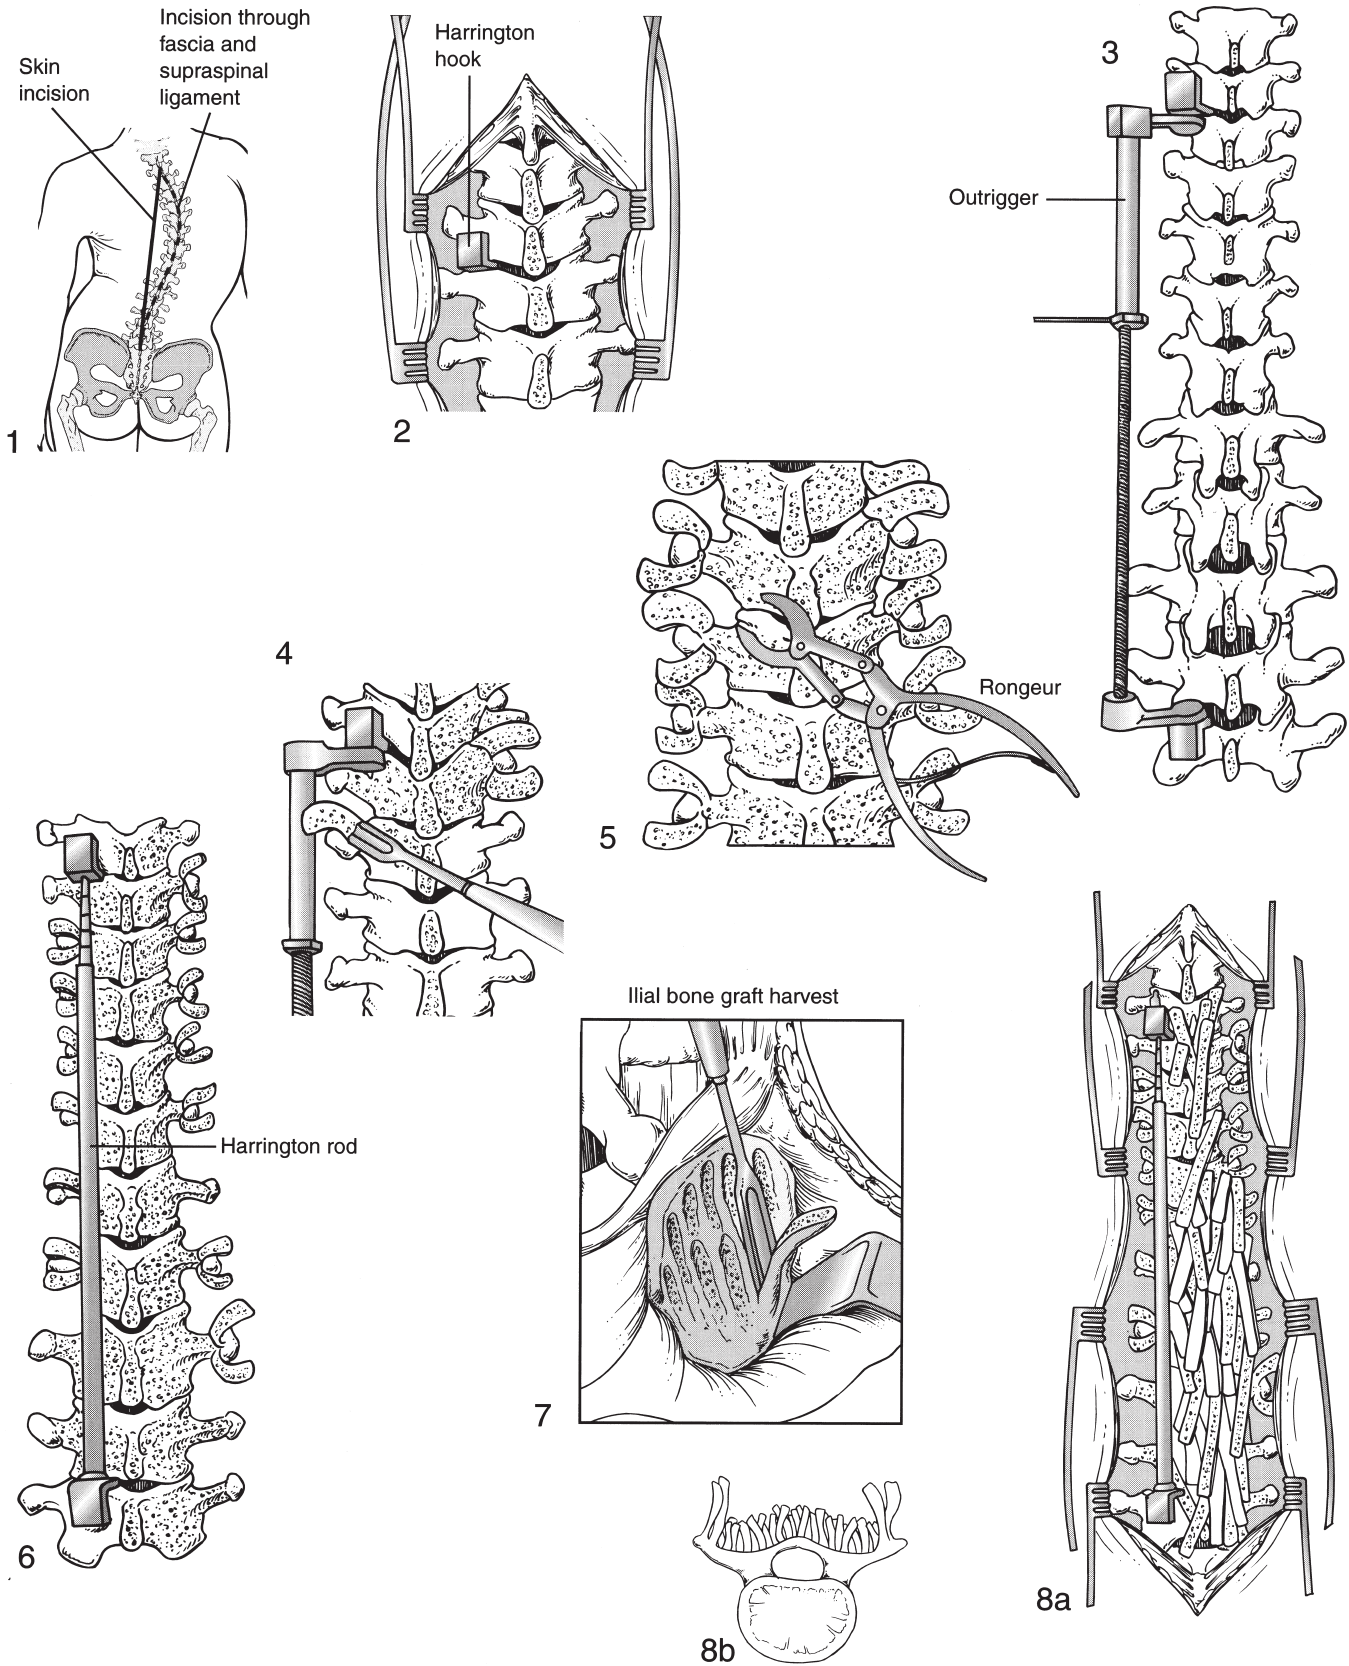

Figure 36-34 Surgical fusion with Harrington rod implantation. This extensive surgery is reserved for patients with curves >45 degrees. A major clinical goal is to stop structural progression of a curve before it seriously compromises cardiopulmonary function.

suggests the following guidelines, which are adapted to each individual patient's evaluation and response.

Anterior lift therapy rotates the pelvis toward the same side; heel lifts may rotate the pelvis away from the lift side. Treatment of both planes simultaneously is often warranted, as side bending and rotation are biomechanically linked motions. A heel lift pushes that side of the pelvis anteriorly in the horizontal plane because the lift is behind the axis of motion (i.e., rotates the pelvis away from the side of the heel lift). Anterior sole lifts create their effect anterior to the axis causing that side of the pelvis to rotate posteriorly in the horizontal plane (i.e., rotate the pelvis toward the side of the sole lift) (see Fig. 36.30).

In the treatment of pelvic rotation assuming coexistent sacral base unleveling, follow these principles:

For pelvic rotation <5 mm: Usually it is not necessary to treat a pelvic rotation <5 mm. However, if the sacral base unleveling is treated with heel lifts, this should be done according to the principles outlined for coronal plane postural balancing. Recheck to determine if any unwanted pelvic rotation occurs secondary to the heel lift therapy.

For pelvic rotation of 5 to 10 mm: For pelvic rotation of 5 to 10 mm, both sacral base (coronal plane) and rotational (horizontal plane) components are treated simultaneously. Begin with appropriate 1/8-inch anterior and heel lifts, progressively increasing in 1/8-in increments every 2 weeks.

For pelvic rotation > 10 mm: Pelvic rotations more than 10 mm should first be treated with an anterior (sole) lift of 1/4 in, and the postural study then rechecked before attempting heel lifts. Thereafter, sacral base unleveling and pelvic rotation are treated simultaneously with 1/8-in incremental changes in anterior (sole) and heel lifts every 2 weeks.

Treatment Considerations—Structural/Pathological Conditions

Rotoscoliosis: See coronal plane structural conditions mentioned earlier.

Sagittal Plane Decompensation

Functional Considerations: Kyphotic/Lordotic Curves

In 1934 Ferguson noted, *Our spines were developed for the four-footed position and are not yet adapted to the erect, so mechanical weakness at the lumbosacral area is usual rather than exceptional. We must consider the lumbosacral area, not as normal or abnormal, but as mechanically sound or mechanically unsound* (115).

Clinical Presentation

Posture-related disorders in the sagittal plane include those defined by the degree of their lordotic and kyphotic curves; those defined by their distinctive pattern of somatic dysfunctions including muscle imbalance and trigger points; and those with related structural or pathological change such as lordosis, kyphosis, or isthmic L5-S1 spondylolisthesis.

Decompensation in predisposed individuals can occur simply by changing the height of the heels in the shoes worn daily or the number of hours spent on a certain type of flooring. Pregnancy, with progressive shifts in regional centers-of-gravity combined with circulating hormonal change (including relaxin), may lead to self-limited sagittal plane decompensation that reverses postpartum, or a more permanent postural condition can be traced back historically to that event.

As with any spectrum ranging from functional to structural disorders, there can be a great deal of overlap in diagnostic findings and treatment strategies. Each relies upon the biomechanical principles discussed in the earlier sections of this chapter. Often, treatment focuses on modifying the underlying functional disorders that aggravated or precipitated the eventual structural changes that define the structural, codable diagnosis.

Often, patients with exaggerated sagittal plane postural decompensation will present with bilaterally tender ILL and a history of recurrent psoas syndrome. They frequently have Barbor's so-called theatre-cocktail party syndrome (116) and, when asked, will tell you that their backs take a significant amount of time to relax after they lie down to rest. They may give a history of recurrent or chronic low back pain, headaches, and other bilateral signs and symptoms of GSP.

Treatment Considerations

Treatment for functional sagittal plane disorders incorporates the same general postural principles as in the other cardinal planes. There are specific recommendations however for the certain aspects of patient education, exercise, and manipulative components.

Patients with increased sagittal plane curves need to be told to avoid heels that exceed more than 1/2 in on their shoes; they may even benefit from a reverse heel. Sleeping on their stomach should be discouraged; sleeping on their sides with a pillow between their knees helps to reduce and relax overused quadratus lumborum muscles. It is particularly useful to advise this group of patients to sit upright with both feet on the floor directly below their knees. A normal lordotic curve should also be maintained at all times; slumping in an easy chair with prolonged bilateral shortening of the psoas muscles should be avoided. When standing in one spot for a prolonged period of time, a small step placed underneath one foot often provides stress relief on the low back.

An ideal exercise for patients with functional or structural sagittal plane problems is the *pelvic narrow-and-coil exercise*. (See Fig. 36.26). Alternatively, the patient can be encouraged to tilt their pelvis in the upright position against a door jamb.

A variety of OMT strategies are appropriate in addressing individuals who have sagittal plane postural decompensation. In addition to treatment of the transitional areas that is a part of every postural model treatment, specific sagittal plane care in the lumbosacral region includes techniques such as the "frog" mobilization for sacral nutation or lumbar hyperlordosis (Fig. 36.35).

Structural/Pathological Conditions: Kyphosis, Lordosis, and Spondylolisthesis

The treatment of pathologic change in the sagittal plane, including lordosis, kyphosis, and isthmic and dysplastic spondylolisthesis builds upon the treatment used for functional sagittal plane problems.

Dysplastic and Isthmic Spondylolistheses

Spondylolisthesis, which is often mistaken to be solely a congenital abnormality, is frequently and incorrectly treated as a single entity; rather, it is a structural outcome of several different processes, each with their own biomechanical and pathophysiological risks (see Table 36.7). Postural care is most beneficial in the case of the dysplastic and isthmic types and the remainder of this chapter will focus on isthmic L5-S1 spondylolisthesis as a bony structural change often initiated by stress occurring predominantly in the sagittal plane (46). This functional stress progresses through the previously described chronic, progression of compensation,

Figure 36-35 Treatment of pelvis. (Courtesy of William Kuchera, D.O., F.A.A.O.)

adaptation, decompensation leading to pathological spondylosis, and finally spondylolisthesis. In the osteopathic postural model, treatment is directed less to these acquired bony structural changes than to reducing functional demands placed on musculoligamentous structures ill-equipped to resist continued postural stresses in the region.

Background

The biomechanical principles of diagnosis and treatment of patients with sagittal plane postural problems can be directly applied to the management of patients with spondylolisthesis. The generic term *spondylolisthesis* is derived from the Greek roots roughly meaning *vertebra sliding down a slippery path*. It describes the common finding of a group of spinal disorders in which there is a forward displacement of one vertebra over another, usually the fifth lumbar over the body of the first sacral segment.

With the advent of modern radiology, the study of spondylolisthesis began, including its true incidence, location, classification, and significance. The classification of spondylolisthesis subsequently evolved into the currently accepted causal categories delineated by Wiltse et al. (117) shown in Table 36.7.

Regardless of specific hereditary and developmental factors, spondylolisthesis refers to a group of disorders having a particular common mechanical consequence. Applying the mechanical perspective permits better understanding of the general symptom complex. Applying mechanical treatment protocols provides the rational basis for osteopathic conservative management of patients diagnosed as having spondylolisthesis.

Causes: Hereditary Predisposition

Two observations argue against a person having a direct inheritance of spondylolisthesis. First, although there is an increased incidence of spondylolisthesis within family groups (118,119), a significant number of these family members exhibit different types of spondylolisthesis. Second, infants are rarely reported to have spondylolysis (also known as *prespondylolisthesis*). The incidence increases after children assume an active upright position and continues up until age 20, when it matches the 5% incidence of the general population (120).

The genetic link appears to be more likely involved in those factors that predispose the region to instability. Posterior defects such as spina bifida occulta and open sacrum are almost invariably inherited in dysplastic spondylolisthesis and in a third of patients with the isthmic type (120). This lack of posterior support may concentrate postural weight-bearing forces in the area, resulting in forward subluxation of the entire L5 unit in dysplastic spondylolisthesis. In this fashion and under certain biomechanical stressors, genetics could predispose a patient to stress fracture of the pars interarticularis which, in isthmic spondylolisthesis at the most commonly involved level, potentiates forward sliding of the anterior elements of L5 on S1 (119).

Conversely, degenerative spondylolisthesis (formally called *pseudospondylolisthesis*) occurs two to three times more frequently in African Americans, who are also known to have greater L5-S1 stability (121). In general, patients with degenerative spondylolisthesis have a low PI for age (68) (see Fig. 36.21) and higher incidences of sacralization of L5 or block-shaped L5 vertebrae. They also have a much lower incidence of posterior defects (121) than seen in the general population. The increased stability at L5 encourages instability higher in the lumbar spine.

Causes: Developmental Factors

Certain developmental factors have been statistically or logically implicated in spondylolisthesis. Foremost among these factors are posture and microtrauma (122–127).

Posture is strongly implicated in the development of spondylolisthesis and spondylolysis (prespondylolisthesis). Spondylolysis does not develop prior to the assumption of the standing posture. In one study, out of 125 institutionalized patients who had never assumed a standing position, none demonstrated a pars defect (123). No other primate has fully adopted human upright posture, nor does any other primate develop a lytic type of spondylolisthesis.

Postural decompensation as measured by the Jungmann PI is substantially higher in patients with L5-S1 spondylolisthesis (122) than in the general population. Increasing PI and increasing lumbosacral instability may, in part, address Wiltse's observation (117) that many patients develop lesions in the pars at approximately age 6 and then have no problems with it until their mid-30s.

Hyperlordosis, in particular, has been the postural fault most implicated in isthmic spondylolysis and spondylolisthesis (125,127,128). Increased lordosis transfers weight bearing from the vertebral bodies onto the articular facets in joint capsules (82). These structures are ill-adapted to continuously carry the body's weight. An anterior weight-bearing line is also known to create similar mechanics and should be looked for and evaluated. Certain activities, such as gymnastics, further increase backward bending demands in the lumbar spine. Subsequently, many young gymnasts permanently adopt an exaggerated lordotic posture. Not surprisingly, many female gymnasts demonstrate spondylolysis; having an incidence four times that of the general female population (129).

Other groups are specifically subject to increased stress in the lumbopelvic area and each has been shown to have an increased incidence of spondylolysis. These subpopulations included weight lifters, soldiers carrying backpacks, and college football linemen. Repetitive lumbosacral motion is a common characteristic in all types of spondylolisthesis except in those due to trauma. Therefore, frequent stress in posturally or congenitally unstable areas is implicated, especially during the adolescent growth spurt, in the development of fatigue fractures, the proposed basic lesion in isthmic spondylolisthesis (119).

TABLE 36.7

Classification of Spondylolisthesis

Diagnosis	Type	Percent	Criteria	Comments
Type I Dysplastic spondylolisthesis	Dysplastic	21	Congenital deficiency of neural arch of L5 or upper sacrum. Insufficiency of superior sacral facets.	Two girls: one boy is the ratio; almost exclusively L5; lumbosacral facets also approach horizontal
Type IIA Isthmic spondylolisthesis	Isthmic Subtype A Subtype B Subtype C	51	Pars interarticularis defect A. Lytic-fatigue fracture of pars B. Elongated but intact pars C. Acutely fractured pars	Almost exclusively L5 A. Most common type below age 50 y B. Probably due to repeated microfractures healing elongated fashion as slippage occurs C. History of severe trauma may heal with immobilization
Type IIB				
Type III Degenerative spondylolisthesis	Degenerative	25	Degenerative changes at apophyseal joints due to longstanding intersegmental instability	Four female: one male; three black: one white; six to nine times more common at L4; sacralization 4× general population; not seen before age 40; rare between 40 and 50; slippage 30% maximum
Type IV Traumatic spondylolisthesis	Traumatic	1	Due to fractures in other areas of the bony hook than the pars	Heals with immobilization
Type V	Pathologic	2	Generalized or localized bone disease	Neoplasm, osteogenesis imperfecta, Paget disease, arthrogryposis, iatrogenic postlumbar fusion; Kuskokwim disease

Diagnosis

Of the estimated 5% of the population with spondylolisthesis, approximately half are asymptomatic (130). Those who become symptomatic commonly do so after the age of 20. Preventive care depends on early and accurate diagnosis.

Diagnostic testing should include the following:

- Radiography
- PI measurement

- History
- Physical examination
- Spinal palpation
- Neurologic testing

Radiographic analysis

Radiology has greatly enhanced our ability to diagnose spondylolisthesis even in totally asymptomatic patients; it is a modality that provides prognostic data (122,131). It must be realized

that there are significant differences between the measurements obtained from weight-bearing and non-weight-bearing x-ray films (131,132). From a pragmatic point of view, the standardized postural standing film series offers reproducible, functional, and postural data that are preferred.

Radiographically, gross spondylolisthesis can be seen and quantified on a lateral x-ray view. However, 45-degree oblique films may be necessary to see a subtle or unilateral spondylolysis (Fig. 36.36). In this view, the pars interarticularis in isthmic Type II-B spondylolisthesis has been described as the Greyhound of Hensinger because of the "long neck" rather than the "collar" on the "Scotty dog" (133).

Meyerding (134) provided the simplest system of grading (Fig. 36.37A). Spondylolisthesis is assigned the classification of I, II, III, or IV, respectively, for each one fourth of the vertebral body that the upper vertebra is displaced forward on the vertebra below. The more precise displacement measurement of Taillard (135) (Fig. 36.37B) can detect minor progression but it is rarely needed clinically. The Meyerding system is more commonly used, more quickly applied, and is clinically relevant.

The fastest progression of isthmic spondylolisthesis is seen between ages 9 and 15. Rarely is there progression in the Meyerding grading over the age of 20, especially in patients having a sclerotic buttress on the anterior lip of the sacrum (123,136).

Other signs of instability or its effects in the area can be seen with radiographic analysis (27,40,128,137,138) including:

- Angle of slip
- Osteophytes
- Calcified ligaments (especially iliolumbar)
- Increased PI
- Anterior weight-bearing mechanics
- Increased lordosis or LSA
- Disc narrowing

Whenever possible, radiographic typing of the spondylolisthesis should be performed because it might affect treatment or prognosis.

Clinical Presentation

The age of the symptomatic patient determines the clinical presentation. While spondylolisthesis is perhaps the most common cause

of persistent low back pain and sciatica in children and adolescents (139), most children with spondylolisthesis in this age group do not have pain. These individuals are often identified when a school official or parent notes a change in gait or posture. If any pain is expressed, it is usually described as a dull ache in the buttock or posterior thigh; symptoms are rarely expressed below the knee (133).

Tight hamstrings (131,140) are found in 80% of young people with symptomatic spondylolysis or spondylolisthesis and to a lesser extent in asymptomatic patients. This finding probably results from postural stress and an attempt to stabilize the unstable lumbosacral junction (and is not from root impingement). Inability to bend over and touch one's toes reveals this deficit. It can also be used to uncover the nonfixed scoliosis (123,141) that exists in approximately 30% of these patients secondary to lumbar irritation and paraspinal spasm. Furthermore, as a result of having tight hamstrings, those patients having spondylolisthesis rated greater than grade II have a pathognomonic stiff-legged, short stride, waddling gait (142,143), in which the pelvis rotates with each step.

Distortion of the pelvis and trunk appears in patients having a Meyerding grade II or III. They have flared ilia in the back and an abdomen that is thrust forward. These young people have a short waist, a transverse abdominal crease at the level of the umbilicus, and flattened heart-shaped buttocks. Only 2% of young people demonstrate any objective neurologic change (82) requiring extensive electromyographic or myelographic workup.

One of the most consistent physical findings associated with patients younger than 30 years of age and with dysplastic or isthmic spondylolisthesis is tight hamstrings that restrict forward flexion of the trunk. In contrast, the most constant physical finding in patients older than 50 years of age with degenerative spondylolisthesis is the ease with which they are able to touch their toes without bending their knees or obliterating their lumbar lordosis.

The flexibility of a patient with degenerative spondylolisthesis is thought to result from laxity of the pelvicochanteric and hamstring muscle groups. The unstable spondylolisthetic joint at the L4-5 level predisposes the patient to manifest L5 root neurologic symptoms. The patient is more likely to have somatovisceral

complaints of a hypersympathetic nature including constipation or irregular menses (72). Symptoms of pelvic congestion and vague lower extremity complaints are also common in adults with spondylolisthesis. These result from the hyperlordosis, visceroptosis, and poor thoracic abdominal diaphragmatic function that accompany spondylolisthesis (25,72,144,145).

Adult patients are more likely to complain of pain. Their pain is usually aggravated by moderate activity or prolonged standing and relieved by rest or limited activity. Because of chronic overt instability of the lumbosacral region, these patients have poorly responsive soft tissues (83), somatic dysfunction, and multiple myofascial points that, when stressed, react out of proportion to the initiating event and produce palpable spasm and low back pain. Pain can thus be caused by several structures in the area other than the spondylolisthetic segment. These structures are also subject to the instability of the region and the mechanical disadvantage that is localized there. It is, therefore, difficult to sort out when the pain is caused by spondylolisthesis, when it is the result of somatic dysfunction of muscular, ligamentous, or joint structures, or when it is of discogenic origin.

In patients older than 20 years of age with spondylolisthesis of <33%, pain is probably caused by one of three mechanisms (123):

- Disc degeneration at the level of the defect
- Root impingement by fibrocartilaginous build-up
- Referral from stressed posterior ligaments and soft tissues

In our clinical experience, pain in these patients is most commonly referred from trigger points in the quadratus lumborum, glutei, and piriformis muscles, and from iliolumbar and posterior sacroiliac ligaments. This best supports the third mechanism above.

The cauda equina becomes physically involved in isthmic spondylolisthesis patients with more than a 50% slip (more than a grade II). In these patients, low back pain is attributed directly to the spondylolisthesis itself. Because the dysplastic type carries the posterior arch forward, no more than 25% slippage is necessary to manifest a cauda equina syndrome (119). Degenerative spondylolisthesis, by nature of its mechanism, does not progress beyond a 30% slip (119,123,128). The instability of this joint (usually L4-5), coupled with physical continuity with the posterior arch, usually results in L5 root impingement. Myelograms performed on these patients generally show hourglass constriction (128) at that level. Therefore, the differential and accurate diagnosis of the primary cause of back pain in a patient with spondylolisthesis requires careful palpatory and neurologic physical examination and diagnosis in addition to the radiographic and historical findings just outlined.

Palpatory Findings

Increased intersegmental motion in the lumbosacral region is usually a sign of instability and severe degeneration. This increased

motion is grossly apparent even on x-ray films. However, palpatory evidence (83) gathered by those trained to palpate segmental motion is generally considered to have twice the diagnostic yield for instability (28.6%) when compared to a diagnosis by x-ray studies (15%).

Palpatory findings in patients with spondylolisthesis reveal an anteriorly located spinous process or drop-off sign (Fig. 36.38). The anterior spinous process is associated with the vertebra that has slipped forward in dysplastic and degenerative spondylolisthesis. It is the adjacent vertebra, above the slipped segment, in isthmic spondylolisthesis.

Sacral base motion is excessively lax when it is rocked anteriorly around the middle transverse axis, which might result in an associated subjective buttock or posterior thigh discomfort. If testing sacral base motion causes neurological symptoms, particular care should be taken in designing a treatment protocol that does not produce neurological symptoms.

Paraspinal tissues vary in palpatory quality depending on the degree of symptoms present. Often, they display multiple myofascial tender points. Even in the asymptomatic state, they are slow to relax and are somewhat boggy (congested) to palpation. Muscle strength testing of the low back muscles demonstrates nearly full flexibility but decreased strength and endurance.

The iliolumbar ligament should be palpated bilaterally in every patient with symptomatic spondylolisthesis. Attached to the transverse processes of L5, the anterior sacroiliac joint, and the iliac crest, the iliolumbar ligament is anatomically positioned to resist any forward slip of L5 on the sacrum (28). Bilateral palpatory tension and subjective tenderness are often noted over its attachments. The patient may experience lateral thigh or groin referral (Fig. 36.9). Palpation of the iliolumbar ligament is a valuable and sensitive indicator for the success of conservative management programs that are designed to reduce mechanical stress in patients with symptomatic spondylolisthesis.

Neurological Findings

The physical examination of each patient should include a neurological evaluation including deep tendon reflexes, muscle strength testing, and straight leg raising. Electromyographic testing or imaging studies are indicated if radicular symptoms are present. It is especially important to assess the condition of the L4 disc (123) if surgical fusion is contemplated.

General Treatment Principles

Conservative management is 85% to 90% successful in degenerative spondylolisthesis (123,128). In the minority of children who are symptomatic, only 50% are successfully managed with conservative care (123,133). For immature patients with Meyerding grade III or IV spondylolisthesis, those with progressive subluxation, or a spondylolisthesis that is secondary to an acute fracture, conservative management is probably not indicated without extensive bracing or surgical fusion. The acute fracture group (Table 36.7) responds best to immediate immobilization (123).

For those patients requiring surgery (or bracing), conservative management should be added afterward because the conditions that led to the instability preoperatively are still present postoperatively. In all cases, conservative management should attempt to maximize structure-function relationships.

Patient Education

Education is a key component in the conservative management (130,146,147) of patients with either asymptomatic or symptomatic spondylolisthesis. Goals should center on decreasing

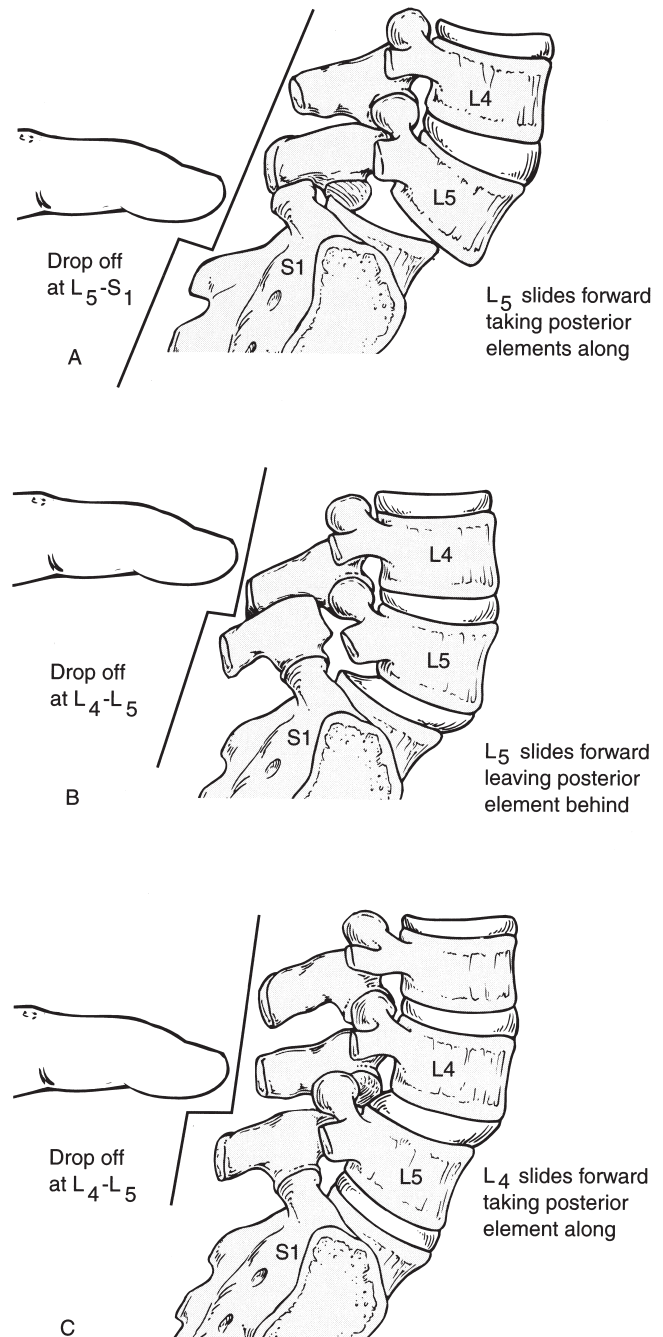

Figure 36-38 Location of anteriorly located spinous process (drop-off sign) depends on underlying mechanism of spondylolisthesis. **A.** In dysplastic spondylolisthesis, L5-S1 horizontal facets allow entire spine to glide forward creating drop-off between L5 and S1. **B.** In isthmic spondylolisthesis, pars defect between L5 and S1 allows anterior elements of L5 to slide forward along with the rest of the spine. Posterior elements of L5 remain behind with the sacrum, creating drop-off between L4 and L5. **C.** Degenerative spondylolisthesis at L4-5 does not affect anterior and posterior elements of the vertebral unit and therefore the drop-off sign is located between L4 and L5. (Courtesy of William Kuchera, D.O., F.A.A.O.)

stress in the unstable lumbosacral region through application of back mechanics, proper exercise and nutrition, and postural improvement techniques. Back schools that offer 36 hours of instruction in teaching back mechanics and appropriate choices for optimum back care are also effective (146). These approaches

immensely increase patient compliance. In the absence of a back school, the individual practitioner should use a minimum of one patient visit (more if necessary) to explain lumbosacral mechanics. Patients are taught to lift properly and to avoid improper lifting, especially over the head, as this increases lumbar lordosis.

The osteopathic physician should advocate proper footwear; high heels in particular increase lumbar lordosis (82). Patients should be advised on correct sleeping, sitting, and standing postures; they should also be counseled on weight loss if necessary. This minimal investment of time reduces the frequency of reinjury or the failure of an otherwise well-conceived conservative program.

Pregnancy significantly affects posture by shifting the weight-bearing line anteriorly and accentuating the lumbar lordotic curve. Unfortunately, this postural stress occurs at a time when the hormonal changes of pregnancy also act to reduce soft tissue stabilization. Women with spondylolisthesis who are contemplating pregnancy should, if possible, prepare their posture and muscle tone in advance. They should also strictly adhere to their obstetrician's weight gain limits. Often, the addition of a Levitor is extremely beneficial, even if it is only for the duration of the pregnancy.

For young, asymptomatic individuals with less than a Meyerding grade I spondylolisthesis, avoid creating a back cripple with excessive restrictions. It is wise to direct these individuals toward a vocation not requiring heavy lifting or strenuous activity (148). In young, asymptomatic people with more than grade I spondylolisthesis, the same vocational goals are upheld but these individuals should also avoid contact sports. Inform young patients and their parents of the concerns and uncertainties involved; stress the need for close follow-up.

Exercise

The response to exercise does not depend on the type of spondylolisthesis (I, II, or III) (147). The goals of exercise are to eventually stabilize the lumbosacral region and diminish the lumbar lordosis (144,147). Weight loss for an overweight patient can also be facilitated by exercise.

Exercise should be of a flexion-type only, rather than flexion-extension combination programs (141). Gramse has reported excellent results with the flexion program (147). The variables examined included relief of pain, need for back supports, return to work status, and recovery. Combination flexion-extension exercise significantly reduced the effectiveness in all of these variables. Pelvic narrow and coil exercise (149–152) with the knees bent in the supine position is extremely effective (Fig. 36.26), although flattening the back against the wall while standing or bringing the chest to the thigh while sitting in a chair can also be beneficial.

The patient must be able to demonstrate their ability to maintain a reduced lordosis before abdominal strengthening exercises such as bent-knee sit-ups are considered. Good abdominal strength adjunctively supports weight-bearing and unloads the spine. Gymnastics, diving, and contact sports are not encouraged. Swimming, however, is considered an excellent activity to cultivate.

Osteopathic Manipulative Treatment

Several authors report a benefit (27,46,72,81,153) from the manipulative management of patients with spondylolisthesis. Manipulative treatment of the patient with spondylolisthesis is extremely helpful in attempting to redress some of the postural decompensation that has occurred over time and to alleviate segmental limitation of motion, which is known to upset the forces resisting spondylolisthesis (128).

The goals (27,46,72,82,154) are reduction of lumbar lordosis and somatic dysfunction. This transfers weight bearing from the posterior elements and tissues back to the vertebral bodies. It specifically relaxes strained, irritable lumbar paraspinal tissues, permitting them to better resist the stresses imposed by the activities of daily living. It also reduces the patient's somatic pain and somatovisceral symptomatology. These goals seek a gradual reestablishment of fascial and muscular balance in order to promote maximal functional weight-bearing posture.

The manipulative program is not simply directed to the lordosis and specific somatic dysfunctions; it also addresses biomechanical support structures. Because of the instability and injury in the lumbosacral junction, high-velocity techniques should be avoided in that area.

In correcting lordosis and recurrent lumbopelvic clinical conditions, the first concern is often balancing the pelvis horizontally (29,82,7). An undiagnosed or uncorrected unilateral, sacral shear somatic dysfunction thwarts the most expert manipulator in achieving this goal and renders functional orthoses such as the Levitor ineffective. This and other nonphysiological somatic dysfunctions can be treated promptly and effectively with OMT.

An unlevel sacral base needs gradual heel lift orthotics before instability and recurrent somatic dysfunction can be effectively addressed. A minimal heel lift, when indicated, can reduce the LSA by 2 to 4 degrees (29) and may move an anterior weight-bearing line as much as an inch posterior (155). Correction of a short leg is also extremely helpful in reducing long-term strain on the iliolumbar ligament. It eliminates somatosomatic referral of groin pain from this structure as well as reducing low back pain and instability in the lumbosacral junction (154,156). A heel lift may also be helpful to the one third of spondylolisthetic young people who have concomitant scoliotic change and the long-term somatovisceral changes resulting from it.

Any intrapelvic somatic dysfunction should be removed; the sacroiliac articulations should be freely mobile. Tight hamstring muscles are gently stretched with isometric muscle energy technique. The use of a vapocoolant spray and stretch over the hamstrings to achieve this goal is often helpful. Fascial unwinding of the lower extremities is well received by patients and eliminates many of the general congestive complaints in this area (J.G. Zink, *personal communication*, 1978).

The thoracic spine and thoracolumbar junction are addressed next. Schwab (153) reported improvement of compensatory lumbar lordotic stresses with mobilization of increased thoracic kyphosis. Fryette (82) emphasized that somatic dysfunction in this area must be corrected before any effective changes could be maintained in the lower lumbosacral junction. Additional consideration of the diaphragm and quadratus lumborum has proven particularly successful in helping to promote lymphatic drainage (25). The quadratus lumborum and the iliolumbar ligament are functionally and structurally related (156) and both should be treated.

Lastly, the lower lumbar region should be approached in a general manner with soft tissue, counterstrain, myofascial release, and fascial unwinding techniques. Address any specific somatic dysfunction with indirect technique. A clinically useful end point is achieved when the intrinsic rhythm of the craniosacral mechanism is easily palpated between the hands as they are monitoring both the thoracolumbar junction and sacrum.

Orthotics, Braces, and Casts

Orthotics play a significant role in the conservative management of patients with spondylolisthesis. The benefits of a heel lift orthotic in helping to lend stability to the lumbosacral region have already been discussed, and the heel lift orthotic is potentially a permanent part

of the patient's treatment program. A corset-like lumbosacral support, conversely, should only be considered for short-term stability (83,130) Grieve (83), however, writes that a support should never be supplied without a plan to eliminate it. Most lumbosacral supports worn for prolonged periods weaken the patient's own supportive mechanisms (130), thereby increasing long-range instability and promoting dependence on the support. For short-term management of lumbar strain, however, these supports can be invaluable in reducing pain and preparing the tissues for a subsequent exercise program.

Types of immobilization, ranging from knee-to-nipple casting to ordinary body casts and corsets, have been studied for their use by patients with spondylolisthesis resulting from an acute fracture (133). The latter two types of immobilization suppress the extremes of bending but do a poor job of diminishing lumbosacral motion with walking (136).

The Levitor functional pelvic orthotic has proven to be extremely effective as an adjunct in the long-term management of symptomatic isthmic spondylolisthesis (27,71,72). Exerting pressure between the pubic symphysis and the base of the sacrum (Fig. 36.27), the Levitor effectively (157) aids in decreasing postural decompensation as measured by PI, in reducing the LSA, and in transferring weight bearing off the posterior tissues and forward to the vertebral bodies. By reducing the chronic strain on these tissues, symptomatic relief from low back pain is accomplished in days to weeks, and implementation of an exercise program can begin shortly thereafter.

Medication

Anti-inflammatory medication, analgesics, muscle relaxants, and bowel softeners all have a limited role in the symptomatic relief of various common symptoms experienced by patients with spondylolisthesis. Because spondylolisthesis is a chronic problem, narcotics have no place in symptom management of these patients. Vapocoolant spray-and-stretch technique and trigger point injection with local anesthetics may be helpful in relieving the secondary myofascial points that occur (152). Injections of proliferative agents are also useful for cases of ligamentous laxity uncorrected by conservative means (158).

Clinical Outcomes

Adjunctive use of the Levitor, for example, has been demonstrated to improve measurable sagittal plane risk factors and to reduce posture-related low back pain (157,159). In a 1985 study involving 109 patients with recalcitrant chronic low back pain, 30% of patients were found to improve with manipulation and postural exercise alone. When a functional orthosis (Levitor) was added to this program, 76% improved.

Degenerative Spondylolisthesis

Acquired degenerative spondylolisthesis has a different etiology and affects a different and more senior patient population. Patients with this pathology typically possess highly flexible hamstrings with very stable L5-S1 junction is in contradistinction with the very tight hamstrings and unstable L5-S1 of isthmic and dysplastic types of spondylolisthesis (see comparative Table 36.7). For this reason, postural care is only indicated in those patients who independently demonstrate the clinical findings to warrant the same.

SUMMARY

The postural-biomechanical model is one of several osteopathic approaches to patient care. It has several overlapping considerations with the neurological-autonomic model and the

respiratory-circulatory model. Therefore, understanding this model is essential for the osteopathic physician.

Head and Suboccipital Region

KURT P. HEINKING, ROBERT E. KAPPLER, AND KENNETH A. RAMEY

KEY CONCEPTS

- Osteopathic manipulative treatment can improve functional outcomes in patients with sinus, eye, and ear disorders.
- Understanding the drainage patterns of the paranasal sinuses, the lymphatic channels, and the venous system assists the clinician to find possible points of connective tissue blockage.
- Knowing the parasympathetic and sympathetic innervation of head and neck as well as the consequences of autonomic nerve dysfunction can guide the clinician in treatment
- Evaluation of osteopathic cranial motion and the consideration of dural continuity are important when treating the head region.
- Somatic dysfunction plays a significant role in sinusitis, middle ear infections, and disorders of hearing and equilibrium.
- Somatic dysfunction may contribute to tension, migraine, and cluster headaches.
- Cranial dysfunction may contribute to facial nerve irritation and Bell palsy.
- Temporomandibular joint dysfunction is a common problem that responds well to manipulative treatment.

INTRODUCTION

Osteopathic manipulative treatment (OMT) in the head region is based on anatomy and physiologic function of the neurologic, vascular, muscular, articular, and lymphatic systems. Somatic dysfunction occurs in the head and face. Clinicians need to be as comfortable diagnosing and treating this region as they are in other regions of the body. Treatment of somatic dysfunction of the involved structures of the head is thought to diminish tissue congestion, improve sinus drainage, resolve motion restrictions, normalize autonomic tone, and decrease pain. Diagnosis for somatic dysfunction in this region is integrated with evaluation of the other HEENT structures. OMT may be used as a primary treatment, or as an adjunctive treatment with pharmacologic agents, hot or cold compresses, gargles, dental appliances, corrective lenses, hearing aids, creams or ointments, shampoos, eye or eardrops, massage, acupuncture, or other treatments. This chapter will demonstrate how the diagnosis of somatic dysfunction is critical to treating patients with HEENT disorders. Many studies have shown that diagnosis of somatic dysfunction and OMT improves patient outcome in a variety of conditions.

DESCRIPTIVE AND FUNCTIONAL ANATOMY

The Adult Skull

The adult skull is composed of 29 bones (Figs. 37.1–37.7). These are summarized in Table 37.1. From an osteopathic cranial perspective, they can be divided into midline and paired bones. During osteopathic cranial flexion, the midline bones (sphenoid, occiput, ethmoid, and vomer) move into flexion around their respective transverse axes. The paired bones externally rotate during osteopathic cranial flexion. During osteopathic cranial extension, the reverse occurs (1).

The Infant's Skull

The infant's skull is divisible into two parts: the neurocranium (vault and base) surrounds and protects the brain and consists of eight

bones; the facial skeleton or viscerocranium (face) consists of 13 bones. The neurocranium (vault and base) can be divided into two parts: the vault or calvaria, from a membranous origin; and the base, from a cartilaginous origin (23). The bones of the vault are separated by membranous spaces, the sutures. The fontanels are present at the angles of the parietal bones and at the junctions between several sutures of the calvarial bones. There are six fontanels: two are medial and unpaired (the anterior or bregmatic, posterior or lambdatic) and four are lateral and paired (the sphenoid and mastoid), two on either side (23). At birth, the skull is quite large in proportion to the other parts of the skeleton, and the neurocranium (vault and base) is, in turn, much larger than the viscerocranium (face).

There is a significant difference in the growth rate of the neurocranium as compared to that of the viscerocranium. The neurocranium grows quickly from birth to about the seventh year. At about 5 years of age, although brain growth is almost complete, the face has grown to only half its adult size (23). The bones of the orbital cavity—the frontal, lacrimal, palatine, zygomatic, ethmoid, maxilla, and sphenoid—develop in membrane and are very reactive to trauma and growth.

Most individual bones of the skull arise from multiple centers of ossification. The cartilaginous portion of the occipital bone is not fused at birth and is derived from five primary centers of ossification. The sphenoid bone is a more complex structure with multiple centers of ossification that unite to result in the three units. The occiput, sphenoid, and temporal bones demonstrate both *endochondral* and *intra-membranous* types of ossification. When developed, the ossification centers form the bones of the calvaria. They are the frontal bones, the parietals, the squamous portions of the temporal bones, and the upper portion of the occipital (supraoccipital) squama (23).

The sutures separating these bones are the sagittal suture between the parietal bones, the metopic suture between the frontal bones, the paired coronal sutures between the two frontal and two parietal bones, the paired lambdoidal sutures between the supraoccipital and parietal bones, and the squamous sutures between the parietal, temporal, and sphenoid bones.

Figure 37-1 Frontal view of skull. (From Agur AMR. *Grant's Atlas of Anatomy*. 9th Ed. Baltimore, MD: Williams & Wilkins, 1991:452.)

At birth, ossification is not yet complete for most of the bones and they still consist of several component parts. For example, consider the occiput, sphenoid, and temporals. At birth, the occiput consists of four portions: the basiocciput, two "exocciputs," and the squama. The different articulations of the cranial base are named synchondroses. By definition, synchondroses are cartilaginous joints in which two bones are united by a fibrocartilage. At birth,

the sphenoid presents essentially as three main parts: a central part that is the body and the lesser wings, and two lateral parts, each consisting of a greater wing and the associated pterygoid process. At birth, the temporal bones each consist of four parts: the squamous, petrous and tympanic portions, and the styloid process. The petrous portion is cartilaginous in origin; the squamous and tympanic portions are membranous in origin (23).

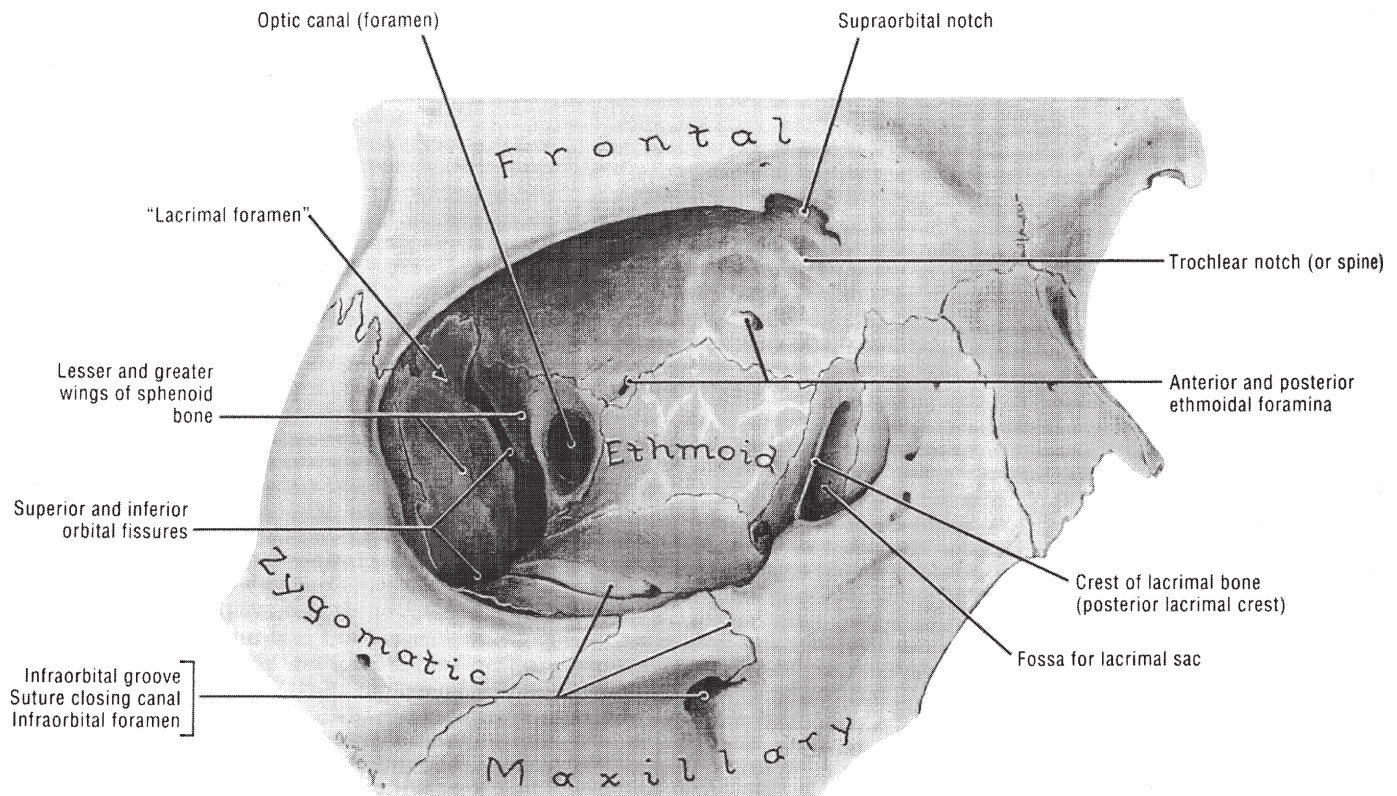

Figure 37-2 Orbital view of skull. (From Agur AMR. *Grant's Atlas of Anatomy*. 9th Ed. Baltimore, MD: Williams & Wilkins, 1991:482.)

During delivery and expulsion of the fetus, the occiput is positioned under the pubic symphysis around which extension of the craniocervical junction takes place. The superior and the inferior parts of the occipital squama may be stressed with resultant cranial somatic dysfunction.

THE PARANASAL SINUSES

The paranasal sinuses are air-filled extensions of the nasal cavity into the following cranial bones:

- Frontal
- Ethmoid
- Sphenoid
- Maxillae

The paranasal sinuses are small at birth and development proceeds at different rates, between individuals. The maxillary and sphenoidal sinuses develop first, about the fourth month of gestation. This is followed by frontal and ethmoidal sinus development, in the 6th month. The ethmoidal air cells reach mature size at 12 to 13 years of age. The maxillary sinuses assume their pyramidal shape between 5 and 8 years, reaching full size by age 15. The sphenoidal sinuses become pneumatized, at about 5 years of age (23).

The sinuses are lined with mucous membranes and connect via openings within the nasal cavities. All of the paranasal sinuses drain directly or indirectly into the nasal cavity. The balance of parasympathetic and sympathetic tone determines the nature of the mucosal secretions. Parasympathetic fibers from cranial nerve (CN) VII synapse in the sphenopalatine ganglion and promote thin, watery, saliva-like secretions. Sympathetic fibers from T1-T4

synapse in the cervical ganglia and promote thick, sticky secretions. Frontal and sphenoidal sinuses are absent at birth, although a few ethmoid cells and small maxillary sinuses are present. The ethmoid and maxillary sinuses enlarge during childhood. The frontal and sphenoidal sinuses develop during childhood and adolescence. Sinus headache referral patterns are predictable because branches of the trigeminal nerve innervate the sinuses.

FRONTAL SINUSES

The frontal sinuses drain into the middle meatus. The innervation is from the supraorbital nerves (4).

ETHMOID SINUSES

The anterior and middle ethmoid cells drain into the middle meatus. The posterior ethmoid cells drain into the superior meatus. The innervation is from the anterior and posterior ethmoidal nerves (sensory supply) and orbital branches of the pterygopalatine ganglion (parasympathetic secretomotor fibers) (4).

SPHENOID SINUSES

These drain into the sphenoidal recess in close approximation to the cavernous sinuses. The innervation arises from the posterior ethmoidal nerves (sensory) and orbital branches of the pterygopalatine ganglion (secretomotor fibers) (4). Infections of the sphenoid sinus are especially dangerous because of close association with the pituitary, brainstem, cavernous sinus, and CNs.

Figure 37-3 Lateral view of skull. (From Agur AMR. *Grant's Atlas of Anatomy*. 9th Ed. Baltimore, MD: Williams & Wilkins, 1991:454.)

Sphenoidal sinusitis is usually severely disabling and is associated with severe, deep head pain.

MAXILLARY SINUSES

The largest of the paranasal sinuses drain into the middle meatus. The innervation is derived from the infraorbital and the anterior, middle, and posterior superior alveolar nerves (4).

Sinus dysfunction (acute and chronic sinusitis and chronic postnasal drip) may result from dysfunction in the cranium. The physician should focus on improving the general health of the mucous membranes by correcting ventilation and circulation, restoring autonomic balance, and eliminating stagnant secretions by removing mechanical hindrances (1). Associated dysfunction in the upper thoracic spine, cervical spine, and sacrum should also be treated. (See *Osteopathy in the Cranial Field* by Magoun (1) and *Osteopathic Considerations in Systemic Dysfunction* by the Kucheras (2) for specific techniques.)

OCCIPUT (C0)—ATLAS (C1) ARTICULATION

The occiput-atlas joint is unique and has atypical motion. The condyles of the occiput are convex, while the articulating surfaces of the atlas are concave. This allows for a small gliding motion into flexion and extension. It also allows for an anterior/posterior translation as well as sidebending.

THE TEETH

When considering the effect of the dentition on somatic dysfunction of the head, face, and jaw, the clinician must understand basics of dental anatomy and malocclusion. There are two sets of teeth that develop in a lifetime. The primary teeth (also called the baby, milk, or deciduous teeth), and the permanent teeth (also called the adult or secondary teeth). Children have 20 primary teeth; they are replaced by the permanent teeth by about age 13. Adults have 32 permanent teeth. Most infants are born with no visible teeth—the

Figure 37-4 Lateral view of skull (close-up of sphenoid and temporal bones). (From Agur AMR. *Grant's Atlas of Anatomy*. 9th Ed. Baltimore, MD: Williams & Wilkins, 1991:502.)

teeth are forming inside the gums. The 20 primary teeth erupt over the time from when a baby is approximately 6 months to a year old. Primary teeth fall out and are replaced by 32 permanent teeth. This happens over the time from when a child is approximately 6 to 14 years old. Wisdom teeth (also called the third molars) are molars that usually erupt from the ages of 17 to 21. When examining teeth, the part of the tooth that is seen on the surface of the gum is the crown. It is made up of the enamel, dentine, and the pulp. The front incisor teeth have a straight edge and are used for cutting. The canine or "eye teeth" are the pointed long teeth between the incisor and the premolar teeth. Premolar teeth (bicuspid) have two cusps. Molar teeth each have four or more cusps. The enamel is the white hard covering over the crown of the tooth. It is the hardest material in the body and does not have a nerve or blood supply. Chipping or damage to enamel only will not be painful. Enamel cannot heal or repair itself as bone or dentine can. Dentine is an off white colored hard material that makes up the bulk of the tooth. Dentine can heal itself, and it can also register pain. The tooth becomes sensitive to temperature changes and feels painful, when the dentine is exposed. The nerves and the blood vessels of the tooth are called the pulp. When the pulp is exposed to infection, by decay or injury, it will die and cause severe pain.

An abscess will develop on the root. The roots are embedded in the tooth socket in the mandible. Roots are covered by cementum and held in place by the periodontal ligament. The periodontal ligament attaches the roots to the alveolar surface of the mandible. It has both a nerve and blood supply. The ligament provides an elastic cushion between the tooth and the bone. Slight movement of a tooth is made possible by the ligament. Teeth are not rigidly joined to bone. There is flexibility. Teeth change their position based on stresses and occlusion patterns.

Occlusion refers to the alignment of teeth and the way that the teeth fit together. Ideally, the points of the molars fit the grooves of the opposing molar. All teeth are aligned, straight, and spaced evenly. Malocclusion is the most common reason for referral to an orthodontist. Very few people have perfect occlusion. By treating moderate or severe malocclusion, the teeth are easier to clean and there is less risk of tooth decay and periodontal diseases. Malocclusion has a hereditary component, as well as an acquired due to habits, bruxism, and strains of the sphenobasilar synchondrosis (SBS). When hereditary, malocclusion may be from a disproportion between the size of the upper and the lower jaws or tooth size resulting in overcrowding of teeth. During infancy and childhood, personal habits like thumb sucking, tongue thrusting, pacifier use

Figure 37-5 Lateral view of interior of skull. (From Agur AMR. *Grant's Atlas of Anatomy*. 9th Ed. Baltimore, MD: Williams & Wilkins, 1991:466.)

beyond the age of three, and prolonged use of a bottle can greatly affect the shape of the jaws as well. Even in the adult, improper fit of dental fillings, crowns, appliances, retainers, or braces may contribute to malocclusion. The position of the teeth and jaw will affect motion of the cranial mechanism. Receiving cranial treatment will change bite patterns and jaw position. Braces and retainers can decrease the palpable motion of the primary respiratory mechanism, causing headaches, jaw pain, and many other

complaints. Osteopathic physicians need to work closely with dentists to achieve the best functional outcome for their patients.

THE MANDIBLE

The mandible forms the lower jaw. The mandible is not part of the neurocranium, nor is it part of the viscerocranium. The mandible develops from membranous ossification (23). It has a horizontal

Figure 37-6 Interior view of nasal cavity. (From Agur AMR. *Grant's Atlas of Anatomy*. 9th Ed. Baltimore, MD: Williams & Wilkins, 1991:519.)

Figure 37-7 Inferior view of skull. (From Agur AMR. *Grant's Atlas of Anatomy*. 9th Ed. Baltimore, MD: Williams & Wilkins, 1991:582.)

body convex anteriorly and two rami ascending posteriorly. The *symphysis menti* is the union of the two halves of the mandible. It is prominent inferiorly as the mental protuberance. The upper part of the body of the mandible is the alveolar part that contains the teeth. A mental foramen is visible below the alveolar part. The angle of the mandible is the meeting point between the inferior margin of the mandible and the posterior margin of the vertical mandibular ramus. The superior part of the ramus extends upward to form a *coronoid process* and a *condylar process*. The head of the condylar process articulates with the mandibular fossa of the temporal bone to form the temporomandibular joint.

THE TEMPOMANDIBULAR JOINT

The TMJ is formed by the head of the mandible and mandibular fossa of the temporal bone. A fibrocartilagenous articular disc

separates these structures. The stylomandibular ligament connects the angle of the mandible to the styloid process of the temporal bone and the sphenomandibular ligament connects the lingula (medial aspect) of the mandible to the spine of the sphenoid. The lateral pterygoid muscle arises from the sphenoid bone and attaches to the articular disk. This muscle draws the articular disk anteriorly when the mouth is opened.

MUSCLES AND FASCIA OF THE HEAD AND FACE

Knowledge of the muscles of the head and face and of muscles that attach from the spine to the head is important to obtain. This knowledge will help the clinician accurately palpate and look for tenderpoints, fascial tension, and tightness of the various muscles. Understanding their innervation and action is also important,

especially if the student physician is studying plastic surgery, neurosurgery, or otolaryngology.

MYOFASCIAL TRIGGERPOINTS

The myofascial system is often involved in head symptoms. Travell and Simons have described various myofascial trigger points (TPs) that may refer pain to and/or cause dysfunction of structures of the head (2) (Fig. 37.8 and Table 37.2). Somatic dysfunction and TPs are closely related and potentiate one another. Emotional stress may be associated with clenching of the teeth and may produce TPs in the masseter and pterygoid muscles. Frowning or squinting may set up TPs in the orbicularis oculi and occipitalis muscles. TPs in the sternocleidomastoid muscle may refer pain to the eye and may be associated with balance abnormalities. Motor vehicle accidents, especially from the rear, may produce TPs in the sternocleidomastoid, splenius cervicis, and trapezius muscles. TPs in the orbicularis oculi muscle may produce such ipsilateral visual disturbances as blurred vision, decreased light perception, tears, and conjunctival reddening. TPs in the occipitalis muscle may refer pain behind the eye and orbit. TPs in the trapezius muscle may refer pain to the orbit (2).

CONNECTIVE TISSUE

The dura mater lines the skull and produces folds, or intracranial membranes, that act as partitions between, and support for, the cerebral hemispheres and cerebellum (Figs. 37.9 and 37.10) (1). These structures form the reciprocal tension membrane and are integrally involved in osteopathic cranial motion. The dura lining the skull extends through the cranial sutures and becomes continuous with the periosteal covering of the skull. The falx cerebelli extends inferiorly from the straight sinus and firmly attaches to the foramen magnum. It attaches to the bodies of the second and the third cervical vertebrae and extends downward as a tube that ultimately attaches to the second sacral segment (Fig. 37.11). The dura becomes continuous with the extracranial fascia at various foramina in the base of the skull and continues outward as sheaths (perineurium) surrounding various cranial and spinal nerves. Extracranial and

intracranial dural continuity explain why dysfunction in the periphery can be referred to the head (1).

NEUROLOGIC STRUCTURES**Cranial Nerves**

Knowledge of CN anatomy and function is important in treating patients with a variety of disorders referable to the head, eyes, ears, nose, and throat. CNs can become inflamed, infected, entrapped, and traumatized. Cranial strains/dysfunction of the sphenobasilar synchondrosis can affect their function as well. Table 37.3 highlights important aspects of the CNs.

Parasympathetics

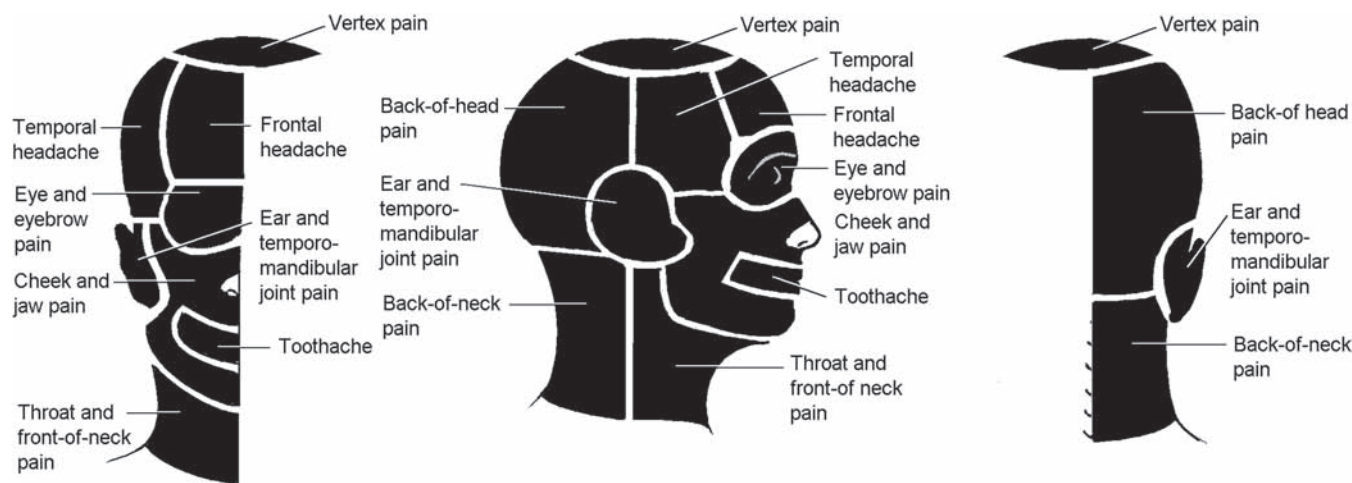

Parasympathetic nerve fibers to the pupil are supplied by CN III (oculomotor nerve) (Fig. 37.12). They innervate the ciliary muscle and cause constriction of the pupil. Parasympathetic activity shortens the focal length of the lens and is associated with visual disturbance. Parasympathetic fibers to the lacrimal gland and nasopharyngeal mucosa originate in CN VII (facial nerve). They synapse in the sphenopalatine ganglion (Fig. 37.13). The postganglionic fibers then travel in the maxillary branch of CN V to the lacrimal gland. Parasympathetic hyperactivity resulting from sphenoid, maxilla, and palatine dysfunction results in excessive tear production and profuse, clear, thin secretions from the mucosa of the nasopharynx and sinuses. Parasympathetic nerves to the thyroid gland arise from the superior and inferior laryngeal nerves, a branch of the main vagus nerve (CN X) (2).

Sympathetics

The structures of the head and neck obtain their sympathetic innervation from cell bodies located at spinal cord levels T1-T4 (Fig. 37.14). Preganglionic and postganglionic fibers synapse in the upper thoracic region and/or cervical sympathetic ganglia. Sympathetic fibers to the head generally form sympathetic plexi that follow the course of the arterial supply (2). The superior, middle, and inferior cervical paraspinal ganglia lie in the fasciae of the cervical region at levels C2, C6, and C7, respectively. Upper thoracic, upper rib, and cervical somatic dysfunction can increase sympathetic tone to the structures of the head.

Visceral afferent nerves stimulated by organ dysfunction usually follow the same fascial pathways as the efferent sympathetic fibers of innervation. Excessive afferent input from head and neck structures is a factor in the production of facilitation in upper thoracic cord segments. Facilitation of cord segments is associated with excessive sympathetic outflow from the affected regions of the cord (T1-T4 to head and neck). Hypersympathetic stimulation to associated viscera, over time, produces physiologic changes in the viscera and in the somatic tissues innervated by the involved cord segments (2). Relevant palpatory changes mediated by viscerosomatic reflexes from HEENT structures can therefore be found in T1-T4 paraspinal tissues and in predictable anterior Chapman points on the anterior chest wall above rib 2.

Palpatory changes in the upper thoracic and cervical paraspinal tissues can therefore be a clue to structural or functional involvement of the head and neck structures innervated by sympathetic fibers. Conditions such as Horner syndrome (constricted pupil, ptosis, and facial anhidrosis on the affected side) indicate significant structural involvement or blockage of the sympathetic nervous system. Increased sympathetic tone also leads to functional photophobia,

unsteadiness, and tinnitus. Hyperesthesia of the pharyngeal tissues causes patients to cough and expectorate in an attempt to rid themselves of an imaginary foreign body in the throat (2).

Increased sympathetic activity alters the normal physiologic responses the tissues can provide. Vasoconstriction results in decreased nutrient supply to and reduced lymphatic and venous drainage from target organs and tissues. The body's ability to mount an immune response and obtain effective concentrations of medications is reduced in areas of vasoconstriction and tissue congestion (2).

Prolonged sympathetic stimulation changes the composition of the cells of the respiratory epithelium resulting in nasal and pharyngeal secretions that are thick and sticky, thereby reducing effective cleaning and clearing by the pseudostratified ciliated epithelium of the mucosa. Epithelial hyperplasia is present,

with a relative increase in the activity and number of goblet cells, constriction of arterioles, decreased vascular and lymphatic drainage of the tissues, and the mechanical difficulty in moving the mucus. Sympathetic stimulation also produces vasoconstriction and inhibits secretion, leading to dryness of the nasopharyngeal mucosa. Dryness and cracking of the mucosa break down the normal mucosal defenses, thereby permitting secondary bacterial infection (2).

Dilation of the pupil (mydriasis) also occurs with increased sympathetic activity to the eye. This elevates intraocular pressures in patients with narrow angle glaucoma. Prolonged upper thoracic and cervical dysfunctions have been associated with the development of cloudiness of the lens (2). The Barr-Lieou syndrome (vertigo, ataxia, vasodilation, and eye pain) results from hypersympathetic activity and proprioceptive dysfunction that often follows whiplash injuries.

The sympathetics innervate blood vessels that supply the thyroid and innervate the cells that produce thyroid secretions. Increased sympathetic stimulation may alter thyroid gland secretion (2).

Dorsal Rami of the Upper Cervical Nerves

Understanding the anatomy of the dorsal rami of the cervical nerves is important in understanding how somatic dysfunction at C2 and C3 may be related to tension headaches and “occipital neuritis.” The greater and lesser occipital nerves have been implicated in the production of tension headaches, so this region is a common area of OMT. These branches of the dorsal rami of the upper cervical segments pierce through the fascia just below the superior nuchal line. Tension in this fascia has been implicated to cause compression and irritation of the greater occipital nerve.

The *greater occipital nerve* is the medial branch of the dorsal ramus of the second cervical nerve. It ascends between the muscles of the suboccipital triangle and the semispinalis capitis. The greater occipital nerve pierces the semispinalis capitis and the trapezius near their attachments to the occipital bone and ascends on the back of the scalp with the occipital artery. The greater occipital nerve supplies the skin of the occipital part of the scalp lateral to the median line and as far superiorly as the vertex of the skull. Its lateral branches communicate with those of the lesser occipital nerve. The greater occipital nerve gives off muscular branches

**Figure 37-9** Dural reflections within skull.

to semispinalis capitis joins with *occipitalis tertius*, the cutaneous branch of the third cervical nerve. The *occipitalis tertius* supplies the skin of the upper part of the back of the neck, near the median line, and the skin of the scalp over the external occipital protuberance.

The cutaneous branches of the cervical plexus are the *lesser occipital*, the *great auricular*, the *transverse cervical*, and the *supraclavicular nerves*. The lesser occipital nerve (C2, sometimes also C3) ascends in the neck along the posterior border of the sternocleidomastoid muscle. It pierces the superficial layer of cervical fascia near the insertion of the muscle and divides into branches, which supply the skin and subcutaneous tissue of the scalp behind and above the ear and of the upper portion of the cranial surface of the ear. The *great auricular nerve* (C2, C3) arises in the posterior triangle at the lateral border of the sternocleidomastoid muscle. It travels below the lesser occipital nerve and crosses obliquely in a course toward the ear and the angle of the mandible.

ARTERIAL SUPPLY**Internal Carotids**

The face and the scalp are supplied by branches of the external carotid artery (primarily the facial artery) (3). The internal structures of the head are primarily supplied by the internal carotid and vertebral arteries (Fig. 37.15). The internal carotid artery passes through the carotid canal in the petrous portion of the temporal bone. It supplies the anterior portions of the cerebrum (3). Cranial dysfunction in the articulations between the temporal bones, occiput, and sphenoid can alter the normal function of these arteries (3). This can produce symptoms including weakness and altered sensation on the opposite side of the body.

External Carotids

The external carotid artery travels from the upper border of the thyroid cartilage to the neck of the mandible. Here, it divides into the superficial temporal and maxillary arteries. It is relatively superficial in the carotid triangle, where it is covered by the superficial layer of cervical fascia and is overlapped by the anterior border of

Figure 37-10 Median section of head and relationship of dural folds to intracranial structures. Superolateral view. (From Moore KL, Agur AMR. *Essential Clinical Anatomy*. Baltimore, MD: Williams & Wilkins, 1996:359.)

the sternocleidomastoid muscle. Leaving the carotid triangle, the artery is crossed by the posterior belly of the digastric and the stylohyoid muscles and separates these muscles from the stylopharyngeus muscle. The facial nerve crosses both vessels. The external carotid artery has eight branches. Of these, four arise in the carotid triangle: the superior thyroid, the lingual, and the facial arteries. Two posterior branches, the occipital and posterior auricular arteries, arise at the level of the posterior belly of the digastric muscle; and two terminal branches, the superficial temporal and maxillary arteries, take origin behind the neck of the mandible (24).

Vertebral Arteries

The vertebral arteries arise from the subclavian artery and ascend through the transverse foramen of C6-3. At C2, they make several right angle turns before piercing the dura to angle anteriorly and enter the skull through the foramen magnum (3). The vertebral arteries supply the visual area of the cerebrum (occipital lobe), brainstem, and cerebellum. Dysfunctions affecting this artery can be associated with visual abnormalities and dizziness (3).

Circle of Willis

The vascular interconnections of the brain, known as the cerebral arterial circle (Circle of Willis), serve to equalize the blood supply to the various parts of the brain under conditions of fluctuating pressure through the major vessels. This anatomic design is unique and vital whenever a major source vessel becomes thrombosed or has to be ligated. The vertebral arteries join to form the basilar artery. The basilar artery splits into the two posterior cerebral arteries. The anterior and posterior communicating arteries indirectly connect the internal carotid arteries of the two sides and the basilar system, so that an

arterial circle is formed at the base of the brain (24). The terminal vessels in and on the brain anastomose, but the larger arteries do not, except in this arterial circle. Effects from an occlusion of one vertebral artery may be dampened by these vascular interconnections.

Venous Drainage

Venous blood flows peripherally via superficial cerebral veins and centrally via the deep cerebral veins into the venous sinuses, which lie between the outer endosteal and the inner meningeal layer of the dura. The cerebral veins are thin walled and have no valves. There are numerous venous connections between cerebral veins and dural sinuses and venous systems of the meninges, skull, scalp, and nasal sinuses. This anatomic arrangement not only allows the spread of infection, but also allows cranial techniques to affect the venous drainage of the cerebral vessels. The venous drainage of the brain begins with the superior and inferior sagittal sinuses, as they drain into the transverse then sigmoid sinuses and finally into the internal jugular vein. The ophthalmic veins from the orbit drain backward to the cavernous sinus or forward to the facial vein. The cavernous sinus drains to the pterygoid plexus of veins, through the superior petrosal sinus to the transverse sinus and through the inferior petrosal sinus to the internal jugular vein. The veins of the scalp drain through veins that accompany the arteries, or through emissary veins, which connect the venous plexus of the scalp with the dural venous sinuses. The maxillary and superficial temporal veins form the retromandibular vein behind the angle of the mandible. The retromandibular vein communicates with the external jugular vein and the internal jugular vein. The facial vein drains into the internal jugular vein. The internal jugular vein lies in the carotid sheath and as it passes down the neck it receives the superior and middle thyroid veins. The external jugular vein lies subcutaneous

Figure 37-11 Dural continuity of skull, cervical vertebrae, and sacrum. (Adapted from Magoun H. *Osteopathy in the Cranial Field*. 3rd Ed. Kirksville, MO: The Journal Printing Co., 1976.)

on the sternocleidomastoid muscle. It joins the subclavian vein. The internal jugular vein and the subclavian vein form the brachio-cephalic veins on the right and left.

Approximately 85% of the venous drainage from the head occurs via the internal jugular veins (Fig. 37.16). These veins pass through the jugular foramen, which is formed by both the occiput and the temporal bones and is located along the occipitomastoid suture. CNs IX to XI course along with the internal jugular vein and exit through jugular foramen as well, which is located between the occiput and the temporal bones. Suboccipital tension of this area is thought to cause fascial obstruction to flow and venous congestion. Specifically, an occipitomastoid compression can compromise venous flow through the jugular foramen, leading to congestion of the large valveless venous sinuses within the head. Sacral, upper thoracic, cervical, and associated regional connective tissue dysfunction can also contribute to congestion and impaired venous flow from the head (2).

Lymphatic Drainage

Understanding the lymphatic drainage patterns assists the physician in localizing pathologic conditions in the head (Fig. 37.17). There

are no lymphatic channels inside the skull. Lymphatic vessels in the forehead and anterior part of the face drain into the submandibular lymph nodes. Lymph vessels from the lateral face and eyelids drain inferiorly toward the parotid lymph nodes and ultimately drain into the deep cervical lymph nodes (3). The superficial lymph nodes of the head include the submandibular, occipital, retroauricular, and superficial parotid lymph nodes.

Lymph from the occipital region of the scalp drains into the occipital lymph nodes. The temporoparietal region drains into the retroauricular lymph nodes. The frontoparietal region drains into the superficial parotid lymph nodes. Lymph from the superficial lymph nodes eventually drains into the cervical lymph nodes. The deep cervical lymph nodes are located along the internal jugular vein. Lymph from the deep cervical structures passes through the jugular trunk into the left (thoracic duct) and right lymphatic trunks (Fig. 37.18) (3).

All drainage from the head passes through the neck, cervical fasciae, and thoracic inlet to return to the general circulation. Dysfunction in any of these structures can hinder the pathways and lead to lymphatic congestion. Increased sympathetic stimulation constricts the smooth muscle of the larger lymphatic vessels of the head and neck (associated with upper thoracic and cervical dysfunction), leading to decreased lymphatic drainage (2).

SENSORY ORGANS

Eye

Each orbit is composed of seven bones (see Fig. 37.2) (1):

- Frontal
- Sphenoid
- Maxilla
- Zygomatic
- Palatine
- Ethmoid
- Lacrimal

Four of the eye muscles (superior, inferior, medial, and lateral rectus) originate from a common tendinous ring surrounding the optic canal in the lesser wing of the sphenoid. The superior oblique muscle arises from the body of the sphenoid bone superomedial to the common tendinous ring and the inferior oblique muscle originates on the maxilla in the floor of the orbit. All are involved in eye movements (Fig. 37.19) (3).

Dysfunction of the frontal, sphenoid, and maxillae may produce muscle imbalance of the eye (1). Restrictions of the orbital bones, through fascial connections, contribute to venous stasis in head structures (1). A lateral strain pattern, maintained by unilateral condylar compression, is often associated with strabismus. A vertical strain pattern, maintained by bilateral condylar compression, is often associated with either myopia or hyperopia. Dysfunction of the occipital bone can obstruct the jugular foramen, leading to backward venous pressure in the orbit. These factors may contribute to such conditions as (1):

- Amblyopia
- Astigmatism
- Diplopia
- Hyperopia
- Myopia
- Strabismus

The patient receives clinical benefit from removal of cranial somatic dysfunction. Gentle eye mobilization using indirect techniques may also decrease ocular tension resulting from glaucoma.

TABLE 37.3

Cranial Nerves

CN	Anatomic Location	Innervation	Dysfunction
I. Olfactory	Foramina of the cribriform plate of the ethmoid bone		Crosses the lesser wing of the sphenoid (1). Altered sense of smell Impression of an odor that does not exist (2).
II. Optic	Optic canal (in the lesser wing of the sphenoid)		Lesions of the sphenoid or membranous tension may affect the optic nerve anywhere between the sphenoid and occiput (1).
III. Oculomotor	Midbrain, lateral wall of cavernous sinus, top of the petrosphenoidal ligament, superior orbital fissure	Levator palpebrae extraocular muscles of the eye (except the superior oblique and lateral rectus). Parasympathetic fibers supply the smooth muscle in the sphincter pupillae and ciliary muscles (3).	Tension on the petrosphenoid ligament causes potential compression
IV. Trochlear	Passes through the petrosphenoidal ligament, and enters the orbit via the superior orbital fissure		The most common symptom, diplopia, occurs when the patient looks downward.
V. Trigeminal			
V1 ophthalmic branch	Passes through the lateral wall of the cavernous sinus Enters the orbit through the superior orbital fissure	Upper eyelid, scalp, forehead, eyeball, ethmoid sinus, nasal cavity, lacrimal gland and conjunctiva.	Dysfunction of temporal bone may affect the function of this nerve.
V2 maxillary branch	Courses through: Inferior portion of cavernous sinus Middle cranial fossa Foramen rotundum Pterygopalatine fossa Infratemporal fossa Inferior orbital fissure	Supplies sensory fibers to the dura, maxillary sinus, maxillary premolar and molar teeth, nasal septum, lower eyelid, nose, and upper lip.	Tic douloureux may be associated with dysfunction of this nerve
V3 mandibular branch	Exits the middle cranial fossa via the foramen ovale	It contains both motor and sensory fibers. Supplies the teeth, gingiva, skin of the temporal region, the ear, lower face, muscles of mastication, floor of the oral cavity and tongue	Trigeminal neuralgia affecting this division. Sensory information from structures innervated by the trigeminal nerve (sinuses) may be perceived as headache
VI. Abducens	Courses underneath the petrosphenoid ligament, through the cavernous sinus, enters the orbit via the superior orbital fissure (3).	The abducens nerve supplies the lateral rectus muscle of the eye	Nerve most often affected and may result in medial strabismus
VII. Facial	Arises from the pons, enters the internal acoustic meatus of the temporal bone, joins the facial canal, and exits the skull via the stylomastoid foramen (3)	The sensory root anterior two thirds of tongue, soft palate, and a small area around the external auditory meatus. Secretory to the salivary glands and sensory to the lacrimal glands The motor root supplies the muscles of facial expression and muscles of the scalp, auricle, buccinator, platysma, stapedius, stylohyoid, digastric	Dysfunction of the sphenoid, occiput (condylar or occipitomastoid compression) cervical and upper thoracic spine, and cervical fascia (1).

(continued)

TABLE 37.3 (Continued)

VIII. Auditory	Both divisions arise in a groove between the pons and medulla and course through the internal acoustic meatus with the facial nerve (3).		Lesions of the sphenoid, occiput, and temporals may affect the functioning of this nerve, producing vertigo or hearing dysfunctions (1).
IX. Glossopharyngeal	It arises from the medulla and leaves the skull through the jugular foramen (3)	Stylopharyngeus muscle Secretomotor to the parotid gland Sensory to the pharynx, tonsils, and posterior portion of the tongue.	Dysfunctions affecting the jugular foramen (temporal, occiput, occipitomastoid suture, or cervical fascia) may interfere with normal function of this nerve (1).
X. Vagus	Arises from the medulla and exits the skull via the jugular foramen (3).	Head, Neck, Thorax, abdomen, half of colon	Referred pain and parasympathetic reflexes headache, nausea, bradyarrhythmia, cough
XI. Accessory	It arises from both the cervical spinal cord and the medulla, and exits the skull through the jugular foramen	Sternocleidomastoid and trapezius muscles; it also supplies muscles in the pharynx and palate.	Dysfunctions affecting the jugular foramen Sternocleidomastoid dysfunction
XII. Hypoglossal	It arises from the medulla and exits the skull via the foramen magnum. It courses through the hypoglossal canal in the occipital bone (3).	The hypoglossal nerve is the motor nerve of the tongue.	Dysfunction of the condylar parts of the occipital bone may affect functioning of this nerve (1), Suckling disorders in infants Dysphagia, dysarthria, and swallowing difficulties in adults

Ear

The ear serves two major functions: maintenance of equilibrium and hearing (3). Most of the structures of the ear reside within the petrous portion of the temporal bone. Hence, dysfunction of the temporal bone can be a factor in impaired hearing and asynchrony of temporal bone motion can be associated with vertigo (Fig. 37.20).

The Eustachian tube connects the middle ear to the nasopharynx (Fig. 37.21) (3). It functions to equalize middle ear pressure with atmospheric pressure. Fixed internal rotation of the temporal bone, typically secondary to occipitomastoid or sphenosquamous compression, maintains partial or complete closure of the Eustachian tube. This is associated with two effects: perception of high-pitched noises and impaired drainage from the middle ear, thereby producing a media for recurrent ear infections. Fixed external rotation maintains patency of the Eustachian tube and is associated with the perception of a roar or low-pitched noises (1). Eustachian tube dysfunction is the most common precursor of otitis media and is often responsive to treatment of somatic dysfunction affecting

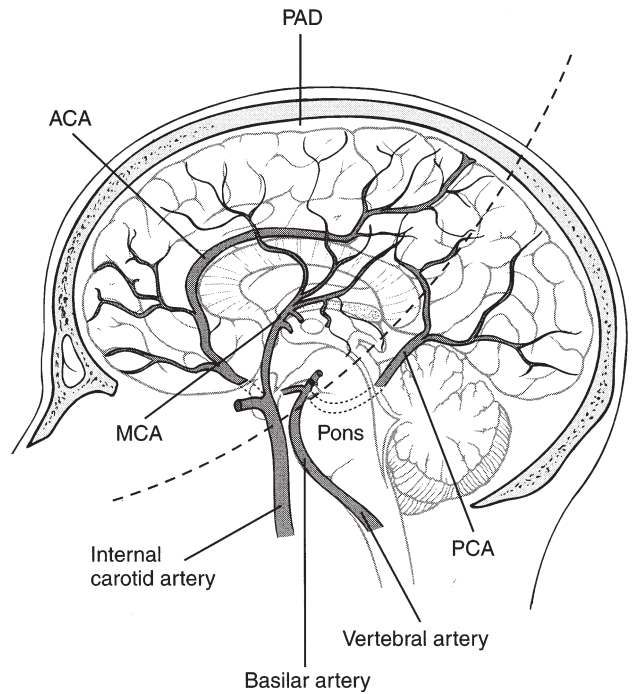

Figure 37-15 Major arterial supply to brain. Areas above dotted line are supplied by internal carotid arteries; areas below dotted line are supplied by vertebral arteries. ACA, anterior cerebral artery; MCA, middle cerebral artery; PCA, posterior cerebral artery; PAD, pia, arachnoid, and dura.

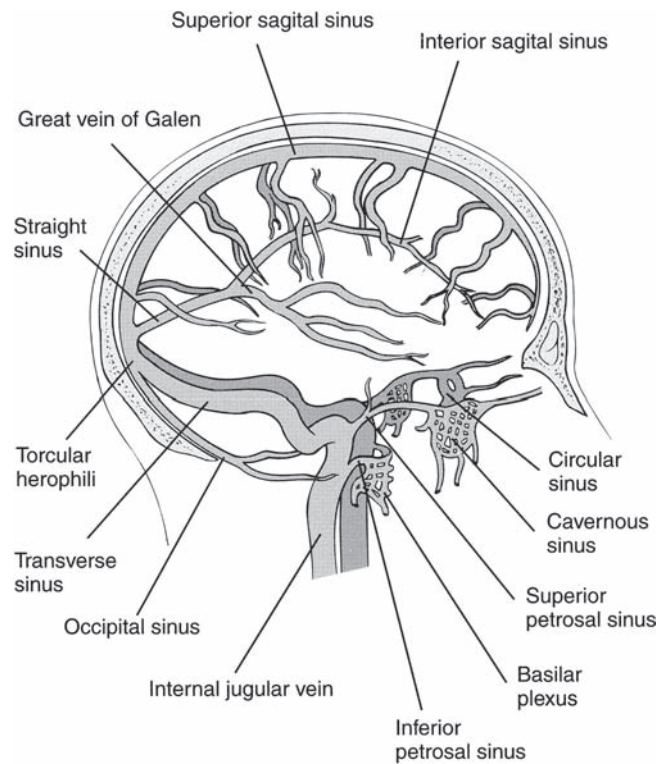

Figure 37-16 Venous drainage of skull. (Adapted from Magoun H. *Osteopathy in the Cranial Field*. 3rd Ed. Kirksville, MO: The Journal Printing Co., 1976.)

the cranium, cervical and thoracic spine, medial pterygoid muscle, cervical fasciae, and sacrum. Dysfunction affecting the ganglion impar is often associated with asthma, chronic otitis media, and chronic sinusitis. The ganglion impar is formed by the convergence of the pelvic sympathetic trunks and lies anterior to the coccyx. This ganglion ultimately communicates with thoracic sympathetic chain (4). Sacral and/or coccygeal restrictions may irritate this ganglion, contributing to increased tension in the upper thoracic and cervical spine. Treatment of sacral and/or coccyx somatic dysfunction will allow the ganglion impar to optimally function. Dysfunction of the ganglion impar is especially responsive to the vibratory percussion hammer techniques developed by Robert C. Fulford, D.O.

Throat

Impaired arterial supply to and venous and lymphatic drainage from the throat predisposes this region to infection. Dysfunction of the sacrum, upper thoracic and cervical spine, and/or hyoid bone is often seen in patients with pharyngitis and tonsillitis.

BIOMECHANICS AND MOTION

Suboccipital Region

A thorough knowledge of the suboccipital region is important, both in the infant and the adult. In the infant, asymmetric molding of the bones can cause functional disturbances such as strabismus, poor feeding, and recurrent otitis media (8). Cranial dysfunctions and asymmetries can cause membranous strain and lead to CN entrapments. Table 37.3 includes dysfunction of the CNs. In the infant, the occiput is formed in four parts. Each part is separated by a synchondrosis, a cartilage union that usually ossifies before adult life. In infants, somatic dysfunction can be classified as *interosseous* (occurring between different bones) or *intraosseous* (occurring between different parts of the same bone) (8). Therefore, diagnosis

of the suboccipital region in an infant or child is different than an adult.

In an adult, dysfunction occurs between the occiput (C0) and the atlas (C1). Knowledge of the anatomy of the region is important to understand the motions that occur.

Functional Anatomy

The occipitoatlantal articulation consists of the superior articular facets of the atlas and the two occipital condyles. The superior facets of the atlas face backward, upward, and medially, and are concave. The surfaces of the occipital condyles match the facets of the atlas, and the joint is best thought of as a sphere (the occiput) gliding in a shallow cup (the articular surfaces of the atlas).

Motion

Flexion-extension of the occiput is the primary motion, producing a small-amplitude nodding “yes” of the head. Approximately 50% of cervical flexion/extension occurs at the occipitoatlantal joint. However, the motion at the occipital condyles is more complex than a small flexion and extension movement. Because the occipital joint surface is convex and the articulating surfaces of the atlas are concave, there is a considerable amount of anterior-posterior glide as well. Flexion of the occiput on the atlas is accompanied by a posterior translatory glide of the occiput; extension is accompanied by an anterior translatory glide (7). During coupled sidebending and rotation, one condyle glides anterior and the other glides posterior.

Dysfunction

Somatic dysfunctions of the occipitoatlantal joint most often involve the minor motions of sidebending and rotation. The dysfunctional pattern between occiput and atlas demonstrates an atypical pattern of coupled sidebending and rotation in opposite directions. The sidebending and rotation of the occipitoatlantal joint in opposite directions occurs in part because of the position of the lateral atlanto-occipital ligament (7). When the occiput rotates left on the atlas, the lateral atlanto-occipital ligament causes the occiput to slide (translate) to the left and therefore sidebend to the right (7). Because sidebending-rotation mechanics between C0 and C1 occur in opposite directions, some authors mistakenly state that this is Fryette Type I mechanics. This is not correct, as C0 and C1 are not typical vertebral segments and, therefore, do not demonstrate Fryette Type I mechanics. In the Chicago model, clinicians refer to a posterior occiput and an anterior occiput. The muscle energy system refers to a flexed occiput (Chicago posterior occiput because the posterior occiput resists extension) or an extended occiput (an anterior occiput resists flexion) (Table 37.4).

Diagnosis

Clinically, the lateral translation test is commonly used (physiologic motion: rotation and sidebending to opposite sides). The clinician will translate the occiput (entire head) to the right and to the left. Freer translation right suggests the dysfunction to be sidebending left, rotation right; or probably a posterior occiput right (or anterior occiput left). The clinician then uses tissue texture abnormality and tenderness to reach a conclusion of which side is dysfunctional. An additional motion test is a posterior occiput resists extension on that side; an anterior occiput resists flexion on that side. Some clinicians use a “figure of 8” motion testing process to determine

Figure 37-18 Lymphatic drainage through thoracic inlet. (From Moore KL. *Clinically Oriented Anatomy*. 3rd Ed. Baltimore, MD: Williams & Wilkins, 1985:78.)

the type of dysfunction. This process simultaneously evaluates the sidebending, rotation, and flexion/extension components.

EXAMPLE

Occiput rotated right, sidebent left. This pattern may be the result of a posterior/flexed occiput on the right or an anterior/extended occiput on the left.

Posterior/Flexed Occiput Right

- Pattern: O-A rotated right, sidebent left
- Right O-A translates posteriorly and will resist anterior translation. (This is the “open” side, and it will resist extension.)
- Left O-A translates freely both posteriorly and anteriorly
- Tissue texture change and tenderness to palpation is greater on the right

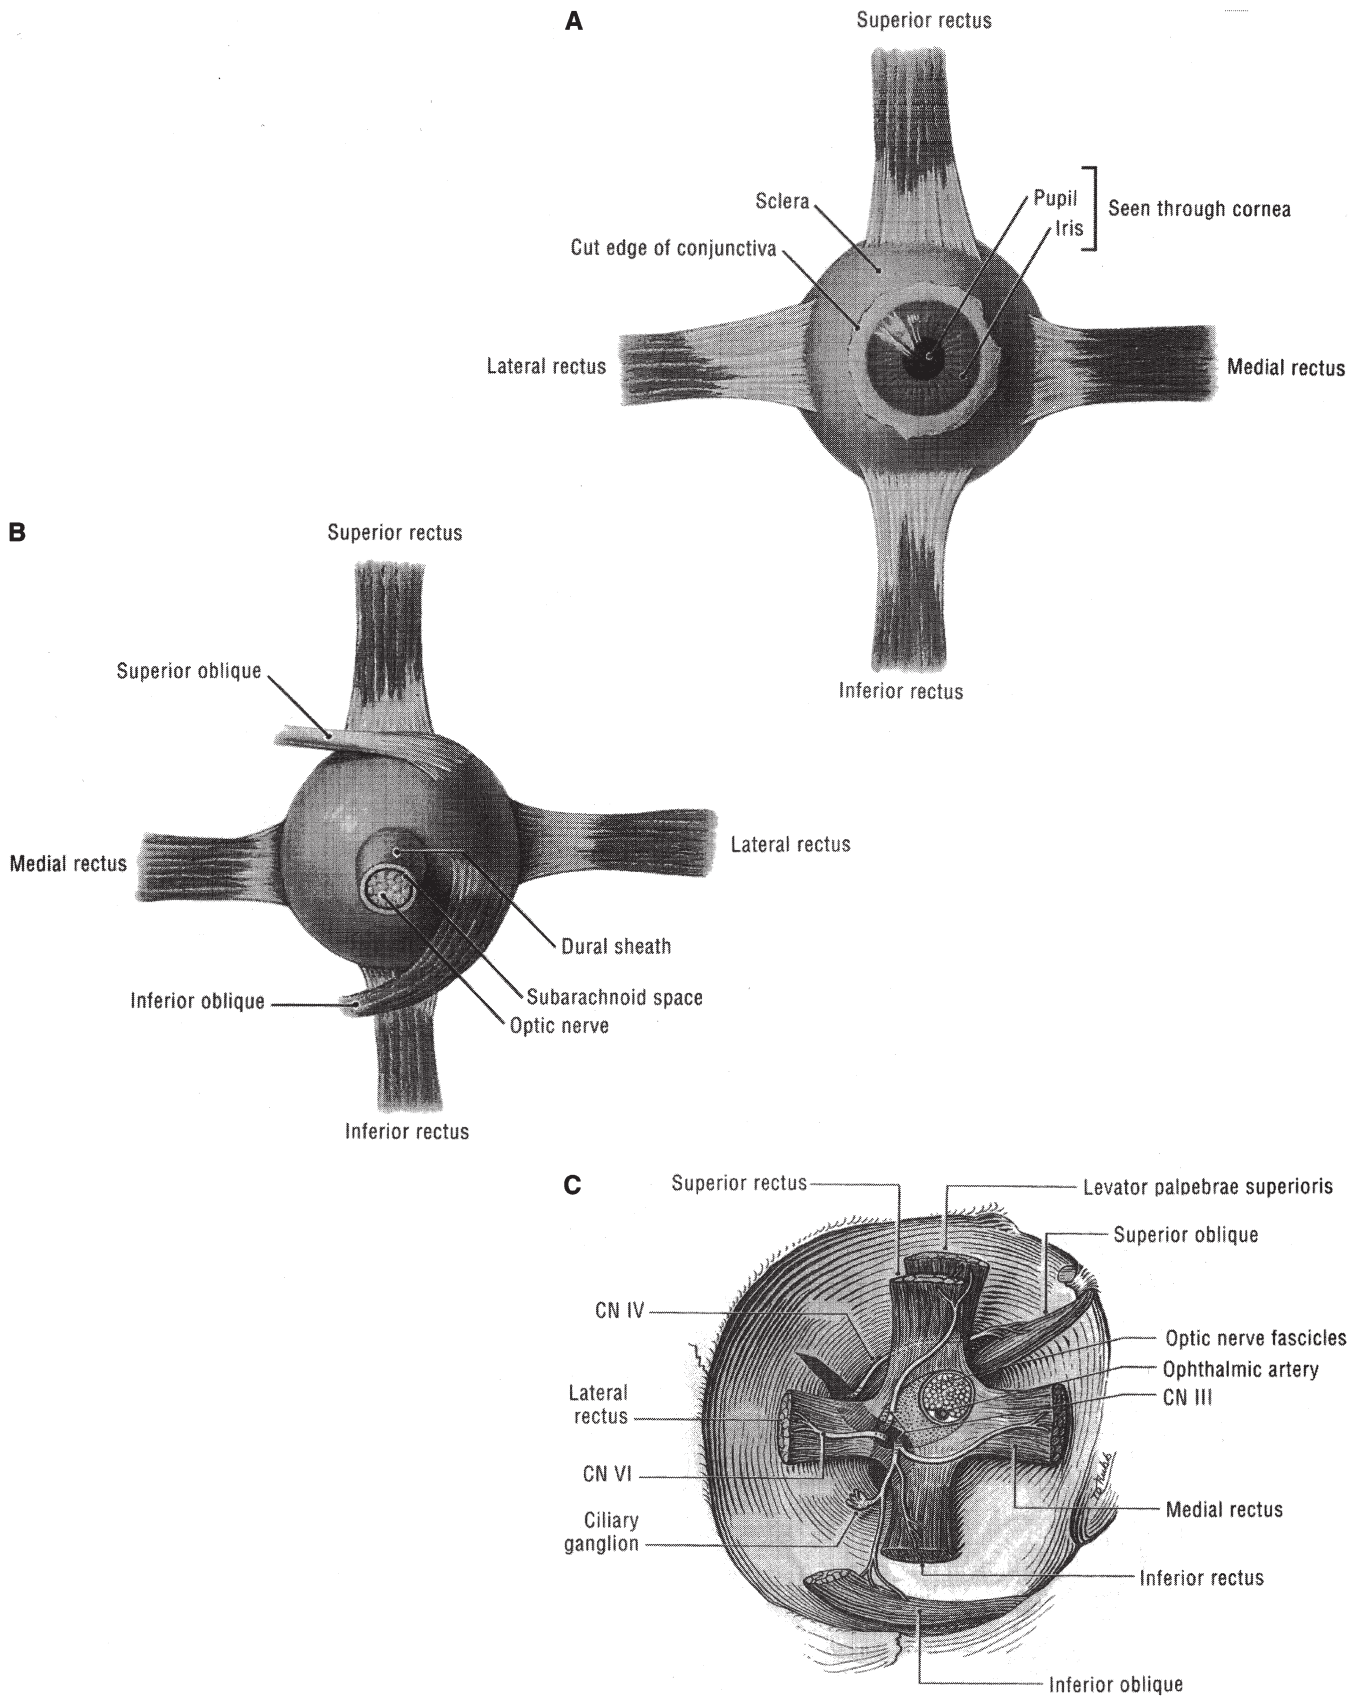

Figure 37-19 Extraocular muscles and nerves. **A.** Anterior view of muscles. **B.** Posterior view of muscles. **C.** Nerves of the orbit. CN, cranial nerve. (From Agur AMR. *Grant's Atlas of Anatomy*. 9th Ed. Baltimore, MD: Williams & Wilkins, 1991:486.)

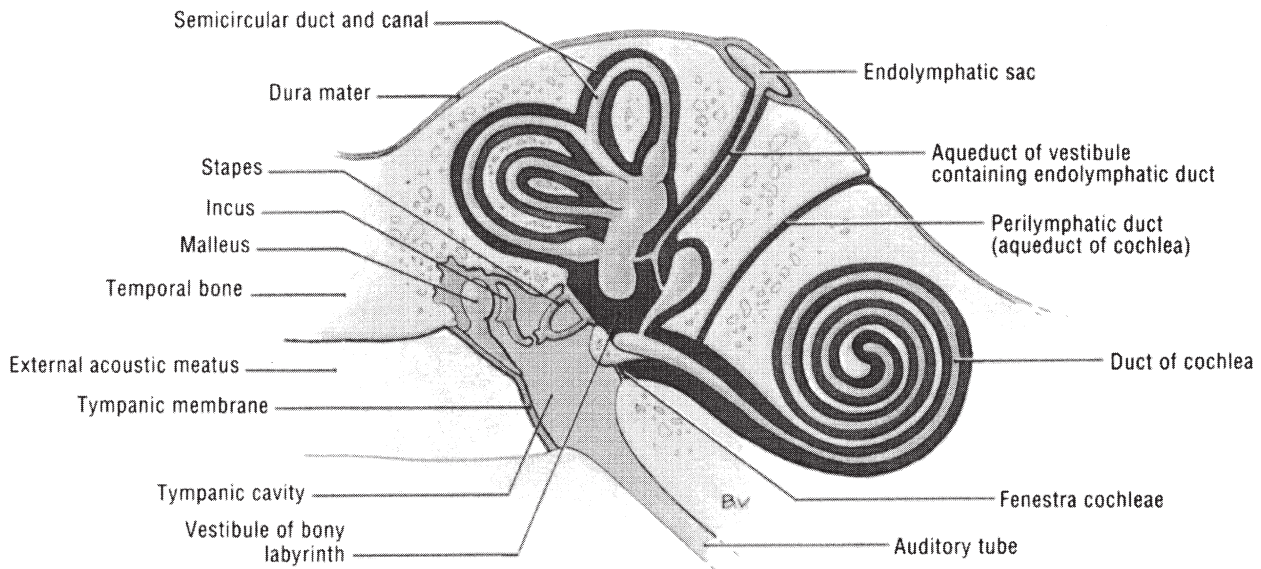

Figure 37-20 Internal structures of the ear. (From Agur AMR. *Grant's Atlas of Anatomy*. 9th Ed. Baltimore, MD: Williams & Wilkins, 1991:534.)

Anterior/Extended Occiput Left

- Pattern: O-A rotated right, sidebent left
- Right O-A translates freely both posteriorly and anteriorly
- Left O-A translates anteriorly and will resist posterior translation. This is the “closed” side, and it will resist flexion.
- Tissue texture change and tenderness to palpation is greater on left

Tempomandibular Joint

The TMJ has been described as the most complex joint in the body because it not only acts as a hinge joint but also permits a gliding

movement (11). Both movements are necessary for adequate jaw opening and closing. The articular surface of the condyles of the mandible is smooth and spherical. A fibrocartilagenous meniscus located between the mandibular condyle and the temporal bone acts as a cushion to absorb the shock of chewing and speaking. The meniscus has three parts, a thick anterior band, a thin intermediate zone, and a thick posterior band (11).

When the mouth is closed, the condyle is separated from the temporal bone by the thick posterior band. When the mouth is open, the condyle is separated from the temporal bone by the thin intermediate zone. The articular surface of the temporal bone is

Occiput Diagnosis

Chicago Terminology	Alternate Terminology
Posterior ("open") occiput	Flexed occiput
Anterior ("closed") occiput	Extended occiput

also complex, consisting of a convex articular eminence anteriorly and a concave articular fossa posteriorly.

When the jaw begins to open, there is a hinge movement like a drawbridge lowering. Then as further opening occurs, the condyle of the mandible glides along the squamous portion of the temporal bone until the mouth is wide open. Opening the mouth activates the suprahyoid muscles (mylohyoid, geniohyoid, and digastric muscles), which provide the hinge-like movement. Anterior condylar glide is provided by the inferior division of the lateral (external) pterygoid muscles (11). Then, as closing begins, a posterior glide of the condyles ensures proper placement of the condyles back into its fossa. Elevation of the mandible (closing the mouth) is accomplished by the temporalis, masseter, and medial (internal) pterygoid muscles (11). The meniscus should stay in contact with both bones during this hinge and glide motion. If it does not, it may slip forward or backward causing a click, or even the patient's jaw becoming locked in position. The jaw can become locked in an open or a closed position, depending on the position of the meniscus and the tension of various muscles. Strachan called "open lock" an anterior lesion. It was characterized by an uneven and painful forward glide (on the affected side); chin deviation toward the contralateral side, and inability to close the mouth. Strachan also termed the "closed lock" a posterior lesion (10,11).

SPHENOBASILAR SYNCHRONODOSIS

Assessment of motion of the SBS is important in any complaint referable to the head, eyes, ears, nose, and throat. In both the pediatric patient and adult, motion of the SBS is assessed through gentle palpation of the cranium. The quality, quantity, symmetry, and type of motion are evaluated. The trained clinician can evaluate gross patterns of articular, membranous, and fluid motion. The astute clinician can evaluate more specific individual bone motion, specific suture restrictions, and cranial related motion in other parts of the body. Individual motion of the temporals and their sutures is an important skill to obtain, especially in HEENT disorders.

Students of osteopathic medicine base the hypothetical biomechanics of the SBS on the observations and writings of William Garner Sutherland, as well as the clinical experience of many other osteopathic physicians. The exact physiology of the cranial rhythmic impulse is still under study; however, there is mounting evidence that this phenomenon is related to the Traube–Herring–Meyer wave. The biomechanical model of the primary respiratory mechanism has as its driving force, the inherent motion of the brain and spinal cord, the fluctuation of the cerebrospinal fluid, and the inherent motion of the intracranial and spinal membranes. In this hypothetical model, there is motion between the sphenoid and the occiput. As the SBS rises during cranial flexion, tension is placed on the dura and is transmitted to the sacrum. This upward pull on the sacrum causes cranial flexion (anatomic extension, or counterrotation) of the sacral base. During the cranial extension phase, the SBS descends and tension is relieved to the dura sheath. During flexion, paired bones exter-

nally rotate, and during extension paired bones internally rotate. The primary respiratory mechanism is palpable throughout the body, due to the dural motion and fascial continuity.

PATIENT EVALUATION

Obtaining the history of the patient with a complaint referable to the head, eyes, ears, nose, throat, face, or jaw requires a knowledge of common clinical syndromes, anatomy of the region, and the physiologic function of the tissues involved. When a patient enters the office with the above type of complaint, the clinician must find out the primary problem, its duration, location, radiation, severity, associated symptoms, and what has been done so far. It is very important to find out if the patient had sustained any trauma to the head or face. Be sure to delineate if they had a closed head injury or witnessed loss of consciousness. If an injury was involved, the clinician should document all possible information regarding where and when the event occurred, how it happened, who was involved, and the patient's initial course of action (did they go to the emergency room?) The clinician must eliminate any urgent conditions that need to be expeditiously treated. They also need to use proper judgment in deciding when and how to utilize OMT and when not to. Evaluating the head, face, eyes, ear, nose, and throat in an infant or child is quite different than an adult or elderly patient. The most commonly encountered clinical conditions change as well. The diagnostic and treatment approach used with OMT is also variable based on the patient's age. The clinical application of knowledge and skills over a diverse and varied patient population takes a long time to learn and perfect.

HISTORY**Adult**

In the adult patient with a chief complaint referable to the head, eyes, ears, nose, throat, face, or jaw requires the clinician to question the patient regarding:

- Pain
- Traumas
- Infections
- Allergies
- Surgeries
- Exposure to chemicals, irritants, alcohol, or drugs
- Tobacco
- Nutrition
- Emotional health
- Hormonal changes
- Last dental and eye exam

If the patient is found to have occupational risk of injury or reinjury, then appropriate preventative measures need to be in place. Some of these include Ear plugs/ear protection:

- Safety glasses/face shields
- Bite guards/dental protection
- Helmets
- Appropriate respirator masks
- Welding masks

When considering effects of the injury or illness on the cranial mechanism, the following needs to be obtained:

- A thorough birth history
- Dental history and dental surgeries

- Eye injuries and visual acuity
- Glasses, type of correction
- Face lift and/or Botox injections
- Head or neck (including sinus surgery)
- History of concussions

Many times, the history will point to the diagnosis prior to performing the physical exam. For example, with proper questioning of a pharyngitis patient, the patient may state that the sore throat is worse upon arising in the morning. When deriving a differential diagnosis from the history alone, this information could point to post nasal drip as a potential cause, as well as acid reflux disease (nocturnal acid secretion). At this point, the clinician would need to examine the posterior pharynx, the abdomen, and the thoracic and cervical spine for areas of related somatic dysfunction. With the additional information from the physical exam, clinicians can either confirm their suspicions, or go back and reprioritize their differential diagnosis.

Infant

Obtaining the history for an infant comes from the mother and or father, other family members, and caregivers. Sometimes, there is a discrepancy in information if multiple people are involved. A simple look at the child can tell the experienced clinician if the child is “sick” or “toxic” appearing. With infants, they can become ill very quickly, so time is of the essence if one suspects a serious condition, like an intracranial bleed. Any trauma case must be fully evaluated, and if there is any indication from the history or physical findings to suspect abuse (or negligence), the appropriate actions need to be taken. In the pediatric patient with a chief complaint referable to the head, eyes, ears, nose, throat, face, or jaw requires the clinician to question the family or medical staff regarding.

Prenatal history

- Maternal health
- Maternal infections
- Use of tobacco, alcohol, or illicit drugs
- Term, preterm, post dates
- Any intrauterine illnesses
- Epidural

Birth history

- Vaginal delivery or c-section
- Forceps
- Vacuum extraction
- Complications

Head Shape

- Craniosynostosis
- Caput secundum
- Cephalohematoma
- Plagiocephaly

Head Control

- Age
- Favors one side

Acute Versus Chronic Illness

- Hospitalizations
- Antibiotic usage

- Immunizations
- Congenital anomalies
- Vision/gaze
- Hearing loss
- Suckling/difficulty latching on

Geriatric

Obtaining the history for a geriatric patient comes partly from the patient as well as other family members and caregivers. Sometimes, there is a discrepancy in information if multiple people are involved. The patient might have dementia and a poor recall of how they are doing or what had occurred in the short term. Similar to the child, a simple look at the elder can tell the experienced clinician if the elder is eating, drinking, or sleeping well. With geriatric patients, they may not seek medical care on their own. Many times, it is a family member who calls for them, concerned that they are not doing well. Any trauma case must be fully evaluated. It is common for elders to fall and strike their head. Many are on blood thinners, so that increases their risks for an intracranial bleed. If there is any indication from the history or physical findings to suspect elder abuse, the appropriate actions need to be taken. In the geriatric patient with a chief complaint referable to the head, eyes, ears, nose, throat, face, or jaw requires the clinician to question the family or medical staff regarding:

- Dizziness
- Fall risk “weakness”
- Visual acuity
- Tearing
- Nocturnal eye pain
- Hearing loss
- Dentures
- Closed head injuries
- Last dental and eye exam

PHYSICAL EXAMINATION

Adult

The physical exam always starts with an interpretation of vitals including height and weight. Comparison is made to past-recorded findings. Observation of the face, head, and neck is important. The clinician needs to look at head position, shape, and symmetry. The same holds true for the face. The clinician needs to look at facial position, shape, and symmetry. A unilateral facial droop may indicate a stroke or Bell palsy. An orbit that is larger or smaller and a protruding ear may indicate torsion of the SBS. The scalp and the hair need to be evaluated. Is the hair dry and brittle? If so they might have hypothyroidism. The skin needs to be evaluated for scars, rashes, and skin lesions. A red nose and cheeks may indicate rosacea or possibly lupus. A dark appearing mole on the top of the ear or near the hairline may be a melanoma. Patients who have had a craniotomy have a curvilinear scar on their scalp near the hairline. The temporal arteries need to be palpated, and sometimes auscultated. Tenderness in a 70-year-old patient with headaches, shoulder and hip stiffness, and elevated sedimentation rate may indicate polymyalgia rheumatica and/or temporal arteritis.

Eyes

Start with observation. An orbit that is larger with an ipsilateral protruding ear suggests torsion of the SBS. Unequal pupils (anisocoria) can be congenital or acquired. More than 3 mm is significant.

There are many causes, from sympathetic dysfunction, Horner syndrome, to brain tumors. Obtain a visual acuity test with and without correction. Check each part of the eye—the lids, pupils, iris, conjunctiva, sclera, lacrimal gland, tear duct, etc. Check the function of the extrocular muscles. Then perform an ophthalmoscopic exam. Check the patient's cranial mechanism with their glasses on and off, focusing on both near and far objects (ceiling).

Ears

When examining the ears, look at their position during the standing structural exam. An ear that protrudes might be related to an externally rotated temporal bone. Look at the skin of the pinna, tragus, and antitragus. If you suspect otitis externa from your history, pull gently upward and posteriorly on the pinna. This will elicit pain if an otitis externa is present. Perform the otoscopic exam. The canal should be clear of wax, if not clean it out and get a good look at the drum. The drum should be pearly-white with a good reflection of light. The drum can be evaluated for motion by insufflation or a tympanogram. A hearing test is appropriate for specific complaints and for the occupational medicine visit.

Nose

The nose (and face) is a common place to get skin cancers, due to sun exposure. Look at the skin for erythema (rosacea, alcoholism, lupus), acne, scars, etc. Examine the nasal cavity. The nasal mucosa and turbinates should be pink, not red or bluish. The septum should be midline and not swollen. Sites of bleeding need to be found. Polyps appear as clear fleshy protrusions in the nasal cavity and may be related to asthma and aspirin sensitivity.

Sinuses

Palpation of the face over the frontal and maxillary sinuses reveals tenderness when they are full of fluid. The tissues may feel boggy or puffy as well also indicating this. If the frontal and maxillary sinuses are transilluminated, in a dark room, a defect in light transmission is seen in either the frontal bone (frontal sinuses) or in the palate (maxillary sinuses) when a sinus infection is present. This author has found that resistance to a light springing pressure over the maxillary or frontal sinuses can correlate with a sinus infection. Determining if there is involvement of the sphenoid or ethmoid sinuses is more difficult clinically. If the majority of mucus is running down the back of the patient's throat and they are not blowing it out through their nose, the deep sinuses may be involved. If they are tender between the eyes to palpation, this is an indicator as well. The patient usually has a severe deep headache. If the clinician questions involvement of the sphenoid and ethmoid sinuses, then a sinus computed tomography (CT) scan can be done.

Oral Cavity

Examine the lips first for signs of cheliasis (cracking near the corners), cyanosis, and herpes simplex lesions. Now look at the buccal mucosa, teeth, and gums. Receding gum lines, bleeding, and discoloration may indicate gingival/periodontal disease. Broken teeth, asymmetrically worn cusps, and crooked teeth may indicate bruxism. Palpate the temporomandibular joint as the patient opens and closes his or her mouth. Feel for clicking, grinding, and local tenderness. Watch the teeth hit when the mouth closes. If the jaw deviates to the right, palpate the cranial mechanism and look for an externally rotated temporal bone. Look at the tongue, posterior pharynx, ton-

sils, and uvula. Have the patient close his or her mouth and open it while palpating his or her CRI. Does it change? How so? If patients have a bite guard, check the motion of their SBS with the guard in and out. If you find that a specific position or motion locks up their mechanism, you know what to have them avoid or change.

Infant

The physical exam of the infant's head, face, eyes, ears, nose, and throat is much different than the adult. Many times, the infant will be sleeping or feeding, which allows a more thorough exam of the head, including the SBS. When the infant is crying, a view of the open mouth and posterior pharynx is possible. Examination should evaluate and document:

- Symmetry and shape of the head
- Head circumference
- Craniosynostosis
- Caput secundum
- Cephalohematoma
- Plagiocephaly
- Fontanel's
- Dilated scalp veins
- Face, paralysis, asymmetry, color, texture
- Head control position and movement
- Eyes, red reflex, hypertelorism
- Visual acuity in children age 3: Snellen E game
- Shape, size, position of ears

Geriatric

The face of the elderly patient tells a lot about his or her health. Sunken eyes and cheeks may indicate dehydration or malnutrition. Geriatric patients tend to not drink much water and their mucus membranes may be dry and thin. Skin lesions are common especially actinic keratoses, seborrheic keratoses, basal cell cancers, and moles. Pupils may be hazy indicating cataracts. Many elderly patients have poor dentition, dentures, and bridges. Evaluate their cranial mechanism and occiput with their dentures in place, as this helps jaw position and facial appearance. When evaluating the cranial mechanism, the hearing aids may need to be removed so they do not whistle. When the patient lies supine, always keep enough pillows under his or head. This is due to their increased kyphosis as well as the patient with spinal stenosis.

COMMON CLINICAL SYNDROMES

Common Cold

Osteopathic treatment of the common cold should have an objective to accomplish. The objective can be based on the patients' symptoms, the pathophysiologic process, the structural findings, or a combination thereof. The primary etiologic factor in the common cold is the loss of physiologic and anatomic integrity resulting in vasomotor imbalance, dry mucus membranes, and a functionally impaired immune system (12). Predisposing factors include patients who are not well hydrated, have dry/irritated mucous membranes, have lowered resistance of the immune system, are exposed to others who are ill, have poor nutritional status, and are not sleeping well. Every patient has a normal amount of bacterial and viral flora of their mucous membranes; however, when this barrier becomes compromised, nosocomial flora can become "invaders." The viral etiology of the common cold, as well as a bacterial superinfection, needs to be considered as a "secondary infection," due to a *primary*

physiologic dysfunction. OMT can address the primary physiologic dysfunction and allow the body's own immune system to fight the invading organism(s).

The process starts with compromised mucous membranes. The mucous membranes are under autonomic control. The vasodilator nerves come from the parasympathetic nervous system via CN seven, by way of the sphenopalatine ganglion. The vasoconstrictor nerves come from the sympathetics. The preganglionic fibers of the sympathetics to the head and neck arise in the upper thoracic spinal cord (T1-4). From here, they follow the great vessels into the neck to synapse at the superior cervical ganglion. From the superior cervical ganglion, postganglionic fibers supply the mucous membranes of the nose and throat as well as other structures of the face and neck. Osteopathic evaluation needs to start in the upper thoracics and ribs. Somatic dysfunction in this area can affect sympathetic tone to the head and neck. This with increasing fluid consumption will decrease the viscosity of the nasal secretions and bronchial mucus, allowing expectoration. It will also shrink the swelling and edema of the mucous membranes (making it easier to breathe) and normalize autonomic tone to the bronchi and lungs. According to Becker, articular treatment of the lower thoracic and lumbar spine will effect vasomotor tone to the abdominal viscera and provide better circulation to the skin of the entire body. He felt that there was a direct relationship between the vasomotor innervation of the nasal mucosa and that of the circulation in the skin (12). Following treatment of the thoracic spine and ribs, the thoracic inlet and cervical spine are treated. Eliminating fascial restrictions of the thoracic inlet can improve lymphatic drainage from the head and neck (2). Treatment of the sternoclavicular joints, first rib, and shoulders may be necessary to free the thoracic inlet. The suboccipital region is usually tender and reactive to palpation. If so, gentle indirect techniques are an appropriate choice. Treatment of the face, and neck, encourages drainage from the sinuses, ears, nose, and posterior pharynx. Tender reflex points are located over the branches of the trigeminal nerve (V1, V2, and V3) as well as in the masseters, temporalis, sternocleidomastoid, and anterior chest wall. Circular inhibitory pressure applied to these points causes vasoconstriction and improves nasal congestion draining of the sinuses. Facial effleurage and lymphatic pump procedures augment drainage. Treatment of cranial dysfunction assists in managing a patient with sinus congestion. If significant frontal sinus congestion is present, performing a frontal lift may be beneficial to facilitate drainage as well.

In summary, osteopathic treatment:

1. Improves the blood supply to the skin, head, and neck
2. Increases venous and lymphatic drainage from the affected area
3. Relieves muscle spasm, thereby improving breathing
4. Relieves pain
5. Reduces reflex disturbances
6. Improves circulation to and from the reticuloendothelial system and thereby improves immune function
7. Normalizes autonomic and somatic nerve function

Sinusitis

Acute sinusitis is a self-limiting problem. Chronic or recurrent sinusitis is more of a diagnostic and treatment dilemma. Always consider anatomic obstruction of drainage. This could be an abnormal osteomeatal complex, a polyp, swollen membranes, nasal septal deviation, or even a tumor. The paranasal sinuses are air-filled extensions of the nasal cavity into the frontal, ethmoid, sphenoid, and maxillary bones. All of the paranasal sinuses drain directly or indirectly into the nasal cavity. The frontal and sphenoidal sinuses

are absent at birth and develop during childhood and adolescence. Sinus headache referral patterns are predictable because branches of the trigeminal nerve innervate the sinuses. Sinus dysfunction (acute and chronic sinusitis and chronic postnasal drip) may result from cranial dysfunction. Removing dysfunctional cranial motion patterns may allow the sinuses to drain more freely and provide symptomatic relief. In cases of bacterial sinusitis, improving blood flow to and lymphatic drainage from the sinuses may allow antibiotics to work more efficiently. Allergy may predispose to swelling, obstruction, mucus production, and superinfection.

The frontal sinuses drain into the middle meatus and are innervated by branches of the supraorbital nerves (CNV1 branch of the trigeminal nerve). Impaired drainage from the frontal sinuses may result from frontal bone restriction. Frontal sinusitis may be associated with palpable tissue texture changes over the supraorbital foramen. Frontal sinusitis may respond to frontal lift technique.

The ethmoid sinuses drain into the superior and middle meatus and are innervated by branches of the ophthalmic nerve (CNV1 branch of the trigeminal nerve). Impaired drainage may result from ethmoid bone restriction. This ethmoid bone restriction usually occurs secondary to frontal bone restriction, sphenoid dysfunction, or maxilla dysfunction. Ethmoid bone restriction may respond to frontal lift technique, vomer pump, and other facial articular techniques.

The sphenoid sinuses drain into the sphenothmoidal recess, in close approximation to the cavernous sinuses, and are innervated by the posterior ethmoid nerve (CNV1 branch of the trigeminal nerve). Infections of the sphenoid sinuses are especially dangerous due to close approximation with the pituitary gland, brainstem, cavernous sinus, and CNs. Impaired drainage may result from motion restrictions affecting the sphenoid bone (torsion, sidebending/rotation, vertical strain, lateral strain, and SBS compression). Impaired drainage may respond to correction of the dysfunctional motion pattern.

The maxillary sinuses drain into the middle meatus and are innervated by branches of the maxillary nerve (CNV2 branch of the trigeminal nerve). Maxillary sinusitis may be associated with palpable tissue texture changes over the infraorbital foramen. The maxillary bone articulates with and is driven by the frontal bone and sphenoid. Maxillary sinusitis may improve with correction of dysfunctional maxillary, sphenoid, and/or frontal bone motion.

Increased sympathetic tone from the upper thoracic region can cause vasoconstriction and a reduction of medication distribution. It will also thicken mucus, decrease lymphatic response and lymphatic flow. Parasympathetic imbalance can cause increased tearing (watery eyes) and a runny nose. Dysfunction of the suboccipital region can irritate the vagus nerve producing a "vagal" headache and nausea. Sinus congestion may irritate the trigeminal nerve producing a headache. Lymphatic and venous stasis contributes to the pressure sensation and headache in these patients. T1-4 is the focus of sympathetic activity for the head and neck. Tissue texture changes at these thoracic levels and especially over the costotransverse area and the rib angles are significant. Parasympathetic innervation to the head and neck is via CNs III, VII, IX and X. Cranial somatic dysfunction can affect the function of these nerves. The occiput, atlas, and C2 should be considered a functional unit. Tissue texture abnormality is significant in this region in the sinusitis patient; this is partly due to the relationship of this area to the vagus nerve.

Tissue texture abnormality at the cranial base and occipitomas-toid area can impair jugular drainage from the head. Thoracic inlet fascial restrictions can also impair lymphatic and venous drainage from the head. Cranial dysfunction, especially the temporal

bone, can affect the autonomic nervous system, drainage from the eustachian tube and CN function.

Goals for Osteopathic Manipulative Management

1. Adequate treatment of sinus infections centers around three principles:
 - Drainage
 - Treat the offending organism or condition
 - Support the host
2. *Drainage* can be accomplished through a variety of techniques. Opening the thoracic inlet and decreasing sympathetic tone prior to sinus techniques works well. Inhibitory pressure over the branches of the trigeminal nerve may decrease nerve sensitivity to the underlying structures. Facial effleurage mobilizes lymph and increases circulation. Percussion over the sinuses loosens mucus. Articulation of the nasal bones opens the osteomeatal complex.
3. *Supporting the host* is directed at balancing sympathetic/parasympathetic tone, removing mechanical restrictions of lymphatic flow, relaxing soft tissue tensions, and improving motion restrictions.

OMT will help drain the sinuses and liquefy mucus. Without achieving adequate drainage and liquefaction of the mucus, antibiotics alone will not work. Suboccipital tissues contain significant (and very tender) tissue findings. Treat the upper thoracic and ribs first prior to addressing the suboccipital region. Dr. McCarty found numerous reflex tenderpoints associated with acute sinusitis (13). He felt that treating these reflex tenderpoints with inhibitory pressure breaks into the autonomic disturbance. Following treatment of these tender reflex points, the patient may feel warm and sweaty. This signifies adequate treatment (13). In addition, cranial dysfunction may result in sinus pain without the presence of infection. It is important to remember the associated neural innervations and treat the associated dysfunctional patterns. Additionally, trigeminal nerve stimulation will help with sinus drainage. Ethmoid articulation will facilitate sphenoid and ethmoid sinus drainage. Lymphatic decongestion of the pterygopalatine fossa area improves overall sinus drainage and eustachian tube function via the sphenopalatine ganglion. Addressing somatic dysfunction in the neck and upper thoracic regions improves lymphatic drainage from the sinuses including drainage through the thoracic outlet and diaphragmatic motion (T-L jct. and rib raising).

Tension Headache

Headache is one of the most common conditions seen in a primary care practice. Every year, 40 to 50 million Americans seek treatment for headaches (5). This condition can be caused by a number of intracranial and extracranial abnormalities. The underlying cause of many headaches is often described as “unknown” or “idiopathic.”

Tension headaches are the result of the body’s response to stress, anxiety, depression, fatigue, and emotional conflicts (work, school, family, and marriage). The body responds by contracting the skeletal muscles of the head, neck, and face. Tension-type headaches usually occur bilaterally and are described as a fullness, tightness, or pressure sensation in the forehead, temporal area, or back of the head or neck (especially in the suboccipital area). They may also be described as a band-like sensation around the head. Tension-type headaches are not usually associated with nausea or vomiting. They may be associated with sleep disturbances. Headaches in combination

with anxiety may result in difficulties falling asleep. Headaches in combination with depression may be associated with early and frequent awakening.

A good history and physical exam is necessary to classify headaches. Quality and severity of pain, localization of pain, timing of headaches, associated symptoms (e.g., auras), dental history, and musculoskeletal pain and/or neurologic symptoms should all be investigated. Has he taken anything for the pain? Is he on any new medications? Has his social history changed (e.g., quit drinking coffee)? What are his current psychosocial issues? A detailed history is vital to the diagnosis and treatment of headache, especially if they are recurrent or chronic in nature. Information regarding the patient’s birth history (length of mother’s pregnancy, maternal complications, length of labor, method of delivery, use of forceps, pitocin or vacuum extraction, neonatal complications) and childhood growth and development may shed light on the precipitating factors for headache. A history of trauma is often important. Clinical experience has revealed that a forgotten fall or head injury that has resulted in a sacral shear has often been overlooked and is the key to providing effective treatment of a chronic headache. Family history should be obtained (5), including information about:

- Headache: onset, frequency, location, duration, and severity
- Associated symptoms
- Trigger factors
- Previous medical, surgical, and dental history
- Prior headache therapy

A thorough knowledge of anatomy and physiology and ability to diagnose structural abnormalities of the cranium, neck, upper thoraces, and sacrum often allows a physician to logically explain and treat previously unknown causes of headache. The implementation of a rational treatment plan significantly reduces suffering of the patient and improves overall functioning.

The head and scalp contain many pain-sensitive structures. These include:

- Skin and its blood supply
- Muscles of the head and neck
- Great venous sinuses and their tributaries
- Portions of the dura mater at the base of the brain
- Dural arteries
- Intracranial arteries
- Cervical nerves
- Trigeminal (V), abducens (VI), and facial (VII) nerves

The pathophysiology of tension-type headaches remains controversial but may involve the trigeminal neurovascular system and unstable serotonergic neurotransmission. Recent evidence supports the hypothesis that the basic pathophysiology of tension-type headache is qualitatively similar to but quantitatively different from migraine. The brain parenchyma itself is not sensitive to pain. Pain from structures above the tentorium cerebelli travel via the trigeminal nerve, so pain referred from structures above the tentorium cerebelli is perceived in the frontal, temporal, and parietal regions of the head. Pain fibers from structures below the tentorium cerebelli travel via the glossopharyngeal (IX) and vagus (X) nerves and the upper cervical spinal nerve roots. Therefore, pain referred from structures below the tentorium cerebelli is perceived in the occipital region (5).

A complete physical examination is performed, including a neurologic evaluation, in addition to the structural examination. The neurologic exam is mandatory, but likely to be normal. Carefully document your findings. Always rule out serious organic causes of headache, such as brain tumor, aneurysm, arteriovenous

malformation, hemorrhage, and temporal arteritis. Neuroradiologic studies such as CT, magnetic resonance imaging (MRI), and/or magnetic resonance angiography are needed if any of the aforementioned is suspected (5).

From an osteopathic perspective, is there a postural component to this patient's problem? What are the specific mechanics of his upper body while he performs his job? Is there something noxious in the work place? Is he feeling anxious about his work performance? Structural abnormalities, usually acting via the fasciae, place tension on pain-sensitive structures and cause discomfort. For example, parietal bone dysfunction produces strain on the superior sagittal sinus, producing discomfort in the parietal region. Upper cervical dysfunction leads to discomfort in the occipital region. Gastrointestinal abnormalities result in headache in the occipital region via vagal transmission.

Upper thoracic and cervical muscle spasm may produce paresthesias in the upper extremity, but there are often limited objective findings for this on exam. Along with upper thoracic and cervical findings, suboccipital tissue texture changes and tenderness will be present as well. Somatic dysfunction in the upper thoracics, cervicothoracic junction, and cranium (internally rotated temporal bone) may result in increased sympathetic tone to the head. This will make the muscles in the upper back and neck tight. Poor posture can contribute to somatic dysfunction in the upper thoracic spine. Many people who work at a desk or computer develop a kyphotic posture where the scapulas are protracted and the shoulders are rolled forward. The upper neck backward bends and the suboccipital muscles tighten. The pectoralis minor muscle subsequently tightens. Workstation problems need to be addressed. Computer screens may need to be raised to eye level to promote good posture. Chair height may need to be altered to promote good posture. The patient may benefit from performing

daily postural exercises, scapular stabilization exercises, pectoralis minor stretches, and scalene stretches. Patients with hypermobility affecting the neck may respond to cervical isometric exercises.

Is there an emotional component to the patient's condition? How does the patient look in general? Is his or her affect appropriate? Does the content and the manner of his speech give any clues to how he is feeling emotionally? Ask if he feels "stressed out." If so, acknowledge the patient's feelings; this may facilitate an important part of the patient's therapy.

Tension-type headache is the ideal situation in which to utilize osteopathic manipulation while addressing the underlying triggers (Table 37.5). Educating the patient regarding postural mechanics, appropriate footwear, and tension-relieving exercises will help reduce the frequency of his headaches. Stress management counseling should be offered to assist the patient in dealing with the emotional component of his condition. By identifying the patient's specific stressors and current coping mechanisms, you can individualize your recommendations to the patient's specific needs. This is also the opportunity to counsel the patient regarding the importance of smoking cessation. It has been clearly demonstrated that smokers experience more pain and heal more slowly. Is it possible that altered respiratory motion with utilization of accessory muscles of respiration is contributing to his headaches? Could hypoxia be playing a role as well?

MIGRAINE HEADACHE

Migraine headaches are a common cause of functional disability in the United States. The annual cost of lost productivity in the United States has been estimated to range from \$1.2 billion to \$17.2 billion. Migraine headaches are frequently described as a unilateral throbbing, pounding pain. They can radiate to the opposite side. They may be associated with nausea, vomiting,

TABLE 37.5

Treatment algorithm for Tension-Type Headache

Treatment Plan	Objective	Technique
Treat upper thoracic and rib dysfunction	Eliminate upper thoracic dysfunction involved in perpetuating the pain; balance autonomic tone	Soft tissue, MFR, ME, FPR, Counterstrain, HVLA, rib raising
Treat cervical dysfunction, particularly involving the occiput, C1, and C2	Eliminate cervical mechanics and soft tissue tension involved in exacerbating the pain	Soft tissue, Occipitoatlantal MFR, FPR, ME, HVLA
Treat cranial dysfunction including TMJ dysfunction	Eliminate cranial strain patterns affecting the trigeminal neurovascular system	Direct and indirect cranial osteopathy; MFR and ME technique for TMJ dysfunction
Treat lumbar, sacrum, and pelvis	Eliminate compensatory or contributing strain patterns from below	Soft tissue, MFR, ME, HVLA, Counterstrain
Address postural mechanics	Reduce exacerbating factors	Core strengthening, scapular retractions, cervical isometric exercises, proprioceptive training
Stress reduction counseling	Reduce exacerbating factors while enhancing overall well-being	One-on-one counseling to identify specific stressors and individualize stress management strategies
Health promotion and disease prevention	Reduce risk of future illness; enhance overall well-being	Smoking cessation, exercise and nutrition counseling; health screening (e.g., fasting lipids, immunizations)

diarrhea, vertigo, dizziness, tremors, photophobia (light sensitivity), phonophobia (sound sensitivity), sweating, and chills. Migraines may be preceded by scotomas (blind spots in the eyes); photopsia (flashing lights); vertigo; paresthesias (abnormal sensations); visual, olfactory, and auditory hallucinations; or syncope (passing out). Migraine headaches are recurrent and vary widely in intensity, frequency, and duration.

The initial episode most often occurs during puberty but can occur at any age between 5 and 40 years. Migraine headaches may be triggered by (5):

- Head injury or other trauma
- Stress
- Hormone fluctuations
- Fasting
- Oversleeping and under sleeping
- Vasoactive substances in foods (wine and cheese, cold foods)
- Changes in weather and temperature (bright light, poor ventilation)
- Physical stimuli (smoking), caffeine

Migraine headaches are thought to occur by the following mechanism. The production of migraine symptoms involves two major events: vasoconstriction and vasodilation. The cerebral blood vessels can be divided into two major systems: the innervated (adrenergic) system and the noninnervated arterial system. The large innervated vascular system consists of the arteries at the base of the brain and the pial arteries. These have a rich adrenergic nerve supply and respond to catecholamines. The noninnervated vascular system consists of the parenchymal arteries and the terminal high-resistance arteries. They respond to local metabolic factors.

Trigger factors (listed above) produce unilateral cerebral vasoconstriction via the adrenergic nervous system. Platelets systemically aggregate and release serotonin, which augments vasoconstriction of these adrenergically innervated blood vessels. The overall result is vasoconstriction with a reduction in cerebral blood flow. When blood flow is sufficiently reduced, an aura develops with symptoms occurring as a consequence of which brain region is affected by the constriction. The vasoconstriction phase causes local anoxia and acidosis and a systemic drop in serotonin. Serotonin sensitizes the pain receptors in the blood vessels. In response to local metabolic factors (anoxia and acidosis), the vessels of the noninnervated arterial system dilate, increasing cerebral blood flow and promoting local vasomotor changes resulting in a combined dilation of the innervated extracranial and intracranial arteries on the same side. This vasodilation, along with the sensitization of pain fibers, produces the pain of migraine (5).

A trigeminal vascular reflex may also explain some of the events seen in the production of migraines. Afferent pain fibers from the cortex, thalamus, hypothalamus, and cervical roots C1-3 communicate with the spinal nucleus of the trigeminal nerve. These impulses can then travel via the facial nerve (CN VII) to produce parasympathetic dilation of the internal and external carotid arteries. Pain perception is increased when the effects of this dilation feed back into the spinal nucleus of the trigeminal nerve. Stimulation of the trigeminal ganglion, through vasodilation, can also produce edema in the dura (5).

The biologically sensitive nervous system is confronted with trigger factors (listed above) that can provoke a migraine. The neurochemical balance of the nervous system changes and symptoms, recognized as *prodromal*, may occur. This change progresses until the migraine threshold is crossed and an area in the brainstem called the “migraine generator” is activated. This may initiate a wave of neuronal depression to move across the cortex and activate

trigeminal afferents and the vascular structures they innervate. As branches of the first division of the trigeminal nerve are activated, neuropeptides are released at the neurovascular junction. The neuropeptides produce a sterile inflammation of the meningeal arteries associated with platelet aggregation and release of serotonin, which may potentiate the migraine process. Bidirectional conduction conducts nerve impulses back into the CN V nucleus located in the brainstem. These impulses are then routed to various neurons in the thalamus and cerebral cortex. The upper cervical cord gets involved through this nucleus, too, and that explains the neck pain that is often involved. Brainstem reflexes are activated that produce the migraine-associated symptoms, including nausea, vomiting, photophobia, and phonophobia. Autonomic activation occurs via the facial nerve and results in nasal congestion, rhinorrhea, and lacrimation. Pain in the face over the sinus cavities is also common and may be due to CN V2 activation. Researchers have found evidence of breakdown products of serotonin in the urine of those who have just experienced a migraine headache. They have also found that injecting anyone with a *serotonin-depleting chemical* can produce a migraine headache, even if the person has never had a migraine in the past. Medications (Imitrex and Zomig—5HT1 receptor agonists) are effective in treating a migraine headache even during the attack. The pain from a migraine seems to be due to cerebral vasodilatation. In migraine patients, local vasodilatation of cerebral vessels seems to be produced when platelets line up in a portion of a cerebral artery and release humoral vasodilating substances. The vasodilatation is not autonomic—it is humoral.

Somatic dysfunction in the upper thoracic spine increases the level of sympathetic tone to the innervated blood vessels of the head. Increased sympathetic tone produces vasoconstriction and a resultant decrease in cerebral blood flow. This results in a relative anoxia and may lower the threshold for vasodilation, thereby contributing to the production of migraine symptoms. Cranial dysfunction affecting the cortex, thalamus and hypothalamus, and upper cervical dysfunction affecting cervical nerve roots C1-3 may result in the transfer of afferent pain stimuli to the spinal nucleus of the trigeminal nerve. The trigeminal nerve courses through various portions of the sphenoid bone. An elevated greater wing of the sphenoid (torsion) may apply dural pressure resulting in irritation of the trigeminal nerve, thereby feeding into the trigeminal vascular reflex. A sphenosquamous compression can compromise the function of the middle meningeal artery. The facial nerve courses through the temporal bone. Dysfunction of the temporal bone, such as internal rotation, can result in reflex vasodilation of the internal and external carotid arteries via the facial nerve. Occipito-mastoid compression can result in reduced venous drainage through the jugular foramen, thereby producing congestion and dysfunction in the cortex, thalamus, and hypothalamus as well as CNs IX and X.

Migraine headaches are more than just a problem with the head. They are a total body problem. Myofascial strain patterns stored within the abdomen or elsewhere in the body can cause tension changes on the base of the skull contributing to the disorder. Excessive tension around the sacrum and coccyx can contribute to increased tension in the upper back and neck. Vasodilation of cranial vessels during a classic migraine is a local phenomenon. Patients with common migraine or mixed tension-type headaches often have upper thoracic somatic dysfunction associated with (autonomic) dysfunction to the head and neck. An extended upper thoracic somatic dysfunction is typically acutely painful; keep muscle tone of the head, suboccipital, and neck increased and motion restricted. It is common to find suboccipital dysfunction related

to upper thoracic and rib somatic dysfunction. Treating the upper thoracics and ribs with Counterstrain or myofascial release techniques improves suboccipital tissue texture abnormality.

Somatic dysfunction of the sphenoid, temporal, and occiput may also be involved in trigeminal dysfunctions and headaches. The trigeminal ganglion provides sensory nerves from the forehead and upper and lower jaw. According to Magoun, normal movement of the temporals is critical, especially in migraine patients—they must move properly. It is difficult to treat a patient during an acute migraine. Treatment of a patient with a migraine can reduce the severity and frequency of acute migraine attacks, but the immediate treatment of an acute migraine in progress is medical.

OMT will enable many patients to either reduce the dosage or frequency of their medication. Several patients, when treated, may only occasionally require Motrin or Tylenol for rare minor headache. Does OMT work when the patient is actively having a migraine headache? Usually. It is always best to treat the patient between headaches. It is possible, however, to provide some relief while the patient is presently having a headache. It does take some time, however, for the inflammatory mediators and other chemicals involved in migraine headaches to be removed from the head by the lymphatics.

Most patients will be placed on a home exercise program that focuses on stretching exercises to reduce the amount of tension in the body (especially in the upper back and neck) and to help return balance to the body. OMT is used to improve motion in the body. The patient's responsibility is to maintain the improvements by performing the prescribed home exercise program. Stretches seem especially important.

TMJ SYNDROME

An estimated 10 million people in the United States (1 in 25) have TMJ disorder. The greatest incidence is in adults aged 20 to 40 years. The female-to-male ratio is 4:1 (11).

TMJ dysfunction is the most frequent source of facial pain after toothache. Patients with TMJ syndrome commonly complain of facial pain and jaw range of motion (ROM) restriction. Earache is fairly common. Facial pain is usually periauricular, worsened by chewing. The patient may also have clicking, popping, and snapping sounds, headaches, or neck pain.

The current diagnostic criteria divide TMJ dysfunction into three categories: myofascial pain dysfunction (MPD) syndrome, internal derangement (ID) injury, and degenerative joint disease (DJD) (11). MPD syndrome is best characterized as a psychophysiological disease primarily involving the muscles of mastication, frequently provoked by tension as well as somatic dysfunctions elsewhere in the body (11). ID is defined as an abnormal relationship between the articular disc and the mandibular condyle (11). Dental procedures are a common source of trauma (particularly work on molar teeth) and can cause ID.

A common example includes acute and chronic disc displacement. Anterior disc displacement is the most common cause of ID. The disc dislocation reduces upon opening of the jaw, which causes an *opening click*. The disc dislocates again upon closing of the jaw, which causes a *closing click*. If the condyle cannot override the displaced disc, jaw locking occurs. DJD involves arthritic degeneration of the articular surfaces within the TMJ. This can occur with long-standing dental malocclusion, bruxism, and ID of the TMJ. The other causes of DJD are osteoarthritis, rheumatoid arthritis, ankylosis, infections of the bone or joint, and neoplasia.

The TMJ has been described as the most complex joint in the body because it not only acts as a hinge joint but also permits a

gliding movement, in which the condyle of the mandible slides along the squamous portion of the temporal bone (11). The articular surface of the temporal bone is similarly complex, consisting of a convex articular eminence anteriorly and a concave articular fossa posteriorly. The stylomandibular ligament connects the angle of the mandible to the styloid process of the temporal bone and the sphenomandibular ligament connects the lingula (medial aspect) of the mandible to the spine of the sphenoid. The condyle and the temporal bone are separated by an articular disc or meniscus that divides the joint cavity into two small spaces. The meniscus has three parts: a thick anterior band, a thin intermediate zone, and a thick posterior band (11). When the mouth is closed, the condyle is separated from the temporal bone by the thick posterior band. When the mouth is open, the condyle is separated from the temporal bone by the thin intermediate zone. The suprahyoid muscles (mylohyoid, geniohyoid, and digastric muscles) provide a hinge-like movement to open the mouth. Anterior condylar glide is provided by the inferior division of the lateral (external) pterygoid muscles. Closing the mouth is accomplished by the temporalis, masseter, and medial (internal) pterygoid muscles. Lateral displacement (grinding movement) activates the ipsilateral temporalis and the contralateral medial and lateral pterygoids and masseter muscles.

During the physical exam of the patient, observe for lateral tracking of the mandible away from midline as the mouth is slowly opened. A deflection of the jaw to one side may occur in a C- or S-shaped pattern. While testing jaw ROM, palpate for clicking or popping of the joint as well as crepitus. Sometimes, the jaw will become locked when opening or closing. Strachan called the open lock position an *anterior lesion*, characterized by an uneven and painful forward glide on the affected side, and chin deviation toward the contralateral side, with an inability to close the mouth (9). He called the closed lock a *posterior lesion*. He describes manipulative techniques for treating each condition.

When considering the work-up of patients with TMJ, laboratory and imaging studies generally are not indicated. MRI, although costly, is the study of choice if articular or meniscal pathology is suspected and an endoscopic or surgical procedure is contemplated and in a case of traumatic TMJ syndrome (11). If the patient has associated tinnitus, hearing loss, or other neurologic complaints, an MRI of the brain should be ordered.

Treatment needs to address the pathology present, the exacerbating factors, and the symptoms that the patient is suffering with. Pain is usually controlled with medications; however, reducing tension in the jaw muscles, decreasing swelling and inflammation, and improving tissue congestion can reduce pain. The key to relaxing jaw muscles is keeping the teeth slightly apart. Nonsteroidal anti-inflammatory drugs can reduce inflammation and control pain, especially after dental procedures. Gabapentin (Neurotin) and its new analog pregabalin (Lyrica) have been prescribed for chronic TMJ syndrome (11). Any chronic painful condition, such as chronic TMJ syndrome, will worsen any pre-existing anxiety or depression. Therefore, treatment should include stress management, relaxation techniques for the face and neck, as well as medications when necessary. According to Nelson, benzodiazepines and codeine have no place in chronic TMJ syndrome (11). Exercise sheets and other resources can be obtained online from the TMJ Association. With long-standing dysfunction, the joint capsule may stretch, making the joint unstable. In this instance, injection of a proliferating agent into the joint (sclerotherapy) may tighten the capsule and help normalize motion.

Improving somatic dysfunction of the cranium, upper cervical and upper thoracic region is of great benefit in TMJ patients.

These are common regions of dysfunction in these patients; however, somatic dysfunction of any region may contribute to the TMJ patient through the continuity of the fascia. Postural imbalance from short leg syndrome has also been associated with TMJ (2).

When considering cranial somatic dysfunction, evaluation of the occiput and temporals is critical. In a study of 130 TMJ patients, nearly all presented with at least one type of biomechanical cranial dysfunction. Since the mandible hangs from the temporals, asymmetric tension of the jaw muscles, bruxism, and malocclusion will affect the position and motion of the cranium. Cranial dysfunction can affect TMJ motion because as the temporal bone externally rotates, the ipsilateral mandibular fossa moves posteriorly and medially. Internal rotation allows the ipsilateral mandibular fossa to move anteriorly and laterally. The mandible will deviate toward the side of the externally rotated temporal bone or away from the side of the internally rotated temporal bone. Sphenoid dysfunction can affect the TMJ through its direct articulation with the temporal bone or by its articulation with the mandible through the sphenomandibular ligament. Occlusal splints (mouth orthotics) are controversial (8). Manipulative treatments should be given before and after fitting for occlusal splints and before and after restorative dentistry. Normalize function of the temporal bone, since the squamous portion of that bone directly affects articular function of the TMJ.

Dysfunction of the occiput and atlas is commonly associated with the temporal bone. Tender points located in the soft tissues between the ramus of the mandible and the mastoid process are commonly found. Sometimes referred to as atlas Counterstrain points, treatment of this area with Counterstrain, effleurage, or the William Galbreath technique is useful. Articular dysfunction of the occiput on atlas usually has an upper thoracic component maintaining it. The occiput dysfunction will return if adequate treatment of the upper thoracics is neglected. Treatment of the upper thoracic spine is important in TMJ patients.

Bell Palsy

Bell palsy is caused by an inflammation and compression of the facial nerve and results in unilateral paralysis or paresis of the face. The condition affects approximately 23 in 100,000 persons; with onset typically occurring between the ages of 10 and 40 years (15). Bell palsy affects men and women at a roughly equal rate of occurrence (15). Many patients recover within 1 to 3 weeks. The cornea must be protected and kept lubricated while the condition is resolving (6).

The physiologic mechanism responsible for Bell palsy appears to involve inflammation of the facial nerve within the osseous facial canal, causing compression and ischemia of the nerve (15). A viral cause of Bell palsy has been suspected since the mid-1990s. Herpes simplex virus–type 1 was isolated from the facial nerve in patients affected by Bell palsy (16).

Symptoms of Bell palsy may be mild or quite severe (15). Severe symptoms of facial paralysis and ineffective tear production sometimes progress to corneal ulcerations. Physical signs of Bells palsy include drooping of the corners of the mouth, indistinct skin folds and facial creases, and an unfurrowed forehead. The clinical presentation is worrisome, in the outpatient setting, as Bell palsy has signs similar to a stroke. When patients eat, food may collect between their teeth and lips, and they may drool from the corner of their mouth. Smiling may reveal a marked contrast between the two sides of the face, with the affected side drawn without wrinkles. Depending on where the lesion occurs in the osseous facial canal, a patient's taste reception in the anterior two thirds of the tongue

may be altered. A patient may also experience pain in or behind the ear and hyperacusis (15).

When considering treatment for Bell palsy, the conventional treatment involves the use of oral prednisone (60 to 80 mg daily) for 5 days, followed by a tapering in dosage for 5 additional days (15).

Understanding the anatomy of the facial nerve and facial canal is important prior to treating patients with OMT. When using OMT to treat a patient who has Bell palsy, knowledge of the anatomy of the facial nerve as it traverses the temporal bone is important in understanding the nature of symptoms. The facial nerve travels through the internal acoustic meatus, located in the petrous portion of the temporal bone. It travels through the temporal bone via the facial canal. Here lies the geniculate ganglion, which supplies taste to the anterior tongue and cutaneous sensation of the external acoustic meatus. Branches of the facial nerve include:

- the greater petrosal nerve
- the stapedius nerve
- the nerve of the chorda tympani

The petrosal nerve provides parasympathetic innervation of the lacrimal gland. The stapedius nerve innervates the stapedius muscle, allowing dampening of loud sounds, and the chorda tympani supplies taste to the anterior two thirds of the tongue and parasympathetic innervation of the submandibular and sublingual glands (15). The facial nerve exits the cranium through the stylomastoid foramen to give rise to six terminal motor branches leading to the muscles of facial expression (17).

The osteopathic treatment plan should include treatment of the whole person, not just the face and head. Dysfunction of the sacrum, upper thoracic and cervical spine, and osteopathic cranial mechanism can contribute to impaired lymphatic drainage from the facial canal, leading to inflammation of the facial nerve. Start by treating the patient's lymphatic system by freeing up restrictions found in four key diaphragms: the thoracic outlet, respiratory diaphragm, suboccipital diaphragm, and cerebellar tentorium. Treatment of the patient began in the area of the thoracic duct and thoracic outlet with myofascial release of the supraclavicular fascia and use of the thoracic pump technique. The respiratory diaphragm was treated to allow for deeper breathing, thus creating greater pressure gradients to aid in lymphatic flow (18). Primary respiratory mechanism and osteopathy in the cranial field were used to release restrictions in the cerebellar tentorium, which attaches to the temporal bone and allows for physiologic temporal motion. Osteopathic physicians commonly find restricted ipsilateral motion of the temporal bone and upper cervical restrictions in patients with Bell palsy (19). Another area commonly restricting temporal motion is at the occipitomastoid suture. Look for a compression of the occipitomastoid maintaining an internally rotated temporal bone on the side of facial paralysis. OMT can decrease the severity of symptoms and help speed recovery. In one case study, the application of OM procedures focusing on the enhancement of lymphatic circulation resulted in complete relief of the patient's unilateral facial nerve paralysis within 2 weeks—without the use of pharmaceuticals (16).

OTITIS MEDIA

Ear pain is a common patient complaint in the practice of the primary care physician. Acute otitis media is a significant worldwide problem commonly affecting children between 6 and 18 months. Otitis media is the most frequent reason for a childhood visit to a physician in the United States. By 3 years of age, 50% to 70% of children will have had one episode, while one third will have had

more than three (20). Acute otitis media can affect a person of any age, although it is more often seen in children than in adults. The disease is usually caused by *Streptococcus pneumoniae* or *Haemophilus influenzae*. The standard of care for otitis media is based on following the 2004 AAP/AAFP Guidelines. The standard care for recurrent acute otitis media includes long-term antibiotic prophylaxis and surgery. The risks of standard care are recognized, and alternative means of treating acute disease and preventing recurrent otitis media are needed. For over a century, osteopathic physicians have reported favorable clinical outcomes in children treated with osteopathic manipulative medicine in addition to standard medical care. During the birth process, the forces of labor can affect the position and function of the cranial bones. These forces can alter the position and motion of the cranial bones. If left untreated, these cranial dysfunctions are thought to predispose the child to middle ear infections. Multiple studies have shown a beneficial effect of cranial osteopathy on children with otitis media (20–22). In regard to recurrent otitis media, OMT has shown a potential benefit when used as adjuvant therapy to the standard of care (20–22). Benefits included fewer tubes, improved tympanography, and less frequent use of antibiotics.

The manipulative techniques chosen are based upon the physician's skill and training, the type of dysfunction found, and the patient's presentation. The objectives to be accomplished are the following:

- Improve lymphatic drainage from the inner ear
- Decrease inner ear effusion
- Improve function of the Eustachian tube
- Improve cranial and temporal bone motion
- Decrease pain

OMT should be applied to only structures surrounding the ear. The upper thoracic spine and ribs, the thoracic inlet, the sacrum and pelvis, and the abdominal diaphragm may need to be treated as well. Locally, improving motion of the suboccipital region, releasing the occipitomastoid suture, and balancing the temporal bones are beneficial. One manipulative technique, called the *Galbreath technique*, is useful as well. First described in 1929 by William Galbreath, D.O., this technique involves mandibular manipulation, causing the eustachian tube to open and close in a "pumping action" that allows the ear to drain fluid more effectively.

KEY CONCEPTS

- Neck pain, second only to low back pain, is one of the most common complaints of patients seeing a primary care physician.
- Accurate diagnosis and treatment of the cervical spine is an important aspect of patient care.
- Dysfunction of the cervical spine is very common and may be related to numerous mechanical, systemic, and traumatic situations.
- Diagnosis of the cervical spine should consider basic imaging deemed necessary by any questionable clinical presentation or history.

INTRODUCTION

The cervical spine is of great significance to those who use manipulative treatment. The cervical region is a pathway between the head and the thorax with neural, vascular, and musculoskeletal communication. Injury, pathology, or dysfunction may interfere with these vital communications.

Accurate, gentle diagnosis and treatment of the cervical spine is an important aspect of patient care. Dysfunction of the cervical spine is very common and may be related to head and neck infections, trauma, stress, posture, sleeping, overuse, breathing, and orthopedic or rheumatologic conditions. The cervical spine is diagnosed based upon the patient's history and the circumstances present at the time of the evaluation. For example, the cervical spine evaluation of a young athlete in the emergency department following a head or neck injury is different than a 50-year-old patient with chronic neck stiffness upon arising in the morning. Some basic principles hold true, however. One caveat for the clinician is to have little reluctance to image the cervical spine in any patient in which the history, presentation, or situation deems it necessary or appropriate. An undiagnosed cervical spine fracture can have devastating consequences. This chapter will provide the reader with a basic understanding of cervical spine anatomy, physiology, dysfunction, and common conditions that would necessitate osteopathic diagnosis and/or manipulative treatment of cervical somatic dysfunction.

EPIDEMIOLOGY OF CERVICAL SPINE PAIN

Neck pain is one of the most common complaints of patients seeing a primary care physician. It is only second to low back pain for patient's seeking manual treatment (1). When discussing cervical spine pain, one must consider if it is acute or chronic and if it is related to a trauma. Acute neck pain by definition is pain on most days that has been present for at least 2 weeks. Chronic neck pain by definition needs to be present for 6 months. Posttraumatic neck pain needs to have ample history to support the mechanism of injury. Knowing these elements, the clinician has a better grasp of the epidemiologic statistics. The incidence of neck pain peaks between 20 and 40 years of age (2). Females present with neck and upper back pain more than males. The lifetime prevalence of neck pain is 71% (2–5). Patients with multiple medical problems, significant job stress, and occupational factors tend to have a

higher incidence of neck pain. Neck pain has been associated with psychological factors, such as high quantitative job demands. The combination of chronic illnesses adds to the severity of neck pain. Motor vehicle accidents are a common etiologic factor in patients with neck pain. Neck pain is the most frequently reported symptom in whiplash injury (6). It has been estimated that 66% to 82% of neck injuries seen clinically result from rear-end collisions (6). There is general agreement that acute neck injuries are more frequent among front seat passengers than among rear seat passengers. If head restraints are present, the use of seat belts alone results in fewer injuries. Without head restraints, the use of seat belts alone appears to cause a slight increase in injuries. A majority of studies show a higher incidence of whiplash injuries in women; some studies show the frequency of neck injury among women to be twice as high as among men (6). Lightweight people appear to be more susceptible to acute neck injury than heavier people. There is also a positive correlation between increased height and neck injuries. Neck somatic dysfunction was the most commonly reported somatic dysfunction found by a cohort of osteopathic physicians board certified in neuromusculoskeletal medicine, over a 6-month period (7).

HISTORY

Taking a thorough history is critical. This is especially true when it comes to neck trauma or closed head injuries, as many times these cases can have catastrophic outcomes and frequently become legal cases. Remember that assessment and treatment of the cervical spine is useful for a variety of presenting complaints, not necessarily just neck pain or headache. The type and specific location of the pain needs to be characterized, as well as the duration and severity. What has the patient tried to make it better? What has worked and what hasn't? Do certain activities make it worse? Have they ever had anything like this in the past? If so when and how did it resolve? Have they seen any other practitioners, or received any other treatments for their condition? Have they had any imaging of their cervical spine? If so, what is their understanding of their condition? Is their condition getting better, worse, or staying the same? How does their condition affect their day-to-day functioning?

An important aspect to the history of a cervical spine-related complaint is the involvement of trauma. Cervical spine trauma can be repetitive overuse, blunt trauma, or even emotional trauma. Multiple traumas may be layered upon one another. Delineating the

mechanism of the trauma is important. This will explain the forces introduced into the tissues at specific direction, rate, and amount. The specifics of each trauma need to be quantified and subjective complaints separated from objective physical findings. Documentation of any neck pain or issue prior to a trauma is important, as well as resolution or persistence of symptoms.

Many times, there are elements in the history that point to a specific clinical condition. For example, consider the patient with “cervicogenic angina” (8). Pain may radiate to the left shoulder or arm and be accompanied by upper extremity numbness. The patient seeks out medical advice thinking that they might be having a “heart attack”; however, it is found that the causative condition is orthopedic in nature. In this condition, compression of cervical nerve roots or cervical spondylosis (9) causes pain to be referred to regions innervated by the C5-T1 nerve roots, most commonly the C7 nerve root (10,11). It is important to elicit a history of shoulder and arm pain that is related to position or movement of the arm as this may be more of an orthopedic etiology. Pain that radiates from the neck into the arm at night, which improves with placing the arm overhead (“Bakody’s sign”), is more suggestive of a cervical nerve root irritation as well (26). Patients with cervical spondylosis commonly have palpable findings in the high thoracic region (12).

In contrast, consider “shoulder-hand syndrome” in which patients with acute coronary events or stroke develop pain, stiffness, and edema of the shoulder, arm, wrist, and hand. In this situation, the mechanism is different. Both local neurogenic inflammation and a hyperactivity of the sympathetic nervous system (upper thoracic spinal cord T1-4) are thought to cause the upper extremity symptoms. Interestingly, tissue texture changes in the soft tissues covering the upper thoracic spine and ribs may persist for years. Larson (13), Beal (14), and Nicholas et al. (15) have reported these tissue texture changes from T2-5 on the left in patients with cardiac disorders.

From the history, a differential diagnosis of the patient’s current problem is made and then the physical examination, imaging, and other diagnostic studies are used to rule out conditions within the differential. Prior to the physical examination, a clinician needs to recall the anatomy of the region, pertinent physiologic principles, and relevant biomechanics. This section will highlight important concepts in each of these areas.

FUNCTIONAL ANATOMY OF THE CERVICAL SPINE

Skeletal Structures

The cervical spine consists of seven vertebral segments. The atlas (C1) and the axis (C2) are atypical. The atlas does not have a vertebral body; instead it rotates around the dens (16). The dens contacts the inner anterior surface of the ring-like atlas. The atlas consists of an anterior and posterior arch, joining to form the heavy lateral masses that bear the superior and inferior articular surfaces. The superior facets articulate with the occiput, and the inferior facets articulate with the axis. The axial articular masses are broader and deeper than other masses because they bear the weight of the skull without assistance from the odontoid process. The atlas has a facet for articulation with the dens on its internal surface, as well as an anterior tubercle for muscular attachments. The posterior arch is longer and bears a small posterior tubercle in place of a spinous process. The transverse processes of the atlas, called lateral masses, are modified and palpable. Each transverse process has a transverse foramen for the vertebral artery. The vertebral arteries traverse through the foramina of C6 through the atlas and pierce

the tectoral membrane to enter the foramen magnum. The second cervical vertebra, or axis, is identified by the projection of the odontoid process, or dens, which develops from the embryologic body of the first vertebra. The dens acts as a pivot point about which the atlas rotates. The posterior surface of the dens has a facet that accommodates the synovial bursa that separates it from the transverse band of the cruciate ligament. The axis does not form a neural foramen for spinal roots. Its transverse processes are the only ones in the cervical spine that are not grooved to allow exit of a nerve root (16). The spinous process of the axis (C2) is larger, palpable, and prominent on x-ray.

The cervical vertebrae from C2-7 are saddle shaped and contain a specialized set of synovial joints on the lateral surface of the vertebral bodies. These are known as uncovertebral joints (or unciniate) joints of Luschka and provide stability to the cervical spine. They may also decrease the likelihood of herniated nucleus pulposus in the cervical region. The joints of Luschka are not synovial; thus, inflammatory arthropathies spare these areas. However, the facet joints and atlantal-axial joint have synovial membranes that can be involved in inflammatory arthropathies. The articulations between C2, C3, and the remainder of the cervical joints are considered typical.

The cervical transverse processes are unique and different than the transverse processes in the thoracic and lumbar spine. The lateral portions of the cervical vertebra (C1-6) are modified to contain a foramen through which the vertebral artery passes. The anterior portion of the transverse process is developmentally a rib, whereas the posterior portion is a true transverse process (16). These portions fuse, but between them persists the transverse foramen, which allows for passage of the vertebral artery. Although this provides protection for the vertebral artery, it also creates the possibility of trauma to the artery from bony insult.

The transverse processes contain a gutter that runs obliquely from anterior to posterior through which the spinal nerves traverse. These nerves exit the spine through the neural foramina, which are largest at the C2-3 level and decrease in size progressively to the C6-7 level. Flexion of the cervical spine increases the vertical diameter of the neural foramen, whereas extension decreases it.

The bone between the facets, which can be palpated, is known as the articular pillar. The lateral portions of the atlas are known as lateral masses. The lateral portions of the cervical vertebra (C1-6) are modified to contain a foramen through which the vertebral artery passes. Although this provides protection for the vertebral artery, it also creates the possibility of trauma to the artery from bony insult. The cervical facets are in a plane that points on a 45-degree angle toward the eye. Rotation motion of the typical cervical segments follows the plane of the facets. Anterior or forward rotation is toward the eye rather than rotation in a horizontal plane. The facet joints are enclosed in a fibrous capsule that is lax to allow movement in multiple planes. Synovial tissue lines the joint capsules. They contain menisci that protect articular surfaces from damage during cervical motion. These menisci may become entrapped in the joint and cause cervical dysfunction. The C7 vertebra has anatomic characteristics that are similar to those of T1. The transverse process of the seventh vertebra does not contain a foramen for the vertebral artery and its accompanying veins and sympathetic nerves (16). The bone between the facets, which can be palpated, is known as the articular pillar.

Ligamentous Structures

The cervical vertebrae comprise a smooth lordosis, held in position by muscles and ligaments. The anterior and posterior longitudinal

ligaments run along both sides of the spinal column and give support to the bony structure. They also help to contain the intervertebral discs. The anterior longitudinal ligament is a broad, strong ligament on the anterior aspect of the vertebral bodies from the atlas to the sacrum. Superiorly, the ligament attaches to the anterior arch of the atlas and the anterior atlanto-occipital membrane. The posterior longitudinal ligament lies on the posterior surface of the bodies of the vertebrae from the axis to the sacrum. The posterior longitudinal ligament is wider in the upper cervical spine and narrower in the lower cervical spine. Its lateral expansions over the discs are thin, weak, and represent a vulnerable area for disc herniation as compared to its strong central band. At the base of the skull, the tectoral membrane (occipital-axial ligament) is a continuation of the posterior longitudinal ligament and lies immediately behind the body of the axis. The alar ligaments are short, strong bundles of fibrous tissue directed obliquely superior and laterally from both sides of the superior portion of the odontoid process and attach to the medial aspect of the occipital condyles. They are often referred to as the “check” ligaments. The transverse ligament of the atlas is a broad, strong, triangular ligament arching across the ring of the atlas and anchored firmly on each side to a tubercle on the medial surface of both lateral masses of the atlas. The transverse ligament has two fascicles layered in a crosswise fashion, which gives it a cruciate configuration. The transverse ligament portion of the cruciate ligament complex supports the atlas in rotating about the dens. The anterior surface of the spinal cord lies immediately posterior to the transverse ligament. Rupture of this ligament (or laxity, which may occur with rheumatoid arthritis) creates the possibility of the dens contacting the spinal cord, causing catastrophic neurologic damage.

The remaining cervical vertebrae, C2-7, have a similar ligamentous configuration. The supraspinous and interspinous ligaments, found between adjacent spinous processes, attach each spinal vertebra to one another. The highly elastic ligamentum flavum (yellow ligament) lies posterior between adjacent lamina. There are two ligamentum flavum at each spinal level, separated by a small cleft posterior medially.

Intervertebral Discs

Each disc is situated between the cartilaginous endplates of two consecutive vertebrae. In the cervical spine, the discs are thicker anteriorly than posteriorly and are entirely responsible for the normal cervical lordosis. Positions of the cervical spine affect intradiscal pressure. Pressure is least in the supine position, and extension of the cervical spine results in the greatest intradiscal pressure (16). Each intervertebral disc is composed of a gelatinous nucleus pulposus surrounded by a laminated, fibrous annulus fibrosus. Successive layers of the annulus fibrosus slant in alternate directions so that they cross each other at different angles depending on the intradiscal pressure of the nucleus pulposus. At birth, the disc has a high water content (88%), which mechanically allows it to absorb a significant amount of stress; however, with age, the percentage of water decreases, and the ratio of proteoglycans changes. After 50 years of age, the nucleus pulposus becomes a fibrocartilaginous mass that has characteristics similar to those of the outer zone of the annulus fibrosus.

Muscular Structures

The majority of neck problems are muscular in nature. The majority of patients with neck complaints will have significant muscular tension in their neck. Palpation of the following muscles for tissue

texture change, tension, Jones tender points, and myofascial trigger points is commonplace for practicing clinicians.

Posterior Neck Muscles

The posterior muscles of the neck are divided into superficial, intermediate, and deep groups. The posterior spinal muscles are continuous from the cervical spine to the sacrum. Superficial posterior muscles that attach to the cervical spine include the trapezius, erector spinae group (semispinalis cervicis, longissimus cervicis, longissimus capitis, and interspinalis), and the levator scapulae. The intermediate group contains splenius cervicis and splenius capitis. The deep group contains iliocostalis cervicis laterally; longissimus cervicis and longissimus capitis centrally; and spinalis cervicis, semispinalis capitis, and semispinalis cervicis medially.

Trapezius

The trapezius muscle is the most superficial muscle of the posterior group and is innervated by the spinal accessory nerve, cranial nerve 11. The trapezius posteriorly and sternocleidomastoid (SCM) anteriorly are jointly protected by a general investing fascia. Because the trapezius muscle attaches to the scapula, it is the primary connection between the head, neck, and the shoulder girdle. The trapezius stabilizes and elevates the scapula and extends the head. The process of lifting with the upper extremity distributes force to the cervical spine via the trapezius and corresponding fascial elements.

Levator Scapulae

The levator scapula muscle originates from the transverse processes of the atlas, axis, and the 3rd and 4th cervical vertebrae and inserts on the upper medial border of the scapula. The levator scapulae elevates the medial scapula and rotates it medially.

Intermediate Posterior Group

The intermediate muscles surrounding the spine function primarily as spinal extensors. This group includes the splenius capitis and splenius cervicis. The muscles originate from the spinous processes of the lower cervical and upper thoracic spine and insert on the transverse processes of the upper cervical spine and the mastoid process. Biomechanical studies have documented the importance of the splenius capitis and cervicis as prime muscle for extension of the head and neck.

Deep Posterior Group

In the deep layer, the erector spinae muscles from the thoracolumbar spine continue to the cervical region including the iliocostalis cervicis laterally; longissimus cervicis and longissimus capitis centrally; and spinalis cervicis, semispinalis capitis, and semispinalis cervicis medially.

The iliocostalis extends from the angles of the upper 6 ribs to the posterior tubercles of the transverse processes of the lower cervical vertebrae. The longissimus group extends from the transverse processes of the upper thoracic vertebrae to the posterior tubercles of the transverse processes of the lower cervical vertebrae. This anatomic relationship links thoracic spine mechanics with cervical dysfunction.

The semispinalis group arises on the posterior tubercles of the transverse processes of the upper thoracic and lower cervical

vertebrae and inserts into the area between the superior and the inferior nuchal line of the occiput. Beneath the semispinalis muscles lies the multifidus from C4 to C7. The small rotatores muscles cross one segment of the spine and extend from the transverse process to the spinous process. In the upper cervical spine, suboccipital muscles (the rectus capitis posterior major and minor and the obliquus capitis superior and inferior) attach from the occiput to the C2 vertebra. These deep posterior cervical muscles are arranged in between each vertebra and form the suboccipital triangle at the base of the skull. Significant modification of these muscles occurs at C2, with a group of oblique muscles traversing from atlas and axis to the occiput. These muscular relationships make the occiput, atlas, and C2 a functional unit.

Anterior Neck Muscles

The anterior muscles of the neck are considered “strap muscles” and attach the sternum to the hyoid bone and the hyoid bone to the skull. There are also attachments from the upper ribs to the neck and skull. The anterior scalene muscles traverse from the lateral tubercles of the cervical spine (C3-5) and insert on the 1st rib. The middle and posterior scalene have a similar origin and insert on the 2nd rib. The scalenes as a group act as lateral stabilizers, as well as accessory muscles of respiration. Anteriorly, many muscles travel from the mandible to the hyoid, sternum, and clavicle. The anterolateral cervical muscles function to flex and rotate the head and neck. These muscles include the platysma, SCM, and hyoid muscles; strap muscles (of the larynx); scalenes, longus colli, and longus capitis. The platysma depresses the lower jaw and lip and tightens the skin of the anterior neck. The SCM is the dividing boundary for the anterior and posterior triangles of the neck. Similar to the trapezius, the sternocleidomastoid muscle is innervated by the spinal accessory nerve. The hyoid muscles do not contribute to the motion of the cervical spine, but they are important in controlling movement of the hyoid bone and larynx. The “strap muscles” attach to the hyoid, thyroid cartilage, and sternum and transverse medial to the SCM (except for the posterior aspect of the omohyoid muscle). The prevertebral muscles of the neck are the longus colli and longus capitis. The longus colli muscles extend from C1 to T3, spanning the lateral portions of the vertebral bodies and attaching at the anterior tubercles of the lateral masses of C3-6. The longus capitis muscles arise on the anterior tubercles of C3-6 and extend cephalad to the basiocciput.

Fascia

The three fascial layers of the cervical spine are superficial, intermediate, and deep. The superficial fascia exists as a single sheet over the anterior and posterior cervical triangles. The superficial fascia surrounds subcutaneous fat, the platysma muscle, the external jugular vein, and cutaneous sensory nerves.

The intermediate fascia layer contains the alar fascia. The alar fascia spreads behind the esophagus and surrounds the carotid sheath.

The deep layer of fascia has an outer, middle, and inner layer. The outer layer of the deep fascia extends from the trapezius muscle over the posterior triangle and then splits to enclose the sternocleidomastoid muscle. The middle layer of the deep cervical fascia encloses the strap muscles and extends laterally to the scapula. The inner layer of the deep fascia is the prevertebral fascia, which covers the scalenes muscles, the longus colli muscle, and the anterior longitudinal ligament. Fascia from the cervical spine follows a “tube within tube” structure and continues into the mediastinum to blend with the pericardium and great vessels.

Neural Structures

In the adult, the spinal cord extends from the medulla in the brain through the cervical and thoracic spine to the L2 level of the lumbar spine. The cervical spinal canal is widest at the atlantoaxial level and narrows maximally at the C6 level. The cervical cord itself is wider from C3 to T2, corresponding to the increase in nerves supplying the upper extremities. The spinal canal can be congenitally narrowed (spinal stenosis) due to orthopedic disease such as osteoarthritis, disc protrusions, and spondylolisthesis. Osteophyte formation contributes to stenosis, as does instability with excess front-to-back or side-to-side translation. A cervical disc may protrude posteriorly into the cord. If this occurs, the term myelopathy is used to indicate long tract signs are present. Patients who have congenitally small spinal canals, disc herniations, Arnold-Chiari malformation, syringomyelia, etc. are at increased risk for cervical cord injury, given the right circumstances. Additionally, damage to the cord may be ischemic as well as physical. Spinal cord injuries may occur from a number of different traumatic events, including:

- Automobile and motorcycle accidents
- Gunshots and stabbings
- Diving into an empty swimming pool
- Football and other violent contact sports

Cord injury due to any etiology can have catastrophic consequences.

Cervical Nerve Roots

The cervical spinal cord gives rise to the cervical plexus and the brachial plexus. Because the brachial plexus innervates the upper extremity, nerve root impingement at the cervical intervertebral foramen produces neck pain and upper extremity neurologic symptoms. Impingement of the nerve roots commonly occurs from disc protrusion or osteophyte encroachment. The mixed spinal nerve contains motor fibers, sensory axons of the dorsal root ganglia, and preganglionic fibers from the autonomic nervous system.

There are eight cervical nerve roots. In contrast with the nerves in the thoracic and lumbar spine, the nerves in the cervical spine take the name of the pedicle above which they exit. For example, the C5 nerve root exits between the fourth and the fifth cervical vertebra. The exception is the C8 nerve root, which exits between the seventh cervical and the first thoracic vertebrae. The C1 nerve root exits the vertebral canal from an orifice in the posterior occipital-atlanto membrane just above the posterior arch of the atlas and posterior medially to the lateral mass of the atlas. The C1 ventral primary ramus unites with the C2 ventral primary ramus to contribute fibers to the hypoglossal nerve. The dorsal primary ramus of C1 enters the suboccipital triangle supplying the muscles of this region. The C1 nerve root has no cutaneous branches. The C5 nerve root provides sympathetic innervation to the arteries of the head and neck. The C6 nerve root has fibers to the subclavian artery and brachial plexus. The C7 nerve root has components supplying the cardio aortic plexus, the subclavian and axillary arteries, and the phrenic nerves.

Cervical Sympathetic Nerves

The cervical sympathetic system consists of preganglionic and postganglionic autonomic fibers, as well as three cervical sympathetic ganglia. The preganglionic fibers originate in the intermediolateral gray column of the T1-5 spinal cord segments. In addition to efferent fibers, small, nociceptive afferents (C fibers) travel with the sympathetics and synapse in the upper thoracic cord as well. Nociceptive input (pain transmission) from the cervical spine produces palpable musculoskeletal changes in the upper thoracic spine and

ribs, as well as increased sympathetic activity from this area (17,18). The three ganglia are the superior cervical ganglion, the middle cervical ganglion, and the inferior cervical ganglion. The first thoracic and inferior cervical ganglia are fused, and this structure is referred to as the stellate ganglion. The largest ganglion is the superior ganglion, located at the C2-3 level. The middle ganglion, the smallest, is located at C6. The inferior ganglion lies between the transverse process of C7 and the 1st rib.

Sinuvertebral Nerve

The sinuvertebral nerve emerges distal to the dorsal root ganglion, but prior to the division into dorsal and ventral rami. This small branch recurs into the intervertebral foramen to reach the vertebral canal. The terminal branches supply the posterior longitudinal ligament, the periosteum on the posterior aspect of the vertebral body, the outer layers of the intervertebral discs, and the anterior surface of the spinal dura. The cervical sinuvertebral nerves supply the level of entry and the disc above.

Irritation of the small caliber primary afferent fibers in the sinuvertebral nerve can refer pain several segments up or down the spinal cord, as well as to the contralateral side of the body.

The sinuvertebral nerve does not supply skeletal muscle or skin, so compression or damage to this nerve alone does not present with signs of denervation, weakness, or cutaneous analgesia. The sinuvertebral nerve contains only sensory and sympathetic fibers, and is very sensitive to stretch and possibly ischemia. This anatomic correlation may be why cervical spine dysfunction can refer pain to the periscapular region, chest wall, and shoulder.

Proprioceptive Reflexes

Cervical spine position has a dramatic influence on proprioception and balance. There are more joint proprioceptors in the cervical facet joint capsules than in the thoracic and lumbar spine. Proprioceptive reflexes from the cervical spine create a muscle response in the lower extremity. Rotation of the cervical spine in unconscious subjects causes involuntary, external rotation of the lower extremity in the direction of cervical rotation (20). Another phenomenon is cervical vertigo (21–23), in which proprioceptive input from suboccipital muscles and ligaments or the sternocleidomastoid muscle can produce vertigo.

Vascular Structures

The carotid, vertebral, and subclavian arteries supply the head and neck with arterial blood. The carotid arteries lie anterior to the cervical vertebra. The carotid pulse may be palpated for diagnostic purposes. Avoid pressure over the carotid arteries while palpating the cervical spine. The vertebral artery is the major source of blood supply for the cervical spine and the cervical portion of the spinal cord. The vertebral arteries typically originate off the subclavian artery (right vertebral) and aorta (left vertebral) and travel through the intervertebral foramen. They then enter the cranium through the foramen magnum. Just before joining, one or both of the vertebral arteries gives off a branch that joins with the branch from the other side and descends in the ventral medial fissure on the anterior aspect of the spinal cord as the anterior spinal artery. The vertebral arteries join together after passing through the foramen magnum to form the basilar artery. The vertebral artery can become occluded by thrombosis, which may be precipitated by injury to the artery as it passes through the intervertebral foramina and over the atlas. If patients complain in the history of symptoms referable to the vertebral artery, or there are related physical signs, vertebral artery tests should be done. Signs and symptoms that may indicate vertebral artery problems are listed in Box 38.1 (24). If there is

Signs and Symptoms That May Indicate Possible Vertebral-Basilar Artery Problems

Signs and Symptoms That May Indicate Possible Vertebral-Basilar Artery Problems (43,46)

- Malaise and nausea
- Vomiting
- Dizziness/vertigo
- Unsteadiness in walking, incoordination
- Visual disturbances
- Severe headaches
- Weakness in extremities
- Sensory changes in face or body
- Dysarthria (difficulty with speech)
- Unconsciousness, disorientation. Light headedness
- Dysphagia (difficulty swallowing)
- Hearing difficulties
- Facial paralysis

clinical suspicion of vertebral artery compromise by the history, and physical findings, high velocity low amplitude (HVLA) manipulation of the cervical spine should not be attempted.

The venous system includes a valveless complex of veins in the spine that forms a continuous connection between the pelvis and the cerebral sinuses, connecting with the caval and azygos systems. The absence of valves allows the reversal of blood from the pelvis to the cervical spine. The venous system of the cervical spine drains into the brachiocephalic veins. Disorders such as heart failure may cause jugular venous distension, which is visible and palpable.

Disturbance of the vascular supply produces neurologic symptoms. Occlusion of a vertebral artery by thrombosis, dissection, or mechanical insult can cause a posterior circulation stroke with permanent neurologic sequelae. Thoracic outlet syndrome is a condition arising from compression of the vascular and neural components of the brachial plexus in the thoracic outlet. It is a diagnosis of exclusion. The brachial plexus and the subclavian artery pass through this space. There are three anatomic regions of compression. These include between the anterior and middle scalene, between the clavicle and 1st rib, and between the pectoralis minor muscle and the costal cage. There are provocative tests used to differentiate the site of compression; however, they lack clinical specificity and reliability (25). The tests must reproduce the patient's symptoms as well as decrease his or her pulse. Symptoms such as paresthesia or hand weakness typically affect the ulnar side of the hand after an inciting activity or position is performed. Typically, shoulder abduction and external rotation worsen the symptoms. Symptoms resolve within minutes of cessation of the activity. Occasionally, distal pulses are absent or decreased and digital cyanosis can be present. Tenderness may be present in the supraclavicular fossa. Some forms of thoracic outlet syndrome are associated with sympathetic autonomic dysfunction, which produces upper extremity symptoms. In this case, somatic dysfunction of the upper thoracic spine and ribs is etiologic. Venous return from the upper extremity is not impaired by scalene tension, as the subclavian vein passes in front of the anterior scalene muscle.

Lymphatic Structures

The brain is devoid of lymphatic channels; vascular return from the cranium is venous. However, cervical lymphatic drainage is important. Infections and inflammation from the head, ear, nose,

and throat require effective lymphatic drainage. Superficial nodes must penetrate the general investing fascia to connect with the deep channels that return lymph to the vascular compartment in the thorax. The thoracic inlet must be free of motion restrictions to allow lymph to return. The use of fascial soft tissue stretching/release facilitates lymphatic return, as lymph channels pass through the general investing fascia.

MOTION, POSTURE, AND BIOMECHANICS

The cervical spine is well suited for mobility and is less suited for bearing heavy loads. The saddle shape of each cervical vertebra provides its mobility and stability. The anterior column is composed of the vertebral body, longitudinal ligaments, and intervertebral disc and provides some weight-bearing capacity, shock absorption, as well as a flexible structure. The posterior elements, composed of the osseous canal, the zygapophyseal joints, and the erector spinae muscles, protect the neural elements, act as a fulcrum, and guide movement of the functional unit. Precise control of head position and unrestricted movement is essential for normal functioning of the special senses.

Alterations in the degree of curvature in one area of the spine result in reciprocal alterations in curvature in other areas of the spinal column to preserve the orientation of the body over the center of gravity. For example, an increase in lumbar lordosis results in increased cervical lordosis.

Gross Motion

The posterior longitudinal ligament limits flexion of the cervical spine. Extension of the cervical spine is limited by the direct contact of the vertebral lamina, the zygapophyseal joints, and the poster superior spinous process. In cervical flexion, the vertebral bodies separate, thereby opening the neural foramina. Compression of the nerve root is minimized because the flexion of the neck not only angulates the nerve but also allows greater space for the neural elements by widening the neural foramina.

In cervical extension, the foramina narrow. The spinal cord ascends and descends in the spinal canal as the neck is flexed and extended, respectively. In lateral bending or rotation, the foramina close on the side toward which the neck moves, while opening on the contra lateral side. The neural foramina is 20% to 30% larger in flexion than extension (26). Normal cervical flexion is 90 degrees, extension is 70 degrees, and rotation is 70 to 90 degrees (26).

Occipito-Atlantal Joint

The major motions at the occipito-atlantal (O-A) joint are flexion and extension. Side bending and rotation are considered minor movements. There is approximately 20 to 25 degrees of flexion/extension at the occipito-atlanto-axial complex. The occipital condyles converge anteriorly. The lateral portion of the atlas articulation is more cephalad than the medial portion. Due to this anatomy, the occiput rotates and side bends in opposite directions. This gliding motion is considered a minor movement of the joint and is the motion involved in occipital joint restriction.

Atlas-Axis Joint

The major motion of the atlas-axis joint is rotation. Half of the rotation of the cervical spine occurs at the atlas. Atlanto-axial (A-A) rotation averages 45 to 50 degrees, which represents about 50% of the axial rotation in the neck, with the lower cervical spine contributing the other 50% of rotation. Cineradiographic studies

show a significant amount of flexion and extension occurring at the atlas (27,28). This motion does not seem to be involved in somatic dysfunction of the atlas. Side bending is not a significant component of atlas movement. Cineradiographic studies have shown that during rotation, the atlas moves inferiorly on both sides, maintaining a horizontal orientation (29). Side-bending restriction is usually not diagnosed or treated. The atlas rotates about the dens, and motion restriction of the atlas involves rotation. Motion testing primarily involves rotation testing.

C2-7

Motion of the typical cervical segments (C2 through C7) is similar to type II mechanics. Cineradiography shows that the cervical spine rotates and side bends to the same side. Type I (neutral) mechanics have not been identified on cineradiography (30,31). The vertebral bodies of typical cervical segments are saddle shaped rather than flat on the superior and the inferior surfaces. Side bending of the cervical spine can produce lateral translation into the convexity. Some osteopathic physicians call this motion sideslip. The motion of the cervical spine as previously described is echoed by Bogduk and Mercer (32).

PHYSICAL EXAMINATION

There are important anatomical landmarks that help one to identify cervical structures. For instance, the angle of the mandible is at the level of the first cervical vertebra. The transverse process of the second cervical vertebra is located between the angle of the mandible and the mastoid process. The hyoid bone is anterior to the third cervical vertebra. The thyroid cartilage is anterior to the fourth cervical vertebra. The sixth vertebra is at the level of the cricoid cartilage (16).

Inspection

The first part of the physical examination of the neck involves observation/inspection. Surgical scars on the anterior portion of the neck most often indicate previous thyroid surgery or cervical fusion. Additionally, torticollis causes the head to be tilted toward the side with the contracted sternocleidomastoid muscle with rotation in the opposite direction. Observe the skin for color changes. Look for asymmetry of position, including:

- Flexion or extension
- Side bending to the right or left
- Rotation to the right or left
- Anterior/posterior curves
- Relationship of the head to the lateral weight-bearing line

The standing osteopathic structural exam does not exclude the neck. Therefore, it is important to perform a structural exam and look at the head and neck position in relation to body posture as well as gait. Following a structural examination, a neurologic examination should be performed. Following the neurologic exam, active then passive range of motion is assessed.

ACTIVE MOTION TESTING

If the patient has neurological complaints or has sustained a significant neck trauma, first determine the amount the patient can move by active motion testing.

With the patient seated, ask him or her to:

- Rotate to the right and left
- Side-bend right and left (attempt to touch the ear to the shoulder)

- Flex or touch the chin to the chest
- Extend or backward bend

If any of these motions produce neurological symptoms, imaging should be reviewed or obtained prior to further testing or treatment. The motions obtained during active motion testing should be recorded in degrees. On follow-up visits, physicians may elect to bypass active motion testing and proceed directly to passive motion testing.

NEUROLOGICAL EXAM

The neurological exam delineates upper motor neuron versus nerve root and/or peripheral nerve lesions.

SENSORY

Sensory changes are a subjective clinical finding and are affected by the patient's emotional state, level of pain, and other factors. The sensory exam primarily involves testing the dermatomes from C5-T1, which are found on the upper extremity. The sensory distribution of the upper cervical segments involves the neck, scalp, and suboccipital region. During nerve compression, sensory changes occur first, followed by reflex changes, motor weakness, and ultimately, muscle atrophy.

DEEP TENDON REFLEXES

Deep tendon reflexes should be bilaterally symmetric and equal between the upper and the lower extremities. It is not uncommon for the patellar reflex to be brisk; however, brisk reflexes in the upper extremities points to cervical spinal stenosis, or an upper motor neuron lesion. With age, reflexes are more difficult to elicit. The biceps reflex has components from both C5 and C6. The brachioradialis reflex is primarily C6. The triceps reflex is C6-7. The C8 root has no reflex, so muscle strength is used to determine the integrity of the C8 nerve root.

Similarly, T1 has no deep tendon reflex, so it is evaluated for its motor and sensory components only. The scapulohumeral reflex

tests the integrity of the cord segments from C4 to C6. The reflex is elicited by striking the lower end of the medial border of the scapula. The response is adduction and lateral rotation of the arm. This reflex tests the supply of the suprascapular (axillary) nerve to the infraspinatus and teres minor muscles.

MOTOR

True muscle weakness is one of the most reliable indicators of persistent nerve compression.

Motor strength quantification by physical examination is not precise; there are different grading regimes and considerations such as age of the patient and whether the muscle is weight bearing or not. A significant amount of motor strength must be absent before any consistent detection of weakness is made on the basis of a physical examination. Motor strength testing of the lower cervical spine (C5-T1) is routinely used during the clinical exam. Performing strength testing in sequence of each nerve root is time efficient. Start with the muscles supplied by the C5 root and progress to the T1 level. The upper cervical segments and their nerve roots are clinically tested less frequently. Table 38.1 summarizes each nerve root, the muscle it supplies, and the motion required to test it.

Upper Motor Neuron Tests

Upper motor neuron lesions present with hyper-reflexia, spasticity of the involved muscles, and a loss of fine motor control. Patients also develop a positive Babinski reflex or a Hoffmann reflex.

The Hoffmann sign can be elicited by placing the patient's middle phalanx of the third digit across the DIP joint of the examiner's third digit on the dominant hand, with the palm facing down. Next, by placing the patient's 3rd digit in slight extension, the DIP joint is "flicked" downward by the examiner's thumb. An involuntary flexion of the DIP joints of the patient's thumb and little finger is a positive test (47). This sign is equivalent to the Babinski sign in the lower extremity.

TABLE 38.1

Neurology of the Cervical Nerve Roots

Disc	Root	Reflex	Muscle	Motion to Test	Sensation	Nerve
C4-5	C5	Biceps	Deltoid	Shoulder abduction	Lateral arm over	Axillary
				Shoulder flexion	Deltoid	
				Shoulder extension		
C5-6	C6	Brachioradialis	Biceps	Elbow flexion	Lateral forearm	Musculocutaneous
			Biceps	Elbow flexion		
			Wrist extensors			
C6-7	C7	Triceps	Triceps	Elbow extension	Middle finger	C7
			Wrist flexors	Wrist flexion		
			Finger extensors	Finger extension		
C7-T1	C8	None	Finger flexors	Finger flexion	Ring/little finger	C8
					Distal forearm	
T1-2	T1	None	Finger abductors	Finger abduction	Medial arm	Medial brachial cutaneous

Nerve Roots

Testing the muscles innervated by the brachial plexus begins with the deltoid and biceps muscles. The deltoid is innervated almost entirely by C5, while the biceps has a dual innervation from both C5 and C6 (34). The next muscle group that should be tested is the wrist extensors. This muscle group has primarily C6 innervation, with some innervation from the C7 nerve root (34). Elbow extension, a function of the triceps, as well as the wrist flexor group can be used to test the C7 nerve root. The next motor group to be tested is the finger flexors. The two muscles that flex the fingers are the flexor digitorum superficialis and the flexor digitorum profundus. These muscles are tested by having the patient curl the fingers around the examiner's index and 3rd digit while the examiner tries to pull out of the grip. Examining the intrinsic muscles of the hand tests the T1 neurologic level. The finger abductors, innervated by the ulnar nerve and largely the T1 root, consist of the dorsal interossei and abductor digiti quinti (34).

SPECIAL TESTS

Distraction Test

This test demonstrates the effect of neck traction in relieving a patient's neck pain. By widening the foramina, distraction relieves pain caused by a narrowed neural foramina and resulting nerve root compression. Distraction also relieves pain in the cervical spine by decreasing pressure on the joint capsules around the facet joints (34).

Compression Test

Compression can cause increased pain by narrowing the neural foramen, putting pressure on the facets, or initiating muscle spasm (34).

Valsalvas Test

This test increases the intrathecal pressure. If a space-occupying lesion, such as a herniated disc or tumor, is present in the cervical canal, the patient may develop pain in the cervical spine secondary to increased pressure (34).

Spurling Maneuver

This is a test of nerve root compression or irritation. This maneuver is designed to provoke the patient's symptoms. The test is done in three stages, each of which is more provocative. If symptoms are produced, one does not proceed to the next stage. The first stage involves compression with the head in neutral. The second stage places the head in extension then adds compression. The final stage places the head in Sidebending away from the effected side then toward the effected side and adds compression. A positive test is indicated by dermatomal pain down the arm in the distribution of the nerve root indicating nerve root compression. The Spurling test had a sensitivity of 30% and a specificity of 93%; thus, it is useful in confirming the absence of a cervical radiculopathy when negative (35).

Lhermitte Sign

The patient is in the long sitting position on the examiner's table. The patient's head and hip are flexed simultaneously. A sensation of lightning-like paresthesias or dysesthesias in the hands or legs

upon cervical flexion is a positive test. This sensation is most often caused by multiple sclerosis or a large disc herniation impinging the anterior spinal cord, causing a cervical myelopathy (35).

Scapular and shoulder movements should also be tested.

PERIPHERAL NERVES

There are three common syndromes associated with compression of the median nerve. These include the pronator syndrome, carpal tunnel syndrome, and the anterior interosseous syndrome. These syndromes can mimic radiculopathy from the C6-8 and even T1 nerve roots. The ulnar nerve has two common areas of entrapment. The most common location of ulnar nerve entrapment is the elbow in the cubital tunnel. The ulnar nerve may also be compressed at the wrist in Guyon canal (36). These syndromes can mimic radiculopathy from the C6 and C7 nerve roots. The radial nerve is most commonly compressed at the elbow. Radial tunnel syndrome is a compression neuropathy of the radial nerve between the supinator muscle and the radial head just proximal to its entrance into the supinator muscle.

HEENT AND ANTERIOR NECK EXAM

It is possible for the temporomandibular joint, dental disease, upper respiratory infections, thyroid conditions, and problems of the shoulder to refer pain to the neck. Therefore, it is important to examine the eyes, ears, nose and throat, the thyroid, and the cervical lymph nodes in patients with neck pain.

SHOULDER EVALUATION

In cases in which it is difficult to differentiate intrinsic shoulder pathologic changes from referred cervical pain, it is possible to do an intra-articular injection of lidocaine (with or without steroid). Within 10 to 15 minutes of injection, it is generally possible to eliminate the component of pain that is due to intrinsic shoulder pathologic changes.

Palpation and Terminology

The cervical spine may be palpated in the seated position or in the supine position. Tissues on the anterior and lateral portions of the neck can be comfortably assessed with the patient seated and the physician standing behind the patient. Palpate muscle tension, tenderness, and tissue texture abnormality (scalenes, SCM, and trapezius). Passive motion testing to evaluate the ability of muscles to lengthen is sometimes performed (e.g., sidebend the cervical spine to evaluate scalene tension).

Palpation of the cervical spine with the patient supine allows for a detailed evaluation of tissue texture abnormality and tenderness surrounding the cervical spine. The suboccipital region contains muscles that are more lateral than the mid and lower cervical region, so paraspinal palpation must involve a more lateral placement of the fingers. Significant suboccipital tissue texture abnormality is usually associated with changes in the ipsilateral upper thoracic and rib angle area. Palpation over the posterior portion of the articular pillars reveals local muscle hypertonicity, tenderness, and tissue texture abnormality associated with segmental dysfunction. These changes are usually apparent with rotational restriction.

Palpate the lateral margins of the articular pillars (locate fingers laterally and direct the palpatory force medially) to reveal tenderness and tissue texture abnormality over the convex (anterior component) side of segmental dysfunction. For example, given C4 rotated and side-bent right (restriction rotation and side-bending left), the

posterior portion of the articular pillar is tender on the right side; the lateral margin of the articular pillar is tender on the left side.

The terms open facet and closed facet are sometimes applied as positional descriptors of cervical spine somatic dysfunction. Flexion motion (in a normal spine without motion restriction) causes the facets to open, and extension motion closes the facets. Side-bending motion with coupled rotation to the same side produces a concave side and a convex side. The facets on the concave side are closed while the facets on the convex side are open. Given a condition of C5 extended, rotated, and side-bent right (restriction of flexion, rotation, and side-bending left), the right side is the concave side and the left side is the convex side. In motion testing, extension is free, so both facets close. During flexion motion testing, the facet on the right side is closed and resists opening. This produces palpable asymmetry in which the right transverse process (technically, the articular pillar) is more posterior, and the paraspinous muscle over C5 right is tight and palpable.

Segmental Diagnosis by Passive Motion Testing

Regional Motion

Test the range of regional cervical rotation, side bending, flexion, and extension with the patient in the supine position. Evaluate these motions by contacting the head bilaterally and introducing the motions through the head. The range of extension may be difficult to evaluate with the patient supine because the table gets in the way.

Segmental Motion

The experienced clinician tests those segments in which palpation and screening motion tests suggest a problem. The suboccipital area can be confusing. Neurologically, C1 and C2 are considered a common neurologic segment. Hyperactivity of the C1-2 segment potentially involves three joints: the O-A joint, the A-A joint, and C2/3. Therefore, positive palpatory findings in the suboccipital region demand testing of these three joints. Each joint is different in its motion, so they must be individually tested.

Occipital Motion Testing of C0-1

Lateral Translation Test

The physician stands or sits at the head of the supine patient. Grasp the head with both hands, with the fingertips of the index and middle fingers over the occipital articulation (Fig. 38.1).

Translate the head to the right and to the left, evaluating freedom or resistance. A more precise method is to perform the lateral translation test in flexion and in extension. Flex the occiput (O-A), and then translate to the right and to the left. Then extend the occiput and translate to the right and to the left. Restriction of right translation with freedom of left translation suggests an occiput rotated left and side-bent right (occiput posterior left). If translation is done in flexion and extension, restriction is encountered when the barrier is engaged. Restriction of right translation in the flexed position suggests an occiput that is extended, rotated left, and side-bent right with restriction of flexion, rotation right, and side bending left.

There are two O-A joints, one on each side. Given a condition of occiput rotated right and side-bent left, the dominant restriction, tenderness, and tissue texture abnormality may be on the right side or it may be on the left side. In treating this dysfunction with high-velocity technique, it may be appropriate to localize force precisely to one side or the other. The terminology that has been used by the osteopathic profession for years is positional terminology. This in no way implies that positional diagnosis is preferred; identification of motion restriction is imperative. In the above

Figure 38-1 Lateral translation test for occipital motion.

example of the occiput rotated right and side-bent left, the right side is called posterior occiput and the left side is called anterior occiput. A posterior occiput right exhibits motion restriction, tissue texture abnormality, and tenderness on the right side. An anterior occiput left exhibits motion restriction, tissue texture abnormality, and tenderness left. Do confirmatory motion tests. Focusing on one side at a time, assess freedom of flexion and extension. The posterior occiput side exhibits restriction of extension. The anterior occiput side exhibits restriction of flexion.

Atlas Motion Test

The atlas rotates in relation to the axis and becomes restricted in rotation. The motion test of atlas function is a rotation test. It is convenient to isolate cervical rotation to the atlas by flexing the cervical spine prior to rotation. This produces physiologic locking of C2-7. This is an example of the third principle of physiologic motion of the spine. Flexion of C2-7 effectively eliminates rotation in this area.

Stand or sit at the head of your supine patient. Grasp the head with fingertips contacting the lateral mass of the atlas. Flex the cervical spine. Rotate to the right and to the left, assessing the range of motion and freedom or resistance (Fig. 38-2).

A right-rotated atlas exhibits restriction of left rotation. Osteopathic positional terminology for this dysfunction is posterior atlas right. Flexion, extension, and side-bending motions are not tested.

Some osteopathic physicians refer to an anterior atlas. The anterior side is opposite the posterior atlas. Given an example of atlas rotated right with restriction of left rotation, the right side would be the posterior atlas side. If the left side exhibited tenderness and tissue texture abnormality, it would be referred to as an anterior atlas left. These are not common, but when present, they are very symptomatic and tender. Retro-orbital pain is often associated with an anterior atlas.

C2-7 Motion Testing

Flexion and Extension Test

At a segmental level, C2-7 motion is difficult to assess by directly flexing and extending, although this has been the method used by

Figure 38-2 Rotation test for atlas motion.

many osteopathic physicians in the past. The lateral translation test, which was used extensively by the muscle energy tutorial committee (15), provides a more precise method of evaluating flexion and extension while evaluating side bending.

Lateral Translation Test

The lateral translation test is similar to the occiput lateral translation test, except that the hand placement is on the cervical region with the fingertips over the lateral portion of the articular pillars. Stand or sit at the head of the supine patient. Support the patient's head with your hands while palpating the lateral border of the articular pillars. Localizing the force to one segment, test lateral translation to the right and to the left with the segment flexed and with the segment extended. Restriction of right translation in the flexed position suggests extension. Right side bending suggests right rotation with restriction of flexion, left side bending, and left rotation (Fig. 38.3).

Rotation Test

Applying force to one segment at a time can do a rotation test. Rotation movement should follow the planes of the facets;

Figure 38-3 Lateral translation test of C2-7.

therefore, the force is directed up toward the eye, rather than in a horizontal plane. Stand or sit at the head of the supine patient. Support the patient's head, with your fingertips contacting the posterior surface of the articular pillars. Rotate (following the plane of the facets) to the right and to the left, assessing restriction or freedom. Remember, any normal segment should rotate both ways with equal range and freedom. Restriction of right rotation of C5 suggests a positional diagnosis of C5 left rotated, left side bent, with restriction of right rotation and right side bending. The posterior transverse process is on the left (Fig. 38.4).

DIAGNOSTIC MODALITIES

Indications for Imaging

Patients with acute neck pain who are older than 60 years of age (malignant tumor) or younger than 15 years of age (benign bone tumor) should be considered for plain roentgenograms of the cervical spine and determination of the erythrocyte sedimentation rate. Patients who sustain blunt trauma to the head or neck, those involved in high-speed motor vehicle accidents, or sports-related injuries should be imaged. There are imaging guidelines, such as the Nexus criteria, for use in the emergency department; however, these are only guidelines, and *an adequate history* is crucial to obtain when determining whether or not to image a patient. Although it is important to be cost effective, if there is any question about orthopedic injury in the patient's neck, image the patient.

Cervical Spine X-rays

Plain roentgenograms remain the initial step in diagnostic imaging of the cervical spine because of their availability, speed, relatively low exposure of tissue to radiation, and reasonable costs. A cervical spine x-ray series includes a lateral view, an A-P view, an open mouth view, and two oblique views. Plain cervical spine x-ray films are commonly used to evaluate the bony detail, alignment, disc space height, the neural foramina, and the facets. The lateral view of the cervical spine is the single most important view in evaluating degenerative conditions. The AP view of the cervical spine shows the cervical vertebrae from C3 through T1. The first two cervical vertebrae are generally hidden from view by the superimposed mandible and occiput and must be evaluated separately on an open-mouth (odontoid) view. The open-mouth (odontoid) view is useful for evaluating

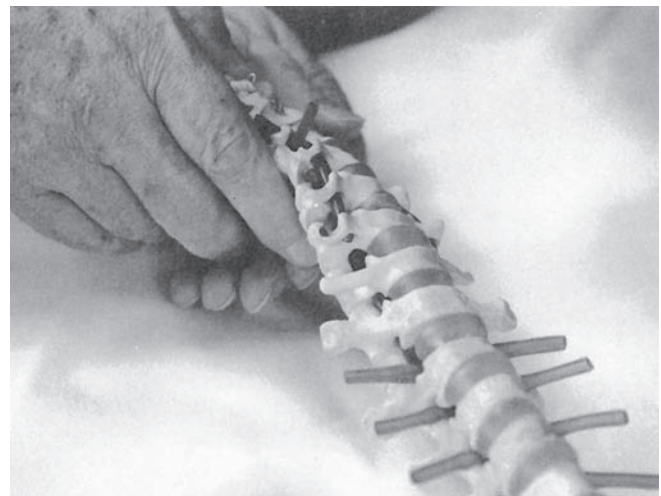

Figure 38-4 Rotation test of C2-7.

the relationship of the occiput, atlas, and axis. In addition, this view detects erosive changes found with inflammatory arthropathies. Oblique views are used to evaluate the intervertebral foramina, the pedicles, the lateral masses, and apophyseal joints.

In a neck-injured patient, the lateral x-ray is obtained first and cleared before the other views are taken. The anterior retropharyngeal space should also be evaluated (should not exceed 5 mm). The posterior margins of the vertebral bodies, the facet joints, and the contour of the spinolaminar line should be evaluated for congruity. As a general rule, on a standard lateral cervical spine film, the spinal canal as measured from the posterior aspect of the vertebral body to the narrowest point on the spinolaminar line should be about 17 mm. If this distance is narrowed by a posterior osteophyte to a diameter of 13 mm or less, it is likely that there is spinal cord compression. An intervertebral disc space separation increase with traction of more than 1.7 mm is also abnormal. A difference in angulation more than 11 degrees between two cervical segments on a lateral radiograph also suggests instability (37).

Determination if a radiographic finding is an acute injury, an older injury, or due to degenerative changes is often difficult (37). A common finding in an older patient with chronic neck pain includes decreased disc space height, marginal osteophytes, narrowing of the neural foramina, sclerosis of the vertebral endplates and facets, and poor alignment of the spinolaminar line. The combined findings indicate cervical spondylosis, a degenerative arthritic condition of the cervical spine. A common radiographic finding in acute neck spasm/pain includes a reversal of the cervical lordosis. This straightening of the cervical spine usually indicates muscle spasm; however, it may indicate an underlying disc injury, fracture or other problem.

CT Scan

CT scan provides more bony detail than plain films and provides a better understanding of spatial relationships. CT is helpful in evaluation of spinal stenosis, infections with paraspinal abscesses, postsurgical epidural scarring, facet and uncovertebral joint arthritis, primary metastatic tumors of the cervical spine, and trauma to the spinal column. CT can also visualize the medullary portion of the vertebral body and detect bone destruction before changes are visible on plain roentgenograms.

CT is particularly useful in the diagnosis and assessment of trauma because the patient is stationary during the procedure, limiting the hazards of moving the patient. Small fragments of bone that may not be detectable by plain roentgenogram are more easily seen on CT scan (38). A CT scan is better than an MR image for bone detail in identifying bone tumors. CT scans may be combined with myelography to outline the spinal cord and nerve roots. Evaluation of the craniocervical and cervicothoracic junctions can be difficult on a plain roentgenogram but is much easier with the CT examination.

MRI

The MR image of the cervical spine visualizes the vertebral column, intervertebral discs, spinal canal, spinal cord, and cerebrospinal fluid (CSF). Although more expensive, it is the preferred study in the evaluation of the discs and spinal cord. It is the preferred imaging modality for syringomyelia, cord atrophy, cord infarction, traumatic injury to the cord, and intramedullary tumors or multiple sclerosis affecting the spinal cord. When evaluating disc herniations, MRI can differentiate the annulus fibrosus from the nucleus pulposus. The MRI is also useful to evaluate postoperative scarring. Many asymptomatic patients have disc protrusions on MRI; therefore,

the history, physical findings, and scan should always be correlated together before embarking on a treatment plan (38).

Treatment of Neck Pain:

General Treatment Guidelines

In the treatment of neck pain, the clinician must rule out urgent conditions that need expeditious treatment. He must determine if neurologic compromise is present, and if the patient needs to be seen in the emergency department, or if they can be treated as an outpatient.

The following are treatment guidelines for symptomatic, unstable cervical spine problems:

1. Avoid high-velocity manipulation of the cervical spine.
2. Decrease muscle tension. Treatment of the upper thoracic spine and ribs is essential to accomplish this goal.
3. Counterstrain, cranial, and indirect techniques are the least traumatic to the neck. Muscle energy technique, if done without pain, is appropriate.
4. Traction, with proper direction of force, is appropriate.

If the initial conservative treatment fails, symptomatic patients may be separated into two groups.

If no symptomatic improvement is achieved after 6 weeks of medical nonoperative therapy, plain roentgenograms should be taken and carefully examined. Patients who have no specific diagnosis and have pain that is resistant to a 12-week trial of medical nonoperative therapy are considered to have chronic neck pain. The primary goal for therapy with chronic neck pain is maximum function, not pain relief.

Common Treatments for Neck Pain

Injections

If there is no significant improvement in symptoms in 3 to 4 weeks in patients with local neck pain, local injections into palpable tender points or trigger points can be beneficial. Patients with chronic neck pain may undergo facet injections, or epidural steroid injections. A pain specialist usually performs these. Some patients with chronic neck pain may benefit from a stellate ganglion (sympathetic) block. A successful sympathetic block is manifested by the development of Horner's syndrome, including ptosis, miosis, and anhidrosis.

Collars

Collars are needed in a small proportion of patients. The collar initially should be worn continuously, day and night. The use of collars can cause the patient's neck muscles to become weak, so use the collar for as brief a time as beneficial. For patients with acute intervertebral disc problems, the use of a collar is generally used for 2 to 3 weeks, slowly decreasing the time worn. Isometric strengthening exercises should be instituted as their pain permits to allow enough neck muscle strength for them to return to full activity. Some patients with acute cervical spine fractures may require immobilization of the neck with a hard plastic collar. These are generally worn from 1 to 3 months, or until bony fusion is seen on x-ray.

Medications

Another component of the initial treatment plan is drug therapy. Anti-inflammatory drugs, analgesics, and muscle relaxants usually improve patient comfort and are commonly used in conjunction with gentle OMT, stretches, ice or heat, and cervical spine support. The use of muscle relaxers is indicated for short-term painful muscular conditions. They can cause drowsiness and decrease a patient's

reaction time, so caution should be exercised if the patient is driving or caring for young children. It is better to prescribe these for night time use to help the patient sleep. Analgesics help decrease the pain-spasm-pain cycle that can maintain a patient's symptoms. Anti-inflammatory drugs (NSAIDs) are useful, if the patient does not have a history of gastritis, reflux, or peptic ulcer disease.

Treatment of Specific Clinical Syndromes

Cervical Myelopathy

Cervical myelopathy occurs secondary to compression of the spinal cord (and nerve roots) in the cervical spinal canal. Historical questions should include a change in gait, balance, paresthesia, or loss of agility in their hands (39). Progressive and profound upper motor neuron signs, including weakness, spasticity, and gait abnormalities, are the clinical manifestations of myelopathy. The main lower motor neuron (radicular) signs are weakness with loss of tone and volume of the muscles in the upper extremity. Pressure on the spinal cord may produce pyramidal tract signs and spasticity in the lower extremities. The most frequent presentation of myelopathy is a combination of arm and leg signs and gait disorder (39). Patients who have the above signs, but do not have cervical myelopathy, should be evaluated for an underlying systemic medical illness as the cause of their neck pain. OMT in these patients may occur postoperatively, or if not a surgical candidate, with caution. Avoid positions that close down the cervical canal, such as cervical extension and rotation. Keep a few pillows under the patients' neck and have them place their feet on the treatment table to keep down dural tension. Indirect techniques and cranial techniques may help symptomatically.

Cervical Radiculopathy

Cervical root irritation from compression by osteophyte or disc protrusion produces nerve-related symptoms in the upper extremity, such as pain, numbness, or muscle weakness. The hallmark of this condition is that the pain and physical findings usually follow a specific nerve root (39). Careful neurologic testing reveals the nerve root dysfunction (see Table 38.1). Look for sensory loss, motor weakness, and decreased deep tendon reflexes. Palpable flaccidity of arm muscles may be present. Correlate the sensory dermatome, deep tendon reflex, palpatory findings and motor weakness with the specific disc level in the cervical spine. Remember that sometimes the nerve root irritation is intermittent and insufficient to produce any neurologic deficit. Occasionally, cervical radiculopathy may be confused with a brachial plexopathy. In the latter, irritation of the plexus in the axilla due to lymphadenopathy, radiation, traction, or trauma will also produce arm/hand symptoms. Remember that the upper portion of the brachial plexus innervates the thumb and the lower portion of the brachial plexus innervates the small finger.

In the acute situation, HVLA technique should be avoided at the level of herniation, as this vertebral level is considered to be unstable. HVLA may be used for articular dysfunctions distant from this spinal level, particularly the upper thoracic spine and ribs, as treating the upper thoracic spine and ribs is crucial in this scenario. Cervical root irritation usually produces a reflex change in the interscapular area, which then produces arm symptoms. A recalcitrant interscapular problem might be due to a reflex from the cervical spine. Many patients with cervical root problems experience shoulder pain when they lie supine on the table. Often, extension of the neck exacerbates the symptoms. In addition to spinal nerve root encroachment, diseases that directly affect the brachial plexus may result in a variety of upper extremity symptoms that must be distinguished from cervical root syndromes. The

patients with arm pain predominant (brachialgia) refractory to nonoperative management may have symptoms due to mechanical pressure from a herniated disc or hypertrophic bone and secondary inflammation of the involved nerve roots.

Systemic Concerns

Constitutional symptoms of fever or weight loss are suggestive of an infection or tumor. Infiltrative lesions of the spinal cord and tumors of the spinal column are associated with nocturnal increase in pain. Benign tumors tend to involve the posterior elements of vertebrae, whereas malignant tumors affect the vertebral bodies. Acute localized bone pain is usually associated with either fracture or expansion of bone. Localized cervical bone pain may be secondary to a systemic process that replaces bone (Paget disease) or a local tumor (osteoblastoma). Any condition that replaces bone with abnormal cells (tumor or sarcoidosis) or increases mineral loss from bone (hyperparathyroidism) weakens bone to the point at which fracture may occur spontaneously or with minimal trauma.

Morning stiffness of the neck lasting for hours is a common symptom of patients with spondyloarthropathies, or rheumatoid arthritis. Patients with this symptom should have cervical x-rays including a flexion-extension view of the cervical spine to detect subluxation. Patients with rheumatoid arthritis of the neck should not have HVLA of the cervical spine, as they are prone to AA instability and subluxations.

Patients with visceral pain have neck pain secondary to disorders in the cardiovascular, gastrointestinal, or neurologic systems. Patients with a visceral cause of their neck pain (angina, thoracic outlet syndrome, and esophageal disorders) have symptoms that affect structures distal to the cervical spine and recur in a regular pattern. Patients may complain of neck and arm pain that occurs with exertion.

Patients with neck pain and fever should be evaluated for any change in mental status or severe headaches. These individuals should have a lumbar puncture and their CSF examined for inflammatory cells, increased protein, or decreased glucose concentration compatible with meningitis.

Somatic Dysfunction

The osteopathic physician needs to determine if somatic dysfunction is present and significant. The clinician also need to determine if OMT is indicated or not, and potentially beneficial. Magee (38) discusses a précis of cervical spine assessment that includes joint play considerations in the evaluation of the patient with neck pain. It must be understood that OMT is used to treat somatic dysfunction, not just "neck pain." If no somatic dysfunction is present, no OMT is required. If a diagnosis of somatic dysfunction has been made and there is no contraindication, OMT may be performed. The type of OMT should be based on the patient's clinical condition and physician's experience and skill. The technique(s) should be safe, effective, and appropriate for the diagnosis made.

Concern has arisen over the years for the safety of cervical HVLA technique. HVLA in the cervical spine is a safe technique and indicated for articular somatic dysfunctions in the neck that have a distinct firm end-feel to their restrictive barriers. It needs to be performed precisely, gently, and in the appropriate patient. The American Osteopathic Association (AOA) has published a position paper on HVLA manipulation in the cervical spine. After considerable review of the literature, they have concluded that HVLA manipulation of the neck is a safe procedure with an incidence of severe injury to be 1/400,000 manipulations (40). It is the position of the AOA that all modalities of OMT for the cervical spine, including HVLA (thrust), should be taught at all levels of education, and that this method of treatment should be offered to patients. Other

forms of osteopathic manipulation used for the cervical spine have not been shown to cause significant injury or harm to patients.

Suboccipital Pain

Suboccipital symptoms of tension and tissue change are almost always associated with upper thoracic and rib problems on the same side. It is important to treat the upper thoracic area first because of sympathetic influence and muscle connections. Testing the sub-occipital area before and after treatment of the upper thoracic reveals a significant decrease in suboccipital findings. Always diagnose and treat the atlas, as 50% of cervical rotation comes from its articulations. Cranial osteopathy is very useful in this situation as well. Cranial base dysfunction is related to the cervical spine, as the occiput, atlas, and C2 is a functional unit. O-A myofascial release is a simple, direct procedure that improves motion of these articulations and soft tissues.

Whiplash

Whiplash injuries occur primarily after rear-end motor vehicle collisions but may also occur during sports, falls, or on-the-job injuries. The mechanism is an acceleration-deacceleration event that leads to soft tissue injury and other “whiplash associated disorders” (WAD) (41). Acute extension trauma (whiplash) with injury to flexor muscles takes prolonged time to treat. Counterstrain, indirect fascial release, and cranial techniques are most appropriate for initial treatment. The sequence of treatment is as follows: the thoracic spine, the suboccipital area, and finally, the rest of the cervical spine. The upper thoracic acts as a functional base for the neck. The clinician should always look for an extended (flexion restriction) upper or midthoracic somatic dysfunction and initially treat it with indirect techniques. Gross cervical motion testing reveals restriction of rotation and side bending to the same side. The cervical prevertebral muscles (scalenes, longus group) are usually involved in acute neck problems and should be addressed only after the upper thoracic spine has been treated. For example, SCM shortening causes rotation and side bending to opposite sides. Counterstrain of the SCM and other anterior/posterior cervical tender points is a valuable initial treatment. In addition, releasing the abdominal diaphragm (redoming) by gentle ventral abdominal inhibition is a useful consideration. This resets the autonomic, removes traumatic myofascial strain, and lets the patient breathe more fully. Cranial treatment for any strains or simply to relax the autonomic nervous system can be used. When the patient can tolerate more direct treatment of the upper thoracic spine, treatment of the commonly found single segment extended dysfunction with HVLA technique is critical to his or her overall improvement.

Acute Spastic Torticollis

Acute Torticollis with massive neck muscle spasm causes motion to be painful and limited. The SCM is usually involved. The SCM is innervated by the spinal accessory nerve, a cranial nerve. Treat the cranial base with a direct myofascial release in hopes to alleviate any fascial compression to this nerve. Then use a muscle energy technique. Position the head at the midpoint of pain-free motion. Hold the head and ask the patient to turn the head toward the restriction and relax. Reposition the head a few degrees toward the restriction and repeat. Sometimes, a significant improvement in range of motion is achieved. This technique is not classified as direct or indirect, in that the barrier is not engaged nor is the neck positioned in the other direction. Instead, the neck is positioned in the middle, with the ultimate objective of reaching the barrier.

BEST EVIDENCE FOR NECK PAIN

The medical literature on neck pain from 1980 to 2006 has been critically reviewed by the Bone and Joint Decade 2000–2010 Task Force on Neck Pain and its associated disorders. Results of their comprehensive, systematic literature reviews have been published in *Spine*. They have evaluated the following topics related to neck pain (41–48):

- Effectiveness and safety of noninvasive interventions
- Course, risk factors, and prognosis of WAD
- Gaps in the current literature
- Epidemiology, assessment, and classification of neck pain
- Nonmodifiable and modifiable prognostic factors in neck pain
- Course and prognosis of neck pain in the general population

The following statements regarding neck pain are derived by review from a best-evidence synthesis of the current published literature (41–48):

- Neck pain is more common in middle-age women.
- Genetics, poor psychologic health, and exposure to tobacco are risk factors to neck pain in the general population.
- Manual therapies, patient education, and exercise are more effective than alternative strategies for patients with neck pain.
- Cervical spine manipulation and mobilization provided short-term benefits for patients with acute neck pain and headache (40).
- For subacute and chronic neck pain, spinal manipulation is more effective when compared with muscle relaxants or the usual medical care. Efficacy was enhanced when combined with other modalities, such as exercise (40).
- There are gaps in the literature when it comes to neck pain in children, neck pain related to culture and social policies, and the prevention of neck pain–related activity limitations.
- Patients who undertook general exercise had a better prognosis; those with little influence on their own work, those with psychological stress had a poorer prognosis.
- Fifty percent of patients with whiplash associated neck pain will report neck symptoms 1 year after the injury.
- Headrest, car seats (aimed at elimination head extension) in rear-end impacts were associated with less repeating of “whiplash-associated disorders,” as was eliminating insurance payments.

The reader is recommended to review the best evidence on neck pain as this knowledge is important in directing the care of patients.

RISKS AND BENEFITS OF MANUAL MANIPULATIVE TECHNIQUES IN PATIENTS WITH NECK PAIN

Risks

The potential risk from manual manipulative techniques used in the cervical spine is from thrust-type (HVLA) procedures. The potential risk is from hyperextension and rotation forces causing a vertebral artery dissection and stroke. Although a few case reports have been published on this topic in the past 100 years, the natural occurrence of spontaneous dissection and stroke is higher than that reported with thrust-type procedures (40). Because of concern over this topic in the literature, the AAO (March 2003) and AOA (August 2004) developed position papers on osteopathic manipulation of the cervical spine. Their consensus after review of the literature was that they supported the appropriate use of cervical manipulation and the use of HVLA technique. (40) There have not been any complications from any of the manipulative treatment procedures,

provided in clinical trials, over the past 25 years (over 100 publications) (40). There is still controversy in the medical literature on when or when not to use cervical thrust (HVLA) manipulation.

Benefits

There are many benefits to cervical manipulation. Some of the primary benefits include increased range of motion, decreased pain, improved activities of daily living, and shortened disability time (quicker return to work). Some secondary benefits include reduced reliance on medications (especially narcotics) and improved postural efficiency (40).

These benefits may decrease the need and cost for physical therapy and, in some cases, prevent unnecessary injections or surgery.

SUMMARY

Manipulative treatment of the cervical spine can greatly assist healing of injury, pathology, pain, or dysfunction of the cervical region. Appropriate treatment of the cervical spine requires a thorough understanding of the anatomy, somatic dysfunction, and orthopedic and systemic conditions. OMT should be integrated throughout the treatment plan of patients with neck pain. Improving motion and tissue restrictions of the neck has far-reaching effects to other regions of the body.

KEY CONCEPTS

- The thoracic and rib cage regions together form a complex region of the body.
- The most vital role of the thoracic and rib cage regions is the contribution to the process of respiration.
- The biomechanical architecture of the thoracic and rib cage regions is a complex system of levers, alteration of which may impair respiration.
- Much of the regulatory outflow of the sympathetic nervous system originates in the thoracic spinal cord.
- Visceral afferent (generally nociceptive) neurons usually follow the same pathway as the sympathetic outflow.

INTRODUCTION

Because the heart and lungs are contained in the thorax, this region's unique significance in life has long been recognized. The inability to draw breath or the perception of pain in the thorax often constitutes real or imagined immediate and life-threatening problems. Movement of the thorax is necessary for normal function in both obvious and not-so-obvious ways. Because much of the regulatory outflow of the sympathetic nervous system originates in the thoracic spinal cord, disturbances in the muscles and joints of the thoracic region often mimic life-threatening problems. Injury to thoracic vertebrae can cause long-term sequelae for health and survival.

The most vital role of the thoracic region and rib cage is the contribution this region makes to the process of respiration. Respiration is a process involving the participation of several systems of the body, none the least of which is the musculoskeletal system. As Cathie (1) noted, "Respiratory activity requires motion in a greater number of articulations and with a greater frequency than any other musculoskeletal function." This not only includes the intervertebral joints of the thoracic spine but also the costovertebral and costotransverse joints at the posterior aspects of the ribs. In addition to the articular motion, optimal respiration also requires a degree of elasticity of the ribs and costal cartilages. The biomechanical architecture among the vertebrae and ribs may be thought of as a complex system of levers; anything that alters the normal movement of this system of levers may impair respiration.

The complexities of the thoracic region and the vital importance of its organ systems underscore the necessity for the osteopathic physician to understand its many functions, diagnoses, and potential treatment approaches. In diagnosis and treatment, it cannot be considered as separate from the other body regions, because dysfunction in it or other regions is always interdependent.

DEFINITION

The thoracic region (also commonly referred to as the *chest*) is that portion of the trunk between the neck and the abdomen that contains such structures as the heart, lungs, esophagus, the aorta and its branches, superior and inferior vena cavae, the trachea and primary bronchi, the thoracic duct, azygous and hemiazygous veins, and the sympathetic chain ganglia. The rib cage is the bony enclosing wall of the chest. It is a structure formed by the thoracic vertebrae, the ribs, the sternum, and the costal cartilages.

ANATOMY AND PHYSIOLOGY

Skeletal Anatomy

The thoracic cage includes 12 thoracic spinal vertebrae, 12 pairs of ribs, and the sternum (Fig. 39.1). Although the scapula overlies the posterior portion of the rib cage, is connected to the sternum through the clavicle, and is often involved in thoracic injuries and pain syndromes, this structure is more properly considered a part of the upper extremity.

White and Panjabi, the noted clinical anatomists and authors, divide the thoracic spine into three anatomical regions:

- Upper (T1-4)
- Middle (T4-8)
- Lower (T8-L1)

It is also helpful to divide the thoracic and upper lumbar spine into four functional divisions that roughly correspond to the thoracolumbar outflow of the sympathetic system:

- T1-4: Sympathetics to head and neck, with T1-6 to the heart and lungs
- T5-9: All upper abdominal viscera: stomach, duodenum, liver, gall bladder, pancreas, and spleen
- T10-11: Remainder of the small intestines, kidneys, ureters, gonads, and right colon
- T12-L2: Left colon and pelvic organs

This functional division is often very useful to the osteopathic physician, because visceral afferent (generally nociceptive) neurons usually follow the same pathway as the sympathetic outflow. Visceral disturbances often cause increased musculoskeletal tension in the somatic structures that are innervated from the corresponding spinal level through the viscerosomatic reflexes. Manipulative treatment at that spinal level is used to reduce somatic afferent input from the associated facilitated segments, which, in turn, reduces somatosympathetic activity to the affected viscus (3).

Generally, the thoracic spine has a mildly kyphotic, forward-bending curve that varies from person to person. In the osteoporotic or older patients, the angle of this curve can become more acute, causing biomechanical problems and necessitating compensatory adaptation in other regions of the spine and in general posture. Individual thoracic vertebrae are parts of a continuum with the cervical and lumbar vertebrae; size increases from cervical to lumbar to account for increased weight bearing. The spinous processes

Figure 39-1 The thoracic region and its relationships.

of the thoracic vertebrae are particularly large and easily palpated, pointing increasingly caudad from T1 through T9 and back to an almost anteroposterior orientation from T10-12.

Thoracic vertebral facet joints are plane-type synovial joints. The interarticular surfaces of these joints are smooth, shiny, compact bone that is covered with hyaline cartilage. The joints are surrounded by a thin, loose articular capsule that is lined with synovial membrane. The facet joints guide and limit gross, segmental, and coupled movements. The superior facets of each thoracic vertebra are slightly convex and face posteriorly (“backward”), somewhat superiorly (“up”), and laterally. Their angle of declination averages 60 degrees relative to the transverse plane and 20 degrees relative to the coronal plane. A tool to remember the facet facing is the mnemonic BUM (backward, upward, and lateral). This is in contrast to the cervical and lumbar regions, where the superior facets face backward, upward, and medial (BUM). Thus, the *superior facets* are

BUM, BUL, BUM from cervical to thoracic to lumbar. In the lower portion of the thoracic spine, the superior facet surface begins to face more posteriorly than laterally, and at T12, it may even face medially, as part of a functional transition to the lumbar spine. The inferior facet of each thoracic vertebra faces in the opposite direction from the superior and has a slightly concave surface.

The thoracic vertebrae are separated by discs, as are the cervical and lumbar vertebrae. The discs act as shock absorbers and permit flexibility between the vertebrae. Each disc is composed of an outer anulus fibrosus and an inner nucleus pulposus, a gel at the center of the disc that acts like a semifluid hydrophilic ball bearing that, under sustained compression, becomes less hydrated and broader. The anulus fibrosus is composed of concentric lamellae of fibrocartilage, running at right angles to the fibers of adjacent layers. Its structural arrangement is more vulnerable to tears posteriorly, where the lamellae are thinner and less numerous. However, the restricted motion of the thoracic spine due to the attachments of the rib cage and the fairly broad posterior longitudinal ligament makes ruptured thoracic discs relatively uncommon. On the other hand, discopathy from trauma, aging, and degenerative disease is relatively common in the thoracic area.

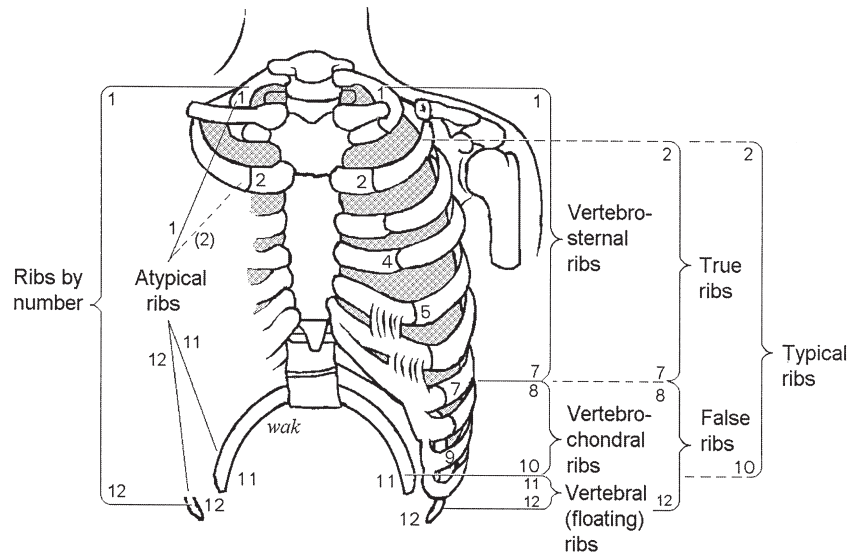

The 12 sets of ribs correspond with the 12 thoracic vertebrae. All ribs are composed of a bony segment and a costal cartilage. Each rib has a cup-shaped depression in its bony segment where the costal cartilage fits into the costochondral joint and where the periosteum of the rib joins the perichondrium of the rib cartilage. The rib heads join with the thoracic vertebrae at the costovertebral articulations. The heads of ribs 2 through 9 articulate with a demifacet on the vertebra above and below. For example, rib 2 articulates by demifacets with T1 and T2. Unlike ribs 2 to 9, the heads of ribs 1 and 10 to 12 articulate with unifacets on their corresponding vertebrae. The transverse processes of vertebrae T1-10 all form synovial costotransverse joints with the tubercle of the corresponding rib.

Ribs 1, 2, 11, and 12 are called *atypical ribs*. Rib 1 is the flattest, shortest, broadest, strongest, and most curved. The subclavian artery and the cervical plexus are vulnerable to muscular compression where they pass over the 1st rib between the tubercles and attachments of the anterior and the middle scalene muscles (the so-called scalenus anticus syndrome). The latter is one of several conditions clinically labeled as *thoracic outlet syndrome*. The subclavian vein may also be compressed between the 1st rib and the clavicle. Rib 2 is considered anatomically atypical because of its tuberosity that attaches to the proximal portion of the serratus anterior muscle. Ribs 11 and 12 are anatomically atypical because they do not have tubercles, do not attach to the sternum or other costal cartilages, and have tapered ends. These 2 ribs are also called *floating* or *vertebral ribs*. Rib 10 is sometimes considered atypical because of its single articulation between the rib head and T10.

The anatomy of the rib cage is shown in Figure 39.2. Anatomically typical ribs (3 to 9, and in most respects 10) have heads, necks, tubercles, angles, and shafts that connect directly or via chondral masses to the sternum. Rib 1 and ribs 2 to 7 connect directly with the sternum by their own individual cartilaginous synovial joints (rib 1 with a stable synchondrosis); therefore, they are often called the *true ribs*. Ribs 8 to 10 merge into a single cartilaginous mass that attaches to the sternum; therefore, these are called *vertebral chondral ribs*. Ribs 11 and 12 do not connect with the sternum and are hence called *floating ribs*. Because ribs 8 to 12 do not connect directly to the sternum, they are often called the *false ribs*.

The costovertebral joints between the heads of the ribs and the vertebral bodies allow gliding or sliding costal motions. The costotransverse joints at the tubercle of the typical ribs, with the facets at

Figure 39-2 The bony anatomy of the rib cage and the naming of rib types.

the tip of the transverse processes of their own vertebra, a synovial membrane, and a thin articular capsule, allow gliding and slight rotational motions. When these motions are restricted, respiratory movements are commonly impeded.

The sternum has three parts:

- Head or manubrium
- Body or gladiolus
- Tail or xiphoid process

The superior portion of the manubrium cradles the clavicles at the sternoclavicular joints, forming the sternal notch or jugular notch, which is a landmark for several anterior thoracic strain/counter-strain tender points. The sternal notch lies almost directly anterior to the T2 vertebral body. The manubrium joins the sternal body via a fibrocartilaginous symphysis, or secondary cartilaginous joint, called the *sternal angle* or *angle of Louis*. This joint lies anterior to the fourth thoracic vertebra. Because the 2nd rib attaches to the manubrium and sternal body with a synovial joint, the sternal angle is an anterior landmark for counting the ribs. The xiphisternal joint is located anterior to the ninth thoracic vertebra. It is also a hyaline cartilage symphysis that fuses into a synostosis in the fifth decade.

Musculature

The muscles of the thoracic area are involved in:

- Actions of the ribs and vertebrae
- Posture
- Head and neck control
- Breathing
- Locomotion
- Stabilization of the extremities
- Visceral function

Table 39.1 lists the major muscles of the thoracic area, with the action, proximal and medial attachments, distal and lateral attachments, and innervation of each (4). It is especially important to note the action of each muscle, because altered tone in these muscles can affect the function of not only the bones to which the muscles are attached but other body areas as well. In addition, increased or decreased tone has the capacity to alter both general and microcirculation in a myriad of ways, such as altered homeostatic regulation and cellular immunity.

As with all muscles, the thoracic muscles are fed not only by circulatory elements but also by physiologically active trophic substances delivered directly by nerves (5). In addition, there is evidence that the sympathetic nerve supply to striated and smooth muscles alters muscle tone and contractile forces. Therefore, the palpatory cues associated with altered muscle tone imply the presence of many differential diagnostic factors that are discussed throughout this text.

The larger muscles of the head, neck, shoulder girdle, and thorax control much of the activity of the thoracic cage and help stabilize the cervical and cranial areas, as well as the arms and shoulder girdle themselves. For example, the splenius capitus and cervicis muscles originate on the lower cranial and upper cervical areas and attach distally along the middle thoracic spine, as low as T6-T8 in some cases. Vertebral dysfunction in the upper thoracic areas can affect the action of these muscles, causing problems with motion outside the thoracic area in the head and neck. Lower down, the internal and external oblique muscles are generally viewed as trunk rotators, but they also attach to the lower ribs along with the diaphragm. Altered tone in these muscles can alter diaphragmatic and respiratory function and vice versa. Experienced palpation readily identifies these relationships.

Of special note are the erector spinae groups (Fig. 39.3), which extend and side-bend the vertebral column, and allow smooth flexion by gradually decreasing resistance to forward bending. These muscles are often involved in group or multiple movement dysfunction (i.e., altered coupling or non-neutral vertebral unit dysfunction), and are vulnerable to insult with unplanned movements or trauma. The deep back muscles, especially the rotatores and multifidus, are also implicated in this type of problem. These small muscles are richly innervated with muscle spindles, which provide proprioception. In fact, one of their primary tasks is to signal position and speed of motion of the vertebral column. (This task makes them important in the maintenance of posture and in directing movement.) They are also very vulnerable to sudden stretch and unplanned movement, which appears to alter the sensory input to the spinal cord and brain, with resultant development of altered motion and pain typical of vertebral somatic dysfunction (6–8).

The abdominal diaphragm is the primary muscle of respiration. It forms the floor of the thorax and attaches to the xiphoid process, the internal surface of the inferior 6 ribs, the upper two (left) or three (right) lumbar vertebrae, and their intervertebral

TABLE 39.1

Regional Thoracic Muscles

Muscle	Action	Proximal/Medial Attachments	Distal/Lateral Attachments	Innervation
Pectoralis major	<ol style="list-style-type: none"> 1. Clavicular head: flexion, adduction, horizontal flexion, and medial rotation of the humerus at the shoulder. 2. Sternocostal head: flexion, adduction, medial rotation, and horizontal flexion of the humerus at the shoulder. Also extends flexed humerus. Through its action on the humerus, it depresses, protracts, and rotates downward. 	<ol style="list-style-type: none"> 1. Clavicular division: anterior surface of the medial 1/2 of the clavicle. 2. Sternocostal head: sternum to 7th rib, cartilages of true ribs and aponeurosis of external abdominal oblique muscle. 	<ol style="list-style-type: none"> 1. Clavicular division: lateral lip of the intertubercular groove of the humerus. 2. Sternal division: lateral lip of the intertubercular groove of the humerus. 	<ol style="list-style-type: none"> 1. Clavicular head: lateral pectoral, C5, C6. 2. Sternocostal head: pectoral, C7, C8, T1.
Pectoralis minor	Depresses scapula and rotates scapula inferiorly. Important anterior shoulder stabilizer.	Anterior surfaces of 3rd, 4th, and 5th ribs near the costal cartilages.	Coracoid process of the scapula.	Medial pectoral, C6, C7, C8.
Teres major	Adducts and medially rotates humerus at the shoulder. Extends the shoulder joint.	Dorsal surface of inferior angle of the scapula.	Medial lip of intertubercular groove of humerus. Medial to latissimus dorsi tendon.	Lower subscapular, C6, C7.
Teres minor	Lateral rotation of humerus at the shoulder. Stabilization of head or humerus.	Superior 2/3 of dorsal surface of lateral border of scapula.	Inferior aspect of greater tubercle of the humerus, capsule of the shoulder joint.	Axillary, C5, C6.
Trapezius	<ol style="list-style-type: none"> 1. <i>Lower fibers:</i> depress the scapula. Retract the scapula. Rotate the scapula upward so the glenoid cavity faces superiorly. Give inferior stabilization of scapula. Help maintain spine in extension. 2. <i>Middle fibers:</i> retract and aid in elevation of scapula. 3. <i>Upper fibers:</i> elevate the scapula as in shrugging the shoulders. Rotate the scapula upward so the glenoid cavity faces superiorly. When acting with the other sections of the trapezius, it retracts the scapula. 	<ol style="list-style-type: none"> 1. <i>Lower fibers:</i> spinous processes of 6th–12th thoracic vertebrae. 2. <i>Middle fibers:</i> spinous processes of 1st–5th thoracic vertebrae. 3. <i>Upper fiber:</i> external occipital protuberance, medial 1/3 of superior nuchal line, ligamentum nuchae, and spinous process of the 7th cervical vertebra. 	<ol style="list-style-type: none"> 1. <i>Lower fibers:</i> medial 1/3 of spine of the scapula. 2. <i>Middle fibers:</i> superior border of spine of scapula. 3. <i>Upper fibers:</i> lateral 1/3 of clavicle and acromion process. 	<ol style="list-style-type: none"> 1. <i>Lower division:</i> spinal root of accessory and anterior primary rami C3, C4. 2. <i>Middle division:</i> spinal root of accessory and anterior primary rami C3, C4. 3. <i>Upper division:</i> spinal root of accessory and anterior primary rami C3, C4.

(continued)

TABLE 39.1 (Continued)

Muscle	Action	Proximal/Medial Attachments	Distal/Lateral Attachments	Innervation
Latissimus dorsi	Extends, retracts, and medially rotates the humerus at the shoulder. Through its action on the humerus, it depresses, retracts, and rotates the scapula downward. Assists in forced expiration.	Flat tendon that twists on itself to insert into the intertubercular groove of the humerus, just anterior to and parallel with tendon of pectoralis major.	Broad aponeurosis that originates on the spinous processes of lower 6 thoracic and all lumbar vertebrae; posterior crest of ilium, posterior surface of sacrum, lower 3 or 4 ribs, and an attachment to the inferior angle of the scapula.	Thoracodorsal C6, C7, C8.
Levator scapulae	Elevates the scapula and rotates the scapula downward so the glenoid cavity faces inferiorly. Working with the upper fibers of the trapezius, it elevates and retracts the scapula. <i>Reversed action:</i> when the scapula is fixed, it laterally flexes and slightly rotates the cervical spine to the side.	Transverse processes of first four cervical vertebrae.	Vertebral border of scapula between superior angle and scapular spine.	Dorsal scapular C5 and anterior primary rami C3, C4.
Rhomboid	1. <i>Minor:</i> retracts and elevates the scapula. Assists in rotating the scapula downward. 2. <i>Major:</i> retracts and elevates the scapula. Inferior fibers aid in rotating the glenoid cavity inferiorly.	1. <i>Minor:</i> lower part of ligamentum nuchae, spinous processes of C7 and T1. 2. <i>Major:</i> spinous processes of T2-5.	1. <i>Minor:</i> medial border of scapula at the root of the spine of the scapula. 2. <i>Major:</i> medial border of scapula from spine to inferior angle.	1. <i>Minor:</i> dorsal scapular, C4, C5. 2. <i>Major:</i> dorsal scapular, C4, C5.
Quadratus lumborum	Lateral flexion of lumbar vertebral column; helps the diaphragm in inspiration.	Iliolumbar ligament, posterior part of the iliac crest.	Inferior border of the 12th rib and transverse processes of the upper four lumbar vertebrae.	Anterior primary rami T12, L3.
Serratus anterior	1. Accessory muscle of respiration. 2. Protraction of the scapula.	Superior lateral surfaces of upper 8 ribs at the side of the chest.	Costal surface of the medial border of scapula.	Long thoracic, C7.
Serratus posterior (superior/inferior)	Accessory muscles of inspiration. Superior elevates superior ribs; inferior depresses inferior ribs.	1. <i>Superior:</i> lower portion of ligamentum nuchae and spinous processes of the 7th cervical and 1st, 2nd, and 3rd thoracic vertebrae. 2. <i>Inferior:</i> spinous processes of 11th and 12th thoracic and 1st, 2nd, and 3rd lumbar vertebrae, and the thoracolumbar fascia.	1. <i>Superior:</i> superior borders of 2nd–5th ribs distal to the angles. 2. <i>Inferior:</i> inferior borders of lower 4 ribs just beyond their angles.	1. <i>Superior:</i> anterior primary rami T2-5. 2. <i>Inferior:</i> anterior primary rami T9-12.

discs. Its fibers converge into a common central tendon that has no bony attachment. When the diaphragm contracts with inhalation, it descends into the abdomen; when it relaxes during exhalation, it moves superiorly into the thorax. This up-and-down movement produces pressure gradients between the thoracic and abdominal cavities, and is important for both efficient respiration and circulation. Because there are one-way valves in the larger lymphatic vessels, the pressure gradients also enhance the movement of lymph and venous blood toward the heart. When the dome of the diaphragm is flattened because of asymmetric load and/or tonus, respiration and lymphatic drainage from anywhere in the body become less efficient. Thus, for example, it would not be surprising to have a lymphatic component in the lower extremity edema of COPD as well as vascular.

Three apertures occur in the diaphragm: one for the vena cava at about the level of T8, another for the esophageal hiatus at T10, and the third for the aorta at the level of T12 (Fig. 39.4). Diaphragmatic muscle fibers are arranged so that when it contracts in inspiration, the vena caval opening dilates, permitting more venous blood to pass from the abdomen to the thorax; at the same time, the esophageal hiatus constricts to prevent gastric contents from rising in the esophagus. Its contraction has no influence on the aortic hiatus, which lies posterior to the diaphragm and does not truly pierce the diaphragm.

The diaphragm does most of the work of breathing under normal conditions and during moderately forced inspiration. With increased respiratory demands, accessory muscles of respiration become involved to move the ribs even more. The scalene muscles, attached to the upper 2 ribs, assist inhalation. Hypertonicity or hypotonicity of segmental intercostal muscles alters rib behavior, making breathing less efficient. Actual spasm in these muscles can result in pain at rest or especially with each deep breath or cough. Quiet exhalation creates passive recoil of the lung as the diaphragm relaxes. Forced exhalation also involves the inferior internal intercostal and abdominal muscles, including the trunk rotators and erector spinae.

Osteopathic manipulative treatments can often restore or partially rehabilitate altered diaphragmatic function. These treatments

are designed to increase motion of the lower costal cage by freeing the diaphragm for better excursion. This, in turn, helps improve breathing mechanics and assists in venous blood return and lymphatic flow. This approach can be especially helpful for individuals with asthma, respiratory infections, loss of general lung compliance, and associated disorders.

Lymphatics

As blood moves through the capillaries, fluid filters into the interstitial tissues. The return of interstitial fluid through the lymphatic system is necessary for health and proper function, and is even more important when the patient has disease. The lymphatic system is illustrated in Figure 39.5. Lymphatic drainage from the lower half of the body is supplied by the thoracic duct (or left lymphatic duct). Smaller lymphatic vessels drain into the cisterna chyli in the abdomen. Trunks from the left side of the head, the left arm, and the thoracic viscera also empty into the thoracic duct before it drains into the junction of the left internal jugular and left subclavian veins. In approximately 20% of the population, three trunks, the right jugular, the right subclavian, and the right transverse cervical, join to form the right lymphatic duct. The remainder of the population varies in the way the three trunks empty into the jugulosubclavian junction in the anterior neck. The right lymphatic duct enters the junction of the right internal jugular and right subclavian veins (9).

In general, the superficial lymph vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes (2,3). The lymph nodes from the deeper tissues of the thoracic wall drain into three groups of nodes:

1. The parasternal (internal thoracic) lymph nodes. These are four or five pairs of nodes located at the anterior ends of the intercostal spaces.
2. The intercostal lymph nodes, located in the posterior parts of the intercostal spaces in relation to the heads and necks of the ribs.
3. The diaphragmatic (phrenic) lymph nodes, located on the thoracic surface of the diaphragm.

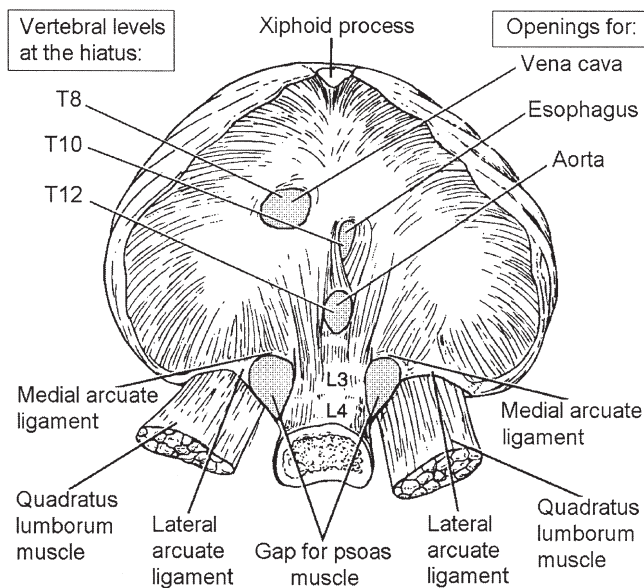

Figure 39-4 Apertures of the abdominal diaphragm.

Connective Tissue and Fascia

Connective tissue unites and surrounds all other tissues. It is found between the cells of organs, as tendons of muscles, and as ligaments joining skeletal parts. Of special importance to the osteopathic physician are the fasciae of the body. These connective tissues surround virtually all organs, muscles, and vessels (10). Fascial elements called the *pericardium* and *pleura* even surround the heart and lungs, respectively. Fascia is a fibrous tissue that is effectively wound around the invested organs at various angles.

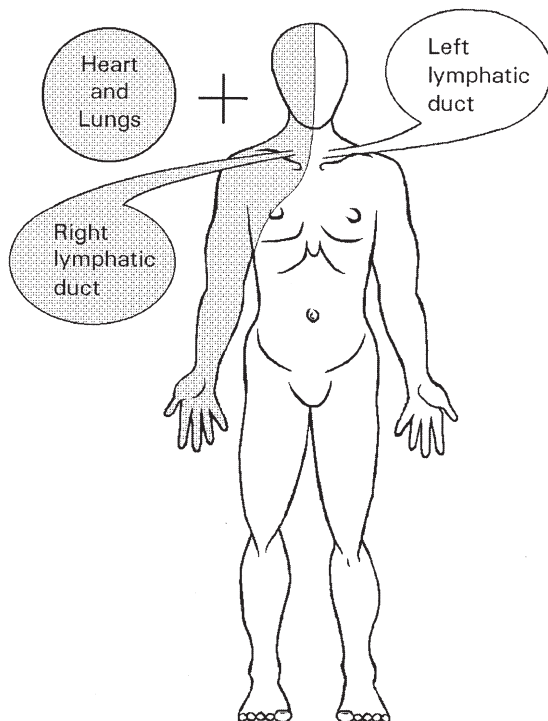

Figure 39-5 The lymphatic system of the body.

The muscles of the thoracic cage are also invested with fascia. The internal thoracic wall is covered by a parietal layer of fascia called the *endothoracic fascia*. This deep fascia invests the internal intercostal, subcostal, and transversus thoracis muscles (10). This fascia blends with the periosteum of the ribs and sternum and with the perichondrial tissue of the costal cartilages. The endothoracic fascia also covers the superior surface of the diaphragm, thus becoming the superior diaphragmatic fascia. The endothoracic fascia is also continuous with the prevertebral layer of the cervical fascia and with the scalene fascia (also called *Sibson fascia*), where it attaches along the inner border of the 1st rib. Behind the sternum, it is also continuous with the fascia of the infrahyoid muscles. This parietal thoracic fascia proceeds through the openings of the diaphragm to become continuous with the transversalis fascia of the abdomen. In addition, there are specialized fascial elements that comprise the pericardium, pleura, and mediastinum.

Trauma, chemical alterations of the bathing fluids (immune changes), and other pathologic agents alter the angles of the fascial bands and change cross-linkages between the bands, causing altered tensions of the fasciae throughout the body. An increase in tension in the fascial sheets leads to altered interstitial fluid (lymph) flows, decreased blood flow, and decreased efficiency of organ function. Normalization of the fascial tensions returns the body to more efficient function, thereby using less energy. Osteopathic manipulative techniques, including direct and indirect myofascial release, have been developed to address these problems in ways not generally found to be effective with most other manipulative techniques. The thoracic fasciae are often involved in dysfunction due to thoracic trauma.

Vascular Structures

The arterial blood supply to the thoracic viscera comes largely from branches of the descending thoracic aorta. These include the pericardial, bronchial, mediastinal, phrenic, posterior intercostal, and subcostal arteries. The venous drainage of the thoracic visceral structures is accomplished by way of a corresponding system of veins that parallel the arteries. Several other structures that participate in the venous drainage of the thoracic regional viscera are the superior vena cava, a short section of the inferior vena cava, and the azygous and hemiazygous system of veins.

The thoracic portion of the spinal cord derives its arterial blood supply from three longitudinal structures: a single anterior and two posterior spinal arteries. In addition, the posterior intercostal arteries make contributions to the longitudinal arterial system (10).

The arterial blood supply to the walls of the thoracic cage comes from three main sources: the axillary and subclavian arteries, and the aorta. The axillary artery provides its contribution to the arterial blood supply of the thoracic cage walls by way of two of its branches: the superior thoracic and lateral thoracic arteries. The subclavian artery gives rise to the internal thoracic artery, which in turn provides arterial blood to the thoracic cage from the following branches: anterior intercostal, perforating, and musculophrenic arteries. It also gives rise to the superior intercostal artery. The aorta gives rise to the posterior intercostal arteries. The superior intercostal artery branches into the first and second intercostal arteries and then anastomoses with the third intercostal artery.

The venous drainage of the thoracic walls is accomplished by way of several venous structures. These include the internal thoracic veins, the anterior, posterior and superior intercostal veins, and the azygous and hemiazygous veins.

The arterial supply of the thoracic vertebrae and musculature is derived from branches of the posterior intercostal arteries. Each

posterior intercostal artery gives rise to a spinal branch, which provides arterial blood to its corresponding spinal vertebra, along with the spinal cord and meninges at that vertebral level. The spinal branch then further divides into medial and lateral musculocutaneous branches. The medial branch provides arterial blood to the spinalis and longissimus thoracis muscles and a corresponding area of skin; the lateral branch provides arterial blood for the longissimus thoracis and iliocostalis muscles, the medial aspects of the latissimus dorsi and trapezius muscles, and a corresponding area of skin.

There is a corresponding network of veins to provide for venous drainage of the thoracic spinal region. These include the anterior and posterior internal plexus of vertebral veins, the anterior and posterior external plexus of vertebral veins, and the basivertebral and intervertebral veins (10).

Neural Structures

The neural connections of the thoracic area are of vital importance to all body functions. Not only do the usual connections to the musculoskeletal system exit the spinal cord in the thoracic region, but a large part of the sympathetic nervous system also originates in the thoracic region. The sympathetic innervation of the body is shown in Figure 39.6. An understanding of the relationships between the thoracic nerves, as well as their relationships to the bony landmarks is vital to understanding neurologic problems associated with the thoracic region.

The spinal cord, which runs from the brainstem to about the level of L3, is a continuous structure with no segmentation. During embryologic development, the spinal nerve bundles are gathered into spinal nerve roots that course between the encircling bones through the intervertebral foramina. This imposes what appears

to be a dermatomal segmentation effect. Inherently, however, the function of the spinal cord is not segmented.

The spinal nerves exit through the intervertebral foramina, which identify their vertebral level. Each spinal nerve is numbered at the level at which it exits, except in the cervical region, because there are eight cervical nerve roots and seven cervical vertebrae. Spinal nerve C1 exits above the atlas, and the eighth root exits below C7. All other roots exit below their corresponding vertebrae. Because the intervertebral foramen is a bounded space and the nerve roots share that space with other tissues, the roots are especially vulnerable to pressure from herniated nucleus pulposus and even edema. Somatic dysfunction in a thoracic area may cause local edema and tissue tightening, which can exert pressure on the nerve root and, importantly, can alter blood and fluid flows to and from the nerve sheaths. Such pressure can alter neural conductivity in the affected roots, although the lack of proper blood and fluid flow to the sheaths can cause irritability in the nociceptors of the sheath, causing pain along the nerve distribution (11). Local disturbances can often be relieved with proper manipulative treatment that is designed to restore proper motion and fluid flow to the region. As stated previously, radiculopathy is somewhat rare in the thoracic region, although discopathy is less rare. These problems in the thoracic area are not easy to diagnose because of overlapping dermatomes and a lack of readily testable deep tendon reflexes.

The abdominal diaphragm receives its motor innervation through the phrenic nerves coming from C3-5. Perhaps more importantly, sensory nerves of the diaphragm innervate the mediastinal pleura, the fibrous pericardium, and the parietal layer of the serous pericardium (10). This relationship helps explain the very common palpatory findings of cervical tension and somatic dysfunction associated with pericardial or diaphragmatic irritation that are mediated via the viscerosomatic reflexes. Manipulative treatment of the involved cervical segments is designed to ameliorate thoracic and diaphragmatic dysfunction through somatovisceral reflex pathways.

The ventral rami of the first 11 thoracic nerves are called *intercostal nerves* (13). They are located between the ribs, although the 12th thoracic nerve lies below the last rib and is thus called the *subcostal nerve*. Each of these nerves is connected to the sympathetic chain ganglia via the *white and gray rami communicantes*. The intercostal nerves provide innervation chiefly to the thoracic and abdominal walls. The first six nerves provide innervation to the thoracic wall, with the first two nerves also providing fibers to the upper extremity. The lower five nerves are distributed to the thoracic and abdominal walls, and the subcostal nerve innervates the abdominal wall and the skin of the gluteal area.

Parasympathetic innervation to the thoracic viscera and many of the abdominal viscera comes through the vagus nerve (cranial nerve X). These relationships are discussed in Chapters 9 and 10. Treatment of problems encountered in the function of the thoracic viscera must include assessment and treatment of cranial and cervical areas to normalize vagal function.

The majority of the outflow of the sympathetic system originates in the thoracic region. The distribution of the sympathetic system to almost every tissue and area of the body makes this system a very important one for all body functions. It has become evident that the sympathetic system is vitally important in regulating immune function (13). The importance of the sympathetic nervous system for all body functions suggests that disturbances within the thoracic vertebra and their associated musculature that affect the function of the sympathetic system can have widespread consequences. Identification and treatment of somatic dysfunction in the

Figure 39-6 The sympathetic innervation of the body.

thoracic region is especially important in treating problems ranging from infectious processes to functional abnormalities.

Visceral Considerations

Visceral dysfunction that alters input to the spinal cord not only increases the sympathetic outflow back to the visceral areas through viscerovisceral reflex pathways but also alters somatic outflow in often unexpected patterns. Understanding this phenomenon provides insight on how to treat many painful and/or functional problems. Due to the overlap of visceral afferents onto spinal pathways that also receive somatic afferents, the sensory experience of visceral irritation is often one of referred pain to a somatic structure, with concomitant increased somatic muscle tone. One of the most common of these patterns is the shoulder pain and muscle tension associated with acute myocardial infarction. The nociceptive input from the compromised myocardium is experienced as shoulder or chest pain. Often, a vicious circle of increased somatic involvement results, as increased somatic activity also increases sympathetic outflow to the heart, further exacerbating the pathologic process. Although obviously not the only course of treatment, treating the somatic component of the process can be beneficial. Recognition of the visceral origin of referred pain patterns can save the osteopathic physician much time and missed diagnoses. Likewise, recognizing that osteopathic treatment of the involved somatic structures can also help the course of the problem. Understanding the somatic areas likely to show effects of underlying visceral pathologic conditions through viscerosomatic reflexes (3) provides the osteopathic physician with another important diagnostic and treatment tool.

BIOMECHANICAL CONSIDERATIONS

Physiologic Motion

In general, thoracic spinal motion occurs according to the mechanical principles formulated by Fryette. In other words, when the thoracic spine is in the neutral position, sidebending of spine in one direction results in rotation of the thoracic vertebrae in the direction opposite to the sidebending. When the thoracic spine is in a non-neutral position (i.e., flexed or extended), sidebending of spine in one direction results in rotation of the thoracic vertebrae in the same direction as the sidebending.

However, there are times when variations from Fryette principles occur in thoracic vertebral motion. Upper thoracic vertebrae may exhibit neutral (type I) motion, which may occur as low as T4, and movements are similar to normal cervical spine behavior. Some suggest that these motions are associated with the interdependent combination of asymmetrical vertebral and upper rib shapes and attachments and their interactions with cervical muscles (such as the splenius cervicis) that attach as low as T5 and T6. Middle thoracic vertebral motion is commonly a mix of neutral (type I) and non-neutral (type II) movements, which may produce rotation to either the formed convexity or to the formed concavity. Lower thoracic vertebral motion is more apt to be similar to lumbar neutral (type I) mechanics.

During inhalation, the thoracic cage widens its vertical, transverse, and anteroposterior dimensions as the diaphragm contracts (14). With deep inhalation, the anterior ends of the superior ribs move more anteriorly and superiorly along with the sternum (Fig. 39.7).

Typical ribs are attached to the sternum by the costal cartilage, and their movements displace the anterior component of the costosternal system superiorly and anteriorly. This motion is described as pump-handle motion. (See Glossary for more detailed defini-

Figure 39-7 Functional transverse rib axis. (From *Gray's Anatomy*. 35th Ed. Edinburgh, Scotland: Churchill Livingstone, 1973:421, with permission.)

tion.); the rib shaft is the handle of the pump, and the vertebral column is the pivot point (Fig. 39.8).

The vertebrosteral ribs (1 and 2) and vertebrochondral ribs (8 to 10) move about functional pivots posteriorly and anteriorly. Functionally, their shafts move laterally and superiorly during inhalation, increasing the transverse diameter of the costal cage (Fig. 39.9). This motion is referred to as *bucket-handle motion* (Fig. 39.10). The anterior/posterior diameter of the chest is increased as the anterior ends of ribs 8 to 10 are elevated by the contraction of the diaphragm. Ribs 11 and 12 are called *vertebral ribs*, because they do not attach to the sternum or the chondral mass. These two atypical ribs have a pincer-type motion. The types of rib motion described clinically are depicted in Figure 39.11.

Nonphysiologic Motion

Both neutral (type I) and non-neutral (type II) vertebral unit dysfunction is common in the thoracic spine. Neutral (type I) asymmetries typically involve three or more segments that are neither flexed nor extended; they are mildly scoliotic. Non-neutral (type II)

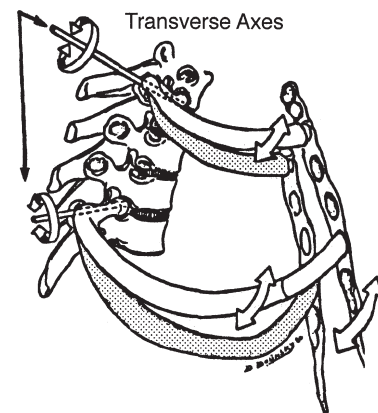

Figure 39-8 Pump-handle rib motion.

Figure 39-9 Functional anteroposterior rib axis. (From *Gray's Anatomy*, 35th Ed. Edinburgh, Scotland: Churchill Livingstone, 1973:421, with permission.)

vertebral unit dysfunction generally involves a single vertebral unit and can have proximal and distal neutral (type I) responses.

Asymmetry of motion in any of the rib cage areas indicates the presence of respiratory rib dysfunction in that region. Respiratory rib dysfunction has either inhalation or exhalation restriction. There is usually one rib within a group of ribs that is responsible for maintaining the inhalation or exhalation restriction. This rib is referred to as the *key rib* and is the rib that must be identified and treated to remove a group restriction. Inhalation restrictions involve a rib or group of ribs that first stops moving during inhalation. The key rib is the most superior rib in the group. Exhalation restrictions involve a rib or group of ribs that first stops moving during exhalation. The key rib is the most inferior rib in the group.

Clinical Characteristics of Thoracic Region and Rib Cage Movement

Available thoracic spinal motion is generally less than in the cervical or lumbar areas. This is because all planes of motion are affected by costal cage mechanics and their complicated relationships with

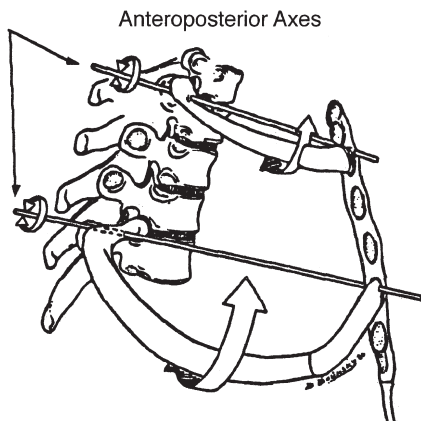

Figure 39-10 Bucket-handle rib motion.

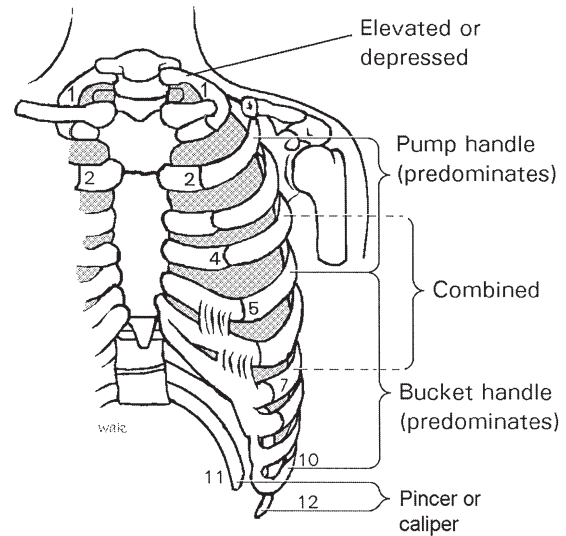

Figure 39-11 Clinical rib movement.

head, neck, shoulder girdle, and lumbopelvic anatomy. Thoracic spinal motion is further complicated by a number of other factors that go beyond basic costovertebral configuration and mechanics. A few of the elements include configuration characteristics of the anteroposterior curves in the sagittal plane, such as:

- Kyphosis
- Costal cage asymmetries, such as pectus excavatum and pectus carinatum
- Osteoporosis/osteoarthritis effects
- Increased chest wall diameter associated with a variety of cardio-pulmonary problems
- Cervical, shoulder girdle, rotator cuff influences (i.e., anterior muscles are generally tighter than posterior groups); under these circumstances, anteroposterior curves tend to become more kyphotic
- Effects of lifestyle and affective states, such as slumping with depression
- Characteristics of primary and secondary lateral deviations include
 - Scoliosis with and without kyphosis
 - Effects of upper and lower motor neuron lesions
 - Effects of repetitive motion activities
 - General thoracic spinal motion characteristics

Because of configuration changes in size and shape, thoracic spinal motion characteristics vary markedly from the cervicothoracic to thoracolumbar junctions. The upper and middle portions demonstrate greater rotation than elsewhere in the spine, with the exception of the atlantoaxial joint. Generally, flexion capability is greater than extension. Side-bending capability is even less, because of rib cage constraints. In the lower portions, flexion and extension capacities are greatest, although side-bending abilities exceed those of rotation (i.e., they are more like lumbar spine mechanics).

Clinically, there is a constant tendency for spinal flexion because of the effects of gravity and the tendency for the back extensors to become inhibited while flexors tend toward contraction. Clinically, it seems that the rotatores, intertransversarii, and multifidi are often involved in postural stress, somatosomatic, and viscerosomatic reflexes. When these muscles are reflexively affected by facilitation, they are often responsible for maintaining non-neutral

somatic dysfunction of the vertebral units that are innervated by the involved muscle, neural network, or viscera. Some refer to this phenomenon as the *somatic* component of impairment, illness, or disease.

Neurologic pathologic conditions, trauma, visceral disease, and intrinsic mechanical asymmetries are common sources of spinal dysfunction. Trauma, for example, often flexes, extends, and/or twists the spine simultaneously in such a way that the accumulated forces localize around a vertebral unit, thereby disturbing the mechanics of both the single vertebral segment and the vertebral units. Deforming injuries of this type often alter physical shapes; that is, they cause plastic deformations with permanent stretching of ligaments and distortions in facet joints and osseous-ligamentous relationships. Not surprisingly, recurring non-neutral/type II vertebral unit dysfunction is common under these circumstances. This type of vertebral unit change is sometimes associated with altered visceral functions; for example, somatic dysfunction is superimposed on vertebral segment and vertebral unit changes with resulting facilitated peripheral, autonomic, and centrally mediated reflex activities. Patients report many clinical symptoms when these processes occur.

The most important function of the rib cage is respiration. The ribs, along with the sternum, and the diaphragm move in a manner that increases and decreases the size of the thoracic cavity during inspiration and expiration. Because of the negative pressure produced with respiratory movements, the rib cage may also assist in returning venous blood back to the heart. The rib cage also protects the organs located within its cavity.

The motion of the ribs has been described earlier as either the pump-handle or bucket-handle type. More specifically, the upper rib cage, from approximately ribs 1 through 5, exhibits predominantly pump-handle motion, while ribs 6 through 10 provide increasing amounts of bucket-handle motion, until the lowest ribs of this group move predominantly in bucket-handle fashion. Ribs 11 and 12 move in a pincer-like fashion.

Rib cage mechanics can also be influenced because of its relationships with head, cervical, shoulder girdle, lumbar, and pelvic anatomical structures. Rib cage motion can be further complicated by a number of other factors beyond basic costal anatomy, configuration, and mechanics. Some of these factors include:

- Thoracic scoliosis or kyphosis
- Rib cage asymmetries, such as pectus excavatum or pectus carinatum
- Effects of bony diseases such as osteoporosis or osteoarthritis
- Increased chest wall diameter associated with illnesses such as chronic obstructive pulmonary disease
- Effects of abnormal tensions in cervical, rotator cuff, or shoulder girdle musculature
- Effects of trauma to the rib cage
- Effects of lifestyle and affective states, such as slumping with depression

Clinically, somatic dysfunction of the rib cage is often present secondary to somatic dysfunction of the thoracic vertebrae. Thus,

the restricted motion in these combined structures may result in some of the same clinical characteristics as occur with problems associated with the thoracic spine.

SUMMARY

The thoracic and rib cage regions together form a complex region of the body, containing and protecting many vital organs. Osteopathic physicians must understand the proper function, diagnosis, and treatment of this area. Osteopathic manipulation is used to improve sympathetic and parasympathetic factors, diaphragm excursion, spinal and rib mechanics, and vascular and lymphatic flow (which improves breathing). The goal is to decrease sympathicotonia and energy wasted on inefficient breathing by decreasing abnormal mechanoreceptor and nociceptive input to the central nervous system (decreasing pain) and assisting the body in mobilizing the immune system.

Manipulative treatment of somatic dysfunction of this region can help the patient to heal from injury or pathology of this area. In addition, osteopathic palpatory diagnosis can be used to help differentiate the cause of sometimes difficult to interpret signs and symptoms with which patients may present.

KEY CONCEPTS

- Delineate a thorough and accurate history; this allows the development of a differential diagnosis.
- Consider serious and life-threatening conditions that require urgent evaluation, and or treatment of the lumbar spine.
- Knowledge of the functional anatomy, normal spinal motion, and somatic dysfunction of the lumbar region improves diagnosis and manipulative treatment.
- Develop an efficient integrated physical examination of the lumbar spine.
- Diagnose and evaluate viscerosomatic and somatovisceral reflexes, Chapman's points, Jones tenderpoints, and myofascial triggerpoints.
- Review the imaging studies of the lumbar spine and relate them to the known palpatory findings.
- Know when and how to utilize OMT in the treatment of somatic dysfunction of the lumbar spine.

INTRODUCTION

An efficient and accurate diagnosis and an effective treatment plan, are critical skills for an osteopathic physician to have. Because of the unique training and expertise in musculoskeletal medicine, many patients and clinicians seek out osteopathic physicians for a variety of concerns.

Common patient complaints that require evaluation of the lumbar spine include, but are not limited to: abdominal pain, lower back pain, and neuralgia of the lower extremities. In each of these situations, the lumbar spine needs to be examined and possibly treated with osteopathic manipulation. An evaluation for somatic dysfunction of the lumbar spine is integrated with the other physical exam procedures. If significant somatic dysfunction is found, and potentially related to the patient's condition, OMT may be utilized in the treatment plan along with analgesics, anti-inflammatories, muscle relaxers, and stretches or active exercises. This chapter will highlight how the diagnosis and treatment of somatic dysfunction is crucial in the overall treatment of the patient with lumbar spine pain.

EPIDEMIOLOGY OF LOW BACK PAIN

The lifetime prevalence of having lower back pain approaches 70%, so it is important for osteopathic physicians to be able to evaluate the lumbar spine. Lower back pain is the second leading cause of work absenteeism (after upper respiratory tract complaints) and results in more lost productivity than any other medical condition. Each year there are 13 million physician visits for lower back pain, with the highest prevalence in the 45 to 60-year-old Caucasian population. Back pain is the most frequent cause of activity limitation in people younger than 45 years of age, the second most frequent reason for physician visits, the fifth most frequent for hospitalization, and the third ranking reason for surgical procedures (1). Osteopathic physicians need to completely understand the anatomy and physiology of the lumbar spine in the healthy, diseased or injured, and postoperative patient. Patients with chronic back pain will search out osteopathic physicians for treatment after having lumbar spine surgery. About 1% of the U.S. population is chronically disabled because of back pain (1). Osteopathic

physicians need to be able to diagnose the lumbar spine in people of all ages, body types, and sizes.

Anthropometric data are contradictory with no strong relationship between heights, weight, body build, and low back pain. Physical fitness is not a predictor of acute low back pain. The physically fit have a lesser risk of chronic low back pain and tend to recover faster than patients who are not physically fit (1). Many physicians consider obesity as a cause of low back pain, but epidemiologic studies have reported both positive and negative associations (1). In summary, most episodes of low back pain or sciatica resolve spontaneously within the first 2 weeks and a relative minority take 6 to 12 weeks. Only 1% to 2% of cases should require evaluation for operative management. Osteopathic physicians should be able to diagnose and treat the lumbar spine of patients of all ages and sizes, paying particular attention to the presentation based on a thorough understanding of the epidemiology.

HISTORY

An appropriate and thorough history of the patient's chief complaint is critical. It is always important to consider urgent, emergent, or other potentially serious conditions. Patients with worrisome historical findings need more comprehensive and expeditious treatment. Emergent disorders associated with acute paraplegia include spinal cord tumors, epidural hemorrhage, epidural abscess, embolus, spinal artery thrombosis, and central herniation of a nucleus pulposus (cauda equina syndrome) (2). The history of severe, tearing pain, and dizziness associated with an abdominal pulsatile mass alerts the physician to the problem of an expanding aneurysm. Patients with the cauda equina syndrome present with acute paraplegia, saddle anesthesia, and rectal or urinary incontinence (2). From the patient's history alone, the clinician should have a pretty good idea of what is going on and then develop a differential diagnosis. The astute clinician allows patients to tell their story in their own words and also steers them in directions that elicit the essential information needed for the diagnostic process. The clinician knows when the history must be abbreviated or prolonged, based on the patient's presentation. If not all the information

is obtained during the initial evaluation, it is worthwhile to review the history on subsequent visits.

Pain needs to be evaluated by documenting a description of the pain, including its intensity, duration, location, radiation, alleviating or aggravating factors, and response to treatment. Not every chief complaint is pain. The chief complaint can be stiffness, a decrease in athletic performance, postural or muscular asymmetry, a localized mass, a skin lesion, etc. The important aspect to consider is: how does the chief complaint disturb the patient's day-to-day functioning?

Quality and Intensity

Initially patients should describe the quality of pain themselves without suggestions from the examining physician. Listed below are useful documents that assist with clinician documentation of pain, one of which is the McGill Pain Questionnaire. If the McGill Pain questionnaire is not used, the examining physician should include a line drawing of the body in the patient's history. The pictorial representation of the patient's pain helps delineate its extent. The "visual analogue scale" is a visual way to quantify pain based upon a 10-cm line drawing (2).

Another differentiation is between organic and psychogenic pain. A standardized way to differentiate psychogenic from organic pain is to use the Minnesota Multiphasic Personality Inventory (MMPI). The MMPI is a 566-question, self-administered true-false test formulated to identify psychological traits, for example, hypochondriasis, depression, hysteria, or psychopathic deviance, associated with elevated scale scores in patients with chronic pain (2).

A test that validates the presence of pain is the Mensana Clinic Back Pain Test (MPT). MPT is a 15-item questionnaire that takes about 10 minutes to complete. Patients are classified as objective-pain patients, exaggerating-pain patients, and affective-pain patients corresponding to increasing test scores (2). The MPT is more successful than MMPI in differentiating organic from function low back pain and is useful for patients with chronic low back pain. Roland and Morris developed a questionnaire consisting of 24 items (2). The test not only measures disability resulting from back pain but also measures response to therapy.

Consideration of the onset, duration, and progression of a complaint is essential. An inventory by systems is taken, especially those systems that could be related to the lumbar region. Although the history is discussed as an entity that precedes the physical examination, further questioning (history) may take place as positive clues are obtained during the physical exam. This approach to history taking will prompt the physician to ask questions about areas that the patient does not consider important.

The ability to visualize the underlying anatomy and apply that knowledge as the physician palpates is an important skill to develop. An understanding and recall of the physiologic spinal motion patterns is also necessary before performing the physical examination. Using this knowledge, the physical exam will help the clinician rule out specific conditions on the differential diagnosis list.

A prior knowledge of Chapman reflexes, viscerosomatic reflexes, and the autonomic innervation of the viscera is also useful during the physical exam. For example, if a patient complains of lumbar dysfunction, questions about bowel and bladder function, whether the urinary stream is full and forceful, and whether there is any pain or burning on urination are all functionally relevant questions to ask. During the physical examination, if the patient complains of acute tenderness when the iliotibial bands are palpated, questions about bowel habits and function are relevant, if

the clinician understands Chapman reflexes. In women, these findings should also initiate questions about menses and pelvic discomfort; in men, questions about prostate or penile discomfort or deep, uncomfortable pressure in the perineal region are indicated. Asking if chilling or muscle-stressing activities increase the symptom might alert the physician to consider and examine for select *myofascial trigger points* related to the symptomatology.

Trauma History

When planning total management of patients with lumbar complaints, it is also important to ask the patient about past injuries or accidents that could have produced significant lumbar or sacroiliac (SI) dysfunctions, atypical spinal mechanics, or have affected the craniosacral mechanism. Most patients forget about these types of accidents.

Historical Points May Point to a Specific Etiology

Ask the patient about unexplained weight loss, night sweats, breast changes or masses, hematuria or hematochezia (blood in the stool). These questions explore the possibility of cancer of the organs that usually metastasize to bone and can produce pain in the back. The patient with nonspecific mechanical lower back pain usually has significant somatic dysfunction of the lumbar, sacral, and pelvic regions. If they do not, clinical suspicion for a visceral cause may be heightened. In evaluation of the patient with lumbar pain, understanding the "Red Flags" for more serious conditions is important (Fig. 40.1). These include:

- Age 50 years or older
- Previous history of cancer
- Unexplained weight loss
- Failure to improve with 1 month of therapy
- No relief with bed rest.

An algorithm to guide the initial assessment of acute low back pain symptoms is shown in Figure 40.1.

If the patient has leg pain or paresthesia, ask the patient to show exactly where it is located, and then decide if this could represent a dermatomal, myotomal, sclerotomal, or radicular pain pattern. Sclerotomes and myotomes have been documented and mapped (3). They are important and are often overlooked pain patterns. A radicular pattern would indicate that there may be nerve root pressure, perhaps related to a herniated intervertebral disc or a tumor in the cauda equina. In this particular case, traditional orthopedic and neurologic testing, which includes deep tendon reflex assessment, assessment of muscle strength/weakness, and testing key dermatomes for sensation and/or pain, is important.

When evaluating the lumbar region in a low back pain patient, it is imperative to consider the psychosocial stresses the patient is under. Emotional tension, stress, and job dissatisfaction are contributing and sometimes causative factors in lumbar spine pain. Psychological and psychosocial work factors including monotony at work, job dissatisfaction, and poor relations with coworkers have been found to increase complaints about low back pain (1). Prospective studies have concluded that these psychological risk factors were more predictive than any of the physical risk factors. In contrast to pain from nerve root irritation, psychogenic pain is not well localized. Large nondermatomal areas are affected. In this situation, radiation of pain follows no consistent pattern (1). Physical factors found to be associated with increased risk of low back pain include heavy work, lifting, static work postures, bending with twisting, and vibration.

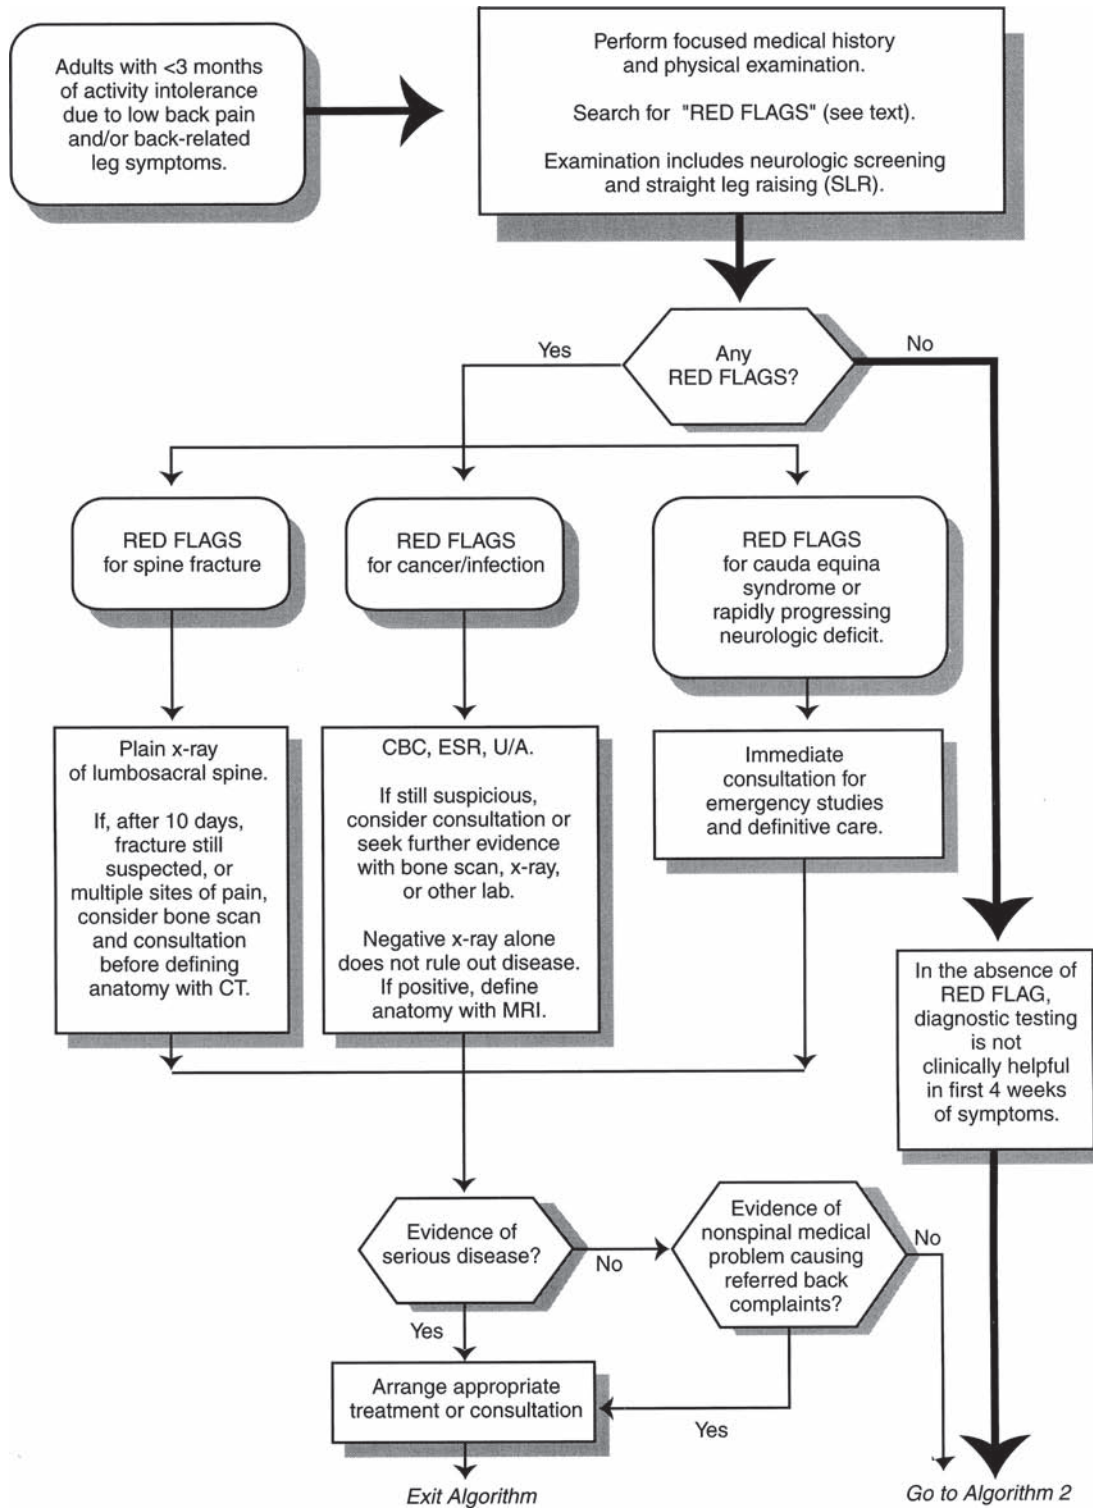

Figure 40-1 Initial assessment of acute low back pain symptoms. CT, computed tomography; CBC, complete blood count; ESR, erythrocyte sedimentation rate; U/A, urine analysis. (From Bigos S, Bowyer O, Braen G, et al. *Acute Low Back Pain Problems in Adults*. Clinical Practice Guideline, No. 14, Rockville, MD: U.S. Department of Health and Human Services; December 1994. Public Health Service Agency for Health Care Policy and Research AHCPR publication 95-0642, with permission.)

Consider the Following:

- Job dissatisfaction
- Preexisting depression or anxiety
- Stressful, monotonous work
- Low control over work
- Unappreciated/unsupported at work
- Low level employment
- Low socioeconomic status

Stress plays a major role in the treatment of the low back pain patients well. When patients are stressed, their muscles tighten and become less flexible. Techniques that foster relaxation, improve soft tissue tension, and help the patient relax are useful. When patients are stressed, GI complaints are frequent, and these can produce viscerosomatic palpatory changes in the thoracic and lumbar spine.

An adequate social history is important to take in the patient with low back pain. There is a definite link between smoking and low back pain that increases with the duration and frequency of the low back pain. Several investigators have found an association between smoking, herniated discs, and low back pain (1).

The age of the patient can affect the clinician's ability to formulate a differential diagnosis. For example, spondyloarthropathies, including ankylosing spondylitis, reactive arthritis, and spondylitis associated with inflammatory bowel disease, and benign tumors of the spine occur between the third and the fourth decades (2). Diseases of middle age include diffuse idiopathic skeletal hyperostosis, gout, Paget disease, and osteomyelitis. A different set of diseases occurs more commonly during and following the sixth decade. These diseases include malignant disease (metastases), metabolic disease (chondrocalcinosis), and degenerative diseases (expanding aortic aneurysm) (2). Approximately 80% of patients with malignant disease affecting the lumbar spine are older than 50 years of age (2). The causes of back pain are outlined in Table 40.1.

TABLE 40.1

Causes of Back Pain

Mechanical	Tumor
Spinal arthritis	Primary
Degenerative disk disease	Myeloma
Facet arthritis	Sarcoma
Fracture	Neural tumor
Spondylolysis	Secondary (metastatic)
Spondylolisthesis	Prostate
Congenital	Lung
Genetic malformations	Breast
Achondroplasia	Kidney
Nonmechanical	Rheumatologic
Viscerogenic	Seronegative spondyloarthropathy
Renal colic	Ankylosing spondylitis
Inflammatory bowel disease	Psoriatic arthritis
Endometriosis	Reiter syndrome
Vasculogenic	Behçet syndrome
Aortic aneurysm	Fibromyalgia
Ischemic spinal claudication	Polymyalgia rheumatica
Epidural venous anomalies	Rheumatoid arthritis
Infection	Metabolic
Discitis	Osteoporosis
Herpes zoster	Paget disease
Osteomyelitis	

FAMILY HISTORY

In the presence of a particular histocompatibility locus antigen (27), members of a family are at risk of developing ankylosing spondylitis, reactive arthritis, psoriatic spondylitis, and spondylitis associated with inflammatory bowel disease. Each of the conditions can cause low back pain.

OCCUPATIONAL HISTORY

Workers doing heavy lifting at their job are at risk of developing mechanical low back pain, but this symptom also occurs in sedentary workers. Lifting a light object from a rotated position or stretching far overhead to reach an object on a shelf may be associated with the onset of low back pain.

It is incumbent on the physician not to assume that, because workers' compensation is involved or litigation is pending, the patient's symptoms are fictitious or exaggerated. Physicians should give the patient the benefit of the doubt. A self-employed individual may push the physician into cutting corners of evaluation and therapy to obtain the "quick fix" needed to allow a return to normal activities. On the other hand, the salaried employee may delay return because of the fear of reinjury.

Social History

Increased consumption of alcohol, coffee, or cigarettes is associated with osteoporosis, and illicit drug use results in immunosuppression and predisposition to infection. Marital discord causes severe stress and the propensity for muscles of the lower back and neck to tighten. Job stress and dissatisfaction has been linked to lower back pain.

Review of Systems

The presence of constitutional symptoms is a worrisome finding and requires a more thorough evaluation. Fever in the setting of new-onset neck or back pain may be associated with influenza, pyogenic discitis, or osteomyelitis to 83% for spinal epidural abscess (2).

Review of the integumentary system may reveal a history of scaling patches over the elbows (psoriasis), vesicular lesions following a dermatome (shingles), or a tick bite (Lyme disease). Each of these conditions can be related to lower back pain. Poor sleep habits, anxiety, or depressive symptoms can also clue the physician in toward an emotional etiology for the low back pain.

Aggravating and Alleviating Factors

Characteristically, mechanical lesions of the lumbosacral spine improve with rest and worsen with increased activity. Prolonged sitting with forward flexion causes back pain if the patient has a herniated disc, and prolonged standing in the extended position causes back pain if the patient has spinal stenosis.

Older patients with spinal stenosis will "lean on the shopping cart" because this forward bending of the spine opens the canal and foramina reducing nerve root pressure. Pain from tumors involving bone, muscle, or the spinal cord is often increased with recumbency. Patients with tumors seek relief by sleeping in a chair or pacing (2). However, other patients find relief of pain only with absolute immobility. This is a sign of acute infection, compression fracture related to metabolic bone disease, or pathologic fracture secondary to a tumor or infiltrative disease. Disc herniation causes radiating pain at rest, while with spinal stenosis radiating pain occurs in positions that extend the spine and decrease room in the spinal canal

for the neural elements. Once the disc is extruded and the pressure on the annulus from disc protrusion is relieved, leg pain continues while back pain resolves (2).

In contrast to pain from nerve root irritation, psychogenic pain is not well localized. Large nondermatomal areas are affected. Radiation of pain follows no consistent pattern. Patients with psychogenic pain have difficulty describing factors that relieve or worsen their pain. The pain is present all the time. There is no position that is comfortable (2). Activities that involve little physical effort have an exaggerated effect on their pain. In general, patients with chronic spinal conditions experience some variability of symptoms that can be correlated with changes in barometric pressure and temperature.

Time of Day

Classically, inflammatory arthropathies cause morning stiffness. Patients have great difficulty getting out of bed in the morning because of stiffness and pain. Benign tumors, a prime example being an osteoid osteoma, cause severe nocturnal pain. The risk of disc herniation is greatest in the morning when the disc is extended to its greatest degree (2). At the end of the day, when the disc is less tense, symptoms related to joint compression are more likely.

SUMMARY

The history allows the clinician to select those parts of the physical examination that will help the clinician most efficiently make the

correct diagnosis from the possibilities included in the differential diagnosis list. Special tests, such as labs or MRI scans, can support or refute the differential diagnosis and help with the treatment plan. Prior to performing the physical exam and ordering tests, the physician needs to recall their descriptive and functional anatomy.

DESCRIPTIVE AND FUNCTIONAL ANATOMY

The lumbar spine normally consists of five vertebrae and forms a smooth lordotic curve just above the pelvis. The five lumbar vertebrae are the most massive individual segments of the vertebral column. This is perfectly logical, in that the lumbar spine carries the weight of the upper half of the body. The area is functionally compensatory for the relative immobility of adjacent spinal areas (thoracic cage and pelvis). This creates quite a dilemma. As mobility is gained, stability tends to be lost. Yet, the lumbar region accommodates for both stability and mobility. Understanding the functional relationship between the individual vertebral segments, and between the vertebrae and their associated soft tissues, is the first step in understanding somatic dysfunction of, as well as the impact of disease upon, the region. This understanding comes directly from a thorough knowledge of anatomy. Both the normal anatomy and the abnormal anatomy need to be appreciated as some patients require spinal surgery or have lumbosacral anomalies that disrupt anatomic relationships.

Lumbosacral anomalies are fairly common (Fig. 40.2). Sometimes during embryologic development, the lumbar spine may

Figure 40-2 Common lumbosacral abnormalities: **A.** Batwing transverse processes of L5. **B.** Lumbarization of S1. **C.** Sacralization of L5. **D.** Facet asymmetry (zygapophyseal tropism) of L4. **E.** Partial sacralization of L5 (Bertolotti). **F.** Spina bifida occulta of both L₅ and of S₁.

form six vertebra. Even more rare is the patient with four lumbar vertebrae. Although this alters muscular attachments, it usually does not hinder stability during activity. The lumbar region normally has a lumbolumbar lordotic angle extending from L2-5 that averages 43 degrees. The normal lordotic curve of the lumbar spine functionally permits more extension than flexion.

The lumbar spine occupies half to two thirds of the posterior skeletal and myofascial wall of the true abdomen. It is directly linked to the thoracic and pelvic regions. Because of its functional anatomic connections, it can influence the head and neck, the upper extremities, the lower extremities, and even the viscera. This means that the location of symptoms does not necessarily indicate the region of their etiology. Problems in the pelvis, abdomen, leg, arm, head and thoracic regions, as well as the lumbar region, need to be considered.

Although the lumbar facets are relatively aligned in the sagittal plane, analysis reveals that the lumbar and thoracolumbar regions provide most of the motion of the trunk. The facets of the thoracic region, oriented in a coronal plane, would seem to allow more motion around all three axes. However, the rib cage hinders the ability of the thoracic region to rotate, side-bend, flex, or extend.

The Anterior Elements

Vertebral Body

A lumbar vertebra is larger than other spinal vertebrae. It is distinguished by the absence of costal facets (like the thoracic vertebrae) and transverse foramina (like the cervical vertebrae). The vertebral body is wider transversely and deeper anteroposteriorly than any other vertebrae (4). This large, cross-sectional area and its longitudinal and vertical trabecular arrangement increase its strength and stability. Lumbar vertebrae are capable of sustaining the heavy, functional, longitudinal loads that will surely be acting on them. The vertebral bodies also act as accessory organs for hematopoiesis.

Intervertebral Disc

An intervertebral disc is located between each lumbar vertebra. If all the intervertebral discs were stacked up one on another, they would normally account for one fourth of the length of the spine. Lumbar discs are large and built to tolerate and dissipate heavy loads. They are composed of glycosaminoglycans, mucopolysaccharides, proteoglycans, and collagen.

Intervertebral discs are named according to their region (lumbar in this case) and numbered according to the vertebral unit of which they are a part (i.e., the number corresponds to the first vertebra of the vertebral unit). Example: The intervertebral disc for the L2 vertebral unit would be the second lumbar disc. Each disc is joined to the inferior plate of the vertebra above it and the superior plate of the vertebra below it.

There is a compressible nucleus pulposus located at its center, and this is surrounded by layers of the anulus consisting of concentric lamellae of collagenous fibers. These anular fibers are oriented 65 degrees from vertical, and the layers alternate in a right/left direction as they encircle and contain the nucleus pulposus (5). Clinically, it is important to note that the anulus of a lumbar disc is fairly thick anteriorly but is noticeably thinner posteriorly. Historically, L4 and L5 intervertebral discs are at the greatest risk for rupture. Operation rates for herniated lumbar discs vary. It is estimated that the rate per 100,000 is 100 in Great Britain, 350 in Finland, 200 in Sweden, and more than 450 in the United States. More than 95% of operations are at the L4 and L5 levels. The mean age of surgery is 40 to 45 years, with men being operated on twice as often as women (1).

The nucleus pulposus is composed of 70% to 90% water, and is semifluid and hydrophilic. It is deformable, but not compressible. With postural weight bearing, the nucleus expands laterally against the anulus, and these two parts work together mechanically to act as a shock absorber between each vertebral body of the spine. When load is applied and the nucleus is compressed, it loses water. This results in a 1.5-mm creep in the first 2 to 10 minutes of compressive stress (5). Resting supine with the lower extremities flexed and raised is the optimal position for rehydrating the discs. With this rest, discs normally return to their full or optimal height. With aging, however, the hydrophilic properties of a disc are reduced, just as is its ability to reform after being stressed by prolonged pressure or a sudden and severe stress. The intervertebral discs are innervated by fibers from an elaborate plexus supplied by the sinu vertebral nerve on the posterior longitudinal ligament and the somatosympathetic nerve on the anterior longitudinal ligament. In initial stages of compression, the sinu vertebral nerve on the posterior longitudinal ligament irritated giving rise to lower back pain (3,5). In a normal healthy disc, branches from this plexus penetrate through the outer one third to reach the middle third of the annulus fibrosus. The annulus fibrosus receives nociceptive innervation to its outer fibers (3). However, degenerative disc material obtained at the time of surgery shows that the small-caliber fibers have expanded their territory into the center of the disc. In patients with degenerative discs, discography is painful (generally a nonpainful procedure in normal individuals), as this might indicate some small-caliber fibers have expanded their territories in these patients.

The Posterior Elements

Pedicles

Pedicles connect the posterior elements to the vertebral body and mark the site where the posterior vertebral elements begin. In the lumbar region, pedicles are located on the superior third of the posterior surface of the vertebral body. This protects the nerve root of a vertebral unit from being injured by a significantly herniated intervertebral disc of that same unit. The nerve winds around the pedicle and exits its intervertebral foramen before it crosses the intervertebral disc.

Anatomically and radiographically, all of the posterior elements of a vertebra can be accurately identified if the pedicles of that vertebra are first identified. On an anteroposterior (AP) radiograph, the pedicles appear as two longitudinal rows of opaque ovals on the lateral, superior third of the vertebral bodies. These are used as landmarks for finding the other posterior elements (Table 40.2).

Transverse Processes

A transverse process projects laterally from the region of each pedicle. In the lumbar region, these processes are anatomically located directly lateral (in the same horizontal plane) to the spinous process of the vertebra of their origin. This fact helps in locating and palpating the pair of associated lumbar transverse processes after palpating and identifying a specific lumbar spinous process. This also permits accurate testing of the proper vertebra for rotational motion of a specific lumbar vertebral unit.

Superior and Inferior Articular Processes

An inferior articular process projects in a caudad direction from the region of the pedicle, and its articular facet faces laterally. A superior articular process projects cephalad from the same pedicle, and its facet faces medially (4). The joint space of an intervertebral synovial joint is formed by the facet of an inferior articular process of one vertebra and the facet of a superior articular process of the

TABLE 40.2

Osterior, Middle, and Anterior Spinal Elements Related to Back Pain

Elements	Possible Etiologies
<i>Posterior elements—most common</i>	
Spinous process, transverse processes, lamina, pedicles, ligaments, and joining capsule, intervertebral joints	Somatic dysfunction—TART ^a
	Especially the “half-dirty dozen”
	Age-related and activity-related strains—arthritis, overuse
	Severe or chronic twists
	Strains and sprains
	Spondylosis, overuse, or chronic trauma
	Spondylolisthesis
	Severe trauma and twists
Fractures of pedicle, transverse process, or spinous process ^b	
<i>Middle elements</i>	
Central spinal canal, meninges, spinal cord, and nerves	Compression of the spinal canal or nerve root
	Cauda equina syndrome ^b
	Intrinsic
	Intradural tumors
	Meningeal infections
	Extrinsic pressure through foramen and/or the thecal sac
	Metastatic tumors
	Ruptured disc with contents free in spinal canal
	Neurofibromas
	Spurs or other symptom, of aging or degenerative conditions (osteoarthritis)
Benign tumors or fibromas	
Reflex etiologies—visceral dysfunctions and diseases	
<i>Anterior elements</i>	
Posterior longitudinal ligament, vertebral body, anterior longitudinal ligament, and intervertebral disk	Compression fractures of the vertebral body
	Vascular causes—abdominal aneurysm ^b
	Traumatic disc disruption with pressure on nerve root or thecal sac
	Infection

^bEmergency.

next vertebra. Zygapophyseal joint tropism is the most common lumbar congenital abnormality and is found in 30% of patients. This term describes a composite arrangement where the articular pillars on one side of a vertebral unit are twisted so that the plane of the resulting synovial intervertebral joint on that side does not match the orientation of the synovial joint on the other side. However, asymmetric joints at the same level may be associated with asymmetric muscle tensions and altered spinal motions.

Lumbar Facet Joints

Lumbar facet joints have long been thought to represent a source of low back pain. Figure 40.3 shows sagittal plane standing postural radiographic measurements and their normal ranges. The facet

joint is innervated by branches from the medial divisions of the dorsal rami above and below the joint. Inflammatory or degenerative diseases of any facet joint will activate multiple segments in the spinal cord. Pain from the facet joints may be referred to the lower extremity. The lumbar facet joints contain both nociceptive and proprioceptive innervation. Some studies have also found sympathetic axons detected in the joint capsule separate from the vasculature (6).

Lamina

A lamina projects medially and caudad from each pedicle, and normally meets its partner in the posterior midline to form a typical rectangular lumbar spinous process. In some instances, the laminae will not completely meet in the midline, and a spina bifida is

Figure 40-3 Sagittal plane standing postural radiographic measurements and their normal ranges.

produced. The most common congenital anomaly of this type is the “hidden” spina bifida, called spina bifida occulta. Spina bifida occulta is frequently found at the L5-S1 level of the spine. The only physical clue to its presence may be a midline patch of coarse hair on a patient’s skin over its site (7). In this type of spina bifida, the skin is intact and there are no meningeal components. It may modify muscle attachments, however, and can be associated with a higher incidence of other posterior vertebral anomalies, including congenital or acquired spondylolisthesis. In the more serious forms of spina bifida, meningocele and meningomyelocele, the spinal membranes protrude, with or without cord tissue. These are disabling.

Spinous Processes

Clinically, the spinous process of a lumbar vertebra is located in the same horizontal plane as its associated transverse processes. Lumbar spinous processes are distinguished by their palpable, thick, quadrangular, “spade-like” distal ends. This is in contrast to the fingertip-shaped palpatory characteristic of the thoracic spinous processes. Their distinguishing shape provides palpatory evidence of where the lumbar region begins and where the thoracic spine ends. This also aids in counting lumbar or thoracic vertebrae. There is one exception; the spinous process of the fifth lumbar vertebra is smaller, lies in a hollow just above the sacral base, and its distal end is about one-third smaller than the rest of the lumbar spines (4). It feels more like a thoracic than a lumbar spinous process. This L5 spinous process characteristic helps to identify it as the last lumbar vertebra and not the first spinous process of the sacrum. Another, less accurate way of counting lumbar vertebrae is to find the most superior portion of the iliac crests and then follow a horizontal plane from there to the midline. This should cross the spinous process of L4, and counting can begin from there.

Spinal Canal

The spinal canal is actually an anatomic space between the posterior margin of a vertebral body and parts of its posterior elements (i.e., its two pedicles, and the laminae). It contains the dural tube, spinal cord, and origins of the spinal nerves down to approximately the L2-3 level, where the spinal cord ends. From that level on, the dural tube contains the cauda equina and the filum terminale interna. The entire spinal canal is wider transversely than it is anteroposteriorly. In the lumbar spine, it is also triangular. The spinal cord usually terminates at the L2 level as the conus medullaris. Each of the remaining dorsal and ventral roots of the lumbar, sacral, and coccygeal nerves hangs in the dural tube and spinal canal, forming the cauda equina (horse’s tail); they exit the conus medullaris or the dural tube as they approach their appropriate intervertebral foramen.

The Intervertebral Foramen

Intervertebral foramen (one on the right and one on the left) are formed by two adjacent vertebrae of a vertebral unit. They are defined by:

- Two adjacent vertebral bodies and the intervertebral disc between them
- Two adjacent pedicles
- The inferior articular process of one vertebra and the superior articular process of the next, including the synovial joint between them

A spinal nerve and a recurrent meningeal nerve, each carrying the same identification number as the vertebral unit, pass through a lumbar foramen (4). The recurrent meningeal nerve then re-enters the foramina. These nerves only occupy 35% to 40% of the

foramina area. A lumbar intervertebral foramen is normally two to three times larger than the area taken up by the lumbar nerves, so it seems that compression of the nerve would be difficult. With flexion, the facets and pedicles glide away from one another, and the size of the intervertebral foramen increases. With extension, the pedicles glide toward one another, and the foramen is reduced in size. Reduction of the foramen size also results from arthritis or spurs, hypertrophy of the posterior longitudinal ligament, extrusion of the nucleus pulposus, tissue congestion or edema, inflammation, and perineural edema. Removal or reduction of the effect produced by any of these factors may be enough to allow a symptomatic patient to become asymptomatic—pain free and able to work. This is important to remember when considering management of patients with back pain etiologies, paresthesias, or radiculopathies.

Ligaments

The ligamentous structures of the lumbosacral connection form a continuous, dense connective tissue stocking that houses the lumbar vertebrae and sacrum and provides attachment sites for the associated muscles. This complicated ligamentous structure plays a key role in the self-bracing mechanism of the pelvis, a mechanism that functions to maintain the integrity of the low back and pelvis during the transfer of energy from the spine to the lower extremities (6). The ligamentous support mechanism of the lumbosacral region is influenced by several major muscle groups in the low back and pelvis.

Ligamentum Flavum

The ligamentum flavum attaches the posterior elements of each vertebra together. It runs from each pedicle and lamina to the next, and makes up the posteriolateral boundary of the neural foramen. Thickening and calcification of this ligament can cause foraminal narrowing, spinal stenosis, and nerve root compression.

The ligamentum flavum is the main opposition to flexion loading of the lumbar spine. The ligamentum flavum can be injured with excessive spinal flexion. Unfortunately, there is little or no regenerative capacity in the elastic tissue of the ligamentum flavum; thus, a damaged ligament is replaced by a dense connective tissue cicatrix (6). The innervation of the ligamentum flavum and its potential role in the genesis of low back pain is of special note. Nerve fibers have been detected in the sections of the flaval ligament stained with protein $\times 100$, a calcium-binding protein that is not entirely specific for neural tissue. Small-caliber sensory nerve fibers immunoreactive for protein gene product 9.5 (a pan-neuronal marker) were detected in a sample of flaval ligaments taken from patients with low back pain at surgery. Previous studies had failed to detect innervation of the ligamentum flavum. It is a hypothesis that the normal ligament has a paucity of sensory fibers that could increase in distribution in pathological conditions (6).

Interspinous Ligament

This ligament anchors the thoracolumbar fascia and multifidus sheath to the facet joint capsules, and becomes the central support system for the lumbar spine. Condensation of the interspinous ligament occurs after the third decade of life. These pathologic events occurring to the interspinous ligament should diminish the ability of the thoracolumbar fascia to influence the alignment of the lumbar vertebrae and thereby increase their risk of injury. Both proprioceptive and nociceptive axons have been described in the supraspinous and interspinous ligaments (6).

Anterior Longitudinal Ligament

The anterior longitudinal ligament courses along the anterior vertebral bodies from the second cervical down to the sacral base, where it blends into the ligamentous encapsulation of the sacrum (4). The lateral borders of the anterior longitudinal ligament are attachment sites for the psoas muscle. In the lumbar spine, the anterior longitudinal ligament is thicker than the posterior longitudinal ligament. The anterior longitudinal ligament may generate pain, as Substance P has been detected in the small fibers of anterior longitudinal ligament samples from degenerate lumbar discs (6).

The Posterior Longitudinal Ligament

This ligament extends from the basiocciput to the sacrum caudally. The attachments are strongest to the outer layer of the annulus fibrosus of the intervertebral disc and the weakest to the vertebral body where the ligament arches over the opening of the foramen for the central vein. The posterior longitudinal ligament is broad in the cervical region and begins to narrow when it reaches the first lumbar vertebra (4). It takes on a scalloped appearance and is only one-half its original width when it reaches L5. The scallops produce a deficiency in the posterior longitudinal ligament that is located over the posterolateral portions of each lumbar intervertebral disc. The posterior portion of the intervertebral disc is also the thinnest portion of the annulus. Therefore, this is the region of a lumbar disc that is most likely to rupture; if it does, it is most likely to be associated with nerve root pressure. An extensive nerve plexus is present in the posterior and anterior longitudinal ligaments of the lumbar region. Very few large fibers with encapsulate endings have been found. Small primary afferent axons containing neuropeptides have been identified in the posterior longitudinal ligament and the peripheral portion of the annulus fibrosus.

The Iliolumbar Ligament

This ligament is located in the lumbosacral region. It is attached to the transverse processes of L4 and L5, and extends to the iliac crest and the anterior and posterior regions of the SI joint. It has been reported that this “ligament” may consist of muscle fibers in neonates and children and gradually becomes ligamentous over the next 30 years, but this has recently been disputed by some anatomists. The major function of the iliolumbar ligament is to restrict motion at the lumbosacral junction, particularly that of sidebending. Bilateral transection of the iliolumbar ligament, rotation is increased by 18%, extension by 20%, flexion by 23%, and sidebending by 29% (6).

Clinically, the iliolumbar ligament is typically the first ligament to become tender to palpation when there is lumbosacral postural stress and decomposition (6). A tender point on the iliac crest, located 1 inch superior and lateral from the inferior margin of the PSIS and in the iliolumbar ligament, becomes acutely tender to palpation. The tenderness palpated at the insertion of the iliolumbar ligament has been thought by some to be related to irritation of the cutaneous dorsal ramus of the L1/2 spinal nerve (7). Patients with early postural decompensation may not realize that the iliac attachment of this ligament is tender until it is palpated. Its tenderness is a physical clue that should prompt the physician to ask questions about posture and to carefully examine the spine, lower lumbar region, and SI joints for somatic dysfunction, scoliosis, and/or evidence of sacral base unleveling. An example would be an adult who has, for years, been successfully compensating for continuous low back strain secondary to a congenital sacral base unleveling or an acquired short leg. As a result of decompensation in the lumbosacral region, this patient finally becomes symptomatic with back pain. The first complaint of a patient with irritation of

Figure 40-4 Referral pain pattern of a patient with an irritated right iliolumbar ligament syndrome.

the iliolumbar ligament may be groin pain, concerning the patient that they have a hernia (Fig. 40.4).

Muscles and Fascia

The first few lumbar vertebrae provide posterior attachments for the abdominal diaphragm. The left crura of the diaphragm attaches to the first two, and the right crura attaches to the first three lumbar vertebral bodies. The diaphragm then arches cephalad past these and the lower thoracic vertebrae, with its apex sometimes as high as the fifth intercostal space. It then curves caudad to attach to the xiphoid process. For this reason, somatic dysfunction of the first three lumbar vertebrae can be associated with a flattened, ineffective, dysfunctional, resting abdominal diaphragm. A flattened diaphragm is often associated with a lumbar lordosis and/or psoas and quadratus muscle spasms. In this flattened resting condition, the diaphragmatic dome is unable to develop efficient, appropriate pressure gradients between the thorax and abdomen during contraction and relaxation, and this results in decreased lymphatic flow and venous return from anywhere in the body. The physician should also remember that the innervation to the diaphragm is the phrenic nerve, which originates from nerve roots C3-5 of the spinal cord. Therefore, cervical somatic dysfunction can be involved in diaphragmatic dysfunction.

The lumbar spine also supplies partial origin for the erector spinae mass of muscles that extend from the pelvis all the way to the occiput. Unilateral contraction of extrinsic or intrinsic muscles of the back will side bend or rotate the spine. When working together, these muscles extend the spine. Through the lumbosacral aponeurosis and fascial divisions, the lumbar region is functionally attached to the gluteal muscles, the hamstrings, and via the iliotibial band, to the lower extremity. Through the lumbodorsal fasciae, with its continuity surrounding the external and internal oblique muscles and the rectus abdominus muscle, the posterior lumbar region is functionally related to the lateral and anterior abdominal wall.

Iliopsoas Muscle

A key muscle in lumbar spine complaints is the psoas major. The psoas muscle originates off the anterior portions of the upper lumbar vertebrae, near the insertion of the diaphragmatic crura, and joins with the iliacus inserting on the lesser trochanter of the femur as the iliopsoas. The psoas minor muscle (absent in 40% of patients) connects the lumbar spine to the pelvis. The iliopsoas muscle balances the lumbar spine and pelvis on the femur (8). The iliopsoas muscle is a primary hip flexor; however, it also has a role in postural balance. Iliopsoas tension is a common etiologic culprit in the patient with lower back pain. Bilateral iliopsoas spasm can increase pressure across the disc spaces as well as cause the patient to lean forward. Unilateral spasm will give the classic psoas posture, a listing to one side and forward bent. A tight psoas typically has a vertebral type II somatic dysfunction maintaining it both mechanically and through neurologic facilitation. The iliacus muscle may be considered separately, or in unison, with the psoas. Unilateral tension in an iliacus has been implicated in the production of a recurrent anterior ilium dysfunction.

“CORE Muscles”

In recent years, emphasis has been placed on training the “core” muscles of the abdomen, trunk, and pelvis in order to stabilize and support the lower back. However, there is still controversy as to what muscles make up the “core” and exactly how to train them. It is generally accepted that training certain muscles is critical in providing a stable lumbar spine. The transverse abdominus is one such muscle. The multifidus is another important muscle to train as well as the gluteus. The gluteus maximus tends to be a muscle that is weak and inhibited. This may be related to disuse, lumbar or sacral somatic dysfunction, or chronic nociception from the lumbar spine. These muscles are strengthened in many physical therapy programs for patients with back pain. Equally important is the gluteus medius muscle. The gluteus medius is typically inhibited and commonly has Jones tenderpoints in it. The Trendelenberg test is useful in assessing for unilateral weakness of the gluteus medius muscle.

Multifidus Muscle

The multifidus is divided into five bands each band arising from each lumbar vertebrae and associated tissues. Its distal attachments are the sacrum, interosseous SI ligaments, thoracolumbar fascia, and extreme medial edge of the iliac crest. Tendinous slips of the multifidus muscle pass under the long dorsal SI ligament to join with the sacrotuberous ligament. These connections integrate the multifidus into the ligamentous support system of the SI joint. The fibers of the multifidus are aligned in the vertical plane with only very slight horizontal deviations. This arrangement is specific for movement in the sagittal plane, making the multifidus a significant lumbar spine extensor muscle, along with the erector spinae muscles. The long fibers in the body of the muscle span multiple segments, thus giving the portion of the multifidus muscle an additional role as a stabilizer of the lumbar spine. Finally, by increasing tension of the thoracolumbar fascia, SI ligaments and sacrotuberous ligaments, activation of the multifidus also contributes to the self-bracing mechanism of the pelvis and to the transfer of energy from the upper body to the lower extremities (6). The multifidus muscle plays an important role in standing or seated posture, gait, trunk movement, and when lifting or carrying a load. Dysfunction of the multifidus muscle can lead to injury of the low back and to low back pain. Scoliosis and lumbar disc herniation have been associated with histochemical changes in the multifidus muscle.

Latissimus Dorsi

Although it is not a prime mover of the lumbar spine, the latissimus dorsi is clinically important to discuss. The latissimus dorsi muscle is one of the muscles which anchors the upper extremity to the trunk. The latissimus dorsi muscle has its axial attachment to the thoracolumbar fascia, iliac crest, and to the caudal three or four ribs. It attached to the humerus in the intertubercular groove between the pectoralis major anteriorly and the teres major posteriorly. The muscle can be divided into four parts: the thoracic portion attaches to the lower six thoracic spines, a transitional portion attaches to the upper two lumbar spines, a raphe portion attaches to the lateral raphe of the thoracolumbar fascia, and an iliac portion that attaches to the iliac crest (4). For osteopathic physicians, the latissimus dorsi muscle is the link between shoulder problems and low back problems.

Thoracolumbar Aponeurosis

There is continuity of the abdominal wall fascia and the thoracolumbar fascia posteriorly. The rectus sheath splits around the rectus abdominus and is continuous with the transversalis fascia as well as the deep fascia of the lumbar spine. The lumbar vertebrae act as anchors for the fascia. The thoracolumbar deep fascia surrounds, compartmentalizes, and protects all of the lumbar muscles and bones (Fig. 40.5). This fascia gives attachment to the latissimus dorsi muscle, which extends to the proximal end of the humerus. Next to the spine, it compartmentalizes the interspinalis, multifidi, and rotatores muscles. More laterally, but still near the midline, it encloses the longissimus muscle. Even more laterally, it encloses the iliocostalis muscle group that inserts on and provides a landmark for locating the angles of the ribs. The angle of the ribs marks the most lateral extent of the erector spinae mass. Deeper layers of the deep fascia form compartments for the intertransversarii. Anterior to the transverse processes, the deep fascia surrounds the psoas and quadratus lumborum muscles. The quadratus lumborum muscle can clinically and functionally be thought of as the posteroinferior extension of the abdominal diaphragm. Disturbances in vertebral motion or position place asymmetric tension

on this three-dimensional fascial structure. The thoracolumbar fascia contains a small-caliber fiber system typical of nociceptive and sympathetic axons, and a large-caliber fiber system capable of proprioception (6).

Self-Bracing Mechanism

Activation of these muscles helps to tighten the connective tissue support structures, stabilizing the lumbosacral spine, and thereby contributing to a mechanism that has been referred to as self-bracing. The multifidus, gluteus maximus, and biceps femoris muscles play major roles, while the piriformis and latissimus dorsi play a lesser role. This arrangement of muscles and fascia facilitates the transfer of energy generated by movement of the upper extremities through the spine and into the lower extremities. The close coupling of these extremity and back muscles through the thoracolumbar fascia and its attachments to the ligamentous stocking of the spine, allow the motion of the upper limbs to assist in rotation of the trunk and movement of the lower extremities in gait, creating an integrated system (6). A summary of the “core” muscles affecting the lumbar spine is provided in Table 40.3.

Mesenteries

Approximately 30 ft of small intestines and portions of the ascending and descending colon are located anterior to the lumbar region. The abdominal mesenteries are formed by reflections of the parietal peritoneum from the posterior abdominal wall. These mesenteries carry arteries and efferent autonomic nerve fibers to the viscera. They also carry veins, lymphatic vessels, and visceral afferent nerves away from the viscera. In this way, somatic dysfunction of the myofascial tissues of the lumbar region can functionally influence the local environment of the abdominal viscera.

Myofascial trigger points in the gluteus medius, rotatores, multifidi, iliopsoas, quadratus lumborum, and the piriformis muscles

Figure 40-5 The deep fascia and thoracolumbar aponeurosis of the low back. It compartmentalizes, protects, and gives attachments for the erector spinae mass and lumbar muscles.

TABLE 40.3

Lumbar Spine Muscles Origin, Insertion, Action, and Innervation

Muscles	Origin	Insertion	Action	Innervation
Spinalis dorsi	Spinous processes of lumbar/thoracic vertebrae	Spinous process of four to eight vertebrae above	Extends vertebral column	Dorsal rami of spinal nerves
Semispinalis dorsi (most medial of erector spinae muscles)	Transverse processes of the 6th to the 10th thoracic vertebrae	Spinous processes of the upper four thoracic and lower two cervical vertebrae	Extends and rotates vertebral column	Dorsal rami of spinal nerves
Longissimus thoracis/lumborum (intermediate muscle of erector spinae muscles)	Transverse process of lumbar/thoracic vertebrae	Transverse processes of all the thoracic vertebrae into ribs 2–12 between their tubercles and angles	Extension, lateral flexion of vertebral column, rib rotation	Dorsal rami of spinal nerves
Iliocostalis thoracis/lumborum (most lateral of erector spinae muscles)	Upper borders of the angles of the lower six ribs	Upper borders of the angles of the upper six ribs and into the transverse process of the seventh cervical vertebra	Extension, lateral flexion of vertebral column, rib rotation	Dorsal rami of spinal nerves
Rotatores thoracis	Transverse processes of thoracic vertebrae	Spinous process of vertebrae above	Extends and rotates vertebral column	Dorsal rami of spinal nerves
Interspinales	Spinous processes of lumbar, thoracic and cervical vertebrae	Spinous process vertebrae of above	Extension, flexion and rotation of vertebral column	Dorsal rami of spinal nerves
Intertransversarii	Transverse processes of lumbar, thoracic and cervical vertebrae	Transverse process of vertebrae above	Lateral flexion of trunk	Dorsal rami of spinal nerves
Multifidus	Sacrum, Erector spinae Aponeurosis, PSIS, Iliac crest, and transverse processes of lumbar, thoracic and cervical vertebrae	Spinous processes of 1–4 vertebrae above	Stabilizes vertebrae in local movements of vertebral column	Dorsal rami of spinal nerves
Latissimus dorsi muscle	Spinous processes of thoracic T6-12, thoracolumbar fascia, iliac crest and inferior 3 or 4 ribs	Floor of intertubercular sulcus of humerus	Extends, Adducts, and medially rotates humerus (depresses, retracts, and inferiorly rotates scapula)	Thoracodorsal nerve

(continued)

TABLE 40.3 (Continued)

Muscles	Origin	Insertion	Action	Innervation
Quadratus lumborum	Iliac crest and iliolumbar ligament	Last rib and transverse processes of lumbar vertebrae	Unilateral: lateral flexion of vertebral column. Bilateral: depression of thoracic rib cage	The twelfth thoracic and first through fourth lumbar nerves
Psoas muscle	L1-5 transverse processes	Lesser trochanter of the femur	Lumbar plexus via anterior branches of L2-4 nerves	Flexes and rotates laterally thigh
Iliacus muscle	Iliac fossa	Lesser trochanter of the femur	Femoral nerve	Flexes and rotates laterally thigh
Rectus abdominus	Pubis	Costal cartilage of ribs 5-7, xiphoid process of sternum	Segmentally by thoracoabdominal nerves (T7-12)	Flexion of trunk/lumbar vertebrae
Transverse abdominus	Ribs and the iliac crest	The pubic tubercle via the conjoint tendon, also known as the falx inguinalis	Compress the ribs and viscera, providing thoracic and pelvic stability	Lower intercostal nerves, as well as the iliohypogastric nerve and the ilioinguinal nerve
Internal oblique	Inguinal ligament, iliac crest, and the lumbodorsal fascia.	Linea alba, Xiphoid process, and the inferior ribs	Compresses abdomen and rotates vertebral column.	Lower intercostal nerves, as well as the iliohypogastric nerve and the ilioinguinal nerve
External oblique	Lower eight ribs	Iliac crest and ligamentum inguinale	Both flexion and rotation of the vertebral column.	Innervated by ventral branches of the lower six intercostal (thoracoabdominal) nerves and the subcostal nerve on each side.

Figure 40-6 Pain patterns produced by myofascial trigger points in the quadratus lumborum, piriformis, iliopsoas, rotatores, and multifidi muscles of the back.

produce pain patterns in the lumbar region and sometimes into the sacral region and lower extremities (9,10) (Fig. 40.6).

Innervation of the Lumbar Region

Spinal Cord

In an adult, the spinal cord usually terminates at the L2 level as the conus medullaris (terminal range T12-L2, and some say to L3). The dural sac and a string of fibrous tissue and pia, known as the filum terminalis internus, continue on. The dural sac terminates by attaching to the spinal canal at the S2 level. Fibrous tissue and cells from the dura continue on as the filum terminalis externa, which attaches to the first coccygeal segment. Remember that the posterior longitudinal ligament is anterior to the spinal cord and has lateral deficiencies in the areas of the lumbar discs. The dural sac of the spinal canal, below the conus medullaris, contains the filum terminalis internus and lower lumbar, sacral, and coccygeal dorsal and ventral rootlets of the cauda equine (Fig. 40.7).

The lumbar spinal canal takes on a triangular configuration and normally decreases in its AP dimension as it progresses from L1 to L5 (4). As a person ages, the diameter of the lumbar spinal canal or intervertebral canal may be further compromised by factors that include hypertrophy of the posterior longitudinal ligament, thickening of the ligamentum flava on its anterior wall, osteoarthritis, exostoses, osteophytes, tumors, and ruptured lumbar intervertebral discs.

Tissue congestion, frank edema, and perineural edema can also compromise the nerves in the spinal canal or an intervertebral foramen, especially if the region already has somatic dysfunction and/or an anatomic/pathologic deformity. If there is enough pressure on the spinal cord or the nerves in the cauda equina, there will be loss of reflexes, weakness of muscles, and paralysis of the lower extremities and sphincters of the bladder and rectum. This symptom complex describes a severe form of spinal stenosis called cauda equina syndrome.

Spinal Nerve Roots and Spinal Nerves

The lumbosacral spinal cord gives rise to numerous nerve rootlets from the dorsolateral and ventrolateral sulci. In the subarachnoid space of the vertebral canal, between five and seven dorsal rootlets form each lumbar segment bundle together to form a dorsal spinal nerve root, which joins with a similarly derived ventral spinal nerve root. These nerve roots descend in the vertebral canal, exiting at each intervertebral foramen. At the level of the foramen, a complex relationship occurs. The nerve roots enter a funnel-shaped lateral recess of the spinal canal that narrows to form the lumbar nerve root canal. The distal end of the root canal is the intervertebral foramen. The walls of the nerve root canal are composed of the pedicle and

the pars interarticularis of the vertebra, the ligamentum flavum, and the lateral aspect of the intervertebral disc, the obliquity of the canals and their length increase. As the nerve root enters this canal, it is enveloped by a sheath of spinal dura termed the epineurium. In the canal, the nerve root is deflected laterally around the pedicle and over the surface of the intervertebral disc. The dorsal root ganglion is located at the point where the root passes around the pedicle and can leave an impression in the bony structure of the pedicle. The dorsal root ganglion contains the primary afferent cell bodies distal to this structure, the dorsal and ventral roots fuse to form the spinal nerve and the dural layer seals to the spinal nerve. In the lumbar region, as the spinal nerves leave their canals, they are attached to the foramen by several fibrous expansions of the canal wall. As the nerve root traverses the canal and foramen,

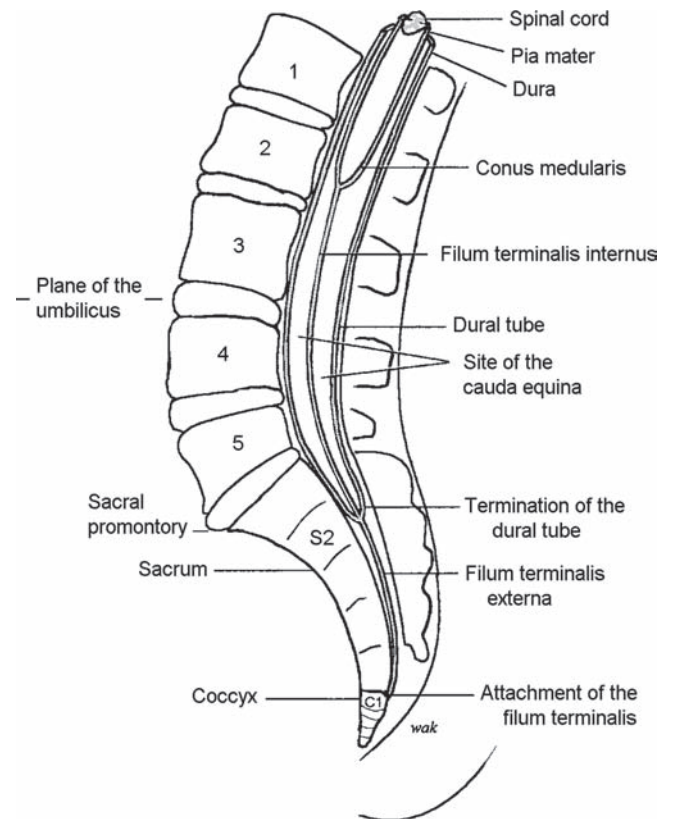

Figure 40-7 The relationships of the spinal cord, dural tube, conus medullaris, filum terminalis internus, cauda equina, and filum terminalis externa to the lumbar and sacral regions.

Figure 40-8 Pedicles located on the superior third of the posterior side of a lumbar vertebra protect the nerve from being injured by a herniated disc at its own level. It is more likely that a lumbar nerve would be affected by a herniated disc of the previous vertebral unit. That is why an S1 nerve root is usually affected by a herniated L5 intervertebral disc.

it is at risk from several structures: the pedicles and intervertebral discs, the ligamentum flavum, the capsule of the facet joint, and the foraminal ligaments (Fig. 40.8) (6).

In addition, the intervertebral canal transmits branches of the spinal artery into the spinal canal along with veins drain-

ing the epidural plexus and associated lymphatic vessels. Venous congestion, arteriovenous malformation, and epidural hematoma have all been demonstrated to mimic disc herniation or lumbar spinal stenosis. Whether by mechanical compression or fluid congestion, the traumatized lumbosacral nerve roots experience edema and ischemia, which lead to inflammatory and fibrotic alterations in the neural tissue with concomitant loss of motor function, paresthesia, and hypesthesia. Finally, an additional nonmechanical method for irritating neural tissue in the foraminal area appears to involve the release of nuclear fluids containing proinflammatory compounds as the proteoglycans and tumor necrosis factor- α from a leaky disc (6). Although we tend to think of disc herniation as the etiology of nerve root compression/irritation, there are certainly others. Table 40.4 reviews the lumbar roots, their dermatomes, innervated muscles, and physical findings.

Lumbosacral Dorsal Rami

The dorsal ramus leaves the spinal nerve as the nerve exits the lumbar intervertebral canals. As this ramus wraps around the facet joint directly below, it divides into several main branches: (I) Lateral branch that innervates the lateral fascial compartment containing the longissimus muscle; (II) Medial branches that innervate the medial fascial compartment containing the multifidus muscles. Specifically, the medial compartment contains the multifidus, interspinalis, and intertransversarii medialis muscles. It also contains skeletal elements such as the interspinous ligament, the facet joints,

TABLE 40.4

Neurologic Influence of the Lumbar Roots

Root	L1	L2	L3	L4	L5	S1
Sensory dermatome	Back to trochanter	Back	Back	Inner calf to medial portion of foot (first two toes)	Lateral lower leg	Sole
	Groin	Anterior thigh to the level of knee	Upper buttock to anterior thigh			Dorsum of foot
Innervated muscle(s)	Iliopsoas	Iliopsoas	Iliopsoas	Tibialis anterior	Extensor hallucis	Gastrocnemius
		Sartorius	Quadriceps femoris	Gluteus medius	Tibialis posterior	Gluteus maximus
		Hip adductors (longus, brevis, pectineus, magnus, gracilis)	Sartorius	Gluteus minimus	Hamstrings	Hamstrings
		Hip adductors	Tensor fasciae latae	Quadratus femoris	Peroneus	
Functional limitation	Hip flexion	Hip flexion	Hip flexion	Knee extension	Toe extension	Ankle plantarflexion
		Hip adduction	Hip adduction		Ankle dorsiflexion	Knee flexion
Affected reflex	Cremasteric	Cremasteric	Patellar	Patellar	Tibialis posterior	Ankle
		Adductor		Gluteal	Gluteal?	Hamstring

and the ligament flavum (6). Inferiorly, the dorsal and possibly ventral rami of L5 and of the sacral roots provide innervation of the SI joint capsule. Irritation of the small-caliber primary afferent fibers of the dorsal ramus results in the perception of pain. This perception is usually a sharp, burning pain that is similar to spinal root pain and can refer to the area supplied by the corresponding ventral ramus, thus mimicking sciatica (6). As the dorsal ramus also innervates muscle groups in the back, compression or damage to this nerve can present with signs of denervation weakness, as well as with pain.

Lumbar Plexus

The lumbar plexus is composed of nerve roots L1-4 and a branch from T12. Lumbar nerve roots enter directly into the psoas muscle, where the lumbar plexus is formed. Lumbar nerves emerge from the borders and surfaces of the psoas muscle. (4) Psoas muscle spasm can compress these nerves producing pain referred into the anterior thigh.

Sympathetic Nervous System

The sympathetic nervous system has thoracolumbar outflow. Therefore, somatic dysfunction of the lumbar spine can affect the sympathetic nervous system. Somatic dysfunction in the thoracic spine can affect the lumbar spine via this neural pathway as well. Abdominal and pelvic viscera stimulate general visceral afferents that synapse near the sympathetics in the lumbar spinal cord. Therefore, visceral disease or dysfunction can cause palpatory findings in the lumbar spine. Sympathetic axons have been detected in the posterior longitudinal ligament, the ventral dura, the periosteum of the vertebral body, the intervertebral disc, and the vertebral body where they reach into the marrow cavity. The lumbar sympathetic trunk courses along the border of the psoas attachment.

Sinu Vertebral Nerves

The sinu vertebral nerve emerges distal to the dorsal root ganglion but prior to the division into dorsal and ventral rami. This small branch recurs into the intervertebral foramen to reach the vertebral canal. The terminal branches supply the posterior longitudinal ligament, the periosteum on the posterior aspect of the vertebral body, the outer layers of the intervertebral discs, and the anterior surface of the spinal dura. This nerve can travel up or down the vertebral canal at least two or three segments from the point of entry. Additionally, it can cross the midline to innervate tissue on the contralateral side. Some fibers cross the vertebral canal and subsequently pass outward through the contralateral intervertebral foramina. Dissection has demonstrated that the L1 and L2 roots have a complex array of multiple branches re-entering the intervertebral foramen, whereas the low lumbar vertebrae had only a few branches (6).

Small-caliber, primary afferent nociceptors—as well as sympathetic fibers—appear to be contained within the sinu vertebral nerve. Irritation of the small-caliber primary afferent fibers in the sinu vertebral nerve can refer to pain several segments up or down the spinal cord, as well as referring pain to the contralateral side of the body (6).

The sinu vertebral nerve does not supply skeletal muscle or skin, so compression or damage to this nerve alone does not present with signs of denervation weakness or cutaneous analgesia.

Somatosympathetic Nerves

No somatic nerves (direct branches of the dorsal or ventral rami or spinal nerves) reach the anterior aspect of the vertebral bodies. However, this area is richly supplied by sensory fibers traveling

in branches of the sympathetic trunk. These small-caliber, primary afferent nociceptors, wrap around the anterior longitudinal ligament and the periosteum on the anterior aspect of the vertebral body and penetrate into the outer layers of the intervertebral discs. The pathway of return of these sensory fibers to the spinal cord follows the sympathetic trunk and appears to use the white rami in gaining access to the spinal nerve and dorsal root ganglia. Therefore, sensory fibers entering the trunk below L2 pass upward to reach the L1-2 white rami. Noxious stimuli in the lower lumbar and sacral levels will ascend in the sympathetic trunk and enter the spinal cord at the thoracolumbar junction. This results in the referral of pain, subsequent facilitation, and palpatory findings in the spinal segments at the thoracolumbar junction (6).

Somatosympathetic axons do not supply any skeletal muscle or skin, so damage to these nerves alone will not present with signs of denervation weakness or cutaneous analgesia.

While these nerves do not innervate muscle or skin, once facilitation has been established, the muscles are hypertonic and the skin is hypersensitive.

Dermatomes, Myotomes, and Sclerotomes

Lumbar dermatomes are located on the posterior lumbar paraspinous region and the anterior part of the thigh, leg, and foot. Pain or paresthesia in these areas of skin provides clues to the level of nerve root involvement and nerve dysfunction and/or irritation. One method is for the physician to mentally construct three oblique lines, from superolateral to inferomedial, on the anterior thigh, dividing it into three equal sections. The inferior of these three oblique lines must go through the patella. From superior to inferior, these lines delineate dermatomes L1, L2, and L3. A line visualized from the patella to the big toe delineates the medial L4 dermatome from the lateral L5 dermatome. A small section on the lateral side of the foot is the first sacral dermatome. Figure 40.9 approximates the location of lumbar dermatomes of any patient. Note that different books illustrate dermatomal patterns of various complexities. However, remembering that these divisions will vary slightly from person to person, this method provides an easy to recall, good general clinical pattern from which to work.

Figure 40-9 Dermatomal or radicular (nerve root) patterns. (Illustration by W. A. Kuchera.)

Myotomal pain is associated with cramps, weakness, and myofascial trigger points in the muscles that share innervation from the same irritated nerve roots.

Sclerotomal pain is described as vague, deep, toothache-like pain. It arises from ligaments, bones, or joints that share innervation from the same irritated nerve root. Knee pain, for example, can be the result of irritation of the L3 vertebra, ligaments in the L3 region, the pubic symphysis, the hip, or the knee. All of these sites have the same L3 sclerotomal origin.

Vasculature and Lymphatics

Blood Vessels

The lumbar spinal cord receives its arterial blood supply from segmental radicular arteries. In the lumbosacral region, one of these radicular arteries, the arteria radicularis magna, is larger than the rest and is the source of blood for the inferior two thirds of the spinal cord (4). The rest of the cord receives blood from associated segmental arteries. Arteries supplying a lumbar vertebra enter around the circumference of the vertebral body, especially near its transverse processes.

Evaluation of the patient with lower back pain should include an abdominal exam. Abdominal bruits over the renal arteries, iliac arteries, or the aorta indicate disease. A pulsatile mass to deep palpation always warrants investigation. Although more commonly seen in the elderly, an abdominal aortic aneurysm can be seen in young people with certain conditions (such as Marfan disease). The back pain in a dissecting aortic aneurysm is described as “ripping” in nature; however, it may be progressive and less intense as well.

Venous blood drains the spinal cord via a profuse plexus of thin-walled veins that communicate with the profuse, valveless venous plexus in the vertebrae and the anterior and posterior longitudinal veins of the dura. Venous blood from the profuse vertebral plexus of valveless veins drains into a large basivertebral vein (4), which exits from a foramen located in the posterior surface of each vertebral body. *All of these veins are valveless.* Venous blood from the spinal cord can drain into radicular veins or can drain cephalad into the large, valveless venous sinuses of the dura.

The profuse, valveless venous plexus of the spinal cord, vertebrae, communicating veins, and large, intracranial venous sinuses are of great clinical importance. An increase in intra-abdominal or intrathoracic pressures, as occurs with coughing, Valsalva maneuvers, or fascial tensions, can reverse the flow of venous blood and become a factor in the metastasis of primary abdominal and pelvic malignancies to the spine and brain. This mechanism also explains headaches and other central nervous system symptoms from increased venous pressure associated with visceral, spinal cord, or vertebral dysfunction. The blood from the muscles of the lumbar region drains into the inferior vena cava. It does not drain into mesenteric veins or pass through the portal system of the liver, as the venous blood from the abdominal and pelvic viscera does.

Lymphatics

Lymphatic fluid from all abdominal and pelvic viscera drains into the thoracic duct, which is also called the left lymphatic duct (LLD). All somatic lymphatic vessels at and inferior to a horizontal plane through the umbilicus drain into the inguinal nodes, the deep pelvic external and common iliac nodes, the preaortic and lateral aortic nodes, and then into the LLD. Note that lymphatic vessels from the gonads or the viscera *do not* drain into the inguinal region, but drain into the deep lymphatic vessels of the pelvis and then into the cisterna chyli. Therefore, gonadal and prostate inflammation or malignancy is not associated with enlarged,

palpable inguinal nodes. The LLD passes through the fasciae of the left side of the thoracic inlet twice before emptying into the left brachiocephalic vein. All lymphatic fluid (from anywhere in the body) must pass through the fasciae of the thoracic inlet on its way to the venous circulation and the heart.

Biomechanics Motion

The Vertebral Unit

From a functional anatomic or osteopathic perspective, a vertebral unit “is composed of two adjacent vertebrae with their associated disc, arthrodial, ligamentous, muscular, vascular, lymphatic, and neural elements” (11) (Fig. 40.10). In *Clinical Biomechanics of the Spine*, White and Panjabi label a vertebral unit as a functional spinal unit (FSU) (12). They define FSU as “two adjacent vertebrae and the connecting ligamentous tissues.” Therefore, the vertebral unit is different and more comprehensive than the FSU of the orthopedic specialist; the two should not be confused when communicating or when reading the literature. With stress, a vertebral unit behaves according to its structure, strength, flexibility, and the functional ability of its ligaments, muscular, neural, vascular, and lymphatic connections. Both the vertebral unit and the FSU are given the same number as the cephalad vertebra of the unit. For example, the third lumbar unit is named L3. According to the vertebral unit definition, however, it not only indicates L3 moving on L4, but also includes their associated disc, arthrodial, and ligamentous, muscular, vascular, lymphatic, and neural elements.

Normal Motion

Moore (4) cites that the cervical and lumbar regions of the vertebral column are the most mobile and the most common sites of aches and pains. Lumbar motion is especially visible when the vertebrae of the lumbar spinal region move together as a group. The major motions are flexion, extension, side-bending, and rotation.

Note that side-bending and rotation are coupled motions. Their direction of motion may be opposite (type I motion) or in the same direction (type II motion), but side-bending and rotation occur together in the lumbar spine; one cannot occur without the other.

There are also minor translatory motions occurring in opposite directions on each of the three planes of motion. A vertebral unit normally has 12 possible movements available to it and, therefore, 12 movements that can be restricted in a somatic dysfunction of a joint. Somatic dysfunction usually involves these minor motions,

Figure 40-10 Vertebral unit.

and that dysfunction then affects the major motions that are possible for that joint. The pattern for multiple plane motion of a vertebral unit depends on the position of the sagittal plane of the spine when a vector of rotation or side-bending is introduced.

When the spine is in its neutral positional range, side-bending and rotation normally occur to opposite sides in multiple units, and this is called type I motion or type I mechanics. Type I motion occurs when it is predominately the vertebral bodies and discs that influence spinal action.

When the lumbar spine is flexed far enough or extended far enough that it is out of the neutral sagittal plane range and into the nonneutral sagittal plane range, rotation and side-bending normally occur to the same side, usually in the vertebral unit where the forces are localized. This is called type II motion or type II mechanics. Type II motion occurs when the facets exert the major influence on spinal motion.

There is another way of stating these two normal motion principles. In the neutral mechanical range for the sagittal plane (where multiple plane motion is predominately directed by the vertebral bodies and discs), side-bending and then rotation occur to opposite sides in a group of vertebrae, or rotation occurs toward the convexity of the curve. This is type I motion and is expected to occur in a group of vertebral units because of the joint facings, as well as the construction and ligamentous attachments of the lumbar vertebrae. In the lumbar region, this type of multiple plane motion occurs through a greater arc of extension than flexion.

If the lumbar sagittal plane is in a mechanical range where flexion or extension is sufficient to engage the facets as the prime movers of the spine, multiple plane motion will result in rotation and then side-bending occurring to the same side. This can also be stated as rotation into the concavity of the intended side-bending and is type II motion or type II mechanics. Positioning in the sagittal plane that is sufficient to induce type II mechanics with multiple plane motion is usually localized in a single vertebral unit. After type II motion occurs in that one vertebral unit, the other vertebral units involved in the group side-bending curve normally move according to type I mechanics.

Neutral, type I, and non-neutral, type II, motions are a usual and normal biomechanical occurrence during the performance of daily activities. When an activity is over, the spinal units that are free of somatic dysfunction will return to their neutral, resting positions. If motion is tested, they will exhibit ease of motion in all of their usual planes of motion.

Although the lumbar spine can normally flex about 40 degrees and extend about 30 degrees, non-neutral, type II motion is more likely to occur in the lumbar and thoracic spine when the spine is in a straightened configuration. Therefore, non-neutral mechanics with type II motion for the lumbar spinal region are more likely to occur when the lumbar spine is flexed. However, it is possible to produce type II motion with extreme lumbar hyperextension, as might occur when a high diver enters the water, when a gymnast does a back walkover, or when a painter stands on a ladder and reaches up to paint a high ceiling.

Atypical Motion

Atypical motion patterns found during motion testing of single spinal segments do exist. These are typically thought to be traumatically introduced, or due to disc disease, facet tropism, or asymmetric muscle tensions. Palpating motion of L5 reveals many different findings. L5 has normal Type II physiologic motion (as described by Fryette) where sidebending and rotation occur to the same side when significant flexion or extension is introduced. When testing L5 in a neutral position: sidebending and rotation may occur to

opposite sides. This may be due to a group curve, or to congenital facet tropism, or a sacral torsion. When L5 is part of a forward torsion dysfunction of the sacrum its diagnosed motion is found to be rotated in an opposite direction to the rotation of the sacrum and sidebent toward the involved oblique axis.

INTEGRATED PHYSICAL EXAMINATION

A complete physical examination is performed, with special emphasis on regions that are spotlighted by the history, or that have a functional association. Examining the part of the body that is painful is best left for the last portion of the evaluation. Do not forget to evaluate the vital signs in a patient with low back pain. Vital signs can document the presence of fever associated with an infection or neoplasm. Tachycardia may be the sympathetic nervous system's response to the patient's pain. Many times, objective physical examination findings do not correlate with lower back pain. However, reliable physical examination signs consist of measurements of lordosis, flexion range, determination of pain location on flexion and lateral bend, measurements associated with straight leg raising (SLR) test, determination of pain location in the thighs and legs, and sensory changes in the legs (7). Repeat re-examination is needed to correlate the validity and reproducibility of physical findings with other components of patient evaluation for low back pain. There also are ways to evaluate for functional deficits and disabilities in low back pain patients. The following physical examination functional assessment questionnaires evaluate for disabilities:

- Oswestry disability index
- Roland-Morris disability questionnaire
- Hendlar 10-minute screening test

Prior to the examination, evaluate the patient's body type and anticipate positions you will need to have the patient in to obtain the physical findings. Obtain as much information in each position as possible. Be efficient. Portions of various exams will need to be integrated based on the patient position. Obtaining palpatory information is integrated with the other aspects of the physical exam. There is not an "add-on" osteopathic exam at the end of the patient encounter. In this chapter, only the more common points related to the lumbar spine and low back pain are described. The physical examination is extremely important in formulating a differential diagnosis.

Observation and Gait

What is the patient's appearance? Observation of posture and activity often provide the first clue to dysfunction. Posture mimics a patient's inner self more than his or her complaints or responses to direct questioning. An example would be the slumped posture of a depressed patient. During observation, it is important to expose the skin of the area in question in a professional manner. Be sure to evaluate the skin, especially in a back pain patient. A number of the spondyloarthropathies cause dermatologic abnormalities. Psoriasis causes erythematous raised plaques with overlying scales that occur on extensor surfaces (elbows and knees) and on the scalp. Painful vesicles distributed in a dermatomal pattern may indicate herpes zoster. Erythema migrans, a large, raised erythematous skin lesion, is the cutaneous hallmark of Lyme disease. Abnormalities of any superficial structures are noted. These abnormalities include a tuft of hair over the spine, which may indicate a congenital abnormality, such as spina bifida occulta. Café au lait spots are associated with neurofibromatosis.

Is there asymmetry of a region of the body when the whole body is observed? Clues to lumbar dysfunction may be indicated by observing the spacing difference between the arms and the hip/waist on each side of the body. This sign may indicate the presence of scoliosis, strain from sacral base unleveling, or a unilateral muscle spasm. If the protective spasm is unilateral owing to injury of the tissues on one side of the spine, scoliosis develops. The spine is tilted to one side because of one-sided muscle spasm. If the patient likes to stand in a forward-bent position, consider bilateral psoas muscle spasm, or a condition that is putting pressure on lumbar nerves in the intervertebral foramen. If the patient is leaning forward, to one side and has the ipsilateral foot everted when standing or walking, consider a unilateral psoas spasm. If this develops into a full psoas syndrome on one side, the patient may also complain of pain in the contralateral hip and leg, rarely past the knee. When a patient stands very erect and dislikes bending forward, he or she may be protecting a herniated disc or be suffering the effects of spinal stenosis, especially if there are other symptoms, such as muscular weakness, reflex changes, or muscle atrophy. Patients with legitimate back pain tend to resume the erect position with a fixed lordosis and without any spine movement (7). Arching the back and increasing the lordosis forces the facet joints together, narrows the foramen through which the nerves exit the spine, and compresses the disc posteriorly.

Patients with herniated discs have changes in their posture and gait. Disc herniation can also cause scoliosis by irritating nerves on one side of the spine. This usually occurs at the L4-5 level. Herniation of a nucleus pulposus *lateral* to the corresponding nerve root causes a sciatic list away from the side of the irritated nerve root. Herniation of a nucleus pulposus *medial* to the corresponding nerve root causes a sciatic list toward the side of the irritated nerve root (7). Patients do not like to bear weight on the leg that has sciatica or radicular pain.

Evaluating gait is important in evaluation of the lumbar spine and in the patient with back pain. In normal gait, the following events occur: Heel strike, Pronation, Midstance, Swing Phase, Loading medial foot, and the Push-off. Deficiencies in each of these phases may mean different things. Patients with an abnormal gait may limp, lurch, turn their foot outward, or hike their hip. Neurologic disorders such as Parkinson disease can cause a fenestrating or shuffling type of gait.

Standing Postural Examination

The standing postural examination gives useful information prior to evaluating the lumbar spine. There are specific findings to consider from the standing structural exam that will help you diagnose and treat the lumbar region. The presence of paravertebral muscle humping on one side or the other may be indicative of a group lateral curve (scoliosis). Unequal iliac crests, unequal greater trochanters, and asymmetric sacral sulcus depth may indicate a short leg syndrome and sacral base unleveling. During the lateral view, an increased or decreased lumbar lordosis is important to note. The presence of pelvic sideshift may correlate with an iliopsoas spasm on the side opposite the shift.

Active Motion Testing

Active motion is motion performed by the patient without assistance. It is always a good idea (especially after an injury) to have the patient actively move (prior to passive testing) to see his or her limits due to pain. The normal lumbar range of motion for forward flexion is 40 to 60 degrees, for extension 20 to 35 degrees,

for lateral bending 15 to 20 degrees, and for rotation 3 to 18 degrees (7). Passive motion testing is performed by the physician with the patient remaining relaxed. It is important that the physician observe not only the quantity of motion, but also the quality of motion.

Examination of Other Body Systems

In the low back pain patient, always evaluate heart, lungs, and abdomen on each patient visit. Auscultate the four quadrants of the abdomen to determine the presence, location, frequency, and pitch of peristaltic waves. An intermittent, low, occasional slow gurgle is normal. Conversely, high-pitched tinkling sounds may denote a developing bowel obstruction. Absence of bowel sounds may indicate a paralytic ileus. A bruit in the midline of the abdomen between the xiphoid process and the umbilicus could indicate renal stenosis or abdominal aortic aneurysm (especially when associated with a pulsating abdominal mass). A bruit at the junction between the middle and outer two thirds of the inguinal region could indicate a significant atherosclerosis of the common iliac or femoral artery. A bruit over the umbilical region could indicate a saddle thrombosis or severe atherosclerosis at the bifurcation of the abdominal aorta. The abdomen is also palpated for masses. Palpation is aided by mental visualization of the liver, kidneys, stomach, small intestines, bifurcation of the aorta at the level of the umbilicus, and the colon. The midline region between the xiphoid and umbilicus should be palpated for any pulsating tumor (abdominal aneurysm). Anteriorly occurring pulsations are normal, but lateral pulsations of the aorta suggest an aneurysm, especially if it is widened greater than 1 in (a normal adult abdominal aorta should not be wider than 1 in). Anterior Chapman points related to organs associated with symptoms in the lumbar region are located around the umbilicus, the pelvis, and in the iliotibial bands. Tender points in these locations may be associated with hypersympathetic activity resulting from viscerosomatic reflexes initiated in an irritated colon or pelvic organ, and the physician should question the patient regarding dysfunction of the organ most likely to be associated with that particular tender point. A positive response to specific questioning helps position a somatic clue according to its significance and rank when considering a differential diagnosis. Other physical examination tests for the abdomen of a patient are covered in other chapters.

If you suspect an arthritic process or other rheumatologic presentation, the eye examination may reveal the presence of conjunctivitis (reactive arthritis) or iritis (ankylosing spondylitis). Examination of the oropharynx may reveal painless (reactive arthritis) or painful (Behçet syndrome) oral ulcers. Lymphadenopathy may be associated with neoplastic processes (lymphoma) infectious processes (tuberculosis and subacute bacterial endocarditis) or idiopathic processes (sarcoidosis).

Neurologic Testing and Muscle Strength

It is important to perform a good thorough neurologic examination prior to evaluating the lumbar spinal segments. Attention is paid to the sensory, motor, and deep tendon reflex aspects of the neurologic examination. It is common practice to evaluate for muscle atrophy (lower motor neuron), dural tension signs and nerve root irritation (radiculopathy), and muscle spasticity with clonus (upper motor neuron). The differentiation of upper motor neuron, nerve root, and peripheral nerve lesions is an important one. Here are some clinical pearls that are helpful in evaluating sensation, strength, and deep tendon reflexes (DTRs).

Sensation

The clinician can evaluate gross sensory loss, or more specific sensory loss. A knowledge of the dermatomes is important as well as a knowledge of the distribution of the peripheral nerves. The best way to evaluate sensation is by two-point discrimination. Many clinicians use a bent paper clip for this test. Testing for hot/cold evaluates the spinothalamic tract. Evaluation for balance and proprioception evaluates the dorsal column/medial lemniscal system.

Muscle Strength

Of the possible neurologic abnormalities, true muscle weakness is the most reliable indication of persistent nerve compression with loss of nerve conduction (5). The patient should perform 10 toe raises on both feet and 10 more on each foot separately. Repeated testing causes fatigue, which accentuates differences in strength in the lower extremities. Patients may also be asked to walk on their heels to test for strength of the dorsiflexors of the foot (L5), or walk on their toes, which test the gastrocnemius/soleus complex (S1).

Deep Tendon Reflexes

DTRs are monosynaptic. Performing them correctly and symmetrically is important. You can reinforce the reflex by having patients attempt to pull apart their locked hands will distract them, allowing for relaxation of muscles. Unilateral loss of an ankle reflex is a significant neurologic sign, irrespective of age (5). Hyperactive reflexes may indicate an upper motor neuron lesion. Certain metabolic conditions can affect the deep tendon reflex (thyroid disease, calcium, and magnesium abnormalities).

Abdominal Reflexes

The superficial abdominal reflex is elicited by rubbing a sharp object in a rhomboid shape on the abdomen. A positive abdominal reflex, results in the retraction of the umbilicus in the direction of the quadrant stroked. Unilateral absence of the reflex suggests a lesion of an ipsilateral nerve root between T7 and L2, depending on the quadrant affected. If a positive Babinski reflex is present, the absence of abdominal reflexes takes on greater significance.

The clinician who evaluates the patient with low back pain needs to understand sensory, motor, and reflex changes that can occur at the L1 through S1 levels (see Table 40.4).

Autonomic Dysfunction

Nocioception from the low back, and especially the low lumbar spine, is transmitted to the cord by way of the C-fibers. These fibers travel with the sympathetic chain, enter the thoracolumbar area, synapse in the intermediolateral cell columns, and produce significant thoracolumbar irritability. To the palpating clinician, the muscles are hyperactive, hypertonic, and irritable. The sympathetic chain terminates in the ganglion impar, which is the lowest level of sympathetic ganglia in the spinal area.

Palpation and Motion Testing

The lumbar region is assessed during the physical examination in the same fashion as all other regions of the spine. Regional and segmental mechanics should be identified by evaluating the patient's overall body pattern; looking for tissue texture change, asymmetry of position, restriction of motion, and tenderness. As a rule,

osteopathic physicians treat functional restrictions of motion, not only positional changes. Therefore, the lumbar spine's relationship to mechanics above and below must be evaluated.

Palpation of Tissue Texture Changes

Palpation for tissue texture changes and motion testing of the lumbar spinal segments is typically done seated or prone. Sometimes, palpation of the lumbar spine is done in the supine position, especially in the hospitalized patient. Tissue texture changes are palpable evidence of physiologic dysfunction. This may be due to positional change of a vertebral segment or perhaps from a viscerosomatic reflex from the kidneys, ureters, colon, or pelvic viscera. These patterns called viscerosomatic reflexes may or may not be related to the patient's chief complaint. Finding such reflexes may require the physician to perform a more detailed history or modify the patient's work-up.

Once an area of tissue texture change is found, segmental motion testing in that region is performed. This includes determining rotational, sidebending/translation, and flexion/extension motion restrictions. Determination is made if the findings support the diagnosis of a type II single segment dysfunction or a type I group curve dysfunction. For dysfunction to be present, the components of Tissue texture change, Asymmetry, motion Restriction, and Tenderness need to be present. The more of these that are present indicates the stronger association with somatic dysfunction. Besides palpation for restrictions in spinal joint motion, the astute clinician will also check for the presence and significance of Jones tenderpoints, Chapman's points, and myofascial restrictions. The presence of Chapman reflexes and puffy or boggy tissue texture changes may indicate that a viscerosomatic reflex is present. Motion of the lumbar spine when significant viscerosomatic reflexes are present is described as a "reluctance to motion," as contrasted to an absolute restriction. The barrier is "rubbery," as if more and more tight muscles are being engaged as the end point of permitted motion is reached. When motion testing, the clinician may find less segmental findings and more muscle/group findings.

Group Curve: Fryette Type 1 Mechanics

Group Curves are best identified with the patient standing or seated. The curve appears as prominent muscle mass over the convexity. The prominent muscle mass is a reflection of the rotational component of the curve. Curves can be tested for rotation and sidebending (seated position preferred). Standing behind the seated patient, control the patient's upper torso with one hand over the patient's shoulder girdle with your forearm in front of the other shoulder. (e.g., the physician's left hand would be over the patient's right shoulder, while the physician's left forearm would be in front of the patient's left shoulder) For gross motion testing, the physician's right hand would contact the patient's lumbar paraspinal area. The physician, using both the upper torso control and pushing directly over a lumbar transverse process, would introduce left rotation. To test right rotation, the physician has to change hands (right hand and forearm controlling the upper torso, left hand on left paraspinal area). Sidebending can be evaluated by providing a sidebending force through the upper torso and monitoring movement at the lumbar segments. Lateral curves are relatively free when attempting to increase the curve and somewhat resistant when attempting prone motion testing.

Sacral base unleveling from inequity of leg length, among other things, will result in lumbar type I mechanics. Typically, the resulting

curve will be convex on the low side of the sacral unleveling. Pelvic sideshift to one side usually results in a lumbar curve convex on the opposite side. A type I lumbar curve may also develop as compensation for group curve mechanics above, as in idiopathic scoliosis. In idiopathic scoliosis, if the primary curve is thoracic, the convexity will commonly be on the right side. Typically, the

compensatory lumbar curve will be convex on the side opposite the thoracic primary scoliotic convexity. A thoracolumbar convexity may also be seen with idiopathic scoliosis. In this case, the curve may be convex left or right (Fig. 40.11). If a lumbar curve is the primary curve (greater as determined by Cobb method) (Fig. 40.12), the compensatory thoracic curve will be on the

Figure 40-11 Curve patterns in idiopathic types of scoliosis classified by location.

Figure 40-12 Measurement of curvature and rotation using the Cobb method. In the Cobb method, identification of the top and bottom of each curve is most important.

opposite side. In both these examples, the lumbar spine will demonstrate type I mechanics as described above.

Diagnosis of group curves involves a significant component of inspection. On forward bending, the rotational component of the curve produces a “humping” of the paravertebral muscle mass. In the thoracic spine, the scapula protrudes posteriorly. A group curve is group motion (two or more segments), with rotation and sidebending to opposite sides. Motion of a group curve can be evaluated by sidebending the curve. A lateral curve will increase with sidebending toward the concavity and will resist sidebending toward the convexity. A rotational test may yield confusing results depending on which part of the curve you are trying to rotate. If you push on the convex side from the apex down, you will experience resistance to rotation. However, if testing a segment above the apex, you will have to push on the concave side to encounter motion restriction. Relative to tissue texture change, there is muscle hypertonicity on the convex side, greatest at the apex. The muscles on the convex side of a lumbar group curve have been stretched. The muscles on the concave side of a group curve are shortened. Remember, palpate from side to side to pick up these tight superficial muscles. Relative to clinical problem solving, you need to ask the question: What is the cause of the curve? Some curves have existed for a long period of time so that anatomic adaptation has taken place. Given an anesthetic and curare (which paralyzes muscles), the curve will persist. The cause is often from postural imbalance, scoliosis, or trauma. Some curves are not fixed, and are of short duration. The cause may be postural imbalance. However, sometimes a focal muscle contraction on the concave side is the cause of the curve. This focal contraction may be associated with a type II dysfunction with rotation into the concavity of the group curve. The curve represents a positional adaptation to the local muscle pull from a single segment dysfunction. If you treat the cause of the local muscle pull (or “kink”), the curve will disappear (13).

Segmental Dysfunction: Fryette’s Type II Mechanics

Most students of the osteopathic medical profession prefer the *prone* position for determination of type II mechanics of the lumbar spine. The prone position is ideal for evaluating tenderness and tissue texture abnormality. To diagnose the lumbar spine in the prone position, place your thumbs over the transverse processes. “Grab some torso” with the rest of the hand. Instead of attempting to rotate a segment by pushing on a transverse process, rotate the torso with your hands in addition to applying pressure over the transverse process. Rotation is evaluated by grasping the patient’s torso with the thumbs over the transverse process area. Rotation testing of each of the five lumbar vertebrae is the most accurate and time-efficient method of screening for lumbar somatic dysfunction, because the transverse processes are directly lateral to the spinous process of the lumbar vertebra being tested. Instead of simply pushing anteriorly over the transverse process, attempt to rotate the entire segment and the torso. Compare freedom versus resistance. Remember from a terminology issue, the direction of movement of the most anterior superior portion of the vertebral body is the direction of rotation. Additionally, you should be able to palpate tissue texture abnormality in an area of motion restriction. Sidebending with the patient in the prone position is tested using the same physician hand placement, but lateral translation is applied instead of rotation. Right translation is similar to left sidebending. Flexion and extension are tested with downward (anterior) pressure over the spinous process. Resistance to anterior pressure suggests a flexed dysfunction, while excess freedom with anterior pressure suggests extension. Most psoas dysfunctions are associated with a flexed upper lumbar dysfunction.

For *seated* segmental motion testing, force can be localized to a segment by placing your thumb on the side of a lumbar spinous process. Evaluating translation is particularly effective. In addition to introducing and controlling motion through the patient’s

shoulder girdles, introduce a translatory motion by contacting the patient's torso (left side) with your torso. While you can provide some force with your thumb, it is a "monitor." Given a lumbar segment that is type II, rotated and sidebent right, translating the segment right produces left sidebending. The quality and quantity of motion can be assessed. You have to switch your hands to evaluate the left side.

Flexion/extension can be tested initially monitoring the lumbar segment (spinous process area) while a flexion or extension force is introduced from above. For extended dysfunctions, excess freedom of backward bending is easier to detect than restriction of forward bending. For flexed dysfunctions, the spinous process will resist an anterior force, and will resist extension from above.

Diagnosing flexion vs. extension is critical. Dr. Robert Kappler, D.O., F.A.A.O., describes a corollary he developed to the Muscle Energy diagnostic model. Called "Kappler's Corollary" by osteopathic students in Chicago, the process involves diagnosing type II dysfunctions through segmental motion testing (lateral translation and/or rotation) when the restrictive barrier is engaged or not engaged. When the barrier is engaged, segmental motion will be excessively restricted. For example, assume L2 is extended, rotated and sidebent right. With the lumbar spine relatively extended, rotational restriction at L2 will be minimal. When flexion at L2 is introduced, and rotation is tested, restriction of left rotation will be very obvious. Additionally, with L2 flexed, translation of L2 to the right will be significantly restricted. Remember, treatment of type II (non-neutral) dysfunctions requires a proper diagnosis of the flexion/extension component as well as the rotation and sidebending component.

Atypical Findings

It is not uncommon to find single segment dysfunction that does not obey Fryette's principles of spinal motion. This is especially true at the L5 level. Variations in anatomy (facet tropism, transitional segments etc.) can cause atypical mechanics as well as traumatic injuries to the area. Figure 40.13 shows palpatory findings of spondylolisthesis. Disc protrusions with local muscle splinting/guarding can also make accurate diagnosis of the mechanical pattern inconsistent. When atypical segmental mechanics are present at L5, look for group curve mechanics and if a forward torsion is present. L5 may have single segment dysfunction, be part of a group curve, or be part of a forward or backward torsion.

Specific Tests

Straight Leg Raising Test (Lasègue Test)

The classic test of sciatic nerve (L1-5, S1) irritation is the SLR test (Fig. 40.14). Its purpose is to stretch the dura. The more useful SLR test is done by raising the leg with the knee extended. When the sciatic nerve is stretched and its nerve roots and corresponding dural attachments are inflamed, the patient experiences pain along its anatomic course to the lower leg, ankle, and foot. The test is performed with the patient in the supine position and the hip medially rotated and adducted, with the knee extended, the examiner flexes the hip until the patient complains of pain in the back of the symptomatic leg (18). Symptoms should not be produced in the lower leg until the leg is raised to 30 to 35 degrees. Initiation of the radicular pain at a lower angle of leg elevation (i.e., 30 degrees) is associated with a larger disc protrusion documented at the time of surgery (7). Until 30 degree elevation, there is no dural movement. Between 30 and 60 to 70 degrees, tension is applied to

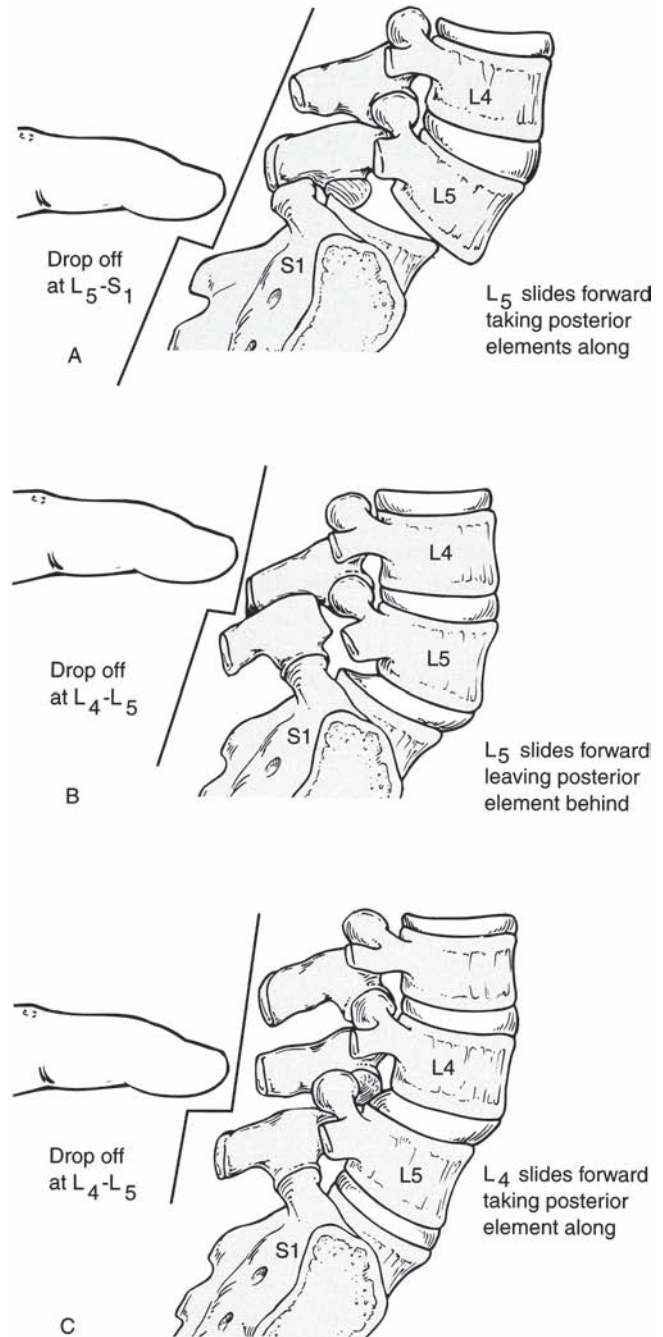

Figure 40-13 Location of anteriorly located spinous process (drop-off sign) depends on underlying mechanism of spondylolisthesis. **A.** In dysplastic spondylolisthesis, L5-S1 horizontal facets allow entire spine to glide forward creating drop-off between L5 and S1. **B.** In isthmic spondylolisthesis, pars defect between L5 and S1 allows anterior elements of L5 to slide forward along with the rest of the spine. Posterior elements of L5 remain behind with the sacrum, creating drop-off between L4 and L5. **C.** Degenerative spondylolisthesis at L4-5 does not affect anterior and posterior elements of the vertebral unit and therefore the drop-off sign is located between L4 and L5.

the dura and nerve roots. Symptoms produced at elevations above 70 degrees may represent nerve root irritation, but may also be related to mechanical low back pain secondary to muscle strain or to joint disease (7). The test is considered positive when the patient's radicular symptoms are reproduced. The diagnostic

Figure 40-14 Straight leg raising.

accuracy of the SLR test is limited by its low specificity. The diagnosis of a radiculopathy should not be based on an SLR test alone but on the totality of evidence from all the physical findings.

Bragard Test

A modification of the SLR test, called Bragard test, involves dorsiflexion of the patient's ankle (Fig. 40.15). As the leg is lowered back toward the table, until the patient experiences no pain, the examiner then dorsiflexes the ankle. If the dorsiflexion movement of the ankle reproduces the patient's symptoms, then the test is positive indicating a radiculopathy (18).

Contralateral—Straight Leg Raising Test

A positive contralateral SLR test is when the clinician lifts the uninvolved leg and the patient experiences radicular symptoms down the involved leg (Fig. 40.16). A positive contralateral SLR test is less sensitive but more specific than the SLR test for disc herniation (1). The test is usually indicative of a large disc herniation usually medial to the nerve root affecting both exiting roots (18).

Nachlas Test (Prone Knee Bending Test)

For “high” discs (L2-3 and L3-4), dural irritability is checked by the *Nachlas test*, which assesses irritation of the roots of the femoral

Figure 40-16 Contralateral SLR.

nerve—L2, L3 (Fig. 40.17) (1,18). With the patient prone, the L2-3 nerve roots are stretched by bending the knee until the heel reaches the ipsilateral buttocks. In patients who cannot achieve this, the examiner should flex the patient's knee as far as possible, then passively elevate the thigh up from the examining table. The flexed knee position should be maintained for 45 to 60 seconds. The test is positive if unilateral pain is reproduced in the lumbar area, buttocks, and or posterior thigh (18). If unilateral pain is produced in the front of the thigh (femoral stretch test), this indicates tight quadriceps muscles or a stretching of the femoral nerve (18).

Slump Test

The slump test adds more specificity to the SLR test by placing more dural tension on the affected nerve roots. The seated patient is asked to slump all the way forward and extend the neck (Fig. 40.18). If no symptoms are produced by this position, the examiner then holds the patient's head down (keeping the patient's shoulders slumped) to see if patient's pain is produced. If no pain is present, the clinician extends one of the patient's knees. If still no symptoms are produced, then the clinician should passively dorsiflex the patient's foot (18). Each of these provocative maneuvers applies more tension causing impingement of the dura and spinal cord or nerve roots.

B

Figure 40-18 A,B. Slump test.

A

B

Figure 40-19 A,B. Schober test.

Schober Test

Schober test is typically used to measure the amount of lumbar flexion (Fig. 40.19). A point between the sacral dimples (level of S2) is marked with a horizontal line. The second point is marked 5 cm below this line. A third point 10 cm superior to the sacral dimples is also marked. The patient is asked to bend forward and the distance is measured. Patients with less than 4 cm of movement have decreased lumbar flexion. Lumbar extension can also be measured in this fashion. Patients with spondyloarthropathies have abnormal measurements and an abnormal Schober test (18).

Cauda Equina Syndrome

Cauda equina syndrome is a condition of spinal nerve root compression, usually by a massive disc protrusion, fracture or tumor that results in bowel and/or bladder dysfunction. Cauda equina syndrome requires emergent management and surgical decompression within 48 hours or permanent neurologic damage can ensue. Although there is not one single test to determine cauda equina syndrome, the clinician needs to be aware of this medical emergency. In suspected cases, sensory loss of the perineum (saddle anesthesia) and decreased anal sphincter tone are found. If these

findings are present, additional tests and emergent management must be undertaken.

Tests for Malingering

To evaluate patients with these functional disorders, a list of physical signs was developed by Waddell and colleagues (7). Any of the individual signs count as one if positive. A finding of three or more of the five types is clinically significant. Isolated positive signs are ignored. The physical signs include Nonanatomic/nonorganic tenderness, thoracic, or low back pain with vertical pressure on the skull of a patient who is standing, neck or back pain reported when the shoulders and pelvis are passively rotated in the same plane, numbness in the forearm in the supinated and pronated positions, and over reaction to a normal stimulus.

Testing the Abdominal Diaphragm

This test is for the diagnosis of abdominal diaphragmatic dysfunction, or testing for evidence of flattening of the dome of the diaphragm. Diaphragm somatic dysfunction can occur in relationship to upper lumbar dysfunction. The physician grasps the lateral sides of the patient's lower rib cage and tests for right and left rotational preference of the deep fasciae. Freedom of rotation in both directions is a negative test. The patient is instructed to, "Take a deep breath in and out." At this point, if the patient has a flattened diaphragm, movement can be detected on only one side of the thoracoabdominal region.

Hip Drop Test

This test is a screening procedure to determine how well the lumbar spine compensates to sacral base declination. It is performed by having the patient stand on one leg and observing the position of the pelvis. *Negative test:* The iliac crest on the unsupported side drops 20 to 25 degrees, and there is a smooth lumbar curvature toward the weight-bearing side of the body. *Positive test:* The iliac crest does not drop 20 to 25 degrees on the non-weight-bearing side, and there is an angled, uneven, or poor lumbar spinal curve toward the weight-bearing side. A positive test indicates that the lumbar and/or thoracolumbar spine has difficulty side-bending toward the weight-bearing side of the body (i.e., the side *opposite* the positive test) (5).

Thomas Test

The Thomas test for psoas tension (hip flexion contracture) is the standard evaluation tool in physical therapy and orthopedics (Fig. 40.20). Patients are tested in the supine position. The patient

Figure 40-20 Thomas test.

lies supine on the examination table and holds the uninvolved knee to his or her chest, while allowing the involved extremity to lie flat. Holding the knee to the chest flattens out the lumbar lordosis and stabilizes the pelvis. If the iliopsoas muscle is shortened, or a contracture is present, the lower extremity on the involved side will be unable to fully extend at the hip (i.e., the thigh and popliteal region will not lay flat on the table). Degrees of hip flexion can be measured with a goniometer. The Thomas test is a "positional test," and unlike the prone evaluation of hip extension provides limited "end feel."

Evaluation of the Iliopsoas Muscle

Evaluation of the psoas muscle is a critical component to the evaluation of the lumbar spine. Iliopsoas hypertonicity is a common finding in acute and chronic lower back pain. Though a patient with chronic or subacute shortening of the psoas muscle can usually lie prone, the patient with acute psoas spasm or shortening cannot usually lay prone (flat) on the table. In this case, the physician can have the patient turn to the lateral recumbent position and attempt to extend the leg at the hip.

Iliopsoas hypertonicity has a neurologic component in the upper lumbar spine (L1, L2 FRS dysfunction). Treatment of psoas problems must not neglect this upper lumbar component (8). Clinicians need to diagnose this and treat the L1, L2 region, in addition to treating or stretching the tight psoas muscle. Psoas tightness may be reflex from disc herniations as well. Sometimes, psoas tension causes pelvic side shift so that the painful side bears less weight. For example, right lumbosacral pain will result in side shift right.

The basic biomechanical function is hip flexion. The psoas muscle is a long restrictor muscle. Long restrictors span two or more joints. Hypertonicity/shortening of the psoas compresses the hip joint, the SI joint, and the lumbar spine. When the psoas muscle is dysfunctional, it may also be weak. Attempting to exercise the psoas major simply compounds the problem. The hypertonicity and shortening (with resistance to lengthening) is the problem. Psoas problems can produce anterior thigh neurologic symptoms. The lumbar plexus passes through the psoas muscle, and anterior thigh discomfort results from nerve irritation.

Since the psoas is a muscle of postural balance, postural imbalance is a consequence of psoas problems. Pelvic side shift occurs with psoas tension; contraction of the left psoas produces pelvic side shift right. With pelvic sideshift right, a lumbar curve convex left is produced. Psoas hypertonicity causes restriction of SI motion, from compression and sometimes sideshift. If the seated flexion test is positive, you must evaluate the psoas as a possible cause. Diagnosis of psoas problems involves two separate components:

1. Restriction of hip extension, and
2. Ipsilateral upper lumbar (L1 or L2) which is flexed, rotated, and sideshift to the side of the shorter psoas.

Jones Tender Points, Chapman Reflexes

In a thorough physical examination of the lumbar spine, the clinician should evaluate for the presence of Jones tenderpoints. Remember that Jones tenderpoints correlate to lumbar segmental dysfunction. If a Jones L5 anterior tenderpoint is present, the clinician should evaluate the L5 segment for somatic dysfunction and vice versa. Treatment of the tenderpoint may improve or resolve the segmental dysfunction at L5. Treatment of the lumbar spine and/or sacrum may resolve the anterior L5 tenderpoint. So, Jones tenderpoints can give the clinician a clue of where articular dysfunction exists. Jones tenderpoints can also give the clinician a clue

Figure 40-21 Setup.

of which muscle is dysfunctional and what muscles need exercises or stretches (Figs. 40.21 and 40.22).

Chapman reflex points are palpated to determine if there is a visceral relationship to the patient's lumbar spine complaint. Chapman reflex points are one of the early diagnostic clues to irritation and dysfunction of viscera. If Chapman reflex points for the lumbar region are to be evaluated, palpate for them at the beginning of the physical examination, because motion and repeated palpation or stretching of the myofascial tissues in their location will decrease their sensitivity and diagnostic value; their tenderness to palpation will disappear, at least for a period of time. Chapman points found around the umbilicus may be related to the bladder, kidney, or adrenal glands. Those over the pubic symphysis may be related to gonadal tissue. Posterior Chapman points to the large intestine lie in a triangular area on either side of the lower lumbar spine. If large bowel problems are suspected, do not give lumbar soft tissue treatment until you have palpated the anterior points related to the colon (found in the iliotibial bands) to secure data that would help confirm this suspicion. Chapman points should be carefully correlated with history, palpation, tenderness of the collateral

Figure 40-22 Rotation to left.

abdominal ganglia, and spinal somatic dysfunction, as well as with the palpation of the suspected organ system to determine their significance. (Figs. 40.23 and 40.24).

DIAGNOSTIC IMAGING

Diagnostic imaging of the lumbar spine is useful especially in young patients (<18 years old), patients >50 years old (malignancy might be a concern), trauma cases, or patients who have a neurologic deficit. For patients with uncomplicated lower back pain and no other medical issues, radiographs should be reserved until patients have documented that they are refractory to conservative management (14).

Asymptomatic patients commonly have some x-ray and MRI changes in the lumbar spine. It is important to remember that just because anatomic change is present and identifiable on radiographs, it is not necessarily the cause of any particular component of a patient's pain. A study that highlights this point is one performed by Friedenber and Miller. They found that in asymptomatic patients between 30 and 70 years of age, 35% had radiographic evidence of spondylosis (14). Jensen and coworkers found only 35%

Figure 40-23 Treatment for upper thoracic type II dysfunction.

Figure 40-24 Treatment for lower thoracic, type I dysfunction. **A.** Anterior and **B.** Posterior view.

of 98 asymptomatic individuals (mean age, 42.3 years) had normal lumbar MR scans (14).

Most neurodiagnostic imaging studies have a high sensitivity (the ability to detect anatomic abnormalities) but a low specificity (the ability to remain negative in the absence of clinical disease). The CT scan and MRI of the lumbosacral spine detect anatomic changes that are not associated with symptoms in a significant proportion of patients. Strict adherence to the 1994 Acute Low Back Pain Guidelines to obtain plain roentgenograms for

individuals with fever, unexplained weight loss, cancer history, neurologic deficits, drug abuse history, an age older than 50 years, or trauma results in overutilization of roentgenograms compared to usual ordering patterns (14). As patients reach age 50, up to 95% of adults who come to autopsy show evidence of aging changes in the lumbosacral spine with disc space narrowing calcification, or marginal sclerosis. Therefore, not everyone with acute low back pain requires a set of plain roentgenograms. If the clinician is comfortable with diagnosis of an acute low back strain in a young patient,

treatment may proceed without radiographic evaluation for the first 4 to 6 weeks after the onset of pain (14). Roentgenograms are indicated if there is no response to the treatment. On the other hand, roentgenograms are indicated on the first visit if the patient is older (>50 years of age) or there is additional medical information that requires investigation.

X-Ray of the Lumbar Spine

When interpreting roentgenograms, an organized and orderly process should be used by the physician to avoid missing subtle findings. It is generally recommended to look at the area of highest interest last. In general, three roentgenographic views are all that are required to assess the lumbosacral spine. An AP view, a lateral view, and spot lateral view to better visualize the lower two interspaces. When a lumbar spine series is ordered, two oblique views are also taken in order to help identify spondylolysis.

AP View

When looking at an AP radiograph of the lumbar region, the transverse processes will not be located directly lateral to the spinous process of their parent vertebra. The primary soft tissue structure seen in the AP projection is the psoas muscle. The psoas forms a triangular shape with the top at the transverse process of L1 and the base on the iliac crests. Asymmetrical visualization of the psoas muscle indicates clinical pathology in a minority of patients since positioning, muscle contraction, and rotation may affect the definition of the muscle border. The loss of a pedicle (“winking-owl” sign) is frequently seen in patients with metastatic disease to the spine. Scoliosis is commonly seen in this view and measurement of the degree of curvature using the Cobb method may be useful.

The lateral view is useful for evaluating for spondylolisthesis, an anterior slippage of one vertebra on the spinal segment below. When the vertebrae slips posterior, it is termed a retrolisthesis. Disc space narrowing, compression fractures, facet joints, vertebral endplate changes, and Schmorl nodes are evaluated in this view. It is also possible to measure the amount of lordosis of the lumbar spine using Cobb method as was done in the AP view. Normal lumbar lordosis ranges from 35 to 50 degrees.

The close-up view (spot view) of the L5-S1 area provides information about the status and alignment of the L5-S1 intervertebral disc space, and the upper portion of the sacrum. The L5-S1 disc space and intervertebral foramina are narrower than the spaces between the other lumbar vertebrae. The lumbar intervertebral foramina are best visualized in the lateral projection. Another radiographic interpretation is the determination of Ferguson lumbosacral angle. It is a measurement of the degree of lordosis or anterior tilt of the sacral base in relation to the horizontal. It is usually 35 to 45 degrees. An increased Ferguson lumbosacral angle relates to lumbosacral instability (5).

The oblique projection is obtained to demonstrate the facet joints and pars interarticularis. In this view, the posterior elements outline a shape that is reminiscent of a “Scotty dog.” A collar on the “dog” suggests the presence of spondylolysis, or a stress fracture of the pars interarticularis, an area between the superior and inferior articular facets. The Scotty dog eye is the pedicle, its nose is the transverse process, its fore leg is the inferior articular facet, and its hind leg is the spinous process.

MRI (MR) of the Lumbar Spine

MR has been clinically available since the middle 1980s. Since then, MR has been used increasingly for evaluation of the musculoskeletal system, including low back and neck pain (14). MR is an

excellent technique to view the spinal cord within the spinal canal (14). MR is the preferred imaging modality for syringomyelia, atrophy, cord infarction, traumatic injury, intramedullary tumors, or multiple sclerosis affecting the spinal cord. MR also shows early changes in discs and vertebral endplates with infectious discitis (14). The sensitivity of MR is equal to or greater than that of myelography. Most studies suggest that MR is more accurate in the detection of degenerative disc disease than discography or myelography (14). MR is better at imaging soft tissue structures, whereas CT is superior for imaging bony structures. MR is more sensitive than CT for the diagnosis of herniated discs (14). MR, especially when used with gadolinium, has clear advantages for demonstrating intraspinal tumors, detecting disc space infection, and distinguishing recurrent disc herniation from postoperative scar (14).

CT Scan of the Lumbar Spine

CT creates cross-sectional images of the internal structure of the spine at various levels, and, with reformatting, one can also obtain coronal and sagittal sections. The CT scan assesses not only the bony configuration and structure-space relationship but also the soft tissue in graded shadings so that ligaments, nerve roots, free fat, and intervertebral disc protrusions can be evaluated as they relate to their bony environment in a single scan. The CT scan has the great advantage of being noninvasive and safely administered. CT is the study of choice for delineating the bony detail of the lumbar spine. CT is useful in the diagnosis and assessment of trauma, and tumors of the lumbosacral spine. CT scan can visualize the medullary portion of the vertebral body and can detect bone destruction before changes are visible on plain roentgenograms (14). Fragments of bone that may not be detectable by plain roentgenograms are localized to the spinal canal by CT techniques (14). Helical CT scanning is the technique that allows for the continuous spiral motion of the x-ray gantry tube. Helical CT is not used for the evaluation of spinal disorders. However, for detection of viscerogenic causes of low back pain, helical CT is an effective diagnostic tool. For example, helical CT imaging surpasses conventional roentgenograms for detection of ureteral stones and is used commonly in the emergency department in patients with back pain.

When compared with two-dimensional planar imaging (CT scan), SPECT offers improved image contrast and more accurate localization of lesion. For example, in patients with a spinal tumor, activity can be localized to specific positions, such as the vertebral body, pedicle, spinous process, or lamina (14). Lesions that affect the pedicles are a strong indicator of malignancy, whereas lesions in the apophyseal joints are more likely to be benign (14). SPECT scan is useful in the evaluation of vertebral lesions, spondylolysis, stress fractures, facet arthritis, sacroiliitis, pseudoarthrosis, and spinal fusion status.

Radionuclide Imaging (Triple Phase Bone Scan or Bone Scintigraphy)

Radionuclide imaging is a sensitive yet not specific technique for the detection of bone abnormalities. Any process that disturbs the normal balance of bone production and resorption can produce an abnormality on bone scan. Increased osteoblastic activity (hot spot) is associated with greater concentration of radionuclide tracer on the bone scan. Interruption of the blood flow to the bone results in the absence of tracer on the scan (cold spot). The most useful study is a form of three-phase scan that involves an immediate blood pool image that is obtained by sequential images 3 to 5 seconds apart. Images are then obtained after several minutes, at 2 to 4 hours after injection, and occasionally at 24 hours to detect residual increase of bone activity (14). The most commonly used radiopharmaceutical

for bone scanning is technetium 99m. A bone scan is particularly useful in circumstances of radiographic changes lagging behind increased bone activity. A bone scan will be positive in infection, inflammation, acute fracture, or malignancy. Because of this, the bone scan has been used most commonly for detecting metastatic disease. Approximately 80% of metastatic lesions are found in the axial skeleton (14). One notable exception to early detection of metastatic bone lesions by bone scan is multiple myeloma. Therefore, the lytic lesions of myeloma do not cause increased activity on bone scan until a fracture occurs (14).

In regard to infections of the bone (osteomyelitis) or discs (discitis), bone scans are useful because radiographs may not be positive for 10 to 14 days after the onset of the disease, whereas the bone scan may be abnormal within the first day (14).

In regard to fractures, trauma to bone, particularly stress fractures, may be difficult to detect by conventional radiography. Bone scintigraphy can detect lesions within 3 days of fracture. In children, the epiphyseal and metaphyseal growth plates are sites of active bone turnover in the areas of increased radionuclide concentration. Other diseases associated with abnormal bone scans include Paget disease, hemoglobinopathies, and aseptic necrosis of bone. Patients with sickle cell anemia have positive bone scans. In patients with acute infarcts of bone, the bone scan may demonstrate a cold spot.

LABORATORY TESTS

The vast majority of individuals with spinal pain do not require laboratory studies with their initial evaluation. Laboratory tests should be used in the situation in which a physician has developed a differential diagnosis by means of a history and physical examination for which laboratory data are needed to confirm or reject specific diagnoses. Laboratory test results should never replace a careful history and physical examination in the evaluation of the patient with spinal pain.

Obtaining baseline lab tests does have a role in separating mechanical from systemic diseases. They are also useful in distinguishing metabolic-endocrinologic disorders from those with more inflammatory characteristics. Patients who are candidates for laboratory evaluation include a patient who fails to respond to medical therapy; a patient who develops a significant change in the character of his or her pain; a patient with a known or suspected history of infectious or rheumatic condition; or an elderly patient with new onset spinal pain. The laboratory tests that are important in the study of disorders associated with spinal pain include acute-phase reactants, complete blood counts, blood chemistries, urinalysis, immunologic studies (cellular and humoral), body fluid analysis, cultures, and tissue biopsy.

Acute-Phase Reactants

Acute-phase reactants are a group of plasma proteins that increase or decrease by at least 25% during an inflammatory disorder (12). The degree of increase is greatest with cancer, severe infections, vasculitis, and burns. However, from a diagnostic or therapeutic orientation, the measurement of inflammatory cytokines does not help identify specific disorders. The most useful test in helping to differentiate medical from mechanical spinal pain is the erythrocyte sedimentation rate (ESR) (15). In general, an elevated ESR suggests the presence of inflammation in the body. The ESR is elevated with tissue injury, whatever the source. The ESR is used to screen for inflammatory disease and to follow the response to therapy. The ESR is normal in mechanical spinal pain. The ESR value must be interpreted according to the sex and age of the patient. The upper limit continues to rise as patients grow older. The change in ESR

may be more important than the absolute value when a patient is evaluated by a clinician.

Markedly elevated ESR (≥ 100 mm/hr) is most commonly associated with malignancies, particularly those that are metastatic (15). Other diseases associated with markedly increased ESR include connective tissue disease (polymyalgia rheumatica-temporal arteritis), acute bacterial infection (meningitis), and vertebral osteomyelitis with epidural abscess. The ESR also has utility as a means of following the progression or resolution of an inflammatory disorder. The ESR may be normal in patients with systemic diseases, including cancer. The ESR may remain elevated for up to 3 to 5 weeks after spinal surgery, in the absence of infection.

C-reactive protein (CRP) is an acute-phase protein synthesized by hepatocytes. CRP increases within hours of an inflammatory stimulus. CRP usually reaches a peak in 2 to 3 days and then recedes in 3 to 4 days. CRP is more accurate than ESR in detection of infections after spinal surgery because it returns to baseline more quickly than ESR (15). Serial determinations of CRP may also be helpful in following the course of acute and chronic inflammatory illnesses (15). Elevated CRP after disc surgery has been associated with retrodiscal infection that has been detected with magnetic resonance evaluation (15).

The Complete Blood Count

The hematocrit (Hct) level is normal in mechanical spinal pain, including herniated nucleus pulposus, spinal stenosis, and muscle strain. A decrease in Hct is a common finding associated with disorders mediated through chronic inflammation. A decreased Hct level should be evaluated with RBC indices, reticulocyte count, serum iron level, total iron-binding capacity, haptoglobin level, and examination of the stool for occult blood.

The white blood cell (WBC) count is normal in mechanical spinal pain. The WBC count is also normal in many forms of medical spinal pain. An elevated WBC (leukocytosis) count suggests the presence of an infection, particularly if early forms of polymorphonuclear leukocytes (band) are present. Increased numbers of WBCs are also seen in malignancies, particularly those of bone marrow or lymphatic origin. Patients on corticosteroids for their lower back pain have an increased WBC count in the 12,000 to 20,000 cells/mm³ range.

Platelets are normal in mechanical spinal pain and most medical causes as well. In malignancies, platelets are commonly abnormal and may be elevated (thrombocytosis). Platelet levels are frequently decreased in bone marrow and lymphatic tumors (15).

The Chemistry Panel

Calcium and phosphorus levels are also unaltered in osteoarthritis and mechanical causes of spinal pain. However, malignancies are associated with hypercalcemia. Malignancies with elevated serum calcium levels include those with parathormone activity (parathyroid adenoma and oat cell carcinoma of the lung), bone metastases, and multiple myeloma. In patients with lower back pain potentially related to inflammation, infection, or malignancy, (i.e., positive bone scan) indicating osteoblastic activity, one must consider evaluation of alkaline phosphatase (ALP). ALP is produced to the greatest extent by osteoblasts. Any condition that increases osteoblastic activity increases ALP (15). Disorders associated with ALP elevations include Paget disease, metastatic carcinoma, hyperparathyroidism, osteomalacia, fractures (during healing phase), and hypophosphatemia. Of the illnesses that cause spinal pain, metastatic tumors and Paget disease cause the greatest increases (2 to 30 times normal). Up to 86% of patients with metastatic prostate

carcinoma and 77% with metastatic breast cancer to bone have ALP elevations (15). Not all elevations of ALP are associated with bone disease. Disease of the hepatobiliary system may be associated with marked increases of ALP activity.

In patients with lower back pain potentially related to chronic inflammation, infection or malignancy, the total protein may be increased. Patients with increased total protein should be evaluated with a serum protein electrophoresis. Marked increase in total protein associated with elevated globulin levels should raise the possibility of multiple myeloma.

The Urinalysis and Renal Function Tests

Abnormalities detected during a routine urinalysis are most helpful in identifying those individuals with viscerogenic-referred lumbar spine pain of genitourinary origin. The presence of proteinuria on a dipstick determination requires further evaluation. Twenty-four-hour urine collections may be helpful in patients with proteinuria to see if they have nephrotic syndrome. If multiple myeloma is suspected, a negative dipstick protein does not rule out the diagnosis because myeloma proteins are not detected by dipstick methods. Elevations in blood urea nitrogen (BUN) and serum creatinine are associated with decreased renal function. Patients with visceral back pain of genitourinary origin may have elevations of these parameters. The drug history is important in a patient with abnormalities of BUN and creatinine.

Rheumatologic Studies

The three tests most commonly ordered are the rheumatoid factor (RF), antinuclear antibody, and uric acid level. The predictive value of these tests is only 35% in a population of individuals with joint disease and an estimated combined prevalence of the three resulting illnesses of 10% (15).

RFs are a group of autoantibodies to human immunoglobulin G. The classic rheumatoid factor is an IgM antibody. Rheumatoid factors occur in a wide range of autoimmune and chronic infectious diseases. Approximately 80% of patients with rheumatoid arthritis are seropositive for RF. RF in low titer may also be identified in and increasing proportion of normal individuals as they grow older. More than 40% of healthy individuals who are 75 years of age have detectable RF (15).

ELECTRODIAGNOSTIC STUDIES

Electromyography with Nerve Conduction Velocity

Electromyography (EMG) with nerve conduction velocity is the study of how action potentials propagate to their corresponding muscle fibers. Electrodiagnostic studies are commonly used in the evaluation of diseases affecting the peripheral nervous system. These studies are extensions of the neurologic examination and provide an objective measure of nerve damage. They can confirm the clinical impression of nerve root compression, define the severity and distribution of involvement, and document or exclude other illnesses of nerves or muscles that could contribute to the patient's symptoms and signs. These studies are also useful in differentiating abnormalities associated with entrapment neuropathies, distal peripheral neuropathies, myopathies, and myelopathies (16). An abnormal EMG is corroborative evidence of organic disease and helps the surgeon select patients who are candidates for surgery. In many patients, electrical signs of nerve damage do not appear until 21 days after the initial insult. EMG

examination done too quickly in the course of events misses the lesion. The test is painful but usually does not require sedation or analgesics. Conduction is measured in the fastest-conducting fibers only. In addition, the extent of EMG abnormalities does not necessarily correlate with the extent of nerve damage. These studies may identify a specific nerve root lesion when clinical symptoms suggest abnormalities at two levels. Electrodiagnostic examination has a degree of accuracy in identifying patients with nerve root compression similar to that of myelography and clinical examination.

Osteopathic Manipulative Approach to Clinical Conditions

When a clinician treats a patient for acute or chronic lower back condition, the treatment approach chosen should follow the medical evidence supporting the most appropriate course of action. It should also take into consideration the clinician's experience, skill, time available, cost, and safety. The efficacy of spinal manipulation has not been clearly demonstrated in either acute or chronic nonspecific low back pain. Tables 40.5 and 40.6 outline nonsurgical treatment guidelines based on clinical evidence.

Acute Lumbar HNP

In patients with acute lumbar herniated discs, OMT can still be used and is quite helpful. Using HVLA technique at the level of herniation is a relative contraindication, especially if neurologic signs are present. Lumbar spinal segments that have an acute disc herniation are considered to be unstable, so mobilization by applying an impulse is counterintuitive. A more appropriate approach is to work on areas of dysfunction above and below the symptomatic area, to off-load pressure across the disc space. Relieving iliopsoas tension will reduce compressive load across the disc spaces. Counterstrain is a great way of reducing muscle irritability and decreasing pain in an acute setting. Working on the patient in a supine "constant rest" position with his or her hips and knees flexed can be beneficial. Most patients with acute lumbar pain syndromes have somatic dysfunction in the mid-to-upper thoracic spine and ribs. Treating this area, as well as the cranial region, helps reduce overall facilitation and the sympathetic nervous systems response to pain.

Acute Low Back Pain Due to "Psoas Syndrome"

A patient with psoas syndrome will walk into the office flexed forward and listing to one side. They will have significant central lower back pain. They may or may not have sciatic type pain down the opposite leg. In patients with psoas syndrome, the psoas muscle has become significantly tight as demonstrated by restricted hip extension. Acute, severe cases may have a hip flexion contracture and an inability of the patient to lie prone. The causes of an acute psoas spasm are varied; some considerations include prolonged sitting (long car ride), reflex mechanisms from nociceptors (disc protrusion), or a visceral etiology (endometriosis, ureteral stone). The key in this situation is to treat the flexed upper lumbar component of the problem (8). This can be done by direct or indirect methods. After treating the flexed lumbar component, the psoas muscle itself may be treated with any number of techniques, including muscle energy, Still technique, counterstrain, direct stretching, etc. Giving the patient home exercises to stretch the psoas may be helpful. If an underlying disc protrusion is causing the spasm, the constant rest position, ice, and medications are usually required as well to control

TABLE 40.5

Nonsurgical Treatment for Acute, Nonspecific Low Back Pain

Recommended	Efficacy Unclear	Not Recommended
Patient education	Back school	Bed rest
Continue usual activity	Narcotic analgesics	Trunk strengthening exercises
Moderate aerobic activity	Lumbar corsets/belts	Systemic steroids
Acetaminophen	Spinal manipulation	Antidepressants
NSAID or COX-2	Massage	TENS
Muscle relaxants	Multidisciplinary biopsychosocial rehabilitation	Traction
Local ice or heat		Trigger point injections
Cognitive-behavioral		Epidural steroids
		Facet joint injections
		Acupuncture

the symptoms and provided some relief to the patient. In cases where an underlying visceral issue is causing the psoas hypertonicity, then treatment of the visceral condition must be undertaken as well.

Iliolumbar Ligament “Syndrome”

The iliolumbar ligament is a small, yet clinically important, ligament that originates from the iliac crest and inserts on the transverse process of L4 and L5. The iliolumbar ligament is pain sensitive and refers pain to the groin, SI region, and lateral thigh. The ligament located on both sides of the lower lumbar spine acts as guide wires to stabilize the lower segments. In patients with L5 disc protrusions, instability, or spondylolisthesis, the iliolumbar ligament may become irritated and painful. There is tissue texture change at the ilial insertion of the ligament. Pelvic sideshift toward the iliolumbar ligament is common. The adductor muscle on the side of the tender ligament is commonly tight. Manipulative techniques for tenderness on or near this ligament primarily include an indirect/

counterstrain approach. Treating this ligament and its surrounding tissues with counterstrain has significant clinical value.

Lumbar Compression Fractures

Despite their apparent strength, the lumbar spine is the most common site for compression fracture. This is because there is a weak spot located in the anterior portion, where the trabecular arrangement and density is reduced. Sufficient flexion with anterior stress can result in a compression fracture of the vertebral body. This anterior area fractures at 75% of the force needed to fracture the posterior portion of the vertebral body. With or without lifting, compression fractures occur most frequently in persons who have reduced calcium and/or frank osteoporosis. Risk factors include Caucasian race, osteoporosis, cigarette smoking, poor diet, prolonged steroid use, prolonged inactivity, or hypoparathyroid disease. Compression fractures may also be a consequence of a malignancy. Even in the absence of risk factors, a compression fracture may be

produced in anyone by forceful flexion, for example, in automobile accidents, and jumping off or falling from a considerable height. Early clues to a vertebral compression fracture are provided by the history and physical examination—not radiographs. The history will most likely reveal activities or risk factors like the ones described. If a compression fracture is suspected, do not ask the patient to perform flexion or side-bending. Instead, place the person in a lateral recumbent position for an examination. The physical examination will reveal discomfort, even with light palpation, percussion, or vibration over the spinous process of the involved vertebra. Palpatory discomfort and a history of discomfort with certain spinal motions will be out of proportion to the physical signs of injury. Pain is usually increased by leaning on the patient's shoulders, causing compression of the spinal column, and is eased by pulling cephalad from under the patient's arms, or by holding a gentle extension to the patient's spine. Although pain in the low back is usually immediate, it will be several days after the accident before a routine lateral lumbar radiograph will show a compression deformity of the vertebral body. The spine then angulates at the site of the compression fracture, and the spinous process at that vertebral unit becomes more prominent than normal. For treatment, the patient is given instructions and exercises that encourage gradual extension of the lumbar region, and/or a brace that is specifically ordered for the patient and is applied to prevent active flexion and maintain slight extension. Adequate pain relief medication is provided, taking care not to induce dependency or habituation. The use of codeine in lumbar fractures may be counterproductive, as both the pharmacologic properties of the medication and the nociceptive thoracolumbar reflex facilitation from the injury tend to constipate the patient. Most types of direct osteopathic manipulative treatment over the site of a compression are contraindicated, although classic direct and indirect myofascial treatment may be used to improve lymphatic flow, to reduce segmental facilitation, and to comfort the patient. Pain and Nocioception are also reduced by myofascial treatment directed toward relief of sympathicotonia and general improvement of lymphatic drainage. Secondary sites of somatic dysfunction that develop as a result of the injury are treated to reduce their secondary facilitation of related cord segments. Only methods and activations that are comfortable for the patient and that do not stimulate the site of injury are used to reduce discomfort and promote normal healing (5).

KEY CONCEPTS

- Consider serious and life-threatening conditions that require urgent evaluation and/or treatment in the pelvic region.
- Manipulative treatment of the pelvic girdle is dependent on applying knowledge of the functional anatomy of the region.
- Understanding the biomechanics and physiologic motion of the innominates, pubes, and sacroiliac joints is needed to understand somatic dysfunction of their anatomic elements.
- Delineate a thorough and accurate history; this allows the development of a differential diagnosis.
- Effective historical questioning can help pinpoint the diagnosis, as well as the presence of somatic dysfunction.
- Physical examination procedures are integrated with palpatory diagnosis and motion testing of the pelvic region.
- Pelvic diagnoses can be suspected or confirmed with appropriate special tests.
- Treatment of sacroiliac dysfunction needs to take into account stability deficits, abnormal neuromuscular firing patterns, manipulation, as well as other treatments available.
- Diagnose and evaluate viscerosomatic and somatovisceral reflexes, Chapman points, Jones tenderpoints, and myofascial trigger points.
- Review the imaging studies of the pelvic region and relate them to the known palpatory findings.
- Know when and how to utilize osteopathic manipulative treatment (OMT) in the treatment of somatic dysfunction of the lumbar spine.

INTRODUCTION

Accurate and efficient diagnosis of the pelvic girdle is of great importance to practitioners of manual medicine. The pelvis holds a central role in coupling the mechanical forces of the lower extremities with the axial skeleton above, as it is the foundation for body support and locomotion. Alterations and restrictions of motions in the pelvic girdle may have a profound effect on vertebral function, the thoracoabdominal diaphragm, the urogenital diaphragm, the craniosacral mechanism, and the lower extremities. Somatic dysfunction of the pelvic girdle may be causative, contributory, or diagnostic for a wide range of patient complaints. Such complaints may be somatic, visceral, or emotional in nature. Common patient complaints that require evaluation of the sacrum and pelvis include, but are not limited to abdominal pain, pelvic pain, dysmenorrhea, lower back pain, urinary tract complaints, lower gastrointestinal issues and neuralgia of the lower extremities. In each of these situations, the sacrum and pelvis needs to be examined and possibly treated with osteopathic manipulation. An evaluation for somatic dysfunction of the lumbar spine is integrated with sacral-pelvic diagnosis and the other physical exam procedures. If significant somatic dysfunction is found, and potentially related to the patient's condition, osteopathic manipulative treatment (OMT) may be utilized in the treatment plan along with other appropriate therapies. The role of manual medicine in the management of the pelvic girdle is the restoration of functional symmetry between the arthro-dial, neural, vascular, lymphatic, and connective tissue elements.

EPIDEMIOLOGY OF LOW BACK PAIN RELATED TO THE SACROILIAC JOINT

Although lower back pain is only one clinical condition related to dysfunction of the sacroiliac joint (SIJ), it is important to

understand the correlation from an epidemiological standpoint. The lifetime prevalence of a patient having lower back pain approaches 70%, so it is important for osteopathic physicians to be able to evaluate the lumbar spine. Each year there are 13 million physician visits for lower back pain, with the highest prevalence in the 45- to 60-year-old Caucasian population (1). Back pain is the most frequent cause of activity limitation in people 45 years of age, the second most frequent reason for physician visits, the fifth most frequent for hospitalization, and the third ranking reason for surgical procedures (1). The incidence of sacroiliac (SI) dysfunction in persons with low back pain is highly variable depending upon the population being studied (2).

HISTORY

A history is not just the complaint, the symptoms, and the history of the disease, but it is the history of the patient who has the disease. In the diagnosis of pelvic girdle dysfunction, the importance of taking a complete history and performing an in-depth physical examination cannot be overemphasized. An appropriate and thorough history of the patient's chief complaint is critical. It is always important to consider urgent, emergent, or other potentially serious conditions. From the patient's history alone, the clinician should have a pretty good idea of what is going on, and then develop a differential diagnosis. If the physician listens carefully, the patient's history usually reveals the diagnosis (3).

Allow patients to tell their story in their own words and steer them in directions that elicits the essential information. The clinician knows when the history must be abbreviated or prolonged, based on the patient's presentation. Although the history is usually discussed as an entity that precedes the physical examination, further questioning (history) may take place as positive clues

are obtained during the physical exam. This approach to history taking will prompt the physician to ask questions about areas that the patient does not consider important. If not all the information is obtained during the initial evaluation it is worthwhile to review and document the history on subsequent visits. In patients with pelvic girdle complaints, physicians should always be aware of their expressions, remarks, and gestures. A diseased organ does not walk into the physician's office, but an anxious and fearful patient does, who may misinterpret or be sensitive to the issues at hand.

THE CHIEF COMPLAINT

A physician should never assume that a patient's low back or pelvic pain has a solely muscular cause. The history should always clarify if a visceral or an emotional cause exists. Because the pelvic region includes the sexual organs, the patient's sexual history needs to be obtained when the patient presents with a complaint in the pelvic region. Considerations of the chief complaint should include several questions (4). Initially, patients should describe the quality of pain themselves without suggestions from the examining physician. Pain needs to be evaluated by documenting a description of the pain, including its intensity, duration, location, radiation, alleviating or aggravating factors, and response to treatment. Not every chief complaint is pain. The chief complaint can be stiffness, a decrease in athletic performance, a missed menstrual period, postural or muscular asymmetry, a localized mass, a skin lesion, etc. The important aspect to consider is how does the chief complaint disturb the patient's day-to-day functioning?

In addition, ask the following questions:

- Are there any associated symptoms?
- Have the symptoms stopped you from performing any activities?

- Have there been any changes in bowel or bladder habits?
- Have you had any diagnostics or received any medical care for this condition?
- What was the diagnosis and treatment outcome?
- Are you taking any medications, for the condition?
- Are your symptoms improving, staying the same or worsening?

Even when pain is the primary complaint and clinical suspicion centers on musculoskeletal causes, the physician remembers that pain is a "liar" and they should address the contributory topics listed in Table 41.1. Following obtaining the medical history, an inventory by systems is taken, especially those systems that could be related to the sacral and pelvic region.

HISTORY OF SACROILIAC DYSFUNCTION

There is no pathognomonic clinical picture, of SIJ dysfunction; however, pain referred to the groin is suggestive. Pain referred to the medial buttock, laterally to the sacrum, and below the iliac crest is a reasonable indication of SIJ dysfunction (26). The quality of pain that patients have with SIJ dysfunction is usually described as sharp, dull, or aching. The pain can refer to the groin, buttocks, posterior thigh, and occasionally below the knee. Symptoms are usually unilateral, are aggravated by sitting and are relieved by standing or walking (26). It is rare to have associated neurologic symptoms. Hamstring tightness is frequently present in SIJ dysfunction. Patients with short leg syndrome and sacral base unleveling complain of lower back or SIJ pain that is worse as the day goes on. Patients with a backward sacral torsion have significantly more pain than other sacral dysfunctions. Because of the location of the pain, patients will describe SI pain to the physician as "hip" pain. Since the hip joint affects position and motion of the ilium, it also

TABLE 41.1

Considerations for Complaints of Pelvic Pain

In Male and Female Patients	In the Female Patient	In the Male Patient
Employment risks	Menstrual history	Difficulty maintaining or achieving erection
Exercise risks/contact sports	Obstetric history	Difficulty with ejaculation
Hernia	Cleansing routines	Discharge or penile lesion
Past genitourinary surgeries	Douching history	Infertility
Cancer of the genitourinary tract	Abnormal vaginal bleeding	Urinary symptomatology
Chronic illness	Vaginal discharge	Urinary stream, good or poor
Family history	Date of last pelvic examination	Enlargement of the inguinal area
Psychiatric history	Date of last Pap smear and results	Testicular pain or mass
Medications, including contraceptive use	Past gynecologic procedures or surgery	Testicular self-examination practices
Sexual activity history		
Sexual orientation		
Sexually transmitted diseases		
Cancer of the reproductive organs		
Infertility

affects the sacrum. When obtaining historical information for “hip pain,” the clinician needs to include in the questioning any medical issues of the hip joint, the SIJ and the lower back. SIJ dysfunction has a relatively unknown incidence and variable clinical findings and takes skill and time to develop a consistent clinical diagnosis.

FUNCTIONAL ANATOMY

Skeletal/Ligamentous Anatomy

The pelvis consists of three bones and three joints forming an open ring shape. The false pelvis is a part of the lower abdomen and is walled laterally by ilia. The true pelvis is located inferior and posterior to the abdomen. It begins at the level of the sacral promontory, arcuate line, pectinate line, and pubic bones, ending with the inferior fascia of the pelvic diaphragm.

Growth and Development

In Vleeming’s book, *Movement Stability and Low Back Pain*, the growth and development of the SIJs is described in detail (26). The following paragraphs based on this reference summarize this topic (26). The SIJ develops slowly; as cavitation is delayed until the 8th to 10th week of intrauterine life and is not well established until the second trimester. Since the ilium is the first bone to ossify in the pelvis, and the SIJ is late in developing. There are also very distinct microscopic differences between the sacral and iliac sides of the joint. On the iliac side of the joint, the cartilage is thinner. As a child grows, the SIJ undergoes unique age-related changes. Before puberty, the iliac side is rough in texture and looks bluish in color. The sacral surface appears smooth, glistening and creamy-white in color. The sacral surface has characteristics of hyaline cartilage, the iliac side, that of fibrocartilage. These differences in gross appearance are maintained throughout life. After puberty, there is considerable difference between the SIJ of men and women. In men, these ligaments remain well developed and strong. In women, the SIJ ligaments are not as well developed, thereby allowing the mobility required during childbirth. By the second decade of life, a crescent-shaped ridge develops along the iliac surface that interdigitates with a corresponding depression on the sacral side of the joint. By the third decade, this interdigitation is more pronounced, which further limits SIJ motion. In males, degenerative changes can occur on the iliac side of the SIJ as early as the third decade of life. However, similar changes do not affect the sacral side until the fourth or fifth decade of life. By the fourth and fifth decades, fibrous ankylosis can further limit joint motion. The SIJs can develop “accessory articulations” that may be acquired due to repetitive stress. These partial parallel accessory joints are estimated to be present in approximately 8% to 35% of the population. It is not known whether the presence of these joints changes palpable sacral motion.

The Iliia

Functionally, each innominate can be viewed as a lower extremity bone; and the sacrum, as a component part of the vertebral axis. In the past, the hip bones were referred to as the innominate bones because each was composed of three bones joined together at the acetabular notch. Initially there is a single cartilaginous model for the entire element, and the ischium, ilium, and pubis are the primary ossification centers before birth. Epiphyseal centers form in the cartilaginous iliac crest, anterior superior iliac spine (ASIS), and ischial tuberosities (at puberty) and eventually fuse in the late

teens or early 20s. The only remnants of the original cartilaginous model are the bilateral SIJs (26).

The acetabulum occupies the lateral aspect of the ilium and articulates with the head of the femur to create the hip joint. The two innominates are joined anteriorly by the symphysis pubis and cephalically with the sacrum via the bilateral SIJs. The female pelvis is less robust than the male pelvis, with smaller weight-bearing areas and less height.

Spinal Articulations

The three joints of the pelvis include the symphysis pubis and the two SIJs. The sacrum is attached to the lumbar vertebra by a lumbosacral disc, two lumbosacral synovial joints, and ligaments. The superior articular processes of the sacrum are concave and face posteromedially. They articulate with the inferior articular processes of the fifth lumbar vertebrae. Anomalous development commonly results in asymmetric lumbosacral facets (facet tropism) and, less commonly, incomplete separation and differentiation of the fifth lumbar vertebrae (sacralization). When the transverse processes of the fifth lumbar vertebra are atypically large, a pseudoarthrosis may occur with the sacrum or ilia (um). When this occurs bilaterally, it is termed a bat-wing deformity.

The Pubic Bones and Pubic Symphysis

The pubic symphysis is a fibrocartilagenous joint that has motion determined by its anatomic shape, ligaments, and muscular attachments. Muscular forces acting on each pubic ramus can cause rotation upon each other at the symphysis, about a transverse axis.

The Sacrum and Coccyx

The sacrum is shaped like an inverted triangle with the superior aspect being the base and the inferior aspect being the apex. The most anterior and superior portion of the first sacral vertebral body is called the sacral promontory. The anterior surface is concave, and the posterior surface is convex with palpable spinous tubercles. The medial row of tubercles is formed by fusion of the sacral articular processes. The lateral row is formed by the fusion of sacral transverse processes and inferiorly ends in a curve of the bone called the inferolateral angle. The sacrum contains the sacral canal and four bilateral sacral foramina for the passage of the ventral and dorsal rami of the first four sacral spinal nerves. The sacral hiatus is a defect near the apex, formed by a failure of laminal closure of the fifth sacral vertebra. It is at this location that sacral epidural nerve blocks are performed. The coccyx attaches to the sacral apex via the sacrococcygeal joint. The ganglion impar (where the right and left sympathetic chains join) rests on the anterior surface of the coccyx.

The Pelvic Articulations

The SIJs have been described as L- or C-shaped and are contoured with a shorter upper arm and longer lower arm, with the junction occurring approximately at S2. The articular surfaces are subject to a great deal of variation even in opposite sides of the same bone (5). The apex, or junction of the two arms of the SIJ, points anteriorly. The SI articulation is typically convex at the upper arm and concave at the lower arm. The longer arm of the joint surface is directed posteriorly and caudally, and the shorter arm faces posteriorly and cranially, therefore the SIJs converge inferiorly and posteriorly. It is a diarthrodial joint because it contains synovial fluid and matching articular surfaces. The articular surfaces, however, are different

from those in any other joint in the body. It is in this joint alone that hyaline articular cartilage faces and moves against fibrocartilage. On the sacral side, this hyaline cartilage is usually 1 to 3 mm in depth. On the ilial side, there is fibrocartilage (26). The sacrum decreases in width from above downward; it is wedged between the two ilia. The predominant direction of fibers of the SI ligaments is such that they prevent excessive separation of the innominates and downward gliding of the sacrum (5).

The lumbosacral facets are predominantly coronal with the surface of the inferior lumbar facet slanting posteriorly. The sacral sulcus is a palpable groove just medial to the PSIS (Fig. 41.1). Much variation exists between anatomic description and an individual patient's anatomy. Weisl's work (6) demonstrates the varying contours of the articular surfaces of the sacrum and the ilia at their articulation with each other.

Frazier Strachan, D.O. (5), studied the anatomy of the sacrum extensively. He found that there was significant anatomic variation of the sacrum. Some sacra are significantly curved, while others are relatively flat. After studying the anatomy of numerous sacra, he came to the conclusion that there were three basic types, which he labeled type A, type B, and type C. The type A sacrum was wide dorsally and more narrow on the ventral surface. Type B was more wide ventrally than dorsally, and type C was a combination of both. The anatomic asymmetry will effect how the sacrum seats against the ilia and its stability (see concept of *form closure*). This will also affect the type of dysfunction and treatment required (5).

Ligaments

The sacrum is suspended between the innominate bones by three true and three accessory ligaments. The true pelvic ligaments include the anterior SI ligaments, interosseous SI ligaments, and posterior SI ligaments. The accessory pelvic ligaments include the sacrotuberous, sacrospinous, and iliolumbar ligaments. The iliolumbar ligaments attach from the anterior surface of the iliac crest and the anterior surface of the sacral base to the transverse processes of L4 and L5 (Fig. 41.2). The lower fibers blend in with the anterior SI ligament, thus integrating SI mechanics with the lumbar spine. There are anterior and posterior portions to the SI ligaments. The anterior ligaments are flat bands, while the posterior ligaments are thicker with multiple layers. The long dorsal SI ligament, which connects the PSIS to the lateral aspect of the third and fourth sacral segments, has a close anatomic relationship with the erector spinae muscles, posterior layer of the thoracolumbar

Figure 41-1 Cross-section of pelvis. Differential static landmarks for determining sacral sulcus depth (A and B) versus sacral base anterior or posterior (a and b). (Illustration by W.A. Kuchera.)

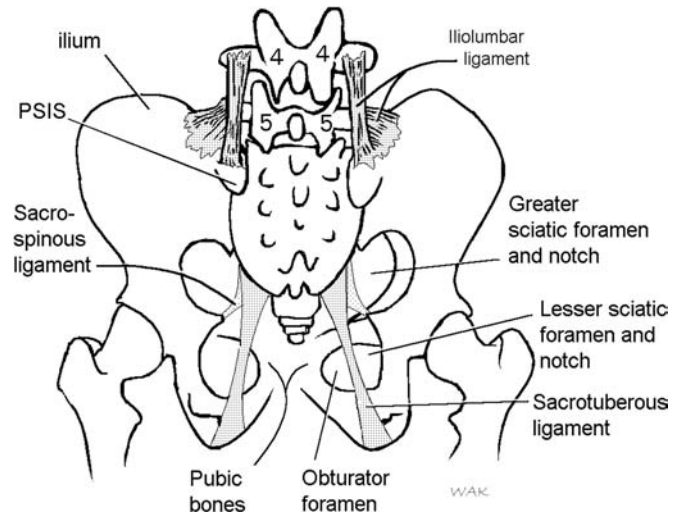

Figure 41-2 Pelvic ligaments and foramen. (Modified from Kuchera WA, Kuchera ML. *Osteopathic Principles in Practice*. 2nd Ed. Rev. Columbus, OH: Greyden Press, 1994.)

fascia, and a specific part of the sacrotuberous ligament (27). Another significant relationship of the long dorsal SI ligament is that this ligament becomes stretched when the sacrum is rotated in a posterior manner relative to the ilium (27). Thus, in situations where there is a decrease in lumbar lordosis, such as in the early stages of pregnancy or in aging, backward torsions, or unilateral/bilateral sacral extensions, this ligament may be stretched.

Accessory Ligaments

The bilateral sacrotuberous ligaments run from the inferior medial border of the sacrum and insert on the ischial tuberosities and the posterior margins of the sciatic notches. The bilateral sacrospinous ligaments lie anterior to the sacrotuberous ligaments and attach to the ischial spines, dividing this space into a greater and a lesser sciatic foramen. The sacrospinous and sacrotuberous ligaments restrain the anterior movement of the sacrum within the pelvic bones. The long head of the biceps femoris, piriformis, and gluteus maximus muscles often have direct attachments to the sacrotuberous ligament. It has been hypothesized that these muscles, interacting with the sacrotuberous ligament, have a role in SIJ mobility and stability. Detailed dissections of anatomic material by Vleeming et al. (1989) noted that, in all the sections, the gluteus maximus fascia was connected to the sacrotuberous ligament. In most dissections, a portion of the long head of the biceps femoris tendon is in continuity with the sacrotuberous ligament, traversing the ischium (27).

In the weight-bearing position, without strong pelvic ligaments, the sacral base tends to rock anteriorly. The downward effects of gravity, combined with environmental and genetic factors, can stress the tensile strength of these ligaments. These ligamentous stresses can create lumbosacral imbalance, chronic back pain, and joint degeneration. The iliolumbar ligament is prone to irritation by lumbosacral instability. When an iliolumbar ligament becomes irritated, its attachments to the crest and transverse processes of L4-5 become tender to palpation. Pain may be referred to the groin via the ilioinguinal nerve, mimicking the pain felt in an inguinal hernia. The iliolumbar ligament has also been implicated in a nerve entrapment syndrome under the iliolumbar ligament (Fig. 41.3). Palpatory diagnosis should therefore always include these ligamentous attachments.

Figure 41-3 Pain referral pattern from iliolumbar ligament. (Modified from George S. Hackett, MD.)

Muscles and Connective Tissue

Muscles and connective tissue of the thoracoabdominal wall, aid in coordinating movements and pressures between the thoracic cage and the pelvic girdle. Muscles acting on or through the pelvis can be classified as primary (intrinsic muscles of the pelvic diaphragm) and secondary (muscles considered to have partial attachment to the true pelvis).

Primary Intrinsic Pelvic Muscles

Primary muscles and connective tissue intrinsic to the pelvic girdle include the pelvic and urogenital diaphragms. The pelvic diaphragm consists of the levator ani and coccygeus muscles, which form a basin, supporting the pelvic viscera and closing the pelvic outlet. The levator ani group includes the pubococcygeus, puborectalis, and iliococcygeus muscles. The urogenital diaphragm spans the area between the ischiopubic rami and is formed by the deep transverse perineal and sphincter urethrae muscles and their fasciae. The pelvic diaphragm slants downward from the lateral wall to the midline perineal structures while the urogenital diaphragm is rather level. This creates a small potential fingerlike space (ischio-rectal fossa) on either side superior to the urogenital diaphragm and inferior to the pelvic diaphragm, which may provide an anterior avenue for the spread of perineal infections. The pelvic floor muscles work in a synergistic way with the abdominal diaphragm to increase intra-abdominal pressure. They also provide support during defecation, inhibit bladder activity, and assist in providing lumbosacral pelvic support (25).

SECONDARY MUSCLES (PARTIAL PELVIC ATTACHMENT)

Secondary muscles include:

- Rectus abdominis
- Transverse abdominis

- Internal and external oblique
- Quadratus lumborum

The external abdominal oblique muscle forms the inguinal ligament as it courses between the ASIS and the pubic tubercle.

The lower extremity may influence the pelvic girdle through its musculature and connective tissue.

Each compartment of the lower extremity has unique actions on the sacrum and pelvis. The anterior and medial compartments of the thigh may affect iliac and pubic motion and contain the following muscles:

- Quadriceps femoris
- Sartorius
- Gracilis
- Adductor group
- Iliopsoas (functionally)

The muscles of the “lateral compartment” of the leg include only the tensor fascia lata muscle and the iliotibial band. The deep fascia of the thigh (fascia lata) is continuous with the superficial thoracolumbar fascia of the thorax and splits to form the compartments of the lower extremity.

The muscles of the posterior compartment of the leg and gluteal region include:

- Glutei maximus, medius, and minimus
- Piriformis
- Obturator externus
- Superior and inferior gemelli
- Biceps femoris
- Semimembranosus
- Semitendinosus

Dysfunction of muscles or fascia of the posterior compartment or gluteal region may affect function of the pelvic girdle. The fascia covering the posterior aspect of the piriformis muscle and the biceps femoris have been found to be continuous with the posterior SI ligament. The implication of these findings is that physical activity and diagnostic tests, such as the straight leg raising tests, could stress the SIJ due to this arrangement. Inflammation of the SIJ could affect the piriformis muscle and biceps femoris through resultant reactive muscle spasm.

Collectively, the muscles of the gluteal region, the quadratus femoris, and the iliopsoas comprise the rotator cuff of the hip (Fig. 41.4).

According to anatomic dissections by Vleeming et al. (27), in all specimens, traction on the posterior layer of the thoracolumbar lumbar fascia transmitted force to the contralateral side, specifically into the fascia of the gluteus maximus. He related that the contralateral latissimus dorsi to the involved gluteus maximus could affect the stability of the SIJ owing to the connecting fascia. Stability of the SI region is achieved by a combination of ligamentous and dynamic muscular function crossing the SIJs (27). Through anatomic study, the gluteus maximus tendon has fibers that blend with the posterior iliosacral ligaments and it overlies the lower half of the SIJ. The tendons of the erector spinae run inferiorly from the paraspinal areas to attach to the posterior surface of the sacrum directly through the perimysial membranes of the multifidus muscles. The multifidus muscle takes its origin from the median sacral crest and runs laterally to attach to the medial PSIS (7).

Integrated Function

There is an integrated function between the muscles of the gluteal region, the abdominal diaphragm, and the muscles of the pelvic and urogenital diaphragms. The pelvic diaphragm consists of the

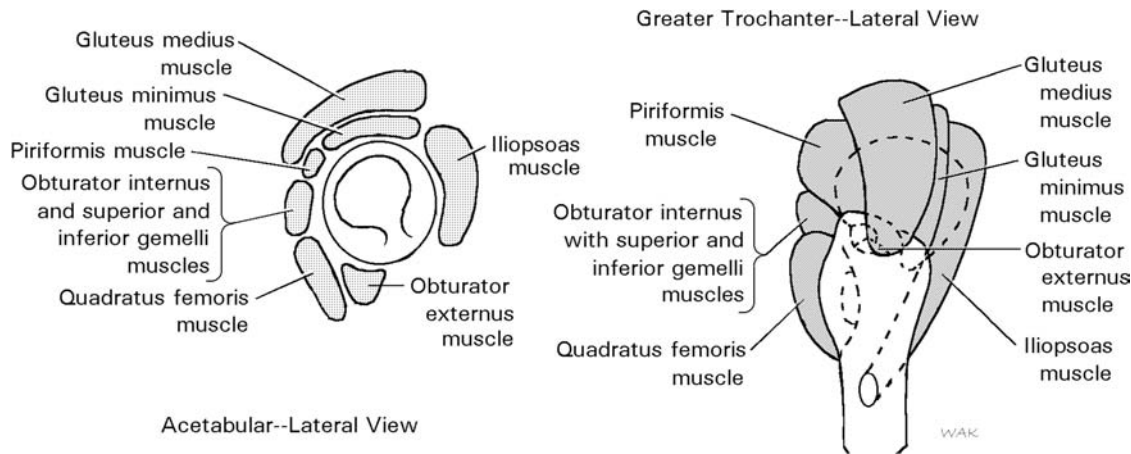

Figure 41-4 Rotator cuff muscles of right hip. (Modified from Kuchera WA, Kuchera ML. *Osteopathic Principles in Practice*. 2nd Ed. Rev. Columbus, OH: Greyden Press, 1994.)

levator ani and coccygeus muscles, which form a basin, does not rhythmically contract, but when relaxed, it works synchronously with the abdominal diaphragm. This synchronous movement with the abdominal diaphragm preserves interstitial fluid homeostasis in the true pelvic region. A relaxed pelvic diaphragm is absolutely necessary for the efficient movement of lymphatic fluids away from the pelvis and perineal tissues. Somatic dysfunction of the symphysis pubis or disturbed ilioliial mechanics (asymmetry of the relationship between the two innominates) can place asymmetric tensions on the pelvic and urogenital diaphragms. These tensions may result in tension myalgia or pain of the pelvic floor, low back pain, dyspareunia, and painful defecation with associated constipation (8). The muscles of the gluteal region become tense and tender to the touch. Tension on the pubovesicular and puboprostatic fascia from innominate dysfunction (especially pubic shears and compressions) may produce urinary tract symptoms such as burning, frequency, fullness, and a weak stream. Such tensions on the inguinal ligament from disturbed ilioliial mechanics can affect the lateral femoral cutaneous nerve, resulting in anterior thigh pain.

Dysfunction of any of the abdominal muscles or their fasciae may disturb respiratory excursion, compromising the intra-abdominal pressure changes that promote lymphatic and venous return. The thoracolumbar and lumbosacral fasciae contribute to the origin of the internal abdominal oblique and the transverse abdominis muscles. Fascial restrictions in these areas can restrict both thoracolumbar and sacral motion. The inner-membranous layer of the superficial thoracolumbar fascia (Scarpa) attaches to the iliac crest and pubic symphysis. It is continuous with the fascia of the thigh inferior to the inguinal ligament (fascia lata), the posterior perineal membrane, and the tunica dartos scroti. Fascial restrictions along its course may affect the thigh, perineum, or abdomen, as fluid collections can traverse along these planes.

Dysfunction of the rectus femoris, the iliacus, or the ipsilateral adductor group may cause an anterior rotation of the innominate and inferior shear at the pubes. Adductor dysfunction may be related to reflex changes at the ipsilateral iliolumbar ligament, while a pubic shear may affect the pelvic and urogenital diaphragms. Gait may be affected by lumbosacral somatic dysfunction, affecting the superior gluteal nerve (L4-5, S1) and the gluteus medius and minimus. Piriformis hypertonicity related to sacral somatic dysfunction may produce benign sciatica. Hamstring tension may cause a posterior rotation of the innominate and affect pelvic mechanics.

Female patients under the influence of hormonal and structural changes during pregnancy are prone to pelvic somatic dysfunction. There are many biomechanical causes such as changes in their center of gravity, an increased lumbar lordosis, and anterior rotation of the pelvis.

Vascular/Lymphatic Anatomy

Following the bifurcation of the abdominal aorta at the approximate level of the umbilicus, the right and left common iliac arteries diverge and descend to the lumbosacral junction. Here they divide into the internal and external iliac arteries. The internal iliac arteries have two trunks that supply the pelvic viscera, perineum, and gluteal region. The proximal anterior trunk supplies the urinary bladder, uterus, vagina, and rectum. Distally, the artery branches into the internal pudendal artery, supplying the genitalia and perineum, and the inferior gluteal artery, supplying the gluteal region. The posterior trunk contains the iliolumbar, lateral sacral, and superior gluteal arteries collectively supplying the intrinsic muscles of the pelvis, the sacrum, and the superior gluteal region.

Veins of the pelvic girdle form venous plexi encircling the pelvic organs and the sacrum and generally following the arterial distribution. The rectal venous plexus communicates with the portal system via the superior rectal vein, which is valveless (Fig. 41.5).

Lymphatic drainage from the pelvic girdle generally follows the corresponding arteries. Lymphatic flow from the lower extremities and pelvic viscera (apart from the gut) passes through the pelvic girdle, terminating ultimately in the lateral aortic groups. Organs and tissues drained by these groups include:

- Testes
- Ovaries
- Fallopian tubes
- Uterus
- Kidneys
- Ureters
- Posterior abdominal, pelvic, and perineal walls

Lymph from the remaining viscera (bladder) and gluteal region passes initially to regional nodes along the internal iliac arteries. The external genitalia drain to the inguinal nodes and then deeper into the external iliac and the intermediary lumbar groups.

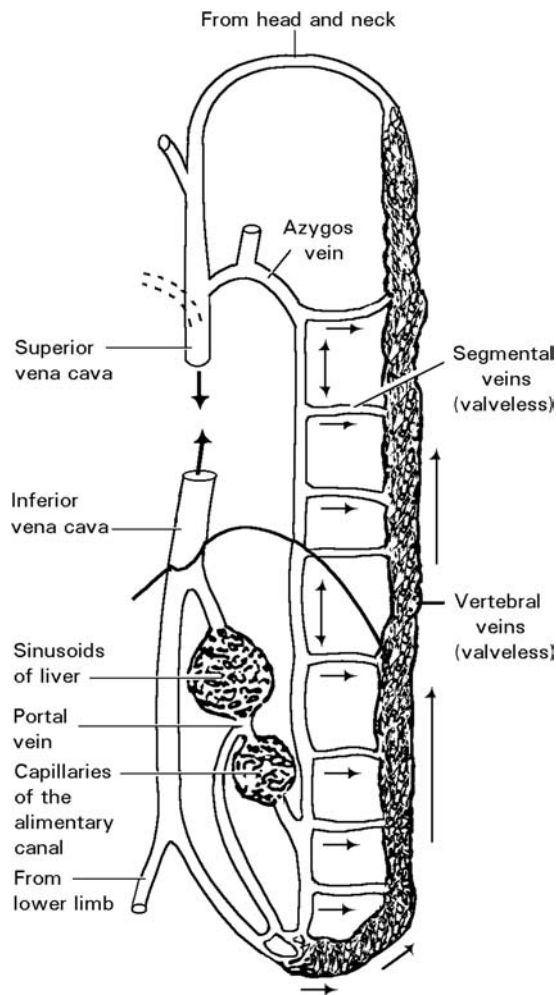

Figure 41-5 Valveless vertebral venous plexus. (Illustration by W.A. Kuchera; adapted from G. Zink.)

Lymphatic drainage of the rectum and anal canal is unique in that, above the pectinate line, lymph follows a deep course to the internal iliac nodes and preaortic nodes. Below the pectinate line, the lymph drains superficially to the inguinal nodes. As lymph flows through a number of intermediary groups in the lumbar region, on up to the cisterna chyli and thoracic duct, the diameter of the thoracic duct and lymphatic channels is under sympathetic control similar to blood vessels. Hypersympathetic activity can reduce lymphatic flow capacity. Accumulation of pelvic lymph may occur in the preaortic, lateral aortic, or retroaortic lymph node groups. Peripherally compromised lymphatic drainage has been linked to the pathogenesis of atherosclerosis and to the development of hypertension (9). Correction of pelvic girdle dysfunction, as well as piriformis tension, may allow improved lymphatic venous return, blood flow, and gait for a patient whose activities of daily living are already compromised by a cardiovascular condition.

Nerves

The nervous system may influence the pelvic girdle through one of four areas. These are the:

- Lumbar plexus
- Sacral plexus

- Coccygeal plexus
- Autonomic nerves of the pelvis

The lumbar plexus lies between the anterior and posterior masses of the psoas major, anterior to the transverse processes of the lumbar vertebrae. The plexus is formed by the contributions of the ventral rami from T12 to L4 with only partial contributions from T12. The lumbar plexus gives motor supply to muscles in the abdomen and thigh, which act on the pelvic girdle. These muscles include the:

- Psoas major and minor
- Iliacus
- Pectineus
- Internal abdominal oblique
- Transverse abdominis
- Quadriceps group
- Adductor group
- Sartorius
- Gracilis

The lumbar plexus also supplies sensation to the thigh, buttocks, lower abdomen, and pubic area. The sacrum contains sacral foramina for passage of the sacral nerve roots, which exit anteriorly and posteriorly. The innervation of the SIJ and its ligaments is derived exclusively from the dorsal branches of the sacral spinal nerves. The joint capsule contains complex encapsulated and unencapsulated nerve endings capable of providing position sense and pressure information. The numerous thick myelinated axons in the nerve branches to the SIJ ligaments indicate the presence of special encapsulated mechanoreceptors and nociceptors (26,27). The posterior innervation to the SIJ is from the posterior primary rami of L4 through S3 (26). The anterior innervation arises from branches of the anterior primary rami from L2 to S2. The posterior and anterior rami are variable and this may account for the inconsistent pain referral pattern seen with SIJ syndrome (2). Since the SIJs have a wide distribution of innervation, it is possible that pain referred from the SIJ will not be associated with any motor, reflex, or sensory deficit on physical examination.

The lumbosacral trunk (ventral rami of L4 and L5), the first three sacral ventral rami, and a portion of the fourth form the sacral plexus. The ventral rami divide into anterior and posterior branches. The anterior branch forms anterior nerves that innervate the flexors and adductors; the posterior branch forms posterior nerves that innervate the extensors and abductors.

The sacral plexus has motor and sensory innervations in the pelvis and lower extremities and contains parasympathetic fibers (S2, S3, and S4) for innervation of the left colon and pelvic organs. The sciatic nerve is a muscular branch of the lumbar and sacral plexi composed of fibers from the ventral rami of L4-S3. Pathology at the L4-5 or L5-S1 level is the usual cause of nerve root compression, as it is uncommon within the sacrum. The sciatic nerve is closely associated with the piriformis muscle. Eighty-five percent of the time the sciatic nerve passes through the greater sciatic notch just inferior to the piriformis; it passes through the muscle in <1% of the population. Since injections are sometimes given in myofascial triggerpoints when the muscle is spastic, it is important to realize that more than 10% of the time the peroneal portion of the sciatic nerve passes through the muscle, and in 2% to 3% of instances it exits above the piriformis and passes posterior to the piriformis muscle (10) (Fig. 41.6). Piriformis hypertonicity can cause sciatica. Evidence indicates that this may not be due to pressure, but to a chemical reaction that irritates peroneal fibers of the sciatic nerve. For this reason, there is referred pain down the posterior thigh.

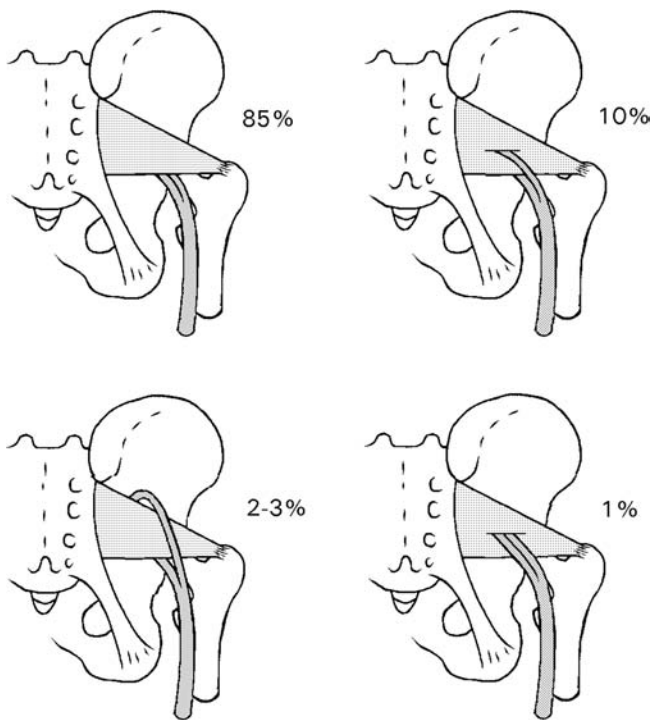

Figure 41-6 Position of sciatic nerve in relationship to the piriformis muscle. (Adapted from Beaton LE, Anson BJ. The sciatic nerve and the piriformis muscles: their interrelation as a possible cause of coccygodynia. *J Bone Joint Surg (Br)*. 1938;20:686–688.)

The coccygeal plexus is located on the pelvic surface of the coccygeus muscle and formed by the coccygeal nerve with contributions from S4 and S5. This plexus gives rise to the anococcygeal nerve that pierces the sacrotuberous ligament to supply the skin over the coccyx.

The autonomic nerves of the pelvis include the sacral sympathetic trunks, the parasympathetic nerves of the pelvic splanchnics, and the inferior hypogastric plexus. The right and left sacral sympathetic trunks are extensions of the lumbar sympathetic chain ganglia and are located on the ventral surface of the sacrum medial to the sacral foramina. They contain four or five ganglia and eventually fuse over the coccyx to form the single ganglion impar. The sacral sympathetic trunks have gray rami communicantes that follow the sacral and coccygeal nerves for innervation of blood vessels and sweat glands in the body wall and extremities. Because the sacral and coccygeal nerves do not have white rami, visceral afferent impulses returning from sites of sympathetic innervation by the sacrum and coccyx refer viscerosomatic symptoms to the thoracolumbar region of the body. Examples include anterior lower thoracic or sacral exostoses and anterior disc protrusions or ruptures. Contractions of the uterus refer pain to the thoracolumbar region, as the visceral afferent nerves travel to this level from the uterine body. The sacral splanchnics come off the chain and contribute to the formation of the inferior hypogastric plexus. The pelvic splanchnics arise directly off the ventral rami of S2-4 and supply parasympathetic innervation to the left colon and inferior hypogastric plexus for pelvic viscera. Visceral afferent nerves following parasympathetic nerve pathways produce viscerosomatic symptoms over the sacrum. An example is sacral pain and pressure from uterine contractions. The inferior hypogastric plexus contains both sympathetic and parasympathetic fibers; it gives rise to smaller plexi to the rectum, bladder, prostate, uterus, and vagina.

Somatic dysfunction of the lumbar spine may affect the lumbar plexus and produce symptoms in both the pelvis and lower extremity. Dysfunction of the *Quadratus lumborum* may produce symptoms similar to a groin pull or hernia, by irritating the ilioinguinal and iliohypogastric nerves (L1) as they pass just anterior to this muscle. Dysfunction of the piriformis, or sacrum, can affect the sciatic nerve and cause signs and symptoms of sciatica.

Many visceral complaints are related to an imbalance in the autonomic control of the pelvic viscera. When irritable bowel syndrome is dominated by parasympathetic hyperactivity (headache, nausea, diarrhea, and cramps), relaxation of the pelvic diaphragm through ischiorectal fossa techniques relieves the congestion and pain by influencing the pelvic parasympathetic (S2, S3, S4). Normalizing parasympathetic tone and encouraging venous and lymphatic return with firm continuous pressure over the sacral base can help treat primary dysmenorrhea.

MOTION AND DYSFUNCTION

The pelvic girdle holds a central role in coupling the mechanical forces from the lower extremities to the axial skeleton. The two primary functions of the SIJ are to dissipate the load of the upper trunk to the lower extremities and to facilitate childbearing by ligamentous relaxation during pregnancy. Somatic dysfunction of the pelvis occurs when there are motion preferences during activity that become restricted when activity is completed and the joint has returned to an abnormal resting position. Consider a patient bending forward and to one side, to pick tomatoes. The sacrum flexes initially, and then moves posteriorly into extension. With prolonged forward bending (at the hips and low back) the sacrum can become “stuck” in extension. When the patient stands up and walks they develop lumbosacral pain. Clinical examination will typically reveal a bilateral sacral extension or a backward torsion. During normal walking, physiologic motions of the sacrum and ilium occur around various theoretical axes of motion. Somatic dysfunction affecting any of these axes hinders gait, requires compensatory changes, and increases energy expenditure.

Individual axes of the pelvic bones are described in the following paragraphs, as well as the motion about or around those axes. This is followed by a discussion of the biomechanical stability of the SIJs, and an integration of the coupled movements during the motion cycle of walking.

Innomimates

The innomimates can be functionally considered as part of the lower extremity. The innomimates rotate anteriorly and posteriorly about the inferior transverse axis of the sacrum. The innomimates may also be considered to rotate posturally around an axis passing through the greater trochanters of the femur. Reynolds (11) demonstrated that there were multiple varying instantaneous axes of rotation of the ilium about the sacrum when the thigh was used to introduce motion at the SIJ.

If the clinician considers the ilium functionally, each lower extremity, including the attached innominate, is likely to shear superiorly or inferiorly as well as have rotation around a horizontal/transverse axis. Innominate motion can be induced by hip motion as during gait, or by muscular forces from below or above. When the innominate rotates anteriorly, it glides in the direction of the short arm of the “L” and posteriorly along the longer length of the “L.” When the innominate rotates posteriorly, it glides in the direction of the longer length of the “L” and superiorly up the short length of the “L” (25). According to Fryette (12), it is thought

that the sacrum follows the motion of the ilia, however to a lesser degree.

Pubes

Pubic bone motion is complex. The pubic bones are thought to correspond to ilial motion by rotating anteriorly and posteriorly about a transverse axis. With anterior rotation of the ilium the ipsilateral pubic bone is commonly found to be inferior. With posterior rotation of the ilium the ipsilateral pubic bone is commonly found to be superior. However, the pubic bones may also be sheared (subluxed) superiorly or inferiorly along with the rest of the respective innominate. Pubic somatic dysfunctions usually occur when iliac movement is maximal. Strachan came to these conclusions in the SI research in the 1930s (5,14). Anterior and posterior pubic shears can also occur, as well as a “gapped” pubic symphysis. These are rare and usually result from a significant traumatic event.

Sacrum

Ordinarily, SI motion is a result of mechanical forces acting on the sacrum. These forces can come from above, associated with changes of position or center of gravity within the torso, or from below, as in walking. While muscles are attached to the sacrum, sacral motion is not caused by sacral flexors, extensors, lateral flexors, or rotators (13). Describing motion of the sacrum about certain theoretical axes is a model by which the osteopathic physician explains how the sacrum seems to work as a result of the forces acting upon it. The osteopathic physician is also able to gather palpatory information, use this model, and describe the motion present and motion restricted. The palpatory findings become objective evidence of SI motion disturbances. It is then possible to design methods of manipulative treatment to remove the dysfunctions. By palpating landmarks and passive motion testing after manipulation the effectiveness of treatment can be evaluated.

Theoretical Axes of Motion

Mitchell (13) describes three transverse axes. The *superior transverse axis* is at the level of the second sacral segment, posterior to the SIJ, in the spinous process area. This is the respiratory axis where flexion and extension associated with respiration occur, as well as nutation and counternutation when using this terminology. The *middle transverse axis* is located at the anterior convexity of the upper and lower limbs of the SIJ. Sacral postural flexion and extension occur about this axis. The *inferior transverse axis* is located at the posterior-inferior part of the inferior limb of the SIJ and is the axis about which innominate (ilial) rotation occurs. Conceptually, one can consider each axis to roughly correspond to the anatomical remnants of the embryological transverse processes of the S1, S2, and S3 vertebrae, found on the sacral side of the SIJ (7).

There are two oblique axes of the sacrum, named according to the side of the body toward which the superior end of the oblique axis is located. Motion about an oblique axis may actually result through motions occurring about a vertical, anterior-posterior (AP) and transverse sacral axis (combination of rotation and side bending). Sacral movement can occur around an individual axis or simultaneously around multiple axes. Sacral shears do not rotate around an axis. Many studies of sacral/pelvic motion document movement of the SIJ and movement of the ilia in relation to the sacrum (14). However, many of the studies do not assess SI motion that is evaluated passively during clinical motion testing, or other osteopathic diagnostic procedures.

Sacroiliac Motion Research

There has been considerable debate over the years as to the mobility of the SIJs. Both in vivo and in vitro kinematic studies have demonstrated various types of motion in the SIJ, including rotation, gliding, tilting, nutation, and translation (27). In the late 1930s, Fraser Strachan, D.O., (CCO anatomy professor) et al. (14) conducted a cadaveric SI motion study. One innominate was encased in concrete. The sacrum and other innominate were free to move. Steel pins were fixed in all the bones. Forces were applied to the lumbar spine. C.R. Nelson, D.O., an engineer, made all the measurements and calculations. There are two excellent reports of this study (14). Strachan's research looked at how the sacrum moved in relation to the ilium when forces were applied to the cadaveric spine. The following summarize his findings:

- All of the movements of the sacrum on the ilium are gliding movements. These include flexion, extension, rotation, lateral flexion, and a gliding upward and downward.
- When force is transmitted vertically downward from the lumbar region, the sacrum glides downward and flexes. When traction is applied, the sacrum glides upward and extends.
- When rotation to one side is applied from above through the lumbar spine, the sacrum rotates to the same side and laterally flexes to the opposite side.
- When lateral flexion to one side is applied from above through the lumbar spine, the sacrum laterally flexes to the same side and rotates slightly, but the direction of rotation is inconsistent.
- When rotation to one side is applied from above through the lumbar spine, the sacrum rotates to the same side and laterally flexes to the opposite side.
- When lateral flexion to one side is applied from above through the lumbar spine, the sacrum laterally flexes to the same side and rotates slightly, but the direction of rotation is inconsistent.
- Freedom of movement is greater in flexion-extension and in gliding upward and downward than in rotation or lateral flexion.
- The ilium always moves in the same direction as the sacrum, but to a lesser degree.

Studies on SI motion in living subjects were performed by Weisl with lateral x-rays in the 1950s (6). Weisl noted a 6 mm displacement between end points of motion, but the error of measurement was calculated to be 3 mm (6). Colachis et al. (1963) performed a study with rods in the iliac bones and reported 5 mm of translation but no other results (28). Selvik, in 1974, described a technique called roentgen stereophotogrammetric analysis (RSA), by which it was possible to measure sacral movement in all three planes (28). The RSA technique could measure very small SIJ movements with a high degree of accuracy and specificity. According to Vleeming, the RSA technique could not identify SI dysfunction. While treatment was effective in relieving symptoms, the bony relationships were not altered. The research could not find significant differences of motion between movements of symptomatic and asymptomatic joints (28). However, these studies did not assess passive motion induced to the patient's SIJ by the physician, as is done in the clinical arena.

According to Vleeming, in 1983, Grieve used a RSA method to analyze movements of skin markers placed on the PSISs and sacrum. She measured iliac and sacral movement between standing and standing with one leg in flexion. She found the average movement at approximately 10 mm between the two positions. The sacrum was shown to rotate anterior relative to the ilia when standing up from lying supine. There was also an inward movement of the iliac crests, noted as positive values around the Z-axis for the left side and negative values for the right (28).

An *in vivo* SI motion study was carried out by Stuesson et al. (28). It used the RSA technique. In this technique, small metal balls were implanted in skeletal structures under local anesthetic. The motion between the metallic reference points of the ilium and the sacrum were measured in various positions by dual radiographic techniques. He found that in healthy young people, moving from a normal posture to hyperextension produced the greatest degree of motion. This was slightly more than 2 degrees on average, with a maximum of 4 degrees (15).

In 1990, Vleeming performed a similar study showing range in motion from zero to about 4 degrees, on individuals who had been found to have SI dysfunction based on a consensus from two physiotherapists, an orthopedic surgeon, and a chiropractor.

Sacroiliac Joint Stability

Much attention and research has been placed on stability of the SIJs. This is primarily due to the clinical finding of SIJ dysfunction in the patient with lower back pain, as well as the general medical consensus that the majority of back pain sufferers have poor lumbar-pelvic motion and stability. Therapeutic exercise and osteopathic treatment for the core lumbar and pelvic musculature helps patients with low back pain and SI syndrome. The SIJ is one in which a small amount of motion is desirable, as excessive motion is much more difficult to treat clinically.

Click-clack Phenomenon

This postural transition from lumbar lordosis to lumbar kyphosis is called the lumbopelvic “click-clack” phenomenon. The click-clack phenomenon implies unfavorable loading of the lumbosacral and SI region. This motion occurs when a patient goes from a seated position to a standing position. It is thought that the intermediate position between kyphosis and lordosis is unfavorable, because of a lack of stability. This positional change, as well as counterrotation (anatomic sacral extension), is unfavorable because of loading of the long dorsal SI ligaments. This ligament has been reported to be painful in 42% of patients with peripartum pelvic pain, and 46% with nonspecific low back pain. Control of the click-clack phenomenon depends on the rate of muscle action: the muscle forces must be generated at precisely the right time. This process may be viewed as a joint protecting or an arthrokinetic reflex. Weakness or tightness of involved muscles of the kinetic chain may delay muscle reaction and impair the functional stability of the SIJs.

Self-Bracing Mechanism

When considering the biomechanics of the sacrum, the forces applied to the joint and the shape of the joint surfaces must be taken into account. Gravitational force is applied to the SIJs in the standing position. Unlike other joints, this force is almost parallel to the surfaces of the SIJs. Because of this, there is considerable shear loading in the SIJ and a risk of damaging the ligaments. In general, the strong ligamentous structures surrounding the SIJ are assumed to be sufficient to prevent shear force and stabilize the joints. However, Vleeming et al. states that the ligaments alone are not capable of transferring lumbosacral load effectively to the iliac bones during standing and sitting. Research has shown that muscles and fascia contribute to the self-bracing or self-locking mechanism of the SIJ. The muscles involved apply a tension cross-brace to the SIJs, similar to the effect of wearing a SI belt. The muscles include the latissimus dorsi, the thoracolumbar fascia, gluteus maximus, and the iliotibial tract. Ventrally the muscles involved include the external

abdominal obliques, the linea alba, the internal abdominal obliques, and the transverse abdominals. In both standing and sitting, the activity of the oblique abdominal muscles, especially the internal obliques, was found to be significant. Interestingly, research showed that leg crossing correlates with a significant decrease in activity of the internal obliques, causing an unstable situation. The psoas muscles are continuously active in erect postures acting as muscles of postural balance (16,23). This muscle, however, produces shear loading of the SIJs as well, because its orientation is almost parallel to the SIJ surfaces. Clinically, the authors find this muscle to be the most common culprit in restrictions of SI motion.

Form and Force Closure

According to the self-locking mechanism, *resistance against shear* results from the specific properties of the articular surfaces of the SIJ (form closure) and from the compression produced by body weight, muscle action, and ligament force (force closure). Different aspects of this mechanism operate depending on if the patient is standing, sitting, walking, or lifting. According to this model, the SIJ becomes especially prone to shear forces if loaded in anatomic sacral extension. This position with flattening of the lumbar spine, is thought to lead to abnormal loading of the lumbar discs and, in the end, herniation. The SIJs remain in place by friction forces between, and tangential to, the contact surfaces. These forces are generated by compression. The SIJs have symmetric ridges and grooves in the joint surfaces that apply friction. Form closure refers to a stable situation with closely fitted joint surfaces, in which no extra force is needed to maintain the state of the system, given the actual load situation. Form closure requires the proper size, shape, and attitude of the articulating surfaces, on which the load is dependent.

Additional compressive forces are needed to resist high load situations when shearing of the SIJ surface occurs. Force closure by this musculotendinous cross-bracing system is essential when form closure is absent, or insufficient. Vleeming described three muscle slings (one longitudinal and two oblique) that can be activated differently, based on the load applied. Compression by these slings can be produced by muscle forces, in combination with forces in ligaments and fascia that cross the SIJ surfaces. For example, consider postural scoliosis with unlevelness of the sacral base. To counter the torque that results from sacral unlevelness, muscular force is necessary to stabilize the situation by formation of scoliosis.

SACRAL MOTION

Considering these principles, four general categories of sacral motion can be described. These include:

- Postural
- Respiratory
- Inherent
- Dynamic

Postural Motion

In the standing or seated patient, postural motion of sacral flexion or extension occurs about a middle transverse axis. Flexion and extension of the sacrum correspond to anatomic nomenclature, with a reference point at the anterior portion of the sacral base. Flexion (forward bending, nutation) occurs when the sacral base is moving forward or anteriorly. Extension (backward bending, counter-nutation) of the sacral base occurs when the sacral base moves

posteriorly. Terminology for sacral motion uses the same reference point as terminology for spinal motion, the most anterior superior part of the body (in the case of the sacrum, the sacral base). Postural flexion/extension of the sacrum is sometimes referred to as sacral base anterior (for flexion) or posterior (for extension). This prevents confusion of understanding sacral motion that occurs during flexion and extension of the Sphenobasilar synchondrosis during craniosacral motion (see “Inherent Motion”). When a person is seated and the torso is forward bent, the sacral base moves anteriorly. When a person is standing and begins forward bending, the sacral base begins to move anteriorly, tightening the sacrotuberous ligaments. As forward bending continues, the pelvis moves posteriorly in relation to the feet. This shift in the base of support causes the sacral base to move posteriorly.

Respiratory Motion

Respiratory motion also affects the sacrum, partially because the diaphragm is attached to the top three lumbar vertebrae (L1-2 on the left and L1-3 on the right). Mitchell and Pruzzo (17) showed that the sacrum moves in response to respiration along the superior transverse axis at the second sacral segment. As inhalation occurs, the lumbar lordotic curve decreases, and therefore the sacral base moves posteriorly. As we exhale, the lumbar lordosis increases and the base of the sacrum moves slightly forward.

Inherent Motion

Cranial terminology defines cranial sacral flexion/extension as the position of the sacrum when the sphenobasilar synchondrosis (SBS) is in flexion or extension. In flexion, the sacral base moves backwards (posteriorly). Therefore, cranial flexion is anatomic extension. Students were taught that relative to the sacrum, cranial flexion or extension was the opposite of anatomic flexion or extension. If anyone was referring to sacral motion from a cranial perspective, it was imperative to state cranial flexion or cranial extension. Because of this confusion, the Educational Council on Osteopathic Principles (ECOP) has encouraged the use of the terms *nutation* and *counter-nutation* to describe sacral movement in the cranial cycle of flexion/extension. Nutation means nodding forward, referring to anterior motion at the sacral base. During the flexion phase (of craniosacral inherent motion), the sacrum counter-nutates. During the extension phase (of craniosacral inherent motion), the sacrum nutates.

ECOP added the term to the Glossary to satisfy those ECOP members who felt that use of this term would clarify the difference between anatomic flexion and cranial flexion. The Glossary of Osteopathic Terminology (created by ECOP and published in Foundations) defines **nutatation** as “nodding forward; anterior movement of the sacral base around a transverse axis in relation to the ilia, occurring during sphenobasilar extension of the craniosacral mechanism.” This definition clearly implies that nutation, and counter-nutation, are terms to be used in describing sacral motion/position in relation to the cranial concept. With the expanded use of these terms, our profession has created a new set of confusions. Nutation is also being used to describe and name biomechanical flexion (sacral base moving forward) of the sacrum. Another term approved by ECOP concerns tissue texture abnormality, asymmetry, restriction of motion, and tenderness (TART Criteria), as outlined in Table 41.2.

Dynamic Motion

Dynamic motion of the sacrum and pelvis occurs during walking. As weight bearing shifts to one leg, unilateral lumbar sidebending engages the ipsilateral oblique axis by shifting weight to that SIJ. The sacrum now rotates forward on the opposite side, creating a deep sacral sulcus. With the next step, this process reverses as weight bearing changes to the other leg. The sacral base is constantly moving forward on one side, then the other, about the oblique axes. As this occurs, the two innominates are rotating in opposite directions to each other about the inferior transverse sacral axis. One side rotates anteriorly as the other side rotates posteriorly. With the next step, this process reverses as the anteriorly rotated ilium moves into posterior rotation. Interacting with the bony and ligamentous structure during this motion are the viscera, the weight of the upper body, the muscles of locomotion and balance, and the pelvic diaphragm, all revolving around the constantly changing instantaneous axes at the pelvis.

NORMAL MOTION OF WALK CYCLE

In the following passage from his paper, “Structural Pelvic Function,” Mitchell (13) described the interplay of locomotion and balance as being the walking cycle:

The cycle of movement of the pelvis in walking will be described in sequence as though the patient were starting to walk forward by moving the right foot out first.

TABLE 41.2

Tart Criteria for Identifying Somatic Dysfunction

Tissue Texture Abnormalities	How the Tissue Feels to the Palpating Hand	Classify as Acute or Chronic
Asymmetry	Apparent relationship of landmarks and tissues	Made by observation, not palpation; is generally static positional asymmetry
Restriction of motion	How the tissue moves	Arthrodiagonal, muscular, or fascial elements
Tenderness	Pain elicited by palpation	Generalized as in traumatic tissue damage, such as contusion, or specific for individual muscles or sclerotomal levels, as in tender point diagnosis

To permit the body to move forward on the right, trunk rotation in the thoracic area occurs to the left accompanied by lateral flexion to the left in the lumbar with movement of the lumbar vertebrae into the forming convexity to the right. There is a torsional locking at the lumbosacral junction as the body of the sacrum is moving to the left, thus shifting the weight to the left foot to allow lifting of the right foot. The shifting vertical center of gravity moves to the superior pole of the left SI, locking the mechanism into mechanical position to establish movement of the sacrum on the left oblique axis. This sets the pattern so the sacrum can torsionally turn to the left, thereby the sacral base moves down on the right to conform to the lumbar C curve that is formed to the right.

When the right foot moves forward there is a tensing of the quadriceps group of muscles and accumulating tension at the inferior pole of the right SI at the junction of the left oblique axis and the inferior transverse axis, which eventually locks as the weight swings forward allowing slight anterior movement of the innominate on the inferior transverse axis. The movement is increased by the backward thrust of the restraining ground, tension on the hamstrings begins; as the weight swings upward to the crest of the femoral support, there is a slight posterior movement of the right innominate on the inferior transverse axis. The movement is also increased by the forward thrust of the propelling leg action. This iliac movement is also being influenced, directed and stabilized by the torsional movement on the transverse axis at the symphysis. From the standpoint of total pelvic movement one might consider the symphyseal axis as the postural axis of rotation for the entire pelvis.

As the right heel strikes the ground and trunk torsion and accommodation begin to reverse themselves, and as the left foot passes the right foot and weight passes over the crest of the femoral support, and the accumulating force from above moves to the right, the sacrum changes its axis to the right oblique axis and the sacral base moves forward on the left and torsionally turns to the right.

The cycle on the left is repeated identically to the right half movements. The shifting vertical center of gravity moves to the superior pole of the left SI locking the mechanism into mechanical position to establish movement of the sacrum on the left oblique axis.

Somatic dysfunctions may accentuate and retain portions of the motion described above. These are called physiologic somatic dysfunctions, because the muscles, connective tissue, and joints remain in positions that are normally a part of physiologic motion but are dysfunctional when the body should have returned to a neutral position but did not do so. Nonphysiologic somatic dysfunction is generally induced by trauma. It is evidenced by the joint, muscle, and connective tissue elements being in positions and/or relationships that are not part of the physiologic range of motion and do not involve the physiologic axes of motion. Examples include sacral, innominate, and pubic shears.

Integrated Physical Examination

The osteopathic examination is not a traditional history and physical with a palpatory examination added to it. An osteopathic examination strives to provide a time- and cost-effective diagnosis while encompassing the interrelationship between structure and function. Integration of the physical findings with the emotional, environmental, and genetic factors allows the osteopathic physician to understand their impact on body unity. An understanding and recall of the physiologic spinal motion patterns is also necessary before performing the physical examination. Using this knowledge, the physical exam will help the clinician rule out specific conditions on the differential diagnosis list. A prior knowledge

of Chapman reflexes, viscerosomatic reflexes, and the autonomic innervation of the viscera are also useful during the physical exam. While performing the physical exam, osteopathic physicians may discover paraspinal tissue texture changes that have characteristic palpatory qualities and conclude that these changes are due to visceral disturbances. These tissue texture changes are palpated in the subcutaneous tissue, and superficial and deep fascia, rather than in the muscle. Palpation leads to motion testing of tissues. Passive motion testing is performed as part of the integrated physical exam. In this fashion, through palpation and motion testing, an osteopathic physician examines the homeostatic reserve of each patient, an area crucial in determining prognosis, treatment design, and prevention. *To find health is the object of the physician, anyone can find disease* (18).

Begin with observation of the patient's gait. Do they turn one foot outward or inward? Do they hike a hip, lean to one side, or limp? Any of these findings can relate to dysfunction of the sacrum and pelvis. Perform a structural examination including a standing flexion test, a pelvic sideshift test, and a seated flexion test. Look for un-level iliac crests as well as greater trochanters. If they have a low greater trochanter, low iliac crest, and deep sacral sulcus on the same side, and have pelvic sideshift away from this side, they probably have a leg length inequality. This situation will un-level the sacral base, and affect pelvic stability. Do they have a group curve in the thoracic or lumbar region? This finding correlates with sacral base unleveling and is commonly seen with forward sacral torsions. Look for a reversal of their A-P curves. A flattened upper lumbar spine and an increased lumbar lordosis of the lower segments correlate with bilateral iliopsoas tension. If the entire lumbar spine is flattened, look for a sacral base that is held in extension (counternutation). If they have a significant increase in their lumbar lordosis, their sacrum will be bilaterally flexed, almost parallel to the ground. In this situation L5 frequently is unstable and may develop disc protrusions or other orthopedic changes. A Trendelenberg test can be done to evaluate for gluteus medius weakness (Table 41.3). As an addition to this examination, some physicians (and physical therapists) include a scanning examination for myofascial triggerpoints or tenderpoints. The assessment and treatment of myofascial trigger points is important when dealing with pelvic pain and dysfunction. If performed properly, a standing structural exam and evaluation of gait can provide useful clinical information to aid in the diagnosis and treatment of sacral and pelvic dysfunction.

Have the patient sit on the table and perform a cardiopulmonary examination. The palpatory examination should include an assessment of the patient's cardiovascular status. Pulses should be palpated and auscultated for bruits bilaterally. An abdominal pulse should be palpated, identified, classified, and auscultated. Peripheral edema, sacral edema, and trophic changes in the skin should be evaluated. In addition to the auscultation over arteries in the periphery, auscultation of the heart, lungs, and abdomen should accompany any patient evaluation. If atheromatous disease is suspected, auscultation over the carotid and femoral arteries is imperative, if an abdominal aneurysm is suspected, the diameter of the abdominal aorta is evaluated carefully.

While the patient sits on the table, perform a neurologic examination. Muscle testing and sensation are the primary focus of the neurologic examination of the pelvis and hip (21).

Muscle Testing

Muscles of the lower extremity and buttocks require assessment when evaluating the pelvis and hip. Descriptions of the innervation, functional anatomy, and dysfunction are discussed in the chapters

TABLE 41.3

Special Orthopedic and Physical Therapy Tests Performed on the Pelvis

Orthopedic Tests of the SIJs	Characteristics
Ipsilateral prone kinetic test	Prone
Gapping test	Supine, compress/IR both ilia Positive test = SI pain
Approximation test	Supine, or prone, ER both ilia Positive test = SI pain
SI rocking test	Supine, passively flex, and extend sacrum Positive test = SI pain
Squish test	
Femoral shear test	Supine, Flex hip and knee, compress Positive test = SI pain
Prone springing test	Prone, anterior pressure, springing motion Positive test = pain
Special Tests of the Pelvis (30)	Characteristics
Straight leg raising test	Supine, flex hip, knee extended Positive = radicular pain 30–70 degrees
Prone knee bending test (Nachlas)	Prone, Flex knee, extend hip Positive = pain anteriorly
Gillet test	Standing, flex hip and knee maximally Positive = asymmetry of PSIS, sacral spines
Ipsilateral anterior rotation test	Standing, side-lying, Passively rotate ilium Positive = pain
Flamingo test	Standing, hip flexed, abducted, ER, knee flexed Positive = pain
Leg length tests	Supine, Measure ASIS to medial malleolus Positive = discrepancy
Sign of the buttock	Supine, Flex hip with knee extended, then flex knee Positive = knee flexion does not allow further hip flexion
Gaenslen test	Side-lying, Flex lower hip, hold. Examiner extends top hip. Positive = pain in SIJ
Leaquer sign	Supine, flex, abduct, laterally rotate symptomatic hip with overpressure Positive = positive = pain in SIJ
Supine-to-sit (long sitting) test	Supine, legs straight, patient sits up. Positive = one leg moves proximal farther than the other = pelvic dysfunction
Yeoman test	Prone, flexes knee to 90 degrees, extend hip Positive = pain anterior SI ligaments
Thomas test	Supine, flex hip, hold knee to chest, allow other leg to extend Positive = un-held hip remains semiflexed
Trendelenberg test	Standing, one leg stance, evaluate pelvic position, evaluates stance leg: gluteus medius strength Positive = hip drops on nonstance side

on lumbar spine and lower extremity. Primary intrinsic muscles of the pelvis, although not tested for strength, may be palpated for tension, tissue texture changes, and tender points. Lumbar and pelvic muscles that may have triggerpoints referring pain to the pelvis should also be investigated (19,20).

Sensation Testing

The dermatomal distribution of sensory nerves to the pelvic girdle ranges from T10 to S5, involving nerve roots from the thoracic,

lumbar, and sacral regions (Fig. 41.7). Dermatomes of the anterior abdominal wall run in transverse and oblique bands. These dermatomes begin at the umbilicus with the T10 strip followed inferiorly by the T11 strip. The T12 strip lies just superior to the inguinal ligament, while L1 lies just inferior to it. Inferior to the L1 dermatome lie the L2 and L3 strips covering the anterior thigh and ending at the patella. The buttocks, PSISs, and iliac crest are supplied by the cluneal nerves (21) (posterior primary divisions of L1, L2, and L3). The posterior femoral cutaneous nerve (S2) supplies sensation to a longitudinal band traversing the posterior thigh.

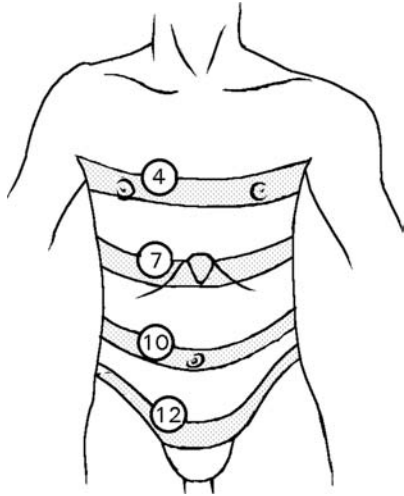

Figure 41-7 Anterior thoracic dermatomes. (Reprinted from Kuchera WA, Kuchera ML. *Osteopathic Principles in Practice*. 2nd Ed. Rev. Columbus, OH: Greyden Press, 1994, with permission.)

The lateral femoral cutaneous nerve (S3) supplies sensation to the lateral thigh. The cutaneous innervation of the perineum is arranged in concentric rings around the anus: the outermost (S2), middle (S3, S4), and innermost (S5).

Orthopedic Sacroiliac Joint Testing

In addition to observation of landmarks for asymmetry, palpation for tissue texture changes, and passive motion testing of joints and tissues; the orthopedic and physical therapy literature also stresses the performance of pain provocative tests, kinetic tests, and special tests. Pain provocative tests include traditional orthopedic tests, motion demand tests and ligament tension tests (25). Kinetic tests can be assessed either weight bearing or non-weight bearing. These tests assess SI motion during patient-generated movements.

DIAGNOSIS OF ILIOSACRAL AND PUBIC SOMATIC DYSFUNCTION

Iliosacral Somatic Dysfunctions

Iliosacral somatic dysfunctions include:

- Innominate rotations, anterior and posterior
- Innominate subluxations (shears), superior and inferior
- Innominate flares (inflares and outflares)
- Pubic shears (subluxations), superior and inferior
- Unequal hamstring length
- Unequal iliopsoas length

Anterior Innominate Rotation

This exists when the dysfunctional side has the following positional characteristics:

- Entire innominate appears to be rotated in a direction anterior to the other hip bone.
- ASIS is more inferior (caudad).
- PSIS is more superior (cephalad).

Subjective complaints may include ipsilateral hamstring tightness and spasm and sciatica (secondary to piriformis dysfunction). Palpatory findings may include the following:

- Tissue texture changes at the ipsilateral ILA of the sacrum.
- Iliolumbar ligament tenderness
- Positive ASIS compression test on the involved side (Fig. 41.8)
- Positive standing flexion test on the involved side
- Motion characteristics should indicate freedom of anterior rotation, about an inferior transverse axis, on supine motion testing, and resistance to posterior rotation.

Posterior Innominate Rotation

This exists when the dysfunctional side has the following positional characteristics:

- Entire innominate appears to be rotated in a direction posterior to the other hip bone.
- ASIS is more superior (cephalad).
- PSIS is more inferior (caudad).

Subjective complaints may include inguinal/groin pain (secondary to rectus femoris dysfunction) and/or medial knee pain (secondary to sartorius dysfunction).

Palpatory findings may include:

- Inguinal tenderness
- Tissue texture change (TTC) at the ipsilateral sacral sulcus
- Positive ASIS compression test on the involved side (see Fig. 41.8)
- Positive standing flexion test on the involved side
- Motion characteristics include freedom of posterior rotation about an inferior transverse axis on supine motion testing and resistance to anterior rotation.

Superior Innominate Shear (Subluxation)

This exists when the dysfunctional side has the following characteristics:

- ASIS is more superior (cephalad).
- PSIS is more superior (cephalad).
- Pubic ramus may be more superior (cephalad).
- Positive ASIS compression test on the involved side
- Positive standing flexion test on the involved side

Note: The reciprocal positioning of the ASIS and PSIS exists only if there is a pure superior shear without any rotation of the innominate.

The two innominates appear to be sheared so that the one hip bone is subluxed superiorly to the other.

Figure 41-8 ASIS compression test. (Modified from Kuchera WA, Kuchera ML. *Osteopathic Principles in Practice*. 2nd Ed. Rev. Columbus, OH: Greyden Press, 1994.)

Subjective complaints may include pelvic pain. Palpatory findings may include tissue texture changes at the ipsilateral SIJ and ipsilateral pubes. Motion characteristics include freedom of superior translation.

Inferior Innominate Shear (Subluxation)

This condition exists when the dysfunctional side has the following characteristics:

- ASIS is more inferior (caudad).
- PSIS is more inferior (caudad).
- Pubic ramus may be more inferior.
- Positive ASIS compression test on the involved side
- Positive standing flexion test on the involved side

The two innominates appear to be sheared so that the one ilium is subluxed inferiorly to the other. This condition is rare, and walking tends to reduce it. Subjective complaints may include pelvic pain. Palpatory findings may include tissue texture changes at the ipsilateral SIJ and ipsilateral pubes. Motion characteristics include freedom of inferior translation.

Innominate Flares

This condition is a positional change of an innominate in which the ASIS is medial or lateral to its usual position. This may be thought of as rotation of an innominate in relation to a vertical axis. If the ASIS is more lateral on the dysfunctional side, the patient has an innominate outflare. If the ASIS is more medial on the dysfunctional side, the patient has an innominate inflare. Inflares and outflares tend to occur simultaneously with innominate rotation. It would be common to see an anterior rotation of the ilium with a component of an inflare. It would also be common to see a posterior innominate with a component of an outflare. Subjective complaints may include pelvic or SI pain. Palpatory findings may indicate greater laxity in the muscles on the side that is more lateral and more tautness on the side that is more medial.

Pubic Somatic Dysfunction

Vertical Pubic Shears

Isolated vertical pubic shears (subluxations) may or may not actually exist. There may be evidence of a rotation or subluxation that is difficult to diagnose. However, there are times when the ASISs appear to be equal, the PSISs appear to be equal, and yet the pubes are definitely displaced so that one is detectably superior and the other inferior. Since the ASISs and PSISs are equal, it does not appear that the ilium is rotated or sheared. When the dysfunctional side is superior, it is said to be a superior pubic shear; if the dysfunctional side is inferior, it is an inferior pubic shear. More commonly, the clinician will find a superior pubic shear with an associated posterior ilium or an upslip. The same hold true for an inferior pubic shear and an anterior ilium or a down slip. Anterior pubic shears are uncommon, and are usually associated with trauma. In these cases, one side of the symphysis is anterior to the other.

Pubic Symphysis Compressions/Gapping

Pubic symphysis compressions occur, evidenced by bilateral tenderness of each pubic rami as well as tenderness centrally over the symphysis. Using the adductor muscles of the thigh in a muscle energy technique can reduce these compressions.

The L5 anterior counterstrain point is also located on the pubes. Treatment of this tender point with counterstrain technique

may be appropriate and necessary in treating pubic symphysis symptoms because what appears to be a pubic dysfunction may actually be reflexive evidence of L5 dysfunction.

Gapping or subluxation of the pubic symphysis can occur after childbirth, after pelvic fractures, or other traumas. Pelvic x-rays clearly document the degree of gapping. These are usually quite painful, and not easily treated. Treatment of the SIJs, core muscles, and applying lateral and anterior compression to the lateral aspects of the ilia with a SI belt may help. To review iliosacral and pubic diagnoses (Tables 41.4 and 41.5).

Other Considerations of the Pelvis

Unequal Hamstring Length

Unequal hamstring length can be considered either a pelvic or a lower extremity somatic dysfunction because the hamstrings are attached to both the pelvis and the lower extremity. If the hamstrings are of unequal length, standing flexion test results may be either falsely positive or negative. Therefore, it is imperative to treat the hamstrings and retest. If the standing flexion test and pelvic landmark positions normalize, the dysfunctional hamstrings were the problem. Otherwise, treat as indicated by the second diagnosis. If an innominate is anterior, it will separate the origin and insertion of the hamstrings, making the muscle tight and irritable.

Unequal Iliopsoas Length

Unequal psoas length may be suspected when pelvic side shift is present, when the upper lumbar lordotic curve is flattened, or when seated or prone evaluation suggests upper lumbar flexed somatic dysfunction. To test the ability of the psoas muscle to lengthen, place the patient in a prone position. Stand at the side of the table. Stabilize the ipsilateral pelvis with your free hand. Grasp the thigh just above the knee and extend the hip until the ASISs begin to rise off the table. Note the ease and degrees (quality and quantity) of hip extension on both sides. Also, on the tighter side, the leg appears heavier. Compare the two sides.

TABLE 41.4

Pubic Symphysis Dysfunctions

Diagnosis	Characteristics
Superior right	Positive right standing flexion test Superior right pubic tubercle Tense, tender right inguinal ligament
Superior left	Positive left standing flexion test Superior left pubic tubercle Tense, tender left inguinal ligament
Inferior right	Positive right standing flexion test Inferior right pubic tubercle Tense, tender right inguinal ligament
Inferior left	Positive left standing flexion test Inferior left pubic tubercle Tense, tender left inguinal ligament

TABLE 41.5

Iliosacral Somatic Dysfunction

Diagnosis	Characteristics
Anterior rotation right	Positive right standing flexion test Inferior right ASIS Superior right PSIS
Anterior rotation left	Positive left standing flexion test Inferior left ASIS Superior left PSIS
Posterior rotation right	Positive right standing flexion test Superior right ASIS Inferior right PSIS
Posterior rotation left	Positive left standing flexion test Superior left ASIS Inferior left PSIS
Outflare right	Positive right standing flexion test Lateral right ASIS Medial right PSIS
Outflare left	Positive left standing flexion test Lateral left ASIS Medial left PSIS
Inflare right	Positive right standing flexion test Medial right ASIS Lateral right PSIS
Inflare left	Positive left standing flexion test Medial left ASIS Lateral left PSIS
Superior shear (upslip) right	Positive right standing flexion test Superior right ASIS Superior right PSIS
Superior shear (upslip) left	Positive left standing flexion test Superior left ASIS Superior left PSIS
Inferior shear (down slip) right	Positive right standing flexion test Inferior right ASIS Inferior right PSIS
Inferior shear (down slip) left	Positive left standing flexion test Inferior left ASIS Inferior left PSIS

DIAGNOSIS OF SACROILIAC JOINT SOMATIC DYSFUNCTION

The most common and standard diagnoses of SI somatic dysfunction include (but are not limited to):

- Sacrum anterior
- Sacrum posterior
- Forward torsions (rotation of the sacrum on the same oblique axis):
 - Left rotation on left oblique axis
 - Right rotation on right oblique axis
- Backward torsions (rotation of the sacrum on the opposite oblique axis):
 - Right rotation on left oblique axis
 - Left rotation on right oblique axis

- Bilateral sacral flexion
- Bilateral sacral extension
- Unilateral sacral flexion (sacral shear)
- Unilateral sacral extension (sacral shear)

In the osteopathic profession, several models of SI dysfunction have been described. Three systems of nomenclature currently used to define sacropelvic mechanics are those described by Strachan (HVLA), Mitchell (muscle energy), and Van Buskirk (Still technique). The HVLA system is described in Walton's text, *Osteopathic Diagnosis and Technique, Sacroiliac Diagnosis* (22). Both the Chicago and Mitchell models describe similar events, but from differing points of reference. Both systems are based on physiologic motion of the sacrum, pelvis, and lumbar spine. However, the Strachan model does not describe or identify what the Mitchell system refers to as backward sacral torsions; just as the Mitchell system has no equivalent for Strachan's posterior sacrum.

The Still (Van Buskirk) model looks at the sacrum in a unique way (7). It looks at sacral dysfunction as more of a myofascial restriction that is present after the lumbar spine and pelvis has been already treated. The student of osteopathic medical profession needs to understand these three approaches in dealing with SI and pelvic somatic dysfunction.

Table 41.6 outlines the examination for somatic dysfunction of SI articulation.

The Mitchell Model

The model of SI motion and dysfunction most commonly taught in Colleges of Osteopathic Medicine is that developed by Fred Mitchell, Sr., D.O. and amplified by his son Fred Mitchell, Jr., D.O., and others. Mitchell introduced a new vocabulary, new concepts regarding SI motion, and new diagnostic tests. The first publication was an article in the 1958 *AAO Yearbook* entitled "Structural Pelvic Function" and republished in 1965. The following paragraph summarizes the new vocabulary, concepts and diagnostic tests contributed by Mitchell.

In the paper, the nomenclature never defined a relationship between the sacrum and the ilium, although he recognized that during the motion cycle of walking the ilia move back and forth in opposing directions. The focus was more centered of what was occurring between the sacrum and L5. The paper explained how the motion cycle of walking was utilized to analyze sacral, lumbar, and ilial motion. Three transverse axes of sacral motion were identified (superior, middle, inferior) and an oblique axis (upper pole on one side and lower pole on the opposite side). The Seated flexion test indicated the side of the SI dysfunction while the Standing flexion test indicated the side of the iliosacral dysfunction.

Mitchell described sacral torsions as oblique axis dysfunctions. They are named for the rotation of the sacrum in relation to L5. The terminology of sacral torsions does not name ilial motion/position in relation to the sacrum, although this is described in the diagnostic findings of sacral torsions. In torsions, lumbar side-bending engages the oblique axis, and the sacrum rotates about an oblique axis. *Forward torsions* were named right on right; or left on left with L5 following neutral mechanics. *Backward torsions* were named right on left, or left on right with L5 following nonneutral mechanics.

In relation to unilateral flexions, he described that they have a shallow sulcus and a posterior/inferior inferior lateral angle (ILA) on the same side.

TABLE 41.6

Examination for Somatic Dysfunction of SI Articulation

Position	Examination	Results
Step 1. Patient standing	Evaluate anatomic landmarks, standing flexion test	A positive standing flexion test means dysfunction in the leg and/or pelvis on that side.
Step 2. Patient seated	Perform seated flexion test	Will specifically determine whether there is a SI dysfunction, and if so, which side (but not which arm) of the SIJ is dysfunctional.
Step 3. Patient supine	Positional assessment of ASISs, pubic tubercles, and medial malleoli	Helps determine the etiology of the problem and whether it is purely sacral or a "mixed" problem, incorporating iliac and pubic dysfunction.
Step 4. Patient prone	Palpate for tissue texture changes, motion testing of the sacrum, motion testing of L5, ligamentous tension testing	Helps the physician discover which axis is involved, find what portion of the SIJ is restricted, determine L5 motion and position, and evaluate pelvic ligamentous tensions.

In the Mitchell muscle energy model of diagnosis, two assumptions are made when determining an iliosacral diagnosis. The first is that the dysfunction is due to neuromuscular imbalance, with the muscle(s) on one side being hypertonic and their opposites being hypotonic. The second is that the side of dysfunction is the side of the positive standing flexion test.

With regards to the innominates Mitchell's paper described the inferior transverse axis for innominate rotation. The anterior and posterior innominate rotation was basically unchanged from the older models. He also discussed the innominate upslip (superior translation or shear) as first described by Fryette. He also commented on pubic shears.

The Mitchell model, being based on the motion cycle of walking, teaches that a pubic shear prevents normal motion of the pelvis, lumbar spine, and sacrum during walking.

The following are the diagnostic tests he described:

- Standing and Seated flexion test
- Lumbosacral spring test
- Backward bending test
- Positional assessment was utilized
- All motion testing is limited to sagittal plane motion
- Palpation for tissue texture abnormality was not described in 1958.

The Mitchell model uses positional asymmetry and the backward bending and spring tests to obtain a diagnosis of sacral dysfunction. Palpation for TTC and passive motion testing of sacral motion about the oblique axes was not part of their diagnostic process.

Following introduction of his concepts to the osteopathic profession, a Muscle Energy Tutorial Committee was created. The Muscle Energy Tutorial Committee met for a number of sessions, and developed a curriculum for teaching the "Mitchell Model" and muscle energy technique. With the development of new schools of osteopathic medicine (in addition to the five existing schools), the faculty of the new schools received tutorial training in the Mitchell muscle energy model. By sheer numbers, the Mitchell model became the language of the osteopathic profession.

The Chicago Model

The Chicago model dates back to the late 1930s, when Strachan, D.O. (CCO anatomy professor) et al. conducted a cadaveric

SI motion study. Strachan's findings are discussed in the section on Biomechanics and motion. The Chicago/HVLA system is described in Walton's text, *Osteopathic Diagnosis and Technique, Sacroiliac Diagnosis* (22). Strachan's model describes sacral dysfunction in relation to the ilium rather than to L5. Historically, prior to Mitchell's paper in 1958 on structural pelvic function (13), SI problems were described as the sacrum in relation to the ilium, or the ilium in relation to the sacrum. Dysfunctions include anterior sacrum and posterior sacrum. Sacral movement is around an oblique axis: motion may be restricted at either the upper or lower arm of the L- (C-) shaped SIJ. Note that the ILA is not the lower arm of the joint, but a portion of the sacrum used for palpation and positional reference. The sacrum is diagnosed as either anterior or posterior to the ipsilateral ilium (Table 41.7).

Any discussion of the Chicago model must begin with an understanding that the sacrum is described in relation to the ilium. This seems a very logical approach when discussing the SIJ. There are two SIJs, one on either side. It is entirely logical when evaluating the relationship of the sacrum to the ilium that both sides can and should be explored for diagnostic findings. It always has depended on palpation for tissue texture changes as well as looked at anatomic asymmetry. In the early days, Philadelphia preferred to name the ilial position in relation to the sacrum. The Chicago model recognized a right and a left SIJ. SI dysfunctions were further classified as upper pole dysfunctions and lower pole dysfunctions. The model uses asymmetry of position, tissue texture change, and motion testing about each oblique axis to arrive at the diagnosis. In the Chicago model, the relationship between the sacrum and L5 (the lumbosacral joint) is not defined. Assessment of L5 requires a separate assessment. L5 position is not a part of the terminology of a Chicago SI lesion. Ordinarily, L5 rotates in the opposite direction of the sacrum. The term "compensated L5" has been applied to this relationship. (See Nelson, the Sacrum, a bone of contention.) The Chicago model delineates two primary sacral dysfunctions; the anterior sacrum and the posterior sacrum. Both dysfunctions involve the oblique axis. Described below are the clinical findings of each.

An anterior sacrum left would be described as an upper pole dysfunction on the left. The left sacral sulcus would be deep in relation to the ilium. The sacrum dysfunction would be described as sacral rotation right, sidebending left, with a deep sulcus left,

TABLE 41.7

Chicago Model Sacral Dysfunctions

Diagnosis	Characteristics
Anterior right	Positive seated flexion test right Deep and tender right sacral sulcus Left ILA immobile to downward/ anterior compression
Anterior left	Positive seated flexion test left Deep and tender left sacral sulcus Right ILA immobile to downward/ anterior compression
Posterior right	Positive right or left seated flexion test Deep left sacral sulcus Posterior and inferior right ILA TTC over lower pole of SI joint Right ILA immobile to downward/ anterior compression
Posterior left	Positive right or left seated flexion test Deep right sacral sulcus Posterior and inferior left ILA TTC over lower pole of left SI joint Left ILA immobile to downward/ anterior compression

tenderness and tissue texture abnormality were found in the deep sulcus. In the early days, the term oblique axis was not used. However, sacral rotation right and sidebending left would be motion about a right oblique axis.

A posterior sacrum is a lower pole dysfunction. A posterior sacrum right involves sacral rotation right and sidebending left. However, the right ILA is posterior, with tissue texture abnormality and tenderness over the lower pole of the SIJ on the right. A posterior sacrum is a form of oblique axis dysfunction in which the deep sulcus and posterior ILA are on opposite sides.

Both the anterior sacrum left and a posterior sacrum right could be described as “right on right” dysfunctions. Yet they are quite different. From the perspective of someone who understands the difference, treatment can be very specific. The muscle energy technique for torsions is a form of lumbar sidebending technique.

What about unilateral flexions and extensions? Strachan reported in 1938 “When a force is transmitted vertically downward from the lumbar region, the sacrum glides downward and flexes. When traction is applied from above, the sacrum glides upward and extends.” Strachan has defined the motion of unilateral flexions and extensions. If a downward force causes the sacrum to glide and flex, and for some reason the sacrum gets “stuck” on that side, a unilateral flexion exists. Positionally, the sulcus will be deep, and the ILA is posterior/inferior on the same side. Since gravity is always producing a downward force, unilateral flexions are reasonably common.

Unilateral extensions are rare, because a traction-type force from above is necessary to glide the sacrum upward. Strachan also stated that the major motions of the sacrum are flexion-extension and gliding up and down. He considered restrictions of the minor motions (rotation and sidebending) to be treated first.

Pelvic Sideshift

The Chicago model also describes the concept of pelvic sideshift. The model looks at pelvic side shift as an etiology and a maintaining factor of SI dysfunction.

Pelvic side shift is not a part of the Mitchell model. Pelvic side shift is a significant cause of SI dysfunction. If the pelvis is side shifted to the right, the body compensates by shifting lumbar mass to the left. A curve, convex left, is created. The sacrum must sidebend to accommodate the curve. The sacrum side bends left. Since the sacrum normally rotates to the opposite side of sidebending, the sacrum rotates right. This will produce an anterior sacrum left or a posterior sacrum right (or a right on right torsion). What causes pelvic sideshift? There are two general causes: (a) muscle-pull mechanics, dominantly psoas, and (b) postural imbalance from short leg, curves, trauma, etc. Since sideshift is not a part of the Mitchell model, many students are not taught to test for pelvic side shift. Side shift is a condition where the base of support (sacrum) is lateral to the midline. Significant side shift can be determined by simple inspection. Given the reality that positional change and freedom of motion are in the same direction, sliding the pelvis to one side or another will reveal freedom in one direction and restriction in the other direction. Dysfunctions are named for the freedom (which is also the position).

Side shift can also be evaluated with the patient prone. Simply grasp the pelvis and translate it to either side.

Chicago Philosophic Approach

The Chicago model is more than just two sacral dysfunctions and the pelvic sideshift test. The philosophic approach taught for generation's stems from the teachings of Robert Kappler, D.O., F.A.A.O. His pragmatic clinical approach cuts through the didactic biomechanical models and focuses on the patient. The approach starts with the clinician looking for an answer to the question, “Why is the sacrum in trouble?” It also stresses palpation for TTC as they signify altered physiology. Lastly, the philosophy stresses the concept of repeating the seated flexion test at the end of treatment to objectify the treatment response. In conclusion, anterior sacrum's and posterior sacrum's are definite clinical entities. Understanding these conditions, and knowing how to diagnose them, will provide a more specific and comprehensive understanding of the SI problem, and its causes.

Approach by Edward G. Stiles, DO, FAAO

Dr. Edward G. Stiles has put forth the idea that in the normal physiological relationship between the ilia and the sacrum each of these three axes performs a different function (personal communication). According to his research the superior pole corresponds to the axis of rotation for craniosacral motion and the cranial rhythmic impulse. Dr. Stiles proposes that the middle poles have to do with sacral flexion and extension (e.g., lumbosacral flexion and extension). The middle pole is therefore the natural axis for ili-osacral interaction. The inferior poles are proposed to be the axes for diagonal rotation of the sacrum in relation to the innomates and the lumbar spine.

Contributions of Richard L. VanBuskirk, D.O., F.A.A.O.: The Still Technique Model

Another important concept that is the emerging nature of SI disturbances which remain after treatment of the lumbar spine and pelvis is ligamentous and fascial and contrasted to a bony positional change of the sacrum and the ilium. A. T. Still commented (Research and Practice) that after a technique is done, and the restriction comes back, the problem is the ligaments and fascia. (Still) The Still model demonstrates that after treatment of lumbar and innominate somatic dysfunctions, only two types of sacral dysfunctions seem to remain. Both of these sacral dysfunctions behave as if the sacrum was fixated at two of four restriction points, one superior, and one inferior on each side. The two superior restrictive axis points are on the sacral base just medial to the PSISs of the ilia and inferior to L5. The two inferior restrictive axis points are in the area of the origins of the sacrotuberous ligaments on the lower part of the sacrum, the ILA. (7) A restriction in one of the two superior axis points is identified during a seated flexion test in which the sensing fingers are firmly placed on the sacral sulcus. If there is a restriction the sacral sulcus will ride superior during the patient's flexion at the waist. A restriction in one of the inferior axis points can be identified by tightness of the tissues to any form of direct motion testing, tightness in the sacrotuberous ligament, and by inferior and/or posterior position of the ILA.

The seated flexion test as done by Van Buskirk differs from the Mitchell model seated flexion test. The tips of the sensing fingers are placed over the SI joint just medial to the PSIS at the level of the sacral base or sulcus. A positive test is indicated when the patient bends forward and the sensing finger travels superior in relation to the other side.

The second test is the position of the ILA, with the patient seated. This is checked at the sacrotuberous ligament. This is said to be positive if one ILA is posterior and doesn't move anteriorly, if the sacrotuberous ligament is tight on that side, or if the ILA is more inferior on that side. The positive side is that of restriction.

A positive seated flexion test on one side and a positive ILA test on the other side are diagnostic of a *diagonal sacrum*. Van Buskirk describes that whenever a diagonal SI dysfunction is found, there will be a corresponding single segment lumbar neutral dysfunction. This neutral lumbar dysfunction commonly will be found at L5.

If the positive seated flexion test and the positive lateral angle test are on the same side, the diagnosis is a *unilateral sacrum* (Table 41.8). The sacral diagnosis will be named for the pattern of free axis points (i.e., whether they are diagonal to each other or on the same side) and the free direction of rotation of the sacral base. These dysfunctions are effectively treated with a Still technique.

Despite the differences of the various models of SI dysfunction, from a clinical perspective, there is a generalized agreement among practicing physicians that the pubes, pelvis, and lumbar spine must be effectively treated before treating the SIJ.

Ilia

Innominate function and dysfunction involve shifts in iliosacral motion among the three described axes. Van Buskirk finds that most of the motion is across the superior and inferior axes with little or no motion in the middle axis (7). The Still Model uses the following five tests to evaluate the ilia:

- PSIS position
- ASIS
- Pelvic translation or ASIS compression test

TABLE 41.8

Still Model Sacral Dysfunctions

Diagnosis	Characteristics
Diagonal right	Positive right seated flexion test Positive left ILA test
Diagonal left	Positive left seated flexion test Positive right ILA test
Unilateral right	Positive right seated flexion test Positive right ILA test
Unilateral left	Positive left seated flexion test Positive left ILA test

- ASIS tenderpoint
- Standing flexion test

There is no single test or even pair of tests that predict the nature of the iliosacral somatic dysfunction. Van Buskirk finds that innominate somatic dysfunctions act as if the normal axis of motion at the middle pole of the SIJ has been transferred to the other axes. The anterior innominate dysfunction, characterized by PSIS superior and ASIS inferior on the affected side, acts as if there were a restriction at the inferior pole of the SIJ. That is, attempts to move the innominates seem to isolate to the inferior SI pole rather than the normal middle pole. The posterior innominate dysfunction, characterized by PSIS inferior and ASIS superior on the affected side, acts as if there were a restriction at the superior pole of the SIJ.

The Still model also recognizes up slipped and down slipped innominates. Down slipped innominates are rare in clinical practice, and are usually created by a traumatic pull to the leg. Listed below, Van Buskirk relates how up slipped innominates can occur:

- Asymmetrical weight bearing on one leg for a prolonged time
- Upward shear on the side of the shoe lift
- Longer leg may develop an upward pelvic shear.
- Trendelenberg gait (see gluteus medius below) or a limb can cause an up slipped innominate.

No single treatment using the Still Technique has been found which resolves the up slipped innominate completely. According to Van Buskirk, the only complete success requires treating each of the three restriction poles. When treatments focused on each of the three poles are performed during the same session, the dysfunction seems fully released, and does not reoccur as readily.

Pubes

Regarding the pubes, Van Buskirk feels that pubic ramus evaluation is a poor test for iliosacral dysfunction. With the Still technique model, treatment of innominate dysfunctions often reduces pubic ramus dysfunctions. For that reason, Van Buskirk typically evaluates and treats the innominate dysfunctions first. Clinically, Van Buskirk will evaluate and treat the external abdominal oblique and the ilioinguinal ligament when there is a pubic dysfunction. When diagnosing these muscles and the pubes, evaluation includes palpating for tenderpoints on the ASIS and lateral pubes. If a tenderpoint is present at both sites the dysfunction will involve the external abdominal oblique. If the tenderpoint includes only the insertion on the lateral pubes, the ilioinguinal ligament is involved.

The pubic dysfunction is treated before the external abdominal oblique and/or the ilioinguinal ligament.

Psoas

With psoas dysfunction, leg extension will be markedly restricted and the foot will tend to be everted. Leg extension is evaluated with the ilium stabilized. Another finding related to psoas dysfunction is a referred tenderpoint found on the anterior-lateral aspect of the thigh, just inferior and about 1 cm medial to the inferior ASIS (7). Van Buskirk finds this tenderpoint routinely when there is a psoas restriction.

Clinical Application of the Models

SI dysfunction is described in this chapter using the most consistent criteria of all three systems. No matter which model is used, to integrate the following information into the clinical arena, the physician must consider three questions:

1. Is the sacrum in trouble?
2. Why is the sacrum restricted?
3. What are we going to do for the patient?

Somatic Dysfunction of the Sacrum

Sacral Torsions

The Mitchell system, based on the cycle of walking (as previously detailed), describes sacral motion relative to L5. The sacrum can move forward or backward about left and right oblique axes depending on the individual's center of gravity and gait, can flex or extend around a transverse axis, or can shift in the L- (C-) shaped articulation, causing a shear. Mitchell's dysfunctions include sacral torsions. Sacral torsions refer to motion at the lumbosacral junction where the sacrum and L5 are rotating in opposite directions. Rotation of the sacrum is movement about an oblique axis or diagonal axis. Sacral torsion does not describe a relationship between the sacrum and the ilium.

Forward Torsions

Forward torsions occur when the lumbar spine is in neutral. In this example, side bending of the lumbar spine to the left (during the motion cycle of walking) engages the left oblique axis. The lumbar spine, in neutral, rotates right with left side bending. Since the left oblique axis is engaged, the sacrum rotates left about the left oblique axis, producing a deep sacral sulcus on the right. Torsion implies that the sacrum has rotated left, while the lumbar spine has rotated right. (Note that, with neutral lumbar mechanics, left side bending produces rotation right.) The term forward torsion is derived from the observation that, in the erect posture, the sacrum is in a flexed forward position (45 to 55 degrees from the vertical, or 35 to 45 degrees from the horizontal). The Ferguson lumbosacral angle is measured from the horizontal. There are two forward torsions: left rotation on a left oblique axis (left on left), and right rotation about the right oblique axis (right on right). Positional findings with each of the two forward torsions include those shown in Table 41.9.

In the normal motion cycle of walking, the sacrum rotates from side to side. Dysfunction in the form of a forward torsion occurs when the sacral base rotates forward, becomes restricted, and does not rotate back as far as it should. The forward sacral torsion and anterior sacrum have several findings in common. Subjective complaints include SI, inguinal, or groin discomfort and low back pain. Objective findings include freedom of rotation anteriorly about

TABLE 41.9

Mitchell Model SI Somatic Dysfunction

Diagnosis	Characteristics
Unilateral flexion right	Positive right seated flexion test Deep right sacral sulcus Inferior/posterior right ILA
Unilateral flexion left	Positive left seated flexion test Deep left sacral sulcus Inferior/posterior left ILA
Unilateral extension right	Positive right seated flexion test Shallow right sacral sulcus Superior/anterior right ILA
Unilateral extension left	Positive left seated flexion test Shallow left sacral sulcus Superior/anterior left ILA
Left on left torsion	Positive right seated flexion test Deep right sacral sulcus Posterior left ILA L5 rotated right, sidebent left Left base restriction
Right on right torsion	Positive left seated flexion test Deep left sacral sulcus Posterior right ILA L5 rotated left, sidebent right Right base restriction
Right on left torsion	Positive right seated flexion test Shallow right sacral sulcus TTC right sulcus Posterior/inferior right ILA L5 rotated left, sidebent left, nonneutral Left base restriction
Left on right torsion	Positive left seated flexion test Shallow left sacral sulcus Posterior/inferior left ILA L5 rotated right, sidebent right, nonneutral Right base restriction
Bilateral flexion	Bilateral positive seated flexion test Bilaterally deep sacral sulcus Bilaterally posterior/ILA Middle pole restriction
Bilateral extension	Bilateral positive seated flexion test Bilaterally shallow sacral sulcus Bilaterally anterior ILA Inferior pole restriction

an oblique axis, with sacral side bending and rotation in opposite directions. There is an increased lordotic curve. Spinal asymmetry and postural imbalance are noted: The sacrum has rotated in a direction opposite to the supported lumbar. There is an ipsilateral positive seated flexion test, deep sacral sulcus with tissue texture abnormality, possible psoas tension, and short leg. Neutral mechanics

apply to L5, with side bending and rotation to the opposite side. However, rotation of L5 is also in a direction opposite to that of the sacrum.

Backward Torsions

Backward torsions (nonneutral) occur when the lumbar spine is in nonneutral (flexion or, where the curve exceeds normal lordosis, extension) and the sacral base rotates posteriorly about the opposite oblique axis. While they do not occur within the cycle of walking, they are associated with physiologic motion when a person forward bends and then side bends. Consider a patient in the standing position who bends forward. The sacrum actually extends or backward bends at this time. The lumbar spine is flexed to a point where any multiple plane motion results in nonneutral multiple plane motion. The patient reaches sideways to pick up an object. The lumbar spine side bends to the right from the nonneutral sagittal plane position. The right oblique axis is engaged as a result of the right side bending. L5 rotates right according to nonneutral lumbar mechanics. The sacral base moves posteriorly at the left base as the sacrum rotates to the left according to sacral nonneutral mechanics. This example is called left on right (left rotation about the right oblique axis). There are two types of backward sacral torsions: right rotation on a left oblique axis (right on left), and left rotation on a right oblique axis (left on right). Positional findings with each of the two backward torsions include those shown in Table 41.9.

A backward torsion is not the same as a posterior sacrum. A posterior sacrum is a type of forward torsion in which the inferior portion of the sacrum is posterior. In a backward torsion, the posterior portion is at the sacral base (the shallow sulcus).

Subjective complaints include low back pain or SI discomfort that gets worse when bending forward or walking. Objective findings include those listed above, plus a decreased lordotic curve. Palpatory findings include tissue texture abnormality and a shallow sacral sulcus on the side of the dysfunction, with tissue texture abnormality at L5. Nonneutral mechanics apply to L5, with rotation and side bending occurring to the same side and opposite the side of the sacrum's rotation. According to Kappler, his experience treating backward torsions involves the following findings (R.E. Kappler, *personal communication*):

- Significant tissue texture abnormality and tenderness is located over the shallow sulcus.
- Sacrum resists applied flexion, and it is painful.
- There is usually a mid-lumbar flexed type II dysfunction on side opposite the shallow sulcus.
- Psoas tension is usually not a factor.
- Treatment of backward torsions:
 - Treat the innominates
 - Treat the mid-lumbar flexed dysfunction

Bilateral Sacral Flexion

If the sacrum is flexed forward, with the sacral base anterior, the lumbar lordosis appears to be increased, the seated flexion test is negative, the sacral sulci are bilaterally deep, and the ILA's are posterior. It is postulated that this motion occurs about a middle transverse axis of the sacrum. This is called a bilateral sacral flexion. When the lumbosacral spring test is performed, there is good spring (a negative test) because the sacral base, already anterior, moves forward easily. If the backward bending test is done, the sacral sulci is still deep (if not deeper), and the ILA's are still posterior (or more posterior) because the base of the sacrum normally moves forward and the apex moves posteriorly during backward bending of the lumbar region.

This is an extremely common dysfunction in the postpartum female because of birth mechanics. Subjectively, the patient complains of low back pain that becomes worse when bending backward. Objective findings include:

- Increased lumbar curve
- Deep bilateral sacral sulci with tissue texture changes
- Bilateral ILA's posterior
- Negative lumbar spring test
- No change with the hyperextension test

Motion characteristics include resistance to posterior rotation of the base of the sacrum if pressure is placed on the apex.

Bilateral Sacral Extension

In some cases, the patient does not have a positive seated flexion test, yet complains of low back pain, and the sacrum seems to be at the center of the problem. At that time, the sacral sulci should be examined, the ILA's checked, the spring test and backward bending test performed, and a careful analysis made of the relationship of the sacrum to the lumbar spine. The lordotic curve may be increased or decreased. With postural flexion at the lumbar spine (forward bending), the sacrum extends (the base moves posterior), and there is a decrease in the lumbar lordotic curve. If the lordotic curve seems to be decreased, it may be that there is a posterior sacral base. In a bilateral extension, the sacrum is held in a backward bent position and does not easily bend forward. The lumbosacral spring test is therefore positive, which means there is either poor spring or no spring. Sacral sulci and ILA's should appear symmetric in either prone or backward bending positions, and, if there is any difference on the backward bending test, the sulci look more shallow, and the ILA's more anterior.

Subjectively, the patient complains of low back pain or fatigue that becomes worse with forward bending. Objective findings include:

- Decreased lumbar curve
- ILA's equal and perhaps anterior
- Positive lumbar spring test
- ILA's stay equal during hyperextension test (superior/inferior)
- Sacral sulci are bilaterally shallow, with tissue texture changes
- Sacrum resists posteroanterior pressure at base, but yields to posteroanterior pressure on apex

Sacral Shears

The sacrum can appear as if it has slipped anteriorly or posteriorly around a transverse axis that allows it to shift within the L- (C-) shaped SIJ. If it slips forward, it produces a finding called a sacral shear or unilateral sacral flexions and extensions. ECOP has concluded that "shears" and unilateral sacral flexions and extensions are the same thing.

Unilateral Sacral Flexion

If there is a positive seated flexion test, with the base of the sacrum anterior on the dysfunctional side (sacral sulcus deep on that side) and the ipsilateral ILA is posterior, the patient has a unilateral sacral flexion. The ipsilateral medial malleolus is more inferior, and the transverse process of L5 is more posterior on the dysfunctional side. Both sides of the sacral base move anteriorly with exhalation but do not move easily in a posterior direction with inhalation. The spring test should be negative, since the base of the sacrum moves anteriorly easily when it is flexed. The backward bending test should show improvement because, while the one side is flexed

forward, making the sacral sulcus deep, when the patient bends backward the other side of the sacral base should be pulled forward, increasing symmetry.

Unilateral Sacral Extension

If there is a positive seated flexion test, with the base of the sacrum posterior on the dysfunctional side (sacral sulcus shallow), and the ipsilateral ILA is anterior, the patient has a unilateral sacral extension. To confirm this, test the patient with the spring test and the backward bending test. The spring test should be positive, since the base of the sacrum does not move anteriorly easily when the sacrum is held in an extension position. On the backward bending test, the sulci and ILAs should look even less symmetric because, while the one side is held backward, making the sacral sulcus shallow, when the patient bends backward; the other side of the sacral base should be pulled forward, making the results look worse.

Anterior Sacrum

An anterior sacrum is a positional term describing a somatic dysfunction in which the sacral base has rotated forward and side bent to the side opposite the rotation. The upper limb of the SIJ has restricted motion, and the dysfunction is named for the side on which forward rotation occurs. An anterior sacrum is probably one type of Mitchell's forward torsion. For example, anterior sacrum left describes a condition in which the sacrum is rotated right and side bent to the left, the directions of ease of motion. (This could also be considered right rotation about a right oblique axis.) There is restriction of left rotation and right side bending. The sacral sulcus is deep on the left, with tenderness and tissue texture abnormality in the left sulcus. When downward pressure is applied over the right ILA, attempting to rotate the sacrum about the right oblique axis, the left superior portion of the sacrum resists moving posteriorly, toward the ilium.

The anterior sacrum is clearly an "oblique axis dysfunction". Therefore, it is one form of a forward torsion with motion restriction, tissue texture abnormality, and tenderness associated with the deep sulcus side. An anterior sacrum (e.g., anterior sacrum left) has the following characteristics:

- Deep sulcus left, (right ILA posterior)
- Tissue texture abnormality and tenderness in the deep sulcus
- Right rotated, left sidebent
- Positive seated flexion test left
- Left sacral base will not move posteriorly when pressure is applied to right ILA.
 - (This motion test would involve the right oblique axis.)
- The conceptual model is that anterior sacrum's are an upper pole dysfunction (upper part of the "L" shaped articulation.).
- Because the sacrum is sidebent left, the left SI is the "compressed side". In the standing position, the left sacral base will be lower (inferior).
- Gluteus medius hypertonicity and tenderness were commonly found on the side of the anterior sacrum.

Posterior Sacrum

A posterior sacrum is diagnosed when the sacrum has rotated backward and is side bent to the side opposite of rotation. It is named for the side of the backward or posterior rotation. This rotation side bending to the opposite side could be considered rotation about an oblique axis. The posterior sacrum is on the side opposite the deep sulcus at the inferior pole of the joint. The patient

experiences discomfort at the inferior arm of the SIJ and possibly sciatic pain. There is a pelvic side shift to the side of dysfunction, spinal asymmetry, and postural imbalance. The seated flexion test may be positive on either side of a posterior sacrum dysfunction. There is ipsilateral piriformis tension, and the ipsilateral ILA is posterior and inferior. There may be contralateral psoas tension, and there is generally a contralateral short leg. For example, a posterior sacrum right has rotated right and side-bent left, the directions of ease of motion; rotation left and side-bending right are restricted. A posterior sacrum involves restriction of motion at the lower limb of the SI articulation. Tissue texture abnormality and tenderness are located over the inferior portion of the dysfunctional SIJ; in this example, the tenderness is on the right. The rotation, in this case, is in relation to the right oblique axis. A posterior sacrum is probably a form of forward torsion in which the major joint motion restriction is on the side opposite the deep sulcus. A motion test for lower pole (lower limb of the L) restriction (e.g., posterior sacrum right) is to contact the inferior borders of the sacrum with both thumbs and apply a cephalad/anterior force, attempting to glide the sacrum in the direction of the lower limb of the joint. Restriction is felt on the posterior sacral side. Although there are similarities between the posterior sacrum and the forward torsion, there is no true Mitchell equivalent to Strachan's posterior sacrum. A posterior sacrum should not be confused with a backward torsion, a posterior sacral base, or an extension of the sacrum.

The posterior sacrum is an oblique axis dysfunction. Therefore, it is a form of forward torsion with tissue texture abnormality, tenderness, and motion restriction on the side of the lower pole. A posterior sacrum (e.g., posterior sacrum right) has the following characteristics:

- Right ILA posterior (deep sulcus left)
- Tissue texture abnormality and tenderness at the right inferior pole (lowest part of the SI joint)
- Right rotated, left sidebent.
- Positive seated flexion test on right (usually)
- Confirmatory motion test, patient prone. Pressure on the inferior surface of the sacrum applied in a superior-anterior direction, trying to glide the sacrum superiorly along the lower limb of the "C"-shaped articulation, is met with resistance. The ILA is inferior, and resists moving superiorly. The conceptual model is that of a lower pole SI restriction.
- From a sidebending perspective, the posterior sacrum is on the "stretch side" of the SI problem
- A posterior sacrum is not included in the Mitchell model.
- Piriformis muscle hypertonicity and tenderness is commonly found on the side of the posterior sacrum.

Unilateral Sacrum

A positive seated flexion test on one side and a positive ILA test on the other side are diagnostic of a *diagonal sacrum*.

Diagonal Sacrum

If the positive seated flexion test and the positive lateral angle test are on the same side, the diagnosis is a *unilateral sacrum*. To review sacral diagnoses, refer to Table 41.8.

Integrated Diagnosis of the Lumbar Spine, Sacrum, Pelvis

Understanding all the above-mentioned portions of the physical examination, and the characteristics of the specific dysfunctions,

the clinician now needs to evaluate the sacrum and lumbar spine. Start with interpreting the standing flexion test, pelvic sideshift and the seated flexion test. Before diagnosing the sacrum, diagnose the lumbar spine in the prone position. To review the specifics of this see the chapter on lumbar spine. It is a good time to evaluate for segmental dysfunction and Jones tenderpoints. In addition to generalized changes in the pelvic girdle tissues, the physician may detect small myofascial tender points. Such areas may be characterized by a small, palpable, circumscribed thickening of tissue that is tender with moderate to deep palpation. These tender points may be associated with autonomic dysfunction or refer pain to a neurologic distribution. Muscles containing tender points reveal pain with active or passive range of motion. There may be areas of patchy weakness in the range of motion of muscles containing painful tender points. Joints controlled by muscles with tender points may have a diminished range of motion. The pelvic girdle contains many of these myofascial tender points because myofascial structures are constantly working to maintain postural balance. Numerous authors (18–20) have indicated continuous postural strain as the cause of precipitating and/or perpetuating myofascial tender points. Tenderpoints also correspond to segmental dysfunction.

Segmental dysfunction in the upper lumbar (L1-2) that is flexed is typically involved with a tight psoas muscle (23). A tight psoas muscle is characterized by a decrease in hip extension on physical examination. A tight psoas will cause pelvic sideshift and apply a compressive load across the SIJ, contributing to the dysfunction (23). Another relationship commonly found by Kappler (R.E. Kappler, *personal communication*) is a flexed lumbar segment at L2 or L3 is seen in conjunction with a backward torsion. The segment will be rotated in the opposite direction of the torsion. Treatment of this segment, many times will improve the backward torsion. When there is a forward sacral torsion, there is usually a group curve convex opposite to the side of sacral rotation. For unilateral sacral flexions, L4 or L5 may be extended rotated and sidebent to the same side. For unilateral sacral extensions, L5 may be flexed or significantly restricted. Sometimes in these dysfunctions, there is unilateral muscle hypertonicity over and along the whole SIJ. In this situation, there is usually significant ipsilateral thoracolumbar tension/findings as well as findings in the upper thoracic spine and cranium. Many times in patients with significant SI restrictions, there are alternating single segment lumbar dysfunctions (e.g., L1 left, L2 right, L3 right, L5 left). In the patient with significant SI dysfunction that has little or no findings in the lumbar spine, carefully check L5. It is not uncommon for disc herniations to have minimal lumbar somatic dysfunction, yet maximal leg symptomology. Another evaluation method is to apply the lumbosacral spring test to the L5 spinous process. Decreased spring indicates a backward torsion. If sharp or severe pain occurs with the spring test, they may have a disc protrusion or a spondylolisthesis. In either situation, they will commonly have bilateral muscle tension from T10-L1 as well as an anterior L5 Jones tenderpoint. With significant pain the sympathetics become involved and travel up to the low thoracic cord, cause facilitation and this produces palpable muscular tension. Patients with L5 discs, spondylolisthesis, backward torsions, or any significantly painful L5 condition, will have the anterior Jones tenderpoint nearly 100% of the time. If no pain occurs with springing L5, look more closely at the ilia and pubes, as well as the cranium. Palpable strains in the cranial mechanism correlate to sacral motion restrictions due to the continuity of the dural membrane. Skilled osteopathic physicians are able to palpate inherent motion of the human body. Physicians trained in cranosacral diagnosis can palpate this motion in the sacrum as the cranosacral mechanism moves the sacrum between the two ilia.

Following assessment of the lumbar spine, check for restriction of hip extension, indicating a tight psoas muscle. From here, evaluate the sacrum for position and motion. Check the sacral sulci for depth, tenderness and tissue texture change TTC. A deep sulcus may indicate an anterior sacrum or forward torsion. A shallow sulcus with diffuse TTC and significant tenderness usually correlates with a backward torsion. A positive backward bending test confirms this. Then motion test the sacrum on each theoretical oblique axis. Look for the restriction of motion, but name it for the freedom of motion. Palpate for TTC over the upper and lower poles of the SIJs, as well as for tenderness/tension of the piriformis muscle. From here, the clinician will attempt to glide the lower aspect of the sacrum cephalad along the joint by applying a firm pressure alternating between the thumbs. Resistance to motion is seen with a posterior sacrum dysfunction, or any dysfunction in which the lower pole of the sacrum is involved. If a posterior sacrum is present, check the piriformis for tenderness, and the pelvic floor on that side. Checking for tension in the ischiorectal region is important, especially in patients with pelvic pain, and postoperative cases. When the patient coughs muscular tension, or pressure, is bilaterally palpated. If no movement occurs, the SI dysfunction is affecting the movement of the pelvic floor musculature. If there are findings associated with a backward torsion such as a shallow sulcus with diffuse TTC and significant tenderness, confirmation can be done with the backward bending and spring tests.

Have the patient lie supine and perform an abdominal examination. For evaluation of the pelvic girdle, a complete examination of the abdomen is required. Following inspection, auscultation, and palpation, the physician can percuss the liver, spleen, and stomach, and palpate for any pelvic masses. A rectal examination, a pelvic examination in the female, and a prostate examination in the male should be a part of a complete examination of the pelvic/sacral region.

At this point, evaluate the ilia in the supine position. Start with the position of the ASISs by evaluating their position at the inferior portion of each ASIS. Perform the ilium compression test, pushing downward, cephalad, and lateral to the ASIS. An assessment of rotational restriction of the pelvis can be performed as well. At this point, palpate for tension of the musculature of the inguinal region. The more localized areas of tension usually have more tenderpoints. Assess for Jones anterior tenderpoints, and correlate them to what was found segmentally in the lumbar spine. Assess the pubic ramus for asymmetry and motion. Evaluate to see if one pubic ramus is superior or inferior, as well as anterior or posterior (rare). A direct motion test on the pubes can be performed if necessary. If the pubes is anterior the pelvis will rotate away from the dysfunctional side. Screen the hip joints for restrictions in internal rotation, flexion, and abduction/external rotation. Special orthopedic tests of the hips SIJs, and ilia can be performed at this time. See Table 41.10 for these tests. Check the attitude of the feet, the levelness of the medial malleoli, and fascial drag in each extremity by a brief light internal rotation motion.

Evaluation of the sacrum and/or pelvis can be done in the seated position for those patients who cannot lie down. The seated flexion test should be done before treatment and at the end of treatment. Although a positive seated flexion test is not a very sensitive or specific test, its greatest utility is that it returns to negative after manipulative treatment is completed. Kappler, D.O., F.A.A.O. (R.E. Kappler, *personal communication*) has devised a translation test performed in the seated position that assess motion at the sacral sulci by translating the lumbar spine back and forth. The authors find this a very useful test in older, obese, and pregnant patients. In the seated position, the motion of the abdominal diaphragm

TABLE 41.10

Commonly Used Osteopathic SI Tests**Osteopathic SI Tests Characteristics**

Standing flexion test	PSIS moves cephalad Indicates SIJ dysfunction
Seated Flexion test	PSIS moves cephalad Indicates SIJ dysfunction
Pelvic sideshift	Pelvis shifts off to one side Indicates contralateral psoas or lumbar dysfunction
Hip drop	One leg standing produces lumbar curve Indicates lumbar dysfunction
Backward bending test	Prone, prop-up alters sulcus depth Asymmetry of sulcus depth increases
Spring test	Prone, anterior springing of L5 Poor spring = positive test
Iliac compression test	Supine, posterior/lateral compression Poor motion = positive test
Posterior sacrum confirmatory test	Prone, superior glide of sacral lower pole Restricted superior glide = positive test
Kappler Seated Translation Test	Seated, palpate sacral sulci for motion as the lumbar spine is translated toward the sulci. Restricted motion = positive test

(as well as its excursion) can be evaluated, which many clinicians assess when evaluating the pelvic region.

TOP 10 CAUSES OF SACROILIAC DYSFUNCTION**Cause No. 1: Psoas**

Treatment of psoas dysfunction is the first step in treating SI dysfunction (R.E. Kappler, *personal communication* (23)). Psoas muscle tension compresses the lumbosacral area and the SIJs. Psoas tension will also cause pelvic sideshift, another cause of SIJ dysfunction. The sacrum cannot function properly with excessive psoas tension. There are two components to a tight psoas: (a) tight psoas and (b) a flexed Type II dysfunction at L1 or L2, with rotation to the side of the tight psoas (23). To check psoas tension, in the prone patient, grasp the thigh just above the knee, and extend the hip. Compare both sides. This method of testing provides excellent “end feel”. If the psoas is tight, examination of the upper lumbar spine is essential. Treatment of the upper lumbar dysfunction by itself will many times resolve the psoas tension and improve hip extension. Some clinicians utilize the Thomas test for psoas assessment. This test is mostly a test of inspection, and does not provide the clinician with proper end feel. Additionally, it fails to evaluate

the flexed upper lumbar dysfunction. Management of SI problems always involves checking the psoas. Clinicians who fail to remove the psoas component and pelvic sideshift will find that the SI dysfunction will recur very quickly (23).

Cause No. 2: Lumbar Somatic Dysfunction

Lumbar somatic dysfunction, particularly type II flexed dysfunctions, may contribute to SI dysfunction. Effective treatment of the lumbar somatic dysfunction will often release the SI restriction. Lumbar group curves can be due to sacral base declination, or they can be there prior to the SI dysfunction, such as in idiopathic scoliosis. In either situation, improving the group’s function as a whole can help with dysfunction of the SIJs or pelvis.

Cause No. 3: Short Leg Syndrome/Postural Imbalance

The first symptoms of short leg syndrome are usually SI discomfort or pain. Symptoms are worse with excessive walking or running. Examination of the sacrum usually reveals a deep sacral sulcus on the short leg side with significant tissue texture abnormality and tenderness. Short leg and postural imbalance are a cause of SI dysfunction. The typical pattern for an anatomic short leg is a chronic, recurrent anterior sacrum (or forward torsion) on the short leg side, pelvic side shift to the long leg side, and lumbar curve convex on the short leg side (31). A chronic anterior sacrum on the side of the short leg is a classic finding of short leg syndrome. The status of the sacrum, the depth of the sacral sulci, and pelvic sideshift can be used clinically to evaluate progress of lift therapy. Psoas tension may exist in a patient with a symptomatic anatomic short leg. Depending on which psoas tightens, psoas tension can help compensate for a short leg, or it can exacerbate a short leg problem. Given an anatomic short leg left with a chronic left anterior sacrum and pelvic side shift right, tightness of the right psoas will correct the pelvic side shift tendency and improve the patient’s condition. However, tightness of the left psoas will exaggerate the side shift right and make the problem worse.

Cause No. 4: Pelvic Side Shift

Pelvic sideshift is usually assessed with the patient standing. It can be assessed with the patient lying prone as well, although gravity is not a factor. When the patient is standing observation may show that the pelvis is shifted from midline. When a slight lateral force is applied to the pelvis in either direction, the pelvis will sideshift away from the tight psoas or if a group curve is already present, away from the convexity of a lumbar group curve. For example, with pelvic side-shift right, the compensatory change is for body mass to be moved to the opposite side producing a lumbar curve convex left. In this example, the sacrum has to side bend left to accommodate the lumbar curve. When the sacrum side bends left, it rotates right, producing SI dysfunction. This is one mechanism of SI dysfunction associated with the tight psoas, a lumbar group curve, or a short leg problem.

Cause No. 5: Simple Traumatic Sacral Somatic Dysfunction

It is not uncommon to see patients following simple traumatic somatic dysfunction. Two common mechanisms are patients who slip and fall on their buttocks, or are involved in a motor vehicle accident where the force of the impact travels through their brake leg into their pelvis. The trauma causes the SIJ to become wedged

or “stuck” in an abnormal position. Depending on the severity and duration of their injuries, these patients usually “limp into the office and leap out,” and are forever grateful for the one-treatment cure.

Cause No. 6: Pubic and Pelvic Floor Dysfunction

It is very important to assess and treat the pubic symphysis in sacral and pelvic dysfunction. When treated, improved pubic motion will allow each ilium to move as it is supposed to during gait and daily activities. Pubic dysfunction is also related to pelvic floor tension/dysfunction. With pubic dysfunction, fascial tension on the urogenital diaphragm can affect genitourinary function. Pelvic floor dysfunction is thought to cause congestion to the pelvic viscera, such as the prostate or uterus.

Cause No. 7: Reflex Causes

Reflex causes such as viscerosomatic reflexes from pelvis or unilateral sympathetic nervous system dysfunction are causes of SI pain. Viscerosomatic reflexes are associated with tissue texture abnormality along the SIJ, which is puffy and warm. This is similar to acute tissue texture abnormality found in the thoracic area from abdominal or thoracic visceral problems.

Cause No. 8: Cranial Dysfunction

Sacral motion restriction and somatic dysfunction can be related to strains or compression of the SBS. An evaluation of the sacrum should include an evaluation of the cranial mechanism. An evaluation of tension in the anterior abdominal wall, and the respiratory diaphragm is important to assess with the cranial mechanism. Poor abdominal diaphragm motion, compression of the SBS, and SIJ restriction are commonly found co-existing in the same patient. In this clinical situation, the clinician must treat each of these regions to affect change of the whole mechanism.

Cause No. 9: Lumbosacral Instability

SI pain may be caused by orthopedic problems of the L5-S1 segment (spondylolysis, spondylolisthesis); congenital anomalies can predispose the patient to SI dysfunction. In these cases, mobilization of the SIJ does not relieve the pain. Many times with the above-mentioned conditions, there is lumbosacral instability. However, lumbosacral instability may also occur with poor force and form closure of the joint (26,28). In cases of lumbar L5-S1, the iliolumbar ligament insertion on the ilium may become very tender. Other causes of iliolumbar ligament tenderness include ipsilateral lumbothoracic irritability, anterior rotation of L5, and pelvic side shift to that side. In orthopedic disease of L5, such as a spondylolisthesis, bilateral tenderness of these ligaments is commonly found. This may be the first ligament to be strained with postural decompensation. L5 is a frequent site of disc disease and may be unstable, as well as painful. In an unstable L5 situation, manipulative treatment needs to address the adjacent segments that are restricted. Avoid excessive HVLA to L5, especially if it is thought to be an unstable segment.

Cause No. 10: Disc Protrusions

Lumbar disc protrusions at L4 or L5, in the early stages, radiate pain into the buttock region that is interpreted as SI pain. Often the sacrum is restricted from secondary muscle hypertonicity. In these cases, treating the SI restriction is not associated with the relief of pain.

Treatment

Treatment of the sacrum and the pelvic region needs to be individualized, based on the location, duration, and severity of the somatic dysfunction present. Taken into consideration is the age of the patient, and concurrent medical or orthopedic conditions. The techniques chosen need to be matched to the type of somatic dysfunction present, and the skills of the physician. The techniques should be safe, effective, and well executed. Dysfunction of the sacrum, ilium, pubes and lumbar spine commonly co-exist and affect one another. Dysfunction distant from the sacrum and pelvis may be critical to resolving the sacral or pelvic dysfunction.

Sequencing Lumbar-Sacrum-Pelvis Treatment

The sequence of treatment is important; however, this is not the always the same from patient to patient. It is generally accepted (and taught) to treat the lumbar spine, psoas, ilium and pubes prior to treating the sacrum. There is some controversy as to which region listed above to start with. Starting with the greatest area of restriction is appropriate, as long as it was not acutely injured. Since the sacrum and SIJs respond to forces directed from above (gravity) and also from those coming from below (ground reactive force), leaving it to last in the treatment scheme seems logical.

The muscle energy model (24) bases SI dysfunction on the motion cycle of walking. Dysfunction of the pubes significantly affects this motion cycle, thus sacral-pelvic motion. Because of this the muscle energy model stresses the importance of treating the pubes is first. The muscle energy approach does not consider pelvic side shift. The muscle energy diagnostic approach also does not include tissue texture abnormality. The remainder of the muscle energy model is to treat the pelvis, then the lumbar spine, before the sacrum.

The Chicago Model as proposed by Kappler insists that the pelvis and lumbar spine must be treated first (23). The psoas muscle is included with the lumbar. The psoas must be effectively treated first. There are a number of different techniques which can be used for dysfunction of the psoas. Sometimes the thoracolumbar area must be treated, or included in the process.

The Still technique approach is very specific that the pelvis and lumbar area must be treated first. If they are treated appropriately, then the Still model of oblique sacrum dysfunction (R, L) and unilateral sacrum dysfunction (R, L) is all that remains. (The Still Technique model treats innominate up-slip as a unique entity.)

Specific technique procedures are beyond the scope of this chapter; however, listed below are goals to accomplish when treating the sacrum and pelvis.

Goals of treatment include:

- Treat segmental upper lumbar dysfunctions
- Improve hip extension (iliopsoas tension)
- Improve asymmetry/alignment of the innominates
- Treat any pubic dysfunction
- Level the sacral base
- Improve cranial motion
- Improve abdominal and pelvic diaphragm motion
- Resolve anterior or posterior lumbar tenderpoints
- Obtain a negative seated flexion test

OMT is not just the application of a technique. During treatment, the experienced physician will constantly reassess the “change” that is being made in the tissues and adjust the treatment accordingly. One of the more difficult things to master for students of osteopathy is being able to tell if they made “change” or not. Another

difficulty is when to say: “enough treatment for today.” The amount of dosage given to an anatomic area must be monitored.

OMT is a critical element in returning a patient to health and wellness; however it is only one aspect to the overall care of the patient. It treating sacral and pelvic problems, corrective exercises for weak inhibited muscles and stretches for tight muscles can be beneficial.

Assessing Muscle Function and Stability of the Pelvic Girdle

Addressing these muscular issues with appropriate stretches and exercises will contribute to the improvement of the patient. Assessing the neuromuscular firing patterns that occur when the patient extends their hip is also useful. The common pattern for patients is the following sequence of muscle activation as the patient extends their hip from a prone position (24):

1. Hamstring
2. Gluteus maximus
3. Contralateral erector spinae
4. Ipsilateral erector spinae

The most common sequence seen in patients with sacral, pelvic, and lumbar somatic dysfunction is:

1. Hamstrings
2. Upper lumbar and low thoracic erectors
3. Inhibited gluteus maximus

Treatment of somatic dysfunction and addressing muscle weakness and tightness helps to normalize these patterns and resolve sacral and pelvic somatic dysfunction. According to Janda, specific muscles become tight and others become weak and inhibited. Listed below are the “phasic” muscles of the pelvic girdle that commonly become weak or inhibited.

Weak phasic muscles of the trunk and pelvic girdle:

- Gluteus maximus, medius, minimus
- Transverse abdominis
- Multifidus
- Vastus medialis, lateralis

Janda also described muscles that become tight. It is not only important to address the strength of the muscles, but also their length.

Tight “postural” muscles of the trunk and pelvic girdle:

- Iliopsoas
- Hamstrings
- Lumbar erector spinae
- Quadratus lumborum
- Rectus femoris
- Tensor fascia lata/iliotibial band
- Thigh adductors
- Piriformis

In addition to evaluating muscle groups that are inhibited or tight, co-contraction of groups of muscles acting together will affect the stability of the SIJs. Muscles of the pelvic floor act together with the transverse abdominus to stabilize the pelvis during lifting (25). Groups of muscles contribute to the force closure mechanism proposed by Vleeming. An “inner muscle unit and an outer muscle unit” have been described as providing stabilizing forces for the pelvis. It is important that these groups work synchronously with sufficient recruitment and balanced muscle function (25). They are comprised of the following groups of muscles:

Inner Muscle Units

- Pelvic floor
- Transverse abdominus
- Multifidus
- Abdominal diaphragm

Outer Muscle Units

- Posterior oblique system (Latissimus dorsi, gluteus maximus, thoracolumbar fascia)
- Deep longitudinal system (Erector spinae, deep laminae of thoracolumbar fascia, sacrotuberous ligament, biceps femoris)
- Anterior oblique system (External and internal oblique, contralateral thigh adductors, anterior abdominal fascia)
- Lateral system (gluteus medius and minimus, contralateral adductors)

There are many other ways to help treat your patient besides OMT and exercises. These can include foot orthotics, heel lift therapy, acupuncture, injections, massage, physical therapy, etc. Find the best combination for your patient. Consider cost, time required, access to care, and availability.

SUMMARY

OMT is a critical component of the overall treatment of patients with conditions found attributable to sacral and pelvic somatic dysfunction. Manipulative treatment should be applied with an objective to accomplish, and for a given diagnosis. Manual techniques can restore functional symmetry between the arthrodiol, vascular, lymphatic, and connective tissue elements of the pelvic girdle. When coupled with corrective exercises and other treatment modalities, it is a powerful, safe and efficacious tool for the clinician to use when treating a wide variety of patients.

KEY CONCEPTS

- The lower extremities provide support and locomotion through the use of strong bones and powerful muscles.
- The final common platform for postural alignment is provided by the lower extremities.
- Structural pathologies and somatic dysfunction in the lower extremities have local, postural, and systemic implications.
- Palpation assists in differential diagnoses of a wide range of structural and functional disorders in this region.
- The balance and improvement of biomechanical and homeostatic functions influences a wide range of patient conditions.

INTRODUCTION

The lower extremities provide for support and facilitate locomotion through the use of strong bones and powerful muscles. In each foot alone, there are 126 muscles and ligaments, 33 joints, and 26 bones (plus 2 sesamoid bones under the first metatarsophalangeal joint).

The structure and function of the lower extremities also allow them to play several other significant roles. They contribute to balance and the body's postural strategies as well as housing the muscular "pumps" involved in locomotion. The latter function means that the lower extremities are a major contributor in the returning of venous and lymphatic fluids back to the central vascular system. Furthermore, their condition is a key factor in designing a number of exercise protocols that are important for a person's general health. Because of their many roles, structural pathologies and somatic dysfunction in the lower extremities have local, postural, and systemic implications.

Basic clinical screening evaluation of the lower extremities (as a discrete region) typically includes an initial observation of the region during normal walking as well as walking on toes or on heels; standing with both eyes open or eyes closed; squatting; bending, integrated with a standing flexion test evaluation of PSIS motion; one-legged stork (or modified Trendelenburg) test; and joint range of motion including straight-leg raising test. These musculoskeletal screening tests are integrated with standard screening functional tests for neural, lymphatic, and vascular disorders. A positive finding in any of these screening examinations, or an indication in the history of a need for closer examination of the region, indicates the need for palpation; assessment of the end-feel during range-of-motion testing of each joint; and assessment of muscle strength, stability, and flexibility. Often in recognition of the biomechanical-postural model, a standing flexion test will be repeated *after* correction of somatic dysfunction above the pelvis in order to screen for possible biomechanical influence of the lower extremities on the structures above.

Systemic Relevance

The regional structure and the function of the lower extremities are inexorably linked to systemic clinical issues. Possessing motor, sensory, and autonomic innervations that extend from the lower thoracic region to the sacrum, the lower extremities are often targets of referred pain from the somatic structures in the lumbar and pelvic regions or from certain abdominopelvic viscera. (Although these relationships are mentioned in this chapter, readers are

encouraged to also consult those chapters in this text associated with the primary region or disorder.)

Furthermore, while many clinicians consider the pelvis to be the foundation on which the spine balances, the lower extremities actually form the final common platform for postural alignment (1). In order to keep upright, the body slightly sways over its base of support using the ankles and hips especially to counter imbalance. Sway is caused by actions of the ankle musculature that attempt to keep the center of mass over the base of support. This *ankle strategy* focuses on minor disturbances in balance; while the body's *hip strategy* manages major balance disturbances. Hip strategy uses the trunk musculature to bring postural center of mass over the base of support; it is quicker than the ankle strategy and can overcome larger variances in balance. In the most extreme circumstances, the body will step in the opposite direction of the disturbance to prevent a fall, which moves the base of support in order to maintain balance (2). For these reasons, osteopathic manipulative treatment (OMT) and lower extremity rehabilitation (including foot orthotics, ankle exercises, and other lower extremity adjunctive strategies) are used to address local, regional issues—such as a pronated foot or an anatomically shortened femur—to affect the more systemic postural issues. (Refer to Chapter 36: for lower extremity diagnostic and management issues associated with this biomechanical model.)

In clinical practice, the osteopathic practitioner seeks to ensure and enhance those structure–function relationships that are important to the biomechanical, bioenergetic, neuromusculoskeletal, and circulatory functions of the lower extremities. Clinical goals include:

- Promotion of energy-efficient, painless locomotion
- Maintenance of optimal stability-flexibility balance in and around the joints
- Reduction of mechanical stress on somatic (skeletal, arthrodiagonal, myofascial) structures
- Motor, sensory, proprioceptive, and autonomic neural balance
- Elimination of nociceptive drive
- Elimination of afferent referral from the colon or pelvic organs
- Elimination of entrapment phenomena and compartmental syndromes
- Safe, effective venous, and lymphatic return

Regional Relevance

Functionally, the lower extremities extend to the iliosacral joint; anatomically, most texts begin at the hip. Regardless of the systemic

implications, this chapter will limit its review to the functional anatomy and basic examination of the lower extremities while emphasizing the following regional relationships:

1. Skeletal, arthrodial, and ligamentous structure and function
2. Neuromuscular structure and function
3. Vascular and lymphatic structure and function

Throughout this chapter, these relationships will be linked to a number of regional clinical considerations ranging from ankle sprains (with techniques detailed in a case study at the end of this chapter) to the impact of piriformis syndrome.

SOMA: SKELETAL, ARTHRODIAL, LIGAMENTOUS STRUCTURE AND FUNCTION

Embryologically, limb development begins with the activation of a group of mesenchymal cells in the lateral mesoderm that in turn gives rise to bone, cartilage, and ligamentous structures. Limb buds adjacent to the lumbar and sacral sclerotomes will first be seen at about 4 weeks' gestation. As the limbs elongate, mesenchymal models of the bones are formed. Chondrification centers appear in the fifth week and by the end of the sixth week, the entire limb skeleton is cartilaginous.

Osteogenesis of long bones begins in the seventh week from primary ossification centers located in the middle of the cartilaginous

models of the long bones. Ossification centers are present in all long bones by the 12th week, although ossification of the foot bones and of the tibial tuberosities is not complete until approximately 20 years of age.

Tibial tuberosity ossification begins at 7 to 9 years. Clinically, this is worthy of notice because the patellar tendon attachment at the chondro-osseous junction of the tibial tuberosity is the site of one of the most common apophysitides, Osgood-Schlatter disease (3). This exercise-induced growth disorder affects boys aged 10 to 15 and girls aged 8 to 13 years causing pain, especially in the physically active individual, but is also occasionally severe at night thereby warranting consideration of a malignancy in the differential diagnosis.

The bony skeleton and joints of each lower limb are depicted and named in Figure 42.1. The bones making up these joints are covered in articular cartilage. The majority are synovial joints consisting of a capsule and synovial membrane; however, the distal tibiofibular joint is a fibrous syndesmosis with an interosseous membrane. Each of these joints is stabilized by ligaments, which limit joint motions and are a part of the normal end-feel sensed when palpating joint motion.

Differential Diagnosis of Lower Extremity Joints

Several systemic or nonregional disorders might manifest with signs and symptoms in the lower extremities and must be differentiated

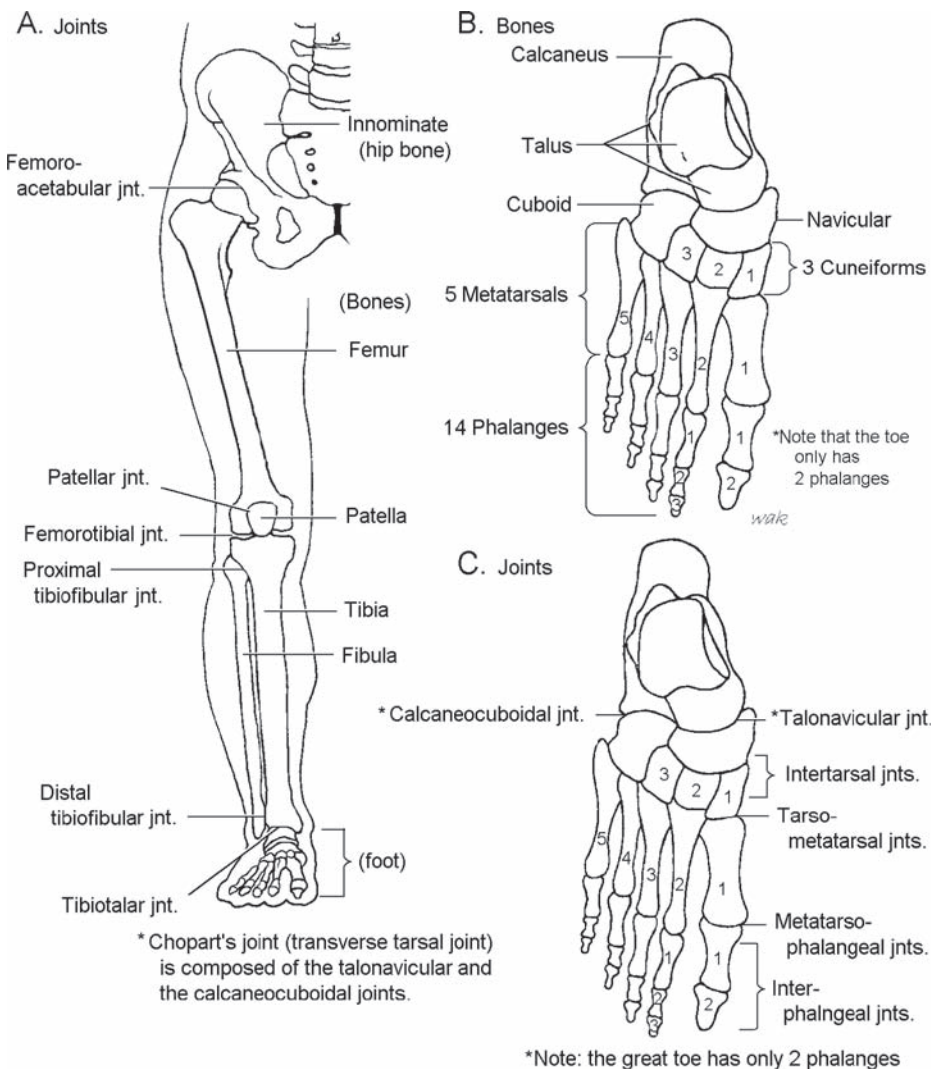

Figure 42-1 Bones and joints of the lower extremity.

from alternative local diagnoses. Differential diagnosis of a given lower extremity symptom begins with a clinical interpretation of the patient's history and a physical examination that integrates the osteopathic palpatory structural examination. Each of the major structure-function models that are available to osteopathic physicians for interpreting their findings is capable of adding relevant information with respect to this region; the neurological and biomechanical models are particularly useful.

Application of the neurological model, for example, requires a thorough understanding of the lower extremity pain patterns that are associated with pain referral from skeletal, arthrodiagonal, ligamentous, and myofascial structures as well as from a variety of neural, vascular, and visceral structures. In applying the respiratory-circulatory model to this region, the more pertinent knowledge comes from understanding lymphaticovenous drainage patterns and the compartmentalization of the lower extremity.

In order to apply the biomechanical model, lower extremity joint function should be examined and treated while recognizing that each joint has both major and minor motions that are distinct to the structure and function of that joint, each being adapted for an optimal balance between flexibility and stability. Major motions of

the lower extremity joints are best recognized by the patient; minor joint motions are glides that are often not able to be produced voluntarily in isolation and that are typically assessed with end-feel palpation. It is often the minor motion of the joint that is responsible for somatic dysfunction and often the failure to address the minor motion of a joint with OMT leads to failure in fully restoring normal joint motion. The pattern of major and minor joint motions helps in the differential diagnosis of each joint. That is, is the pattern one of orthopedic origin (e.g., absent end-feel), rheumatologic origin (e.g., a capsular pattern), or biomechanical origin (e.g., a somatic dysfunction "STAR" pattern)? (Sensitivity, Tenderness, Asymmetry, and Restricted motion are "STAR" objective findings commonly used in making the diagnosis of somatic dysfunction, with the restricted motion pattern of barriers and freedoms providing the greatest differential diagnostic component in this discussion.)

Pain Quality and Referral

Joint capsules are subject to pathological and inflammatory processes. Such processes result in *capsular patterns* of restricted motion in which all or most passive movements of the joint prove painful and limited (Table 42.1). A capsular pattern due to inflammation or

TABLE 42.1

The Capsular Patterns

Region Involving Capsular Pattern (Common Diagnoses)	Capsular Pattern of Motion Specific to Joint (Contrast with Somatic Dysfunction Patterning)	End-Feel and Other Comments
"Sign of the Buttock"		
Indicates major lesion such as osteomyelitis, ischiorectal abscess, iliac neoplasm, etc.	Passive hip flexion more limited and more painful than straight-leg raise	A prematurely empty end-feel on passive hip flexion accompanies the sign of the buttock
Hip		
Rheumatoid, traumatic, or spondylitic arthritis; osteoarthritis	Marked limitation of internal rotation and flexion, some limitation of abduction, little or no limitation of adduction and external rotation	Hard end-feel palpated especially at the end of internal rotation (advanced cases: patient may walk with foot turned outward)
Knee		
Traumatic arthritis, rheumatoid arthritis, osteoarthritis, Baker cyst	Gross limitation of flexion, slight limitation of extension	In arthritis, the palpated end-feel on passive flexion is usually hard. Most common primary capsular conditions signaled by warmth, fluid, and synovial thickening
Ankle		
Osteoarthritis, reactive arthritis	More limitation of plantar flexion of dorsiflexion	Capsular patterns unusual
Talocalcaneal Joint		
Osteoarthritis, rheumatoid or subacute rheumatoid arthritis	Increasing limitation of varus until fixation in valgus position	Reduces efficacy of shock absorption placing other joints at risk for arthritic change from accumulated impact loading
Big Toe		
Rheumatoid arthritis, osteoarthritis, gout	Gross limitation of extension, slight limitation of flexion	Advanced pattern demonstrates fixation in neutral position (hallux rigidus)

pathology is palpably different from the patterns of tenderness and restricted motion assessed in somatic dysfunction (4). Palpation of the capsular pattern is also dramatically different from the laxity assessed in ligamentous sprains. Thus, palpation of the end-feel provides significant information about the differential diagnosis of a painful or improperly functioning joint. Many rheumatological diagnoses present with deep-seated, toothache-like, sclerotomal pain and a capsular palpatory pattern.

Pain is also used in making a presumptive diagnosis of the temporal-pathophysiological condition of a joint. Pain occurring prior to resistance to movement might indicate an acutely inflamed joint, that pain that is synchronous with resistance might indicate a less acutely inflamed joint, and that pain occurring after resistance might indicate a noninflamed joint. Pain upon active motion that disappears when the joint is passively moved might reflect that the pain generator lies in muscles around the joint rather than within the joint itself.

Ligamentous Sprain Classification

In the diagnosis of ligamentous sprains, the joint line and stabilizing ligaments should be palpated directly for tenderness followed by end-feel assessment for arthrodial motion or laxity. The greater the structural damage due to ligamentous spraining, the greater the laxity that results in a loss of normal end-feel and stability. Palpation of joint play end-feel is, therefore, useful in classification of traumatic and orthopedic conditions such as sprains and in differentiating these from somatic dysfunction.

Ligamentous sprains are generally classified by degree. A first-degree sprain assumes that the integrity of the ligament is undisturbed, which results in generally intact tensile strength. Some label this degree of injury a *strain*, while others reserve the term, *strains*, for muscle injuries. A first-degree sprain, while tender to specific palpation and painful when stressed, is generally stable to most orthopedic ligamentous tests. Patients with first-degree sprain respond well to conservative osteopathic care focusing on functional strategies and might even return to activity within days of the injury (5,6). With proper care, such sprains typically recover with normal function and no ligamentous laxity.

A third-degree sprain (also known as a *grade III sprain*) indicates complete disruption of the ligament with no remaining tensile strength. Orthopedic testing indicates the “sloppy” end-feel of complete instability. Good splinting and early surgery may offer the best prognosis when dealing with third-degree ligamentous sprains around the structurally unstable knee. With ligaments of the inherently more stable ankle joint, surgery may be delayed or unnecessary to reestablish stability; recovery can be as long as 4 months (7).

Second-degree sprains make up the ligamentous injuries in between these two diagnoses. Second-degree sprains may be further divided into grade I (partial tearing with slight laxity) and grade II (more complete tearing and moderate laxity) sprains. Second-degree sprains, even when grade II, do not usually require surgical repair if they are immobilized for a duration that is appropriate to stabilize the amount of structural damage. Prolotherapy (8) or certain rehabilitative procedures may be employed to restore a component of the laxity and lost joint stability.

HIP: Femoroacetabular Joint

Structure

The hip, or *coxa*, is a term used loosely to indicate the articulation of the femoral head with the acetabular socket of the innominate bone. (Recognize that the term, *hip*, may also be used by patients

to refer to any part of the region between the waist and the thigh.) Throughout this chapter the term, *hip*, will be interchangeable with the structural and functional elements associated with the femoroacetabular joint itself.

The hip is a ball-and-socket synovial joint with a socket deeper than the glenoid fossa of the shoulder that reflects the characteristic stability of the joint. In a newborn with a congenitally shallow acetabulum, this lack of stability can be evaluated using the *Ortolani test* for dislocation (Fig. 42.2) and the *Barlow test* for reduction (Fig. 42.3). Early discovery permits satisfactory results with triple diapering or conservative brace management. Failure to perform a satisfactory examination risks a late diagnosis and the necessity for surgical correction.

Femur

The femur is the longest and heaviest bone in the body, attaining a length about one-fourth the height of an adult (9). This fact allows the forensic pathologist or archaeologist to estimate an individual's height from the femur alone. The angle formed by the intersection of the anatomic axis of the shaft of the femur and the longitudinal

Figure 42-2 Ortolani test for hip dislocation. Used in the first few weeks of life, in neonates with a subluxated hip, this maneuver creates resistance felt at 45 to 60 degrees. A positive sign is a palpable click (not heard) when resistance is overcome and the femoral head reduces. (**Top:** From Kuchera ML, Kuchera WA. *Osteopathic Principles in Practice*. 2nd Ed. Rev. Columbus, OH: Greyden Press, 1994:636, illustration by W.A. Kuchera. **Bottom:** Modified from Burnside JW. *Physical Diagnosis: An Introduction to Clinical Medicine*. 16th Ed. Baltimore, MD: Williams & Wilkins, 1981:246.)

Figure 42-3 Barlow test for hip reduction. Test for hip reduction is a modification of the Ortolani test; it is used to identify an unstable hip in infants up to 6 months of age. The Ortolani test is first performed followed by a posterolateral pressure over the inner thigh. If the femoral head slips out over the posterior lip of the acetabulum and reduces spontaneously when the pressure is released, then the joint is not dislocated but is unstable. (**Top:** From Kuchera ML, Kuchera WA. *Osteopathic Principles in Practice*. 2nd Ed. Rev. Columbus, OH: Greyden Press, 1994:636, illustration by W.A. Kuchera. **Bottom:** Modified from Burnside JW. *Physical Diagnosis: An Introduction to Clinical Medicine*. 16th Ed. Baltimore, MD: Williams & Wilkins, 1981:246.)

axis of the neck of the femur is called the *angle of inclination*. This angle normally measures 120 to 135 degrees. If the angle of inclination is larger than 135 degrees, the condition is referred to as *coxa valgus*. If it measures less than 120 degrees, the condition is called *coxa varus* (Fig. 42.4). The femoral shaft is twisted so that the condyles of the distal femur are in a transverse plane even though the femoral neck angles forward 12 to 15 degrees; this is called the *angle of anteversion*.

Ligaments

The *iliofemoral ligament* on the anterior aspect of the hip joint is the strongest ligament in the body. Because it is shaped like the letter Y, it is also called the Y-ligament of Bigelow. This ligament tenses with full hip extension and helps to maintain posture in the military at-ease position with minimal muscle activity. On the posterior side, the *ischiofemoral ligament* attaches to the ischial portion of the acetabular rim and wraps over the posterior and superior part of the hip joint where it attaches just medially to the base of the greater trochanter of the femur. This important anatomic

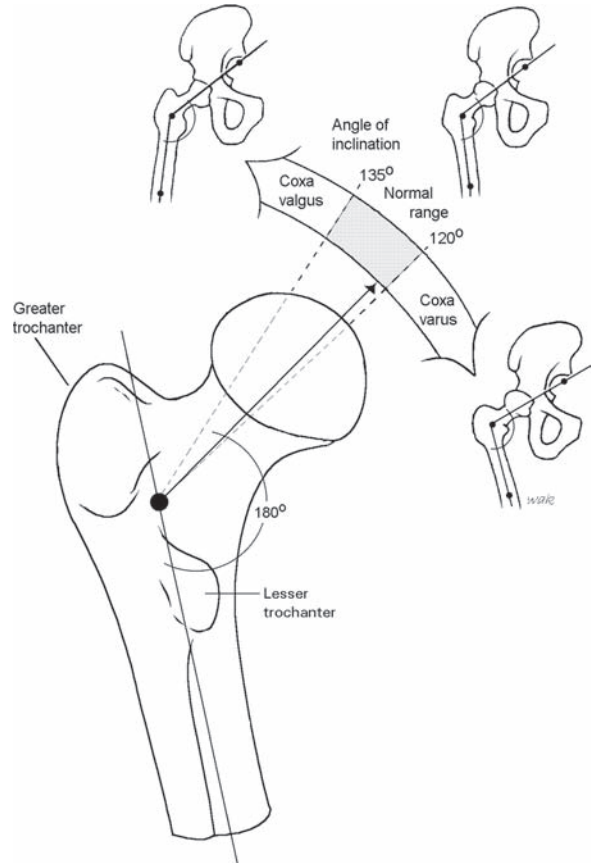

Figure 42-4 Angle of inclination. Measures less than 120 degrees in coxa varus; greater than 135 degrees in coxa valgus. (Illustration by W.A. Kuchera.)

configuration tends to screw the femoral head into the acetabulum with extension, which prevents hyperextension. Normal extension is typically limited to less than 35 degrees. Functional hip ligaments are illustrated in Figure 42.5.

Structure–Function Relationships

Motion

The major motions of the hip (femoroacetabular) joint that the patient can voluntarily create and are grossly tested are shown below along with ranges and approximate means for a 30 to 40 year old population (10):

- Flexion 120 degrees (range: 90 to 150 degrees)—extension 10 degrees (range 0 to 35 degrees)
- Abduction 40 degrees (range: 15 to 55 degrees)—adduction 30 degrees (15 to 45 degrees)
- External rotation 35 degrees (range: 10 to 55 degrees)—internal rotation 30 degrees (range: 20 to 50 degrees)

Minor joint motions of the hip assessed with end-feel palpation include:

- Anterior glide occurring with external rotation
- Posterior glide occurring with internal rotation

Gross hip ranges of motion and passive assessments of end-feel are usually tested with the patient supine and the pelvis stabilized. Ranges of motion vary from individual to individual and differ in different populations tested. For example, expect different averages

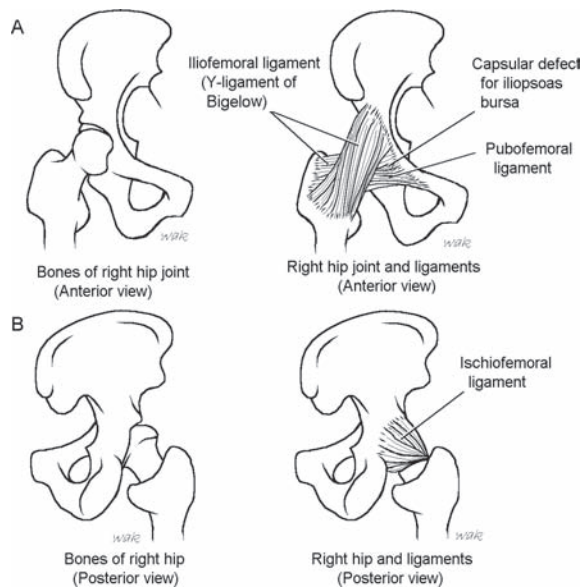

Figure 42-5 Functional hip ligaments. **A.** Bones and ligaments of the right hip joint (anterior views). Iliofemoral ligament (Y-ligament of Bigelow) and pubofemoral ligament. The iliofemoral ligament on the anterior aspect of the joint is the strongest ligament in the body and is used in military posture. **B.** Bones and ligaments of the right hip joint (posterior views). The ischiofemoral ligament on the posterior side of the joint limits extension to less than 35 degrees. (Illustration by W.A. Kuchera.)

when testing male collegiate football players compared to teenage female gymnasts. Therefore, a side-to-side comparison of both symmetry and the quality of the barrier at the end of motion is much more important than measuring the absolute number of degrees in the range of motion. Moreover, such side-to-side comparisons can be reliably counted upon (11). This holds true as well for the assessment of all of the lower extremity joints. In the presence of asymmetric motion, the quality and pattern of the barriers helps to differentiate hypomobility on one side from hypermobility on the other hand to distinguish somatic dysfunction from pathology.

The character and pattern of the end-feel of each hip motion may be springy (physiologic) or it might suggest a capsular, traumatic, or dysfunctional pattern. Subtle differences in somatic dysfunction of myofascial rather than articular origin may also be appreciated by evaluating the quality of the end-feel of the hip joint.

The muscles and soft tissues of the hip typically limit flexion more than the ligaments. Straight-leg raising at the hip around a transverse axis is limited by the hamstring muscles to approximately 85 to 90 degrees. If the knee is bent in order to remove the hamstring influence, the thigh can normally be flexed up to 150 degrees at the hip. If significant improvement in range of motion is not seen after flexing the hip, the situation is not consistent with a biomechanical cause. Thus, when more pain and limitation of motion coupled with an empty end-feel coincides with bent-knee hip flexion rather than with straight-leg raising, serious conditions including septic bursitis, ischiofemoral abscess, osteomyelitis or neoplasm of the upper femur, or other significant pathology of the ilium must be ruled out (12) (see Table 42.1).

Extension while the subject is prone and their legs are extended might measure as much as 35 degrees; bending the hip and knee of the opposite lower extremity relaxes some of the muscular restriction to hip extension and should increase this measurement.

Around an anteroposterior (AP) axis through the femoral head, the hip might abduct and adduct by as much as 55 and 45 degrees, respectively. To test adduction in a supine patient with the knee locked, the leg must be lifted to cross over the opposite leg.

Around a functional longitudinal axis, hip external rotation might measure up to 55 degrees and internal rotation up to 50 degrees.

In summary, the major motions of the hip and the minor motion glides of anterior glide (with external rotation) and posterior glide (with internal rotation) should be assessed and their pattern evaluated. A physiological end-feel to one motion compared to a barrier in the opposite direction is consistent with a dysfunctional pattern. A capsular pattern of marked limitation to internal rotation and limitation to flexion and abduction as well should raise suspicions of an underlying inflammatory process. If the initial findings from the examination of the hip do not follow functional biomechanical principles, they warrant further evaluation.

Longitudinal Axis

The anatomical longitudinal axis that runs down the shaft of the femur is not its functional axis. The *functional longitudinal axis* of the femur runs distally from the femoral head to a point midway between the condyles. With internal rotation at the hip on this functional axis, the femoral head glides posteriorly; with external rotation, the femoral head glides anteriorly. Internal rotation with posterior glide and external rotation with anterior glide represent the linked minor motions of the femoroacetabular joint.

Because arthritic change modifies gliding motions and occurs early in the minor motions of the joint (13), screening for hip problems should combine the standard Patrick screening test (Fig. 42.6) with evaluation for a hip capsular pattern. The acronym FABERE is often used to describe the order in which the *Patrick FABERE* test is performed:

- Flexion
- Abduction
- External Rotation
- Extension

As a screening test, the Patrick FABERE test is more reliable for hip pathology than sacroiliac dysfunction (14). Hip joint pathology, such as osteoarthritis, will usually create pain in the inguinal region. A positive Patrick test that lacks a hip capsular palpatory pattern or has pain limited to the posterior pelvis is more likely to reflect sacroiliitis or pain arising from the sacroiliac joint or anterior sacroiliac ligament than hip pathology.

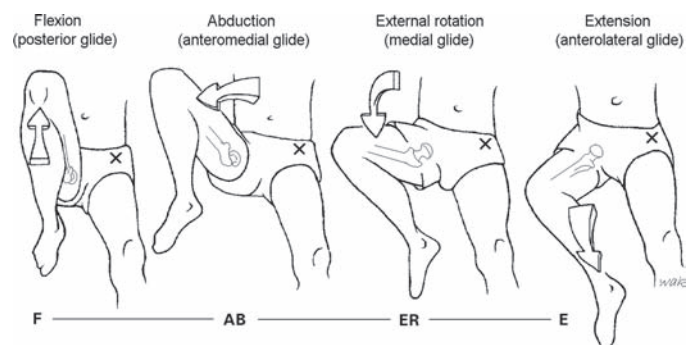

Figure 42-6 Patrick FABERE test of the hip. X, opposite hand should stabilize the left ASIS. Test may reproduce back or buttock pain from sacroiliitis or severe SI joint dysfunction; groin pain is often indicative of hip joint pathology. (Illustration by W.A. Kuchera, D.O., F.A.A.O.)

Arthritic change progresses from functional demand accentuated by biomechanical stress to pathophysiological response and structural change. For example, the biomechanical stress placed on the hip joint by a short lower extremity results in a higher incidence of greater trochanteric bursitis and of osteoarthritis (15,16), both occurring on the long leg side. Somatic dysfunction and arthritic pathology often coexist within this structure-function spectrum; each should be addressed with appropriate therapeutic tools that are integrated into a regimen for total patient treatment (17).

KNEE: FEMOROTIBIAL AND PATELLOFEMORAL JOINTS

Structure

The true knee, *genu*, or femorotibial joint is a double condylar, complex synovial articulation formed by the femoral condyles and the tibial plateau (Fig. 42.7). This joint contains medial and

lateral semilunar cartilages to provide some stability, smoothness, and resilience to pressure.

The medial condyle of the knee is longer than the articular surface of the lateral condyle (Fig. 42.8). This structural configuration affects joint function and the end result is dependent upon whether the tibia is moving on the femur (seated) or the femur is moving on a stationary tibia (standing). With extension of the knee, the lateral condyle reaches its physiologic limit of motion, whereas the medial condyle of the femur continues to track posteriorly on the tibial plateau. This results in a posterolateral glide of the tibia with full extension of the knee. Full extension locking requires this minor rotational glide. The opposite (anteromedial glide) occurs with full flexion of the knee. These minor motions of the joint should be checked for somatic dysfunction by adding an anteromedial glide while inducing external rotation of the tibial plateau and a posterolateral glide while inducing internal rotation of the tibial plateau (Fig. 42.9).

In testing the gross range of motion of the knee, the median motions will be approximately 145 degrees (115 to 160 degrees) for flexion and for extension or hyperextension, -2 degrees (0 to -10 degrees) (18).

This section also covers the patellofemoral joint in the area of the true knee joint.

Ligaments and Cartilage

Lateral and medial collateral ligaments, adapted to limit lateral glide of the tibia with adduction and medial glide of the tibia with abduction, stabilize the true knee joint. The lateral (fibular) collateral ligament does not attach to the lateral semilunar cartilage (*lateral meniscus*), while the medial (tibial) collateral ligament does attach to the medial semilunar cartilage (*medial meniscus*) (see Fig. 42.7). This anatomic arrangement makes the medial meniscus more susceptible to tears. It also predisposes the structure to displacement, especially from a blow to the knee that comes through the knee from the lateral to the medial side or to twisting injuries of the knee.

Valgus stress testing of the knee at 30 degrees (Fig. 42.10A) induces abduction of the tibia with medial glide and provides information on stability of the medial collateral ligament. Varus stress testing at 30 degrees (Fig. 42.10B) induces adduction of the tibia with lateral glide and provides information on stability of the lateral collateral ligament. In addition to ligamentous evaluation, these positions permit assessment for medial and lateral glide somatic dysfunction.

A palpable click accompanied by pain while performing *McMurray meniscal tests* (Fig. 42.11) strongly suggests displacement or a meniscal tear, but the test may only be positive in 35% of cases. Although the most sensitive (but least specific) single assessment is actually palpation of a tender meniscus at the joint line (19), usually a combination of maneuvers based upon pain provocation with compression, traction, or shear forces is required to confirm the diagnosis (20).

It is important to understand that one function of the menisci is to limit extreme knee flexion and extension. In extreme knee extension during the screw-home motion, the menisci are forced anteriorly and the anterior horns of the menisci block further extension. In full flexion, the posterior horns of the meniscus are driven posteriorly and block knee flexion (21). Therefore, during meniscus testing, if the pain or snapping occurs near maximum knee flexion, the posterior horns are probably involved, and if the pain or clunk occurs toward knee extension, the middle to anterior portion of the meniscus is probably involved. Again, sensitivity for meniscal damage is less impressive than specificity with each

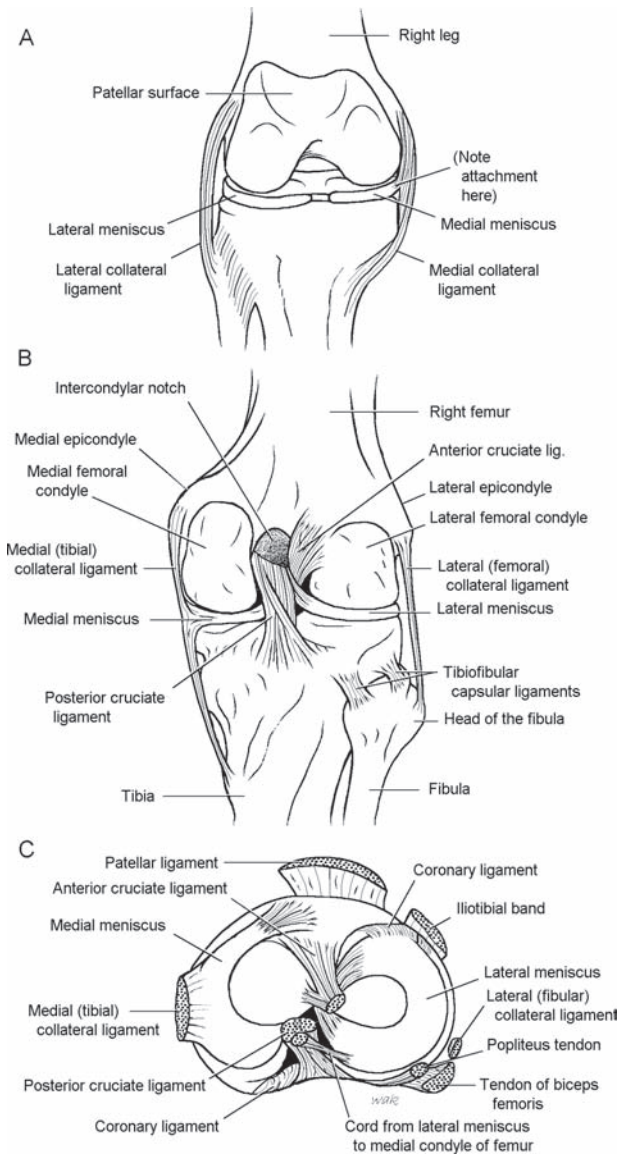

Figure 42-7 Knee joint. **A.** Anterior view. **B.** Posterior view. **C.** Relationship of collateral ligaments to knee cartilage (anterior view). (Illustration by W.A. Kuchera.)

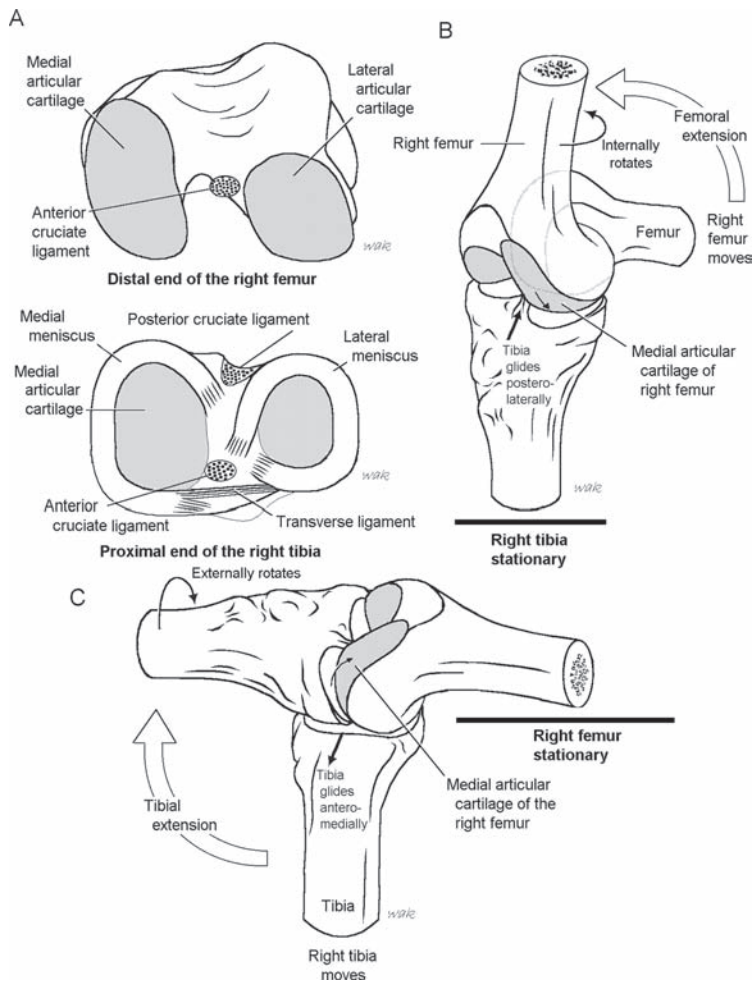

Figure 42-8 Longer medial condyle influences knee joint function. Structure–function relationship of the medial condyle. In knee extension, the medial, but not the lateral, femoral condyle will continue to track posteriorly, resulting in internal rotation of the femur (if the tibia is stationary) or external rotation of the tibia (if the femur is held stationary). The condylar glide occurring with external rotation of the tibia is called the *anteromedial glide*. (Illustration by W.A. Kuchera.)

given test (22,23)—Fouche variation (see Fig. 42.11), for instance, is almost pathognomic for a posterior meniscal tear (24), but such tears are only detected with physical examination in about % of cases.

In addition to pain, patients with a meniscal tear experience swelling, popping, or clicking, limited knee motion, and occasional joint locking during walking. Meniscal tears decrease the

shock-absorption properties of the knee joint and can predispose to arthritic change in the joint itself over time.

Interestingly, treatment of locking due to displacement or medial meniscal tear might be accomplished by modifying the McMurray test, starting from the flexed neutral knee position. First, gently externally rotate, abduct, and gap the medial side of the knee joint until a slight bulge is felt at the joint line; follow with pressure over the medial meniscus (and the medial collateral ligament to which all or a fragment of the meniscus may be attached) to reduce the bulge. Complete the procedure by holding firm digital pressure over the medial meniscus during knee extension and internal rotation.

The cruciate ligaments run between the tibia and the femur and are named according to their tibial attachments. The posterior cruciate ligament attaches to the posterior part of the tibia and prevents excessive posterior glide. The anterior cruciate ligament attaches to the anterior part of the tibia and prevents excessive anterior glide of the tibia at the knee joint. Stability of the anterior cruciate ligament (Fig. 42.12A) is checked with an anterior drawer test (knee flexed toward 90 degrees) or, with greater specificity, a *Lachman test* (knee flexed up to 30 degrees). Stability of the posterior cruciate ligament is checked with a *posterior drawer test* (Fig. 42.12B). These maneuvers also permit assessment of anterior and posterior glide end-feel for dysfunction.

The combination of torn anterior cruciate and medial collateral ligaments along with a torn medial meniscus occurs predictably from certain traumas featuring valgus stress forces such as a tackle

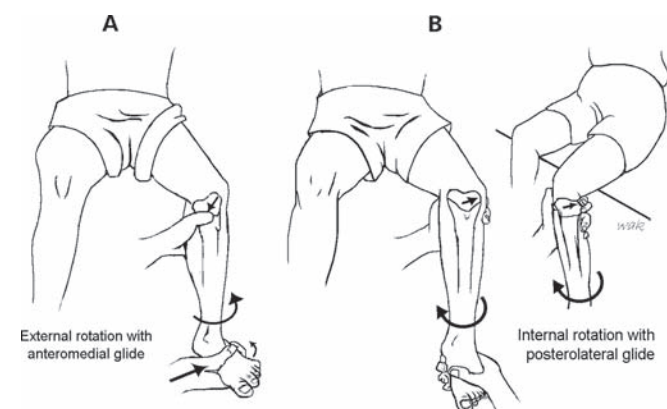

Figure 42-9 Physical examination of minor tibial glides. Physical examination of anteromedial glide with external rotation (**A**) and posterolateral glide with internal rotation (**B**) of the knee. (Illustration by W.A. Kuchera.)

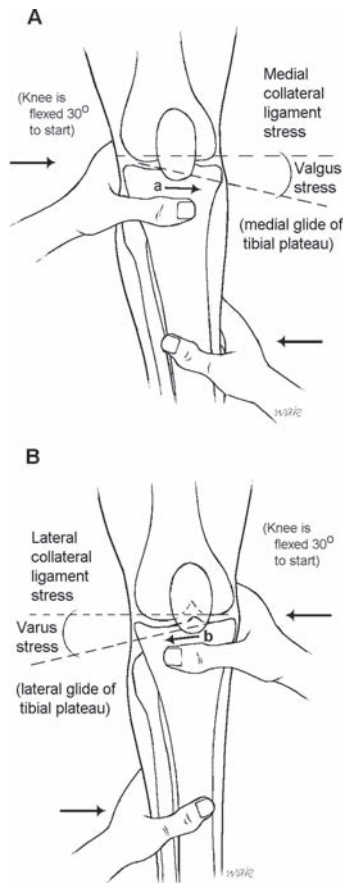

Figure 42-10 Valgus and varus testing. Tests for collateral ligament injury at the knee. **A.** Tibial abduction with medial glide or genu valgus stress also tests for medial collateral ligament stability. **B.** Tibial adduction with lateral glide or genu varus stress also tests for lateral collateral ligament stability. to the outside of the knee with the knee extended fully and the foot fixed. Because this injury causes significant knee instability, historically many clinicians referred to this constellation as *O'Donoghue's triad* or more commonly as the *unhappy (or terrible) triad* (25).

Q-Angle and the Patella

The angle formed by the intersection of the functional longitudinal axis of the femur and the tibial longitudinal axis is referred to as the *Q- (or Quadriceps-) angle*. Normally, the Q-angle measures 10 to 12 degrees (Fig. 42.13). An angle of 20 degrees or more is definitely abnormal with some practitioners suggesting an increased biomechanical risk for individuals with Q-angles greater than 15 degrees (26). As the Q-angle increases, the patient appears more “knock-kneed,” a condition referred to as *genu valgus*. A “bowlegged” appearance is known as *genu varus*. Biomechanically, coxa varus increases the Q-angle, as does a pronated foot, and both enhance the possibility of genu valgus.

The Q-angle has a major effect on the tracking of the patella, a sesamoid bone in the tendon of the quadriceps femoris muscle group. Patellofemoral joint dysfunction and structural change may each arise from abnormal tracking of or pressure on the patella.

Accentuated Q-angles might be associated with symptoms of patellar pain due to ligamentous stress at the knee or through secondary development of muscle imbalance and trigger points (TrPs). The patella might even sublux laterally with these

Figure 42-11 Meniscal diagnostic tests. Tests for medial, lateral, or posterior meniscus injuries: In these tests, start with the knee fully flexed. One hand (1) palpates the knee at the medial and lateral joint line. The other hand (2) holds the foot to control external and internal rotation of the foot and tibia. For the **McMurray medial meniscal test** (a), the foot and tibia are externally rotated (b), the two hands (c) place the tibia into abduction (genu valgus), and while holding this positioning the leg is slowly extended. For the **Fouché variation for lateral and posterior meniscus injuries** (b), the foot and tibia are internally rotated, the two hands (c) place the tibia into adduction (genu varus), and while holding this positioning, the leg is slowly extended. Pain with a palpable “click” constitutes a positive test. Note that starting with the leg extended and reversing the steps essentially constitute Steinmann I meniscal signs. (Illustration by W.A. Kuchera.)

biomechanical forces, especially with dysfunction or weakness of the vastus medialis muscle. Locking of the patella strongly suggests myofascial trigger points (MTrPs) in the vastus lateralis muscle. Complete locking of the patella immobilizes the knee joint in slight flexion, while partial locking causes difficulty in straightening the knee after sitting in a chair.

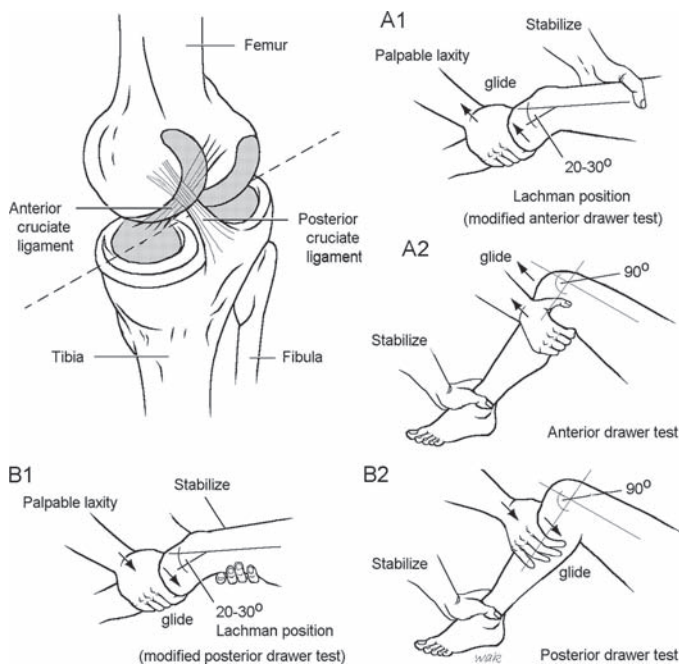

Figure 42-12 Testing cruciate ligaments and A-P glide dysfunction. Structure-function tests of the anterior (A) and posterior (B) cruciate ligaments using the Lachman (1) and drawer (2) tests.

Prolonged patellofemoral dysfunction, due to these biomechanical factors, predisposes an individual to structural changes including irregular or accelerated wearing or roughening of the articular surface on the posterior surface of the patella (*chondromalacia patellae*) (27). This coexistence of structural and functional disorders must be considered, appropriately diagnosed,

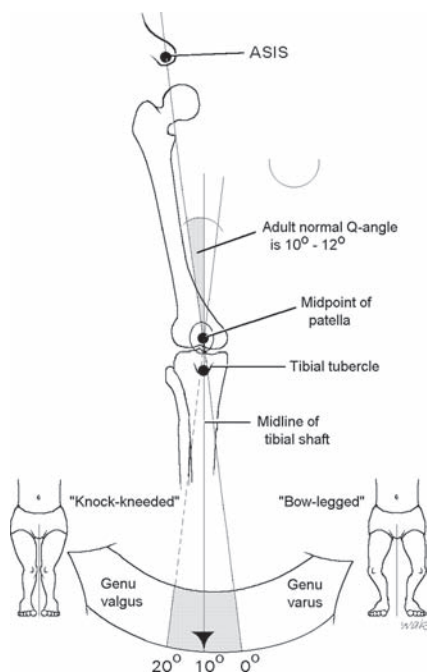

Figure 42-13 Q-angle. Q-angle (quadriceps angle) normally measures 10 to 12 degrees. Key landmarks for establishing the Q-angle are the ASIS, the patella, and the tibial tuberosity. Note the change in the Q-angle in genu valgus and varus.

and treated to encourage optimum healing. When the tracking disorder is secondary to muscular imbalance, it is very important to consider neural agonist-antagonist relationships and, therefore, to sufficiently stretch any tight hamstrings prior to trying to strengthening weak quadriceps (28).

Patellar structural problems also arise from:

- Patellar dislocation
- Chronic or direct patellar trauma
- Fracture of the lower extremity

Structural problems of the patella are evaluated, in part, by palpating over and around the patella. Look for subpatellar tenderness, crepitus, grinding or clicking with compression against the underlying femur (patellar grind test) when gliding the patella medially, laterally, superiorly or inferiorly. Effusion within the knee joint also strongly suggests structural change.

As a consequence of secondary bony alignment and muscular imbalance, functional patellar tracking difficulties may also be the presenting symptom of postural disorders.

Motion

The major motions of the knee joint are flexion and extension. Because of the irregular shape of the joint surfaces, these two motions are combined with some minor involuntary glides, rolling, and rotational motions. Minor motions of the tibial plateau at the knee include:

- Anterior and posterior glides
- Medial and lateral glides
- Internal rotation with posterolateral glide
- External rotation with anteromedial glide

Complete extension of the knee creates a bony lock. Testing of minor motions of the joint and ligament assessment should therefore be performed with the knee in variable degrees of flexion. Abduction and adduction of the tibia are passive motions of the knee that cannot be voluntarily created by the patient. A varus stress motion applied in an attempt to create adduction of the tibia produces a lateral glide (with slight internal rotation). A valgus stress motion—inducing abduction of the tibia produces a medial glide (with slight external rotation) of the tibia. Restriction of glide in one direction suggests somatic dysfunction; laxity in one direction suggests ligamentous sprain or tear.

The knee should move into full extension and lock, freely and without restriction. This is tested by grasping the foot of the supine patient with one hand and raising that lower extremity just off the table. The knee is flexed slightly with the other hand and then released, allowing it to extend. A normal knee drops freely into extension and bounces off the ligaments. Structural injuries, especially medial meniscal tears, might result in inability to extend fully or in guarding on extension.

The hyperextended knee is referred to as *genu recurvatum*.

Diagnostic Testing

The osteopathic palpatory examination of the knee incorporates standard knee testing positions and maneuvers while noting the presence and pattern of these findings:

- Gross range of motion
- Restricted gliding minor motions (end-feel)
- Hypermobility and loss of stability (end-feel)

As with other lower extremity joints, all findings are compared from side to side for asymmetry and the quality of the end-feel motions.

The same testing maneuvers needed to diagnose somatic dysfunction offer orthopedic and rheumatologic information about knee structure. In general during testing, if the asymmetrical end-feel of the test is too loose, there is an orthopedic diagnosis. If generally restricted in both directions of a given paired motion (e.g., flexion–extension), there is often a rheumatologic diagnosis. If a pattern of paired motions are assessed to be physiologically free in one direction but ends too abruptly in the other, the diagnosis is joint somatic dysfunction. Thus, interpreting each test for the available dual structure–function information provides twice the diagnostic power in the same amount of time that is usually spent on examining the knee structure alone.

A knee with gross limitation of flexion and slight limitation of extension is consistent with a capsular pattern of that joint. This palpatory finding, correlated with history and other physical findings, leads to an appropriate differential diagnosis of varying types of arthritis and synovitis affecting the knee. The capsular pattern of the knee (29) differs significantly from a somatic dysfunction, in which minor motions of the joint are restricted in one aspect of each paired motion and free in the opposite direction.

Fibular Motion

The proximal tibiofibular joint is a separate synovial joint at the knee (Figs. 42.14 and 42.15). Although the angulation of the articulation actually permits the minor motions of anterolateral and posteromedial glide of the fibular head, clinicians simply report fibular head glide as *anterior* or *posterior*. The fibular head lies in the same horizontal plane as the tibial plateau.

The distal tibiofibular articulation is a syndesmosis. This joint allows the fibula to move laterally from the tibia to accommodate the increased width of the talus presented during dorsiflexion. Restricted dorsiflexion of the ankle warrants examination and treatment of this syndesmosis.

When the fibular head glides anteriorly, reciprocal motion is initiated at the distal fibula (lateral malleolus), which glides posteriorly. Posterior fibular head motion is accompanied by anterior motion at the distal fibula. External rotation of the tibia and ankle carries the distal fibula posteriorly and elevates and glides the proximal fibular head anteriorly. The opposite occurs with internal rotation of the tibia and ankle (see Fig. 42.15).

With pronation of the foot, ligamentous attachments glide the distal talofibular joint posteriorly with reciprocal glide of the head of the fibula anteriorly. The opposite occurs with supination.

Fibular Head Dysfunction

Fibular head dysfunction is checked by gliding the fibular head posteriorly (and slightly medial) and anteriorly (and slightly lateral). In grasping the fibular head, the physician must take care not to cause undue pressure on the peroneal (fibular) nerve, which lies directly posterior to this structure. Posterior fibular head somatic

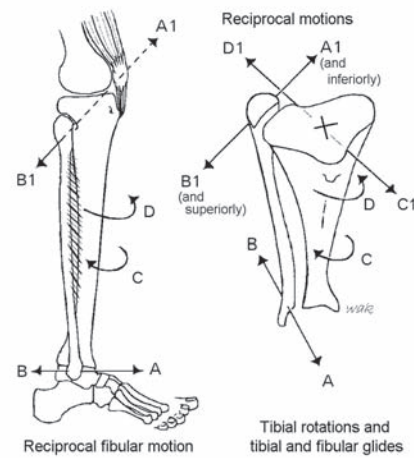

FIGURE 42-15 Reciprocal motions. External rotation of the tibia (C) moves the distal fibula posteriorly (B) and reciprocally is associated with the fibular head moving anteriorly (B1). The opposite is true (A, A1) with internal rotation (D) of the lower leg. (Illustration by W.A. Kuchera.)

dysfunction can itself cause symptoms related to entrapment neuropathy or compression of the common peroneal (common fibular) nerve. (Habitual crossing of one leg over the opposite knee—“crossed leg peroneal palsy”—can also lead to this condition due to prolonged pressure on the nerve against the fibular head. It is especially prevalent in patients with cachexia who have lost significant soft tissue “padding” in this region.)

Fibular head dysfunction often occurs in recurrent ankle sprains and responds well to manipulative procedures (30). In the more common ankle sprain in which the foot tends to supinate, the distal fibula is often found to be anterior and the fibular head posterior. In ankle sprains, however, the physician must be sure to check both ends of the fibula, because, with trauma and disruption of the anterior talofibular ligament, the physiological, reciprocal motion described earlier may not occur.

Palpation and manipulative treatment of tibiofibular interosseous membrane strain can also help in treating patients who have incurred an ankle sprain. This can be achieved with ligamentous balancing techniques between fibula and tibia while palpating at both ends of the fibula.

ANKLE: TALOCRURAL AND TALOCALCANEAL JOINTS

Structure–Function Relationships

The ankle has both an upper and lower joint that act together as a functional unit (31). The upper joint is the tibiotalar (talocrural) joint and the lower is the subtalar (talocalcaneal) joint. As the patient walks forward and bears weight on the foot, there is visible medial rotation of the tibia with increasing dorsiflexion at the ankle. However, the calculated amount of medial rotation of the tibia is greater than that attributable to movement occurring solely at the tibiotalar joint (32,33). The increased medial rotation coincides with a relative calcaneal eversion about the subtalar axis. As the stance phase of the walking cycle continues to the toe-off interval, the tibia externally rotates with simultaneous calcaneal inversion about the subtalar axis. Without movement at the subtalar joint, it would be difficult for a person to balance their body over one lower limb (34).

Figure 42-14 Proximal tibiofibular joint. Note that the fibular head and the tibial tuberosity are on the same horizontal plane.

Tibiotalar/Talocrural Joint

The tibiotalar (or talocrural joint) involves the talus moving in the ankle mortise. Until the publication of Inman's studies (35,36), the axis of the tibiotalar joint was thought and described in anatomy textbooks to be a horizontal axis that corresponded with the articular surfaces of the joint. Inman demonstrated that the single empirical (functional) axis in 80% of his specimens was not horizontal. He described an oblique axis directed laterally and downward (average 8 degrees) on a coronal plane and laterally and posteriorly (average 6 degrees) on a transverse plane. Despite this knowledge, the major motions of the tibiotalar joint are simply described as dorsiflexion and plantar flexion. Minor motions occur with each; posterior glide with dorsiflexion and anterior glide with plantar flexion. These minor motions are important when setting up manipulative techniques of the talus or of the fibula.

The gross ranges of motion for the ankle average 15 degrees (range: 5 to 40 degrees) for dorsiflexion and 40 degrees (range: 10 to 55 degrees) for plantar flexion (37). Interesting for patient care, studies suggest that people with inflexible ankles have nearly five times the risk of ankle sprain of people with an average flexibility (38). As in all other lower extremity joints, a side-to-side comparison for symmetry and quality of the end-feel of motion is recommended.

Recurrent somatic dysfunction of the ankle at the tibiotalar joint is more commonly found to prefer plantar flexion with anterior glide with a resistant barrier to posterior glide at the end of dorsiflexion. The tibiotalar capsular pattern is, however, restricted in both directions and especially resistant to plantar flexion. Ankle sprains, more likely to occur when the tibiotalar joint is plantar flexed, are discussed with foot position (supination and pronation) later in this chapter and were classified by severity earlier in the chapter.

Adduction, toeing-in, and some supination of the foot accompany plantar flexion. This motion carries the lateral malleolus anteriorly. Through reciprocal action of the fibula, the proximal fibular head also glides posteriorly and inferiorly. The talus glides anteriorly, placing the narrow portion of the talus in the ankle mortise, a less stable position.

Since the tibiotalar axis passes distally to the tip of each malleolus, its position may be estimated by placing the fingertips at the most distal ends of the malleoli. At this position, the fingers are over the transverse axis of the tibiotalar joint.

Abduction, toeing-out, and some pronation of the foot accompany dorsiflexion. This type of motion carries the lateral malleolus posteriorly and, through reciprocal action, glides the fibular head anteriorly and superiorly. With dorsiflexion, the talus glides posteriorly. Because the talus is structurally wider anteriorly, it fits more securely with the posterior glide component in the ankle mortise. Dorsiflexion is, because of its structure, a more functionally stable position. This stability is the reason taping techniques to treat or prevent ankle sprains usually emphasize a dorsiflexed position. Major and minor ankle motions are shown in Figure 42.16.

Subtalar/Talocalcaneal Joint

The subtalar or talocalcaneal joint (Fig. 42.17) has been called the main *shock-absorber* joint (39,40) of the lower extremity. It earned this designation because, in coordination with the intertarsal joints, it determines the distribution of forces upon the skeleton and soft tissues of the foot. This synovial joint has a single oblique axis that declines backward and laterally; it is stabilized by the strong talocalcaneal ligament.

The shock-absorbing function of this joint is particularly important in absorbing *accumulated impact loading* (calculated by multiplying the number of steps times the person's body weight times an activity "magnifier" ranging from a factor just above 1 for walking activities to up to 10 to 12 times the person's weight for jumping; the magnifying factor for running varies from 1.5 to 5 times body weight) (41). Such calculations become important in predicting outcomes such as aggravation of the lower extremity arthritis pain from prescriptive treadmill activity to risk of tissue injury in athletes with heavy running or jumping activities. Running is one of the most widespread activities during which overuse injuries of the lower extremity occur and the majority of biomechanical risk factors for such injury stem from this rear portion of the foot (42). Examples of overuse injuries that commonly occur during running include stress fractures, medial tibial stress

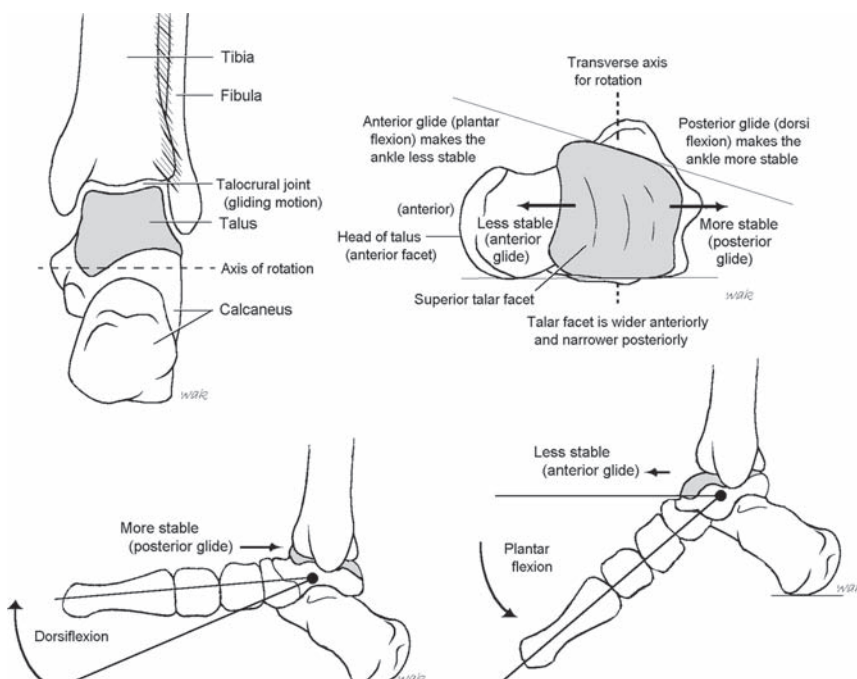

Figure 42-16 Major and minor ankle motions. Dorsiflexion with posterior glide is the more stable joint position because the wedge-shaped talus is engaged. (Illustration by W.A. Kuchera.)

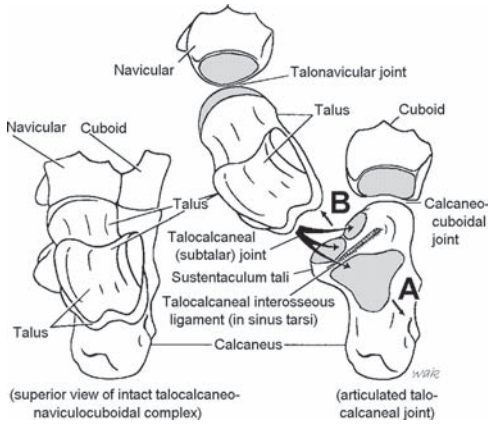

Figure 42-17 Subtalar joint. Persons with flat feet have a more horizontal axis and greater foot motion. Those with a more vertical axis have a more rigid, pes cavus foot. **A.** Posterolateral glide. **B.** Anteromedial glide. (Illustration by W.A. Kuchera.)

(shin splints), chondromalacia patellae, plantar fasciitis, and Achilles tendinitis.

Normal subtalar joint function is, therefore, critical to normal foot and lower-extremity functions (43); it should be a major focus of sports medicine physicians. In addition to its shock-absorbing function, the subtalar joint acts like a mitered hinge by allowing triplanar translation of motion between the foot and the lower extremity. Movement of the calcaneus produces leg rotation— inversion of the calcaneus produces external rotation of the tibia, and causes the talus to glide posterolaterally over the calcaneus; eversion of the calcaneus produces medial rotation of the tibia and anteromedial glide of the talus on the calcaneus. Clinically, these mechanics seem to explain the palpable talocalcaneal motions:

posterolateral glide of the talus when the ankle is supinated and the anteromedial glide at the talocalcaneal joint when the ankle is pronated.

Inman (44) found the average inclination of the subtalar axis from the horizontal plane on the sagittal plane to be 42 degrees (ranging from 20 to 68 degrees). If the inclination of the axis is 45 degrees, rotation of the tibia and calcaneus has a one-to-one relationship. The more horizontal the axis, the more the calcaneus rotates and the less the leg rotates. Because the metatarsals of the forefoot appear to remain stationary, this calcaneal rotation is not very obvious during walking. Inman's studies concluded that approximately half of the population has some linear displacement of the talus along the axis with movement in the subtalar joint.

Ankle Sprains

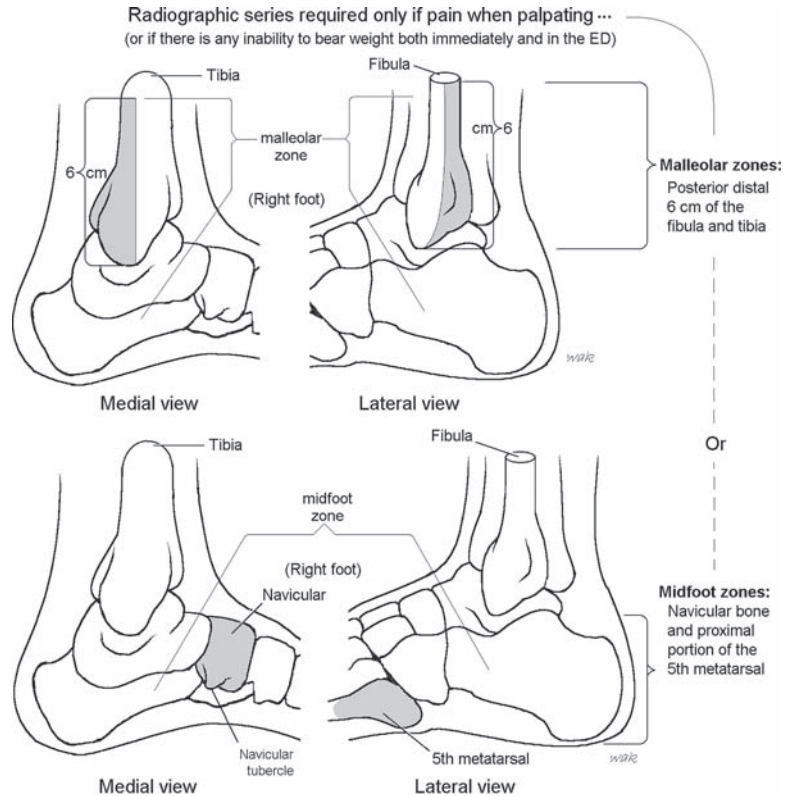

Lateral Stabilizing Ligaments and Ankle Sprains

Ankle sprains are very common in a general practice. When a patient presents with ankle trauma, the Ottawa ankle rules (45) help determine when a radiograph is needed to rule out a fracture (Fig. 42.18). This test has a sensitivity of nearly 100% and a modest specificity; its use calculated to reduce unnecessary radiographs by 30% to 40% (46).

Approximately 80% of all sprains are of the supination type (47). The supination position, which includes the less stable tibiotalar plantar flexion position, simply predisposes the ankle to ligamentous sprain injuries (especially the lateral stabilizing ligaments of the ankle). Additionally, somatic dysfunction occurs during the mechanism of injury, which extends well beyond the local ligamentous stress (Fig. 42.19).

In a supination sprain, eversion of the calcaneus and posterolateral glide at the talocalcaneal joint occurs. Abrupt stretching of the lateral and anterior compartments often initiates peroneus (fibularis) or other MTrPs (Fig. 42.20) (48). The distal fibula may be drawn anteriorly with reciprocal posterior glide of the fibular

Figure 42-18 Ottawa ankle rules for suspected fracture.

Figure 42-19 Supination sprain dysfunctions. Somatic dysfunctions and structural stress occurring in the more common supination ankle sprain.

head. If the anterior talofibular ligament is torn, the distal fibula can move posteriorly with anterior glide of the fibular head. Because sprains are traumatically induced, somatic dysfunction might not follow simple biomechanical predictions.

Somatic dysfunction does not stop here. The tibia often externally rotates with an anteromedial glide of the tibial plateau. The femur internally rotates. Myofascial forces (postural forces) then continue upward into the pelvis and spine. Failure to diagnose and treat or rehabilitate beyond the ankle itself increases recurrence rates and prolongs the healing and rehabilitation processes. It also increases complaints in distant sites due to the patient's involuntary attempts to compensate for continued dysfunction.

Three separate ligaments stabilize the lateral side of the ankle (Fig. 42.21). From anterior to posterior, these are the:

- Anterior talofibular ligament
- Calcaneofibular ligament
- Posterior talofibular ligament

Because the biomechanical stresses associated with a supination strain progress from anterior to posterior, ankle sprains are often named by type according to the extent of ligamentous involvement: Type 1 involves anterior talofibular ligament only; Type 2 involves the anterior talofibular and calcaneofibular ligaments; and Type 3 involves all three lateral supporting ligaments.

Classification of sprains by severity was discussed earlier in this chapter; a clinical treatment scenario with useful techniques for treating a supination sprain appears near the end of this chapter.

A pure inversion sprain can result in sprain of the calcaneofibular ligament alone. This occurs in basketball players during rebounding when they land—without any plantar flexion—directly on the lateral aspect of the foot. An understanding of the biomechanics of the foot and ankle explains why this is an uncommon ankle sprain.

MEDIAL STABILIZING LIGAMENTS

The deltoid ligament (Fig. 42.22) stabilizing the medial side of the ankle is so strong that trauma stressing this structure is more likely to fracture a piece of medial malleolus than tear the ligament. The Ottawa Ankle Rules for palpatory pain that prompts strong consideration of an ankle radiograph for fracture recognize this (see Fig. 42.18). Fortunately, pronation sprains are uncommon. This is due both to the strength of the deltoid ligament and the stability imparted by gliding the wide portion of the talus into the tibiotalar joint during dorsiflexion.

Foot Bones, Joints, and Arches

Structure–Function relationships

The movement of the foot (or *pes*) is a composite movement of the talocalcaneal joint of the hind foot and movement of the forefoot about the talonavicular and calcaneocuboid joints. Inversion is that movement in which the heel (calcaneus) faces medially as the inside edge of the foot is lifted. Eversion occurs when the heel faces laterally as the outside edge of the foot is lifted. In the non-weightbearing foot, inversion and eversion can be applied to the forefoot as it moves more medially or more laterally, respectively (Fig. 42.23).

Gray's Anatomy has described pronation and supination in the foot as movements of the forefoot that do not include movement of the calcaneus. This is not true with weightbearing and active motion. In the upper extremity, pronation and supination are movements of the forearm and muscles of the forearm produced by supinator and pronator muscles. In the foot, however, there are no muscles anatomically labeled as *pronators* or *supinators*. An active attempt to supinate the foot results in a combination of adduction, plantar flexion, and inversion. Likewise, an attempt to pronate the foot results in abduction, dorsiflexion, and eversion.

With weightbearing, supination of the foot is accompanied by eversion of the calcaneus and posterolateral glide of the talus with respect to the navicular at the talocalcaneal joint.

The foot plays a major role in gait; typically by reciprocally reflecting stability and flexibility characteristics with the ankle. For example, while providing less stability at the ankle, supination locks the foot. This allows stabilization at heel strike and propulsion at toe-off. Pronation during weightbearing stabilizes the ankle and creates eversion of the calcaneus with anterolateral glide of the talocalcaneal joint. Pronation unlocks the foot for surface adaptation and shock absorption during running. The various stages being described with respect to the structure–function relationships during gait include (Fig. 42.24):

- **Contact stage**—The contact stage begins with heel strike on the lateral border of the calcaneus. The tibia internal rotation occurs to the tibia as the foot pronates at the subtalar joint through the contact phase. Contact is made by the fifth metatarsal with the ground as the foot continues rolling medially until the metatarsals become fully loaded at the conclusion of the contact phase. The contact phase is designed to convert the foot into a mobile adaptor and shock absorbing mechanism

Figure 42-20 Supination somatic sources of pain in common supination injury. Muscles are stressed (in order)—peroneus, tibialis anterior, and extensor digitorum longus—leading to strain or TrPs. Ligaments (*lig.*) stressed are (in order): anterior talofibular, calcaneofibular, and anterior tibiotalar. *T*, talus; *N*, navicular; *C*, cuboid leading to sprain.

- **Midstance stage**—The midstance phase converts the foot from a mobile adaptor into a rigid lever. The tibia externally rotates during this phase and the foot supinates at the subtalar joint preparing the foot for the propulsive phase
- **Propulsive phase**—Heel lift commences the propulsive phase. The subtalar joint should approach the neutral position just prior to heel lift. It is at this point that the forefoot and the rearfoot lock together to enable effective toe-off. Supination continues during toe-off with the resultant external tibial rotation

TRANSVERSE TARSAL JOINT

The transverse tarsal joint contains the talonavicular and calcaneocuboid articulations, which are separate joints that act together as a functional unit. Because it responds to eversion or inversion of the

heel, the functional unit has its greatest influence during the stance phase of the walking cycle. The talonavicular and calcaneocuboid joints plus the two small talocalcaneal joints are collectively called *Chopart joint*. When amputating a foot, the surgeon follows the articulations of the Chopart joint.

Between the intertarsal joints and the subtalar joint is a groove called the *sinus tarsi*. Attached along this groove is the very strong interosseous talocalcaneal ligament that provides stability for the subtalar and intertarsal joints. Following injury or overuse, an inflammatory sinus tarsi syndrome may occur leading to medial or lateral heel pain on weightbearing; a conservative biomechanical approach is typically successful (49).

With internal rotation of the leg and inversion of the heel, the lines of the talonavicular and calcaneocuboid axes coincide. This produces enough freedom in the transverse tarsal joint so that

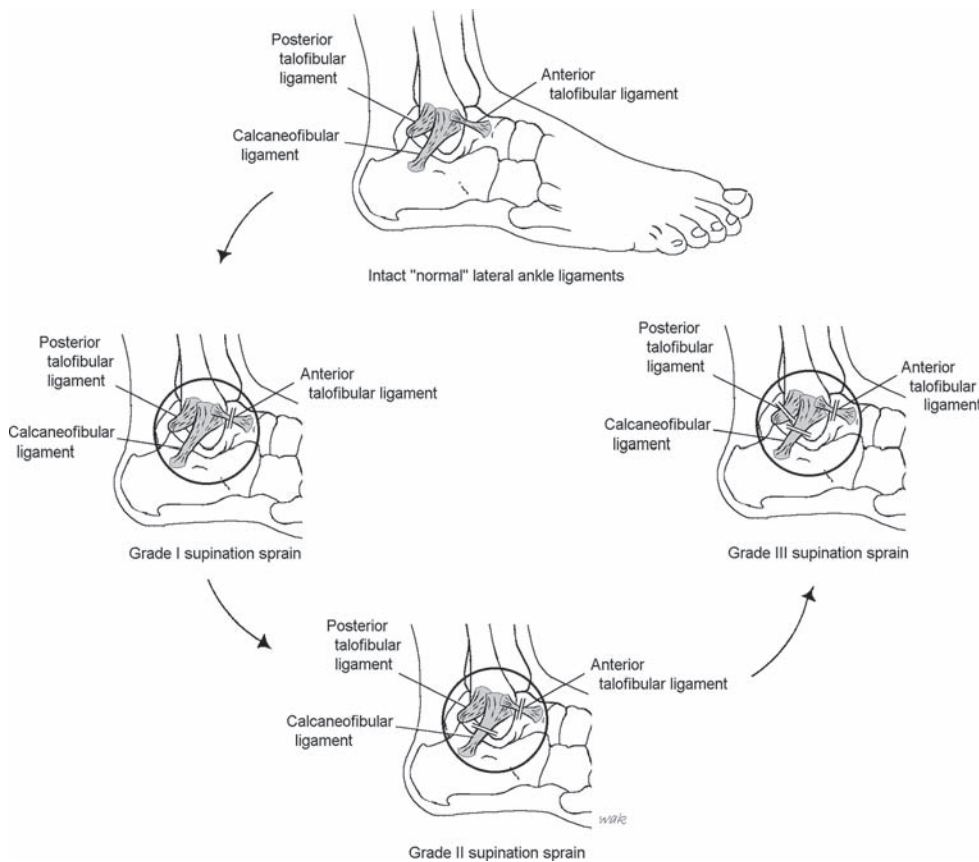

Figure 42-21 Ligamentous stability of the lateral ankle. Consider discussing types in legend

the forefoot can evert or invert to accommodate for an uneven terrain.

When the leg rotates externally and everts the heel on a weightbearing forefoot, the transverse tarsal joint appears to become more rigid. This is because the two axes do not coincide. In this position, the forefoot no longer accommodates for an uneven terrain.

As the heel rises in plantar flexion, the transverse tarsal joint must follow the movement about the subtalar axis and invert with the heel to assist the toe-off interval.

FUNCTIONAL ARCHES OF THE FOOT

The two main functional arches of the foot are the longitudinal arch (with medial and lateral components) and the transverse arch. They are maintained by:

- Interlocking articular facets of the bones
- Interosseous ligaments
- Special fascial sheathes
- Plantar ligaments
- Muscles and muscle tendons

A so-called metatarsal arch is not a functional arch; it refers to the heads of the five metatarsals. Restrictions or altered relationships here are usually secondary to dysfunction of the other foot arches (50).

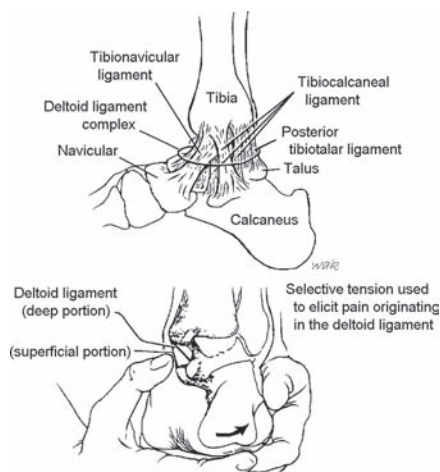

Figure 42-22 Deltoid ligament.

Figure 42-23 Combined motions (left foot): Inversion versus eversion, supination versus pronation.

Figure 42-24 Feet in the motion cycle of walking.

Longitudinal Arch

The *longitudinal arch*, which is supported by the tibialis posterior muscle, is divided into medial and lateral components. Its tendon attaches to the navicular, first cuneiform and bases of the second, third, and fourth metatarsals. The bony lateral longitudinal arch is the calcaneus, the cuboid, and the fourth and fifth metatarsals. The bony medial longitudinal arch consists of the talus, navicular, the three cuneiforms, and the first three metatarsals (Fig. 42.25A).

Transverse Arch

The *transverse arch* is composed of the cuboid, the navicular, the three cuneiforms, and the proximal ends of the metatarsals. This arch is supported inferiorly by the peroneus (fibularis) longus

muscle and by the tibialis anterior muscle that attaches to the medial and undersurface of the first cuneiform and proximal first metatarsal (Fig. 42.25B).

PLANTAR LIGAMENTS AND FASCIAE

The *plantar aponeurosis* extends from the calcaneus to the phalanges and encompasses the sesamoid bones under the great toe (Fig. 42.26). Functional demand causes chronic stress on this structure, resulting in so-called *plantar fasciitis*. Irritation may be caused by either excessive pronation or a high-arched cavus foot. With time, calcium is laid down along lines of stress, which leads to the formation of a *calcaneal heel spur*. The exact relationship between plantar fasciitis and heel spurs is not entirely understood. Some argue that the regional condition is a “degenerative fasciosis without inflammation” (51), rather than a true fasciitis that would also bring the use of steroid injections as a treatment for either condition into question. Consider as well that 60% to 70% of patients with plantar fasciitis have a heel spur that can be seen on an x-ray; however, many patients without symptoms of pain can have a heel spur.

Plantar fasciitis affects approximately 10% of runners and a similar proportion of the general population at some point in life (52). It is typically worse in the morning and after sitting for a long period. Approximately one third of patients have the condition bilaterally and only about 20% have flat feet (53). MTrPs in the soleus muscle will also refer to pain to the heel and must be considered in the differential diagnosis of heel spurs and plantar fasciitis (54). Even in absence of soleus TrPs, studies document strength and flexibility deficits in the supporting musculature of the posterior calf and foot on the side affected by plantar fasciitis (55). These anatomical and physiological alterations create a functional deficit in the normal foot biomechanics. Correction of such underlying biomechanical dysfunctions in the foot and calf along with weight reduction for overweight patients is the treatment of choice; surgery is rarely necessary and the scar from the surgery may even aggravate the condition.

The *long plantar ligament* runs from the calcaneus to the lateral three metatarsals (see Fig. 42.26). It forms a tunnel for the passage of the peroneus longus muscle as that tendon passes under the foot to the first cuneiform and first metatarsal. The short plantar ligament is, by definition, short. It lies medial to the lateral longitudinal arch and is attached between the calcaneus and the proximal end of the cuboid. The *spring ligament* (calcaneonavicular), which strengthens the medial longitudinal arch, runs from the sustentaculum tali of the calcaneus to the navicular.

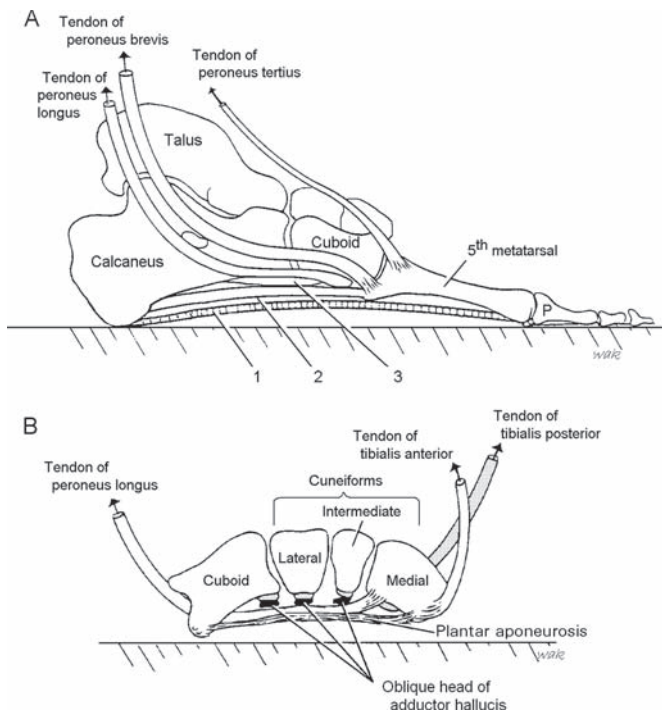

Figure 42-25 Supports of the (A) longitudinal and (B) transverse arches of the foot. 1, plantar aponeurosis, abductor digiti minimi, and flexor digitorum brevis IV and V; 2, long plantar ligament; 3, short plantar ligament; P, phalanges. (From Hamilton JJ, Ziemer LK. Functional anatomy of the human ankle and foot. In: AAOS Symposium on Foot and Ankle. St. Louis, MO: CV Mosby, 1983:13.)

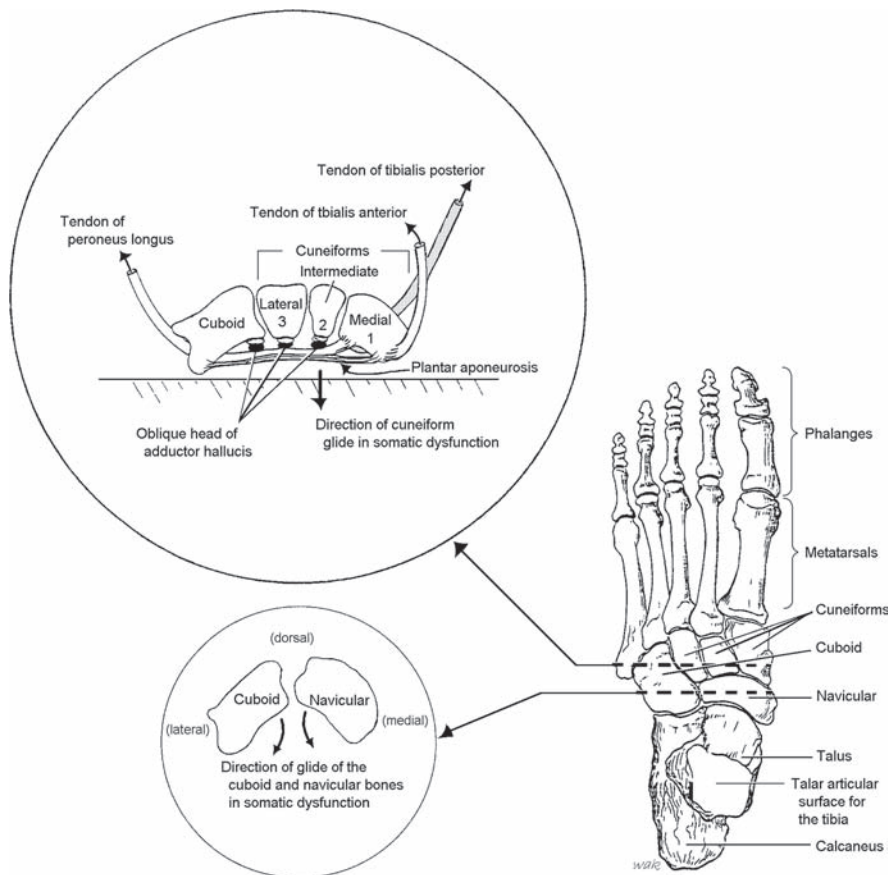

Figure 42-26 Plantar ligaments supporting the arches of the foot.

Pes Planus and Pes Cavus

By observation alone, most experienced clinicians are able to agree if a foot is pronated (flat), supinated (cavus), or rectus (normal) (56); unfortunately, observation of the static foot is much less relevant than its dynamic properties (57).

Persons with *pes planus* (flat foot) have a defect of the foot that eliminates their arch; they have a more horizontal subtalar axis and greater motion in their feet. This explains why they break down their shoes quickly and prefer to go barefoot. The condition is most often inherited; however, arches can also fall in adulthood, in which case the condition is sometimes referred to as *posterior tibial tendon dysfunction*. This occurs most often in women over 50, but it can occur in anyone. Risk factors for developing pes planus include obesity, diabetes, surgery, injury, rheumatoid arthritis, or use of corticosteroids; some studies suggest that the earlier in life that children start wearing shoes, the more likely the risk of a flat foot later on. Unilateral flat foot can sometimes account for a genu valgus and knee pain or a functional short leg on the same side with secondary postural changes above. It can also be problematic if the foot is unable to supinate during the propulsive phase of gait.

Persons with *pes cavus* (high arch) have a more vertical subtalar axis angle; biomechanically, they have a more rigid foot and a less stable ankle. Therefore, athletes with pes cavus have a greater risk of lateral foot injuries such as stress fractures of the fifth metatarsal and ankle sprain (58).

METATARSAL AND PHALAGEAL FINDINGS

Hallux valgus and bunions have a significant hereditary component; hammer toes are acquired. Each of these manifests structural

changes with associated biomechanical effects and related somatic dysfunction.

Hallux Valgus, Bunions, and Hammer Toes

Hallux valgus is a structural deformity resulting from the contracture of various periarticular structures of the first metatarsophalangeal joint—it is progressive.

Bunion protrusion is accentuated by varus deviation of the first metatarsal. Muscle imbalance aggravates symptoms, but surgical intervention of the structure may be required for symptomatic relief. Applying counterstrain OMT to a tender point on the medial aspect of the great toe often provides symptomatic relief.

Hammer toes are often functional and can be associated with MTrPs in the dorsal interossei. Deformation might disappear after treatment of this particular somatic dysfunction (59).

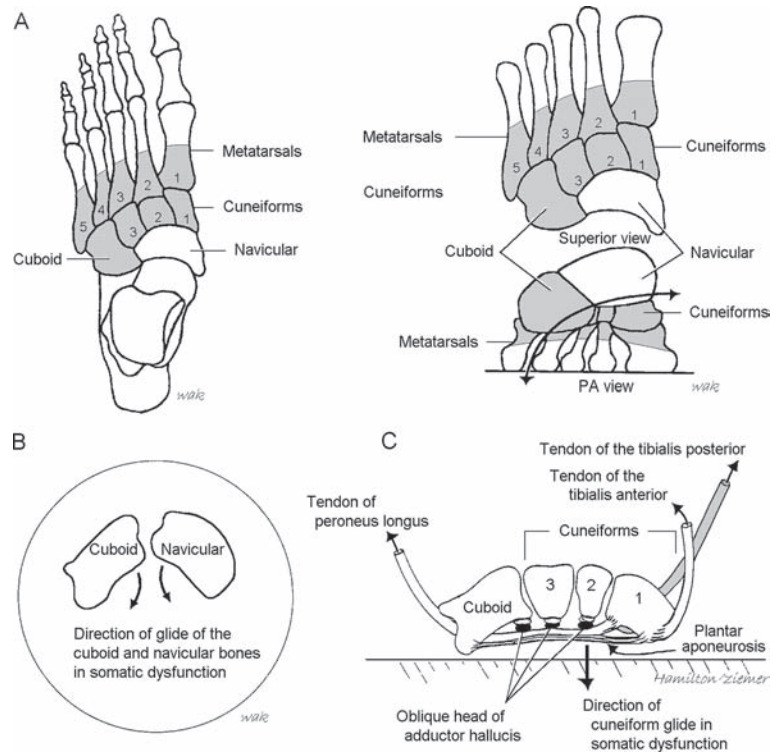

Somatic Dysfunction–Related Elements

Tarsal Somatic Dysfunction

Somatic dysfunction of the tarsal bones (cuboid, navicular, or cuneiforms) is relatively common. In middle- and long-distance runners, these bones might even sublux.

Somatic dysfunction of the cuboid involves the edge nearest the middle of the foot. This edge glides toward the plantar surface of the foot and rotates laterally around its AP axis; somatic dysfunction of the navicular involves the edge nearest the middle of the foot gliding toward the plantar surface and rotating medially around its AP axis (Fig. 42.27). Cuneiform somatic dysfunction usually manifests as a consequence of the second cuneiform gliding directly plantarward.

Figure 42-27 Navicular, cuboid, and cuneiform somatic dysfunction; relation to supports of the transverse arch of the foot. Stippled tube represents tendon of tibialis posterior; black areas represent oblique head of adductor hallucis. (From Hamilton JJ, Ziemer LK. Functional anatomy of the human ankle and foot. In: *AAOS Symposium on Foot and Ankle*. St. Louis, MO: CV Mosby, 1983:13, with permission.)

Somatic dysfunction of these tarsal bones can be diagnosed by the combination of tenderness and increased tissue tension over the plantar surface of each of these bones. Osteopathic manipulative treatment (OMT) is effective, although some patients find orthotics to modify predisposing biomechanical factors useful as well.

There are five metatarsophalangeal joints. As the forefoot inverts with plantar flexion, the body weight is transferred to these articulations for push-off. Foot structure provides two functional axes for push-off: an oblique axis that passes through the heads of the second through fifth metatarsals, and a transverse axis that passes through the heads of the first and second metatarsals.

Structurally, a *Dudley J. Morton foot* is characterized by a short first metatarsal that is not designed to accept the normal weight-bearing function involved in the push-off portion of gait. Callus forms under the second and third metatarsal heads as they assume the weightbearing function. Increased functional demand remodels bone. This results in thickening of the second metatarsal; the thickening is evident on x-ray films. Painful walking in 76% of soldiers suffering as a consequence of this condition was relieved by treatment of an in-shoe orthotic (60) to add support under the short first metatarsal to modify the structure–function relationships and OMT to permit realignment. This foot configuration has been identified as one of the perpetuating and precipitating factors of Travell MTrPs and muscle imbalance as distant as the temporomandibular joint (61). Figure 42.28 shows an orthotic used to modify structure–function relationships in Morton foot.

Somatic Dysfunction

Somatic dysfunction of the tarsometatarsal, metatarsophalangeal, and interphalangeal joints involves their minor motions:

- Plantar or dorsal glide
- Internal or external rotation
- Lateral or medial glide

It also involves compression or, less commonly, traction.

Indirect stacking OMT techniques are especially helpful in jammed toes. A stacking technique is one where the physician moves a joint in the direction of preference in all of its planes, stacking one motion upon the other. Compression or traction is then applied to that combined position. The technique may require holding the position of ease for 90 seconds or until the joint tensions relax. The joint is then slowly returned to a neutral position and rechecked for motion.

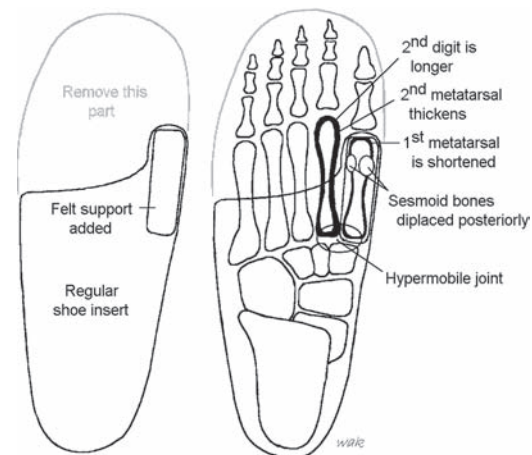

Figure 42-28 Orthotic used to modify structure–function relationships in Dudley J Morton foot. Toe portion of the sole insert is removed so support is under only the first metatarsal head. Lateral side of the support must not extend under second metatarsal head. Insert should reach to the distal end of the first metatarsal.

SOMA: NEUROMUSCULAR STRUCTURE AND FUNCTION

With respect to the lower extremities, the osteopathic *neurological model* considers the motor and sensory innervations of somatic structures in the region as well as the influence of spinal facilitation, proprioceptive function, the autonomic nervous system, and the various processes leading to the phenomenon of pain referral. Therapeutic application of OMT within this model focuses on the reduction of mechanical stresses, balance of neural inputs, reduction of pain with elimination of nociceptive drive, and coordination of processes in the motion cycle of walking.

Differential Diagnosis of Neuromuscular Conditions

A traditional neurological examination used to rule out associated neurological diseases or structural problems affecting the nervous system is a part of the lower extremity work-up. At a minimum, this should include Achilles and patellar deep tendon reflexes, assessment for ankle clonus, straight-leg raising assessment, and evaluation of lower extremity muscle tone, strength, flexibility, and coordination. Palpation of potential entrapment structures or sites is important. Evaluation of sensation can be indicated as well.

Upper motor neuron disorders are characterized by hyperreflexia and associated pathological reflexes such as ankle clonus or Babinski upgoing toe reflex. Lower extremity muscles may demonstrate spasticity or rigidity.

Lower motor neuron disorders are generally characterized by hyporeflexia accompanying muscle weakness or flaccidity. Dermatomal patterns of pain and/or dysesthesia associated with radicular (nerve root) problems in the lower extremities follow general patterns as depicted in Figure 42.29. Depending on the location of the lower motor neuron problem, the pattern might be that of a plexopathy, a neuropathy, or a peripheral neuropathy instead of a radiculopathy. In any case, reviewing the lumbar and pelvic regions is necessary to thoroughly understand the neuromuscular problems affecting the lower extremities.

Radicular Patterns

Radiculopathy might have as its cause, for example, a herniated nucleus pulposus, osteoarthritic spur, advanced spondylolisthesis,

or mass lesion. Regardless of the cause, there are relatively predictable structural and functional effects that need to be evaluated in the lower extremities. History and physical findings will uncover patterns of lower extremity sensory changes, pain, and reflex changes as well as muscle weakness, atrophy, predisposition to TrPs, and imbalance. The diagnosis of lumbar or upper sacral radiculopathies by electromyography focuses on the discovery of fibrillation potentials in patterns of lower extremity muscles sharing a common involved nerve root.

L4 radiculopathy is suspected when there is a reduction of the patellar deep tendon reflex, dysesthesia in the L4 distribution and patterns of weakness, cramping, or TrPs in those muscles innervated by the L4 nerve root, such as the quadriceps and tibialis anterior. Often, a patient exhibiting these symptoms will complain that a knee gives way or that climbing stairs is difficult.

L5 radiculopathy has no abnormal deep tendon reflex; it is suspected when there is dysesthesia in the L5 distribution and patterns of weakness, cramping or TrPs in the gluteus medius and ankle dorsiflexors, such as tibialis anterior, extensor hallucis, and extensor digitorum brevis. This patient may often complain of tripping over carpets or “small cracks in the sidewalk” because of a foot drop.

S1 radiculopathy is suspected with reduction of the Achilles deep tendon reflex, dysesthesia in the S1 distribution, and patterns of weakness, cramping, or TrPs of intrinsic foot muscles, the gastrocnemius-soleus complex and the buttock/gluteal muscles. This is the most common radiculopathy, often resulting from a herniated disc between L5 and S1.

Acute lumbosacral radiculopathies are capable of disturbing efficient gait and have a significant impact on the bioenergetic and biomechanical structure-function models of osteopathic care. Even after their resolution, chronic changes such as atrophy and residual lower extremity muscle weakness can continue to disturb efficient gait. Muscles in the particular radicular pattern are also at high risk to develop MTrPs.

Other Neural Patterns

Pain descriptions and pattern distributions extend beyond dysesthesia or anesthesia associated with a nerve root or dermatomal pattern. Other lower extremity patterns of pain occur in sclerotomal and myotomal distributions. Often, the pain quality and patterns are mixed. For example, pain patterns referred from the facet joints of the lumbar spine (sclerotomal structures) overlap MTrP pain (Fig. 42.30) that arises from the following muscles (myotomal structures) (62):

- Multifidi
- Quadratus lumborum
- Glutei
- Piriformis
- Obturator internus

Myotomal pain referral often results in a sensation described as a *charley horse* or a crampy sensation that *reaches out and grabs* with a particular movement. A myotomal distribution is associated with the location of muscles that share the same neural innervation and the trophic substances conveyed by neural axoplasmic flow. Muscle innervations are reviewed in Tables 42.2 to 42.4. Pathological or biomechanical entrapment of a nerve root, plexus, or peripheral nerve can leave weakness or TrPs in the muscles distal to that site in the particular neural pattern associated with the involved structure, even after the pain resolves. Reinnervation associated with processes leading to axonotmesis (or higher degree injury) typically occurs at a rate of one inch per month; muscles not supported by

Knee Joint Myofascial Dysfunction: Structure and Clinical Impact

Structure → Functional Anatomical Features	Clinical Implications of Somatic Dysfunction
Knee Flexors	
Biceps femoris (L5-S2; <i>sciatic n. long head = tibial portion; short head = peroneal portion</i>); Attachment—both heads plus semimembranosus establish a tripartite anchor on the fibular head <ul style="list-style-type: none"> • Long head crosses both hip and knee • Short head crosses only knee • Short head active in knee flexion for toe clearance during walking • Active contraction also induces some external rotation of the knee 	Postural muscle (hypertonic when stressed) <ul style="list-style-type: none"> • History/Symptoms: Often wakes patient at night • Referral: Distalward from TrPs in the posterior thigh to the back of the knee or to the region of the fibular head

(continued)

TABLE 42.3 (Continued)

Semimembranosus and semitendinosus

(L5-S2; sciatic n. tibial portion)

- Also hip extensors
- Hamstrings are not consistently active for knee flexion during walking (passive knee motion when the hip is flexed is more common)
- Active contraction also induces some internal rotation of the knee

Postural muscle (hypertonic when stressed)

- History/Symptoms: aggravated by walking often causing limp; TrPs often misdiagnosed as “sciatica” or “osteoarthritis of the knee” or “growing pains”^a; TrPs remaining post-op often cause of “postlaminectomy syndrome”
- Referral: proximally to lower buttock
- Exam: Tightness in the hamstrings is associated with secondary inhibition and laxity of the gluteal muscles

Also **popliteus** and **gastrocnemius**

- Popliteus initiates flexion from fully extended knee before hamstrings act

Knee extensors**Quadriceps** (L2-4; femoral n.); Attachments—All four tendons unite into patellar tendon with patella; anchored to tibial tuberosity by patellar ligament

- **Rectus femoris** crosses both hip and knee joints (proximal attachment to anterior posterior iliac spine [ASIS]); also a hip flexor
- Three **vasti** cross only knee joint
- **Q-angle** is the quadriceps angle measured from ASIS to midpatella to tibial tuberosity

Rectus femoris is a postural muscle (hypertonic when stressed); the other quadriceps are phasic muscles (inhibited when stressed)

- History/Symptoms: Thigh and knee pain and weakness of knee extension especially going up stairs; may interrupt sleep. TrPs in v. medialis cause “buckling knee” and may cause patient to fall; TrPs in v. lateralis may restrict motion of the patella; pain with walking; TrPs in v. intermedius create difficulty straightening knee after prolonged sitting
- Referral: Anterior knee pain is referred from v. medialis and rectus femoris; Posterior knee pain and pain anywhere along the lateral thigh to the iliac crest referred from v. lateralis
- Exam: Include Q-angle and patellar grind tests; Imbalance in quadriceps with one another or with the hamstrings predispose to chondromalacia patellae (as does an increased Q-angle); Direct trauma to the quadriceps should be observed for myositis ossificans

Knee external rotator**Biceps femoris** (L5-S2; sciatic n.)

- Also a knee flexor

See description with Knee Flexors above

Knee internal rotators**Popliteus** (L4-S1; tibial n.)

- Unlocks knee at the start of weight bearing by “externally rotating the thigh on the fixed tibia”; internally rotates tibia when thigh is fixed
- Prevents posterior glide of tibia relative to femur while crouching

- History/Symptoms: Aggravated by braking forward motions during twists (e.g., skiing), high heels by excessive foot pronation and by training on uneven ground
- Referral: Pain behind the knee when crouching, walking down stairs, or running downhill
- Exam: Mimics symptoms of Baker cyst but no associated swelling in the region

Semimembranosus and semitendinosus

- Also knee flexors (primary)

See description under Knee Flexors above

Also **sartorius** (L2-3; femoral nerve) and **gracilis** (L2-3; obturator n.)

- Sartorius is the longest muscle in the body crossing both hip and knee; it is a hip flexor and knee internal rotator
- Gracilis is the second longest muscle in the body crossing hip and knee

- Pain from the sartorius in the anterior thigh is superficial and described as tingling or sharp; may exhibit symptoms of meralgia paresthetica (entrapment of lateral femoral cutaneous nerve)^e
- Pain from gracilis is a hot stinging, superficial pain in the medial thigh; it may be relieved by walking

TABLE 42.4

Ankle-Foot Joints Myofascial Dysfunction: Structure and Clinical Impact

Structure → Functional Anatomical Features	Clinical Implications of Somatic Dysfunction
Ankle dorsiflexors	
Tibialis anterior (<i>L4-S1; deep peroneal n.</i>) <ul style="list-style-type: none"> • An anterior compartment muscle • A dorsiflexor at the talotibial joint • Also supinates foot at the talocalcaneal and transverse tarsal joints 	Phasic muscle (inhibited when stressed) <ul style="list-style-type: none"> • History/Symptoms: Might complain of tripping over carpets, dragging foot, or “foot slap”. Weakness in muscle may be caused by L5 radiculopathy, peroneal mononeuropathy, the habit of crossing the legs at the knee, or posterior fibular head somatic dysfunction • Referral: Pain and tenderness referred into great toe and anteromedial ankle • Exam: Weakness leads to varying degrees of foot drop (rule out other causes)
Extensor digitorum longus (<i>L4-S1; deep peroneal n.</i>) <ul style="list-style-type: none"> • Also everts the foot balancing inversion of tibialis anterior • Helps prevent posterior postural sway 	<ul style="list-style-type: none"> • History/Symptoms: Dysfunction often results in foot slap after heel strike • Referral: Dorsum of foot and ankle • Exam: TrPs might entrap deep peroneal n fibers; Ms imbalance → formation of hammer toes
Peroneus tertius (<i>L5-S1; deep peroneal n.</i>); Attachment—Tendon passes in front of lateral malleolus to insert on proximal 5th metatarsal <ul style="list-style-type: none"> • An anterior compartment muscle • A dorsiflexor at the talotibial joint • Also everts foot 	Phasic muscle (inhibited when stressed) <ul style="list-style-type: none"> • History/Symptoms: Weakness in ankle dorsiflexion predisposing to ankle instability and repeat sprains; Might be mistaken for ankle arthritis. Weakness in muscle might be caused by L5 radiculopathy, peroneal mononeuropathy, the habit of crossing the legs at the knee, posterior fibular head somatic dysfunction or prolonged immobilization (as in an ankle cast) • Referral: Anterolateral ankle and sometimes to lateral heel • Exam: Failure to identify and treat TrPs post-ankle sprain can prolong rehabilitation process
Ankle plantar flexors	
Gastrocnemius (<i>L5-S2; posterior tibial n.</i>); Attachment—shares Achilles tendon attachment to calcaneus <ul style="list-style-type: none"> • Gastrocnemius-soleus complex referred to as triceps surae; constitutes close functional unit 	Postural muscle (hypertonic when stressed) <ul style="list-style-type: none"> • History/Symptoms: Often nocturnal leg cramps; “tennis leg” (partial tearing of gastrocnemius) with a sudden intense calf pain, as if kicked, followed by swelling and local tenderness • Referral: Upper posterior calf and/or to instep • Exam: Failure to recognize “tennis leg” might lead to a posterior compartment syndrome
Soleus (<i>S1-2; tibial n.</i>); Shares Achilles attachment to calcaneus <ul style="list-style-type: none"> • Gastrocnemius-soleus complex constitutes close functional unit • Soleus function during gait is to add to knee and ankle stability • Acts as “second heart”^g in moving venous and lymphatic fluid from lower extremity (e.g., fainting with military “attention” position) • Also aids in inversion of foot and extension of knee 	Postural muscle (hypertonic when stressed) <ul style="list-style-type: none"> • History/Symptoms: pain severe walking up hill or stairs; May cause growing pains in children • Referral: Heel pain with TrPs in this muscle and/or may refer proximally to sacroiliac joint or even temporomandibular joint • Exam: May restrict dorsiflexion at ankle; Soleus TrPs easily mistaken for Baker cyst, thrombophlebitis, and/or Achilles tendinitis

this reinnervation growth or by local collateral sprouting within an 18-month time frame typically become connective tissue incapable of reinnervation (63).

Sclerotomal referral is a deep, achy sensation that is toothache-like in quality. Sclerotomal (bony/ligamentous) distribution has also been mapped out (Fig. 42.31), but it is often overlooked and patients might dismiss it as lower extremity arthritic pain. (Notice that different aspects of the knee and the hip joints share the L3 and L4 sclerotomes.)

In general, referred pain is reproducible; as a consequence, diagnosis can be enhanced by stimulating the postulated pain generator to cause the pain symptom and by anesthetizing (or deactivating) that structure to see if the pain is eliminated. An understanding of the patterns associated with each referral improves patient diagnosis and treatment design. Failure to appreciate nondermatomal patterns may lead a practitioner to ineffectively treat symptoms rather than causes or to incorrectly consider a patient with legitimate symptoms a malingerer.

Referral from Lumbopelvic Structures

In addition to lumbar nerve roots and sclerotomes discussed earlier, a number of other lumbopelvic region myofascial, arthroal, ligamentous, and visceral structures commonly refer pain to the inguinal area or hip. Somatic examples include iliolumbar and posterior sacroiliac (PSI) ligaments (64), quadratus lumborum muscle (65), and lumbar zygapophysial joints (66). Referral from visceral structures in this region are also often seen—as in a urinary tract stone passing down the ureter—radiating pain into the ipsilateral flank and the inner thigh region (67). Tissue texture changes in the form of Chapman reflexes may also occur as seen along the iliotibial band in patients with colon, prostate, or broad ligament viscerosomatic conditions (68).

Referral Originating in the Lower Extremities

Structures in the pubic or hip region often refer pain to the knee. For example, an adolescent male with knee pain and no sign of knee dysfunction or structural abnormality should have a hip x-ray to rule out a slipped capital epiphysis or other hip joint pathologies. Lower extremity MTrPs create predictable patterns of pain and dysfunction. In addition, nociceptive input from structures in the lower extremity may facilitate areas in the spine at the levels of T11-L2 that subsequently initiate symptoms from other structures sharing that same innervation (69).

Myofascial Trigger Point Patterns

Myofascial somatic dysfunction in this region leads to a number of patient symptoms that range from pain to weakness and that often limit range of motion and alter joint function. MTrPs as described by Travell and Simons also have predictable referral patterns not associated with dermatomes (see Fig. 42.30 for a synopsis of representative TrPs associated with the lower extremities). By definition, these points are a form of somatic dysfunction. They represent impaired or altered function of myofascial tissues with effects also in related neural, vascular, and lymphatic elements. TrPs respond to a wide range of treatment techniques: counterstrain, muscle energy, vapocoolant spray and stretch, dry needling, and procaine injection to name but a few. It is important however to identify any precipitating or perpetuating factors including coexistent lumbosacral radiculopathy, muscle imbalance, or poor ergonomics used in a repetitive manner.

Integrated Firing Patterns

Asymmetric postural stress creates recurrent and predictable patterns of lower extremity muscle somatic dysfunction that are characterized by neuromuscular imbalance or MTrPs. In neuromuscular imbalance, stressed postural (antigravity) muscles exhibit an increased irritability (short and tight), whereas their antagonists demonstrate inhibition (weak and atrophic) (Fig. 42.32) (70). When stressed, the iliopsoas, piriformis, hamstrings, gastrocnemius-soleus complex, adductor magnus, rectus femoris, and tensor fasciae latae all tend to tighten, while the vasti (especially the vastus medialis), glutei, peroneus, and tibialis anterior all tend to be inhibited and weak (71). Application of the biomechanical—postural model coupled with an understanding of the myotatic unit, muscle agonists and antagonists, and patterns of use is necessary for efficient diagnostic and therapeutic approaches to the treatment of lower extremity dysfunction that arise from this pattern of neuromuscular dysfunction.

Hip-Thigh Neuromuscular Considerations

Structure–Function Relationships

The muscles of the hip and thigh are generally large and powerful. They can be grouped according to their functional role (see Table 42.2).

The nerves innervating this region include the largest nerve in the body, the sciatic nerve, as well as the gluteal and femoral nerves. Based upon their location, some of these nerves are particularly vulnerable to trauma.

The sciatic nerve exits the pelvis through the greater sciatic notch and divides into a posterior tibial and a common peroneal nerve somewhere variably high in the thigh. In most individuals, it passes under the piriformis muscle; however, in approximately 10% of the U.S. population, the peroneal portion of the sciatic nerve actually passes through the piriformis muscle (72). (This anatomic variation occurs in one third of patients of Asian descent.) In the buttock or thigh, the sciatic nerve might be affected functionally by the piriformis muscle. Primary causes for such piriformis dysfunction can arise from direct trauma such as a fall onto one buttock or sitting for a prolonged period of time on a hard surface such as a toilet seat. Secondary dysfunction of the piriformis might be postural in origin or due to articular somatic dysfunctions involving the sacrum (sacral shears in particular) or the hip. Because of the close anatomical relationship between the two, biochemical irritation of the sciatic nerve is possible with irritation of the piriformis. Piriformis structure–function relationships are depicted in Figure 42.33.

Another source of iatrogenic trauma to the sciatic nerve comes from accidental injection into the nerve. Because the peroneal fibers are the more superficial, they are the most commonly involved in injection injuries; the resultant side effects include foot drop. Injections into the buttocks should be in the upper outer quadrant to avoid this problem in general injections; injections for piriformis TrPs should avoid steroids to decrease the risk of permanent

damage from accidental introduction of the injected contents into the nerve. A more complete synopsis of the causes of foot drop may be found at the end of this chapter in the clinical section.

Numerous other lower extremity neural conditions can be found from the iliac region (*meralgia paresthetica*) to the toes (*Morton neuroma*). These and other conditions can arise from either trauma or somatic dysfunction and can be complicated by either. Meralgia paresthetica is a consequence of jeans that are too tight or pelvic somatic dysfunctions affecting the lateral femoral cutaneous nerve as it passes under the inguinal ligament near its attachment at the

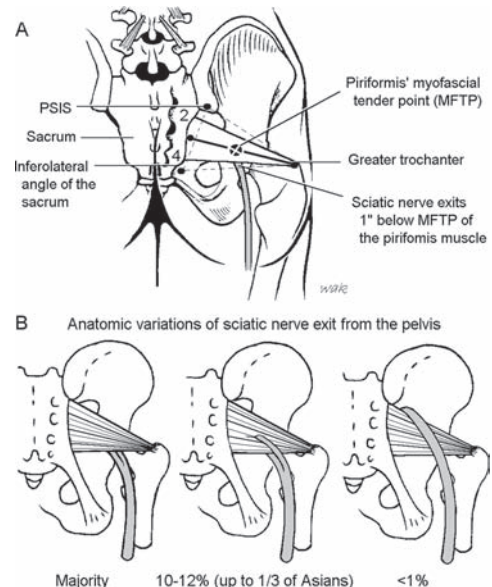

Figure 42-33 Piriformis structure–function relationships.

anterior superior iliac spine (ASIS); it manifests as superficial pain and numbness in the anterolateral thigh. Morton neuroma is an enlarged nerve that usually occurs in the interspace between the third and fourth metatarsals where the local pain is worsened by wearing shoes and by walking. Morton neuroma can be diagnosed by palpating this interspace and squeezing the forefoot from side to side to recreate the patient's pain or to palpate an audible click (*Mulder sign*).

Knee-Leg-Foot Neuromuscular Considerations

Structure–Function Relationships

Muscles of the thigh and leg that affect knee, ankle, and foot function (see Tables 42.3 and 42.4). Several thigh muscles have already been described in relation to their effect at the hip. These include the:

- Hamstrings
- Rectus femoris
- Tensor fasciae latae

The hamstrings and the short head of the biceps femoris are the chief flexors of the knee. The hamstrings, by definition the muscles that attach to the ischial tuberosity, attach to the leg below the knee and are supplied by the tibial division of the sciatic nerve (73). The head of the biceps femoris crosses the knee and is innervated by the peroneal portion of the sciatic nerve. Both heads of the biceps femoris also cause external rotation of the knee, while the remaining hamstrings cause internal rotation.

The quadriceps femoris group (three vasti and the rectus femoris) muscles are the chief extensors of the thigh; they are innervated by the femoral nerve. While the rectus femoris is a postural muscle and can become hypertonic on one side in relationship to tight hamstrings on the other side when there is pelvic rotation, the three vastus muscles are phasic and become pseudoparetic when stressed. Muscle imbalance that leads to MTrPs in the vastus muscles (especially vastus medialis) are often responsible for the so-called buckling knee syndrome (74). In this syndrome, no other reason except the trigger point for failure of the knee—which simply gives way without warning—can be identified; however, secondary

patellar tracking problems might be noted. (See the discussion of chondromalacia patellae earlier in this chapter.)

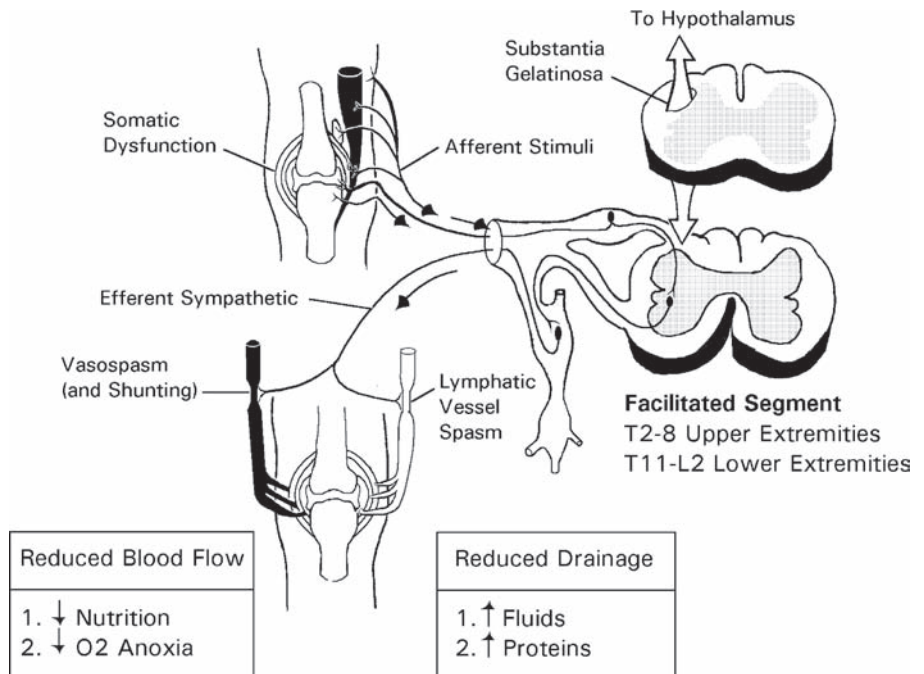

The remainder of the nerve supply in the thigh, leg, and foot is derived from the posterior tibial and common peroneal (common fibular) nerves (Fig. 42.34). A vulnerable site for entrapment or trauma exists as the common peroneal nerve (common fibularis nerve) passes behind the fibular head. The tibial nerve supplies the posterior compartment of the leg and the muscles of the foot. The deep peroneal nerve supplies the anterior compartment of the leg with sensation to the webbing between the first and second toes. The superficial peroneal nerve supplies the lateral compartment of the leg as well as the skin on the anterolateral side of the leg and the dorsum of the foot. OMT to the fibular head is often effective in treating this entrapment.

The posterior tibial nerve runs through the tarsal tunnel—a narrow space that lies on the inside of the ankle next to the ankle bones. The tunnel is covered with a thick ligament, the *flexor retinaculum*, that protects and maintains the structures, which includes the posterior tibial nerve, contained within the tunnel; therefore, compression of the posterior tibial nerve at this site is referred to as *tarsal tunnel syndrome*. This syndrome, that causes pain anywhere along the bottom of the foot, is often associated with diabetes, back pain, or arthritis. It can also be caused by an injury to the ankle, such as a sprain, or by a growth, abnormal blood vessels, or scar tissue that press against the nerve. A flat foot increases the risk for developing tarsal tunnel syndrome, because the outward tilting of the heel can produce strain and compression on the nerve. Treatment for tarsal tunnel syndrome includes in-shoe orthotics designed to help redistribute weight and take pressure off the nerve or corticosteroid injections. Tarsal tunnel syndrome caused by known conditions, such as tumors or cysts, might respond better to surgery than when the cause is not known.

Example of Differential Diagnosis Considerations: Foot Drop

There are numerous sites where structural or functional conditions could create weakness in the muscles that help to dorsiflex the foot.

Figure 42-34 Sciatic branches. Nerve supply of the lower extremity arising from the sciatic nerve and its branches.

The differential diagnosis of foot drop is therefore quite extensive and encompasses systemic conditions such as multiple sclerosis to focal conditions such as an L5 radiculopathy.

The most common regional neuromusculoskeletal conditions in the differential diagnosis include (75) from proximal to distal anatomical sites:

- L5 radiculopathy (e.g., secondary to herniated L4 disc)
- Cauda equina lesion (e.g., secondary to spinal adhesions)
- Lumbosacral plexopathy (e.g., secondary to colorectal carcinoma)
- Sciatic nerve injury (e.g., secondary to injection injury)
- Peroneal entrapment neuropathy
 - At piriformis (e.g., due to piriformis syndrome)
 - At fibular head (e.g., due to posterior fibular head somatic dysfunction or to Baker cyst)
- Peroneal or tibialis anterior MTrPs (e.g., due to prior severe supination ankle sprain)

The dorsiflexors of the foot are primarily phasic muscles (antagonists to postural muscles); dysfunction or trigger points in these muscles, especially the tibialis anterior, might also lead to weakness and a tendency for mild foot drop symptoms especially after using the muscle(s) for a period of time (76).

Techniques that remove joint or myofascial somatic dysfunction in the areas discussed above are considered helpful in reducing foot drop symptoms (77,78). Recommended techniques (depending on the site of entrapment) include:

- Counterstrain for the piriformis muscle after correction of the joints associated with this muscle's bony attachments (sacroiliac and femorohumeral joints)
- Balanced ligamentous and membranous tension for the fibular head and lower leg interosseous membrane

OTHER RELATED VASCULAR AND LYMPHATIC ELEMENTS

Enhancing homeostasis associated with vascular and lymphatic elements is a significant portion of an integrated osteopathic treatment regimen in the lower extremities. By definition, removal of somatic dysfunction is linked to its influence on related neural, vascular, and lymphatic elements (Fig. 42.35). As with other regions, the respiratory-circulatory model plays a central role in this aspect of care. In the respiratory-circulatory model, both diagnosis and treatment of the lower extremity begin proximally and move distally. Terminal lymphatic drainage sites are located just inferior to the inguinal ligament in the femoral triangle and as severity increases the congestion extends to fullness in the popliteal region and eventually to the tissues around the Achilles tendon. In addition to fullness or bogginess, dysfunctional drainage results in tissues that are tight, tender, or ticklish. Should one of these peripheral sites be congested without the more proximal site(s), this would indicate a localized trauma rather than a problem involving the entire lower extremity.

In the lower extremities, a number of potential spaces are subject to trauma and swelling. Therefore, this section will also focus on clinical understanding of compartment syndromes and a number of bursitis complaints in the lower extremity.

Arterial Supply

The inferior margin of the acetabulum is incomplete, forming an acetabular notch through which the hip joint receives its blood vessels (Fig. 42.36). These vessels could easily be disrupted by a femoral neck fracture, which creates the possibility of delayed healing or

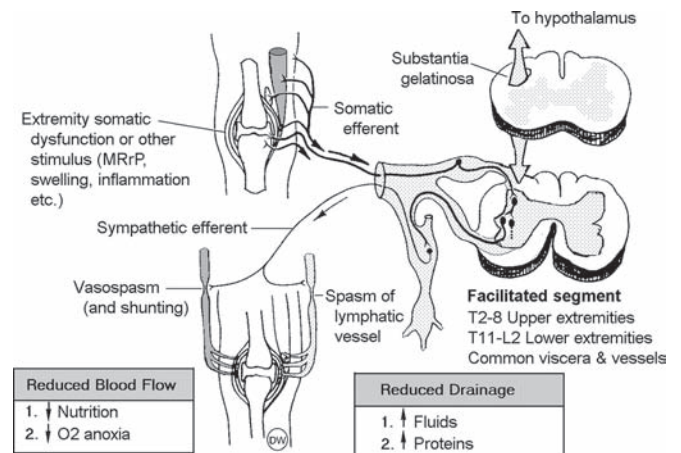

Figure 42-35 Segmental facilitation. Influence of somatic dysfunction on normal vascular and lymphatic elements of the lower extremity. (From Kuchera ML, Kuchera WA. *Osteopathic Considerations in Systemic Dysfunction*. 2nd Ed. Rev. Columbus, OH: Greyden Press, 1994, with permission.)

nonunion; somatic dysfunction rarely causes problems with these large vessels.

The femoral artery is the major vessel supplying the lower extremities. Easily located in the femoral triangle, this artery is bounded by the sartorius and adductor muscles and the inguinal ligament. The mnemonic NAVEL provides a reminder of the order, from lateral to medial, of the structures in the femoral triangle:

*N*erve
*A*rtery
*V*ein
*E*mpy space
*L*ymphatics

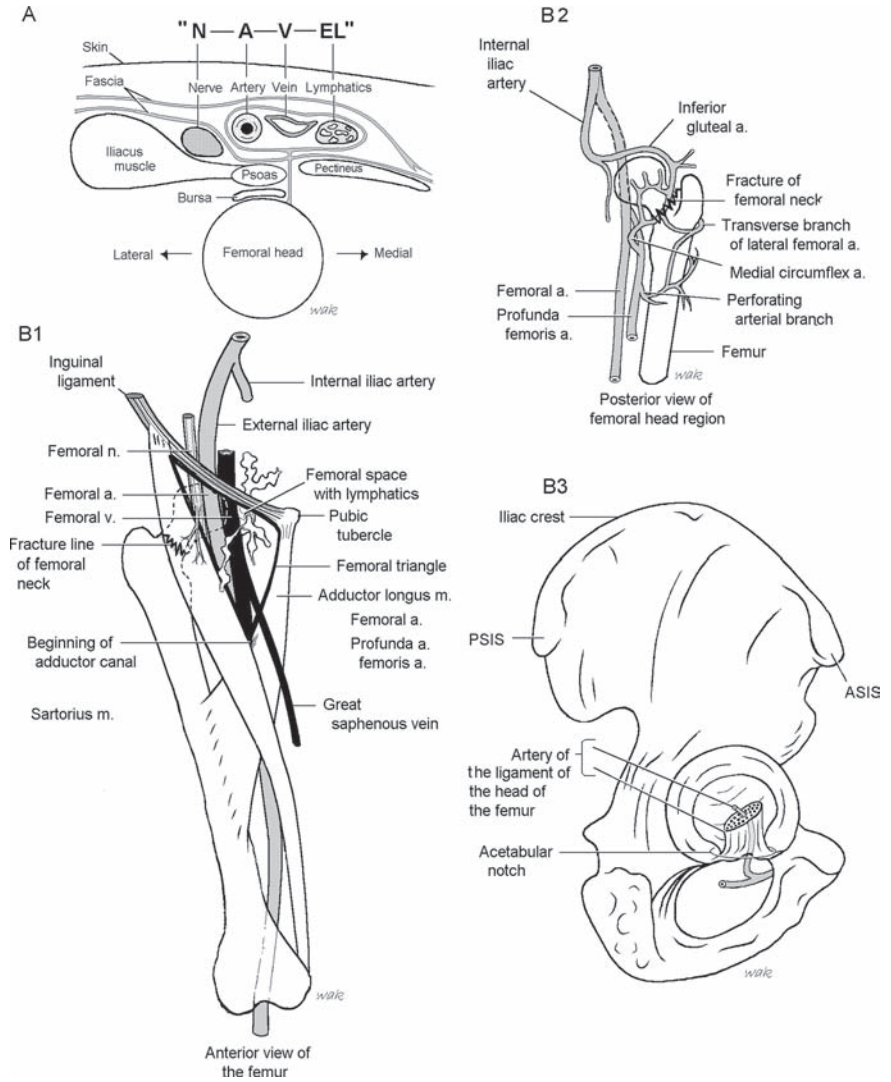

The arterial pulse in the femoral triangle helps to establish all of the other palpatory landmarks in this region. Acute loss of pulses in the lower extremity is usually a contraindication to the use of OMT.

The vascular supply is very poor to the menisci in the knees (especially the central section) and to synovial joint tissues in general. In large part, nutrition to the joints depends on good blood flow to the region and subsequent diffusion into the synovial fluids. Metabolic waste products moving out of the arthroal tissues likewise diffuse into the synovial fluid. This vascular supply limitation also affects decisions concerning surgery (79) in meniscal tears:

- If a tear is within 3 mm of the periphery, it is considered vascular and often heals with conservative care.
- The area 3 to 5 mm from the periphery is considered a gray zone and may benefit from OMT or heat to improve blood flow, but surgery may need to be considered.
- More than 5 to 7 mm from the periphery is considered to be avascular.
- Unstable tears or tears within the vascular zone are repairable.

Treatment of somatic dysfunction is postulated to improve blood delivery by reducing hypersympathetic activity. This is important for the nutritional status of the tissues in the lower extremities. It would also benefit the delivery of medications such as non-steroidal anti-inflammatory drugs to target tissues in the lower extremities where pharmacological effectiveness is proportionate

Figure 42-36 Hip vasculature. Anatomy of the acetabular notch (A) and femoral triangle (B).

to tissue or synovial concentration of the drug. Cell bodies for the sympathetic nerve supply to the lower extremities' vasculature are found at the level of T11-L2.

Venous and Lymphatic Drainage

The very act of locomotion plays an important role in lymphatic-venous return. Use of the lower extremity muscles in walking and running moves these fluids through one-way valves back toward the central vascular system. OMT to open fascial pathways and eliminate MTrPs can improve venous and lymphatic drainage of the extremities. Drainage can also be enhanced using a variety of lymphatic pump techniques such as those performed on the chest cage to maximize pressure gradients between the thorax and abdomen or directly through the lower extremities as with the pedal pump (Dalrymple) technique (each is described more fully in Chapter 51). Lymphatic pumps performed in this manner have been shown to be as effective as treadmill or bicycling exercise and to release nitric oxide at levels consistent with those produced through the upregulation of endothelial nitric oxide synthase (80). The Dalrymple pump is contraindicated in patients with positive Homans or Moses tests or other findings that suggest deep vein thrombosis (81).

Drainage using the respiratory-circulatory model is the most likely added osteopathic component to be used in the treatment of swelling in the various compartments and bursae of the lower extremities.

Bursae and Bursitis

Bursae are small, synovial tissue-lined structures that help different tissues glide over one another, such as a tendon sliding over another tendon or bone. A number of bursae are located around the hip, knee, and ankle (Fig. 42.37). They may swell and become painful when infected or when irritated as a response to direct trauma or stresses placed on the joints of the lower extremities.

Bursitis is inflammation of a bursa. There is palpable swelling that can be defined and that is sensitive to deep pressure. Pain alone in the region of the bursa often leads to misdiagnosis.

Trochanteric Bursitis

In the hip region (see Fig. 42.37), *trochanteric bursitis* is a common clinical diagnosis or, in many cases, a misdiagnosis. The subgluteus maximus (trochanteric) bursa lies at the root of the iliotibial tract. Here, it separates the greater trochanter of the femur from the converging fibers of the gluteus maximus and the tensor fasciae latae.

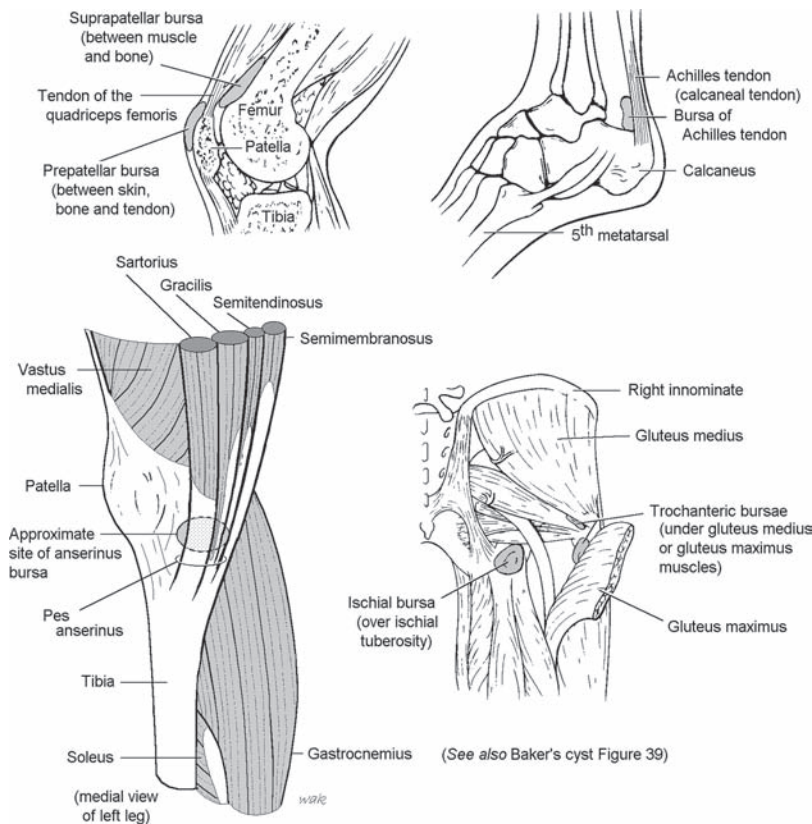

Figure 42-37 Bursae of the lower extremity.

The bursa also separates these fibers from the origin of the vastus lateralis muscle. TrPs in any of these muscles can refer pain to this site and are commonly misdiagnosed as a trochanteric bursitis; this is also the case in quadratus lumborum TrPs (82) and in the ligamentous pain referral from iliolumbar ligament (83).

True inflammation and swelling of the trochanteric bursa (trochanteric bursitis) causes an intense pain over the bursal location that radiates into the lateral thigh. Palpation of the bursa just below the greater trochanter reveals the swelling and heat. Pressure applied to this site increases the pain that can be further aggravated by walking, hip abduction, or internally rotating the hip. Injection of the bursa with a local anesthetic with or without accompanied steroids quickly and significantly reduces pain. A higher incidence of trochanteric bursitis is found on the long leg side of individuals with unequal leg length (84).

Patellar Bursitis

The knee is a common site for trauma to the bursa designed to protect the relatively exposed superficial structures from injury against those underlying them. A large prepatellar bursa separates the patella from the skin anterior to it. Inflammation of this bursa from long-term kneeling or from other trauma results in a condition known as *housemaid's knee*.

The suprapatellar bursa connects to the synovial cavity of the knee joint and can be used in physical diagnosis to determine if knee trauma has caused significant swelling. The physician first milks any fluid in this bursa from the medial to the lateral side. Then, by palpating anteromedially for a fluid wave initiated by a gentle squeeze from the anterolateral side of the suprapatellar tendon, it is possible to detect 10 to 15 mL of effusion in the knee. This *bulge test* is used for small effusions (Fig. 42.38A). If the

effusion is so large that the tissues become turgid, a fluid pulse might not be able to create a bulge and the test can provide a false-negative result. Large effusions are more accurately diagnosed with a ballotement test (Fig. 42.38B) in which the kneecap is tapped gently (ballotted). A palpable transmission of bony contact is palpated if the effusion is large enough to have distanced the patella from the bone behind it.

The superficial and deep infrapatellar bursae are less often involved in clinical problems.

A *Baker cyst* arises from enlargement of either the semimembranosus bursa or the bursa behind the medial head of the gastrocnemius (Fig. 42.39). The swollen cyst is often painful, especially with flexion of the knee, and the swelling is more prominent in the standing position. Both of these bursae commonly communicate with the synovial cavity of the knee. For this reason, knee trauma such as a meniscal tear, or diseases such as rheumatoid arthritis, can initiate the cyst. Rupture of a Baker cyst may be misdiagnosed as thrombophlebitis; extension of a Baker cyst may compress the common peroneal nerve near the fibular head and lead to a foot drop.

Pes Anserine Bursitis

Pes anserine bursitis is a common finding in patients or athletes who present with complaints of anterior knee pain. The pes anserine bursa, along with its associated medial hamstring tendons, is located along the proximomedial aspect of the tibia (see Fig. 42.37). This condition is usually found in patients who have tight hamstrings, although it also can be caused by trauma (as in a direct blow). In most patients, pes anserine bursitis is a self-limiting condition that responds to a program of hamstring stretching and quadriceps strengthening.

Figure 42-38 Tests for effusion in the knee. The bulge test (A) is useful for finding a minimal amount of effusion in the knee. The ballottement test (B) is positive if there is a large amount of effusion present. (Illustration by W.A. Kuchera.)

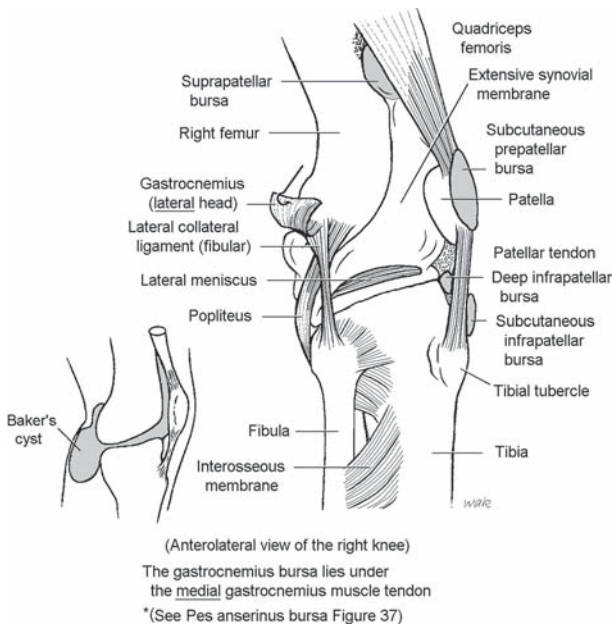

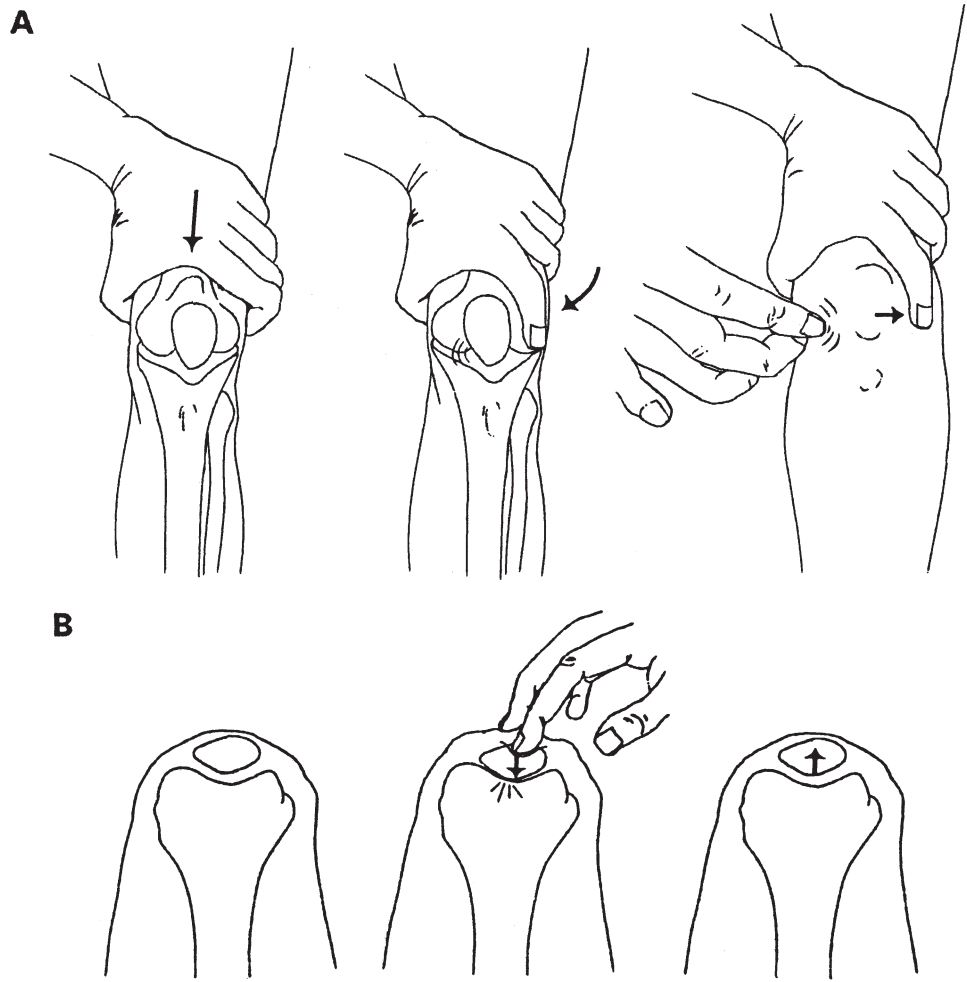

Figure 42-39 Bursae of the knee and Baker cyst.

Bursa of the Achilles Tendon

In the ankle region, the superficial bursa of the Achilles tendon can be irritated by poorly fitting shoes and can swell (see Fig. 42.37). This results in a tender *pump bump*.

Compartments in the Lower Extremity

The lower leg is divided into three compartments (Fig. 42.40):

- Anterior osseofibrous compartment
- Lateral osseofibrous compartment
- Two posterior osseofibrous compartments—deep and superficial

Clinically, a compartment syndrome can arise from trauma or vigorous overuse, leading to a rise in intracompartmental pressure. This in turn compromises the circulation, including venous return, within that compartment.

Recurrent mild compartment symptoms are managed with ice and OMT. Ice decreases pain and metabolic demand after activity. OMT also decreases pain and improves venous and lymphatic return. Management of coexisting TrPs is also helpful but not with injections; they would increase pressure in an already tight compartment. Modification of the running surface or the running shoe may also be required in order to prevent recurrent compartment syndromes.

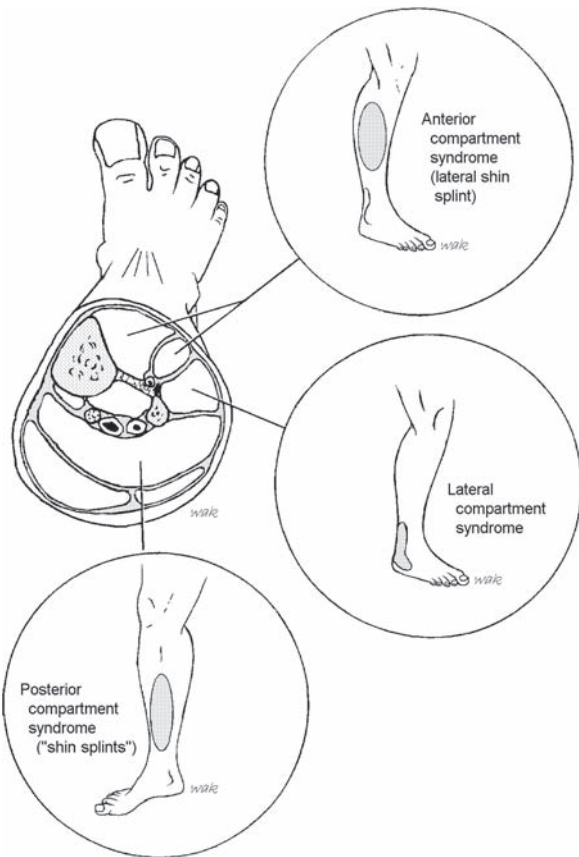

Figure 42-40 Fascial compartments of the lower extremity.

Anterior Compartment

The anterior compartment is covered anteriorly by a relatively nonexpansile fascia. Structurally, this creates the potential for development of an anterior compartment syndrome. Bleeding into this compartment from a fracture or other trauma creates increased pressure in this enclosed space. For runners, sometimes muscle swelling impairs venous outflow, which results in a rise in intracompartmental pressure. If intracompartmental pressure becomes great enough, arterial circulation is reduced, and ischemia with potential necrosis of muscle in the compartment can occur. An *acute compartment compression* is a surgical emergency requiring fasciotomy. Such a situation is more likely to occur in the anterior compartment than in other divisions of the leg. The acute compartment compression may occur in runners where symptoms of intense pain develop during the run but do not subside afterward.

Palpation reveals the entire tibialis anterior muscle to be hard and tender. Anterior compartment muscles may also exhibit weakness upon testing and peripheral pulses are usually present. Decreased sensation is often present between the first and second toes as a result of entrapment of the deep peroneal nerve. While primarily a clinical diagnosis, intracompartmental pressure can be measured with a wick catheter (85). Because of the location of the pain on the anterolateral side of the leg, recurrent anterior compartment syndrome is also sometimes called *anterior shin splints*.

Lateral Compartment

In the lateral compartment syndrome, pain is located diffusely along the lateral aspect of the lower leg. It recurs in runners with excessive pronation of the foot or might result from rupture of the peroneus longus muscle.

Posterior Compartment

The posterior compartment syndromes typically refer pain anteromedially. While some reserve the term *shin splints* only for periostitis along the line of attachment of a repeatedly overloaded muscle (86), others include posterior compartment syndrome in the differential diagnosis along with stress fractures of the tibia and chronic periostitis (the soleus syndrome). Posterior compartment syndromes are often bilateral and difficult to manage conservatively.

CLINICAL PATTERNS AND OSTEOPATHIC MANAGEMENT

To this point in the chapter, the lower extremity has been discussed as a series of component parts; in reality, each of these parts interact. Somatic dysfunction or pathology in any one skeletal, arthroal, or myofascial component affects the rest of the somatic structures as shown in both the common compensatory malalignment syndrome (87) and a traumatically induced problem such as an ankle sprain (88).

Case Management 1: Supination Ankle Sprain

A 22-year-old amateur rugby player presents with acute swelling and lateral ankle pain after twisting his ankle by stepping in a small pothole in the playing field 24 hours earlier. The description of his injury matches that of a classic supination sprain. He has his right ankle wrapped with an over-the-counter elastic bandage using a figure-of-eight pattern extending from metatarsals to mid-calf. He is able to bear weight gingerly, but prefers to use a set of crutches from a prior ankle injury 1 year ago on the same side. He has been icing and elevating the ankle, which had been his only care in the prior injury.

Examination incorporating the Ottawa ankle rules (see Fig. 42.18) suggests no ankle or forefoot fracture. In addition to the tenderness, swelling, and ecchymosis over the anterior talofibular ligament, he has the typical somatic dysfunction pattern depicted/summarized in Figure 42.19.

One fourth of all individuals who have experienced a significant ankle sprain will continue to have pain, instability, and sprain recurrence (89). Two theories, each with valid support, explain why. One theory blames mechanical instability due to damaged support structures while the other blames functional instability owing to dysfunctional neural-proprioceptive pathways that inaccurately report ankle position. Regardless, somatic dysfunction is thought to play a role in both.

The somatic dysfunction associated with a supination sprain was previously described (see Fig. 42.19) (90). OMT as part of the biomechanical-postural model is prescribed to improve ankle dorsiflexion—reduced ankle dorsiflexion increasing the risk of recurrent ankle sprains by 500% (91)—and to remove somatic dysfunction in joints and muscles known to impair proprioceptive balance mechanisms (92). Furthermore, osteopathic treatment for this condition involves opening and implementing the respiratory-circulatory model to provide reduction of the swelling, loss of function, and residual dysfunction seen in acute ankle trauma (93). Outcomes associated with the use of manual treatment suggest more rapid resolution of pain, swelling, and dysfunction and might reduce the risk of reinjury (94–99). Consideration of the biopsychosocial model is also part of the osteopathic approach in this (and other cases)—what, if any, health impact might be associated with the inability of an athlete to miss a key game; to ignore advice and play on an injured ankle; or to fail to regain function with subsequent loss of scholarships and self-image?

What follows is a safe and effective method for the local hands-on treatment of an acute supination ankle sprain on the right side; it is also an effective combination for use in chronic conditions where OMT was perhaps not part of the rehabilitation process. All use balanced ligamentous and balanced membranous techniques (BLT/BMT) appropriate even immediately after a sprain. In chronic conditions or when the swelling recedes in a recent ankle sprain, gentle direct muscle energy technique to the talocrural joint may be added if needed.

With practice, transitioning from the subtalar joint into the talocalcaneal joint (Figs. 41A,B) and from that balanced anatomy carrying the indirect fascial unwinding technique up through the anterior talofibular ligament into the interosseous membrane can be done seamlessly without changing hand positions around the talocalcaneal joint. Fascial unwinding from the foot-ankle up and from the hip down (Fig. 41D) is also a time-effective approach to this injury.

Diagnosis: Supination with posterolateral glide of the talocalcaneal joint.

OMT: Balanced Ligamentous Tension of Forefoot to Hind Foot and Talus to Calcaneous (see Fig. 42.41A)

1. Doctor takes the right foot in the right hand with the thumb and first digit pinching the talus; the remainder of the fingers holding the arch of the foot. The left hand stabilizes the calcaneus between fingers and thenar eminence. (Patient is supine)
2. Using a motion between the two hands like “wringing out a wet cloth,” glide the talus posterolateral on the calcaneus to the point of BLT. The right hand will move slightly counterclockwise while the left hand moves clockwise; the right hand will also slightly increase the foot’s arch

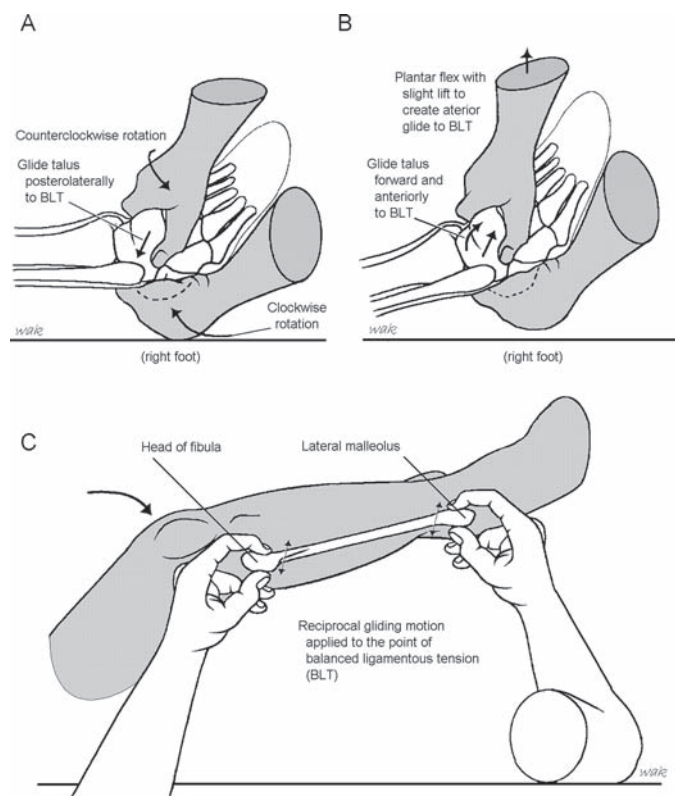

Figure 42-41 BLT/BMT OMT for Patients with Supination Sprain (A) Posterolateral talocalcaneal SD; (B) Plantar flexion with anterior glide SD; (C) Fibular SD with interosseous strain.

3. Concentrating on the persistent yielding between the talus and the calcaneus, continuously adjust the BLT until a release is palpated

Diagnosis: Plantar flexion with anterior glide of the talocrural joint.

OMT: Balanced Ligamentous Tension (see Fig 42.41B):

1. Maintaining the same hand hold as above, gently lift the lower extremity off the table to create a gentle anterior glide of the talus in the ankle mortise and add just enough plantar flexion (and additional anterior glide) to feel BLT between the talus and the rest of the lower leg at the ankle
2. Concentrating on the persistent yielding between the talus in the mortise, continuously adjust the BLT until a release is palpated
3. If the doctor wishes a slight shift of focus can be made at this point to gently pull in an anteromedial direction through the anterior talofibular ligament into the distal fibula and the interosseous membrane

Diagnosis: Fibular head dysfunction (usually posterior) with strain of interosseous membrane.

OMT: BLT of Fibula and BMT of the Interosseous Membrane (see Fig. 42.41C):

1. Doctor’s left thumb pad contacts the right fibula just posterior to the fibular head; the right thumb pad is placed just posterior to the lateral malleolus. The supine patient’s hip and knee on that side are bent so that the lower extremity sits comfortably on the doctor’s thumbs. The weight is adjusted to avoid compression over these thumbs. (The doctor may use fingers or even a forehead to help take weight off of the thumbs.)
2. The lower extremity is adjusted by modifying the hip and knee bend (and perhaps a bit of external rotation at the hip) so that the fibula at both ends feels as if the same slight weight is resting on each thumb. (The doctor will typically have their elbows both resting on the table.)
3. The fibula is then balanced (to BLT) with either a slight amount of inferior-superior glide from the lateral malleolus thumb to move the fibular head posterior to balance -OR- with a slight amount of superior-anterior pressure from the fibular head thumb to glide the fibular head anterior to balance
4. Final fine tuning usually consists of an inferior longitudinal balancing force through both thumbs along the long axis of the fibula that often also needs slight medial glide of the distal fibula (in the direction of the sprained anterior talofibular ligament) to the point of BMT
5. Concentrating on the persistent yielding of the fibular head in the direction it first preferred, and along the interosseous membrane between the tibia and fibula adjust the BLT/BMT until a release is palpated

Diagnosis: Edema, inflammation, and fascial torsion in lower extremity.

OMT: Popliteal Spread, Fascial Unwinding, and Lateral Fluctuation of the Lower Extremity to Enhance Homeostasis to Handle Inflammation and Edema:

1. Patient is supine with leg slightly flexed and abducted to allow the doctor (standing at the end of the table) to place the patient’s ankle/foot between his or her lower thighs to help control the patient’s leg

2. Using the fingers of both hands, the doctor contacts the medial and lateral edges of the hamstring muscle tendons and gently spreads these away from the midline of the popliteal region. ("Popliteal spread technique.")
3. Abduct/adduct, flex/extend, and internally/externally rotate at the hip to the point of balanced ligamentous tension
4. Maintain hip but stack major and minor motions at the knee (flex/extend, abduct/adduct, and externally/internally rotate with anteromedial or posterolateral glides, respectively)
5. Maintain hip and knee balanced tensions and now add an approximation of pronation/supination of the foot
6. Add a little traction or compression along the longitudinal axis of the lower extremity again to BLT
7. As "fascial unwinding" is performed, ask where the patient feels warmth. It should progress from thigh to knee to calf to foot to toes over a period of a minute or less. (If the progression stops, it indicates a site of significant somatic dysfunction that may require specific OMT.)
8. Place the patient's feet flat on the table with knee flexed to 90 degrees and hip flexed to 45 degrees
9. The doctor's caudad hand holds the dorsum of the patient's foot and ankle and the cephalad hand rests on top of the patient's knee
10. The patient's knee is moved medial and lateral at the knee to find the position of greatest ligamentous balance
11. From that point of balance, the doctor institutes a small rhythmic medial to lateral excursion that is maintained until treatment is finished

After appropriate diagnosis of the patient (including his ankle), osteopathic treatment of the patient focuses first to limit pathophysiology and promote inherent motions during the "PRICE" (Protection, Relative rest, Ice, Compression/support, Elevation) approach in the acute state; indirect OMT plays a role at this point. Subsequently, strategies shift to effective rehabilitation including early mobilization, correction of somatic dysfunctions that could limit shock absorption, ankle range of motion (especially dorsiflexion), or muscle-proprioceptive imbalance. Patient education and exercise (strengthening, range of motion, and proprioceptive) (100,101) often play a role in this stage for full return of function and prevention of recurrence.

SUMMARY

A thorough understanding of the functional anatomy of the lower extremities, coupled with grounding in osteopathic practice principles, establishes a foundation for the osteopathic approach to the lower extremities and their effect on the whole person. Palpation assists in differential diagnoses of a wide range of structural and functional disorders in this region. The osteopathic physician then seeks to balance and improve biomechanical and homeostatic functions to influence a wide range of patient conditions.

From a sports medicine practice to the care of patients with deep vein thrombosis in an internal medicine practice, the osteopathic approach to the lower extremities offers an effective approach to diagnosis, prevention, and treatment.

KEY CONCEPTS

- A knowledge of functional anatomy of the upper extremities is needed to perform an accurate assessment of the upper extremity and manipulative treatment procedures.
- Muscle anatomy, actions, and innervations are necessary prerequisite knowledge in dealing with extremity complaints.
- Diagnosing the location, etiology, and the significance of the axial somatic component to a distal extremity is critical.
- The rotator cuff includes the supraspinatus, infraspinatus, teres minor, and subscapularis muscles.
- Arterial compression by the scalenes may produce arm symptoms.
- Fascial restrictions can affect the lymphatic drainage of the upper extremities.
- Sympathetic stimulation from thoracic dysfunction can cause symptoms in the extremities.
- Peripheral nerves of the upper extremity can become entrapped by muscular, fascial, or ligamentous tension.
- Understanding the configuration, physiologic motion, and somatic dysfunction of the shoulder, elbow, forearm, wrist, and hand improves patient treatment.
- Orthopedic tests of the upper extremity can help pinpoint the diagnosis.
- Treatment of carpal tunnel syndrome, rotator cuff tendonitis, tennis elbow, adhesive capsulitis, and thoracic outlet syndrome needs to include manipulative treatment of associated somatic dysfunction.

INTRODUCTION

The upper extremities are vital to performing the activities of daily living. Even minor injuries may produce disabilities that significantly affect overall function. Effective diagnosis and treatment necessitates a thorough understanding of the structure and function of this important region.

FUNCTIONAL ANATOMY

Skeletal and Arthrodiol Structures

Functionally, the upper extremity can be divided into the (2):

- Acromioclavicular joint (A-C joint)
- Sternoclavicular joint
- Scapulothoracic joint
- Glenohumeral joint
- Elbow (ulnohumeral joint)
- Wrist (radiocarpal joint)
- Intercarpal, carpometacarpal, metacarpophalangeal (MP), and interphalangeal (IP) joints

Motion restrictions in one joint will require compensatory movement in the other joints. Painful joints can be restricted in their motion or have excessive motion beyond their usual functional requirement. Excessive motion or inflammation of a joint will cause the surrounding muscles to contract in an attempt to stabilize or protect the joint.

Scapulothoracic Joint

The scapulothoracic joint is formed by the articulation of the anterior surface of the scapula with the posterior thorax. It is a

pseudoarticulation. The position of the scapula is controlled by muscular forces. The scapula is attached to the spine and ribs by the rhomboids, trapezius, serratus anterior, pectoralis minor, and levator scapulae. Tension in these muscles controls the position of the scapula. The levator scapulae and trapezius provide postural support, while the middle trapezius and rhomboids retract the scapulae. The serratus anterior protracts the scapulae, and when contacting with the upper trapezius, these muscles will cause upward rotation and elevation (27). The position and motion of the scapula controls the glenohumeral joint. Abnormal position of the ribs, such as that seen in scoliosis, will affect the positional alignment of the scapula, bringing it more into a protracted and elevated position on the side of the convexity of the scoliotic curve. Motion of the shoulder on the convex side of the scoliotic curve will be different than on the concave side. Somatic dysfunction of a single rib, or a group of ribs, will affect the smooth gliding motion of the scapula over the posterior rib cage. The rotator cuff muscles attach the humeral head to the scapula. If the position of the scapula is abnormal, these muscles are required to function differently, based on their length/tension relationships. The various motions of the scapula are:

- Elevation (upper trapezius and levator scapula)
- Depression (lower trapezius, lower rhomboids)
- Protraction (serratus anterior)
- Retraction (rhomboids and middle trapezius)
- Rotation about a transverse axis

A-C Joint

The A-C joint is formed by the articulation of the lateral end of the clavicle with the acromion process of the scapula. The A-C joint is a planar joint with a crescent-shaped rudimentary incomplete meniscus (22). The acromion has a variable shape and slope, and

forms the roof of the coracoacromial arch (26). The coracoacromial ligament attaches from the outer portion of the coracoid process to the undersurface of the acromion and makes up the anterior portion of the coracoacromial arch (26). Under the coracoacromial arch is the subacromial bursa and rotator cuff tendons. This is the region in which extrinsic or outlet impingement of the rotator cuff occurs. The A-C joint depends on its ligamentous attachments for stability; these are the A-C and coracoclavicular ligaments. The strongest ligament between the clavicle and scapula is the coracoclavicular ligament. It has two portions. The coronoid portion of this ligament prevents anterior rotation of the distal clavicle; the trapezoid portion resists posterior rotation of the distal clavicle. Although a planar joint, functionally, this joint acts similar to a ball and socket, providing anteroposterior, superoinferior, and rotational motion. A small, yet important, amount of clavicular motion occurs with shoulder movement; there is controversy over the amount of motion occurring at this joint. Large amounts of axial motion have been described, as well as rotation axially less than 10 degrees over the arc of shoulder abduction (27).

Sternoclavicular Joint

The sternoclavicular joint is formed by the articulation of the medial end of the clavicle with the manubrium of the sternum. The sternoclavicular joint has a saddle-shaped articular surface. The clavicular notch on the sternum is shallow and small compared to the articular surface of the medial end of the clavicle. Fortunately, this is a complex synovial joint that contains a cartilaginous meniscus. This provides needed stability. The interclavicular ligament resists superior displacement of the sternal end of the clavicle. The costoclavicular ligament attaching to the first costal cartilage acts as a fulcrum and limits upward movement of the lateral end of the clavicle (22). As the clavicle abducts, this ligament helps produce a downward glide to the sternal end of the clavicle. The subclavius muscle depresses and pulls the medial end of the first rib forward when the lateral end of the clavicle is elevated.

Glenohumeral Joint

The glenohumeral joint is formed by the articulation of the head of the humerus with the glenoid fossa of the scapula. The humeral head is large, smooth, slightly elliptical, and covered in articular cartilage. The glenoid is small, concave, and has a cartilaginous lip (labrum) that helps locate the humeral head into the glenoid. The proximal humerus is separated anatomically into four parts: the articular surface, the lesser tuberosity, the greater tuberosity, and the diaphyseal humeral shaft (27). The humeral head is angulated medially 45 degrees to the long axis and retroverted 30 degrees. The joint has significant mobility, but lacks stability due to its design. The joint undergoes spinning, sliding, and rolling. The joint is synovial and enclosed by a strong ligamentous capsule. The joint capsule has a superior, middle, and inferior glenohumeral ligament complex. The capsule is weak anteriorly and inferiorly (inferior glenohumeral ligament complex), allowing for instability or dislocation to commonly occur in that direction. The posterior capsule is commonly tight, which causes anterior translation and elevation of the humeral head. This situation can cause secondary impingement of the rotator cuff (26). The fibrocartilagenous labrum surrounds the periphery of the glenoid. The labrum acts as an attachment site for the capsuloligamentous structures, and as a “cup” to increase the surface area of the glenoid, as well as providing a negative intracapsular pressure that helps to center (or capture) the humeral head.

Ulnohumeral Joint

The ulnohumeral joint is the true elbow joint (6). The hinge-like elbow joint allows for motion around a transverse axis. It has a ligamentous capsule that is thickened on the medial and lateral sides, yet is weak anteriorly and posteriorly. For anterior and posterior stability, muscles such as the biceps brachii and triceps serve the function as ligaments.

The trochlear notch of the ulna is closely fitted to the trochlea of the humerus. The surfaces are lined with articular cartilage and fit together in a spiraled fashion. This is so that as the elbow is extended, the hand is held away from the body (carrying angle) and when the elbow is flexed the hand is close to the mouth. The motion occurs without requiring any rotation of the humerus at the shoulder. The minor motions (such as abduction/adduction) are allowed by the relative looseness of the fit of the trochlea in the trochlear notch, and the presence of articular cartilage (22).

Proximal Radioulnar Joint

The head of the radius at the proximal end of the radial bone near the elbow is not a part of the elbow joint. The pivotal motion for pronation and supination of the forearm is provided by the proximal radioulnar joint. The radial head rotates on the capitellum during pronation and supination. During elbow extension, the radial head glides posteriorly on the capitellum. During elbow flexion, the radial head glides anteriorly on the capitellum (22).

The Wrist (Radiocarpal) Joint

The wrist is formed by the junction of the ulna, radius, and the carpal bones. The joint is considered an ellipsoidal synovial articulation. The true wrist joint is the radiocarpal joint, formed by the distal end of the radius and the three proximal carpal bones: the scaphoid, lunate, and the triquetrum. The convexity of the scaphoid, lunate, and the triquetrum fit into the concavity of the radius and the articular disc. The disc separates the distal radioulnar joint from the wrist joint cavity and attaches the ulna to the radius. The capsular ligaments are sufficiently loose to allow some minor movements of the carpal bones (22). Possible motions include flexion, extension, abduction, and adduction, as well as supination and pronation of the hand and forearm. Flexion and adduction of the wrist are typically freer.

Table 43.1 outlines the major motions of the shoulder, elbow, wrist, and MP joints.

THE HAND

Intercarpal Joints

The scaphoid, lunate, and the triquetrum articulate with the greater and lesser multiangular bones, the capitate and hamate. Motion between these rows of bones is more free in flexion. If bony point tenderness is present in the face of hand trauma, always x-ray the hand to make sure a scaphoid fracture is not present.

Carpometacarpal Joints

The first carpometacarpal articulation is concave, and classified as a saddle-shaped joint. It is freely movable in two planes and rarely subject to dysfunction. The second to fifth carpometacarpal joints are gliding joints. The fifth is the most mobile, then the fourth. The second and third are fairly restricted in motion.

TABLE 43.1

Major Motions of the Shoulder, Elbow, Wrist, and MP Joints

Glenohumeral Joint	Elbow	Wrist	Metacarpophalangeal
Abduction 180 degrees	Flexion 135 degrees	Supination 90 degrees	Flexion 90 degrees
Adduction 45 degrees	Extension 0–5 degrees	Pronation 90 degrees	Extension 30–45 degrees
Flexion 90 degrees		Flexion 80 degrees	
Extension 45 degrees		Extension 70 degrees	
Internal rotation 55 degrees		Ulnar deviation 30 degrees	
External rotation 40–45 degrees		Radial deviation 20 degrees

MP Joints

These joints allow for more mobility than the carpometacarpal joints. These joints are commonly affected by rheumatoid and osteoarthritis, and can become enlarged and stiff. Flexion, extension, abduction, and adduction occur, as well as a slight amount of rotation. There is a joint capsule surrounding each joint as well as a synovial membrane.

IP Joints

The proximal IP joints are called the “PIP joints,” the distal IP joints are called the “DIP joints.” The DIP joints can become enlarged with firm nodules (Herberden nodes) on either side of the dorsal midline. These are usually painless and indicate osteoarthritis. The PIP joints and metacarpal phalangeal joints are usually involved in rheumatoid arthritis and demonstrate Haygarth nodes. The joint may be thickened, inflamed, and tender, with a fusiform appearance. In males, the ring finger is typically longer than the index finger, in females, the opposite holds true.

Table 43.2 outlines the major motions of the proximal and distal IP joints, and Table 43.3 includes the major motions of the joints of the thumb.

Muscles

Muscles generally act in groups to produce specific motions. Detailed assessment of the upper extremity necessitates an understanding of these groups and their innervations (2). Tables 43.4

through 43.7 present the muscles and nerves of the following joints (2):

- Glenohumeral joint (Table 43.4)
- Scapulothoracic joint (Table 43.5)
- Elbow (Table 43.6)
- Wrist (Table 43.7)

The rotator cuff muscles are critical to maintaining stability of the glenohumeral joint, as well as providing precision movements and propulsion in throwing or swinging motions. The cuff is formed by the confluent tendon of the supraspinatus, infraspinatus, teres minor, and subscapularis. The supraspinatus, infraspinatus, and teres minor insert on the greater tuberosity. The subscapularis inserts on the lesser tuberosity of the humerus. The supraspinatus has been thought to initiate abduction; however, it is currently felt that it is more of a glenohumeral joint stabilizer. Because of its angle of insertion (70 degrees from the glenoid), the supraspinatus acts as a fulcrum, applying a compressive force to hold the humeral head in the glenoid, as the synergistic action with the deltoid causes abduction. The supraspinatus is active during the entire arc of abduction; paralysis of the suprascapular nerve causes a 50% reduction in abduction torque (27). Without a properly functioning supraspinatus, impingement of the cuff between the humeral head and undersurface of the acromion occurs.

The teres minor and infraspinatus depress, extend, and externally rotate the humerus. The infraspinatus is more active with the arm at the side, the teres minor is more active with the shoulder in 90 degrees of elevation. The subscapularis internally rotates, flexes, and depresses the humeral head. The tendinous insertion is

continuous with the anterior capsule, helping to limit anterior instability. During throwing and eccentric activity, the subscapularis and infraspinatus are the two most important stabilizing forces of the shoulder (26,27).

The long head of the biceps is intimately associated with the rotator cuff and has been considered the “fifth tendon” of

the rotator cuff (26). The biceps tendon is intra-articular, yet extrasynovial, and passes deep to the “rotator interval” a space between the supraspinatus and subscapularis tendon insertions. The coracohumeral ligament and the superior glenohumeral ligament complex surround the biceps tendon and act as a pulley as it enters the intertubercular groove. The long head of the biceps

tendon then travels in the intertubercular sulcus, which has a variable shape and slope. Because of differences in the shape and slope of this groove, the tendon can translate back and forth causing degenerative changes in the tendon. The biceps function is controversial as some believe it is a humeral head depressor; others feel it is a passive player in most shoulder motions (26).

The teres major muscle is not considered a rotator cuff muscle. It is sometimes used as a donor muscle in shoulder surgeries. The teres major acts in synergy with the latissimus dorsi muscle, to cause humeral extension, internal rotation, and adduction (27).

Arterial Supply

The left subclavian artery arises from the posterior part of the aortic arch. It passes posterior to the left sternoclavicular joint. The right subclavian artery arises from the brachiocephalic trunk (3). The subclavian arteries pass over the top of the first rib between the anterior and middle scalene muscles. This is an area of compression in thoracic outlet syndrome. The subclavian artery becomes the axillary artery at the lateral border of the first rib. The axillary artery passes posterior to the pectoralis minor muscle and becomes the brachial artery at the inferior border of the teres major muscle. Branches from the axillary and brachial arteries supply the structures of the shoulder, arm, forearm, and hand. Somatic dysfunction of the following structures may affect arterial supply:

- Anterior and middle scalenes
- Upper thoracic vertebrae
- Upper ribs
- Clavicles
- Fascia of the upper extremity

The vascular supply of the rotator cuff has been extensively studied. There is a “critical zone” of anastomotic blood supply to the rotator cuff muscles; in this critical zone, it is hypothesized that rotator cuff tears begin. One such area is in the supraspinatus tendon immediately proximal to its insertion of the greater tuberosity of the humerus (26).

Venous Supply

The axillary vein lies on the medial side of the axillary artery. The axillary vein receives tributaries that correspond to the branches of the axillary artery and receives venae comitantes of the brachial artery. It ends at the lateral border of the first rib, where it becomes the subclavian vein (3). The subclavian vein passes over the first rib anterior to the anterior scalene muscle (3). The subclavian vein unites with the internal jugular vein to become the brachiocephalic vein (3). The left brachiocephalic vein passes posterior to the left sternoclavicular joint and crosses the midline. The right brachiocephalic vein passes posterior to the right sternoclavicular joint. The right brachiocephalic vein joins the left brachiocephalic vein to form the superior vena cava (3). Dysfunction in the upper thoracic vertebrae (causing increased sympathetic tone to the upper extremities), upper ribs, clavicles, and fascia of the upper extremities may impair venous return. Because the vein passes anterior to the scalene muscles, scalene tension does not create venous distention of the upper extremity. A thrombosis in the subclavian vein can cause swelling in the breast and upper extremity due to venous obstruction.

Lymphatic Drainage

The major lymph nodes of the upper extremities are found in the fibrofatty connective tissue of the axilla. They are arranged in five

groups, four of which lie inferior to the pectoralis minor tendon and one which lies superior to it (Fig. 43.1). These groups are:

- Pectoral
- Lateral
- Subscapular
- Central
- Apical

The pectoral group of axillary lymph nodes lies along the medial wall of the axilla. This group receives lymph mainly from the anterior thoracic wall and breast. The efferent vessels from these nodes pass to the central and apical groups of axillary lymph nodes (3).

The lateral group of lymph nodes lies along the lateral wall of the axilla. This group receives lymph from most of the upper limb.

The subscapular group of axillary lymph nodes is located along the posterior aspect of the thoracic wall and scapular region. Efferent vessels pass from here to the central group of axillary lymph nodes.

The central group of axillary lymph nodes is situated deep to the pectoralis minor near the base of the axilla. This group receives lymph from the other axillary lymph nodes. Efferent vessels pass lymph to the apical lymph nodes.

The apical group of axillary lymph nodes is situated in the apex of the axilla. This group receives lymph from the central lymph nodes. The efferent vessels from this group unite to form the subclavian lymphatic trunk. The right subclavian lymphatic trunk drains into the right lymphatic duct. The left subclavian lymphatic trunk drains into the thoracic duct. Somatic dysfunction affecting the venous system may also affect lymphatic drainage, thereby producing congestion in the upper extremity. Fascial restriction of the thoracic inlet and pectoral fascia can also cause lymphatic stasis of the upper extremity.

Sympathetics

The sympathetic innervation to the upper extremities arises from the upper thoracic spinal cord. The sympathetic ganglia lie anterior to the

rib head, in the fascia common to both structures. Dysfunction in the upper thoracic spine and ribs may increase sympathetic tone to the upper extremity and produce altered motion, nerve dysfunction, and lymphatic and venous congestion (28). Increased sympathetic tone is accompanied by palpatory findings in the upper thoracic/rib area and increased sensitivity to painful stimulus. It also prevents arterial blood from getting to the structures of the arm and reduces the amount of lymphatic fluid returning from the arm via the lymphatic vessels. The cause of these musculoskeletal findings may be viscerosomatic; they may be primary somatic in the area, or they may be reflex from the cervical spine. Nociceptive afferents from the cervical spine travel in the sympathetic chain and synapse in the intermediolateral cell columns of the upper thoracic cord. This produces an irritable focus in the cord, with resulting somatic and sympathetic hyperactivity (28).

Brachial Plexus

Nerve roots C5–8 and T1 form the brachial plexus. These nerve roots pass through the intervertebral foramen of the cervical vertebrae and pass between the anterior and the middle scalene muscles (3). The roots unite to form successive trunks, divisions, cords, and branches. The nerve trunks extend from the scalene triangle (formed by the anterior and middle scalenes and the clavicle) to the clavicle. Nerve divisions extend from a position posterior to the clavicle to the axilla. Nerve cords are found in the axilla. Nerve cords divide into branches that innervate various structures in the upper extremity. The neurovascular bundle of the arm contains the subclavian artery, subclavian vein, brachial plexus, and the sympathetic nerve plexus.

Peripheral Nerves and Nerve Entrapment

The three main peripheral nerves of the upper extremity include the median nerve, the ulnar nerve, and the radial nerve. Understanding the innervation of each and site of potential compression is important.

Figure 43-1 Lymphatic drainage of upper extremity. (Illustration by W.A. Kuchera.)

Median Nerve

The most proximal level of compression of the median nerve may produce the pronator syndrome, which is a compression of the median nerve as it passes through the pronator teres muscle, or under the ligament of Struthers (29). It is associated with pain in the proximal volar forearm and sensory signs and symptoms in the radial 3½ digits of the hand. Symptoms are generally aggravated by flexion of the elbow against resistance. Sensory symptoms and signs of the pronator syndrome typically mimic C6 and C7 radiculopathy. The pronator syndrome may affect the function of the median nerve innervated muscles in the C6 and C7 distribution (29).

The median nerve has a motor branch called the anterior interosseous nerve. In anterior interosseous syndrome, there are no sensory abnormalities. Pain in the proximal forearm is typically aggravated by exercise and abates with rest. Motor abnormalities are manifested as weakness and are referred to those muscles innervated by this nerve (flexor pollicis longus, pronator quadratus, and flexor digitorum profundus of the index finger). This syndrome may mimic a C8 radiculopathy because this is the root through which they are all innervated (29).

The next region of compression for the median nerve is at the carpal tunnel at the wrist. Compression of the median nerve in the carpal tunnel (carpal tunnel syndrome) typically causes sensory symptoms such as night pain, paresthesias, and numbness in the hand in the radial 3½ digits. Symptoms may be referred proximally from the hand toward the forearm and even the elbow and may be reproduced or elicited by Phalen maneuver or Tinel sign. Thenar muscle weakness and atrophy represent advanced disease. Sensory symptoms may mimic C6 and C7 radiculopathy, but no C6 or C7 muscle demonstrates abnormalities because they are all innervated proximal to the carpal canal. Thenar motor weakness may mimic T1 radiculopathy because of abnormalities of the opponens pollicis and the abductor pollicis brevis; however, other T1-innervated muscles are normal (29).

Ulnar Nerve

The ulna nerve can become entrapped at the elbow (cubital tunnel syndrome) or at the wrist (Guyon canal). The most typical symptom of cubital tunnel syndrome is aching pain on the medial aspect of the elbow, although radiation of the pain and paresthesia may migrate distally on the ulnar forearm and into the ulnar 1½ digits of the hand. Symptoms may be elicited by percussion of the nerve behind the medial epicondyle or by acute, prolonged flexion of the elbow (29).

The ulnar nerve may also be compressed at the wrist in Guyon canal. Compression at this level usually affects both the superficial and the deep branches of the ulnar nerve. Therefore, sensory symptoms are referred to the volar aspect of the ulnar 1½ fingers. The dorsal aspect of these digits remains unaffected because that area of skin is supplied by the dorsal sensory branch of the ulnar nerve, which originates proximal to the wrist and does not traverse Guyon canal.

The deep branch is essentially all motor, and the superficial branch is essentially all sensory. Therefore, motor symptoms, weakness, and atrophy are referable only to those muscles innervated by the deep branch of the ulnar nerve. These include the hypothenar muscles, the interossei, and the abductor pollicis. The syndrome may mimic T1 and C8 radiculopathy (29).

Radial Nerve

The radial nerve has a deep motor branch that can become compressed in the radial tunnel (posterior interosseous syndrome).

The all-motor deep branch, the posterior interosseous nerve, supplies the brachioradialis, extensor carpi radialis longus and brevis, and supinator muscles, and then splits into a superficial sensory branch that does not enter the radial tunnel. Because only the motor branch is compressed, sensory symptoms are rare, although aching over the site of compression is felt and may be elicited by full extension of the elbow with the which may be caused by an extra cervical rib or by tightened scalene muscles. Compression may occur at the thoracic outlet where the artery passes between the chest and the upper extremity (29).

Osteopathic diagnosis largely involves the assessment of both quality and quantity of motion. General ranges of motion permit effective screening of the skeletal and arthrodiol components of this region. Somatic dysfunction typically involves restriction and the end of a range of motion. It is most likely to be found in the minor motion(s) of each joint. Orthopedic problems associated with disruption of joint stabilizers commonly involve laxity and instability at the end of a range of motion. The most time-effective, yet thorough examination involves screening ranges of motion with careful attention to end-motion palpatory finding.

DIAGNOSIS

History

The clinician must determine the exact nature of the chief complaint, its duration, location, severity, and associated symptoms. The presenting complaint may be pain; however, it may also be weakness, swelling, or stiffness. Obtain as much information as possible in a time-efficient manner. Experienced clinicians continue to pursue historical questions while simultaneously examining the patient.

The following questions will assist the clinician in obtaining a thorough history:

- What is the complaint? For example: (numbness, pain, stiffness, weakness, swelling, coolness/color change) Is there more than one in different areas?
- If pain is the complaint: location, duration, severity, and radiation
- If stiffness is the complaint: morning stiffness greater than 1 hour?
- If swelling is the complaint: unilateral or bilateral?
- If weakness is the complaint: diffuse or a specific muscle?
- If restricted motion is the complaint: articular or muscular?
- If neuralgia is the complaint: what dermatome? unilateral or bilateral?
- If a rash is the complaint: characterize/describe it.
- If coolness or a color change is the complaint: history of Raynaud?

No matter what the complaint, the clinician needs to inquire about the following:

- Location, duration, severity, radiation
- Mechanism of intermittent or constant?
- Improving, worsening, staying the same?
- Aggravating/alleviating factors?
- What has been done so far (diagnosis and treatment)?
- What was the mechanism of injury?
 - Blunt trauma or repetitive overuse?
 - Previous history of trauma?
 - Is this a work-related injury?
 - What are the functional limitations (what they can or can't do)?

When is arm pain something more? Upper extremity discomfort cannot always be attributed to an orthopedic condition or somatic dysfunction in this area. A good clinician must determine whether the discomfort is primarily caused by dysfunction in the extremity or referred from another area.

If the cause lies in the upper extremity itself, there is generally restricted motion. Pain is usually localized to specific dermatomes and may be described as acute, sharp, and severe. Discomfort is usually improved by rest, is frequently reproduced by motion, and may lead to the perception of strength loss.

If the discomfort is referred from another area (e.g., the lungs, diaphragm, stomach, intestines, heart, or cervical spine), passive motion does not appear to be restricted. Pain is diffuse, poorly localized, and may be described as nagging, achy, or dull. Discomfort is usually worse at night. Discomfort is frequently related to symptoms in other areas (difficulty breathing, chest pain, cough, gastrointestinal upset) and may not be reproduced by motion. Motion is generally good, but decreased strength or muscle atrophy is possible (e.g., disc herniation).

Pain is not the only presenting complaint. The patient may relate stiffness, swelling, and weakness as well. Specific points in the history may indicate the diagnosis. For example, pain radiating into the deltoid insertion at night, and an inability to lie on the involved shoulder correlates with a rotator cuff tear. Pain or numbness radiating into the hand when lying down, relieved with pulling the arm overhead may indicate cervical radiculopathy.

Physical Examination

The physical examination of the upper extremities also includes an examination of the cervical spine, the thoracic spine and rib cage, the heart, the lungs, the nervous system, the skin, and the abdomen. A rheumatologic and orthopedic examination is also an important part of the exam of the upper extremities. The examination for somatic dysfunction is integrated with all other parts of the physical exam.

Observation

Observation begins the moment the patient walks into the room. Observe overall posture and motion. Is there any abnormality? Observe the patient in the standing position. Look at the height of the shoulders. A low shoulder may be the result of a short leg or a lateral curve. Look at the spine from the side. Is the thoracic kyphotic curve normal, increased, or decreased? A local area of thoracic spine flattening (“pothole”) may indicate the presence of an extended somatic dysfunction. Begin at the shoulder and examine the skin of the upper extremity. Are there any scars from prior injuries? A transverse scar on the anterior neck may indicate a cervical fusion. Is there any asymmetry? Areas that appear reddened or have pigment changes may have somatic dysfunction. Observe the various muscle groups bilaterally. Is there evidence of hypertrophy or atrophy? Look for the presence of fasciculation (small tremors) in the muscle. Look to see if the clavicles are symmetric. Did the patient ever fracture his or her clavicle or have a acromioclavicular separation? A visual and palpable deformity is usually present. Look at the hands. Is there deformity of the patient’s knuckles or fingers?

Structural Exam

A structural examination is an important part of the evaluation of the patient with an extremity complaint. Postural strain, muscle

imbalance, scoliosis, and forward head position can all contribute to or be the etiologic factor in upper extremity complaints. To review the components of the structural exam, review Chapter 34.

Palpation

Palpation for tissue texture change or tenderness should be focused to a few specific areas.

Begin in the upper thoracics. The upper thoracics usually have significant palpatory findings.

Palpate laterally to the scapula near the posterior axillary fold. In this location, muscles such as infraspinatus and teres minor are usually tender. Anteriorly, tissue texture change and tenderness is found over the pectoralis minor, anterior ribs, and biceps tendon. Palpate the neck for scalene hypertonicity and tissue texture change over the lower cervicals. Now, palpate into the deeper tissues. Look for signs of acute or chronic tissue texture change. Remember to compare the right side with the left side and areas located superiorly with areas located inferiorly. Compare muscle groups bilaterally for size and tone. Palpation needs to include not only the cervical and thoracic spine but also the ribs, clavicles, and scapula. All muscles affecting the upper extremity need to be palpated, especially those which the history indicates. Fascia of the thoracic inlet, pectorals, and latissimus dorsi needs to be assessed. The interosseous membrane of the forearm is important to evaluate in situations where repetitive overuse is a consideration.

Pulses

Thorough examination of the upper extremities necessitates an examination of the brachial and radial pulses. The brachial pulse is found on the medial surface of the arm just medial to the biceps tendon. The radial pulse is best palpated over the lateral and ventral side of the wrist. Examine the arterial pulses with the distal pads of the second, third, and fourth fingers. Palpate firmly but not so hard that the artery is occluded. Arterial pulses can be examined for:

- Heart rate and rhythm
- Pulse contour (wave form)
- Amplitude (strength)
- Symmetry

Lack of symmetry between the left and the right extremities suggests impaired circulation. In thoracic outlet syndrome, the clinician may find that the radial pulse diminishes with specific positioning of the arm and neck.

Table 43.8 outlines the standard method for recording amplitude of the pulse.

Reflexes

The three basic reflexes that evaluate the integrity of the nerve supply to the upper extremity are the biceps reflex, the brachioradialis reflex, and the triceps reflex (Table 43.9). Each of these is a deep tendon reflex (lower motor neuron reflex) transmitted to the cord as far as the anterior horn cells and returning to the muscle via the peripheral nerves. Reflexes may be increased in the presence of an upper motor neuron lesion or may be decreased in the presence of a lower motor neuron lesion (bulging disc with radiculopathy).

Biceps Reflex

This reflex primarily tests the integrity of neurologic level C5. Place the patient’s arm over your opposite arm so that it rests on your

TABLE 43.8

forearm. With your elbow supporting the patient's arm under the elbow's medial side, place your thumb on the tendon of the biceps in the cubital fossa. Instruct the patient to rest the arm on your forearm and relax. Tap your thumbnail with a neurologic hammer. The biceps should jerk slightly. You should be able to see or feel its movement.

Brachioradialis Reflex

This tests neurologic level C6. Support the patient's arm in the same manner used to test the biceps reflex. Tap the brachioradialis tendon at the distal end of the radius with the neurologic hammer.

Triceps Reflex

This reflex tests neurologic level C7. Use the same position as above. Tap the triceps tendon where it crosses the olecranon fossa (2). Remember to use bilateral comparison.

Reflexes may be graded as shown in Table 43.10.

Motor Strength

The strength of various muscle groups can be evaluated by applying force in a manner that loads the muscle as the patient resists. Remember to test the uninjured side first. Table 43.11 shows a standard method of recording motor strength.

Differences in muscle strength may be subtle. Compare the strength of various groups in different positions to get the full clinical picture. There are some simple screening procedures that are useful. For cervical root or brachial plexus problems, perform a grip strength test by asking the patient to squeeze two of your fingers. Another simple test is to ask the patient to squeeze the thumb and

index finger together while you try to pull them apart. If normal strength is present, it is difficult to pull them apart. Although not a test of strength, palpation for flaccidity may reveal muscles that should be tested. Observation, palpation, and measurement (with a tape measure) for muscle atrophy are important in the right clinical situation.

Sensation

This can be tested by light touch, pinprick, or two-point discrimination. Compare both sides and areas located superiorly with areas located inferiorly. Look for areas of either decreased or increased sensation. Sensation around the upper extremity is provided by five different nerve supplies:

1. C5 supplies the lateral arm
2. C6 supplies the lateral forearm
3. C7 supplies the index finger
4. C8 supplies the medial forearm
5. T1 supplies the medial arm

Articular Configuration and Physiologic Motion**The Glenohumeral Joint**

The glenohumeral joint has been compared to a beach ball on a seal's nose. It has significant mobility, but little stability. The depth of the glenoid is increased by a cartilaginous cup or labrum. The joint capsule is normally quite lax and loose, particularly anteriorly and inferiorly, providing for excess movement. Joint stability is maintained by the attachment of the rotator cuff muscles (supraspinatus, infraspinatus, teres minor, and subscapularis) to the articular capsule. Movement then occurs in flexion, extension, internal rotation, and external rotation. In the horizontal plane, with the

humerus at 90 degrees to the trunk, it is also possible to have flexion, extension, internal rotation, and external rotation (23).

Gross Motion Assessment of the shoulder can involve general screening tests or specific motion tests. Perform active *gross motion testing* first, especially if an injury is present. Having the patient raise the arms overhead and touch the back of the hands together is an excellent screening test. Ability to comb the hair tests for external rotation and abduction. Reaching over the shoulder, as if to touch the opposite scapula (Apley scratch test), tests horizontal abduction. Having the patient reach behind his or her back, as if reaching for the patient's pocketbook, tests internal rotation. Shoulder motions can also be screened by the seven motions of Spencer (5).

A gross passive test of stability of the glenohumeral joint is to stabilize the scapula and translate the head of the humerus anteriorly and posteriorly. Compare both sides. An unstable joint moves too freely; with adhesive capsulitis, there is no motion. Orthopedic testing for laxity of the glenohumeral joint will determine if there is unidirectional or multidirectional laxity. Motion of the entire pectoral girdle can be evaluated without stabilizing the scapula to isolate glenohumeral motion. Additional motions can be tested, such as how freely does the arm move overhead? How freely does the arm reach across the torso? It is important to always compare both glenohumeral joints for asymmetry of position and motion. A summary of screening motions is found in Table 43.12.

Specific Motion Tests

Individual motions can be tested with the patient seated. Testing of the shoulder can be localized to the glenohumeral joint by stabilizing the scapula with one hand as the arm is moved with the other. It is important to hold (stabilize) the acromion so glenohumeral motion is assessed, as contrasted to scapulothoracic motion. Flexion and extension motions are simple to test. For abduction, pay attention to the quality and end feel of motion as well as the actual quantity. Lateral (external) rotation can be tested with the humerus parallel to the torso, moving the patient's hand/wrist laterally. From this position, medial (internal) rotation cannot be effectively tested because the forearm contacts the torso. Abduct the arm to 90 degrees. Lateral rotation involves raising the hand superiorly.

Medial rotation involves lowering the hand (with the humerus remaining in the abducted position).

The Scapulothoracic Joint

In evaluating total shoulder girdle motion, observe the amount of scapulothoracic motion as the shoulder girdle moves. For the initial 30 degrees of abduction, glenohumeral motion is greater than scapulothoracic motion. Thereafter, both joints tend to move about the same amount. The ratio of motion in that first 30 degrees has been reported to range from 4:1 to 7:1, the glenohumeral joint moving more (27). Therefore, smooth uninhibited function of both joints is important for shoulder abduction. Malposition of the scapula alters the working length of the shoulder girdle muscles. The scapula glides medially and laterally, superiorly and inferiorly, and rotates over the posterolateral chest cage. The position of the scapula can be evaluated in a seated or standing examination. Asymmetry of position of the scapula usually indicates asymmetry of motion. Scapular motion can be tested with the patient side-lying. Grasp the scapula with both hands and take it through the various motions. The scapula can (5):

1. Glide forward and separate each vertebral border 15 cm and glide backward to bring the vertebral borders closer
2. Glide 10 to 12 cm superiorly and inferiorly
3. Rotate to elevate or depress the glenoid fossa 30 degrees each way

Costovertebral Joints of the First Rib

The costovertebral and costotransverse joints of the first rib are synovial. The first rib is an atypical rib and only articulates with the body of T1. The common somatic dysfunction of the first rib is elevation: the rib moves freely in elevation and has a restriction of motion to depression. Motion is tested by placing your thumbs over the posterior aspect of the rib and instructing the patient to take a deep breath. Assess the quality of motion in both inhalation (elevation) and exhalation (depression). Frequently, T1 is rotated and side-bent to the side opposite the elevated first rib.

Costosternal Joint of the First Rib

This is a synchondrosis, not a synovial joint. It is therefore very stable. Its functional purpose is more for support than for motion. Because of this stability, somatic dysfunction is not often found in this area; however, local tenderpoints do occur.

Sternoclavicular Joint

The sternoclavicular joint is the only true joint that attaches the upper extremity to the thoracic cage. In general, motion at this joint is minimal, yet palpable, and often correlates to visual asymmetry as well. Because of anatomic proximity and ligamentous attachments, somatic dysfunction of the first rib and the sternoclavicular joint is related. The sternoclavicular joint has a saddle-shaped articular surface. The clavicular notch on the sternum is shallow and small compared to the articular surface of the medial end of the clavicle (22). Fortunately, this is a complex synovial joint that contains a cartilaginous meniscus. This provides some needed stability. The interclavicular ligament resists superior displacement of the sternal end of the clavicle. The costoclavicular ligament, attached to the first costal cartilage, acts as a fulcrum and limits upward movement of the lateral end of the clavicle (22). As the clavicle abducts, this ligament helps produce a downward glide to

TABLE 43.12

Active and Passive Range of Motion of the Upper Extremity Components

Area	Active	Passive
Finger	Flexion (MCP: 85–90 degrees; PIP: 100–115 degrees; DIP 80–90 degrees) Extension (MCP: 30–45 degrees; PIP: 0 degrees; DIP 20 degrees) Abduction (20–30 degrees) Adduction (0 degrees)	Flexion Extension Abduction

the sternal end of the clavicle. The subclavius muscle depresses and pulls the medial end of the first rib forward when the lateral end of the clavicle is elevated.

There are three types of motion in the sternoclavicular joint. Greenman states these are abduction, horizontal flexion, and rotation (23). During abduction, the proximal clavicle moves inferior in the frontal plane. Abduction and external rotation are linked, as is adduction and internal rotation. The fulcrum for superior–inferior movement is the costoclavicular ligament, located approximately 1 inch lateral to the sternoclavicular joint (21). In the horizontal plane, the proximal clavicle translates anterior or posterior. Axial rotation also occurs down a theoretical long axis through the bone, as motion is transmitted through the humerus and scapula. It is important to note that the clavicle is not supplied with any rotator muscles, so it will rotate only as much as determined by motion introduced through the scapula.

A-C Joint

A-C function is important in overall shoulder motion. The A-C joint is a planar joint with a crescent-shaped rudimentary incomplete

meniscus. It depends on its ligamentous attachments for stability. The strongest ligament between the clavicle and scapula is the coracoclavicular ligament (22). The conoid portion of this ligament prevents anterior rotation of the distal clavicle; the trapezoid portion resists posterior rotation of the distal clavicle (22). The A-C joint has motion about three axes, each of which is subtle and takes skill to palpate. The motions that occur include abduction (a superior–inferior movement) and rotation about a long axis down the clavicle. When testing motion, it is important to realize that the small flat downward surface of the clavicle faces downward and laterally. According to Greenman, the joint is approximately angled 30 degrees; therefore, treatment needs to be performed in 30 degrees of horizontal flexion (23). When the clavicle is dysfunctional, there will be local tenderness at the A-C joint, but negative orthopedic shoulder separation tests.

Although Strachan (22) describes a mild elevation of the distal end of the clavicle as a somatic dysfunction, a true A-C separation goes beyond somatic dysfunction and is a traumatic injury, often occurring when patients fall on their shoulder. In this situation, the A-C joint can be tested for separation by palpating. With the

patient seated, palpate the A-C joint so that the fingers contact acromion as well as clavicle. With the arm at the patient's side, pull inferiorly. This will gap the joint. A normal joint will resist gapping; a separated joint will gap easily. In an orthopedic injury to the joint, there is typically visual asymmetry, depending on the grade of ligamentous sprain.

Thoracic Inlet

The thoracic inlet can be considered anatomically and functionally. The anatomic boundaries include the manubrium of the sternum anteriorly, the first thoracic posteriorly, and the first rib laterally. When considering the definition functionally, the thoracic inlet comprises the manubrium of the sternum anteriorly, the first four thoracic segments, and the first and second ribs.

Thoracic Outlet

The thoracic outlet is the space between the anterior scalenes, where the subclavian artery and brachial plexus pass.

ELBOW AND FOREARM

Configuration and Physiologic Motion

The ulnohumeral joint is the true elbow joint (6). The head of the radius at the proximal end of the radial bone near the elbow is not a part of the elbow joint. Primary motion of the normal elbow is 160 degrees of flexion and 0 degrees of extension about a transverse axis (10 degrees of hyperextension is found in some individuals). The elbow joint is stable medially and laterally but weak anteriorly and posteriorly. Its anteroposterior stability and strength depends on the muscles that pass anteriorly and posteriorly to the elbow joint and on how firmly the trochlea of the humerus fits into the trochlear notch of the ulna. The medial side of the ulnar notch is anatomically elongated and there is a slight ridge in its joint surface. There is also a grooved spiral in the humeral joint surfaces. The groove/spiral anatomic characteristic causes the hand to normally move toward the mouth when the elbow is flexed and to the lateral side of the hip when it is extended. This structural configuration also produces the normal carrying angle of the arm, greater in the female than in the male. This carrying angle is not very noticeable if the arm is hanging at the side of a person because in this position, the forearm has a natural partial pronation. The elbow also "wobbles" into ulnar adduction during its normal motion.

WRIST AND HAND

Configuration and Physiologic Motion

The hand joins the forearm by way of the true wrist joint. This is a stable joint composed of the radius, three carpal bones, and the attached cartilage. The basic configuration of the true wrist (the radiocarpal joint) is illustrated in Figure 43.2. This joint has two major axes of motion: the transverse axis, around which there is flexion and extension, and an anteroposterior axis, about which there is abduction and adduction. All motions are named according to the anatomic position of the joint and not according to the position in which the physician is holding the hand in relation to the body of the patient. Movement of the wrist toward the thumb side is abduction and toward the little finger is adduction.

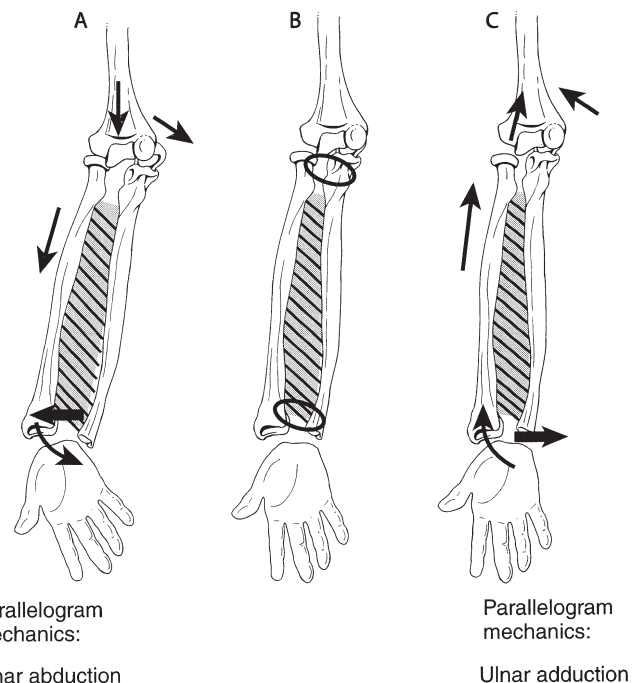

Figure 43-2 Right radiocarpal joint (true wrist joint) and distal radioulnar joint. R, radius; U, ulna; S, scaphoid; L, lunate; T, triquetrum. (Illustration by W. A. Kuchera.)

Each motion of the wrist has a normal range of motion. The wrist can flex 90 degrees and extend 70 degrees about its transverse axis and can abduct 20 degrees and adduct 50 degrees about its anteroposterior axis. Combined motion about both of these axes permits a motion called circumduction. Figures 43.3 and 43.4 illustrate normal motion of flexion and extension.

Axial Component

The axial component to the patient's upper extremity complaint needs to be the first step in the evaluation of an extremity complaint. Key areas to evaluate include the upper thoracic spine (T1-6) and the ribs, the thoracolumbar junction (T10-L2), and the midlower cervical spine (C4-7). Segmental motion restrictions in any or all of these areas need to be evaluated.

Vertebral and rib somatic dysfunction can cause increased sympathetic tone to the upper extremity. Increased sympathetic tone to the upper extremity causes nondermatomal paresthesias, pain, muscular tension/irritability, vascular reactivity, and sweat gland dysfunction. Increased sympathetic tone can occur with any facilitated segment; however, extended single segment dysfunctions tend to be more symptomatic than flexed ones (30). Bilateral rib dysfunction can occur with these dysfunctions. Long-standing dysfunctions will facilitate the segmental spinal cord and affect the organs and tissues served by these levels.

A facilitated segment in the upper thoracic spine can produce symptoms in both upper and lower limbs. Originally described by Dr. Norman Larson (a CCOM grad) as the "T₂₋₃ syndrome" or "Functional Vasomotor Hemiparesthesia," Larson described unilateral paresthesias on one side of the body related to high thoracic somatic dysfunction. This affected not only the arm but the leg as well (28).

Not all axial components are single type II dysfunctions. Also consider group spinal mechanics, short leg syndrome, and idiopathic scoliosis as part of the "axial component." Convexities on the symptomatic side tend to maintain rib dysfunction and referred pain into the involved upper extremity. Poor scapular tracking due to a lateral curve can be involved in an upper extremity complaint.

When considering upper extremity conditions, the thoracolumbar junction (T10-L2) is an important area to diagnose and treat. Dysfunction here can have widespread effects. For example, an extended dysfunction at T12 may cause latissimus dorsi hypertonicity, which limits shoulder external rotation and flexion.

Somatic Dysfunction of the Glenohumeral Joint

Somatic dysfunction by definition occurs in the minor motions of the joint. Due to the ball-and-socket nature of the glenohumeral joint, this would include restrictions of translatory motions, which can occur in many directions. Some authors call this "joint

play," "translation," or "glide." For the glenohumeral joint, the osteopathic profession does not name specific somatic dysfunctions based on this concept. Dysfunctions of the shoulder joint are active or passive exaggerations of its cardinal movements (22). Many osteopathic physicians will evaluate each single plane motion (i.e., extension) and treat restrictions of motion in that single plane. In addition to articular restrictions, there are fascial restrictions that traverse the shoulder joint that can limit shoulder motion. Jones strain-counterstrain points and Simons and travel myofascial tenderpoints occur in the muscles controlling the glenohumeral joint. Dysfunctions elsewhere in the body can produce symptoms referable to the shoulder joint. For example, an A-C joint dysfunction can cause deltoid muscle tension, just as a sacroiliac dysfunction can cause latissimus dorsi tightening. Both situations will produce shoulder pain. Greenman feels that the primary motion loss involves abduction and external rotation. The humeral head moves cephalad and caudad on the glenoid during abduction. Loss of this ability is significant in shoulder function (23).

Somatic Dysfunction of the Clavicle

Although motion is understood, standard terminology of clavicle motion is not well described in the osteopathic literature. It is thought that there is reciprocal motion between the distal end and the proximal end of the clavicle. Anterior motion at the distal end of the bone results in posterior motion at the proximal end. Superior motion that occurs at the distal end of the clavicle results in inferior motion at the proximal end. Rotation of the entire clavicle (anterior or posterior) occurs about a theoretical long axis. Motion at the sternoclavicular joint and the A-C joint is not to the same degree, due to their anatomic configuration. More motion is available at the distal end of the clavicle, due to the type of joint present and the S-like shape of the bone. Motion of the clavicle is important during respiration where it must remain mobile during each phase of respiration, as it is related to the mechanics of the first rib. When there is dysfunction of the first or second rib, assessment of the clavicle is important. The physician needs to determine if an orthopedic injury exists (sprain) versus a subtle motion restriction as seen with somatic dysfunction.

Somatic Dysfunction of the A-C Joint

The primary somatic dysfunction diagnosed at the A-C joint occurs when rotation of the clavicle (about a long axis) becomes restricted. When the humerus is fully flexed, the clavicle will rotate posteriorly. When the humerus is fully extended, the clavicle rotates anteriorly. This subtle motion can be palpated with one finger on the acromion and a second on the clavicle. Restriction of humeral flexion is related to an anterior clavicle dysfunction. In this situation, the supraclavicular space feels wider and the associated fascia is tense. Restriction of humeral extension is related to a posterior clavicle dysfunction. In this situation, the supraclavicular space feels narrower and the associated fascia is less tense.

Greenman determines rotation restriction of the A-C joint differently. According to the orthopedic literature, the A-C joint is inclined in the coronal plane, approximately 20 to 50 degrees (27). Greenman assesses the A-C by placing the glenohumeral joint in 30 degrees of horizontal flexion and abduction to the first barrier. He then applies internal and external rotation of the glenohumeral joint until motion or a restrictive barrier is found at the A-C joint. Greenman describes another dysfunction of the A-C joint, in which he describes restricted abduction. The A-C joint is evaluated with the glenohumeral joint placed in 30 degrees

of horizontal flexion and abduction is introduced until a restrictive barrier is found (23).

Despite the different methodologies of determining dysfunction, the easiest treatment approach for these A-C restrictions is to use the humerus as a lever. Flexing/extending or internally/externally rotating the arm transmits force to the acromion and then through the A-C joint. If the arm exhibits restriction of motion, engage the barrier, hold, and have the patient contract against your holding force (using principles of muscle energy technique).

Somatic Dysfunction of the Sternoclavicular Joint

The proximal clavicle can move/glide anteriorly or posteriorly, superiorly or inferiorly, as well as rotate anteriorly/posteriorly. Motions at the sternoclavicular joint can be palpated as the patient's arm is horizontally flexed, shrugged, or internally/externally rotated. Small gliding motions can also be directly introduced with your fingertips, looking for restriction (or freedom) of motion. Both Strachan and Greenman describe two primary dysfunctions of the sternoclavicular joint (22,23): One in which there was upward displacement of the proximal clavicle and one in which there is anterior displacement of the clavicle. Although terminology is not consistent, the dysfunction is the same. Abduction dysfunction (upward displacement of the proximal clavicle) is tested by having the patient "shrug their shoulders." The normal finding is for the medial end of both clavicles to move caudad. If an abduction restriction is present, the medial end of one will stay superior, in the original position. To test for a restriction of horizontal flexion (anterior displacement), the medial ends of the clavicles are palpated while the supine patient is instructed to reach toward the ceiling. The normal finding is for the medial end of the clavicles to move posteriorly. If a horizontal flexion is present, the medial end of one (or both) will stay anterior in the original position (23). Although not a primary dysfunction, to test for rotation, the patient's arm is placed in 90 degrees abduction, with the elbow flexed. While palpating the sternoclavicular joint, internal/external rotation of the humerus is introduced, transmitting motion to the sternoclavicular joint. At the end range of internal rotation, the proximal clavicle should rotate anteriorly. At the end range of external rotation, the proximal clavicle should rotate posteriorly. Strachan also discusses an element of impaction that occurs with clavicular dysfunction and hypermobility with chronic dysfunctions (22).

Somatic Dysfunction of the Elbow Joint

Somatic dysfunction of the elbow joint is named according to the minor motion that is present of the ulnohumeral joint, that is, ulnar abduction, or ulnar adduction (Fig. 43.5). An abduction somatic dysfunction appears as though the arm is more angulated, as there would be an increased carrying angle. In an adduction somatic dysfunction, the arm appears straighter, decreasing the carrying angle (producing a "gunstock deformity") (Fig. 43.6). Patients may complain of forearm tightness or wrist pain with either dysfunction. Patients occasionally have point tenderness of the lateral or medial epicondyle, confusing this condition with epicondylitis. There is reciprocal motion between the elbow and the wrist. If the elbow prefers abduction, the wrist will prefer adduction and vice versa. Somatic dysfunction of the elbow will affect full flexion and extension of the elbow. An elbow that does not go completely into extension typically has somatic dysfunction, an orthopedic condition, or both. The "smoothness" or quality of flexion and extension of the elbow may also be affected.

Figure 43-5 (A) Ulnar abduction, (B) ulnar neutral, and (C) ulnar adduction. (Illustration by W. A. Kuchera.)

Figure 43-6 Carrying angle and parallelogram effect. (Illustration by W.A. Kuchera.)

Several principles govern the elbow joint area:

1. Somatic dysfunction of the extremity is found in the minor gliding motions of the joint, not the major motions
2. Somatic dysfunction of the ulnohumeral joint is usually primary and somatic dysfunction of the radioulnar joints is usually secondary
3. Impaired function of any joint of the arm produces compensatory changes in all other joints. If total functional demand overtaxes any one of the other joints, secondary somatic dysfunction is also produced in those joints

Somatic Dysfunction of the Forearm

Patients who repetitively use their forearms (D.O.s, carpenters, mechanics, etc.) may have increased tension and tenderness in the whole forearm muscular “system.” This type of finding may be related to increased sympathetic tone from upper thoracic/rib somatic dysfunction, as well as overuse. However, repetitive overuse may strain the forearm, wrist, or elbow and can also very easily strain the forearm muscles and interosseous membrane.

Interosseous Membrane Dysfunction

The true elbow and wrist joints are functionally linked with the radius by the proximal and distal synovial radioulnar joints and a fibrous middle radioulnar joint called the interosseous membrane (Fig. 43.7). The interosseous membrane maintains functional symmetry and stability of the forearm. The proximal and distal radioulnar joints allow pivot action, permitting supination and pronation of the hand. The fibers of the interosseous membrane extend cephalad from attachment on the ulna to a more proximal attachment on the radius. This arrangement allows the bones of the forearm to share the forces of compression whether they occur from the hand upward or the shoulder downward.

Interosseous membrane dysfunction can perpetuate elbow or wrist disability long after proper orthopedic care and complete healing of strains, sprains, or fractures of the elbow or wrist should

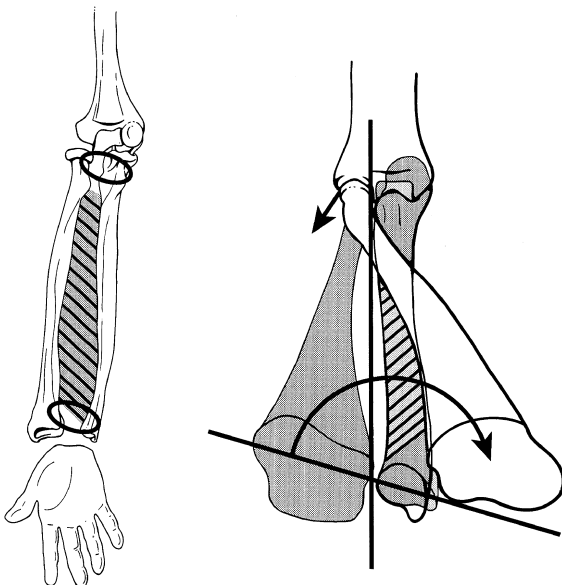

Figure 43-7 Forearm: interosseous membrane. (Illustration by W.A. Kuchera.)

have taken place. In some unknown way, the collagen tissues often retain stress patterns of past injury. This means that clinically, it is important to treat forearm dysfunction right away before these patterns have a chance to develop. In such cases, palpation of the interosseous membrane reveals increased tension and elicits areas of subjective tenderness. Interosseous strains may be treated with direct or indirect fascial treatments.

Ulnohumeral and Radiocarpal Dysfunction

The radius and ulna are held in a parallelogram arrangement by the radiocarpal joints (Fig. 43.8). The ulna is part of the elbow joint, and the radius is part of the wrist joint. The radius is able to move more freely than the ulna. With the ulna relatively fixed at the ulnohumeral joint and the radius fairly fixed at the radiocarpal joint (especially with the scaphoid), abduction or adduction of the ulna results in a reciprocal positioning of the hand. During abduction of the ulna, the radius glides distally and the wrist is literally pushed into increased adduction. During adduction of the ulna, the radius glides proximally and the wrist is pulled into a more abducted position, compared with the position of the opposite wrist. If this reciprocal positioning principle of the elbow and the wrist is incorporated in the direct and indirect treatment of ulnar abduction or adduction somatic dysfunctions, these techniques will become more effective and efficient. The parallelogram arrangement of the forearm bones with the action of the proximal and distal radioulnar joints permits forearm/wrist motions. As these motions occur, the interosseous membrane (a radioulnar fibrous joint) provides stability to the forearm and prevents stress of the ligaments and/or bony compression in the forearm or the wrist.

Strachan described an internal and external rotation dysfunction of the ulna in relation to the humerus (22). This dysfunction was assessed by moving the forearm into complete supination and pronation and attempting to spring it further. When considering somatic dysfunction of the forearm, inspection by itself is usually not very helpful, although it may be helpful when the carrying angle has been affected by somatic dysfunctions of the

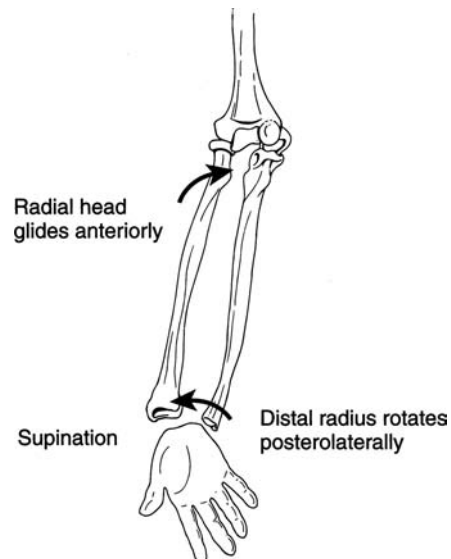

Figure 43-8 Right forearm: parallelogram effect. (Illustration by W.A. Kuchera.)

ulnohumeral joint. Increased abduction of the ulna would increase the carrying angle and encourage adduction of the hand at the wrist. Increased adduction of the ulna at the elbow encourages some abduction of the hand at the wrist. This is noticed as less adduction of the hand at the wrist.

If all ulnohumeral joint somatic dysfunction has been treated, there is no inflammation in the elbow joint, and the elbow still cannot be flexed completely, the problem is most likely one of the radioulnar joints, usually the proximal one. The interosseous membrane may also be involved.

Radial Head Somatic Dysfunction

There is reciprocal motion of the radius. When the hand is pronated, the distal end of the radius crosses over the ulna as it moves anteriorly and medially (Fig. 43.9). Near the end of full pronation, the head of the radius glides posteriorly, that is, there is reciprocal motion of the radial head relative to the distal radius. Motion in an arc opposite from the position of the pronated hand is called supination (Fig. 43.10). When the forearm is supinated, the distal end of the radius moves posteriorly and the radial head glides anteriorly.

Posterior radial head somatic dysfunction is usually produced by a fall forward onto the palm of an outstretched hand because the anterior motion of the distal radius, started by the pronation, is accentuated. Though a fall forward is on the hand, the hand is in a pronated position, and the forward vector of the hand and body pushes the distal radius into a more anterior rotation, causing the radial head to move posteriorly (Fig. 43.11).

An anterior radial head somatic dysfunction is likely to result from a fall backward, where the patient extends the arm posteriorly to break the impact of the fall, lands on the palm, and forces the distal end of the radius posteriorly. In this type of injury, the forearm is in the supinated anatomic position (Fig. 43.12).

These motions are best palpated near the end of full supination or pronation of the hand. They are palpable if the operator's fingers

are under the patient's elbow and the thumb of that hand is palpating the radial head while the other hand supinates or pronates the patient's hand. Motion in the symptomatic forearm is compared with motion in the opposite or normal forearm.

Somatic Dysfunction of the Wrist

If the wrist hurts, look at the elbow. The only sign of somatic dysfunction of the elbow may be a complaint of wrist pain. The true wrist is the ellipsoid synovial radiocarpal joint formed by a concavity in the distal end of the radius, three proximal carpal bones of the wrist (the navicular or scaphoid bone in the snuffbox of the wrist, the lunate, and the triquetral bones), and an articular disc. The articular disc separates the true wrist joint from the distal

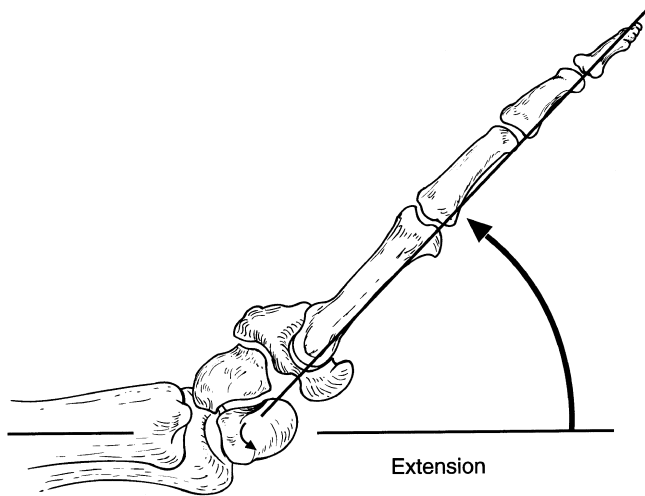

Figure 43-12 Fall backward on extended arm. (Illustration by W.A. Kuchera.)

radioulnar joint. The head of the ulna (the distal end of the ulna) is not a part of the true wrist joint.

Somatic dysfunction is not related to the gross motions of the wrist but to dysfunction of the slight gliding motions of the carpal bones on the radius as the wrist is moved. In Figures 46-11 and 46-12, notice the direction of glide of the carpal bone during each of these wrist motions. Somatic dysfunction of the wrist is named according to the direction of motion preference. If a wrist extends and is restricted in its full flexion, it is an extension somatic dysfunction (Fig. 43.13), with the wrist restricted in flexion. In this extension somatic dysfunction, the three carpal bones glide ventrally and are restricted in gliding dorsally. The opposite is true for a flexion somatic dysfunction of the wrist; similar relationships occur for the other wrist motions. Restriction of wrist extension is more common than restriction of wrist flexion. This is probably due to a more developed and dominant flexor muscle mass. A restriction of wrist extension is typically seen with increased tension of the forearm flexors.

The scaphoid, lunate, and triquetral bones fit into the concavity of the radius. The articular disc between these bones also separates these articulations from the radioulnar articulation and binding of the ulna to the radius. The joint moves around an A/P transverse axis and allows for the movements of flexion/extension and abduction/adduction. Flexion is more prominent as is adduction. The carpals can move slightly forward, backward, medially, or laterally. Carpals can be displaced toward the palm or dorsally. When this occurs, there is usually some visual and also palpatory evidence. There may be associated motion restriction of the wrist. Dorsally displaced carpal may impede wrist extension. Carpals displaced toward the palm can narrow the carpal tunnel. The scaphoid, lunate, and triquetral articulate with the distal row of carpals or the trapezium, trapezoid, capitate, and hamate. Movement is freer in flexion than in extension. There is a slight amount of side-to-side rocking allowed by the gliding between the two rows of bones. Additionally, there may be dysfunction of the intercarpal joints. Actually, this is more of a partial dislocation of a carpal bone.

Dysfunction at the wrist follows the motion restrictions seen at the elbow. There is reciprocal motion. If the elbow moves freely into abduction, the wrist will move freely into adduction and vice versa. Restriction of wrist extension is more common than restriction of wrist flexion. This is probably due to a more developed and

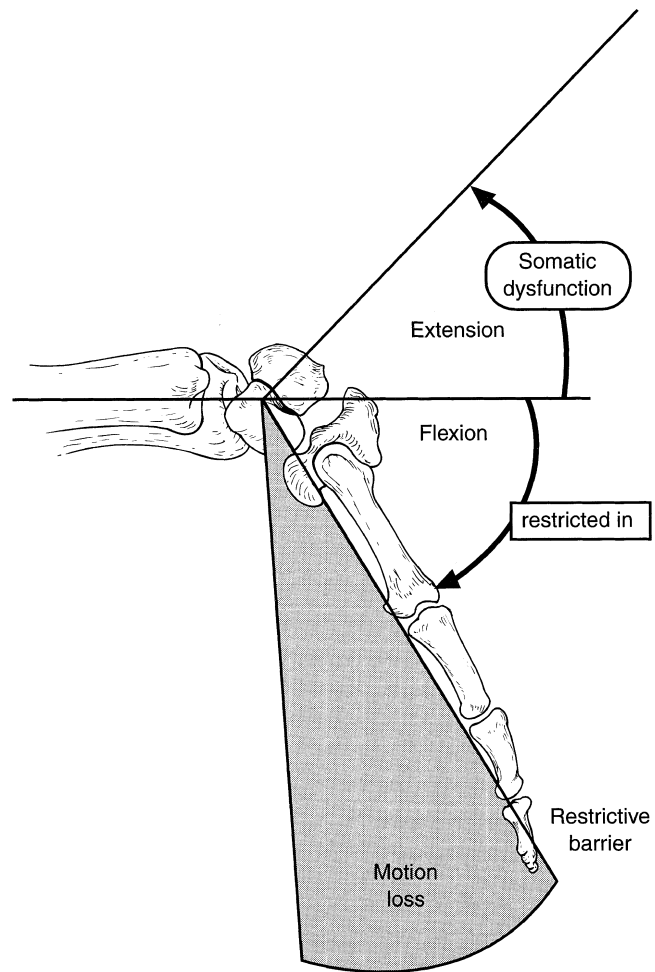

Figure 43-13 Wrist extension: somatic dysfunction. (Illustration by W.A. Kuchera.)

dominant flexor muscle mass. Other factors such as osteoarthritis, cartilage tears, or occult fractures can limit wrist extension as well.

Several principles describe somatic dysfunction of the wrist:

1. Observation is not very helpful when looking for somatic dysfunction; swelling of the wrist is an inconsistent sign
2. Painful compression means dysfunction is present, but this test does not diagnose the specific problem that is present
3. Radial glide and limited parallelogram motions are not obvious until the opposite motion is attempted. If there is an adduction somatic dysfunction at the wrist with a proximal shift of the radius, the problem may not be evident until abduction of the wrist is tested and the results are compared with the opposite side
4. Flexion/extension somatic dysfunction of the wrist is usually caused by a trauma that overcomes the ligamentous restraints and opposing muscle pull. This can often result if a strain or sprain exceeds the extent of a somatic dysfunction. Restricted extension of the wrist is its most common major motion loss caused by dysfunction

Somatic Dysfunction of the Hand

Intercarpal Joints

Intercarpal somatic dysfunction often occurs from a fall on an outstretched hand. For this reason, somatic dysfunction in these areas is very likely to have a compression component. If the wrist joint

is swollen, the physician must rule out fracture of the navicular bone (scaphoid). This is also true if there is pain on pressure over the snuffbox, or if there is persistent pain and dysfunction after proper conservative care, even if the initial posttrauma radiographs showed no evidence of fracture. Sometimes, the scaphoid does not reveal evidence of fracture until the disruption in its blood supply slowly produces degeneration of the bone.

Carpometacarpal Joints

All of these joints, except the thumb, are classified as plane synovial joints, which share a common joint cavity with the intercarpal joints. Their main type of somatic dysfunction is a dorsal glide with restriction in ventral glide. Palpation at the base of the suspected metacarpal may reveal an abnormal anterior or posterior position in relation to the carpals. Mobility is assessed by moving the metacarpal heads back and forth. A restriction of both motions indicates an impaction or compression type of dysfunction.

The carpometacarpal joint of the thumb is different; it is a separate saddle-type joint, having both a concave and a convex articular surface. This configuration permits angular movements in almost any plane with the exception of limited axial rotation. Only a ball-and-socket joint has more motion than the carpometacarpal joint of the thumb. Because it has very good motion, it is more likely to have compression strain or sprain of the ligaments than to have somatic dysfunction.

MP and IP Joints

The MP joints and all the IP joints of the hand are gliding joints. The fifth MP joint has the most motion; there is less motion in the fourth MP joint, and the third and second MP joints have the least motion. The MP and IP joints may develop somatic dysfunction in any one of a combination of six gliding motions:

- Anteroposterior glide
- Mediolateral glide
- Internal-external rotational glide
- All of these motions are minor and cannot be initiated directly by muscle action

Compression is always part of MP and IP somatic dysfunctions, as when a ring on a finger gets caught as a person jumps over a wire fence. Intermetacarpal cramps and pain may be a sign of MP or IP somatic dysfunction. Pain in the metacarpal joints may be referred from an ulnohumeral joint somatic dysfunction. Dysfunction of the fingers typically involves the fascial components. There are usually restrictions of fascial rotation, abduction/adduction, or compression/distraction. These types of problems manifest as impediments in finger flexion, swelling of the digits, or pain. Jones tenderpoints occur in the upper extremity as well. A common tenderpoint called CM1 (thenar point) is found in the thenar muscle mass. It is commonly found in patients who use their hands repetitively.

Special Tests for the Upper Extremity

There are many special tests of the upper extremity that are useful to determine if orthopedic, neurologic, or vascular compromise is present.

OSTEOPATHIC TREATMENT: COMMON CLINICAL CONDITIONS

Carpal Tunnel Syndrome

This condition is most commonly described as an entrapment neuropathy of the median nerve at the wrist producing paresthesia

and weakness of the hands (9). Carpal tunnel syndrome is frequently associated with repeated or sustained activity of the fingers and hands. Incidence rates are reported as high as 25.6 cases per 200,000 work hours (10) and involving 10% of workers. Medical cost estimates vary from \$3,500 to \$60,000 per case (11).

Patients experience numbness or paresthesia on the palmar surface of the thumb, index, and middle fingers, and radial half of the ring finger. Numbness and paresthesia of the whole hand may also occur. Pain may be referred to the forearm and, less commonly, to the neck and forearm regions. Pain or tingling of the fingers often occurs at night and is relieved by shaking or exercising the hand. Weakness and atrophy of the thenar muscles usually appear late and can occur without significant sensory symptoms. On examination, symptoms may be reproduced by percussion over the volar surface of the wrist (Tinel sign) or by full flexion of the wrist for one minute (Phalen maneuver). Decreased touch may be demonstrated over the fingers supplied by the median nerve. Nerve conduction studies are considered to be the gold standard for the diagnosis of this condition (9).

The syndrome is traditionally described as resulting from pressure on the median nerve where it passes with the flexor tendons of the fingers through the tunnel formed by the carpal bones and the transverse carpal ligament (9). Additional explanations exist. Single compressions of dog sciatic nerves have failed to produce significant conduction loss. Both proximal and distal compressions have produced conduction blocks in 50% of test animals (12).

In 1973, Upton and McComas (13) proposed the existence of the "double crush syndrome." This syndrome hypothesizes that neural function is impaired when single axons that are compressed on one region become especially susceptible to damage in another area. The authors report that a slight compression may cause a reduction in axoplasmic flow that is too small to result in denervation changes, but when coupled with the onset of a slowed lesion, might further reduce axoplasmic flow below the safety margin for prevention of denervation at a distal lesion, and clinical symptoms ensue (13). Abramson et al. demonstrated that decreased blood supply to a nerve alters conduction (14). Larson suggested that upper thoracic dysfunction alters upper extremity vasomotion (15). Hurst et al. demonstrated a relationship between cervical arthritis and bilateral carpal tunnel syndrome (16). Sunderland has suggested that lymphatic and venous congestion contributes to this disorder (17).

The treatment of carpal tunnel syndrome has traditionally involved the use of wrist splints, anti-inflammatory drugs, and local injection of steroids. Surgical decompression of the carpal tunnel with release of the transverse carpal tunnel ligament is used if symptoms persist or if motor abnormalities are present (9,18). Evidence in the preceding paragraph suggests that the hand symptoms may be related to dysfunctions in the upper extremity, and the cervical and thoracic spine. Osteopathic treatment incorporates the modalities described above and should also include:

1. Reducing sympathetic tone to the upper extremity by correcting upper thoracic and upper rib dysfunctions. This directly affects nerve function by improving blood flow and reducing congestion through improved lymphatic and venous drainage. An internally rotated temporal bone may be associated with increased sympathetic tone in the upper thoracic spine and, if it is diagnosed, should also be treated.
2. Removing cervical somatic dysfunction to improve brachial plexus function
3. Removing myofascial restrictions in the upper extremity, thereby removing potential sites of additional compression
4. Increasing space within the carpal tunnel using direct release techniques

Tennis Elbow

Tennis elbow is also known as lateral epicondylitis. This condition is thought to be an inflammatory response to overuse of the extensor muscle group attached to the lateral epicondyle of the humerus. There is also the thought that this condition may be related to a degenerative tendonosis and/or ischemic phenomenon. It is usually caused by repeated overload of the musculotendinous units. This condition produces pain that may be localized to the lateral epicondyle or may radiate down the forearm extensor group or up into the brachioradialis muscle. The pain is intensified by resistive extension of the wrist and fingers, or by shaking hands. Pressure over the lateral epicondyle is painful (7,8).

Common areas of somatic dysfunction include the ipsilateral upper thoracic spine and ribs, the radial head and ulnohumeral joint, the lower cervical spine, and the pronator teres muscle. OMT directed to the upper thoracic spine and counterstrain for the affected ribs will decrease muscle tension of the forearm as well as tenderness of the lateral epicondyle. Counterstrain for the extensor tendons is useful as well. Treatment of a radial head dysfunction or an abducted ulna may completely resolve symptoms in patients with lateral epicondyle pain, but not true epicondylitis.

Rotator Cuff Tendinitis

Rotator cuff disease and impingement syndromes are commonly seen disorders in occupational, athletic, and traumatically injured patients. They are also common in the aging athletic or active patient, who becomes more sedentary. Rotator cuff disease can be caused by repetitive overuse (micro trauma), a single traumatic event (macro trauma), instability of the glenohumeral joint, or musculotendinous fiber failure. Most rotator cuff problems are muscular and result from a degenerative tendonopathy due to intrinsic muscular fatigue. The muscles that comprise the rotator cuff include the supraspinatus, infraspinatus, teres minor, and subscapularis. Supraspinatus is the most commonly involved muscle in rotator cuff injury. Each cuff muscle plays a unique and important role in stabilizing the shoulder. Impingement syndromes are biomechanical causes of, or the effects of, rotator cuff disease. The classic concept of impingement involves “outlet impingement” between the greater tuberosity and the acromion. Narrowing of this subacromial space produces soft tissue encroachment, edema, and tendonitis. Neer classified impingement and rotator cuff disease into three stages: inflammation and edema (I), fibrosis and tendonitis (II), and partial or complete tearing (III) (26). In younger athletes, this type of impingement can occur due to ligamentous laxity and muscle imbalance. Another form of impingement exists, primarily in throwing athletes. Called internal impingement, it involves impingement of the surface of the rotator cuff under the posterior-glenoid rim (26).

Posture, core muscle strength, and anatomic position of the scapula are critical factors in rotator cuff impingement. It is a total body problem, not an isolated joint inflammation. Somatic dysfunction of the upper thoracic spine and ribs contributes to abnormal rotator cuff firing patterns and fatigue. Cervical somatic dysfunction can impair nerve function to the muscles of the rotator cuff, also impairing muscle strength. Sacroiliac and lumbar dysfunction can affect the shoulder through tension in the latissimus dorsi muscle. In patients with poor posture, weak core muscles and somatic dysfunction, muscles of the cuff (and surrounding the shoulder) tend to develop Jones tender points or Simon-Travell myofascial trigger points. Left untreated, these points perpetuate the problem by maintaining muscle inhibition, tightness, and pain. OMT needs

to address the axial spinal component, improve scapular mobility, decrease fascial tensions, improve local blood flow, and reduce pain. The addition of physical therapy is critical, but at the right time, and in the correct fashion. Exercises work better when areas of somatic dysfunction have been improved and inflammation has diminished. Proper strengthening and stretching will decrease the chances of somatic dysfunction reoccurring as well.

Adhesive Capsulitis

Also known as “frozen shoulder,” this condition is characterized by pain and restricted movement of the shoulder, usually in the absence of intrinsic shoulder disease. Adhesive capsulitis may follow bursitis or tendonitis of the shoulder or may be associated with systemic disorders, such as chronic pulmonary disease, myocardial infarction, and diabetes mellitus. Prolonged arm immobility contributes to the development of this condition. Reflex sympathetic dystrophy is thought to be a pathogenic factor. The capsule of the shoulder is thickened, and a mild, chronic, inflammatory infiltrate and fibrosis may be present.

Pain and stiffness usually develop gradually over several months to a year, but may progress rapidly in some patients. Pain may interfere with sleep. The shoulder is tender to palpation, and active and passive motions are restricted (9).

Early mobilization after an injury to the arm or shoulder may help prevent the development of this condition. Local injection of corticosteroids and administration of nonsteroidal anti-inflammatory drugs and physical therapy may help (9). Osteopathic manipulation should be directed to the upper thoracics, upper ribs, and entire shoulder complex. The objective is to improve motion. Avoid taking the patient into the “crampy” pain zone. This only slows progress. Only progress as fast as the patient can respond. Indirect techniques may be especially effective in the initial treatment phases.

Thoracic Outlet Syndrome

This condition results from compression of the neurovascular bundle (subclavian artery, subclavian vein, and brachial plexus) as it courses through the neck and shoulder. Several dysfunctions may compress the neurovascular bundle as it passes from the thorax to the arm, including:

- Cervical ribs
- Excessive tension in the anterior and middle scalene muscles
- Dysfunction of the clavicle, upper ribs, or upper thoracics
- Abnormal insertion of the pectoralis minor muscle
- Patients may develop
- Shoulder and arm pain
- Weakness
- Paresthesia
- Claudication
- Raynaud phenomenon
- Ischemic tissue loss
- Gangrene

Examination is often normal unless provocative maneuvers are performed. Occasionally, distal pulses are decreased or absent and digital cyanosis and ischemia may be evident. Tenderness may be present in the supraclavicular fossa (9). Some forms of thoracic outlet syndrome are associated with sympathetic autonomic dysfunction, which produces upper extremity symptoms. Sympathetic dysfunction has accompanying palpatory findings in the upper thoracic or rib area. Most patients can be conservatively

managed. Patients should avoid positions that aggravate symptoms. Osteopathic treatment should be directed toward improving mechanics in the:

- Cervical region
- Upper thoracics
- Upper ribs
- Clavicles
- Scalene muscles
- Muscles of the shoulder and pectoral girdle
- Surgical intervention is a last resort.

SUMMARY

Osteopathic clinical examination of the upper extremity includes the diagnosis of somatic dysfunction integrated into the examination procedure. The relationship between anatomic structure and physiologic function is considered prior to deciding a treatment plan. Osteopathic treatment needs to address the specific diagnosis, incorporating the innate ability of the patient to heal given the appropriate environment of improved tissue function. OMT directed at the somatic component of the patient's condition will improve the tissue's function and thus the patient's own ability to heal himself or herself.

KEY CONCEPTS

- The abdomen is the region of the trunk below the thoracic diaphragm. It consists of the abdomen proper and the lesser pelvis.
- Evaluation of the abdominal region must include consideration of the spinal region. Careful attention must be given to determination of somatic and visceral interchange in the manifestation of symptomatology.
- Examination of the abdomen should follow a systematic plan of exploration of quadrants. Components of the examination include observation, auscultation, palpation, and percussion.
- Goals of treatment include consideration of asymmetries, motion restrictions, and tissue texture abnormalities which are viscerosomatic reflections of homeostatic disturbances.

HISTORICAL PERSPECTIVE AND SUPPORTIVE EVIDENCE

Osteopathic manipulative techniques can be used as part of a complete treatment approach to abdominal visceral problems. Such techniques have been part of osteopathic practice since the time of Andrew Taylor Still, the founder of osteopathic medicine. One early description of abdominal visceral treatment by Still is that of his first case of “flux,” or dysentery, in a 4-year-old boy. He describes his examination of the child, noting that the child’s back was hot while the abdomen was cold to the touch. In writing about his treatment, he states

I began at the base of the brain, and thought by pressures and rubbings I could push some of the hot to the cold places, and in so doing I found rigid and loose places on the muscles and ligaments of the whole spine, while the lumbar was in a very congested condition. I worked for a few minutes on that philosophy, and told the mother to report next day, and if I could do anything more for her boy I would cheerfully do so. She came early next morning with the news that her child was well (1).

Still described having treated many other similar cases with a high degree of success. His knowledge of the structure–function relationships involved with abdominal conditions was extensive enough to warrant an entire chapter of one of his books being devoted to this topic (2).

Other osteopathic physicians since the time of Still have promoted the use of osteopathic manipulative techniques directed toward the abdominal viscera. Hazzard described how to examine the abdomen and discussed treatment approaches for various abdominal visceral diseases (3). Conrad (4) devoted a section of his book to diseases of the abdomen, specifically diseases of the stomach, intestines, liver, kidneys, and spleen. He described and illustrated specific osteopathic manual techniques for these organs. In a rather extensive treatise on the abdomen, McConnell (5) talked about the osteopathic approach from the ventral plane of the body, and described “ventral technique.” Tender points, described as “gangliform contractions,” were noted by Frank Chapman, D.O., and came to be known as “Chapman’s reflexes.” The only known reference text on this topic was published by Owens (6).

In later years, other osteopathic researchers published studies illustrating the use of osteopathic manipulative techniques for

abdominal conditions. For example, Hermann (7) demonstrated that osteopathic manipulative treatment (OMT) prior to abdominal surgery greatly reduced the incidence of postoperative ileus. He also demonstrated that OMT could be successfully used to treat postoperative ileus when it did occur. In a recent study, Radjeski et al. (8) demonstrated the use of OMT could significantly reduce the length of hospital stay in patients with acute pancreatitis.

Researchers in other health care professions have also noted the clinical relationship between the soma and the viscera. As an example, Pikalov and Kharin (9) found using spinal manipulative techniques as part of the treatment plan for duodenal ulcer disease resulted in pain relief and clinical remission much sooner than conventional medical treatment alone. Travell and Simons (10) have noted that abdominal myofascial trigger points may produce visceral symptoms such as diarrhea, vomiting, belching, food intolerance, and infantile colic. Barral has published extensively on the use of manual techniques for treatment of the abdominal viscera (11,12). Other authors in this area include Finet (13) and Lossing.

Thus, it becomes apparent that optimum treatment of abdominal visceral conditions requires an understanding of the underlying structure–function relationships and of the segmental viscerosomatic reflex phenomena that are involved. An understanding of osteopathic philosophy and principles, and the ability to use OMT as part of a complete treatment approach to abdominal disease, is one of the most unique characteristics of the osteopathic physician.

Definition

The abdomen may be defined simply as the region of the trunk below the thoracic diaphragm. This area consists of two parts: an upper part, the *abdomen proper*; and a lower part, the *lesser pelvis* (14) (Fig. 44.1). These two areas are continuous at the plane of the inlet of the lesser pelvis. This inlet is bounded by the sacral promontory, the arcuate lines of the innominate bones, the pubic crests, and the upper border of the symphysis pubis.

Functional Anatomy

The *abdomen proper* is bounded *superiorly* by the thoracolumbar diaphragm; *inferiorly* it becomes continuous with the pelvis or, as some anatomists describe it, the abdominopelvic portion of the abdominal cavity (15), by way of the superior aperture of the lesser

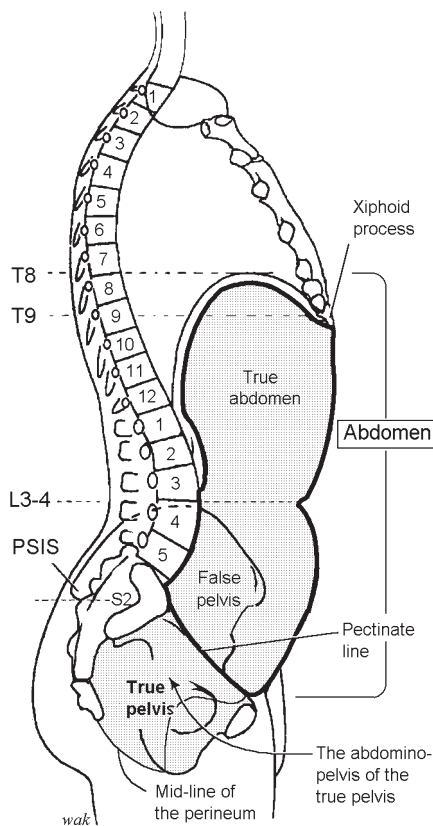

Figure 44-1 Boundaries and skeletal elements of the abdomen.

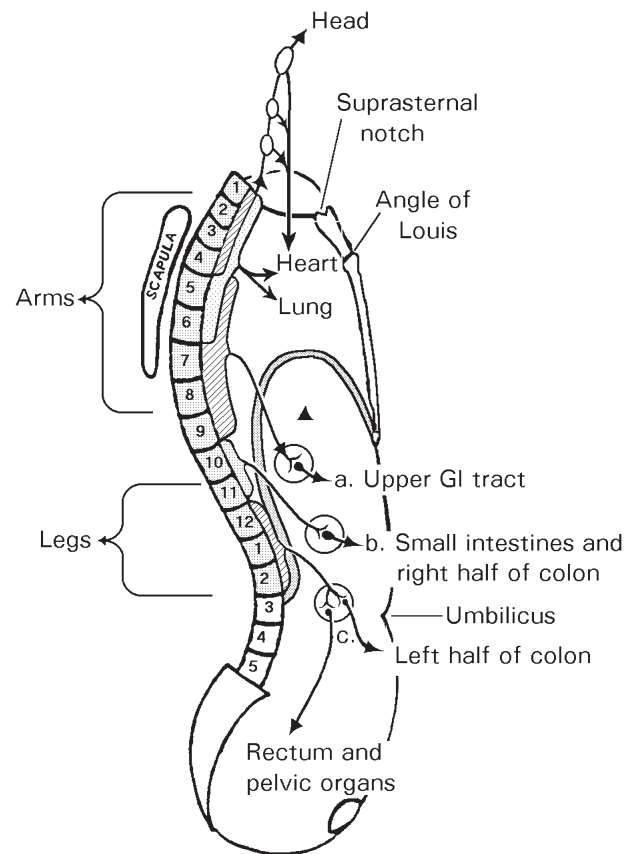

Figure 44-2 Primary sympathetic (efferent) nerves of the body.

or true pelvis. *Anteriorly* the abdomen is bounded by the abdominal muscles, which include the rectus abdominis, the pyramidales, the external obliques, the internal obliques, and the transversus abdominis. *Posteriorly* the abdomen is bounded by the lower thoracic and the lumbar vertebrae, the crura of the diaphragm, the psoas and quadratus lumborum muscles, and the posterior parts of the iliac bones.

The *lesser pelvis* or abdominopelvic portion of the abdomen is shaped somewhat like an inverted cone. Its *anterolateral* boundary consists of those parts of the hip bones below the arcuate lines and the pubic crests, and the obturator internus muscles; its superior and dorsal boundary includes the sacrum, coccyx, and the piriformis and coccygeus muscles; and its *inferior* boundary includes the levator ani muscles and fascial coverings (which together form the pelvic diaphragm).

The abdominal structures of interest in this chapter are the stomach, small intestine, large intestine, liver, gallbladder, spleen, pancreas, kidney, parts of the ureters, suprarenal glands, and numerous blood and lymph vessels, lymph nodes, and nerves. The lower ureters, the urinary bladder, and internal genitalia are not covered in this chapter.

Skeletal Structures

The skeletal elements of the abdomen are the lumbar vertebrae, the sacrum, coccyx, and the innominate bones (see Fig. 44.1).

Muscular Structures

The muscles of the abdominal region may be divided into anterolateral and posterior groups. The anterolateral group includes the rectus abdominis, the pyramidalis, the external oblique, the internal oblique, and the transversus abdominis; the posterior group

consists of the quadratus lumborum, psoas major, psoas minor, erector spinae and iliocostalis (14). The reader should note that somatic dysfunctions of these posterior muscles may mimic the pain of certain abdominal disorders or may be painful because of viscerosomatic reflex activity associated with abdominal problems. The thoracoabdominal diaphragm, while not usually considered part of the abdominal wall, should nevertheless be considered when evaluating the abdomen for somatic dysfunction.

Neurological Structures

Primary sympathetic fibers for innervation of all organs below the diaphragm, except the descending colon and pelvic organs, pass from the intermediolateral cells in the thoracic spinal cord through the thoracoabdominal diaphragm. In the abdomen, these primary fibers enter the celiac, superior mesenteric, and the inferior mesenteric collateral ganglia where they synapse (Fig. 44.2). Secondary or postganglionic fibers continue on to innervate specific groups of organs in the abdomen and pelvis. Parasympathetic innervation is supplied from the craniosacral outflow. All abdominal organs down to the midtransverse colon are supplied by the vagus nerve (cranial nerve X); the rest of the abdominal organs and all of the pelvic viscera receive their parasympathetic innervation from the pelvic splanchnic nerves (S2-4).

Visceral afferent impulses travel back to the cord using the same course used by the sympathetic efferent nerves to that organ (Fig. 44.3). This pain tends to be vague and gnawing, deep, poorly localized, and midabdominal. Visceral afferent fibers from the root of the mesentery report to the somatic cord segment of that organ's sympathetic innervations (14). This type of sensory input produces the paraspinal tissue changes that help the physician to locate

Figure 44-3 Neurologic pathway of visceral pain (afferent fibers).

the viscus that is most likely dysfunctional. The tissue changes are tenderness, asymmetry, range-of-motion differences, and tissue texture changes (TART). The pain and tissue texture changes are primarily localized at the paraspinous level consistent with the organ's sympathetic innervation (Figs. 44.4 and 44.5).

Somatic pain may also be caused by what is known as the percutaneous reflex of Morley. This type of somatic pain is usually located directly over the inflamed organ and is produced by direct contiguous irritation of the parietal peritoneum and the abdominal wall (Fig. 44.6). It is responsible for rebound tenderness and abdominal guarding associated with more severe abdominal pain.

Vascular Structures

Arteries

The thoracic aorta lies along the anterior and left anterolateral side of the thoracic vertebrae. It enters the abdominal cavity through the aortic hiatus in the abdominal diaphragm at the level anterior to the 12th thoracic vertebra. Here, it becomes the abdominal aorta. Its main abdominal branches are the celiac, superior mesenteric, renal, and inferior mesenteric arteries (14).

Figure 44-5 Visceral afferent fibers.

Veins

Various small veins and plexuses in the pelvis eventually flow into the external and internal iliac veins. The two pairs of external and internal iliac veins unite to form the left and right common iliac veins, and these in turn unite to form the inferior vena cava, which conveys blood to the right atrium of the heart (Fig. 44.7). The veins that collect blood from the digestive tract, spleen, pancreas, and gallbladder join to form the portal vein. The portal vein carries blood to the liver, where this vein branches out into a series of very

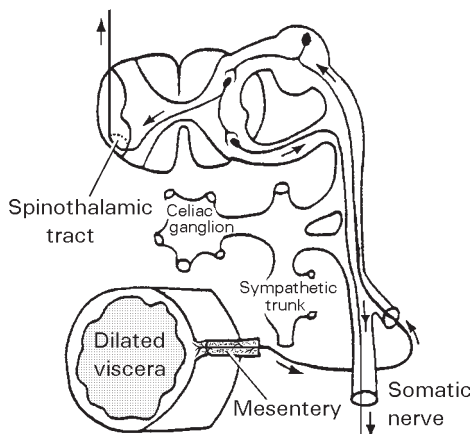

Figure 44-4 Neurologic pathway of viscerosomatic pain.

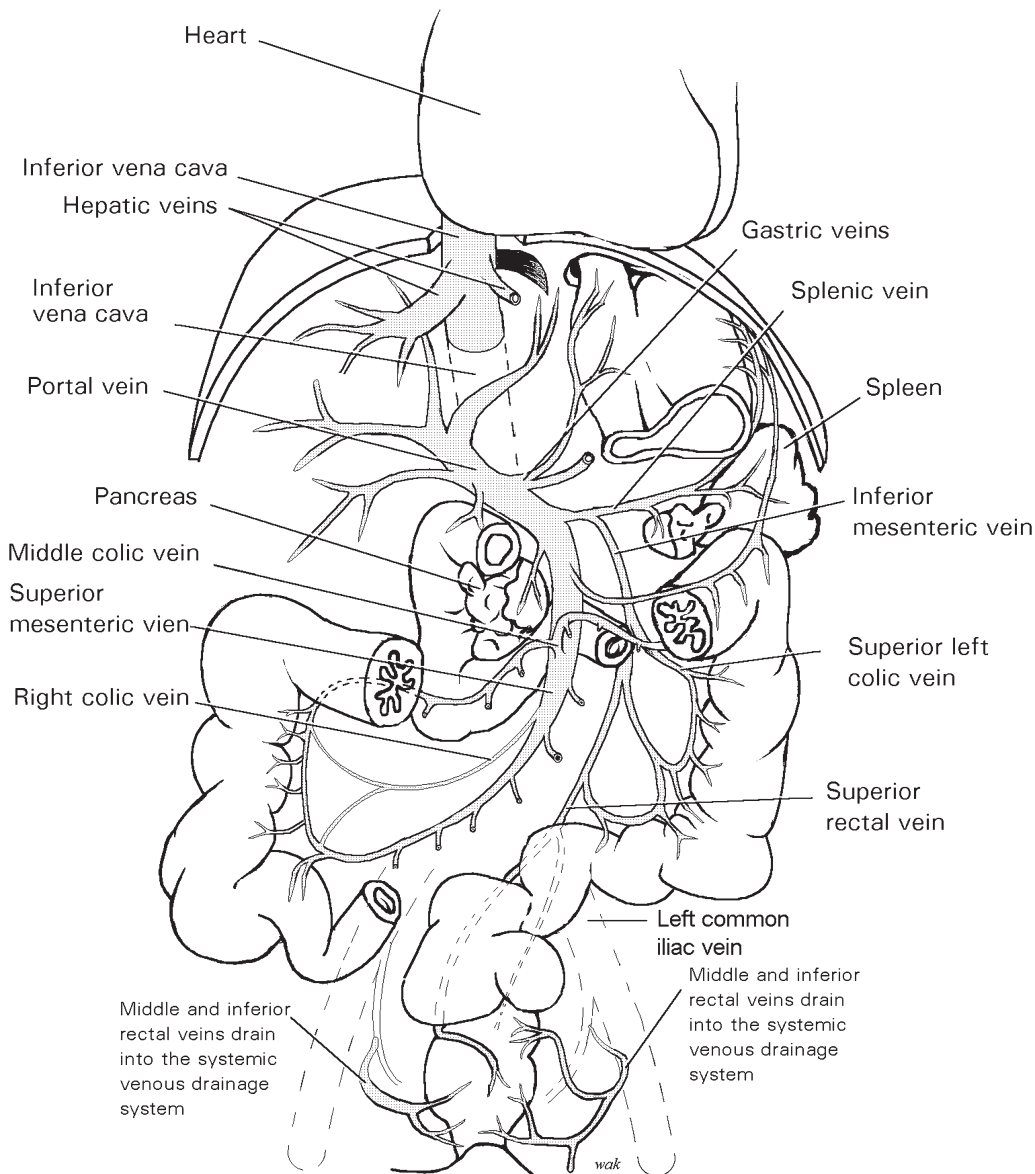

Figure 44-6 Neurologic pathway of pain from the percutaneous reflex of Morley.

Figure 44-7 Venous drainage: portal venous system for the viscera.

small vessels called sinusoids. From here, hepatic veins convey the blood to the inferior vena cava (14).

Lymphatic Structures

The left lymphatic duct (the thoracic duct) drains interstitial fluids from the lower extremities, the pelvic and abdominal viscera, the left arm, and the left side of the head (Fig. 44.8). It begins as the *cisterna chyli*, a 2-inch, yellowish, cylindrical structure that lies just to the left of the thoracolumbar junction at about the level of the first lumbar vertebra. It receives lymphatic vessels that drain interstitial fluids from all the abdominal organs, the pelvic organs, the lower extremities, and all of the superficial lymphatic vessels located below a horizontal plane of the body running through the umbilicus. The superficial lymphatic vessels drain lymph into superficial inguinal nodes. Lymph then travels into the deep nodes, the deep trunks along the common iliac arteries and the aorta, and finally into the *cisterna chyli*. It should be noted that lymph from the ovary, testicles, and prostate does not drain into the inguinal nodes but drains into the deep pelvic nodes (16).

Connective Tissue and Fascial Elements

The muscles of the abdominal region have associated fascial sheaths. The deep fascial layers have names associated with the various abdominal regions. Table 44.1 shows these fascial layers and their associated abdominal regions.

The *peritoneum* is a large serous membrane that consists of two layers: the *parietal* layer, which lines the abdominal wall; and a *visceral* layer, which is reflected over the abdominal viscera. The parietal peritoneum angles from the posterior wall of the abdomen to form very defined mesenteric connections to the abdominal viscera. These mesenteries carry the sympathetic and parasympathetic fibers and arteries to the viscera. They also carry visceral afferent fibers, veins, and lymphatic vessels away from the viscera. The visceral peritoneum is sensitive to stretch. It produces visceral pain only when the distention of the viscus exceeds the length of the visceral peritoneum on the outside of the mesentery.

The root of the mesentery for approximately 30 ft of small intestines is only 6 inches long and is located on the posterior wall of the abdominal cavity, posterior to a point about 1 inch to the

Figure 44-8 Main lymphatic ducts of the body.

Figure 44-9 Roots of the abdominal mesenteries.

left of and 1 inch above the umbilicus (Fig. 44.9). The root of the mesentery runs inferolaterally to a second point just anterior to the right sacroiliac joint (14). Mental visualization of these mesenteries allows a physician to determine more accurately the origin of palpable masses and the origin of auscultated abnormal sounds. It is also important when performing visceral manipulation to free fascial pathways and improve visceral function.

Visceral Structures

The visceral structures with which we are concerned in the abdomen are the following (Fig. 44.10):

- Stomach
- Liver
- Gallbladder

- Pancreas
- Spleen
- Kidneys
- Urinary bladder
- Small intestine
- Colon
- Aorta and common iliac arteries

The adrenal glands are not palpable.

Topographic Anatomy

There are certain surface landmarks of the abdomen that are palpable (17). These landmarks are shown in Figure 44.11 and include:

- Costal margins
- Xiphoid process
- Iliac crests
- Anterior superior iliac spines
- Pubic crests and tubercles
- Inguinal ligaments
- Umbilicus
- Linea alba

For purposes of locating abdominal structures and describing abnormalities, the abdomen is conventionally divided into four quadrants (Fig. 44.12). Another method divides the regions of the abdomen into nine sections (see Fig. 44.10B). Either method may be used, although division into quadrants is most commonly seen.

OSTEOPATHIC ABDOMINAL DIAGNOSIS

History

While beyond the scope of this chapter, it must be emphasized that a thorough history is a critical element in making a correct

TABLE 44.1

Abdominal Regions and Their Associated Deep Fascial Layers

Region	Fascial Layer

Inferior surface of thoracolumbar diaphragm	Diaphragmatic fascia
Psoas and iliac areas	Iliac fascia
Anterior surface of the quadratus lumborum muscles	Anterior layer of the thoracolumbar fascia
Muscles of the pelvis	Pelvis fascia

Figure 44-10 A. Approximate location of visceral organs. B. The nine-quadrant abdomen.

diagnosis of a patient's abdominal problem. The history should include at least the following information:

1. Chief complaint
2. History of the chief complaint
3. Past medical history
4. Past surgical history
5. Current medications
6. Nutritional history
7. Allergies
8. Family and social history
9. Review of systems

The reader is referred to standard textbooks on patient interviewing for more information on this topic.

Physical Examination

A complete physical examination is performed with special emphasis on regions that are spotlighted by the history or that might have functional association with the symptoms expressed by the patient. In this chapter, only the more important points as related to a patient with abdominal symptoms are considered.

General

Before beginning the abdominal examination, care must be taken to ensure that the patient is as relaxed as possible and in a comfortable position. The examination of the abdomen is commonly done with the patient in the supine position, resting comfortably on an examination table or bed. A pillow supports the patient's head; a patient with increased thoracic kyphosis may require more than one pillow for support of the head and shoulders. A pillow may be placed under the patient's knees for additional comfort. If orthopnea is present, raise and support the trunk with a back rest to relax the abdominal muscles (18). The patient should be draped in a manner that allows the abdomen to be exposed from the xiphoid region to the

pubes. The examining room temperature should be adjusted for the patient's comfort, and the room should be adequately illuminated for the performance of the examination. The physician may stand on either side of the patient for the examination. The only instruments required for performing the abdominal examination are the physician's warm hands and warm stethoscope head. The examination should employ the methods of physical examination in the following sequence: observation, auscultation, palpation, and percussion. The osteopathic physician includes examination for the elements of somatic dysfunction commonly noted by the TART acronym.

Observation

For this part of the examination, the examiner should be seated in a chair at the side of the patient so that the examiner's head is only slightly higher than the abdomen. Ideally, there should be a single source of light that shines across the patient's abdomen toward the examiner, or lengthwise over the patient (18). The abdomen is observed for the following:

- Symmetry
- Contour
- Scars
- Pulsations
- Visible masses
- Engorged veins
- Visible peristalsis
- Unusual pigmentation
- Hair distribution
- Distention

Auscultation

Auscultate the four quadrants of the abdomen to determine the presence, location, frequency, and pitch of peristaltic waves. This could reveal the intermittent, low-pitched, occasional slow gurgle

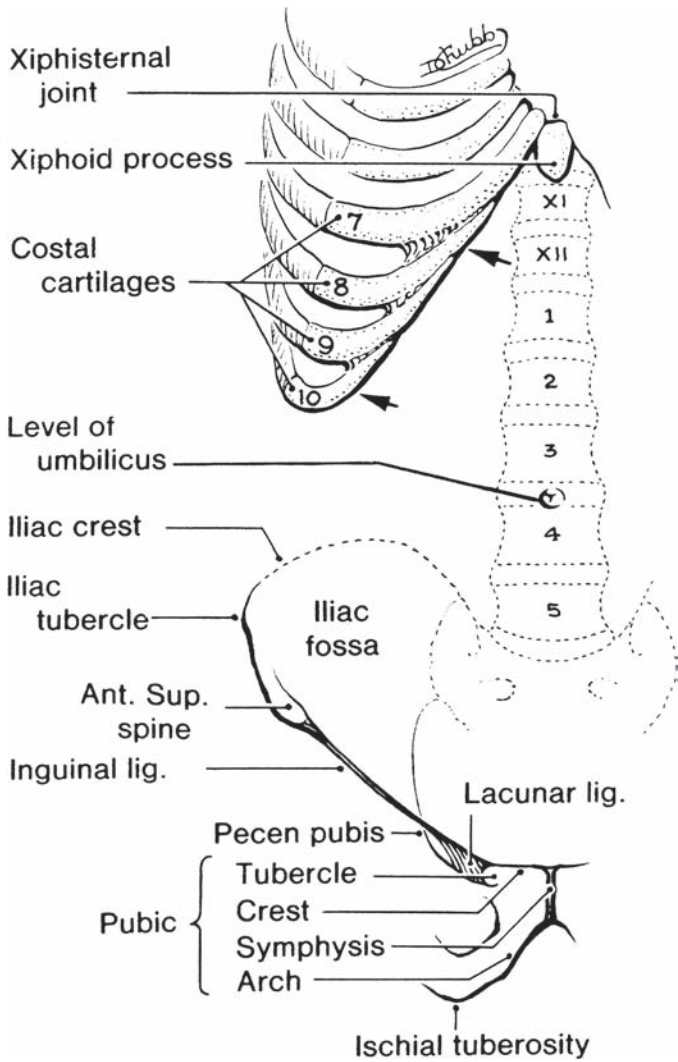

Figure 44-11 The abdominal landmarks.

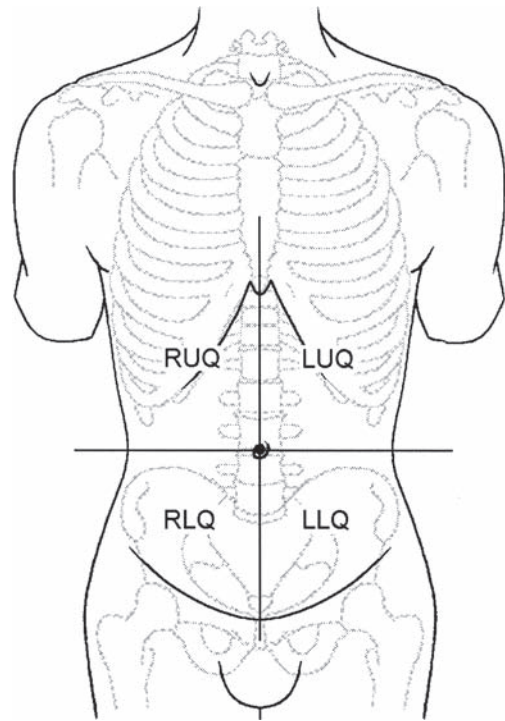

Figure 44-12 The four-quadrant abdomen.

that is normal, or the high-pitched, tinkling sounds of developing obstruction. Bowel sounds may be absent, indicating possible paralytic ileus. The midline of the abdomen between the xiphoid process and the umbilicus is auscultated for bruits. These could indicate an aneurysm and/or renal artery stenosis. The periumbilical region and the junction between the middle and outer two thirds of the inguinal region are auscultated for a bruit that could be associated with a significant atherosclerosis of the common iliac or femoral artery.

Percussion

Percussion of the abdomen is more commonly performed in the asymptomatic patient, since, in the interest of patient comfort, painful conditions of the abdomen may preclude the use of percussion. Ordinarily percussion is used to outline the borders and help to determine the approximate size and position of solid organs, such as the liver, and hollow fluid-filled organs such as the urinary bladder. In general, the hollow viscera that occupy most of the abdomen contain gas and are usually resonant to percussion.

Palpation

Palpation of the abdomen begins with a touch that is light yet firm, using the palmar surfaces of the approximated fingers to contact the abdominal wall. The physician lightly palpates each quadrant,

checking for tenderness, any cutaneous or subcutaneous masses, and any unusual sensitivity. If the patient is apprehensive or is unable to relax during palpation of the abdomen, it is useful to ask the patient to flex his or her hips and knees in order to facilitate relaxation of the abdominal muscles.

During light palpation, the physician can assess the abdominal wall for somatic dysfunction. Each quadrant of the abdomen can be palpated for abnormal myofascial tension, and the presence of tender points such as counterstrain points and Chapman reflex points (Fig. 44.13). One should note that Chapman reflex points related to abdominal visceral pathology are located next to the sternum in the intercostal spaces of ribs 5 through 11 and at the tip of rib 12, along the lateral thigh areas, and posteriorly along the thoracic and lumbar vertebral columns.

After performing light palpation, the osteopathic physician proceeds to deep palpation of the abdomen. Each quadrant is examined for tenderness, masses, or enlarged organs. At this time, the physician also assesses the deep fasciae and soft tissues of the abdomen, looking for abnormal tissue tensions that might indicate disturbance related to the collateral ganglia or mesenteries. The mobility and motility of the various abdominal organs may be assessed according to the theory and techniques described by Sutherland (19), Barral (11), and others.

Osteopathic Manipulative Treatment for Abdominal Disorders

Treatment Goals

As with OMT to any other body region, OMT should be applied to the abdominal region with specific goals in mind. The goals of treatment will vary with each individual patient. Some of these goals include:

- Addressing asymmetries, motion restrictions, and tissue texture abnormalities that are viscerosomatic reflections of homeostatic disturbances

Figure 44-13 Thirty-second screening examination for Chapman reflex points.

- Decreasing or eliminating pain
- Removing segmental motion restrictions
- Improving altered skeletal vertebral unit and myofascial motion arising from aberrant visceral and autonomic activity
- Decreasing or eliminating segmental facilitation
- Decreasing or eliminating trigger point and tender point activity
- Decreasing pathophysiologic musculoskeletal and neuroreflexive factors influencing circulation
- Enhancing musculoskeletal and neuroreflexive-mediated circulatory functions

- Improving organ function
- Altering any or all of the previously mentioned situations as either contributing to, or predictive of, future health problems

Approaches to Using Osteopathic Manipulative Techniques on the Abdomen

Spinal Approach

Any spinal somatic dysfunctions that may relate to an abdominal problem should be treated in order to improve spinal motion and therefore restore normal nerve function in segmentally related

areas. This approach includes typical manipulative methods such as high velocity/low amplitude, muscle energy, counterstrain, and others. Paraspinal rib raising and paraspinal inhibition are used effectively for treatment of sympathicotonia.

Peripheral Approach

This approach includes such techniques as thoracic and pedal lymphatic pumps, diaphragmatic redoming, and thoracic inlet and pelvic diaphragm releases. These techniques are used to improve the ability to move fluids throughout the abdominal region, thus improving the delivery of oxygen, nutrients, and arterial blood to affected areas, and facilitating venous and lymphatic drainage for the removal of the waste products of cellular metabolism. This approach also includes the use of diagnostic Chapman reflexes and their soft tissue treatment, such as treatment of Chapman points for the large bowel that are located on the lateral thigh areas.

Direct Approach

These techniques are applied directly to the abdomen to alleviate TART changes in the abdominal wall structures. Some techniques are applied more deeply to affect structures such as the abdominal mesenteries, the collateral ganglia, or specific abdominal organs.

SUMMARY

One should not forget that somatic dysfunction may be present with abdominal visceral conditions. Optimum treatment of these conditions should be based on osteopathic philosophy and principles, and should include appropriate OMT. Using osteopathic manipulation as part of a complete treatment approach to the patient with an abdominal visceral disorder serves several purposes. It provides a more holistic, total body approach to the treatment of a patient's medical problems, it addresses important structure–function relationships, and it helps to optimize the patient's self-healing and self-regulatory mechanisms.

Thrust (High Velocity/Low Amplitude) Approach; “The Pop”

JOHN G. HOHNER AND TYLER C. CYMET

KEY CONCEPTS

- The high-velocity/low-amplitude (HVLA) (thrust) approach is characterized by positioning to engage the restrictive barrier, followed by a corrective maneuver to move through the barrier.
- Accurate diagnosis is the key to performance of HVLA (thrust) techniques.
- Positioning against the restrictive barrier in all planes is followed by a rapid and brief corrective thrust.
- HVLA (thrust) techniques can be taught and learned easily. The necessary motor coordination for effective use requires extensive practice and experience.

CASE STUDY

D.J. is a 27-year-old female who presented with right-hand numbness of 1 month duration. She started a new job, as a cashier, about 2 months ago. She stated that at first, her entire right hand started to “fall asleep” occasionally while working at her cash register. At the time of her visit, the numbness occurred within five minutes of working and was relieved with rest. She had also noted right-sided upper back pain over the past month. There was no history of injury or previous numbness. There was no past medical or surgical history. She tried ibuprofen and a wrist splint without improvement.

Physical examination revealed normal vital signs, normal cardiac and pulmonary exams. Neuromusculoskeletal exam revealed normal motor, reflexes, and sensation of the right upper extremity. Tinel and Phalen tests were negative. Acute tissue texture changes and tenderness were noted over the transverse process area of T3 right. Motion changes were noted at T3 consistent with somatic dysfunction at T3 E SR right with a *distinct barrier* found at attempts to flex, side bend, and rotate T3 to the left.

The presence of distinct barrier mechanics means that this type of somatic dysfunction would be amenable to HVLA treatment.

DEFINITION OF TECHNIQUE

The Glossary of Osteopathic Terminology defines high-velocity/low-amplitude (HVLA) technique as, “An osteopathic technique employing a rapid, therapeutic force of brief duration that travels a short distance within the anatomic range of motion of a joint, and that engages the restrictive barrier in one or more planes of motion to elicit release of restriction. Also known as thrust technique.”

VARIABILITY OF THRUST TECHNIQUES

“Thrust techniques” are a collection of direct method manipulative treatments that move a restricted joint through its dysfunctional barrier (1). These techniques vary widely in the amount, speed, localization, and application vectors of the treatment forces that are applied. The common treatment goal is that, after the thrust, appropriate physiologic motion is restored to the dysfunctional joint. The term *direct* refers specifically to positioning the restricted

joint(s) to engage the restrictive barrier and then applying a corrective force to move through that dysfunctional barrier. Simply stated, one moves the restricted joint in the direction it won't move. When speaking of osteopathic HVLA thrust manipulation, after precise positioning against the restrictive barriers in all planes, the final force is a quick (high-velocity), short (low-amplitude) thrust. The velocity of the actual thrust is rapid and brief. The amplitude is sufficient to move through the restrictive barrier but precise enough to stop short of or at the anatomic barrier. Greenman (2) describes this force as an “impulse.” Often, a click or pop is heard at the time the force is applied. Upon reassessment of the treated joint, there should be an immediate increase in both the range of motion and the freedom of motion. *Indirect* treatments, involving positioning into the direction of ease, are described elsewhere (3).

HISTORIC PERSPECTIVE

Thrust styles of manipulation have been documented worldwide throughout recorded history (4). The European immigrants brought the techniques of the “bone setters” to America with them (5). The ensuing American schools of osteopathic medicine and chiropractic medicine developed since (Chapter 3).

Robert Kappler, D.O., has theorized on the development of HVLA as a distinctly osteopathic modality as follows:

Thrust technique has been the major type of technique taught in colleges of osteopathic medicine and has been practiced by osteopathic physicians for years. In the 1970s, the osteopathic medical school curricula began to include other types of techniques. Until recently, however, osteopathic manipulation and high-velocity technique were essentially synonymous. Graduates are now exposed to a complete spectrum of direct and indirect techniques; therefore, osteopathic manipulation is no longer synonymous with thrust technique.

It is interesting to speculate why osteopathic manipulative techniques taught in the colleges evolved into the exclusive domain of thrust techniques and remained that way for so many years. Faculty may have been responsible for the change. Students, in the early days, assisted in the teaching of techniques. These students may have played a major role in moving the curriculum to thrust techniques. Thrust techniques can be taught by precisely describing

the nature of the restriction and providing techniques for treating the dysfunction. These techniques can then be memorized and practiced. In contrast, fascial release and indirect techniques require skill in assessing motion patterns in the tissues. The technique is difficult to describe because the physician is responding to tactile and proprioceptive input from his or her hands. Faculty find release techniques difficult to teach and students may perceive them as abstractions. Thrust techniques are easier to teach and to learn. However, although thrust techniques can be described in a precise manner, the motor coordination necessary to use these techniques effectively requires extensive practice and experience.

DIAGNOSIS AND SOMATIC DYSFUNCTION

It cannot be stated strongly enough that the key to properly performing thrust manipulation with the greatest efficacy and the least side effects is the ability to diagnose accurately and to only use HVLA technique when the diagnosis warrants it. The practitioner first must learn to perform a palpatory diagnosis (see Chapter 33) and understand what these findings mean. Only then can the treating physician use those findings to determine the best treatment methodology. Somatic dysfunction is the term used to describe the areas of impaired or altered function of related components of the somatic system which are identified by the palpatory diagnosis. By necessity, this term encompasses a wide variety of musculoskeletal disorders.

“Somatic dysfunction” can include disordered changes among some or all of the bones, muscles, fascia, arthroal structures and their associated neural vascular and lymphatic components. This variety of etiologic elements is reflected both in the wide variance between the possible palpatory somatic dysfunction diagnoses and in the possible treatment choices. This plethora of disparate diagnostic possibilities gives rise to the need for a methodology to differentiate them and thus to be able to choose the optimal treatment modality. Manipulation is much more efficacious when the modality chosen is correctly matched to the type of somatic dysfunction that is found. When examining an area for somatic dysfunction, identify changes from the norm by using the mnemonic TART:

- Are there palpable tissue texture changes (T)?
- Is there visually observable asymmetry (A)?
- Is there a restriction of motion (R)?
- Does the palpatory exam elicit tenderness (t)?

BARRIER MECHANICS

To understand the type of somatic dysfunction that is amenable to HVLA manipulation, one has to understand the Barrier Concept (Fig. 45.1). The Barrier Concept refers to the movement capabilities of a joint during normal and restricted motion. These movement capabilities are evaluated, during the palpatory exam, by both their quantity and quality of motion. The quantity is the amount of movement from the joint's midline or neutral point of motion to a motion barrier. The neutral point of motion is that position of a nondysfunctional joint at rest, with equal myofascial forces pulling it in all directions. Quantity of motion is determined by the amount of movement from the neutral point (Fig. 45.1).

When a healthy joint is actively moved during normal activity, the end of motion is at the physiologic barrier. When the range of motion of a joint is tested passively during a physical examination, the end of the furthest motion is the anatomic barrier. Motion beyond the anatomic barrier implies disruption of osseous or ligamentous structures of that joint. Both the anatomic and

Figure 45-1 Somatic dysfunction: quantity and quality of joint motion. (*Foundations for Osteopathic Medicine*, 2nd Ed., p. 853)

the physiologic barriers are present in healthy joints without any dysfunction. A third barrier, the restrictive or pathologic barrier, is found when a joint experiences the motion loss of somatic dysfunction. The quantity of motion to arrive at the restrictive barrier is less than the amount traveled to reach the physiologic barrier. This shifts the midline of joint motion away from the restrictive barrier. The palpatory experience, when the examiner feels the restricted motion, is that the joint will move better in one direction than in the other. One of the goals of manipulative treatment is to aid a return to normal, unrestricted motion.

The quality of motion refers to the palpatory sense of how smoothly a joint can be moved through its range of motion. A resistance or hesitance through motion implies some type of dysfunction of the joint. End feel is a term describing the quality of motion that is felt by palpation of a joint when it is brought passively to its final barrier of motion. End feel can be a function of both the focal tissue turgor at the region of the somatic dysfunction and the tethering actions of the muscle and fascia which is being stretched. The end feel is nebulous or rubbery with reflex somatic dysfunctions. The end feel is firm and distinctive with mechanical-type arthroal dysfunctions.

The quantity and quality of motion, along with the end feel, allow the examiner to determine the Restriction of motion in the diagnostic TART mnemonic mentioned earlier. It is TART that defines somatic dysfunction. The components of TART that

predominate for any given dysfunction then can dictate how to treat that dysfunction with manipulation. In this author's opinion, HVLA or thrust manipulation would be the modality of choice in a dysfunction that has distinctive barrier mechanics with a palpable loss of motion at a restrictive barrier and with a firm end feel. HVLA is designed to remove motion loss, regain normal motion, and restore normal barriers in somatic dysfunction. If one were to weight the importance of the TART components in the diagnosis of a somatic dysfunction to be treated with HVLA, it would look like this TART. Similarly weighted, the TART for Counterstrain diagnosis might look like TART. All TART is not created equal.

MECHANISM OF TREATMENT

To understand why HVLA works on an area of somatic dysfunction, one must first understand *why* the dysfunctional segment won't move. A somatic dysfunction exhibiting barrier mechanics is *not* "subluxed," "out of place," "out of joint," or "dislocated." Like a door that will not fully close, it is inhibited from completing its full normal motion. What *is* going on is that some external or internal force or factor has caused local segmental irritation sufficient to create focal edema and swelling in a small discrete area (6). This in turn causes a tightening of the fascial structures, myofascial component, and capsular components of a specific articular joint. The articular distortion results in reflex hypertonicity of the musculature crossing the given joint. There is thus a resultant decrease to the range of motion around that area. This is discussed in the osteopathic and scientific literature on proprioceptors and somatic dysfunction (7–12). The palpatory experience is described earlier. In more simplistic terms, on motion testing, "it *will* go this way, it *won't* go that way." Restoration of motion of the articulation results in restoration of normal proprioceptive input from the joint and reflex relaxation of muscles surrounding the joint.

There are special considerations when treatment is applied to a vertebral joint as opposed to an appendicular joint. The "typical" vertebral joints (C2–L5) are assessed in the three cardinal planes of motion. Restrictions are classically found in sidebending, rotation, and flexion/extension. The thrust treatment however is along a summed vector of all these findings. The unique motion patterns found in the sacroiliac (SI), atlantoaxial, and occipitoatlantal joints are addressed in the cervical and sacral chapters. The HVLA treatments for SI and occipitoatlantal joint dysfunctions also tend to be along a summed vector. Atlantoaxial dysfunctions are diagnosed and treated in a rotational manner along a vertical axis. The entire gamut of appendicular motion patterns does not lend itself to treatment generalizations, but a few trends do predominate. Many appendicular joints have a predominant major joint motion and lesser minor joint motions. The patient presents with loss of, and pain with, the major joint motion. This is frequently the result of a restricted minor joint motion and treatment is focused along a single vector of the minor joint motion loss.

The mechanism of the audible pop or snap, which is frequently heard at the moment of the thrust, is a subject of great debate (13). It is frequently, but not always, the harbinger of a successful treatment. The production of noise may merely be the incidental result of treatment forces spilling over to a joint above or below the targeted dysfunction. Similarly, a lack of an audible articulation does *not* mean that the restrictive barrier was not successfully treated. In any case, the treatment should always be followed with thorough reassessment. Box 45.1 addresses the issue of joint noise.

Joint Noise The Manipulative Crack/Pop/Click/Snap/Grind or Thud

Tyler Cymet, D.O.

Joints make noise. Joint noise may occur with regular use of the joint by an individual, and it may occur with motion of the joint induced by a health care provider moving or treating a specific area.ⁱ

The noises that emanate from joints have intrigued and confounded physicians. Laennec was unclear as to the reason for these sounds and noted the presence of joint noise in his treatise on lung sounds.ⁱⁱ

It is the noises that are evident to the patient and provider that attract the most attention, but there are noises that emanate from the joint that are not apparent to the unaided ear. Auscultation of joints can be performed with a myodermatosteophone, which was developed by Heuter in 1885 to help physicians locate areas where joint activity was not fluid.ⁱⁱⁱ

Studies on joint sounds have focused on objective analysis of the sound or vibration signals, also known as vibroarthrographic signals that are measureable.^{iv}

There is also a theory that joints that make noise are more likely to develop medical issues. This theory arose from a study by Walters linking joint noise and early development of arthritis that was published in 1929.^v

Some people argue that a noise or sound is a necessary part of a manipulation, and the occurrence of noise along with a manipulative medicine procedure is what differentiates a manipulation from mobilization of a joint.^{vi} Others contend that the presence or absence of a noise is irrelevant to the effect of a mobilization or manipulation.^{vii}

The reason for joint noise is unclear. A hypothesis explaining the reason for joint noise suggests eventration of gas into the synovial fluid with the breaking of the surface tension of the fluid causing the pop sound.^{viii} It may also be that the noise comes from the snapping or releasing of ligamentous adhesions in the joint,^{ix} or that the bone itself is being pulled out of place and snapping back into a neutral position.^x It may also be a ballooning of the joint capsule that causes the noise to occur (Ehrenfeuchter W, Nicholas AS, *personal communication*).

While we do not know what the relationship is between joint noise and effective manipulative treatments, acknowledging what is seen and experienced by the patient and provider is a necessary part of a good treatment. We may need to reassure our patients that a joint noise isn't necessary for a successful treatment, and presence of a noise isn't considered to be an issue.

TECHNIQUE METHODOLOGY

The HVLA approach involves:

- Initial positioning
- Engagement and stacking of barriers
- Accumulation of forces
- Final corrective thrust

Initial Positioning

Initial positioning refers to both the physician's own position and that of the patient. Once the physician is in a relaxed and balanced position, his or her cortex will be freed up to pay attention to the diagnostic input from the fingers and hands as he or she continually fine-tunes the technique during its application. If the physician's own proprioceptors are firing due to imbalance from an awkward stance during the treatment, or straining to hold up more weight than one's own strength allows, it is difficult to focus on the treatment at hand.

Position the patient comfortably at the start of the treatment. This allows the patient to relax. In turn, this decreases the tonicity of the longer muscles overlying the dysfunction and the pull from muscles above and below the dysfunction. A patient will feel imbalance on the part of a treating physician and tense his or her own muscles in anticipation of a fall or drop. When performing a treatment using HVLA, one wants to focus the vector forces as precisely as possible and use only the minimum force that is necessary. The more variables that can be eliminated from the manipulative equation, the more likely one will obtain a successful solution.

Engagement and Stacking of Barriers

Engage barriers in sidebending, rotation, and flexion/extension. The physician "stacks" these individual components to address each component of the somatic dysfunction just as one would with muscle energy or myofascial release techniques. Maintain each previously engaged barrier as the next barrier is engaged and the forces accumulate. As a clinician becomes experienced, this summation of vector forces, along with the arrival at a single summed vector, becomes very fast and efficient. Experienced physicians sense how the tissues are responding to the force being applied and make subtle alterations in the direction of force to effectively engage the barrier in all planes. If this set up is painful to the patient or the physician, then something is wrong! Move the patient back to his or her neutral position and reassess. The technique set up may be incorrect or the patient may have a somatic dysfunction of a type that is not amenable to HVLA. In that case, use some other modality! One may simply need to treat some overlying soft tissue dysfunction first and then retry the HVLA.

Accumulation of Forces

The basis of most HVLA treatment is that one is treating the dysfunctional relationship between two bones. To treat them, the physician holds one bone still and moves the other the way it would really rather not go at the moment. The discomfort, if any, that a patient experiences during an HVLA treatment, is at the moment when all of the forces are stacked against the restrictive barrier. This is a natural conclusion to correct stacking as mentioned above. A novice frequently runs into trouble at this stage,

by losing concentration and relaxing the forces on the segment. If this happens, do not continue with the thrust. Forces that do not accumulate at the dysfunctional segment dissipate into adjacent structures and could result in an iatrogenic side effect. Instead, reassess and set up the stacking again. The accumulation of forces is not a separate phase. It should be viewed, instead, as an instantaneous transit point between the final summation of forces and the thrust.

Final Corrective Thrust

HVLA thrust techniques use a short, rapid thrust, hence the words high velocity. Once the barrier is engaged, the final force is applied quickly from that position. The proper application has been described as a tack hammer blow, sudden but not forceful. The term *impulse* applied to HVLA technique recognizes that the force is a sudden acceleration and deceleration. Do not back off before delivering the corrective thrust. The exhalation phase of respiration is the relaxation phase, and the final force is often applied during exhalation. If intuition tells one not to thrust, then don't. The physician's "intuition" is probably based on proprioceptive feedback that some part of the treatment is not balanced properly.

Some thrust techniques are not executed at high velocity and some have a larger or variable amplitude of motion during the articulation. Consider an experience where the patient is set up to treat a joint restriction, the joint goes click, and the restriction is released as the physician is positioning the patient and localizing forces. Sometimes, one may instead tease a joint with carefully and slowly applied forces. Again, experience is very beneficial in applying the proper force. Although HVLA is described as thrust technique, the actual speed and force may be modified to fit the patient's needs.

DOSAGE

Give the patient time to respond to the treatment; the sicker the patient, the less the dose. Older patients respond more slowly; young patients respond more quickly. In most circumstances, treating the same segment more than once a week using thrust technique is discouraged (14). When treating hospital patients on a daily basis, Larson (N.J. Larson, *personal communication*, 1967, 1978) would vary the technique, so he did not repeat the same technique on a given area. If the same somatic dysfunction keeps recurring, then the physician needs to assess why this is happening and address that factor first. In this author's opinion, continual thrust treatment on the same segment, without improvement, is a good recipe for hypermobility but not much else.

BENEFITS OF HVLA

HVLA is well tolerated and extremely time efficient in the hands of a skilled practitioner. It is a modality of choice when addressing somatic dysfunction with distinct, firm barrier mechanics. The patient usually experiences immediate relief, with decreased pain and increased freedom of motion.

PRECAUTIONS AND CONTRAINDICATIONS

Some joints are unstable and hypermobile. Within the numerous joints of the spine, a pattern of alternating hypomobility and hypermobility may exist. The loose, hypermobile joints are overworked while the stiff, hypomobile joints escape excess motion. A normal

physiologic reaction to a painful hypermobile joint is for muscles surrounding the joint to splint the joint and protect it from excess motion. Physical examination reveals restriction of motion. Underneath that protective muscle splinting is an unstable joint. A high-velocity thrust technique may work, as evidenced by a decrease in pain and improvement in motion. Unfortunately, the treatment contributes to the joint instability. The more HVLA technique is used, the looser the joint becomes.

Most of the concerns with HVLA center on treatment of the cervical spine (15). Both advanced rheumatoid arthritis and Down syndrome diagnoses should cause the practitioner to consider alar ligament instability. Dislocation of the dens associated with rupture or laxity of the transverse ligament of the atlas can cause death or quadriplegia. Cervical manipulation has been associated with vertebral basilar thrombosis (15). Advanced carotid disease should cause one to be careful with any form of cervical manipulation. With all this having been said, the Position Paper on Cervical Manipulation by the American Osteopathic Association speaks on the overwhelming safety of cervical manipulation in general (16).

General contradictions to HVLA include local metastases and osseous or ligamentous disruption. Apprehension on the part of the patient is a relative contraindication. In other circumstances, consider the risk/benefit ratio. If the risk of harming the patient exceeds the potential therapeutic benefit, the technique is not indicated. Risk also relates to the skill of the physician. There is more risk with an unskilled physician. If forceful, direct techniques may harm the patient, gentle indirect release techniques might be considered.

DIAGNOSES AND TECHNIQUES

739.0 Head-Suboccipital Somatic Dysfunction

OA E RR SL (Anterior/Extended Occiput)

Dysfunction: Anterior left occiput (The occiput is rotated to the right and sidebent to the left, with tissue texture change on the left.).

Objective: To improve left rotation and right sidebending of the occiput.

Discussion: When the occiput is rotated right and sidebent left, the left OA joint is held in a facet “locked closed” position. The OA joint on the right side is held in a “facet locked open” position. This technique addresses the “facet locked closed” position by opening the joint with the applied corrective force. An anterior occiput is a “pull” technique (translate the head toward the “locked close” side, to accumulate force at the anterior occiput).

Patient Position: Supine.

Physician Position: Standing at the head of the table.

Procedure (Fig. 45.2):

1. Place your right 2nd metacarpal-phalangeal joint against the right posterior lateral aspect of the patient's occiput with your fingers projecting around the posterior skull and your thumb angled up toward the patient's eye
2. The head and neck are raised from the table and a small amount of extension is introduced (over your right fulcrum hand) to allow localization of forces between the occiput and atlas
3. Grip the most inferior/lateral aspect of the patient's left occiput with your left fingertips, allowing the patient's head to lie in your left hand. Using a coordinated movement of your two hands, gently rotate the head to the left until the barrier is engaged

Figure 45-2 Occiput on atlas—anterior/extended dysfunction.

4. To localize to the dysfunction, simultaneously exert a cephalad pulling force with your left fingertips and a mild translation force to the left with your right 2nd metacarpophalangeal joint. At this point, you should feel all the forces accumulate at the left OA joint
5. A small amount of additional posterior translation from your left fingers is necessary to localize forces to the OA joint
6. The final corrective movement is a quick rotatory thrust to the left, with more of a “pull” through your left hand and a slight “push” with the right
7. Reassess

OA F RR SL (Posterior/Flexed Occiput)

Dysfunction: Posterior right occiput (The occiput is rotated to the right and sidebent to the left, with tissue texture change on the right).

Objective: To improve left rotation and right sidebending of the occiput.

Discussion: When the occiput is rotated right and sidebent left, the left OA joint is held in a facet “locked closed” position. The OA joint on the right side is held in a “facet locked open” position. This technique addresses the “facet locked open” position by closing the joint with the applied corrective force. The posterior occiput is a “push” technique (translate in the direction of the nose to engage localization at the posterior occiput).

Patient Position: Supine.

Physician Position: Standing at the head of the table.

Procedure (Fig. 45.3):

1. Place your right second metacarpal-phalangeal joint (index finger) over the posterior lateral aspect of the patient's occiput with your fingers projecting around the posterior skull and your thumb angled up toward the patient's eye
2. The head and neck are raised (one inch or less) from the table and a small amount of extension is introduced (over your right fulcrum hand) to allow localization of forces between the occiput and atlas
3. Cradle the left side of the patient's face on the anterior aspect of your left forearm and palm. Contact the soft tissues under the patient's left mandible with the fingertips of your left hand. Gently rotate the head to the left until the barrier is engaged

Figure 45-3 Occiput on atlas—posterior/flexed dysfunction.

- Using your left forearm as a lever, slightly lift the head, while simultaneously applying a mild translation force downward with your right index finger. At this point, you (and the patient) should feel all the forces accumulate at the right OA joint
- A small anteriorly directed translatory force helps to localize forces to the OA joint
- The final corrective movement is a quick rotatory thrust to the left through your right MCP joint. This is actually more of a “push technique” with left rotation achieved by translation toward the nose, pushing the posterior occiput anteriorly
- Reassess motion

739.1 Cervical Somatic Dysfunction

AA N RR (Posterior Atlas)

Dysfunction: Atlas (C1) on axis (C2) rotated right (posterior atlas right).

Objective: Improve atlas (C1) rotation to the left.

Discussion: Unlike other cervical vertebrae, somatic dysfunction of the atlas occurs in its major motion—rotation. A posterior atlas has tissue texture change and tenderness on the freer side of rotation. An anterior atlas has tissue texture change on the restricted side of rotation.

Patient Position: Lying supine.

Physician Position: Standing at the head of the table.

Procedure (Fig. 45.4):

- Place the lateral aspect of your right index finger over the right posterior aspect of the atlas. The fingers of your right hand are allowed to encircle the posterior aspect of the patient’s neck, just below the occiput. Your right thumb should be pointing across the patient’s cheek, contacting the lateral aspect of the right zygomatic process
- Your left hand is placed over the patient’s left temporo-occipital area, with your fingers spread to provide comfortable control of the head. Your left index and middle finger should contact the left atlantoaxial joint to maintain localization of forces
- With hands positioned as above, the head and neck are raised from the table, to a neutral position, and a *small* amount of

Figure 45-4 Atlas on axis dysfunction.

- extension (backward bending) is introduced between the atlas (C1) and the axis (C2), to facilitate localization of forces
- Employing a combined motion with your right and left hands, rotate the head and atlas vertebra to the left until the barrier is engaged. Check to be sure that the right index finger is applying force over the atlas (C1) and has not “slipped” down onto the axis (C2)
- With the barrier engaged, apply a short, quick, final corrective thrust of left rotation
- Return the patient’s head and neck to the neutral position
- Reassess motion

C2-7 Dysfunction (Posterior Cervical)

Dysfunction: (C5 F RR SR) C5 on C6 flexed (forward bent), rotated right, sidebent right (tissue texture change, motion restriction, and tenderness on the right)—also called a “posterior C5 right.”

Objective: Improve left rotation, sidebending, and extension at C5-6.

Discussion: The most common error in this technique is to lose localization as the head and neck are rotated. It is important to sense your way into the barrier prior to applying corrective forces. If well localized, only minimal corrective force is necessary. The physician must control the head at all times.

Patient Position: Lying supine.

Physician Position: Standing at the head of the table.

Procedure (Fig. 45.5):

- Palpate for tissue texture abnormality over the posterior component (C5 right). Place the lateral aspect of your right index finger over the posterior component. Your right thumb should point towards the patient’s eye
- Your left hand (passive) cradles the left side of the patient’s head maintaining comfortable control of the head and neck throughout the procedure
- With your right hand, introduce segmental anterior translation (an “extension break” of the neck) at the C5 on C6 level
- Maintain this extension break over the index finger of your right hand

Figure 45-5 Cervical dysfunction—vertebral segments C2-7.

5. While maintaining this extension break, rotate the head and neck to the left (down to and including C5) until the restrictive barrier is reached. Sidebending left is achieved by keeping the patient's left temple close to the table. Caution—lifting the head away from the table will introduce sidebending in the wrong direction
6. It may be necessary to move your body slightly to the right side of the table to be able to keep yourself “behind your work”, which provides more comfort and control
7. The final corrective force is a quick, gentle, short rotational force through your right hand directed anteriorly and superiorly toward the eye. Do not apply excessive force to the cervical spine. Be very gentle and specific
8. Reassess

Considerations: Do not pivot the head on the table. Do not attempt to control cervical motion by placing your passive hand on the top of the head.

739.2 Thoracic Somatic Dysfunction

Patient Prone, Flexed Thoracic Thrust (Texas Twist/ Cross Hand Pisiform Thrust)

Dysfunction: T5 flexed, rotated right, sidebent right; (T5 F RR SR)—posterior component right.

Objective: Improve extension, left sidebending, and left rotation.

Discussion: REMEMBER: Diagnose a dysfunction before attempting a thrust! This technique is useful for flexed dysfunctions but is not appropriate for an extended dysfunction. There are a number of variations in this technique. The placement of hands varies. Some physicians prefer to stand on one side of the table and treat dysfunction on either side of the spine. A modification of this technique may be used to thrust on the rib angle. **PRECAUTION:** Excessive force may crack ribs, particularly if osteoporosis is present. **This technique is contraindicated for osteoporotic patients or for an extended dysfunction.**

Patient Position: Prone.

Physician Position: Standing at the side of the table, opposite to the posterior component.

Figure 45-6 Patient prone, thoracic thrust—for a flexed thoracic dysfunction.

Procedure (Fig. 45.6):

1. Place your right thenar eminence over the right posterior transverse process of T5. Place your left hypothenar eminence on the opposite side of the spine contacting the left transverse process of T6
2. With firm contact over the transverse processes (refer to diagram on the previous page), push down (anterior) and superiorly on T5 right while simultaneously pushing down (anterior) and inferiorly on the left
3. Downward pressure introduces extension
4. Now translate the lesion right that effectively localizes the sidebending barrier and applies a “twist” to the soft tissues
5. Final corrective force: With your elbows locked, apply a quick, light, HVLA thrust anteriorly, predominately on the posterior transverse process of T5
6. Reassess motion

Flexed Upper Thoracic Dysfunction (Spinous Process Thrust)

Dysfunction: T2 on T3, flexed, rotated right and side bent right (T2 F RR SR)

Objective: To restore motion in extension, rotation, and side bending left.

Discussion: The upper thoracic spine is difficult to treat. This technique is useful on thoracic vertebrae 1-4, flexed and extended dysfunctions. It offers great therapeutic specificity for this problem area. This technique is most effective when the restriction is predominately sidebending. Both the hand on the spinous process and the hand on the patient's head and neck are working in synchrony to rotate and sidebend the dysfunctional segment in the same direction.

Patient Position: Seated.

Physician Position: Standing behind the patient.

Procedure (Fig. 45.7):

1. Place your right foot on the table several inches to the right of the patient's right hip
2. Drape the patient's right axilla over your right knee. You may place a pillow between your knee and the patient's axilla

Figure 45-7 Spinous process thrust—for a flexed upper thoracic dysfunction.

3. With the fingers of your left hand loosely over the patient's left shoulder, place your left thumb in contact with the tissues on the left side of the spinous process of T2
4. Apply a downward pressure with your left hand directed toward your right knee to aid in localizing forces between T2 and T3
5. While maintaining the patient's shoulders parallel to the tabletop, use your knee to translate the patient's upper torso to the right. This introduces left side bending between T2 and T3 from below
6. Place your right elbow over the patient's right shoulder with your forearm stabilizing the patient's neck/head. Your hand drapes over the top of the patient's head. This allows greater control and localization. Physicians with large hands may place their right hand, widespread, over the right side of the patient's face
7. With your right hand, translate the patient's head and neck posteriorly, moving the cervical spine as a unit, introducing extension between T2 and T3
8. With your right hand/arm, sidebend the head and neck to the left until you feel left side bending between T2 and T3
9. Rotate the head and neck to the left until you feel left rotation between T2 and T3
10. Your final corrective force is a short, transverse thrust with the thumb of your left hand producing left rotation and sidebending of T2. Raising your left elbow above the patient's shoulder will enhance the corrective force
11. Reassess

739.3 Lumbar Somatic Dysfunction

Lumbar Flexed Dysfunction (Patient on Side/Lumbar Roll)

Dysfunction: Lumbar type II somatic dysfunction. L2 rotated left, sidebent left, and flexed (L2 F RL SL).

Objective: To improve the ability of L2 to rotate and sidebend right and extend.

Discussion: Many variations of this technique exist. Some schools use patient on side technique for Fryette type I, or II dysfunctions. The mechanics of this technique may be difficult to understand,

because the corrective force is applied to the bottom segment of the vertebral unit. Dr. Kappler uses the analogy of a “two-wrench system” to loosen a bolt/nut in comparison to this technique.

The Chicago side lumbar technique for type II dysfunctions emphasizes sidebending. The applied sidebending opens the “closed facet” or “single segment concavity.” The posterior component (“facet closed”) is placed down. Placing the posterior component down on the table relatively fixes L2 so that “the bottom is brought around to meet the top.” *The bottom of the spine is stretched out; the upper side is compressed.*

Note: Many side lumbar techniques “scissor” the patient with the upper shoulder maximally rotated. The scissor approach stretches the upper side producing inappropriate sidebending. This approach might be ok if treating a group curve.

The sequence of events in this technique is to set up the bottom (pelvis), obtain an extension break from above down, then to thrust.

Patient Position: Lying on left side facing the physician (dysfunctional side, the left side in this case, must be down) with pillow(s) supporting head. *It is crucial (especially in women with a wider pelvis) that in the side lying position, the left side of the lumbar spine is stretched, so it is in contact with the table.*

Physician Position: Standing at the side of the table, facing the patient. The table height is commonly placed at (or below) the level of the physician's hips/pelvis.

Procedure (Fig. 45.8):

1. With the patient lying on his or her left side, palpate over the posterior component and interspinous space of L2 on L3 with your right hand
2. With the patient's hips and knees flexed, grasp both of his or her lower legs and flex the patient's hips until motion is isolated at the L2-L3 interspace. Flex the patient's top leg forward over the edge of the table. The patient's top foot may hook behind his or her other knee. Lock or pin this leg to the table using your left thigh. This will maintain your localization from below
3. Switch hands so that you palpate the L2-3 vertebral unit with your left hand. Grasp the patient's lower arm (above the elbow) with your right hand
4. Extension from above down to the somatic dysfunction is obtained by pushing the patient's lower arm posteriorly and

Figure 45-8 Patient on side, “Lumbar Roll”—for a flexed lumbar dysfunction.

cephalad, while monitoring the accumulation of forces at L2. Rotation from above down to L3 can be obtained by pulling the patient's arm anteriorly and superiorly. Monitor accumulation of force at L2

5. Additional rotation to "take out the slack" is only appropriate if the patient is excessively mobile
6. Slip your right hand underneath the patient's right arm, contacting the anterior shoulder region with your forearm, or the palm of your right hand, while monitoring the dysfunction with your left fingertips
7. Contact the patient's lateral right ilium with your left forearm, while palpating for localization of your force. If you have done a good job setting up the bottom, you don't need much more motion on the pelvis. The terminal objective of this positioning is simply to "stretch out the bottom and compress the top," achieving right lumbar sidebending
8. Prior to the thrust, ask the patient to turn his or her head toward the ceiling. Maintain the holding force with your right forearm or hand to keep the patient's right shoulder from rolling forward during your final localization and thrust. To further localize from below, rolling the patient's hips toward the table is often useful. The final corrective force, through your left forearm, is a combined vector force in an anterior and cephalad direction, dropping your weight downward onto your contact. This directed force is on the patient's pelvis with your left forearm, emphasizing right sidebending of the lumbar spine
9. Reassess motion

Lumbar Flexed Dysfunction (Seated/Walk Around)

Dysfunction: L1 on L2, rotated right and sidebent right, flexed (L1 F RR SR). This technique is useful for lower thoracic and all lumbar somatic dysfunctions.

Objective: Improve rotation and sidebending left and extension of L1 on L2.

Discussion: This technique is especially useful for flexed dysfunctions in the thoracolumbar junction. Much of the rotational force is from above, and extension is maintained throughout the movement. Localize the barrier through lateral translation. When performing this technique, it is important to keep *both* of the patient's ischial tuberosities in contact with the table. Instructing the patient to turn his or her head to the side opposite to the dysfunction may enhance results by adding more rotation from above.

Physician Position: Standing behind the seated patient.

Patient Position: Patient sitting astride the end of the table with his or her back toward the physician. Keep the patient's pelvis close to the edge. An electric table is useful for proper technique execution.

Procedure (Fig. 45.9):

1. Instruct the patient to clasp his or her hands behind his or her neck
2. With your left arm, reach beneath the patient's left axilla (just below the shoulder), crossing the chest anteriorly. Place your left hand over the patient's right arm, grasping the area just below the right humeral head
3. Place the heel of your right hand over the right transverse process of L1. Instruct the patient to slump forward slightly until gaping (flexion) is palpated with your right hand. Now ask the patient to "sit up as straight as possible." Take up the extension with your right hand. Ask the patient to "relax" while you maintain the extension at L1

Figure 45-9 Patient seated, "Walk Around"—for a flexed lumbar dysfunction.

4. Using the heel of your right hand, translate the entire lumbar and low thoracic area across the midline to the right, by applying pressure with your body against the patient's left axilla. This right translation engages the barrier and localizes the left sidebending force to L1 on L2
5. Keep the patient's shoulders level and ischial tuberosities on the table
6. While maintaining your lateral translation, rotate L1 to the left. This is accomplished by pushing with your right hand, and by taking a step or two, or "walking around," the end of the table to the right. Maintain the localization by pressure through your right hand until the barrier is engaged. Your right arm should be functionally fixed to your torso, or you may fix your right elbow to your right side
7. Your right arm keeps the patient's torso extended. Do not allow the L1 somatic dysfunction to flex during the corrective force, as this will probably render the technique ineffective
8. The final corrective force is a quick increase in left rotation of L1 with an anterolaterally directed force through the heel of your right hand by shifting your body around to the restrictive barrier. At this point, your feet don't move. Use your entire body as a unit and maintain good body mechanics. Be sure to engage the barrier prior to your thrust. Do not "wind up and thrust"
9. Reassess motion

739.4/739.5 Sacroiliac Somatic Dysfunction

Trunk Rotation Ilium Thrust—Patient Supine

Dysfunction: Right posterior sacrum (sacrum rotated right on the right oblique axis, restriction of the right SI joint, inferior pole).

Objective: Improve motion of the SI joint.

Discussion: A posterior sacrum is an inferior pole restriction of the SI joint, wherein the ILA on the side of restriction is more posterior/inferior. A posterior right sacrum will be rotated right on a right oblique axis. The sacrum will be sidebent left.

Patient Position: Supine.

Physician Position: Standing at the level of the patient's waist, opposite the side of the posterior sacrum.

Figure 45-10 Ilium thrust, trunk rotation, patient supine—for a posterior sacrum.

Procedure (Fig. 45.10):

1. Slide the patient's upper torso away from you to introduce the proper sidebending. The patient's left shoulder should now be lying in the midline of the table. Leave the patient's legs in the middle of the table
2. Have the patient place the hands behind the neck and interlace the fingers
3. Take your cephalad hand and insert it through the triangle formed by the patient's right arm. The dorsum of your cephalad hand should rest on the sternum
4. Place your caudad hand over the patient's right iliac crest stabilizing the pelvis
5. Rotate the patient's torso to the left with your cephalad arm by pivoting the patient on the patient's left shoulder. Make sure to keep the patient's left shoulder in the middle of the table throughout this arc of motion. Do not flex the patient's torso
6. As the patient's torso is rolled toward you, take up all the slack in the tissues until localization is felt down at the sacrum. The final corrective force is a quick thrust posteriorly on the ilium, moving the ilium to approximate with the posterior right sacrum
7. Reassess motion

Note: If the technique is unsuccessful, do not apply more force. The technique "will go or won't go."

Ilium Thrust—Patient on Side (Anterior Sacrum)

Dysfunction: Right anterior sacrum (sacrum rotated left on the left oblique axis, restriction of the right SI joint, superior pole).

Objective: To improve motion of the right SI joint.

Discussion: This technique moves the ilium to "meet up with" the anterior sacrum.

Repeat the seated flexion test following treatment to evaluate the techniques efficacy.

Patient Position: Lying on his or her left side.

Physician Position: Standing in front of the patient at waist level.

Procedure (Fig. 45.11):

1. Place the fingertips of your right hand in the right sacral sulcus to monitor localization of forces at the right SI joint

Figure 45-11 Ilium thrust, patient on side—for an anterior sacrum.

2. With your left hand, grasp under the patient's ankles, flexing his or her knees and hips together until motion is appreciated (and localized to) the right SI joint with your right index finger
3. Drop the patient's right leg off the front of the table. This results in proper sidebending of the SI joint
4. Place your left forearm posterior to the patient's right iliac crest
5. While monitoring the SI joint with your left hand, place your right forearm in the patient's right axilla and rotate his or her torso posteriorly until you appreciate motion at the SI joint. Your right arm is now a holding force
6. With your left forearm roll the patient's lower torso toward you so that your body weight is above the patient's pelvis. The table must be low enough to do this
7. The final corrective force is a thrust through your left forearm directed anteriorly down the patient's leg (toward the floor), moving the innominate anteriorly and inferiorly to approximate with the anterior sacrum
8. Reassess motion

739.6 Lower Extremity Somatic Dysfunction

Posterior Fibular Head Thrust

Dysfunction: Example: left posterior fibular head. That is, the head of the left fibula is in a position of posterior displacement in relation to the tibia.

Objective: Improve anterior translation of fibular head.

Discussion: The fibular head and lateral malleolus often have reciprocal motions. In this example, it would be common to find an associated anterior lateral malleolus.

Patient Position: Supine.

Physician Position: Standing at the patient's left side at the level of his or her knee.

Procedure (Fig. 45.12):

1. Place the lateral portion (of the proximal end) of your right index finger directly behind the head of the left fibula
2. Your right thumb should project over the anterior surface of the fibula
3. Grasp the patient's left ankle with your left hand positioned anterior to the malleoli (thumb projects downward just above

Figure 45-12 Posterior fibular head thrust.

- the lateral malleolus and the fingers project downward above the medial malleolus)
- Position the patient's left knee in extreme flexion. This will engage the barrier as your right index finger acts as a fulcrum
 - Corrective movement is then applied by anterior pressure against the posterior fibular head using the right hand as a fulcrum, while simultaneously externally rotating the ankle
 - Reassess fibular motion

Tibio-Talar Tug

Dysfunction: Anterior tibia dysfunction—tibia is translated anteriorly on the talus.

Objective: To restore normal motion of the ankle.

Discussion: This technique is useful in the treatment of the common anterior tibia dysfunction. When the tibia is anterior, the talus is relatively posterior and prefers dorsiflexion. This technique involves engaging the restrictive barrier into plantar flexion and “tugging” the talus anterior to correct the dysfunction.

Patient Position: Supine.

Physician Position: Standing at the foot of the table.

Procedure (Fig. 45.13):

- The physician grasps the patient's foot by interlacing his or her fingers of both hands over the dorsum of the foot allowing the thumbs to project under the plantar surface of the foot
- The foot and leg are lifted from the table with the foot held at right angles and the foot is supinated and inverted
- The physician then applies a slight traction force through the foot to disengage the tibial-talar joint
- The patient is asked to relax and the physician applies a corrective force of a quick tug increasing the supination, inversion, and traction

739.7 Upper Extremity Somatic Dysfunction

Anterior Radial Head Thrust (Radioulnar)

Dysfunction: The right radial head is restricted in posterior motion and external rotation of the forearm is restricted (supination).

Figure 45-13 Tibio-talar tug technique.

Objective: Restore free posterior motion of the radial head and improve supination.

Discussion: The anterior radial head is relatively rare.

Patient Position: Seated.

Physician Position: Standing facing patient.

Procedure (Fig. 45.14):

- Grasp patient's right hand with your right hand, as if shaking hands
- Grasp patient's right elbow in such a way that the fingers of your left hand contact the olecranon process. Place your left thumb (alternatively you may use the fingers of your left hand) in the antecubital space applying a firm posterior directed pressure over the radial head. Your thumb will act as a wedge to thrust the radial head posteriorly
- Use your right hand to induce pronation and flexion of the patient's forearm and wrist while introducing rapid flexion of the elbow. This flexion results in the simultaneous posterior thrust of the radial head through the wedging action of

Figure 45-14 Anterior radial head thrust (radioulnar).

your left hand or thumb between the radius and the biceps muscle

4. Reassess motion of the radial head

Posterior Radial Head Thrust (Radioulnar)

Dysfunction: Right radial head is restricted in anterior motion relative to the ulna and is free in posterior motion. A restriction of internal rotation (pronation) may also be found.

Objective: Restore free anterior motion of the radial head and restore pronation.

Discussion: The posterior radial head is relatively common.

Patient Position: Seated.

Physician Position: Standing facing patient.

Procedure (Fig. 45.15):

1. Grasp patient's right hand with your right hand, while stabilizing the wrist
2. Hold patient's proximal forearm in your left hand, with your thumb applying an anteriorly directed pressure to the posterior aspect of the radial head
3. Now, while maintaining the anterior pressure on the radial head, with the arm in a pronated position and the elbow flexed, the corrective technique should be a fluid movement supinating the forearm and wrist and extending the elbow
4. Just before reaching complete extension, apply a HVLA thrust through your left thumb on the proximal radial head moving it anteriorly
5. Reassess motion

739.8 Rib Somatic Dysfunction

Elevated Upper Rib Thrust (Reverse Rib)

Dysfunction: Left 3rd rib is prominent with tissue texture abnormality and restricted motion to an anterior and inferior applied force. Associated limitation of right rotation and sidebending of T2 on T3 is present.

Objective: To restore normal motion to the rib and associated thoracic segment.

Discussion: This is a Chicago technique introduced by Norman J. Larson, D.O., F.A.A.O. This technique may be used for 2nd, 3rd, and 4th "structural" rib dysfunctions. This rib dysfunction is

associated with a primary thoracic dysfunction. This technique is most effective with a flexed upper thoracic dysfunction and less effective with extended dysfunctions. As such, the primary thoracic dysfunction should be treated first before you employ this technique. In the situation in which the left 3rd rib is dysfunctional, T2 is rotated and sidebent left with the body of T2 pushing against the head of rib 3, straining the costotransverse articulation.

Patient Position: Seated.

Physician Position: Standing behind the seated patient.

Procedure (Fig. 45.16):

1. Place your right foot on the table several inches to the right of the patient's right hip. Place your right knee under the patient's right axilla and drape the patient's arm over your knee. Place a pillow between your knee and the patient's axilla. The patient's left arm may be drawn across his or her lap. This moves the scapula laterally to improve access to the area of the posterior rib angle. Stabilize the patient against your leg and torso. Maintain the patient's shoulders parallel to the table
2. Drape your left hand over the patient's left shoulder with your thumb contacting the angle of the dysfunctional 3rd rib. Apply a firm fixing force inferiorly and medially over the rib
3. Place your right hand (and forearm if necessary), with wide-spread fingers, over the right side of the patient's neck, cheek and zygoma. Your third digit should contact the face just inferior to the zygoma. Avoid placing your fingers in the patient's eyes and nose
4. With your right hand, translate the cervical spine as a unit, posteriorly until motion is noted at the T2-3 spinal level. Gently extend the cervical spine until motion is appreciated at the T2-3 spinal level. Rotate the patient's head to the right until forces accumulate at the level of T2. You may make minor adjustments to further enhance localization. These can include small amounts of sidebending or rotation to help localize the barrier
5. The final corrective force is a quick increase in right rotation of the patient's head and neck while maintaining firm fixation with your left hand on the rib. A counter thrust is not executed on the rib. The corrective force has moved T2 in relation to T3 and to the head of rib 3. The rib is usually felt to become suddenly freer following the execution on the technique. Instructing

Figure 45-15 Posterior radial head thrust (radioulnar).

Figure 45-16 Elevated upper rib thrust, "reverse rib."

the patient to shake his or her head “no” before applying the final correcting thrust may enhance results

6. Reassess motion

KEY CONCEPTS

- Muscle energy is a plan of diagnosis and treatment which relies on active patient effort through muscular contraction.
- This approach requires active use of the patient's muscles, on request, from a precisely controlled position, in a specific direction, and against a distinctly executed counterforce.
- Postisometric relaxation is a mobilization technique that applies gentle force to improve "articulation" and thereby restore previously restricted motion.
- The versatility of this approach allows combination with any of the other osteopathic manipulative techniques in total patient management.

CASE STUDY

A.J., a 54-year-old male, presents with recent onset lower back pain. The pain began while he was attempting to push a heavy automobile. The worst pain is located in the region of the lumbosacral junction and spreads across the top of the right iliac crest and into the right groin. The pain is worse with truncal flexion and improves with truncal extension. The pain is a constant dull ache with sharp exacerbations. He denies radicular pain, sensory loss, paresthesias, or lower extremity weakness.

Physical examination reveals normal vital signs, normal cardiac and pulmonary exams. Neuromusculoskeletal exam reveals normal motor, reflexes, and sensation. Gross motion testing notes mildly restricted lumbar range of motion. The standing flexion

test is positive on the right suggesting a possible innominate dysfunction. This is confirmed by palpating passively induced iliosacral motion and discovering loss of right iliosacral motion. The posterior superior iliac spine on the right is more cephalad than on the left. The sacral sulcus on the right is shallow. The diagnosis is a right anteriorly rotated innominate somatic dysfunction.

Mechanism of Injury:

Excessive contraction of the rectus femoris muscle on the right against an unyielding resistance has resulted in the innominate bone being rotated anteriorly relative to the sacrum.

Treatment:

The appropriate muscle energy technique is utilized to treat the right anterior innominate somatic dysfunction. Reassessment reveals restoration of symmetric passively induced iliosacral motion and a normal standing flexion test. Additionally, the patient reports immediate substantial pain relief.

DEFINITION

Muscle energy technique has been defined as a form of osteopathic manipulative treatment in which the patient's muscles are actively used on request, from a precisely controlled position, in a specific direction, and against a distinctly executed counterforce.

Muscle energy techniques involve the patient's active cooperation to contract a muscle or muscles, inhale or exhale, or move one bone of a joint in a specific direction relative to the adjacent bone. For these reasons, muscle energy cannot be used if the patient is in a coma, uncooperative, too young to cooperate, or unresponsive (8).

HISTORY

Muscle energy is a system of osteopathic diagnosis and treatment with roots extending back to Andrew Taylor Still. Dr. Still did not record the way that he treated, preferring to insist that his students conduct an exhaustive study of anatomy while absorbing the osteopathic philosophy. He told students that if they knew anatomy and understood osteopathic philosophy, they would know what to do. As the osteopathic profession sought to increase the efficiency of teaching students how to treat patients, certain key individuals

made contributions by developing a particular type of technique into a plan. Fred Mitchell, Sr. contributed by developing a plan of diagnosis and treatment that he called muscle energy because of its reliance on active patient effort through muscular contraction.

Mitchell (1) credited Kettler as the first to focus (his) attention on the importance of the vast amount of tissue involved between joints, muscle, and fascia, and the changes it undergoes in the lesioning process. Kettler also emphasized that without establishing bilateral myofascial harmony, the lesion pattern is not obliterated and returns again and again. Mitchell also quoted Still, showing that he knew about this: "The attempt to restore joint integrity before soothingly restoring muscle and ligamentous normality was putting the cart before the horse" (1).

Some sources allege that muscle energy techniques are an outgrowth of a method developed by T. J. Ruddy (2) called resistive duction. In Ruddy's method, the physician offers resistance to the patient's active movement, but the patient is required to move quickly, often at a rate of 60 excursions per minute, or equal to the patient's pulse rate. Ruddy's purpose in asking the patient to contract muscle quickly and repetitively was twofold:

1. To increase blood (and other tissue fluid) movements to remove metabolic waste products from the cells and circulate oxygen
2. To tone inactive muscles that might be weak

Mitchell and Kettler must have been unaware of the proprioceptive neuromuscular facilitation (PNF) techniques developed by Kabat, Knott, and Voss at the Kabat-Kaiser Institute during the late 1940s. These techniques were not widely known. PNF uses skills to reeducate muscle for several reasons (3):

*"To gain inhibition in muscles which may be in a protective spasm."
"To improve range (of motion) at an intervertebral level."*

Mitchell first published his work in the *Yearbook of the American Academy of Osteopathy* in 1958 after receiving requests for a written description of the work he had developed in the 1940s and 1950s. He described one method of correction that used the effort of an extrinsic guiding operator as the activating force plus the intrinsic respiratory and muscular cooperation of the patient. He wrote about the direct method treatments of soft tissues (with attention to fasciae) and treatment using Neidner's fascial release prior to articular correction. Muscular energy technique, he wrote, with its many ramifications, is a most useful tool in preparation of the soft tissues. Ligamentous stretching may also be of use before articular correction is attempted (1).

Lewit and Simons (4) wrote that the use of postisometric relaxation was pioneered by Mitchell Sr. and clearly described by F. L. Mitchell Jr. as a mobilization technique that applies gentle force to improve "articulation" and thereby restore previously restricted movement. Later authors believed that Mitchell's muscle energy approach did this more quickly than PNF techniques. Probably because Mitchell's work was not recorded in indexed allopathic literature, Travell and Simons (5) credited Lewit in their text by stating that the concept of applying postisometric relaxation in the treatment of myofascial pain was presented for the first time in a North American journal in 1984.

Mitchell taught his techniques in tutorials to numerous physicians. The first 5-day Mitchell tutorial was held in Fort Dodge, IA, in 1970 and was attended by John Goodridge, Philip Greenman, Rolland Miller, Devota Nowland, Edward Stiles, and Sara Sutton—all osteopathic physicians. Several tutorials followed across the country. In 1972, Mitchell's examination and treatment procedures were videotaped at Michigan State University's College

of Osteopathic Medicine. After Mitchell's death in 1974, the American Academy of Osteopathy organized a committee of physicians who had taken a tutorial with Mitchell and developed a manual for the presentation of 5-day courses to familiarize others with Mitchell's work. Additional tutorials were conducted for new faculty at the newly established colleges of osteopathic medicine from 1977 to 1981. The five earlier established osteopathic colleges began to integrate muscle energy procedures into their curriculum. In 1979, Mitchell et al. (6) published the manual that was and is still used as a reference in most osteopathic medical colleges. In 1999, Mitchell, Jr. completed publication of an exhaustive text on the muscle energy approach (7). Muscle energy diagnostic and treatment procedures developed by Mitchell, Sr. are currently a standard part of the osteopathic manipulative medicine curriculum and are also used by many physical therapists.

INDICATIONS AND CONTRAINDICATIONS

The muscle energy approach is indicated in the presence of somatic dysfunction in the absence of contraindications. Postisometric relaxation and joint mobilization using muscle force type techniques should not be applied to acutely injured or painful muscles. These would be better treated using a reciprocal inhibition technique.

Postisometric relaxation and joint mobilization using muscle force muscle energy techniques should not be requested of a patient with low vitality that could further be compromised (e.g., by provoking internal bleeding) by adding active muscle exertion. Examples would include a postsurgical patient or a patient in an intensive care unit immediately following a myocardial infarction. These patients could still be candidates for the use of those techniques requiring the use of respiratory assistance, oculocephalogyric reflex, reciprocal inhibition, or the crossed extensor reflex as these are exceptionally gentle techniques. Oculocephalogyric reflex techniques are contraindicated in anyone who has undergone recent eye surgery or has recently sustained trauma to the eye.

Muscle energy techniques are contraindicated for any individual who is unable or unwilling to follow the verbal directions of the physician. Examples here would include the very young child or infant; those not able to understand the physician due to a language barrier, or hearing loss; as well as the mentally ill who are unable to cooperate.

Complications: When both the patient and the type of muscle energy technique are chosen properly, no serious complications occur. Minor complications such as posttreatment muscle or joint soreness tend to be self-limiting and resolve within 24 to 36 hours without additional treatment.

Use of inappropriately excessive force has been reported to result in the complications of tendon avulsion from bone (in an 85-year-old man) and rib fracture (in a patient with osteoporosis). Inappropriate application of oculocephalogyric reflex cervical range of motion muscle energy techniques has resulted in anterior chamber intraocular hemorrhage in a single patient postcataract removal and lens implant surgery (C. Walter Ehrenfeuchter, D.O., F.A.A.O.—*personal communication*).

FACTORS INFLUENCING THE SUCCESSFUL APPLICATION OF MUSCLE ENERGY TECHNIQUES

Good results depend on accurate diagnosis, appropriate levels of force, and sufficient localization. Poor results are most often caused

by inaccurate diagnosis, improperly localized forces, or forces that are too strong.

Diagnosis

An inaccurate diagnosis may lead to inappropriate treatment and does not achieve the desired improvement in the patient's condition. Even if a segmental diagnosis is accurate, complicating factors and the entire clinical picture of the patient need to be considered. For example, a careful diagnosis may indicate that side-bending is restricted at a segment superior to the one identified for treatment; this then interferes with the localization required, and the superior segment may need to be treated before the inferior segment.

Localization

The localization of force is more important than the intensity of force. Localization depends on the physician's palpatory perception of movement (or resistance to movement) at or about a specific articulation. Such perception enables the physician to make subtle assessments about a dysfunction and create variations of suggested treatment procedures.

Monitoring the localization of forces and confining the direction of force by the diagnosed muscle group to the level of somatic dysfunction are important to achieve desired results. When the physician introduces motion into an articulation that is a segment or two below the dysfunctional one, the probability of success greatly decreases because the forces have been directed to the wrong muscles.

Amount of Force

Using excessive force is the most common mistake made in applying muscle energy technique. This is not a wrestling match between patient and physician. Excessive force recruits other muscles to assist in stabilization of the body part being treated and may completely negate the intent of the technique. Excessive forces used on older patients may result in tendon avulsion from bone.

Asymmetrical Muscle Strength

Where asymmetry of range of motion occurs, consider and test the possibility of asymmetrical strength. Some ranges of motion may be asymmetrical because of weakness of a group of muscles rather than the shortness of the antagonist group. If asymmetry of muscle strength is present, employ a method to increase the strength of the weak muscle group. Progressive resistance exercises are used to strengthen weakened muscle groups. If weakness and shortness occur in different muscle groups but on the same side, attend to the shortness first. Jull and Janda (10) feel the agonists spontaneously increase their strength if the shortened or hypertonic fibers are lengthened.

TYPICAL SEQUENCE OF STEPS IN TECHNIQUE

Diagnosis

The physician should make an accurate diagnosis prior to initiating any treatment sequence. Although a diagnosis of somatic dysfunction from the muscle energy perspective has some unique elements, they are well described in the chapters on regional examination of the body. The reader is referred to those chapters to learn the appropriate diagnostic techniques.

Sequence

Based on an accurate diagnosis, a muscle energy procedure follows these principles:

1. The physician positions the body part to be treated at the position of initial resistance. It is important that only the "feather edge" of the restrictive barrier is engaged for maximal efficacy of these techniques. The "feather edge" of the restrictive barrier is the point where the restrictive barrier is just beginning to be engaged or where the tissue tension is just palpable.
2. The physician instructs the patient about his or her participation and helps the patient to obtain an effective direction of movement for the limb, trunk, or head. The patient is instructed in the intensity and duration of the muscle contraction.
3. The physician directs the patient to contract the appropriate muscle(s) or muscle group.
4. The physician uses counterforce in opposition to and equal to the patient's muscle contraction.
5. The physician maintains forces until an appropriate patient contraction is perceived at the critical articulation or area. This generally takes 3 to 5 seconds, but the duration varies with the size of the muscle being treated.
6. The patient is directed to relax by gently ceasing the contraction while the physician simultaneously matches the decrease in patient force.
7. The physician allows the patient to relax and senses the tissue relaxation with his or her own proprioceptors.
8. The physician takes up the slack permitted by the procedure. The slack is allowed by the decreased tension in the tight muscle, allowing it to be passively lengthened. The physician notes increased range of motion.
9. Steps 1 to 8 are repeated three to five times until the best possible increase in motion is obtained. The quality of response often peaks at the third excursion, with diminishing return thereafter.
10. The physician reevaluates the original dysfunction.

PHYSIOLOGIC PRINCIPLES

There are nine different physiologic principles of muscle energy technique:

1. Joint mobilization using muscle force
2. Respiratory assistance
3. Oculocephalogyric reflex
4. Reciprocal inhibition
5. Crossed extensor reflex
6. Isokinetic strengthening
7. Isolytic lengthening
8. Using muscle force to move one region of the body achieve movement of another bone or region
9. Postisometric relaxation

The following section describes the goals, physiologic basis, and contraction force for each of these principles. Examples of treatment of somatic dysfunction using each of these principles will be found under the treatment section. (Note: Example numbers correspond to the examples in the techniques section.)

Postisometric Relaxation

Goal

To accomplish muscle relaxation.

Physiologic Basis

Mitchell Jr. (9) postulated that immediately after an isometric contraction, the neuromuscular apparatus is in a refractory state during which passive stretching may be performed without encountering strong myotatic reflex opposition. All the operator needs to do is resist the contraction and then take up the slack in the muscles during the relaxed refractory period. With muscle contraction, there may also be increased tension on the Golgi organ proprioceptors in the tendons; this inhibits the active muscle's contraction.

Force of Contraction

Sustained gentle pressure (10 to 20 lb of pressure)

Example

See 739.5 pelvic somatic dysfunction

Example 5—Hip girdle dysfunction—hamstring muscles

Joint Mobilization Using Muscle Force**Goal**

To accomplish restoration of joint motion in an articular dysfunction.

Physiologic Basis

Distortion of articular relationships and motion loss results in a reflex hypertonicity of the musculature crossing the dysfunctional joint, similar to thrust (HVLA) technique. This increase in muscle tone tends to compress the joint surfaces, and results in thinning of the intervening layer of synovial fluid and adherence of the joint surfaces. Restoration of motion to the articulation results in a gaping, or reseating of the distorted joint relations with reflex relaxation of the previously hypertonic musculature.

Force of Contraction

Maximal muscle contraction that can be comfortably resisted by the physician (30 to 50 lb of pressure)

Example

See 739.5 pelvic somatic dysfunction

Example 6—Innominate dysfunction—anterior rotation

Respiratory Assistance**Goal**

To produce improved body physiology using the patient's voluntary respiratory motion.

Physiologic Basis

The muscular forces involved in these techniques are generated by the simple act of breathing. This may involve the direct use of the respiratory muscles themselves, or motion transmitted to the spine, pelvis, and extremities in response to ventilation motions. The physician usually applies a fulcrum against which the respiratory forces can work.

Force of Contraction

Exaggerated respiratory motion

Example

See 739.4 sacral somatic dysfunction

Example 4—Sacral dysfunction—unilateral extended sacrum

Oculocephalogyric Reflex**Goal**

To affect reflex muscle contractions using eye motion.

Physiologic Basis

Functional muscle groups are contracted in response to voluntary eye motion on the part of the patient. These eye movements reflexively affect the cervical and truncal musculature as the body attempts to follow the lead provided by eye motion. It can be used to produce very gentle postisometric relaxation or reciprocal inhibition.

Force of Contraction

Exceptionally gentle

Contraindications

Fracture, dislocation, or moderate to severe segmental instability in the cervical spine. Evocation of neurologic symptoms or signs on rotation of the neck.

Example

See 739.1 cervical somatic dysfunction

Example 2—Restriction of regional cervical rotation

Reciprocal Inhibition**Goal**

To lengthen a muscle shortened by cramp or acute spasm.

Physiologic Basis

When a gentle contraction is initiated in the agonist muscle, there is a reflex relaxation of that muscle's antagonistic group.

Force of Contraction

Very gentle (think ounces, not pounds of pressure)

Example

See 739.1 cervical somatic dysfunction

Torticollis due to acute sternocleidomastoid muscle spasm

Crossed Extensor Reflex**Goal**

Used in the extremities where the muscle that requires treatment is in an area so severely injured (e.g., fractures or burns) that it is directly unmanipulable or inaccessible.

Physiologic Basis

This form of muscle energy technique uses the learned cross pattern locomotion reflexes engrained into the central nervous system. When the flexor muscle in one extremity is contracted voluntarily, the flexor muscle in the contralateral extremity relaxes and the extensor contracts.

Force of Contraction

Very gentle (think ounces, not pounds of pressure)

Example

See 739.5 pelvic somatic dysfunction

Example 2—Severe acute hamstring strain

Special types of muscle contractions may be used in addition to the classic isometric contraction for special situations. Two specific examples are given below.

Isokinetic Strengthening**Goal**

To reestablish normal tone and strength in a muscle weakened by reflex hypertonicity of the opposing muscle group.

Physiologic Basis

Where asymmetry of range of motion exists, there is also the potential for asymmetry in muscle strength. If there is shortening of an antagonist muscle, attend to that first. Jull and Janda (10) feel the agonists spontaneously increase their strength if the shortened or hypertonic fibers are lengthened first.

Once this is accomplished, further restoration of strength can be accomplished through the use of an Isokinetic contraction. In Isokinetic contractions, the length change occurs at a constant velocity. Typically concentric contractions are used, where the muscle is permitted to shorten, but at a controlled slow rate.

Force of Contraction

Sustained gentle pressure (10 to 20 lb of pressure)

Example

See 739.5 pelvic somatic dysfunction

Example 3—Hamstring shortening resulting in reflex quadriceps weakness

Isolytic Lengthening**Goal**

To lengthen a muscle shortened by contracture and fibrosis.

Physiologic Basis

It is postulated that the vibration used here has some effect on the myotatic units in addition to mechanical and circulatory effects (11).

Force of Contraction

Maximal Contraction that can be comfortably resisted by the physician (30 to 50 lb of pressure)

Example

See 739.5 Pelvic Somatic Dysfunction

Example 4—Hamstring contracture

Using Muscle Force to move one region of the body achieve movement of another bone or region**Goal**

To treat somatic dysfunction.

Physiologic Basis

For some dysfunctions, especially those involving the pelvis, it is often more effective to move one body structure by moving another body structure adjacent to it. Muscular force is used to move the first structure and that body part's response to the muscle force is transmitted to yet another part of the body.

Force of Contraction

Sustained gentle pressure (10 to 20 lb of pressure)

Example

See 739.4 sacral somatic dysfunction

Example 3—Bilaterally extended sacrum

DIAGNOSES AND TECHNIQUES**739.0 Craniocervical Somatic Dysfunction**

Example 1—Acute cervical sprain and strain (Whiplash)

Diagnosis

Position: Occiput is flexed on C1

Restriction: Occiput is restricted in extension on C1

Type of Muscle Energy

Reciprocal inhibition

Treatment Position

Patient: Supine

Physician: Seated at the head of the table

Procedure

1. The physician's one hand is placed beneath the patient's occiput with the fingers in contact with the suboccipital musculature
2. The index and middle fingers of the physician's other hand are placed on top of the patient's chin (Figs. 46.1 and 46.2)
3. The patient is instructed to very gently tilt the head backward so that their chin comes up against the physician's fingers. The physician should be able to palpate the contraction of the suboccipital muscles with the hand beneath the occiput
4. This contraction is maintained for a full 3 to 5 seconds
5. The patient is instructed to relax, simultaneously ceasing your counterforce. Wait 2 seconds for the tissues to relax

Figure 46-1 Occipitoatlantal (C0-1) dysfunction example C0 ESLRR—Post-isometric relaxation. (Reprinted from Atlas of Osteopathic Technique by Nicholas & Nicholas Published by LWW, 2008 with permission.)

Figure 46-2

6. The physician shifts his fingers from the front of the chin to just below the chin
7. The physician lifts the chin cephalad, simultaneously pressing caudad with the hand beneath the occiput until the new restrictive barrier is engaged
8. The physician then shifts his fingers once again to the anterior surface of the chin
9. Steps 3 to 8 are repeated three to five times
10. Success of the technique is determined by retesting occipitoatlantal segmental motion

739.1 Cervical Somatic Dysfunction

Example 1—Cervical segmental somatic dysfunction: C5NRS_L

Diagnosis

Position: C5NRS_L; C5 is neutral, rotated left, and sidebent left
Restriction: C5 Restricted in right rotation and right sidebending

Type of Muscle Energy

Oculocephalogyric Reflex

Treatment Position

Patient: Supine
Physician: Seated at the corner of the head of the table

Procedure (Fig. 46-3)

1. Cradle the head and neck in both hands and with the middle or index fingers palpate the C5-6 facet joints
2. Lift the head forward until you straighten the cervical spine
3. Let the head extend backward from above downward until C5 is positioned in neutral relative to C6
4. Rotate C5 to the right until initial resistance to segmental motion is palpated. Sidebending will occur automatically because sidebending and rotation of coupled motions in the cervical spine. (The left hand is mostly supporting the head and neck while the right hand monitors movement at the C5-6 facet joint.)
5. Instruct the patient “look far to your left.”
6. Maintain this contraction for a full 3 to 5 seconds
7. Direct the patient to “look straight ahead and relax.”
8. Wait 2 seconds for the tissues to relax, then rotate C5 to the right until the new restrictive barrier is engaged

Figure 46-3 Treatment for cervical segmental dysfunction, C2-6.

9. Steps 5 to 8 are repeated three to five times
10. Success of the technique is determined by retesting segmental motion at the C5-6 level

Example 2—Restriction of regional cervical rotation

Diagnosis

Position: Cervical region rotated left
Restriction: Cervical region restricted in right rotation

Type of Muscle Energy

Oculocephalogyric reflex.

Contraindications

Fracture, dislocation, or moderate-to-severe segmental instability in the cervical spine. Evocation of neurologic symptoms or signs on rotation of the neck.

Treatment Position

Patient: Supine
Physician: Seated at the head of the table

Procedure (Fig. 46.4)

1. The patient's head and neck are rotated to the right to the feather edge of the regional motion barrier
2. The patient is instructed “look as far as you can to your left”
3. This position is held for a full 3 to 5 seconds
4. Direct the patient to “look straight ahead again and relax”
5. Wait 2 seconds for the tissues to relax and then rotate the head and neck further to the right, engaging the new regional restrictive barrier
6. Steps 2 to 5 are repeated three to five times
7. Success of the technique is determined by reassessing cervical regional rotation

Example 3—Torticollis due to Acute Sternocleidomastoid Muscle Spasm

Diagnosis

Acute left sternocleidomastoid spasm

Figure 46-4 Cervical range of motion: oculocervical reflex. (Reprinted from Atlas of Osteopathic Technique by Nicholas & Nicholas. Published by LWW 2008 with permission.)

Type of Muscle Energy

Reciprocal inhibition

Contraindications

Fracture, dislocation, or moderate-to-severe segmental instability in the cervical spine. Evocation of neurologic symptoms or signs on rotation of the neck.

Treatment Position

Patient: Supine with the head positioned off the end of the table

Physician: Seated at the head of the table supporting the patient's head

Procedure (Fig. 46.5)

1. The patient's head is flexed approximately 45 degrees, then rotated so that the hypertonic sternocleidomastoid muscle is positioned superiorly
2. The patient's head is now lowered straight toward the floor until the restrictive barrier produced by this hypertonic muscle is engaged
3. Instruct the patient "push your head very gently directly toward the floor"
4. During this contraction, the physician is palpating the involved muscle with one hand to ensure that adequate relaxation is occurring. The contraction is held for 3 to 5 seconds
5. The patient is instructed to relax. After 2 seconds of relaxation, the head is again lowered toward the floor until the new restrictive barrier is engaged
6. Steps 3 to 5 are repeated three to five times
7. Success of the technique is determined by palpating the involved Sternocleidomastoid muscle for reduction in tone and by observing the patient's head position in the erect posture for improved body carriage

739.2 Thoracic Somatic Dysfunction

Example 1—Thoracic segmental somatic dysfunction

Diagnosis

Position: T8ERS_R; T8 is extended, rotated, and sidebent right

Restriction: T8 is restricted in flexion, rotation, and sidebending left

Figure 46-5 Left sternocleidomastoid spasm (acute torticollis): reciprocal inhibition. (Reprinted from Atlas of Osteopathic Technique by Nicholas & Nicholas, LWW, 2008 with permission.)

Type of Muscle Energy

Postisometric relaxation

Treatment Position

Patient: Seated on the side of the treatment table, arms crossed grasping their own shoulders

Physician: Standing behind the patient on the side opposite the direction of rotation

Procedure (Fig. 46.6)

1. Place the pads of your right fingers between the spinous processes of T8 and T9. Have the patient slowly bend forward until you feel a slight separation of these spinous processes
2. Maintaining this forward bent posture, place your left axilla over the top of the patient's left shoulder. Your left hand reaches across the front of the patient to grasp the right shoulder
3. Lean down onto the patient's left shoulder until you feel this sidebending force reach the T8 level
4. You do not have to position the patient in rotation as sidebending and rotation are coupled motions in the thoracic spine
5. Instruct the patient "pull your right shoulder down toward the floor"
6. This contraction is held for a full 3 to 5 seconds
7. Direct the patient to relax, simultaneously ceasing your counterforce
8. Further flex and left sidebend the patient until you reach the new segmental restrictive barrier for T8
9. Steps 5 to 8 are repeated three to five times
10. Success of the technique is determined by retesting segmental motion at the T8 level

739.2 Lumbar Somatic Dysfunction

Example 1—Lumbar segmental somatic dysfunction

Figure 46-6 Treatment of thoracic segmental somatic dysfunction.

Diagnosis

Position: L5FRRSR; L5 (a type II dysfunction) is flexed, rotated right, and side bent right.

Restriction: L5 is restricted in extension, right rotation, and right side-bending.

Type of Muscle Energy

Postisometric relaxation

Treatment Position

Patient: Lateral recumbent and lying with the rotational component closest to the table (in this case on the right side). The hips are flexed 45 degrees and the knees are flexed 90 degrees.

Physician: Standing facing the patient

Procedure (Fig. 46.7)

1. The physician palpates the interspinous space between L5 and S1 with the cephalad hand
2. The patient's lumbar spine is passively flexed and extended by flexing and extending the hips until the dysfunctional segment is positioned in neutral relative to flexion and extension
3. The patient's upper leg is flexed slightly further at the hip and dropped off the side of the table cephalad to the lower leg
4. The patient's pelvis is rotated anteriorly until the initial resistance reaches the segment to be treated
5. The L5-S1 interspinous space is now palpated with the physician's caudad hand while the patient's upper shoulder is carried posteriorly again until the initial resistance reaches the segment to be treated
6. The patient is instructed to "pull gently forward with your shoulder." This contraction is held for a full 3 to 5 seconds. After 2 seconds of relaxation, the shoulder is carried posteriorly until a new restrictive barrier is met
7. The patient is then instructed to "pull your hip gently backward." This contraction is held for a full 3 to 5 seconds. After 2 seconds of relaxation, the hip is carried forward until a new restrictive barrier is met
8. Each sequence of contraction/relaxation/repositioning is repeated three to five times or as long as further segmental

Figure 46-7 Treatment for lumbar, type II segmental dysfunction, lateral recumbent position.

motion is being gained. If coordinated enough, the patient may contract muscles at both the hip and shoulder simultaneously.

9. Success of the technique is determined by reevaluating segmental motion at the dysfunctional lumbar segment

739.4 Sacral Somatic Dysfunction

The diagnosis of sacral dysfunction generally requires just two types of information:

1. *The relative position of the two sacral sulci and the two inferior lateral angles (ILAs)* (Fig. 46.8). The two sacral sulci are designated as feeling either deep or shallow compared with each other. The ILAs are designated as being posterior/inferior or anterior/superior relative to each other. For unilateral sacral dysfunction, when the deep sulcus and the posterior/inferior ILA are on opposite sides of the sacrum, you have torsion. When the deep sulcus and the posterior/inferior ILA are on the same side of the sacrum, you have a unilateral sacral flexion (shear) or extension
2. *A motion test.* Several different motion tests have been devised over the years to assess unilateral sacroiliac dysfunction
 - *Lumbar spring test.* In this test, the patient is prone, and a springing force is directed anteriorly into the lumbar spine

Figure 46-8 Sacral landmarks. **A.** the sacral sulci. **B.** the ILAs.

(Fig. 46.9). Normal spring (negative spring test) indicates the presence of an anterior torsion or a unilateral flexion. Increased resistance to pressure (positive spring test) indicates the presence of either a posterior torsion or a unilateral extension

- *Sphinx test*, also called lumbopelvic hyperextension, employs observation in changes in asymmetry at the sacral sulci (Fig. 46.10). When going from the prone position to the sphinx position, if the sacral sulci become more symmetric, you have an anterior torsion or a unilateral flexion. If the sacral sulci become more asymmetric, you have a posterior torsion or a unilateral extension
- Seated flexion test (see Chapter 41)
- *Seated assessment of ILA asymmetry* (Figs. 46.11 and 46.12). This test is performed in a manner similar to a seated flexion test (special tests of the pelvis), but the ILAs are monitored. As in the sphinx test, if the asymmetry increases, you have a posterior torsion or unilateral extension. If the asymmetry decreases or stays the same, you have an anterior torsion or unilateral flexion
- *Four-digit contact* (Fig. 46.13). Contact the four corners of the sacrum as depicted. Assess motion of the sacrum by direct

Figure 46-11 Test for inferior lateral angle asymmetry, starting position.

Figure 46-9 Lumbar spring test.

Figure 46-12 Test for inferior lateral angle asymmetry, at end of flexion.

Figure 46-10 Sphinx test.

Figure 46-13 Four-digit contact.

pressure on the sacrum, moving it about its various axes, or quietly palpate sacral motion while the patient respires.

Example 1—Sacral dysfunction—*anterior torsion*

Diagnosis

Example: A left on left sacral torsion.

Position: Anterior torsion about a left oblique axis; an L on L sacral torsion (the first L designates the direction of sacral rotation, the second L designates the oblique axis on which this rotation is occurring).

Restriction: Posterior rotation about the left oblique axis is restricted. The oblique axes are not free to alternate during the gait cycle.

Type of Muscle Energy

Complex: the experts are still debating exactly what happens during this technique, but it is likely a combination of multiple muscles simultaneously going through postisometric relaxation.

Treatment Position

Patient: Left lateral modified Sims' position (lying on the side of the axis)

Physician: Stands at the side of the table facing the patient

Procedure (Fig. 46.14)

1. The patient's right shoulder is pressed as close to the table as it will go. Postisometric relaxation technique may be used to obtain optimal positioning
2. The physician's cephalad hand palpates over the right sacral sulcus
3. The patient's hips and knees are flexed to 90 degrees. Both legs are then dropped off the side of the table. A pillow may be necessary to cushion the distal thigh against the table edge
4. The physician's caudad hand is placed just proximal to the lateral malleolus of the upper leg
5. The patient is instructed to "lift your legs straight up toward the ceiling"
6. This contraction is held for a full 3 to 5 seconds

Figure 46-14 Treatment of anterior sacral torsion.

7. Direct the patient to relax, simultaneously ceasing your counterforce
8. Wait 2 seconds for the tissues to relax, and then press both legs toward the floor until a new restrictive barrier is reached
9. Steps 5 to 8 are repeated three to five times
10. Success of the technique is determined by rechecking the symmetry of the sacral sulci and ILAs, and by retesting sacral motion

*Example 2—Sacral dysfunction—*posterior torsion** (Fig. 46.15—treatment of posterior sacral torsion)

Diagnosis

Example: A left on right sacral torsion.

Position: Posterior torsion about a right oblique axis; an L on R sacral torsion (the L designates the direction of sacral rotation, the R designates the oblique axis on which this rotation is occurring).

Restriction: Anterior rotation about the right oblique axis is restricted. The oblique axes are not free to alternate during the gait cycle.

Type of Muscle Energy

Complex: the experts are still debating exactly what happens during this technique, but it is likely a combination of joint mobilization using muscle force and postisometric relaxation.

Treatment Position

Patient: Right lateral recumbent position (lying on the side of the axis)

Physician: Stands at the side of the table facing the patient

Figure 46-15 Treatment of posterior sacral torsion.

Procedure (Fig. 46.15)

1. The patient's left shoulder is carried posteriorly until the initial restriction is sensed
2. The physician's cephalad hand palpates over the left sacral sulcus
3. The patient's hips are flexed to 45 degrees and the knees to 90 degrees
4. The patient's upper leg is flexed further at the hip and dropped off the table cephalad to the lower leg
5. The physician grasps this leg just above the lateral malleolus.
6. The patient is instructed to "lift your ankle up toward the ceiling as hard as you can"
7. This contraction is maintained for a full 3 to 5 seconds
8. Direct the patient to relax, simultaneously ceasing your counterforce
9. Wait 2 seconds for the tissues to relax, and then press the leg further toward the floor until a new restrictive barrier is reached
10. Steps 6 to 9 are repeated three to five times
11. Success of the technique is determined by rechecking the symmetry of the sacral sulci and ILAs and by retesting sacroiliac motion

Example 3—Bilaterally extended sacrum**Diagnosis**

Position: Bilaterally extended sacrum

Restriction: Sacrum restricted in flexion on both sacroiliac joints

Type of Muscle Energy

Using muscle force to move one region of the body achieves movement of another bone or region. (In this case, muscles will move the lumbar spine that will in turn move the sacrum.)

Treatment Position

Patient: Seated on a low stool at the end of the treatment table, with the feet together and the knees separated.

Physician: Seated at the end of the treatment table behind the patient.

Procedure

1. A pillow or pad is placed on the patient's sacral base and the physician's one knee is placed against this, exerting a continuous anterior pressure against the sacral base
2. The patient is instructed to reach back and grasp the edges of the table
3. The physician gently restrains the patient by both shoulders
4. The patient is instructed to "lift the lower end of your sternum up toward the ceiling." (This has the effect of increasing the lumbar lordosis, arching the back in the manner of "an old sway backed horse." Increasing the lumbar lordosis normally makes the sacrum move into flexion, the desired effect here.)
5. This contraction is held for 3 to 5 seconds
6. The patient is instructed to relax while the physician maintains anterior pressure on the base of the sacrum
7. Steps 4 to 6 are repeated three to five times
8. Success of the technique is determined by reassessing sacral motion (sacral rock test) as well as the depth of the sacral sulci and position of the ILAs

Example 4—Sacral dysfunction—unilateral extended sacrum**Diagnosis**

Example: Unilateral extended sacrum—right

Position: Unilateral extended sacrum—right

Restriction: Right sacroiliac joint restricted in flexion

Type of Muscle Energy

Respiratory assistance

Treatment Position

Patient: Sphinx position (prone with the elbows supporting the upper body)

Physician: Standing at the side of the patient opposite the side of dysfunction

Procedure (Fig. 46.16)

1. The hypothenar side of the heel of the physician's right hand is placed in the region of the right sacral sulcus exerting a steady pressure directed toward the table. It is reinforced by the physician's left hand
2. The patient is instructed to "inhale and then exhale quickly"
3. During exhalation, the physician follows forward nutation of the sacrum
4. During inhalation, the physician resists posterior nutation of the sacrum
5. Steps 2 to 4 are repeated three to seven times
6. Success of the technique is determined by rechecking symmetry of the sacral sulci and the ILAs, and by retesting sacroiliac motion

739.5 Pelvic Somatic Dysfunction**Example 1—Superior pubic bone somatic dysfunction****Diagnosis**

Position: Pubic bone on side of dysfunction is displaced superiorly

Figure 46-16 Treatment of unilateral extended sacrum.

Restriction: Pubic bone on side of dysfunction resists inferior movement

Type of Muscle Energy

Joint mobilization using muscle force.

Treatment Position

Patient: Supine, lying near the edge of the table

Physician: Standing at the side of the table on the side of dysfunction

Procedure (Fig. 46.17)

1. The physician abducts the patient's ipsilateral thigh so that the leg and thigh can hang off the side of the table
2. The physician's cephalad hand is placed on the patient's contralateral anterior superior iliac spine to prevent the patient from rolling off the table during the technique
3. The physician's caudad hand is placed just proximal to the patient's ipsilateral knee
4. The physician presses downward on the thigh until the restrictive barrier is engaged
5. The patient is instructed to "lift your knee up toward the ceiling and slightly toward the table"
6. This isometric contraction is maintained for a full 3 to 5 seconds
7. The patient is instructed to relax
8. Wait 2 seconds for the tissues to relax, then reposition the patient's thigh further down toward the floor until the new restrictive barrier is engaged
9. Steps 5 to 8 are repeated three to five times
10. Effectiveness of the technique is determined by reexamining the position of the pubic tubercles and by repalpating passively induced iliosacral motion

Example 2—Severe acute hamstring strain

Diagnosis

Severe acute right hamstring strain with spasm

Type of Muscle Energy

Crossed extensor reflex

Figure 46-17 Right Superior Pubic Shear Dysfunction: Muscle Contraction Mobilizes Articulation. (Reprinted from Nicholas & Nicholas with permission.)

Treatment Position

Patient: Supine

Physician: Standing at the side of the table on the side of acute spasm

Procedure (Fig. 46.18)

1. The patient's *right* hip is flexed to the initial resistance while keeping the knee in extension
2. If the range of motion permits, the leg may be placed atop the physician's shoulder
3. The physician's hands are placed on top of the patient's thigh to maintain the knee in extension throughout the technique
4. The patient is instructed to "very gently push your *left* knee down against the table"
5. This contraction is held for a full 3 to 5 seconds
6. Direct the patient to relax
7. Wait 2 seconds for the tissues to relax, then further flex the *right* hip until the new restrictive barrier is engaged
8. Steps 4 to 7 are repeated three to five times or until no additional motion can be gained
9. Effectiveness of the technique is assessed by retesting *right* hip range of motion in flexion with the knee extended

Example 3—Hamstring shortening resulting in reflex quadriceps weakness

Diagnosis

Reflex weakness of the right quadriceps

Type of Muscle Energy

Isokinetic strengthening

Treatment Position

Patient: Prone

Physician: Standing at the side of the table on the side of the weakened quadriceps

Figure 46-18 Treatment of hypertonic hamstring muscle.

Procedure

1. The right knee is flexed until the motion barrier for the quadriceps is reached. The physician restrains the leg just proximal to the ankle
2. The patient is instructed to “gently push your leg against my hand”
3. While the patient is pushing, slowly, allow the knee to extend through the middle of its normal range of motion. This typically takes 3 to 5 seconds
4. Instruct the patient to stop pushing
5. Steps 1 to 4 are repeated three to five times
6. Success of the technique is determined by retesting quadriceps strength

Example 4—Hamstring contracture**Diagnosis**

Hamstring contracture

Type of Muscle Energy

Isolytic lengthening

Treatment position

Patient: Supine

Physician: Standing at the side of the table on the side of the contractured hamstring

Procedure

1. The patient’s hip is flexed to the initial resistance while keeping the knee in extension
2. The patient’s leg is then placed atop the physician’s shoulder
3. One hand is placed on the thigh, just proximal to the knee; the other is placed just proximal to the ankle posterior to the Achilles tendon
4. The patient is instructed to “push your knee down toward the table as hard as you can”
5. While the patient is pushing, the physician creates an oscillatory motion with both hands. This repeatedly stretches the muscle at a rate of about four times per second (4 Hz)
6. This combined forceful contraction and vibratory stretching is continued for 3 to 5 seconds
7. The patient is instructed to relax and the oscillatory motion is stopped
8. Wait 2 seconds for the tissues to relax and then further flex the hip to the new restrictive barrier
9. Steps 4 to 8 are repeated three to five times
10. Success of the technique is determined by retesting hip range of motion in flexion with the knee extended

Example 5—Innominate dysfunction—anterior rotation**Diagnosis**

Position: Innominate rotated anteriorly

Restriction: Innominate restricted in posterior rotation

Type of Muscle Energy

Joint mobilization using muscle force

Treatment Position

Patient: Supine

Physician: Seated on the table on the side of dysfunction

Figure 46-19 Treatment for anteriorly rotated innominate.

Procedure (Fig. 46.19)

1. The patient’s leg on the side of dysfunction is flexed at the hip and the knee, and the foot is placed on the physician’s shoulder
2. The physician’s hands are placed against the hamstring muscles just proximal to the popliteal region
3. The patient is instructed to “push your thigh against my hands”
4. This contraction is held for a full 3 to 5 seconds
5. Direct the patient to relax, simultaneously ceasing your counterforce
6. Wait 2 seconds for the tissues to relax, and then reposition the innominate into further posterior rotation by further flexing the hip until the new restrictive barrier is engaged
7. Steps 3 to 6 are repeated three to five times or until a sudden release of the innominate dysfunction is palpated
8. Effectiveness of the technique is assessed by rechecking ili-osacral motion

739.6 Lower Extremity Somatic Dysfunction**Knee—Proximal Fibula Posterior (Fig. 46.20)**

Figure 46-20 Treatment of proximal fibula posterior.

Diagnosis

Position: The proximal fibula is posterior.

Restriction: The proximal fibula is restricted in anterior glide.

Type of Muscle Energy

Joint mobilization using muscle force

Treatment Position

Patient: Supine with hip flexed 45 degrees and knee flexed 90 degrees

Physician: Standing at the foot of the table facing the patient

Procedure (Fig. 46.20)

1. The physician's medial hand is placed on the dorsum of the foot with his or her thumb on the lateral aspect and the fingers on the medial aspect
2. The physician's lateral hand anchors the calcaneus
3. The ankle is inverted to the initial resistance
4. The patient is instructed to "push your foot sideways into my thumbs and up into my hand." This eversion/dorsiflexion of the ankle is thought to contract the extensor digitorum longus and the tibialis anterior muscles, drawing the fibula forward
5. This contraction is held for a full 3 to 5 seconds
6. Direct the patient to relax, simultaneously ceasing your counterforce
7. Wait 2 seconds for the tissues to relax, and then further invert the foot until a new restrictive barrier is met
8. Steps 4 to 7 are repeated three to five times or until no additional motion can be gained
9. Effectiveness of the technique is determined by retesting motion at the proximal tibiofibular articulation

739.7 Upper Extremity Somatic Dysfunction

Diagnosis

Hypertonicity of the rhomboid causing medial scapular displacement

Position: Scapula medially displaced

Restriction: Scapula resists lateral displacement

Type of Muscle Energy

Postisometric relaxation

Treatment Position

Patient: Seated on the side of the table

Physician: Standing behind the patient and to the left

Procedure (Fig. 46.21)

1. The physician reaches in front of the patient with the left hand and grasps the patient's right forearm
2. The patient's right arm is drawn across the front of the body from right to left, and downward in a direction paralleling the direction of the fibers of the rhomboid major and minor
3. The physician's right hand is placed to the left of the spine to provide a counterforce to truncal rotation
4. The patient is instructed to "pull your right elbow toward the right," while the physician provides an unyielding counterforce
5. This contraction is maintained for 3 to 5 seconds
6. The patient is instructed to relax

Figure 46-21 Treatment of hypertonic rhomboid, from behind and from the front.

7. After a second or two of relaxation, the physician puts increased tension on the rhomboid musculature by drawing the right arm further across the front of the body until the new restrictive barrier is engaged
8. Steps 4 to 6 are repeated three to five times
9. Success of the technique is determined by repalpating the rhomboid musculature and retesting scapular motion

739.8 Costal Somatic Dysfunction

In general, costal somatic dysfunction is divided into two groups: ribs held in inhalation (inhalation ribs) and ribs held in exhalation

(exhalation ribs). While many rib dysfunctions occur singly, occasionally you will see three or more ribs in a group, all having the same motion restriction. When a group of ribs is held in inhalation, the lowest rib is the key rib to treat. For example, let's say ribs 6, 7, and 8 are held in inhalation. When you treat rib 8, it will in turn draw rib 7 down with it and 7 will draw 6 along as well. Similarly, when a group of ribs is held in exhalation, the upper most rib is the key rib to treat.

Rib dysfunction—ribs 7 to 10 held in inhalation

Diagnosis

Position: Inhalation rib; a rib moves fully in inhalation; a rib is held in inhalation.

Restriction: Restriction of exhalation; rib stops early in exhalation; extent and duration of exhalation movement are decreased.

Type of Muscle Energy

Respiratory assistance

Treatment Position

Patient: Supine.

Physician: Standing at the side of the table

Procedure (Fig. 46.22)

1. The patient's upper body is side-bent to the side of dysfunction until tension is taken off the dysfunctional rib
2. The web formed by the physician's thumb and index finger is placed in the lateral aspect of the intercostal space above the dysfunctional rib on its superior surface
3. The patient is instructed to inhale and exhale deeply
4. On exhalation, the physician exaggerates the bucket handle motion of the rib being treated
5. On inhalation, the physician resists motion of the rib
6. Steps 4 and 5 are repeated three to seven times until maximal motion of the rib has been achieved
7. Success of the technique is determined by retesting motion of the dysfunctional rib

Rib dysfunction—ribs 1 and 2 held in exhalation

Figure 46-22 Treatment for ribs 7 to 10, held in inhalation.

Diagnosis

Position: Exhalation rib; the rib moves fully in exhalation; the rib is held in exhalation.

Restriction: Restriction of inhalation; rib stops early in inhalation; extent and duration of inhalation motion are decreased.

Type of Muscle Energy

Joint mobilization using muscle force and reciprocal inhibition

Treatment Position

Patient: Supine

Physician: Standing at the side of the patient opposite the side of the dysfunctional rib

Procedure (Fig. 46.23)

1. The patient's head is turned about 30 degrees away from the side of the dysfunctional rib
2. The patient's arm on the side of the dysfunction is placed with the dorsum of the wrist against the forehead
3. The physician's caudad hand reaches under the patient and grasps the angle of the dysfunctional rib exerting continuous traction in a caudad and lateral direction
4. The patient is instructed to "lift your head straight up toward the ceiling." This is done without altering the 30 degree rotation of the head
5. This contraction is held for a full 3 to 5 seconds
6. Direct the patient to relax, simultaneously ceasing your counterforce
7. Wait 2 seconds for the tissues to relax, and then exert increasing caudad and lateral traction with your caudad hand beneath the rib
8. Steps 4 to 7 are repeated three to five times
9. Success of the technique is determined by retesting motion of the dysfunctional rib

739.9 Other Somatic Dysfunction

Redoming the diaphragm

Figure 46-23 Treatment for ribs 1 and 2, held in exhalation.

Diagnosis

Position: Diaphragm held in Inhalation

Restriction: Diaphragm restricted in Exhalation

Type of Muscle Energy

Respiratory assistance.

Contraindications

Recent ingestion of a large meal

Hiatus hernia, gastroesophageal reflux disease (relative)

Friability of the liver or spleen (cirrhosis, mononucleosis, leukemia, lymphoma)

Treatment Position

Patient: Supine with hips and knees flexed, feet flat on the table

Physician: Standing at the side of the table facing the head of the table

Procedure (Fig. 46.24)

1. The physician places the thumbs and thenar eminences 2 to 3 in below the costal margin with thumbs pointing toward the Xiphoid process
2. The patient is instructed to “take a deep breath and then breathe all the way out”
3. The physician’s thenar eminences follow the diaphragm in its exhalation motion, exaggerating it by placing a cephalad pressure on the upper abdominal viscera
4. The patient is again instructed to inhale as the physician maintains this pressure on the diaphragm

Figure 46-24 Redoming the diaphragm.

5. As the patient again exhales, further cephalad excursion of the diaphragm is encouraged
6. This procedure is repeated for three to five respiratory cycles
7. Success of the technique is determined by retesting excursion of the diaphragm

SUMMARY

Although muscle energy techniques may be used as standalone techniques for the treatment of somatic dysfunction, they are often combined with other techniques. They can be useful in creating the soft tissue relaxation necessary to accomplish HVLA Thrust techniques. Many muscle energy and HVLA techniques are done in the same position, so no repositioning of the patient is required when moving from one technique to the other.

Used another way, muscle energy techniques are used to lengthen muscles shortened by both hypertonicity and contracture. Once the hypertonicity has been eliminated using the muscle energy technique, the patient is in perfect position to begin applying direct myofascial release techniques to the passive connective tissue elements of that same muscle.

Muscle energy techniques are used to balance muscle tone, strengthen reflexly weakened musculature, improve symmetry of articular motion, and enhance the circulation of body fluids (blood, lymph, and interstitial fluid).

Although these are some of the more common uses, the versatility of muscle energy techniques allows them to be combined with any of the other osteopathic manipulative techniques in total patient management.

Myofascial Release Approach

JUDITH A. O'CONNELL

KEY CONCEPTS

- This approach emphasizes appreciation and recruitment of the innate and inherent motion of the myofascial structures.
- Patterns of motion and ease are identified across proximal and distal structures, diaphragms, compartments, viscera, and organ systems.
- Techniques of this type are myofascial release (MFR), integrated neuromusculoskeletal release, fascial-ligamentous release, and bioelectric fascial activation and release.
- Respiratory assistance, fulcrums, body position, neuroreflexive activities, oscillation, passive progressive motion, and muscular contractions may aid in the progression of MFR.

CASE STUDY

JM is a 49-year-old Caucasian male who has been suffering with right sciatica for 3 months after beginning a cardiac fitness program. He describes the pain as an ache from his right buttock to posterior thigh, but not below the knee. He notices it with walking and standing and it decreases with rest or sitting. He denies any numbness or tingling in his legs, or any weakness with activities. He has noticed that he is wearing out the sole on his left shoe and has had to replace them more frequently. He denies any recent trauma. Ibuprofen helps the pain temporarily.

The rest of his review of systems is noncontributory. Past medical history is negative for neuromusculoskeletal issues other than the present chief complaint and is positive for elevated blood pressure. Family history is positive for hypertension both maternal and paternal. Medications are occasional ibuprofen for sciatica.

Physical Exam

BP: 130/72; Pulse: 70 regular; Resp: 12 and regular and in moderate distress.

Gait:

Antalgic with limp right and pain in right sacroiliac (SI) joint with full weight bearing on right leg and reproduction of sciatica right

Postural exam:

Posterior view: right iliac crest low, right PSIS low with lateral curve changes convex right lumbar and left thoracic with downward tilt of right shoulder. Greater trochanter is low right with externally rotated right hip. Pain in right SI joint with change in position seated to standing.

Palpatory exam:

Pain on palpation of the right piriformis with reproduction of chief complaint of sciatica. Tenderness and tightness of left quadratus lumborum and right thoracolumbar fascia with torsion to the left of the torso on the pelvis and contralateral pattern through the rectus abdominus fascia.

Inhibited right hamstrings with tight right quadriceps femoris and right piriformis.

Neurologic exam:

No signs of peripheral or central compromise and is otherwise normal.

Vascular exam:

Normal

Diagnosis:

- Postural imbalance with short right leg
- Sciatica
- Somatic dysfunction of thoracic, lumbar, sacrum, pelvis, and lower extremity

Treatment:

- Myofascial release (MFR) to the thoracic, lumbar, sacrum, pelvis, and lower extremity
- Postural x-rays
- Consider heel lift after review of x-rays
- Home exercise program

DESCRIPTION OF TECHNIQUES

MFR is a system of diagnosis and treatment first described by Andrew Taylor Still and his early students, which engages continual palpatory feedback to achieve release of myofascial tissues (1). It can be applied as a *direct or indirect technique*. In a direct technique, a restrictive barrier is identified in the myofascial tissues and is engaged with a loaded, constant, directional force until the tissue releases and motion is restored. In an indirect technique, the tissues position of ease is identified and is engaged with directed pressure guiding the tissues along this line of least resistance until free movement of all tissues is achieved. A *combined procedure* (2), whereby the practitioner's hands engage both a barrier and point of ease simultaneously, allows the MFR to occur through the application of both direct and indirect methods interactively.

Activating forces used in MFR techniques are as follows (3–5):

1. *Inherent (intrinsic) force*: using the body's natural tendency to seek homeostasis, inherent force is the rhythmic activity in all tissues that works to improve the hydrodynamics and bioenergetic factors around restricted tissues and articulations
2. *Respiratory force (cooperation/assist)* may be used in four ways:
 - (a) While using a direct or indirect position, *full cycle respiratory effort* is used as a fascial and/or articulatory activating force
 - (b) Once positioned, a *particular phase of respiration* enhances the position of the area being treated
 - (c) *Breath holding* for the maximum time that a patient can tolerate causes air hunger and triggers a generalized relaxation of soft tissues
 - (d) *Coughing or sniffing on command* produces a respiratory impulse to assist in the release of restrictions
3. *Patient cooperation*: the patient is requested to move in specific directions in various planes of an articulation to aid in mobilizing an area of restriction
4. *Physician-guided force*: after engaging a barrier or point of ease, the physician sequentially guides the tissue or joint through various positions following a shifting pattern of easy motion until the path of dysfunction is retraced and released
5. *Springing/vibration*: placing the hands or percussion hammer on a dysfunction and applying variable degrees of pressure and/or frequency of force causing springing or vibration in the structure activating releases of the tissues

TYPES OF MFR

Fascia is ubiquitous connective tissue, enrobing the body in a *big bandage* (6) contributing to form and function that is accessed by manipulative techniques to alleviate somatic dysfunction. Muscular relationships to the fascia contribute to the shifting tightness and looseness identified through range of motion changes and palpation as direct and indirect barriers. Appreciation and recruitment of the *innate and inherent motion* of the myofascial structures allow for the identification and treatment of patterns of motion and ease across proximal and distal structures, diaphragms, compartments, viscera, and organ systems. The *bioresponsive electrical potentials of the fascia* (7) produce palpable changes in fascial motion and ease related to the status of the internal environment of homeostasis and the biomechanical response to the external environment aiding in the diagnosis and treatment of visceral as well as musculoskeletal disorders and diseases. Respiratory assistance, fulcrums, body position, neuroreflexive activities, oscillation, passive progressive motion, and muscular contractions may aid in the progression of MFR (8–10). Techniques of this type are *MFR, integrated neuromusculoskeletal release (INR), fascial-ligamentous release, and bioelectric fascial activation and release*. Related techniques (facilitated positional release, functional release, counterstrain, balanced ligamentous tension, progressive inhibition of neuromuscular structures, soft tissue, articulatory, Still method, osteopathy in the cranial field and visceral) are discussed in other chapters in this text. Other related techniques in present use are facilitated oscillatory release, Fulford percussion vibrator, and balanced membranous tension.

Soft tissue techniques are related techniques that are *not* in the family of MFR techniques discussed in this chapter. They treat the soft tissues of the body with inhibitory pressure, stretching and kneading, petrissage and skin rolling, deep friction, tapotement, and effleurage.

HISTORY

As this philosophy (osteopathy) has chosen the fascia as a foundation of which to stand, we hope the reader will chain his patience for a few minutes on the subject of the fascia, and its relation to vitality. It stands before the philosopher as one of, if not the deepest living problem ever brought before the mind of man (11).

Dr. Still spent a great deal of time writing and pondering on the importance of fascia in health and disease as he developed the science of osteopathy. Dr. Still did not write detailed instructions on how to perform a treatment; instead in *Research and Practice*, he provided a rationale for applying osteopathic principles and integrating osteopathic manipulative treatments into the medical management of diseases. Even though Dr. Still did not leave a technique manual and we only have a short video of him performing a treatment, his emphasis on the fascia affected the development of early osteopathic methods, which are the foundation for this class of technique today. He directed his students and colleagues to hunt in the fascia as "*The ground in which all causes of death do the destruction of Life*" (12), and many did.

Pioneers in early osteopathic thought and education (13,14) continued to develop methods of diagnosing and treating the fascia by applying the principles of osteopathy: the body is a unit with the innate ability to heal where structure and function are reciprocally interrelated. Such osteopathic luminaries as Sutherland, Kaufman, Snyder, Cathie, Cole, Smoot, Zink, Becker (Alan and Rollin), and Fulford all expanded our understanding of fascia and laid the foundation for a renaissance of technique development beyond a joint centric model of manipulation.

In the 1980s, Peckham, Chila, and Ward began to discuss how to describe in a more significant way what was developing as MFR (15). Two models emerged from these discussions, the *biomechanical model* of Ward and the *big bandage of fascial continuum model* of Chila. The *biomechanical model* emphasizes the muscular-fascial relationship and developed the techniques known as MFR and integrated INR that emphasizes mechanics, anatomic relationships, tight and loose relationships, tethering and interdependent neural influences as the base for diagnosis and treatment. The *fascial continuum model of the big bandage* emphasizes the fascia and developed into fascial release and fascial-ligamentous release techniques that use the integrity of the fascial continuum to treat proximal to distal, a fulcrum with leverage, torsion and traction, respiratory assistance, and reflexive neurologic reset. Both Ward and Chila began teaching their respective models influencing the next generation of osteopathic techniques.

Within this resurgence of interest in the myofascia, Sutherland's teachings on the treatment of the membranes and ligaments and Fulford's percussion vibrator techniques were being taught and incorporated into osteopathic education. Harakal and Becker taught the importance of enlisting the aid of the *physician within* a patient in all osteopathic treatments (16). Fulford challenged the osteopathic physician to treat a patient's life force with proper intention and attention to achieve positive results (17). An increased interest in innate motions of connective tissues, vibratory changes across tissues, the bioenergy discussions of Sutherland, Becker and Fulford, and the fluid properties of palpation and treatment emerged. A renaissance of osteopathic thought and technique was fueled by this focus shift from joint-based models to the evolving connective tissue models.

In the 1990s, influenced by osteopathic teachings of Still, Kappler, Larson, Chila, Ward, Harakal, Alan and Rollin Becker, Sutherland and Fulford, O'Connell explored bioenergetic research

TABLE 47.1

Models of MFR Techniques

Models of MFR	Techniques	Tissue Focus	Emphasizes
Biomechanical model	MFR, integrated INR	Muscular–fascial relationships	Mechanics, anatomic relationships, tight/loose concepts, tethering and interdependent neural relationships
Fascial continuum of the big bandage model	Fascial-ligamentous release, fascial release	Fascia	Fascial continuum, treat proximal to distal, fulcrum with leverage, torsion and traction, respiratory assistance and reflexive neurologic reset
Bioenergetic model	Bioelectric fascial activation and release, fascial release, MFR	Fascia, holographic interface in homeostasis	Bioresponsive electrical potentials, diaphragms, longitudinal cables and tubes, fascial interface in homeostasis, holographic diagnosing and treating

as it applies to diagnosing and treating in the fascia. What emerged was the *bioenergetic model* that emphasizes the bioresponsive electric potentials of the fascia, primary and compensatory patterns of dysfunction, the fascial continuity of diaphragms with longitudinal cables and tubes, the fascial interface of internal (ECF) and external (biomechanical) environmental factors on homeostasis, a treatment process of intention, attention, and activation of the bioenergetic fascia with holographic palpation, diagnosis and treatment. This approach allows the totality of the human being to be accessed through a single hand placement, or portal of entry (18). These models are summarized in Table 47.1.

MECHANISM OF ACTION

Embryologic development of the mesodermal germ layer gives rise to connective tissues and muscles. The largest mesodermal derivative is connective tissue encompassing blood, cartilage, bone, and connective tissue proper. Histologically, these tissues are distinguished by the proportions of fiber, cells, and extracellular matrix into six types: areolar, white fibrous, yellow elastic, mucous, retiform, and basement membrane. The principal cell types are fibroblasts, fat cells, fixed macrophages, mast cells, plasma cells, and leukocytes. The extracellular matrix contains collagenous, elastic and reticular fibers, mucopolysaccharides, proteoglycans, and molecules of

collagen, elastin, mucin, reticulin, chondroitin sulfate, keratin sulfate, heparin, chondroitin acid, and hyaluronic acid (19). Collagen is a major component of connective tissue proper and more specifically white fibrous tissue. Fascia, the largest component of white fibrous tissue, contains linear sheets of collagen found in superficial, deep, and subserous layers (Fig. 47.1).

A special property of connective tissue cells is *embryologic plasticity* (20). This property allows differentiated connective tissue cells, when properly stimulated, to dedifferentiate to a polypotential root cell and redifferentiate into another type of connective tissue cell. Histologically, some traumatized tendon or muscle tissues demonstrate islands of cartilage or bone exemplifying this process. Experiments by Becker et al. (21) document that disruption in the collagen of the periosteum creates a bioelectric current that affects the *charge* of the cell membrane of fibroblasts, which triggers their *embryologic plasticity* as part of the healing process in fractures. This cell membrane charge signals changes in the DNA and RNA resulting in cell dedifferentiation into a primitive polypotential root cell. These cells then redifferentiate into the cells needed during the healing process. These expressions of the connective tissues embryologic plasticity illustrate that in the face of traumatic biomechanical stress, connective tissue responds by changing its cell type to meet the demand on the tissue mediated by bioelectric changes at the tissue, cell, and nuclear levels.

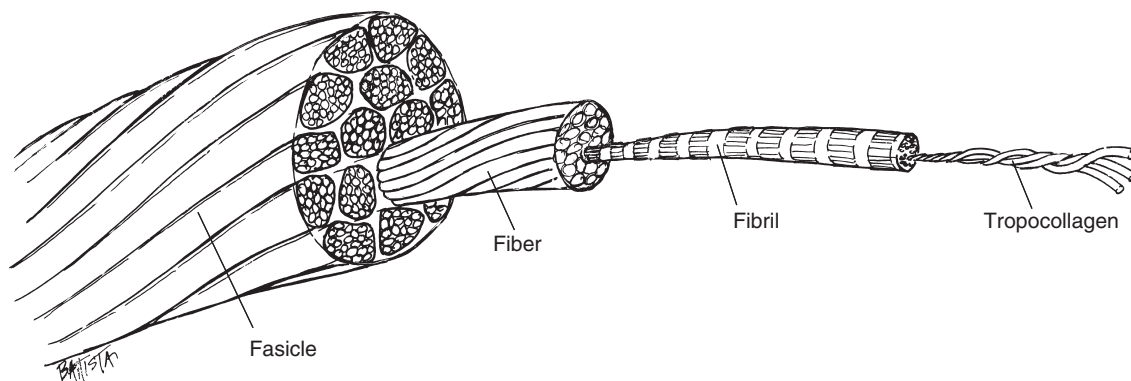

Figure 47-1 Mobility of collagen is demonstrated in its structure.

The extracellular matrix of connective tissue contributes to homeostasis through diffusion, absorption, secretion, diffusion gradients, modification of absorbed substances, metabolism and catabolism, and the excretion of metabolic end products and waste (22). All cells contribute to this extracellular fluid (ECF) interfacing with nerve endings, hormones, vascular and lymphatic structures. This organization allows for coordination of the internal (metabolic, cellular, and organ systems) components of homeostasis within the structure of connective tissues.

The muscles are divided into smooth, cardiac, and skeletal types. They are related embryologically to connective tissue, the vascular system, cranial nerves (CN), and the autonomic and peripheral nervous systems through *migratory segmental differentiation* (Fig. 47.2). Skeletal muscle fibers develop from the mesodermal myotomes and regional mesenchyme and migrate in a sea of connective tissue in response to lines of stress in the developing embryo. Skeletal muscle myofibrils extend along these lines of stress in a linear fashion and become bundled as fascicles by the perimysium. Between the fascicles, the endomysium contains the nerves, blood and lymph vessels, and acts as lubricant and cushion. Fascicles are bundled by the epimysium and the tendons develop connecting the muscles to the developing skeleton. This creates a compact integration of multiple systems residing within a connective tissue container (Fig. 47.3).

Earlier authors like Cathie (23) and Becker (24) suggested that fasciae move independently. A 1987 soft tissue dissection done by Frank George, D.O., in the anatomy laboratories of Michigan State University demonstrates that fascia and muscle are anatomically inseparable and suggests that complex muscle activities act on bones, ligaments, tendons, associated with joints as well as the fasciae.

Fascia is associated with all organs, tissues, cells, and structures. The superficial and deep layers are found everywhere in the body as complete ensheathments. The subserous layer lies innermost on the deep layer anywhere there is a body cavity. The deep layer of fascia is the most complicated of the three, being two layered with intervening septa.

Clinically, it is possible to conceptualize such wrapping as being a *big bandage* of the body. Such an analogy is implied in osteopathic literature. One can find reference to the idea that the body retains form even if everything except the connective tissue framework is removed. If this is so, then it is also reasonable that form permits the consideration of motion. The continuity of this arrangement and considerations of structural–functional interrelationships make it possible to discuss biomechanical attributes of fascia in relation to manipulative treatment. Fascia supports and stabilizes, helping to maintain balance. It assists in the production and control of motion and the interrelation of motion of related parts in concert with muscles. Many of the body's fascial specializations have postural functions in which stress bands can be demonstrated. Finally, the dura mater is a special connective tissue surrounding the central nervous system. Bony anchors for this tissue exist in the skull and at the sacrum. Stiles began teaching an application of Buckminster Fullers tensegrity systems to human anatomy, which has further contributed to the growing understanding of the connective tissue continuum.

Collagen, fibrin, and reticulin of connective tissue act as the body's reactor to motion and stress and coupled with the skeletal muscle interact to produce *irritability, contractility, relaxation, distensibility, and elasticity* (Table 47.2) (25). *Irritability* is the ability of the muscle fiber to react to stimulation. *Contractility* is the ability to actively create tension between its origin and insertion, and the opposing passive state is *relaxation*. *Distensibility* is the ability of

the associated connective tissue to be stretched or deformed by an outside force, and if the force does not exceed the tensile strength of the connective tissue, the muscle will not be injured. *Elasticity* is the ability of the connective tissue to return to its original resting shape when forces are removed (26).

Other force effects in connective tissue of importance are *plastic deformation, elastic deformation, viscosity, stress, strain, and creep* (Table 47.3). In plastic deformation, a stressed, formed, or molded tissue *preserves* its new shape; and in elastic deformation, a stressed, formed, or molded tissue *recovers* its original shape. Viscosity is the capability of a solid to continually yield under stress with a measurable rate of deformation. *Stress* is the effect of a force normalized over an area. *Strain* is a change in shape as a result of stress. *Creep* is the continued deformation of a viscoelastic material under constant load over time (Fig. 47.4). *Hysteresis*, or *stress-strain*, is defined as a connective tissue response to loading and unloading in which the restoration of the final length of the tissue occurs at a rate and to an extent less than during deformation (loading) representing energy loss in the connective tissue (Fig. 47.5) (27). Generally speaking, the body's connective tissues are under some degree of load and extension (expansion). The increase and subsequent reversal of extension produces a degree of tissue response less than the relatively unloaded state. This phenomenon is referred to as *hysteresis*. It implies the occurrence of some flow and dissipation of energy throughout the loaded tissue. Hysteresis occurs less with successive cycles of extension, indicating stabilization of response (28).

It is now clear that the physical properties of fascia and muscles explain how physical laws of adaptability apply to MFR techniques. *Hooke law* (29) states that stress applied to stretch or compress a body is proportional to the strain, or change in length thus produced, so long as the limit of elasticity of the body is not exceeded. Palpatory diagnosing and treating is the systematic application of directed mechanical pressures and motions while monitoring the tissue response. Perceived alterations in motions, symmetry, tissue texture, and tenderness define somatic dysfunction (30). The response in intact fascia to mechanical stress is predictable, detectable, and when dysfunctional, it is treatable with MFR techniques. These physical properties coupled with Hooke law are the foundation for the characteristic palpatory findings of barriers and ease, tight and loose, and strain patterns.

Wolff law of bone transformation (31) states: every change in the function of a bone is followed by certain definite changes in internal architecture and external conformation in accordance with mathematical laws. Function dictates structure. Every change in the form and the function of a bone is followed by certain changes in its internal architecture and secondary alterations in its external conformation. Structure dictates function. Multiple studies examined the application of this law. In the 1950s, Yasuda and Fukada and Bassett and Becker demonstrated that bone is *piezoelectric*. Piezoelectricity is a current produced by a substance that transforms mechanical stress to electrical energy. Piezoelectric substances act as transducers and are able to discharge electrical current when physically stressed, and when placed in an electric current, they vibrate at a frequency dependent upon their crystal lattice structure. Further studies identified *collagen* as the piezoelectric substance in bone (32). *Fascia is a collagen-rich connective tissue*. The piezoelectric properties of collagen are outlined in Table 47.4.

Piezoelectricity is important in the maintenance of bone as well as responses to stress. Studies investigating Wolff law noted that a bioelectric gradient is formed in bone in response to stress. The electronegative charge in the compressed bone stimulates

Figure 47-2 A-C. The transformation of paraxial mesoderm into its derivatives.

osteoblasts, and the electropositive bone stimulates osteoclasts directing the remodeling of the bone. This was further clarified when Becker and Bachman (33) discovered that when mechanically stressed, collagen in bone produces a biphasic signal, negative

with stress (load), and positive with release (unload). This stress-release signal is rectified to a direct current at the junction between the apatite and collagen in the bone. *The strength of this signal indicates the amount of stress and the polarity changes identify the*

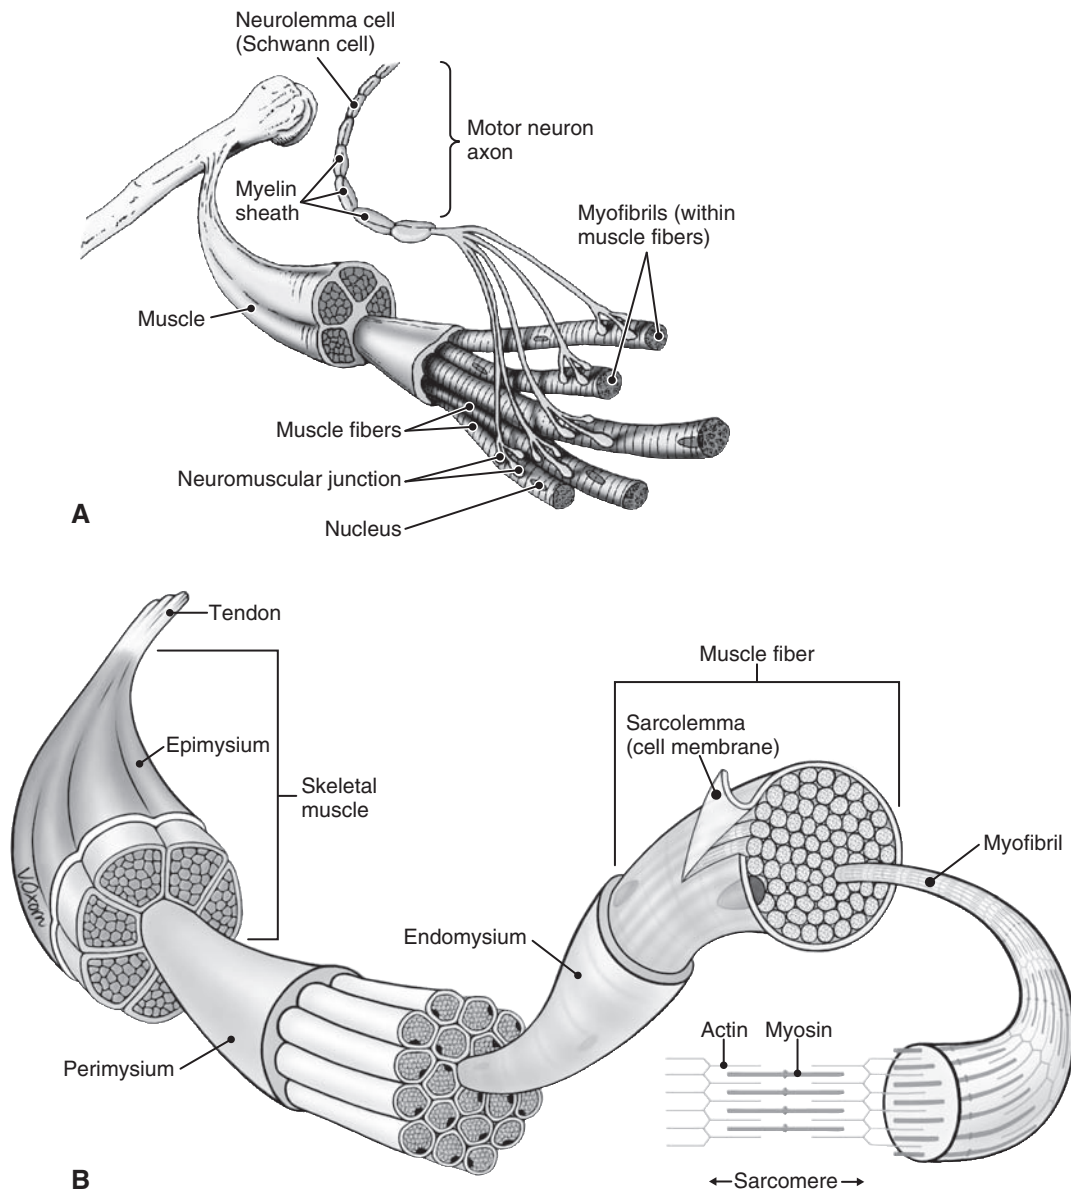

Figure 47-3 A, B: Muscle fiber structure.

TABLE 47.2

Physical Properties of Muscle

Properties	Description
Irritability	Ability of the muscle fiber to react to stimulation
Contractility	Ability to actively create tension between its origin and insertion
Relaxation	Ability to reduce tension between its origin and insertion
Distensibility	Ability of the associated connective tissue to be stretched or deformed by an outside force, and if the force does not exceed the tensile strength of the connective tissue, the muscle will not be injured.
Elasticity	Ability of the connective tissue to return to its original resting shape when forces are removed

TABLE 47.3

Force Effects in Connective Tissue

Force Effects	Description
Plastic deformation	A stressed, formed, or molded tissue <i>preserves</i> its new shape
Elastic deformation	A stressed, formed, or molded tissue <i>recovers</i> its original shape
Viscosity	Capability of a solid to continually yield under stress with a measurable rate of deformation
Stress	The effect of a force normalized over an area
Strain	A change in shape as a result of stress
Creep	The continued deformation of a viscoelastic material under constant load over time
Hysteresis or stress-strain	A connective tissue response to loading and unloading where the restoration of the final length of the tissue occurs at a rate and to an extent less than during deformation (loading) representing energy loss in the connective tissue

direction of the stress. This signal triggers osteocyte activity, allowing the bone to remodel to adapt to the mechanical stress.

The electronegative signal also caused the linear alignment of collagen perpendicular to the lines of compressive mechanical stress (Figs. 47.6 and 47.7). This alignment of the collagen becomes the base for ossification. Also, stress-induced piezoelectric potentials are short in duration while the healing current of bone growth is sustained in duration. This healing current stimulates electrically sensitive connective tissue cells that are embryologically plastic and allow the bone to respond to growth or stress appropriately.

The cells of connective tissue are mobile, allowing migration of cells to meet the needs of the organism. This ameboid motion is exemplified by the fibroblasts, macrophages, and white blood cells and is triggered by positive or negative chemotaxis or in response to a bioelectric potential gradient directing the cells into and out of the area of need. This movement allows tissues to respond to changes in their environment, both internal and external, by releasing chemotactic factors, creating a gradient and activating the movement of connective tissue cells facilitating the clearing of debris and the repair of injured tissues.

Disruption and distortion of the fascia triggers a repair process directed at correction of damage and strengthening of tissue mediated by the release of chemotactic factors activating the congregation and proliferation of fibroblasts. The fibroblasts coat the injured area and collagen is then deposited in a linear fashion along lines of mechanical tension in the tissue (34). Mechanical tension creates bioelectric current changes that guide the orientation of the

fibrin and collagen. If neurologic integrity is compromised or the tissue is immobilized, dense connective tissue is formed. Edema and disruptions in circulation and lymphatic drainage also cause fibrin and collagen to be deposited in a thick and haphazard scar. These thickened areas impede normal function of the linear sheets of fascia causing stiffness, changes in range of motion, pain, and further edema (35). Chronic alterations in fascial integrity impede the normal function of the ECF with consequences to the health of the whole organism. In Dr. Still's words: "I know no part of the body that equals the fascia as a hunting ground ... By its actions we live and by its failure we die" (36).

Other research highlights the importance of fascia in maintaining general proprioception. Since proprioception is ultimately controlled by interdependent neural and muscular elements, after joint and muscle spindle activity is accounted for, 75% of remaining proprioception occurs in fascial sheaths (37). Such responses were actually demonstrated in the 1960s by Earl (38) and Wilson (39) in their work with muscles under stretch.

Patients challenged with chronic pain may seek a position where the pain lessens or is relieved. This infers that positional relief of pain allows a decrease in some critical level of facilitation in the nervous system. Fascial release techniques are designed to reduce afferent input to the cord directly or through central brain influences. Muscle proprioceptors and the gamma motor system are affected with reduction of excitation of the muscle spindle, and the resumption of normal length and motion (40). Further rationales for the mechanism of releases of dysfunction with OMT are found in the works of Korr (41), Becker (42), and Patterson (43).

Collagen is the source of stress-related electrical potentials through its piezoelectric nature as a transducer. Collagen communicates the presence, location, direction, and strength of mechanical stress by producing a biphasic electric current. This bioelectric current affects the charge-sensitive cells that move and change in response. Studies demonstrate how collagen is the ultimate communicator between biomechanical events, bioelectric changes, cellular function, and the ECF. MFR techniques harness the power of collagen through diagnosing and treating in the fascia, the largest collagen pool in the body.

FASCIA AND HOMEOSTASIS

Homeostasis is both a state of equilibrium and the process by which this balance is maintained. It is a dynamic, ever-adapting,

Figure 47-4 Deformation under load.

Figure 47-5 The stress-strain response.

and changing series of events responding to internal and external environmental changes (Table 47.5). *The challenge of homeostasis is to recognize all events, external and internal, communicate needs for adaptation throughout the organism, and direct responses both internal and external.* Nothing is isolated (44).

As previously discussed, fascia responds to biomechanical stress, through its collagen fibers, by producing microelectrical potential

changes. These changes communicate the biomechanical events through electrical changes in the ECF to cellular, neural, vascular, and lymphatic components. These stress-generated potentials are predictable and precise whether traumatic or intentional.

Palpation introduces compressive and distraction forces into fascial tissue, which responds in predictable patterns of motion produced by adaptations to the mechanical stress. Alterations in

TABLE 47.4

Piezoelectric Properties of Collagen

Properties	Description
Transducer	Able to discharge electrical current when physically stressed and when placed in an electric current, vibrate at a frequency dependent upon its crystal lattice structure
Biphasic signal	Negative with stress (load) and positive with release (unload)
Stress related signal	Strength of this signal indicates the amount of stress and the polarity changes identify the direction of the stress
Stimulates osteocytes	Electronegative charge in the compressed bone stimulates osteoblasts, and the electropositive bone stimulates osteoclasts directing the remodeling of the bone
Stimulates and directs the migration of electrically sensitive cells	By releasing chemotactic factors, creating a gradient and activating the movement of necessary connective tissue cells facilitating the clearing of debris and the repair of injured tissues
Activates cells	Stimulates electrically sensitive connective tissue cells which are embryologically plastic

Figure 47-6 Collagen fibers in the unloaded state demonstrating a multidirectional arrangement.

normal patterns and ranges of motion are diagnostic parameters. Abnormal patterns of motion are recognized as restrictions to motion and ease of motion. The asymmetric motion and position of components of the musculoskeletal system are also readily identified through palpation. Responses in the ECF and surrounding structures to adaptations to stress-generated electrical potentials produce acute and chronic tissue textures and areas of stiffness, looseness, tenderness, asymmetry, edema, and pain.

In systemic disease alterations in ECF, electrical potentials result in changes in the biomechanical integrity of the fascia. Areas of acute and chronic congestion, swelling, laxity, stiffness, and pain are produced. Palpatory findings are utilized by the skilled physician to identify the disease produced somatic dysfunction. Integrating an understanding of the patterns of viscerosomatic and somatovisceral relationships adds a deeper diagnostic and therapeutic dimension to the palpatory exam (45).

Homeostasis involves a complex series of events and interfaces between all systems and the internal and external environment. Neuroreflexive coordination is essential in this endeavor. Autonomic, especially sympathetic tone, affects not only pain perceptions but also the balance of neurovascular exchange affecting edema and effusions. This in turn affects motion and tissue function. Proprioception integrated with the special senses of

Figure 47-7 Collagen fibers in the loaded state demonstrating a linear rearrangement.

TABLE 47.5

Components of Homeostasis

Components	Description
Internal environment is the ECF	Complex activities coordinating hormones, nerve impulses, gases, nutrients, ions, and electrical potentials by diffusion, gradients, absorption, secretion, modification of substances, excretion, metabolism and catabolism
External environment is the aggregate of complex events outside of our body that affect us	Adaptation to external stressors and accommodates active manipulation of the environment with posture, movement, coordination, strength, balance, and awareness coordinating cognitive, neural, muscular, skeletal and vascular structures.
Confluence of all organs and systems	Dynamic, ever-adapting, and changing series of events responding to internal and external environmental changes

sight, hearing, and touch is essential to balance, posture, and gait. Evaluating the patient in multiple positions (standing, seated, prone, supine) and activities (walking, standing, squatting, changing positions, bending, work positions) adds another dimension to fascial diagnosis and treatment. Dysfunctions in these areas are important contributors to chronic recurring somatic and visceral dysfunctions. Identification of such patterns and their neuromyofascial components allows the clinician the opportunity to affect and extinguish self-perpetuating cycles. Once this is accomplished, repatterning the neuromyofascia into a more physiologic response is appropriate.

McEwen at the Rockefeller Institute has postulated that the shift from homeostasis to the disease state is related to the systems response to stress, whether traumatic, psychological, emotional, physiologic, or environmental. The body under stress of any source enters a state of allostasis, where epinephrine and cortisol are released. If this state becomes long term, an allostatic load ensues with physiologic consequences such as elevated blood pressure and heart rate with increase risk of cardiovascular disease. Cortisol levels can suppress the immune system, affect organ function, alter metabolism, and contribute to depression. The allostatic load may become somatized and be expressed as somatic dysfunction with *body language significance* (46), which may help in identifying the nonsomatic cause of chronic, recurrent dysfunction in light of appropriate treatment. Examples of this are when the body seems to act out its underlying stress condition. A patient with chronic emotional stress may have low back pain; mental and emotional feelings of “shouldering” a heavy burden may cause shoulder pain; refusing to change behaviors leads to a stiff neck. Understanding homeostasis now is expanded to include the interface and interaction

between the physical, emotional, mental, and spiritual bodies. Insights into these connections can be found in many sources outside the medical literature. One very helpful little book in understanding and interpreting connections between thought patterns and disease is *Heal Yourself* by Louise Hay who has been working with patients with cancer, AIDS, and other life-altering diseases.

Disease occurs when one or more system(s) fail to maintain their part in homeostasis. It begins as a clinically undetectable change in ECF and progresses until clinically detectable signs and symptoms appear making the diagnosis apparent (47). The goal of the clinician is to detect the disease and institute appropriate treatment as early as possible. This will limit the amount of damage to the systems and organs as well as enhancing the bodies healing capabilities. Learning to diagnose and treat with MFR techniques is a clinical advantage for **in the fascia, no disease escapes notice and no cure occurs without its assistance.**

INDICATIONS, CONTRAINDICATIONS, AND COMPLICATIONS

Indications

Diagnosing in the Fascia

The skilled physician is able to identify altered fascial patterns from any source, internal or external, as somatic dysfunction. Once identified, the pattern, location, and type of somatic dysfunction assist in the diagnosis of visceral and somatic disease, which is then treated with the appropriate application of MFR technique and/or combination of osteopathic techniques with standard medical/surgical care. Monitoring changes, immediate and distant (over time), in the form and function of fascial structures indicate the status of diseases and their response to all treatment endeavors.

Treating in the Fascia

MFR techniques are used to alleviate the visceral and somatic components of somatic dysfunction in the connective tissues of the body, with a focus on fascia, muscles, and related structures (neuroreflexive, circulatory, lymphatic, respiratory, bioenergetic, systemic, holographic, and homeostatic). In systemic disease, MFR techniques address structural imbalances and somatic dysfunction indicative of and pursuant to changes in homeostasis and aid in the normalization of function in all systems. MFR techniques address somatic dysfunction by normalizing motion, relieving edema, reestablishing symmetry, relieving pain, aiding circulatory and lymphatic function, normalizing neuroreflexive activity, supporting visceral function, restoring bioenergetic balance, and supporting homeostatic function.

The key to clinical success is the systematic development and application of the MAN acronym—*Mechanics, Anatomic relationships, and interdependent Neural influences with tethering, tight-loose relationships, three-dimensional patterns (Ward), harnessing a fulcrum, balanced points of tension, expanding releases of dysfunction over time within the connective tissue continuum (Chila), utilizing the holographic fascial structure of tubes, diaphragms, and longitudinal cables, identifying primary somatic and visceral dysfunctions with their related patterns, and activating releases in the bioenergetic fascial continuum supporting homeostasis.* (O'Connell) Treatment is enhanced when the clinician addresses the patient with proper *intention* (humility and respect of the patients process), *attention* (mindfulness of the individuals needs), and with appropriate application of technique, *activation* of releases (supporting the healing process) (Chila, Ward, and O'Connell).

Contraindications

Absolute contraindications include absence of somatic dysfunction, lack of patient consent, and/or cooperation. Relative contraindications may be regional or local.

The safe introduction of motion depends upon multiple factors: integrity of the tissues (open wounds, fractures, recent surgery), the amount of traumatized tissues (thermal injury, contusions, crushing), concomitant diseases (deep vein thrombosis, disseminated or local neoplasms, aortic aneurysm, uncontrolled diabetes), or internal injuries (ruptured viscera or vascular structures), surgical interventions, infections, cooperation of the patient, and the skill of the physician (48).

Complications

A word of caution: overly aggressive interventions are counterproductive. Care should be taken to ensure that any treatment respects the limits of dysfunctional and injured tissues. Exceeding these limits creates a traumatic event. Somatic dysfunction resulting from iatrogenic trauma layered on already dysfunctional or traumatized tissue is the most difficult dysfunction to treat (49).

Patients commonly experience a temporary worsening of discomfort following the first treatment or two. This possibility should be communicated to the patient. The phenomenon is similar to postexercise muscle soreness. Older age groups and general deconditioning are common contributors to the problem. Those with autoimmune, inflammatory, and rheumatologic disorders such as lupus erythematosus and fibromyalgia can experience repeated flare-ups.

SPECIAL CONSIDERATIONS IN DIAGNOSTICS

Subtle Palpatory Skills

Dr. Still: For many years, immersed in extensive study of normal and abnormal positions of the human anatomy, Still had formed in his mind a perpetual image of every articulation in the framework of the human body. Before William Roentgen's discovery of the X-ray machine, visualization, good observation skills, a delicate sense of touch—and that perpetual image—were the only tools Still had to assist him in detecting the abnormal from the normal. He also claimed to see an aura around all of his patients—vibrations emanating from the body—giving him additional clues about his patient's conditions. The Old Doctor, skeptical of the new instrument (x-ray machine), stated to some students, "The x-ray by tremendously increasing the vibrations enables us to see under the surface what our eyes will not discover. Why can't we train our minds to do that?" (50) (Andrew Taylor Still, p. 176).

Ward: Inherent tissue motions are palpably evident, asymmetrically patterned, neuroreflexive activities in the soft tissues. They constantly move, often at variable rates. Palpation that focuses on these motions should readily identify patterns of shifting asymmetric tightness and looseness. Asymmetrically perceived end-feels are commonly referred to as *direct* and *indirect barriers*. As a rule, inherent movements are easier in some directions, less so in others. Myofascially, shifting tightness and looseness identifies unevenly distributed direct and indirect barriers. Many are independent of joint mechanics. Others are tightly linked to joint mechanisms (51).

During treatments with MFR techniques, there is a link between the intrinsic body movements of both the patient and the operator at some level. How this occurs is unknown, but it is likely that both conscious and subconscious brain-mediated factors are at play. In 1989, Grinberg-Zylerbaum and Ramos reported on

their studies of nontouching, silent communication between two or more individuals. Electroencephalography (EEG) was used as a means for studying silent communication patterns between two individuals. Partners who reported feelings of being blended with one another altered their EEG patterns to the point of being virtually identical. Similar blending effects are reported during MFR encounters. Whether these experiences are in any way similar to the Grinberg-Zylerbaum and Ramos work has not been investigated. Skilled palpation in the fascia enables the clinician to “see” anatomic and mechanical detail, much like a blind person senses the environment. As improvements appear, appreciation for seemingly obscure, but important, subtleties emerge (52).

Chila: MFR techniques require refinement of palpatory skills to appreciate subtleties of stress patterns and motion characteristics. Technique application allows the patient to manifest their own potency rather than using blind external force and overpower its assistance. The clinician uses palpation to listen to the effects of the biokinetic energies and forces while allowing the biodynamic intrinsic force to manifest (53). The corrective forces engage the identified resistance to motion and direct it to a point of simultaneous balance and decreased tension, allowing the intrinsic force of the tissues to correct the imbalance. The focus is on the quality of movement, particularly on initiation of motion. The correct gauging of force and velocity provides infinite variation in the delivery of technique. Control minimizes force. The effective physician should be able to vary the applications of force over time during a single manipulative treatment. Appropriate use of a fulcrum and leverage can refine the physician’s diagnostic touch and treatment effectiveness.

Visualization and synthesis of messages received through the fingers are the basis for clinical behavior. Conceptualization of anatomic-physiologic dysfunction peculiar to a given patient is the key to maximizing manipulative responses. The sustained effective response following treatment is contingent on selective and controlled variation of force from an appropriate fulcrum. When these conditions are met, inherent neuroregulatory mechanisms acting in accordance with the capacity of the patient will facilitate the resolution of dysfunction (54).

O’Connell: Fascia can be viewed as an “Intelligent Tissue” functioning as the interface between internal and external events and playing a key role in homeostasis. As discussed previously, embryologic plasticity gives connective tissue the unique ability to respond by cellular adaptation to meet the changing needs of the organism (18). Through the use of “thinking fingers” Sutherland, intelligent palpation interfaces with the fascia in a clinical dialogue giving access to peripheral and central structures, viscera and soma, and the biological and bioenergetic bodies. The body, mind, and spirit are all available to the skilled clinician as the whole of the human condition is recorded and assessable in the holographic fascia. As clinicians improve their palpatory skills, there is an awareness that from any portal of entry into the fascia the whole of the patient’s condition, body, mind, and spirit is available for diagnosis and treatment. Once this skill level is achieved, the practitioner is able to identify the primary dysfunction rapidly from contact at any site within the anatomy. *Within the holographic fascia, the primary dysfunction is not limited to connective tissue structures and may be anywhere in the body, mind, and spirit continuum.* Focused clinician intention to assist in healing and attention to the homeostatic fascial holographic interface allows for the activation of far reaching releases and healing dynamics. This level of skill has been described by many master osteopaths and healers as a “knowing” sensation or viewing an image or movie like projection that flashes into a stilled mind. The power and potency of techniques at this level

demand of the clinician an attitude of humility, respect, suspended expectations, and compassion (55). It is within the patient that the capacity to heal resides.

Dr. Still: “Don’t believe for one second that this was the limit of his vision. According to many who studied with him and others who have spent years studying his works it was his hope that the experience of living, dynamic anatomy would awaken dormant centers of perception in the student. Gradually, over a period of years of focused attention, conscious intention of purpose and deep non-judgmental concentration on the experience of life as manifested in the patient, the physician would evolve to a higher level of interaction with the dynamic mechanism of the patient. He would evolve into an osteopath.” (Osteopathy Research and Practice, p. xix)

THE TECHNIQUES

Fascial Ligamentous Release-Chila

Fascial ligamentous release is a dynamic and expansile form of MFR emphasizing the cybernetic loop between the physician and patient. Selective, controlled reciprocal variation of force and appropriate leverage coupled with inherent neuroregulatory mechanics impact the resolution of dysfunction within the capacity of the patient. Key elements of this dynamic process are as follows:

- Application of force is variable
- Utilization of time is variable
- Visualization and synthesis are mandatory
- Conceptualization is paramount
- Tolerance and response are individual
- Inherent capacity is the standard for health or disease
- Dynamic interchange where the patient allows the physician to enter bodily territorial space
- Physician is a facilitator and observer
- Implication is that the patient’s life story is available through examination and evaluation of body tissues
- Energy flows from thought (56)

In conjunction with these elements, the patient provides breath assistance and/or muscular assistance in the corrective procedure. The establishment of a fulcrum is sought within the physician’s body to match or balance the fulcrum within the patient’s body; this facilitates a continuum of reflex release from within the patient’s body. Once local and regional dysfunctions have been addressed by the establishment of an appropriate fulcrum, expanding leverage is achieved through torsion and traction applied to the extremities. It is the ongoing analysis of dysfunction within this connective tissue continuum that makes possible the integration of multiple manipulative approaches through variable applications of force.

The establishment of an appropriate fulcrum facilitates *diagnostic touch*. The placing of the hands and fingers on the tissues under examination is done with the idea that the fingers can mold themselves to the patient’s body. The initiation of the pattern within the area of complaint is realized by a slight compression at the fulcrum points. The application of the principle of the fulcrum varies with the complaints of the patient. *The use of this method is not a time-consuming process.* Harnessing internal patient mechanisms are used, and it is necessary only to contact them to sense them speaking for themselves. The point(s) of contact is(are) listening posts. Let the tissues tell the story; be quiet and listen. Biokinetic (dysfunctional) energies or forces are always at work in all physiologic and pathologic processes. With the appropriate use

of diagnostic touch, the biodynamic (healing) intrinsic force within is allowed to manifest itself.

Special consideration of respiration-circulation function is essential in diagnosing and treating. Compromised respiratory-circulatory effectiveness is the result of generalized fascial-ligamentous tension throughout the body. For that reason, the character of respiration provides information about such tension. Observe four factors about respiration:

1. *Type of respiration*: diaphragmatic, costal, or mixed
2. *Abdominal wall motion*: visible to the level of the umbilicus; visible to the level of the symphysis pubes
3. *Rate*: slow, rapid; documented before and after treatment
4. *Duration of cycle*: inspiration and expiration equal, inspiration shorter in duration than expiration, inspiration longer in duration than expiration, dilation of the nares during respiration

Generally speaking, the body's connective tissues are under some degree of load and extension (expansion). As previously discussed, connective tissues under sustained load will extend (expand) in response to the load. In biomechanical terms, this continued extension is referred to as *creep*. An imposed constant load will result in relaxation, as the extension remains constant. In either situation, the tissue displays less subsequent resistance to extension than in the original state. Patterns of previous mechanical events affect the tissue's response to load and extension. Physician-applied extension effects tend to revert to their pre-extension responses, whether functional or dysfunctional, if the neuroreflexive processes are not altered. This observation is useful in appreciating recurrence of dysfunctional complaints and patterns. The timed release of tissues associated with the fascial-ligamentous release model considers these factors as the sequential and expanding progression of releases allows the patient to tolerate central nervous system modulation by the lowering of afferent inputs. Significant reduction or elimination of sensitization is proportional to the patient's capacity to appropriately respond. This view is attuned to the idea that central nervous system conditioning over time may be the vehicle for the retention as well as the reduction of dysfunctional states. The physician's role is that of a facilitator. By appropriate facilitation, the physician is able to observe the capacity for change while the patient is enabled to expand the power of the change. The standard for the successful outcome of this interchange is the motivation of the patient.

Integrated INR-Ward

The ability to identify tethering effects that persistently create and maintain pathologic asymmetries is essential. *Tightness suggests tethering, while looseness suggests joint and/or soft tissue laxity with or without neural inhibition.* Sometimes, tethering relates directly to changes in coupled vertebral motions and altered joint play causing the motion segment to be altered. Knowing the difference between neutral and nonneutral vertebral mechanics is essential. Both local soft tissue, neuroreflexive and neurocirculatory changes, such as viscerosomatic reflex changes, are common contributors to tethering. Tethering arises from many sources, as shown in Box 47.1.

Painful sensations are common at loose sites, particularly in chronic cases. Typically, there is little muscle spasm or tightening. Under these conditions, associated muscles are commonly weak and inhibited. Some practitioners refer to these sites as *hypermobile*, implying that ligamentous laxity and joint instability are the fundamental problems. An alternative idea concludes that loose, painful muscles are weak and inhibited over large, often ill-defined areas, including vertebral mechanics.

Common Causes of Tethering

The spine, with altered coupled vertebral motions from any source

Altered soft tissue mechanics (remembering that all tissues and their inherent motions are intrinsically asymmetric)

The synovial joints and their influences on joint play

Asymmetric neural inputs arising from:

Multiple levels of the central nervous system, including CN, brainstem, midbrain, thalamus, and cortex; limbic system and reticular activating system; primary spinal cord; peripheral nervous system at any level

Viscerosomatic reflexes, somato-visceral reflexes, and somato-somatic reflexes

Neurohumoral activities of all kinds

Lowered reflex thresholds from sites of disease, injury, and degeneration

Biobehavioral and sociocultural factors, environmental stressors

From a clinical perspective, whole-body effects are the rule rather than an exception. Loosened sites are often vulnerable to injury under relatively trivial circumstances. Repeated ankle and lumbosacral sprains, as well as neck and shoulder problems arising from altered lumbopelvic and lower limb mechanics, are common examples. The tight-loose concept can be quickly appreciated by the exercise given in Box 47.2.

Tightness of any kind suggests tethering and direct barriers. It also implies the presence of direct barriers and "bind." Some are of bony origin, but many are not. Whether these tethers and areas of bind should be removed requires careful assessment.

One form of tethering is acute muscle spasm, which is almost always self-limited. Another relates to generally tight muscles, which are not always sources of pain and altered function. Stressful lifestyles and personality issues are common in this group. True spasticity, centrally mediated neural tethering, arises from upper motor neuron pathologies. Cerebral palsy, central spinal stenosis, strokes, and effects of head injuries are common examples.

Tight-Loose Concept Exercise

A simple laboratory exercise readily demonstrates the tight-loose concept. With the patient lying supine, the operator grasps the patient's wrists. By slowly raising the upper limb toward full overhead extension, one gets a sense of shifting three-dimensional tightness or looseness that begins at the wrists and eventually involves the whole of the patient's body. By carefully attending to both the quality and the amplitude of these passively induced operator forces, clearly defined mechanically asymmetric sites of tightness and looseness become apparent.

As each limb is moved separately and together, tight-loose relationships vary considerably and their end-feels are different. Some are abrupt, almost like hitting a wall. Others are soft, like either falling into or fluffing a pillow. Importantly, these asymmetric shifts rarely follow classic anatomic patterns. With practice, variable tensions and loads are readily sensed from the hands and wrists distally into the lumbodorsal fascia and pelvis.

Scar tissue implies the presence of passive mechanical tethering that may actually stabilize an otherwise unstable site. Scar tissue changes the ability of a tissue to respond and move in normal planes and produces a new focus of motion patterning. Acute localized muscle tension and tethering generally imply peripheral neural involvement. A history of direct trauma is common for this group.

Looseness generally occurs in association with indirect barriers, neural inhibition, and painful sites. Since inhibition often accompanies neural injury and Wallerian degeneration, pain reports and muscle weaknesses are a common theme with this group.

Three-dimensional vertical, horizontal, and wraparound patterns are the rule and can be identified with some practice. Looking for three-dimensionally related areas of tightness and looseness is the key.

Tightness and looseness should be evaluated from a patterned three-dimensional context that includes:

- Skeletal and soft tissue configurations
- Upper and lower motor neuron influences
- Effects of mechanical modeling and remodeling of bones, joints, and soft tissues
- Effects of general skeletal factors
- Injury history
- Effects of repetitive daily activities
- Psychoemotional states
- Limiting psychosocial and socioeconomic factors

Locating direct and indirect barriers is a useful method for understanding tightness, looseness, and tethering effects. The general goal is to release tightness and restore three-dimensionally patterned functional symmetry to the extent possible without aggravating hypermobility. As forces against direct and indirect barriers are sequentially applied, an experienced operator can efficiently *treat the whole body in a reasonably short time.*

Integrated neuromuscular and MFR approaches and treatment processes are used to diagnose and modify altered reflex and mechanical patterns anywhere in the body. Applying this form of treatment depends on one's ability to palpate and interactively respond to shifting reflex and mechanical changes as they occur. Recognition of active and passive elements influencing both local and general myofascial and skeletal patterns is an important element in the process. The key to clinical success is the systematic development and application of the MAN acronym—*Mechanics, Anatomic relationships, and interdependent Neural influences.*

Bioelectric Fascial Activation and Release-O'Connell

MFR techniques apply compression and distraction forces into the affected fascia directed toward or away from a barrier of motion. Once the barrier or point of ease is engaged, the fascia responds with a decrease in resistance and motion resumes. *The fascia responds rapidly to the light forces applied by all MFR techniques.* As previously discussed, this rapid response is the result of the multiple properties of myofascial tissue: irritability, distensibility, contractility, relaxation, plasticity, elasticity, viscosity, stress, strain, creep, hysteresis, piezoelectric responses, and neuroreflexive activity within the fascial continuum.

During the technique, the fascia releases its restrictions in stages and leads the physician through a pattern of motion. Depending on the skill of the clinician, releases occur in two dimensions, three dimensions, or holographically. This pattern of motion is often complex and traverses any direction or plane, structure or region, organ or system, within the body-mind-spirit continuum.

Viewing this from the bioenergetic model, the response of the fascia is directed and mediated by microelectrical potential changes. Internal or external trauma and dysfunction leaves a pattern of bioelectric potential changes in the fascia that record the direction, strength, and location as somatic dysfunction (see mechanisms mentioned earlier). The application of the diagnostic and corrective forces also produces bioelectric potentials. This activation of bioenergetic tissues opens a diagnostic dialogue within the fascial continuum. Clinician-induced patterns interact with the dysfunctional pattern differently than the normal tissue. This discernable difference unmask the dysfunctional pattern as it leads the physician along its path to the primary dysfunction. With practice, the dysfunctional pattern becomes rapidly obvious, the primary dysfunction is evident, and releases begin almost immediately.

The MFR technique of activating a bioenergetic response and following, both diagnostically and therapeutically, as the pattern releases is *bioelectric fascial activation and release.* BFAR builds on the principles of integrated INR/MFR and fascial-ligamentous release within the family of MFR techniques.

The fascia is a holographic system with a physical structure of a continuum of tubes, diaphragms, and longitudinal cables that contain the record of all events, internal and external, biologic and bioenergetic, in any patient. This design is similar to a transportation system with many connections, lines, and stations allowing the rider to enter at any point and travel throughout the whole system. Understanding the fascia as a readily accessible portal of entry, the clinician has the opportunity to engage in a meaningful and far-reaching diagnostic dialogue with the patient. As dysfunction from any cause occurs, its effects are transported throughout the whole organism via this continuum interfacing with homeostatic mechanisms from the bioenergetic to the systemic to the intracellular. To optimize this dialogue, the clinician needs to have the appropriate *intention* to assist the innate healing properties of the patient to alleviate or eliminate the effects of disease processes and the restoration of the patient's ability to resume command of the clinical situation (Chila), *attention* to the type, structure and pattern of dysfunction diagnostically and therapeutically (Ward) and to *activate* the holographic homeostatic response throughout the patient facilitating the release of dysfunction. (O'Connell) The physician is a partner in this process and the patient's mechanisms are in control. Healing, therefore, is an internal dynamic of the patient and is not imposed by the well-meaning endeavors of clinicians.

Tensegrity systems are another way of looking at the responsiveness of the fascia. As discussed by Edward Stiles, D.O., a tensegrity structure consists of multiple nontouching rods (compression struts) and a continuous connecting system (tension system) embedded or islanding the compression struts. He references Donald Ingber, M.D., Ph.D.'s research suggesting that the bones of the body are compression struts and the continuous tension system is the myofascial and ligamentous tissues of the body representing a tensegrity structure. These totally integrated systems exhibit balanced tension and system wide adaptation when a force is introduced anywhere in the structure. This is accomplished by integrated multilevel hierarchical systems in which an introduced force can influence any part of the total system, from the macro to the micro and vice versa. In this way, the force can be distributed throughout the system in a nonlinear manner. Ingber's research further demonstrates that distortions altering cellular shape and function affect cell differentiation and specialization, biochemical activity, and genetic expression of the affected cells. Stiles stresses the importance of these concepts in the application of OMT in the removal of somatic dysfunction and enabling patients to realize their optimal health potential by restoring their tensegrity potential (57).

Considering the concepts of holographic fascia and tensegrity, diaphragms are especially good portals of entry to the fascia because they occur at important anatomical crossroads where curves change, cavities change, and passage points for major circulatory and lymphatic vessels and organs occur. The central diaphragms are the tentorium, thoracic inlet/outlet, respiratory diaphragm, and pelvic diaphragm. Secondary diaphragms occur in the extremities at the palmar and plantar fascia. Diaphragms are muscular and fascial structures giving shape and form to the tubular structure of the body and counter the physical effects of gravity, entropy, and enthalpy while preserving the body's ability to function and perform in space. Myofascial structures act as longitudinal cables connecting all diaphragms allowing a coordination of motion throughout the system.

Choosing a portal of entry to the fascia is based on the patient's history, test and imaging results, consults, exams, and the provisional diagnosis coupled with knowledge of anatomy and mechanics. This may lead to a very specific structure such as an organ, tendon, or muscle, or need further delineation through active diagnostic palpation. In the case of the latter, choose a diaphragm that you feel the most comfortable palpating or the closest diaphragm to the region of suspected dysfunction to begin diagnostic palpation. In all cases, test tightness, looseness, local tissue quality, and range of motion.

Using compression, distraction, or the *full deep respiration cycle*, induce motion and note the different patterns of interaction between the normal (predictable) and the dysfunctional (unpredictable) tissue response. This discernable difference makes the dysfunctional pattern obvious, and following it leads to the primary dysfunction that may be proximal or distal, in any organ or system, biological and/or bioenergetic, and be a barrier or point of ease. With practice, the dysfunctional pattern, whether a barrier or point of ease, becomes rapidly obvious, making the primary dysfunction evident and releases begin almost immediately. In using BFAR, no more than *three deep respiratory cycles* are needed to activate the release in a progressive fashion. With each respiratory cycle, motion in the tissue begins as a release occurs and a new end point of motion manifests. Each successive deep respiratory cycle continues this process until the release is complete. Return to the original portal of entry and reassess for symmetry and resolution of that pattern of dysfunction.

"Peeling an Onion" of Layered Dysfunctional Patterns

Often, upon reassessing after releasing a primary dysfunction pattern, a new primary pattern of dysfunction is evident. Throughout life, the body is exposed to many traumatic and stressful events that produce a distinct primary dysfunction pattern. Just as the most dysfunctional segment within a pattern of dysfunction is primary, so too the most dysfunctional of the layered patterns is the *primary pattern of dysfunction*. As this pattern resolves, the next most dysfunctional pattern becomes primary. This process is much like *peeling an onion* (58). This onion layer effect continues until all dysfunctional patterns are resolved. A word of caution, after the release of a primary dysfunction pattern, the body needs time to respond and adjust. If the clinician immediately begins the release of other emerging patterns of dysfunction, the system tends to decompensate. To avoid this, address the next emerging primary dysfunction pattern in another treatment session.

Another important consideration is when a pattern of dysfunction is associated with an acute condition, such as, but not limited to, pneumonia, a cardiac event, or uncontrolled diabetes.

These acute patterns are always considered primary and should be addressed first.

There are occasions when a new traumatic event exacerbates an old pattern and makes it primary, such as heading a soccer ball and exacerbating the birth primary dysfunction pattern. In adults, these very early chronic patterns are closest to the core of the onion and all other patterns and dysfunctions are layered on top of it. In releasing these activated primordial patterns, the clinician must be very careful because the changes in the body will be monumental, with both wondrous and devastating effects possible. Another possibility of interaction between multiple traumas is an accumulated trauma vector. This vector is created by a reaction between existing vectors and does not follow the physical pattern of trauma. When releasing these accumulation vectors, changes will occur in the reactive old trauma patterns as well, so be careful to take this into consideration. Gradual releases and close follow-up are necessary to safely harness the body's innate ability to heal.

Be patient: The effects of disorderly and aggressive treatment disrupt the hierarchal balance of dysfunction patterns and systemic chaos results. These patients present significant challenges to first relieve the iatrogenic effects and then to reconstruct and treat the layered dysfunctional patterns in the body. The intelligence of the tissue knows the needs of the system, and it is the prudent physician who honors this and applies the process of releases in peeling the onion of dysfunctional patterns accordingly (Box 47.3).

Trauma Patterns

The effects of trauma and the ensuing trauma patterns are special dysfunctional patterns and warrant further discussion. Trauma and alterations in the ECF precipitate a cascade of events mediated by bioelectric potential changes in the collagen-laden fascia. These events have local and distant effects, ultimately affecting homeostasis. All musculoskeletal treatment medical, surgical, rehabilitative or manipulative engages these properties, whether passively or actively.

Disruption and distortion of the fascia triggers a repair and strengthening process mediated by the release of chemotaxic factors activating the congregation and proliferation of fibroblasts. The fibroblasts coat the injured area with a fibrin matrix and collagen is then deposited in a linear fashion along lines of mechanical tension in the tissue (59). These lines of stress produce bioelectric potential changes that direct the repair of the damaged tissue

Concepts for Peeling an Onion of Dysfunctional Patterns

Always treat the primary pattern of dysfunction

Space out treatments to allow the system to rebalance

Acute patterns are always considered primary

Identify and treat the next primary pattern of dysfunction and continue this process as the layered patterns of dysfunction emerge allowing recuperation time between treatments

Release activated primordial patterns very careful as the changes in the body will be monumental, with both wondrous and devastating effects possible

Treat the effects of disrupted hierarchal balance of patterns of dysfunction by first relieving the iatrogenic effects and then to reconstruct and treat the layered dysfunctional patterns in the body

with respect for the mechanical lines of force affecting the tissue. *Healing therefore takes into account the function of the injured tissue as it repairs its structure.*

If neurologic integrity is compromised or the tissue is immobilized, dense connective tissue is formed. Without the lines of tension and motion, edema and disruptions in circulation and lymphatic drainage also cause fibrin and collagen to be deposited in a thick and haphazard scar. These thickened areas impede normal function of the linear sheets of fascia causing stiffness, changes in range of motion, pain, and further edema (60). This process increases the tissue scarring in a vicious self-perpetuating cycle. Chronic alterations in fascial integrity impede the normal function of the ECF with consequences to the health of the whole organism. *Movement is essential to the appropriate, functional repair of fascia.*

The following healing concepts apply to all connective tissue when injured:

- Linear fibrin and collagen is deposited in response to tension in the tissue and directed by bioelectric potential changes
- Immobilization causes collagen and fibrin to be condensed and haphazard
- Motion improves circulation, exchange of lymphatic fluids and metabolites, and encourages the normal distribution of fibrin and collagen

- It is essential that motion, whether passive or active, be introduced into traumatized tissue as soon as possible
- Appropriate application of OMT will help to restore normal function in traumatized tissue

Tensegrity concepts help to explain relationships between trauma and chronic pain (61). As previously discussed, the body can be viewed as a tensegrity system where trauma affects the whole system and adaptations occur as the body rebalances. As the trauma is distributed, the area of the most intense adaptation is not always at the site of trauma. This site is often the location of the pain complaint, which is secondary by adaptation to the original site of trauma and its related dysfunction pattern. Therefore, evaluation of the whole patient is necessary to identify the site and pattern of the traumatic event, not just the site of pain. Treating the cause of the pain is more efficient and will yield better results than treating the adaptive effect which is pain.

Trauma History

To understand the patient's complaints and condition, a good trauma history is essential (62). Table 47.6 outlines the components of a trauma history; this information will help to identify areas and patterns of related dysfunctions and the state of health of the patient.

TABLE 47.6

Components of a Trauma History

Components	Description
Chronology of trauma	When, where, and what happened during the trauma
Events surrounding the time of the trauma	Circumstances, state of health, state of mind, age, life changes, etc.
Progression of the trauma-related symptoms	Radiation or migration of pain or symptoms, development of other symptoms, etc.
Mechanism of trauma	Motor vehicle accident, birth trauma, fall, surgery, etc.
Direction and motion of trauma	As detailed as possible, e.g., pivoting left on right foot when tackled on the outside of the right knee
Type of trauma	Blunt, sharp or cutting force, compression, traction, active motion against resistance, repetitive, etc.
Original signs and symptoms	Bruising, pain, swelling, asymmetry, fractures, motion changes, organ symptoms, etc.
Changes in signs and symptoms	Progressing, developing or continuing pain, functional changes, neurologic, mental or emotional symptoms, improving symptoms, etc.
Types and responses to treatments	Surgery, medication list, physical therapy, supplements, alternative care, etc.
Pretrauma diseases and changes since the trauma	Any changes in types of disease and response to treatment
Posttrauma diseases	New conditions and response to treatment
Previous trauma	List and any residuals still present at time of present trauma
Subsequent trauma	Relationship to the presenting trauma, e.g., repetitive work injuries, falls due to unstable joints, etc.
Disabilities related to the presenting trauma	Achieved or applied for, e.g., social security, personal injury, worker's compensation, private disability
Disabilities <i>not</i> related to the trauma	Achieved or applied for, e.g., social security, personal injury, worker's compensation, private disability

The creation of a treatment plan for the dysfunctional and/or traumatized patient incorporates these concepts. Osteopathic management of these patients addresses the trauma and its effects with OMT integrated with medical, surgical, rehabilitative, and alternative interventions. Treating somatic dysfunction enhances and supports healing and homeostasis in all levels, body, mind, and spirit. *“To find health should be the object of the doctor. Anyone can find disease”* (63) (*Philosophy of Osteopathy*, A.T. Still, p. 28).

CLINICAL CASES

CASE 1: BIOMECHANICAL MODEL OF WARD

Refer to the chapter-opening case.

CASE 2: “THE BIG BANDAGE” MODEL OF CHILA

P.R. is a 46-year-old African American female who presents with pain in the right shoulder, neck, and upper back after gardening this weekend. She spent a day weeding and planting in her gardens and went to bed stiff and woke up this morning in pain with poor motion of her neck and right shoulder without radiation of pain or numbness. She denies any other recent traumas. She did have a similar problem last spring when she began to garden again and was helped by osteopathic manipulative treatments.

Review of systems is positive for ovarian cysts and is otherwise noncontributory.

Past medical and family histories are unchanged from last year.

Tests: x-rays of the cervical spine a year ago demonstrated mild degenerative changes at the facets and discs at C5-6.

Medications: ibuprofen 200 mg 2 po every 6 hours since yesterday with relief of stiffness but not the pain. Aleve 1 to 2 q12 prn prior to her periods and at midcycle for ovarian pain.

Physical exam: BP: 120/80; Pulse: 76 in acute moderate distress.

Neurologic: normal reflexes and sensation of upper extremities; strength intact with pain with end points of exertion.

Peripheral vascular: pulses normal with good capillary refill and no edema of all extremities.

Musculoskeletal: range of motion of right shoulder limited in abduction with pain, and otherwise both shoulders normal; cervical spine spasms with rotation of head and neck greater than 20 degrees left, otherwise motion intact; thoracic spine limited by pain in all planes of motion with spasms.

Diagnosis

Sprain/strain right shoulder

Sprain/strain cervical spine

Sprain/strain thoracic spine

Somatic dysfunction of the cervical, thoracic spine, and right upper extremity

Treatment

MFR

Stretches

Continue ibuprofen

CASE 3: BIOENERGETIC MODEL OF O’CONNELL

E.G. is a 3-week old female infant brought in by her parents for problems with sucking, torticollis, and inability to move her right arm. She is the product of an uncomplicated term

pregnancy that was augmented with pitocin for failure to progress due to being in an occiput posterior position. Labor lasted 22 hours and she was delivered without further assistance. She weighed 8 lb 2 oz and had APGARS of 7 and 9. Mom states that E.G. had problems latching on from the start and cried a lot keeping her from nursing at the breast or with bottles with expressed milk. They noticed that she did not move her right arm like her left and that her head was always turned left and tilted onto her right shoulder. The pediatrician reassured them that this would resolve on its own. Since it did not, they have brought her to seek osteopathic manipulative treatments at the advice of their lactation consultant.

The rest of the review of systems shows steady weight gain in the 25th percentile, no reflux, and is otherwise noncontributory.

Family history is negative for similar conditions and both parents are healthy and 22 years old.

Physical exam: Pulse 140 regular, respirations nonlabored, distressed with certain positions, nursing and changing clothes.

Neurologic: Inability to actively, grossly move right shoulder; movement of elbow and wrist and grip are maintained but weak on the right with the left being normal. Torticollis with head turned left with upward gaze and inability to actively rotate right. Suck is disorganized with posterior tongue position and inability to maintain suction on digit, nipple, or breast with aerophagia and discomfort. The rest of her neurologic exam is appropriate for age.

Musculoskeletal: Torticollis rotated left with spasm of right sternocleidomastoid (SCM) muscle with pain with passive motion of head and neck right past midline. Group curve cervical spine has the most significant loss of motion at C5 and C1-occiput. Ribs 1 to 2 elevated right with depression of the acromioclavicular joint with a click with motion. Position of ease is head rotated left with upward tilt with right shoulder internally rotated. Cranial motion demonstrates a compression of the mastoid suture and occipital condyle on the right. T1-3 are extended and any attempt at flexion in this region is painful.

The rest of the physical exam is normal and appropriate for age.

Diagnoses

Erbs palsy

Torticollis, spasmodic

CN trauma of birth (9–12)

Feeding problems of the newborn

Somatic dysfunction head, cervical, thoracic, ribs, upper extremity right

Treatment

MFR

Set up for physical therapy

Discussed positional support when feeding

Continue with lactation consultant to support breast feeding

DIAGNOSES AND TECHNIQUES

Techniques are divided according to somatic dysfunction body regions. Ward’s, Chila’s, and O’Connell’s techniques will be described separately.

Figure 47-8 A, B. Craniocervical technique.

TECHNIQUES BY WARD

739.0 and 739.1: Head and Cervical Region

Craniocervical Spine

Patient Supine

This process is shown in Figure 47.8. The goal is to establish three-dimensional movement symmetry in the cervical spine from basiocciput to upper thoracic influences. Particular emphasis is placed on restoration of adequate side bending and rotation, both generally and in relation to single segment mobility. This technique is usually more effective after lower cervical, cervicothoracic junction, and upper thoracic, upper limb factors have been released beforehand.

Note: To protect the vertebral arteries, take particular caution to avoid simultaneous side-bending and extension maneuvers. *While important for all age groups, most injuries have occurred under age 35.*

Procedure

1. The patient lies supine with heels on the table, arms comfortably at the sides. This basically ensures that unusual mechanical stresses transmitted through the Achilles tendons and ankles will be neutralized. For those patients with significant kyphosis,

it is helpful to use a large pillow to minimize cervical and thoracolumbar problems

2. Sit at the patient's head
3. Two hand positions, among many possibilities, are particularly useful:
 - (a) One hand overlapping the other—this permits carefully controlled and focused, twist, traction, and side-bending maneuvers. The maneuvers are used both separately and with patient cooperation
 - (b) By grasping the basiocciput with the palms of each hand, the fingers are left free to sort out both superficial and deep mechanisms
4. From either hand position, traction, turning, and side-bending maneuvers assess myofascial and joint-related tightness and looseness
 - (a) Pay particular attention to tightness, remembering that loose joints with surrounding inhibited muscle groups are common sources of pain and disability. In more acute situations, on the other hand, loose joints are usually associated with tight muscles as they work to protect and stabilize the system. The opposite findings are also common, such as tight joints with accompanying inhibition of overlying muscles

- (b) Facet joints are often tight on one side, loose on the other. Side-to-side motion testing with only a little rotation will determine which facets are failing to effectively open or close
 - (c) The procedure's focus is to carefully, but persistently, apply well-focused stress against tight sites with and without patient assistance
 - (d) INR CN and upper limb activities such as finger tapping and hand rolling are commonly helpful. They also save the practitioner time
5. Linking subtle translatory maneuvers (e.g., combinations of distraction and extension with flexion, extension, side-bending, and rotation) is usually helpful. In particular:
 - (a) Release deep upper cervical muscles by combining CN activities with occipitoatlantal nutation and counternutation. Remember that SCM, trapezius (CN XI), and scalene mechanics are easily accessible primary neck stabilizers that are often asymmetric in relation to each other. For example, the left SCM mechanism is typically tighter than the right from origin to insertion. Commonly, the underlying scalene system is looser (i.e., tightness and looseness occur among ipsilateral layers as well as from side to side, front to back, and circumferentially)
 6. In the process:
 7. Atlantoaxial joints and surrounding attachments are carefully rotated against tightness
 8. Middle and lower cervical attachments and coupled joint movements are stressed using translatory movements with combinations of side bending, flexion, and extension that avoids a lot of rotation (Remember the vertebral arteries!)
 9. Treatment is complete when symmetric movements are restored to facet joints and surrounding soft tissues within the ability of the patient to adapt

739.2 and 739.8: Thoracic Region and Ribs

Thoracic Cage, Spine, Diaphragm, and Lower Costal Cage: Supine

This process is shown in Figure 47.9.

Objective

The goal is to three dimensionally balance scapulothoracic, thoracic spine, and costodiaphragmatic relationships.

Procedure

Supine

1. The patient lies supine with heels on the table, arms comfortably at the sides. This basically ensures that unusual mechanical stresses transmitted through the Achilles tendons and ankles will be neutralized. For those patients with significant kyphosis, it is helpful to use a large pillow to minimize cervical and thoracolumbar problems
2. Sit at the head of the table
3. Resting your elbows on the table, reach under the patient and place the hands firmly against inferior costothoracic attachments on either side of the thoracic spine. Be sure to maintain whole-hand contact across and along the erector spinae as well as around the costal cage
4. Both positional and movement-related tight-loose asymmetries will become apparent
5. Focus on the following:
 - (a) Diaphragmatic asymmetries that become apparent as the patient slowly but deeply inhales and exhales

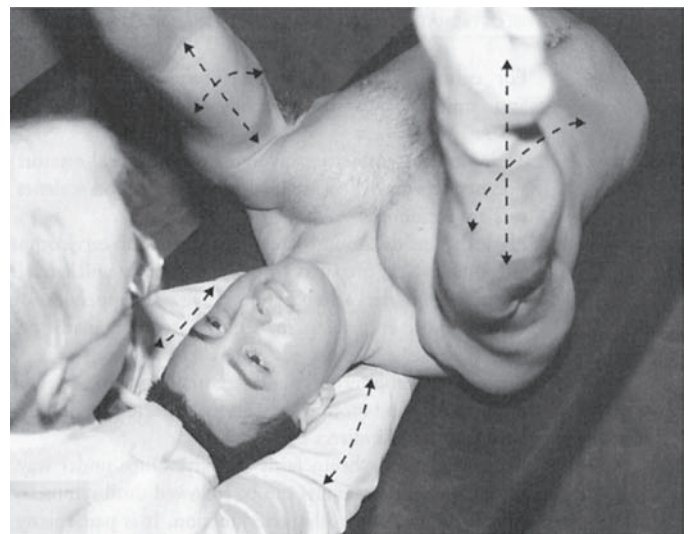

Figure 47-9 A, B. Thoracic and rib technique.

- (b) Upper limb asymmetries that occur as the patient actively moves the upper limbs in a variety of directions
 - (c) Repeat the procedure by passively moving each arm and shoulder with one hand remaining behind the patient
 - (d) Thoracolumbar junction asymmetries are assessed by having the patient move the lower limbs in a variety of directions; focus on the proximal iliopsoas as well more distal, lumbopelvic relationships as they respond to active patient movements
6. As inherent tissue movements become apparent, gently, but firmly, lift the thoracolumbar attachments anteriorly and laterally. Shifting sites of tightness and looseness are balanced against each other until inherent movements become quietly symmetric. Sometimes, considerable traction and twist are needed to release asymmetrically tight areas
 7. As tightness releases, varieties of release-enhancing activities are helpful. Examples are:
 - (a) Three-dimensional upper and lower limb movements
 - (b) Breath holding at neutral, during moderate and deep inhalation, and then during moderate and deep exhalation, which can be combined with three-dimensional upper and lower limb movements
 8. Treatment is complete when thoracocostal movements are as functionally symmetric as can be expected

739.3: Lumbar Region**Thoracolumbar Release**

Figure 47.10 illustrates this process.

Objective

To balance the thoracolumbar junction three dimensionally in relation to lumbopelvic, thoracocostal, and diaphragmatic mechanics.

Review

Review cervical, trapezius, shoulder girdle, and costal cage anatomy for their three-dimensional perspectives and functional relationships to the area.

Procedure*Prone*

1. The patient's feet should be off the end of the table to minimize lower limb stresses in relation to the pelvis and low back
2. Initially, the patient's head should be turned to the most comfortable side. Holding it exclusively in the midline, as many wish to do, often obscures tight-loose effects at the thoracolumbar junction

Figure 47-10 Lumbar technique. **A.** Operator stands beside patient's hip, with head to side. **B.** Head right.

3. The hands and arms are comfortably placed either over the sides of the table, or on the table beside the hips and thighs
4. Stand beside the patient's hip, facing cephalad
5. Place your hands at the thoracolumbar junction, covering posteroinferior rib, trunk rotator, and diaphragmatic sites
6. Place hands widely open with the thumbs pointed cephalad along either side of the spinous processes, while the remainder of each hand spreads over the posteroinferior costodiaphragmatic and upper lumbar areas
7. Identify superficial and deep tightness and looseness patterns three dimensionally
8. Firmly separate the thumbs across the midline as the left hand creates clockwise and the right hand creates counterclockwise traction. The hands should not slide on the skin
9. As the skin is stretched between the thumbs, it will initially blanch. As compression, traction, and twist are maintained, tissues begin to relax both reflexively and mechanically in accordance with principles discussed earlier in this chapter. After initial blanching, the site of major soft tissue tension commonly becomes reddened and warmer, the so-called blush phenomenon
10. Typical releases occur three dimensionally with sustained traction and twist, and they can occur singly or in multiples. The latter often creates a wormlike sensation under the palpating hands. As multiple releases continue, so-called unwinding phenomena often occur, as shifting patterns of tightness and looseness alter three-dimensional relationships. With practice, one learns to feel deeply into the areas surrounding facet joints. Symmetric segmental movements to passive three-dimensional stressing suggest that the procedure is complete. Treatment is complete when repetitive stressing of selected sites no longer creates release activity

739.4: Sacrum**Focused Prone Sacral Base Release:
Two-Handed Technique**

This process is shown in Figure 47.11.

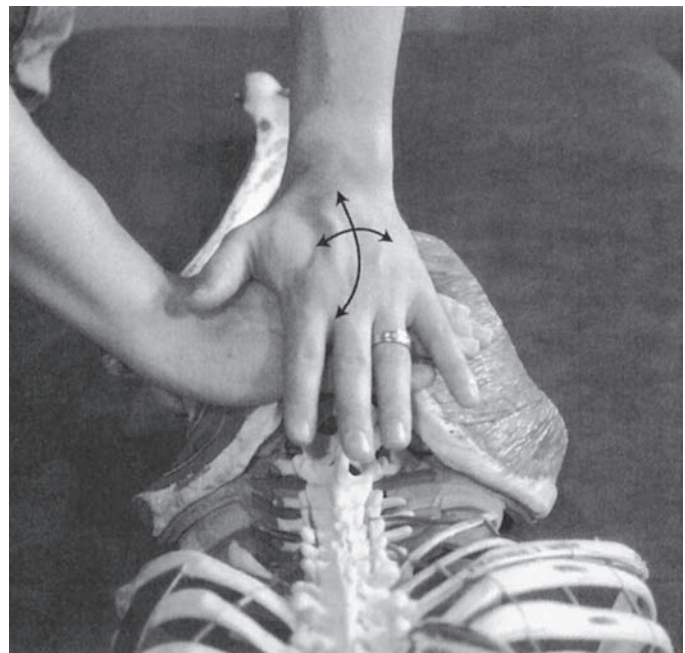

Figure 47-11 Sacral technique. Using a rocking motion, induce lumbosacral joint distraction.

Objective

The goal is to three dimensionally balance the sacral base in relation to L4-5 mechanics, the iliolumbar ligament, and positional innominate asymmetries.

Review

Review lumbopelvic anatomy, L4-5 mechanics in relation to the sacrum and pelvis, iliolumbar ligament, and innominate, hip rotator, and pelvic diaphragm relationships, including distal iliopsoas and piriformis muscle influences.

Procedure*Prone*

1. The feet should be off the end of the table to minimize lower limb stresses in relation to the pelvis and low back
2. The head should be turned to the most comfortable side
3. The hands and arms are comfortably placed either over the sides of the table or on the table beside the hips and thighs
4. If right handed, stand at the patient's left shoulder, facing caudad
5. Place one hand either horizontally, or transverse to the sacrum, contacting the posterior superior iliac spines and medial gluteus maximus attachments bilaterally
6. Place the other hand over the bottom hand along the long axis of the sacrum between the two innominates, with the index finger overlying one SI joint and inferior lateral angle as the ring finger covers the other. By using this hand placement, the long finger falls naturally over the sacral spines and sacral hiatus
7. Evaluate patterns of tightness and looseness by rocking the sacrum in multiple planes:
 - (a) Proximally and distally, by distracting the sacrum and lumbar spine at the sacral base along the long axis of the spine
 - (b) Circumferentially, by transversely translating each hand across the pelvis in opposite directions
8. Using a rocking nutation-counter-nutation gapping motion, induce lumbosacral joint distraction. Be sure to create the motion by moving the distal hand caudally as well as up and over the natural curve of the sacrum. Some sacra are in a more or less straight-line relationship with the spine. Others are sometimes acutely angled with the plane of the sacral base virtually perpendicular to the flow of the operator-imposed forces
9. Both light- and heavy-handed force can be used, depending on your skill. A key to success is the ability to monitor, induce, and enhance both inherent tissue and craniosacral activities
10. As both static and dynamic loading is applied, inherent tissue movement-related tightness and looseness usually becomes apparent. Static forces load the system against direct and indirect barriers without superimposing oscillating movements. Dynamic forces load the system with subtle operator-induced forces that:
 - (a) Follow along behind inherent tissue and craniosacral movements
 - (b) Systematically seek out three-dimensional shifts of direct and indirect barriers as releases occur
11. Success is more apt to occur when special attention is given to the sacral base in relation to L4-5 mechanics, iliolumbar ligament anomalies, degenerative changes, and nonneutral vertebral mechanics.)
12. Treatment is complete when L5 and sacral base mechanics and associated inherent motions are as symmetric as can reasonably be expected

739.5: Pelvis**Pubic Symphysis Release**

Treatment procedures for the pelvis are shown in Figure 47.12.

Objective

The goal is to restore symmetry to the pubic symphysis.

Review

Review the functional three-dimensional relationships among the proximal thigh adductors, anterior and posterior innominates and their asymmetries, as well as changes involving the rectus sheath and transverses abdominis muscles, where they attach to the pubic symphysis.

Procedure*Supine*

1. The patient lies supine with heels on the table and the arms comfortably at the sides or on the abdomen. Short-armed individuals should keep the arms on the table to avoid stressing shoulder and thoracolumbar systems. This more or less ensures that unusual mechanical stresses transmitted through the Achilles tendons and ankles will be neutralized. For those with significant kyphosis, it is helpful to use a large pillow to minimize cervical and thoracolumbar problems

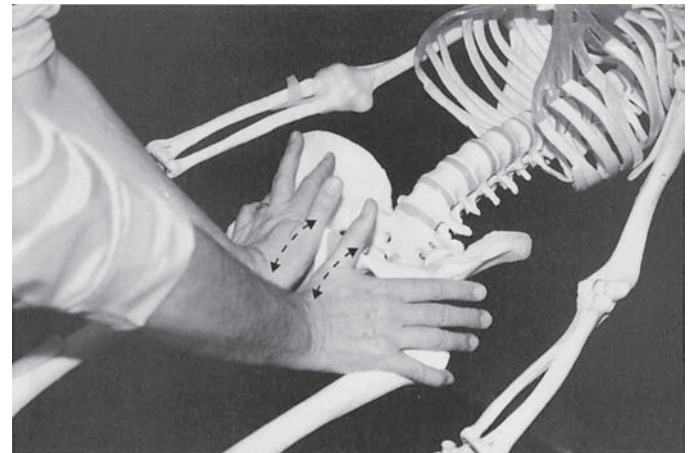

Figure 47-12 Pelvic technique. **A.** Symphysis release. **B.** Thenar eminences are placed on either side of symphysis pubis, thumbs pointed superiorly and anteriorly.

2. Facing cephalad, the practitioner sits or stands beside the patient's right thigh, near the knee
3. First, assess for symphyseal shear and positional asymmetry. Some prefer visual analysis, while others prefer a combination of palpation and vision. Tightness and looseness in the rectus sheath often identify the most problematic site. Sometimes tightness will be on the inferior side, sometimes the superior. Usually, there are strong correlations with innominate positioning, but there are enough exceptions that one must be alert
4. Place the thenar eminences on either side of the symphysis pubis, thumbs pointed superiorly and anteriorly. Proximal adductor and iliacus tendon attachments should be palpably evident under the thenar muscles
5. Induce firm, slow forces that either exaggerate (indirect barriers) or decrease (direct barriers) symphysis asymmetry. Direct rocking back and forth, similar to an articular maneuver, is often effective. Hold against the barriers until releases occur. Mild oscillations usually become evident as the rectus fascia, bony pelvis, pelvic diaphragm, trunk rotators, and thigh adductors become more symmetric

739.6: Lower Extremity

Treatment procedures for the lower limb are shown in Figure 47.13.

Goal

The goal is to release each lower limb from lumbopelvic and hip rotator attachments to the foot and ankle.

Review

Review the following:

1. Functional neurology of the lower limb, including pelvic girdle, low back, trunk rotators, and lumbodorsal fascia, latissimus dorsi, scapulocostal stabilizers in relation to the low back, brachial plexus influences through shoulder girdle structures, as well as diaphragmatic-phrenic influence. Remember that the limbs are precisely represented in cerebellopontine functions as well as in multiple areas of the homunculus and precentral gyrus, among many
2. Functional neuromuscular anatomy of the foot, ankle, knee, and their myofascial elements
3. Functional neuromuscular anatomy of the hips and upper leg

Figure 47-13 Lower extremity technique.

4. Circulatory anatomy of both the lumbopelvic system and the lower limbs
5. The effects of common medical problems, such as arthritis, diabetes, and effects of trauma and surgery

Note 1: Smoking-related circulatory problems, arthritis, and diabetes are among the most common sources of lower limb dysfunctions.

Note 2: Proprioceptive instability on one leg is a common signal of unilateral muscle weakness and neural inhibition anywhere from the low back to the plantar surface of the ipsilateral foot. Pain is a common presenting complaint.

Procedure

Supine

1. To begin, the heels should be on the table with knees extended to minimize lower limb stresses. The head and neck should be comfortable with minimal stress on the spine and pelvis

Note: Remember to check for leg-length inequalities and altered hip mechanics both prone and supine. It is common to find differences supine, prone, and seated. Pelvic obliquities are common when these inconsistencies occur.

2. The hands and arms are comfortably placed either on the abdomen or at the sides
3. Sit or stand beside the patient
4. Grasp distal femur and distal patellar/proximal tibial attachments
5. Using firm, passive, circumferential movements, assess each fully extended knee for three-dimensional tightness and looseness. Particular care is taken in assessing medial hamstring as well as lateral hamstring/iliotibial band/proximal fibular head tight-loose relationships

Note: Myofascially, this is a fairly ambiguous area to assess and treat, so one must subjectively rely on tight-loose end-feels. Remember that both lumbopelvic and foot-ankle mechanics significantly influence the system.

6. Assess hip function in the same way, with the leg in full extension and then with varieties of flexion, internal and external rotation, abduction, and adduction
7. Passively twist the knee in opposite directions (axial twist), being sure that the hand and fingers are firmly in contact with areas of maximum tightness. Usually, maximum tightness is in two places:
 - (a) Laterally around distal iliotibial band attachments and proximal fibular head
 - (b) Medially and posteriorly near and around distal hamstring attachments
8. Asymptomatic lateral knee/fibular head problems (tightness) in response to medial complaints where the knee is generally more mobile are common. Distal tensor fasciae latae problems are also common in this group in conjunction with ipsilateral gluteus medius weakness. A positive standing Trendelenburg test is the most common signal of gluteus medius weakening
 - (a) Remember that proximal SI joint and sacrotuberous-sacrospinous ligamentous factors are also common sources of distal difficulties, and vice versa

739.7: Upper Extremity

Treatment procedures for the upper limb are shown in Figure 47.14.

Figure 47-14 Upper extremity.

Upper Limb and Shoulder

Rotator Cuff and Partially Frozen Shoulder Dysfunctions

Goal

The goal of this treatment is to three dimensionally balance cervical, shoulder, scapulocostal, anterior chest wall, rotator cuff-glenohumeral, upper arm, elbow, wrist, and hand influences.

Review

Review the following:

1. Functional neurology of the neck in relation to the upper limb, including brachial plexus and cervical autonomic elements, as well as CN sensory and motor functions
2. Rotator cuff, glenohumeral, elbow, wrist influences
3. Craniocervical spine relationships with particular reference to large and small muscle influences from basiocciput to upper thoracic and related scapulothoracic, scapulocostal influences

Procedure

The procedure is carried out with the patient prone, with their arm and shoulder off table. Most of the time, this position is used to deal directly with compromised shoulder and scapulocostal mechanics (see also “Spencer Techniques”). Direct myofascial stressing occurs across and around the rotator cuff, acromioclavicular joint, distal glenohumeral attachments, and inferior subscapularis, latissimus dorsi, infraspinatus, teres major and minor attachments:

1. The patient’s feet should be off the end of the table to minimize lower limb stresses in relation to the pelvis and lower limb
2. The patient’s head should be turned to the most comfortable side. Note the effect of head turning on tightness and looseness across the shoulder in question. Proximal and superior cervical attachments are often compromised and need to be released along with the shoulder

Note: Keeping the head in the midline readily neutralizes cranio-cervical asymmetries, but also reduces the chance that significant tight-loose asymmetries will be missed.

3. The patient’s hands and arms are comfortably placed either over the sides of the table or on the table beside the hips and

- thighs. If the hands are over the sides of the table, be sure to note any asymmetric scapulocostal effects
4. The operator sits on a rolling stool that allows movement in response to shifting sites of tightness and looseness
5. Holding the affected arm between the knees allows the operator use of the rolling stool to guide movements as specific stressing against tight barriers occurs
6. Initially, place both hands firmly around the glenohumeral attachments immediately lateral to the acromioclavicular joint. The fingers of one hand firmly contact pectoralis major attachments anteriorly, while the other hand contacts teres/infraspinatus attachments posteriorly
7. Assess tightness and looseness by three dimensionally stressing the system using distraction, compression, twist, and shear
8. Direct and firm stressing against tightness gets the process under way. For example, approximately 5 to 15 lb of load are common before initial releases begin
9. Pay particular attention to posterior and inferior glenohumeral restrictions close to the scapula
10. Long-term problems usually require firmly held movements that assertively stretch the area without interfering with neuro-circulatory functions
11. A well-organized home exercise and/or physical therapy program is usually needed to maintain improvement
12. Side-lying techniques using a similar approach are also helpful

TECHNIQUES BY CHILA

739.0: Head and Suboccipital Region

Cranium

Treatment procedures for the cranium are shown in Figure 47.15.

Occipitoatlantal Articulation

1. One hand contacts the posterior tubercle of the atlas
2. The opposite hand contacts the vertex of the patient’s head. The fulcrum is established by the placement of the elbow on the tabletop

Basilar Axes of the Skull

The patient’s head rests on the interlaced or overlapped fingers of the physician. The physician’s thumbs extend above the ears toward the forepart of the head. The fulcrum is established by the placement of the elbows on the tabletop.

Figure 47-15 Head and suboccipital technique.

739.1, 739.2, and 739.8: Cervical Region, Thoracic Region, and Ribs**Rib Cage**

1. Place one hand beneath the rib cage, with the fingertips just beyond the spinous processes of the associated thoracic vertebrae (Fig. 47.16)
2. Place the other hand on the anterior ends of the ribs. The fulcrum is established by the elbow on the knee

Lower Thorax

Place both hands beneath the patient at the level of the 12th thoracic segment (T12) (Fig. 47.17). This area corresponds to the level of the insertion of the trapezium muscles bilaterally. The fulcrum is established bilaterally by the elbows resting on the tabletop.

Upper Thorax

The patient's head rests on a pillow. One hand and arm contact the upper thoracic spinous processes, with the fingers spread slightly to contact the ribs on each side (Fig. 47.18). Place the opposite hand on the sternum. The fulcrum is established by the elbow on the tabletop, beneath the patient's head.

Cervical Area

Both hands bridge the entire cervical area from the base of the skull to the upper thorax (Fig. 47.19). The fulcrum is established bilaterally by the elbows and forearms resting on the tabletop.

739.3: Lumbar Region

The patient's knees are flexed, and the feet placed flat on the table. Lateralization of the feet, with inversion of the toes, helps to stabilize the pelvis.

Upper Lumbar, Psoas Muscle

Place one hand under the upper lumbar area (Fig. 47.20). The opposite arm and hand bridge the flexed knees. The fulcrum is established by the elbow on the knee (upper lumbar area).

739.4 and 739.5: Sacrum and Pelvis

The patient's knees are flexed, and the feet placed flat on the table. Lateralization of the feet, with inversion of the toes, helps to stabilize the pelvis.

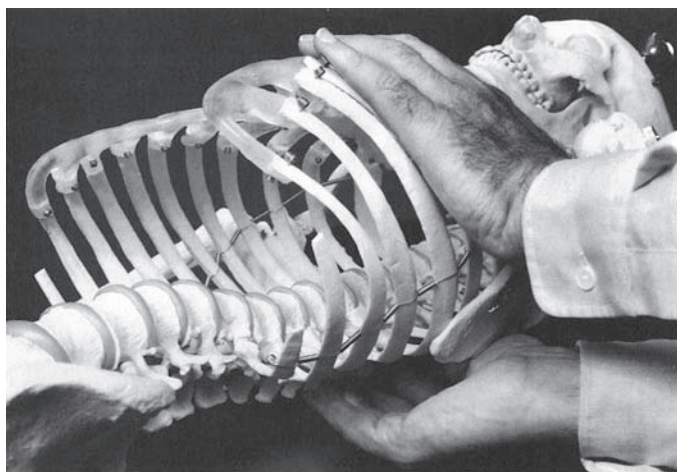

Figure 47-16 Rib cage.

Sacrum and Pelvis

1. Mold with the patient's sacrum with one hand
2. Place the fingertips of this hand at the level of the spinous process of the fifth lumbar segment (L5). The opposite arm and hand bridge the anterior superior iliac spine (ASIS) on each side of the pelvis (Fig. 47.21)
3. The fulcrum is established by the elbow, which is leaning on the treatment table

Sacrum, Iliosacrum, Lower Lumbar

1. Mold with the patient's sacrum with one hand (Fig. 47.22)

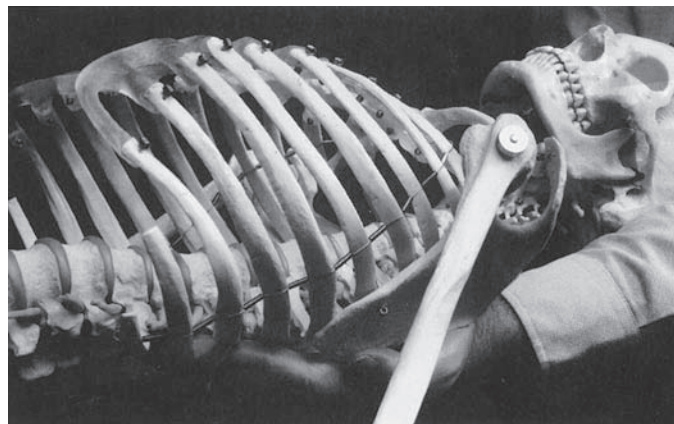

Figure 47-17 Lower thorax.

Figure 47-18 Upper thorax.

Figure 47-19 Cervical area.

- Place the opposite hand under the iliosacral articulation. The fingertips of this hand contact the spinous process of the lower lumbar segments (L3, L4, L5). Both elbows establish the fulcrum: one leaning on the treatment table (sacrum), the other leaning on the physician's knee (iliosacrum; lower lumbar)

Figure 47-20 Upper lumbar, psoas muscle.

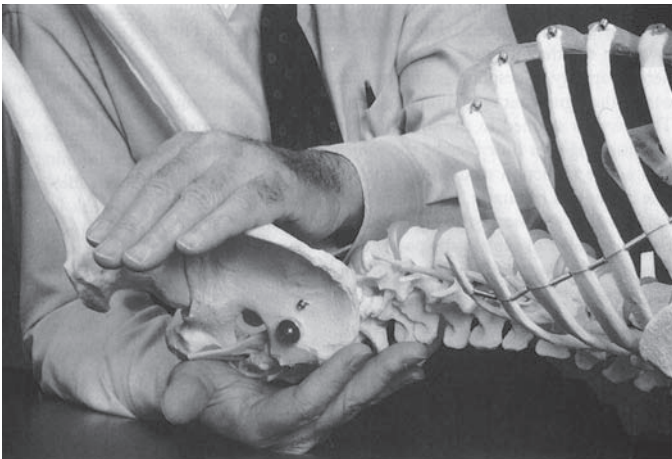

Figure 47-21 Sacrum and pelvis. Bridge ASIS.

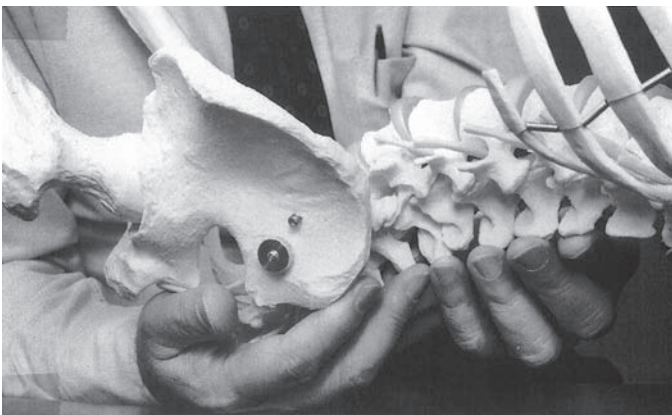

Figure 47-22 Sacrum, iliosacrum, lower lumbar.

739.6: Lower Extremity

Lower Extremity

Selectively employ torsion (rotation) and traction in two phases to release muscular, fascial, ligamentous, and articular dysfunction. The fulcrum is established by the elbows of the physician's arms in supporting the motions of the patient's foot, lower leg, and knee.

Abduction Phase (Lower Leg)

Invert the plantar surface of the foot (Fig. 47.23). Introduce torsion between the ankle and the knee. Advance the effect of torsion by slowly moving the knee across the lower abdomen, resulting in progressive abduction of the lower leg. The torsion will be felt in the lateral malleolar area, the medial compartmental area of the knee, the tensor fascia lata area, and the trochanter area. Upon completion of this phase, gradually extend the lower extremity and slowly return it to the tabletop.

Adduction Phase (Lower Leg)

Evert the plantar surface of the foot (Fig. 47.24). Introduce torsion between the ankle and the knee. Steadily advance the effect of torsion by slowly moving the knee away from the lower abdomen, resulting in progressive adduction of the lower leg. The torsion will be felt in the medial malleolar area, the lateral compartmental area of the knee, the medial thigh area, and the inguinal area. Upon

Figure 47-23 Lower extremity, abduction phase.

Figure 47-24 Lower extremity, adduction phase.

completion of this phase, gradually extend the lower extremity and slowly return it to the tabletop.

Foot

Note tenderness to palpation in the plantar myofascial tissues. Give particular attention to such findings along the medial longitudinal arch. The contour of the foot can be analogized to the spinal complex:

- The calcaneus represents the sacrum
- The tarsal bones represent the lumbar region
- The tarsometatarsal area represents the thoracolumbar junction
- The metatarsal area represents the thoracic region
- The metatarsophalangeal area represents the cervicothoracic junction
- The phalangeal area represents the cervical region

Tender points can be analogized to the ipsilateral spinal level, including paraspinal tissues.

Treatment is by increased plantar flexion of the foot about the point of greatest tenderness (Fig. 47.25). Perform articular release of the small joints of the toes in sequence, from the great toe to the small toe.

739.7: Upper Extremity

Upper Extremity

Scapulofascial Release

Accomplish this by exploring ease and resistance to motion in several planes: cephalad, caudad, medially, laterally, clockwise, and counterclockwise (Fig. 47.26). Both hands are used to grasp the scapula completely, both medially and laterally.

Axillary Release

Accomplish this by manual decongestion of the posterior axillary tissues and the pectoral tissues.

Expansion of the Inferior Thoracic Aperture

Accomplish this by supporting the elbow region with one hand and the wrist region with the other hand. For this and all subsequent procedures, the fulcrum is established by the elbows of the physician's body in support of the motions of the patient's upper extremity. Bring the extended upper extremity of the patient closer

Figure 47-25 Foot

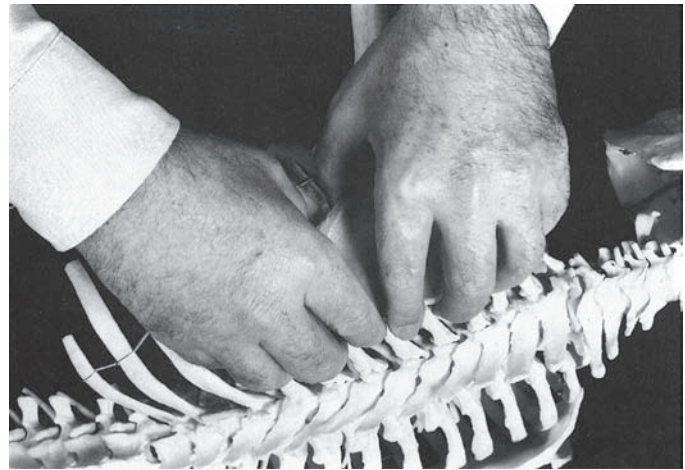

Figure 47-26 Upper extremity, scapulofascial release.

to the side of the body. Sustained supination as the upper extremity is carried toward the posterior thorax facilitates release of the thoracolumbar junction. Sustained pronation as the upper extremity is carried toward the xiphoid process facilitates musculofascial release along the costal margin. The cumulative effect of these forces contributes to ligamentous articular release of the elbow region.

Clavicular and Glenohumeral Release

Accomplish this by placing the extended upper extremity in a neutral position, with respect to the side of the body, and abducting to the point where a continuum exists between the upper extremity and the position of the clavicle. Sustained pronation as the upper extremity is carried toward the manubrial region facilitates release of the manubrial area and the sternoclavicular articulation. Sustained supination as the upper extremity is carried toward the posterior thorax facilitates release of the acromioclavicular articulation and the glenohumeral area.

Radioulnar, Wrist, Hand, and Fingers Release

Accomplish this by sustained alternating supination and pronation. This facilitates the release of fascial ligamentous tension along the course of the interosseous membrane to the flexor retinaculum (Fig. 47.22).

The addition of alternating flexion and extension of the wrist facilitates the release of articular dysfunctions of the carpal bones (Fig. 47.23). Fascial ligamentous release of the palmar area precedes articular release of the small joints of the fingers and thumb. The progress of the sequence is from the small finger to the thumb (Fig. 47.24).

Expansion of the Superior Thoracic Aperture

Accomplish this by grasping the deep webbing between the index finger and thumb of the patient's extended upper extremity. Sustained alternating supination and pronation facilitates the release of congestion in this area and contributes to release of the cervicothoracic junction (Figs. 47.27–47.29).

TECHNIQUES BY O'CONNELL

739.0 and 739.1: Head and Cervical Region

Head/cervical: Release across diaphragms (tentorium cerebelli to thoracic inlet) of a trauma pattern into the neck (birth trauma, personal injury, or MVA) (Fig. 47.30).

Figure 47-27 Upper extremity, radioulnar.

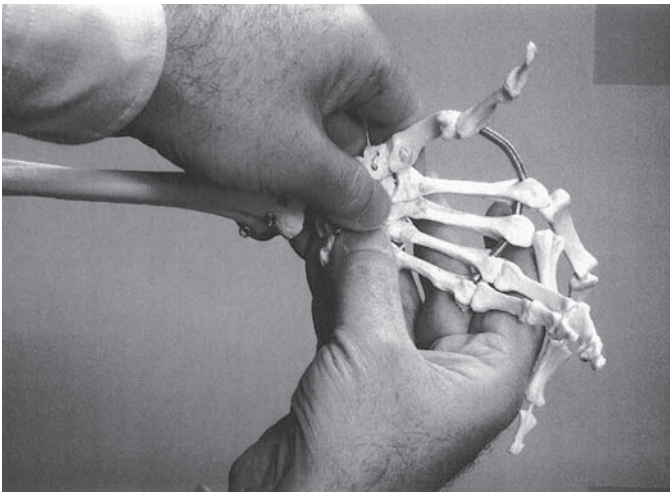

Figure 47-28 Upper extremity, wrist.

Figure 47-29 Upper extremity, hand and fingers.

Figure 47-30 Head and neck technique.

Place the patient in the supine position and sit at the head of the treatment table.

Place your hands on the head with the index fingers above the zygomatic process, the middle finger below the process, and the ring fingers behind and contacting the pinnae, taking care not to overlay the mastoidal suture, while placing the little finger on the occipital squama. Then lay the palms of your hands lightly on the head with your thumbs on the parietals. This captures the tentorium between your hands while allowing contact with the suboccipital fascia.

Sense the motion of the tentorium and note the asymmetries in motion between temporalis and occiput. Now focus on the motion of the posterior external fascial planes of the head into the neck as you continue to monitor the tentorium.

Introduce a compressive or distractive force into the tissues and a pattern of motion will become evident that travels between the tentorium and the thoracic inlet. Following this pattern along its ease or oppose the pattern and engage the motion barrier of this pattern. Since the fascia is a continuum, the trauma pattern will follow a distinct path and move across multiple structures, organs, and regions as the fascia responds intelligently to the forces. This pattern of motion reflects the traumatic pattern of strain in the tissues and reproduces the positions of trauma.

Choose a direct or an indirect approach and follow the pattern along its responsive moving barrier or point of ease as the pattern releases. Three deep respiratory cycles facilitate the release with repositioning continuously as the pattern releases.

Return the patient to neutral and retest as above taking note as to whether the pattern is extinguished.

Trauma patterns are not limited to normal physiologic motion patterns and may be confusing to the clinician, but with practice, can aid the clinician in diagnosis as well as treatment.

739.2, 739.7, and 739.8: Thoracic Region, Upper Extremity, and Ribs

Thoracic/Ribs/Sternum/Clavicle/Upper Extremity

This approach allows for anatomical access to all structures that converge at this diaphragm, the longitudinal connections between diaphragms and an excellent technique to experience a holographic release (Figs. 47.31 and 47.32).

The complexity of the motions that interface and are accessed here usually cause more complex and grosser levels of motion sensed by the clinician and the patient and is referred to as “the dance.”

Figure 47-31 Thoracic inlet approach to thoracic, ribs, and upper extremities technique.

Figure 47-32

It is important to note that this approach allows the clinician to travel the fascial continuum both diagnostically and therapeutically.

Position the patient seated on the table. The clinician stands directly behind the patient making sure the patient is slightly lower so that the clinician is able to place their hands on the thoracic inlet in a comfortable position.

The handhold is designed to capture the whole thoracic inlet with contacts on the bony anchors to the inlet. Place your hands on top of the patient's shoulders with your thumbs posteriorly with the tips pointing toward the spinous processes of C7 and T1. Anteriorly, your third and fourth fingers overly the clavicle with the tip of the fingers contacting the first rib and second rib anteriorly. Place the second finger along the shaft of the clavicle pointing toward the sternoclavicular joint. Place the fifth finger laterally toward the acromioclavicular joint. In this position, relax the hands so that the palms overly and contact the tops of the shoulders.

Assess the motion patterns in both hands simultaneously, remembering that it is usual that motion may occur in different planes and directions. With a respiratory cycle, identify the patterns of motion and choose a direct or indirect approach. With three deep respiratory cycles, follow the shifting release pattern with both hands and stabilizing the patient's torso with your own epigastrum remembering not to limit the motion, but to

dance with the patient's release. Return the patient to neutral and reevaluate the resolution of the pattern.

739.3: Lumbar Region

Lumbar: Iliopsoas release (lifting injury, short leg accommodation) (Figs. 47.33 and 47.34).

Place the patient prone on the table and stand at the side of the patient. Place your hand that is closest to the patient's head perpendicular to the long line of the spine with the spinous processes of T11-L1 in the midline of your hand. Lay your hand down with your fingers on the contralateral side of the spine and your thenar and hypothenar eminences on the ipsilateral side of the spine. This allows for the capture of the posterior fascial attachments of the respiratory diaphragm and the posterior longitudinal fascial planes of the lumbar spine/torso.

Place your other hand parallel to the long line of the spine with the palm of your hand at the sacral base and your fingers extending cephalad and spread capturing the lumbopelvic spine and fascia.

The motion in this region is more tubular in character, and as the release occurs, both hands will be moving in different directions. Assess the motion between your sensing hands with a respiratory cycle, or with palpatory listening to the innate fascial motion. Identify areas of restriction and ease between these listening posts and choose a direct or indirect approach.

Figure 47-33 Lumbar technique.

Figure 47-34

Augment the motion with three respiratory cycles and follow the shifting pattern as it releases.

Return to neutral and reevaluate the motion.

739.4 and 739.5: Sacrum and Pelvis

Sacrum/pelvis: Sacral sling release in three dimensions (fall, pregnancy pain, postdelivery pain) (Figs. 47.26 and 47.35).

Place the patient in the supine position and stand or sit next to the patient facing the pelvis.

Place one hand under the pelvis, perpendicular to the long line of the spine, with the spinous processes in midpalm with your finger tips across to the contralateral SI joint and your thenar/hypothenar eminences on the ipsilateral SI joint and relax your hand.

With your other hand, reach across the ilia grasping the contralateral anterior ilia with your finger tips and contact the ipsilateral ilia with your forearm or elbow.

With your upper arm and hand, compress the ilia toward midline, disengaging the sacrum posteriorly, which now floats in the lumbosacral fascia.

With a deep breath set the fascia in motion, identifying positions of ease and barriers to motion of the sacrum within the fascia. Become aware of the relationship between the posterior fascia and the anterior fascia, the motion into the pelvic floor and the fascial loop up into the rectus, transversalis, internal and external obliques fascia. Now become aware of the bony pelvis within this fascial container and with a deep breath, with your entry into this system, using the sacrum as a guide, go through three respiratory cycles following the three-dimensional release of the structures as direct, indirect, or combined.

Return to neutral and reassess the motion in the structures for resolve of the dysfunctions (Fig. 47.36).

739.6: Lower Extremity

Lower extremity: Tubular release of knee using heel-to-hip approach (twist of knee trauma with a stable knee) (Fig. 47.37).

Place the patient in the supine position and stand at the foot of the table.

Grasp the heel placing it in the palm of your outside hand and grip the calcaneus between your hypothenar eminence and fingers keeping the leg on the table. Place your other hand on the dorsum of the foot with your thumb wrapped under the arch.

Place the ankle in neutral position and maintain this throughout the release. Begin the release in segments from the distal to proximal extremity allowing a gradual accumulative release below and above the injured joint.

With the above handhold, lean back placing a traction force into the ankle to calf and follow the stress pattern in the tissue by positioning of the leg, taking care to make small arc motion adjustments. Continue the release with increased traction to the tibial plateau allowing for the positional pattern adjustments. Repeat this process of gradually increasing traction and following the pattern to the lower femur, mid femur and end at the hip.

Hold this position and have the patient take three deep breaths and follow the shifting pattern throughout. Return the limb to neutral and reevaluate motion, pain, and edema of the knee.

739.9: Abdomen/Other

Abdomen/other: Prostate release through the pelvic floor. Pelvic floor fascial motion is important to the proper placement and

Figure 47-35 Sacrum and pelvis technique.

Figure 47-37 Lower extremity technique.

function of the prostate that sits on top of the diaphragm. Congestion is encouraged by a lack of tone and motion in this diaphragm (Figs. 47.38 and 47.39).

Place the patient supine on the table and sit next the side of the pelvis.

Figure 47-38 Abdomen and viscera technique.

Figure 47-39

Place your hand that is closest to the patient's head perpendicular to the long line of the spine with the coccyx in the palm of your hand and contact the ischial tuberosities, contralaterally with your fingers and ipsilaterally with your hypothenar eminence capturing the posterior pelvic diaphragm.

Place your other hand parallel to and in contact with the edge of your fifth digit with the pubic symphysis. Lay your hand down flat now contacting the lower abdominal wall fascia.

Bring your awareness to the fascial motion loop between the anterior and posterior fascial planes as they converge in the pelvic diaphragm. Traveling that loop, become aware of the motion and tension in tissues, allowing a three-dimensional motion to occur between your sensing hands.

Sense the placement of the prostate (or bladder, vagina, uterus, or rectum) and the tension or ease in the fascia surrounding them.

Identify the pattern of motion ease and restriction. Choose a direct or an indirect approach, and with three respiratory cycles, follow the shifting pattern as it releases. Maintain your awareness of the viscera while you allow both of your hands to move in response to the tissue tension changes as the release progresses with the three deep respiratory cycles. Remember that these motions may take different directions and traverse multiple viscera and are diagnostic as well as therapeutic.

At the end of the release, return to neutral and reassess the motion pattern.

KEY CONCEPTS

- Osteopathy in the cranial field (OCF) delineates an anatomically based understanding of range and vector of motion and physiologic dynamics of cranial bones and intracranial structures.
- The primary respiratory mechanism (PRM) is a functional unit based on the accommodative actions of cranial articular surfaces.
- The traditional model of OCF includes five phenomena: the inherent rhythmic motion of the brain and spinal cord, fluctuation of cerebrospinal fluid, mobility of intracranial and intraspinal membranes, articular mobility of cranial bones, and involuntary mobility of sacrum between ilia.
- Evidence-based research appears to support the vast majority of the PRM phenomena and the palpatory experience of osteopathic practitioners who utilize OCF in medical practice. Ongoing research recognizes the need to provide answers to more questions.

CASE STUDY

R.R. is a 26-year-old female who presents with right-sided facial weakness, which she said she had for 1 week, accompanied by a dulled sense of taste and some trouble hearing. She reported that the day before the onset of symptoms she had been up all night studying. Her medical history was notable for an incident of facial weakness that lasted for one month when she was 7 years old. The physical exam revealed weakness of her right eyelid with delayed blinking, along with right-sided facial droop and lips that remained flat on the right side when she attempted to smile. The patient's appearance was most notable for facial asymmetry with decreased tone on the right side. The structural exam also revealed a side-bending/rotation dysfunction on the right side of the cranium. Cervical vertebrae C2 and C5 were side-bent and rotated right. The diagnosis of Bell palsy was made and osteopathic manipulative treatment (OMT) applied.

The OMT applied integrated muscle energy, myofascial release, soft tissue, and cranial manipulation. The patient's right anterior innominate was treated with muscle energy until symmetry of innominates was achieved. Thoracic outlet and respiratory diaphragms were treated with myofascial release, followed by thoracic lymphatic pump. Cervical rotation dysfunctions were treated with muscle energy. The suboccipital area was treated with soft tissue, occipitoatlanta, and condylar decompression techniques that lead to application of the Galbreath treatment (1) for mandibular drainage, which supports lymphatic drainage and temporal bone-related structure alignment. Finally, osteopathy in the cranial field (OCF) was used to balance the cranial intradural tension membranes and promote symmetry in temporal bone and sacral motion. The cerebellar tentorium served as the focus of this treatment because of its attachments—specifically its lateral attachments to the temporal bones along the petrous ridge enclosing the superior petrosal sinuses, its posterior attachments to the occipital bone forming the transverse sinuses, and its apical attachment to the cerebral falx forming the straight sinus.

The day after the treatment, the patient reported that most of her muscle tone had returned and her sense of taste was normal again. She received a second treatment, and one week after the second treatment, the patient was asymptomatic.

Central to the success of this case is the knowledge of the anatomy of the facial nerve as it traverses the temporal bone. The facial nerve exits the cranium through the stylomastoid foramen to give rise to six terminal branches leading to the muscles of facial expression. This anatomic knowledge allowed the deduction to be made that the patient's lesion was most likely at the chorda tympani. This deduction was also supported by the patient's altered sense of taste and auditory disturbances.

For further information on this interesting case, refer to the article upon which it is based (2).

INTRODUCTION

OCF has its roots in the origins of osteopathic principles, practices, and philosophy going back as far as 1899 when William G. Sutherland observed a disarticulated skull and conceived the notion of the potential for cranial bone motion (3). It has been stated that Sutherland did for the head that which Still did for the rest of the body, which was to delineate an anatomically based understanding of range and vector of motion and physiologic dynamics of cranial bones and intracranial structures. Sutherland's cranial anatomic observations and applications of the osteopathic structure-function tenet regarding cranial neuroanatomy have had reported benefit in clinical practice and have the potential to revolutionize the treatment of many neurological disorders. This chapter surveys the key concepts of OCF, its clinical applications, and the research underlying its theory and clinical applications.

HISTORY

William G. Sutherland, D.O., D.Sc. (Hon) (1873 to 1954), was an early student of Dr. A.T. Still. Sutherland graduated from the

American School of Osteopathy in Kirksville, Missouri, in 1899. While a student, he observed a mounted disarticulated skull. The sphenoid and the squamous portions of the temporal bones caught his attention, and he states, “As I stood looking and thinking in the channel of Dr. Still’s philosophy, my attention was called to the beveled articular surfaces of the sphenoid bone. Suddenly there came a thought; I call it a guiding thought—beveled like the gills of a fish, indicating articular mobility for a respiratory mechanism.”³ He dismissed the thought but it kept returning, as if goading him to study the details of the various articulations of the skull.

Sutherland was an original thinker, and his application of Still’s philosophy is recognized as “one of the most innovative ideas to be advanced by a member of the osteopathic profession” (4). Anatomy books at that time stated that the sutures of the cranium were immovable. This, however, did not deter Sutherland. He was determined to understand why the articular surfaces have such a unique design, and he persevered until he understood that the design was accommodative to the function of the central nervous system (CNS), cerebrospinal fluid (CSF), and dural membranes, all of which function as a unit. He named this functional unit the *primary respiratory mechanism* (PRM).

Sutherland established his practice in Minnesota and devoted 30 years to study, original research on himself, and observation of his patients before he began to share his discovery with his colleagues. The remarkable results he obtained with patients aroused the interest of other physicians. They prevailed upon him to teach them his method of treatment. He agreed to do so, and classes began at his home. The classes and the interest grew, slowly but steadily, because those who were able to learn the concept and apply this method of osteopathic diagnosis and treatment had similar results of relieving patients of pain and distressful conditions when other forms of treatment failed to help.

Development of the Concept

As more physicians studied and practiced Sutherland’s method of osteopathic treatment, they formed an organization, the Osteopathic Cranial Association, for the purpose of joining together to promote further study, support research, and publish literature to help educate physicians and laypersons. This membership organization later changed its name to the Cranial Academy and became a component society of the American Academy of Osteopathic Medicine.

Another, little known, pioneer of the cranial concept was Charlotte Winger Weaver, D.O. (1884–1964), a 1912 graduate of the American School of Osteopathy. Dr. Weaver was reintroduced to the profession by Margaret A. Sorrel, D.O., in the 1998 Sutherland Memorial Lecture. Dr. Weaver considered the cranial bones as modified vertebrae possessing articular surfaces and she taught her concepts through the Doctor Weaver Foundation established in 1927. Dr. Weaver did many dissections of skulls and dural membranous structures, and she had a special interest in the relationship between lesions of the basicranium and neuropsychiatric disorders. She taught that the basicranium could be distorted by birth trauma. Apparently, Dr. Sutherland knew Dr. Weaver, but their researches into the cranium were from two different perspectives and done independently (5).

In 1953 Dr. Sutherland, with Drs. Chester Handy and Harold I. Magoun, Sr, established the Sutherland Cranial Teaching Foundation, Inc., for the purpose of continuing the teaching of the cranial concept. Dr. Sutherland had established that an accurate diagnosis and successful treatment required sensitive and proficient palpation that could not be learned from a book; expert instructors using hands-on teaching and repeated verification were needed.

Dr. Sutherland’s discovery and teachings have supplied knowledge and methods that clarify and expand on the science of osteopathy. Prior to Dr. Sutherland’s work, the body was treated as if the head was incapable of having somatic dysfunction.

OCF is osteopathy of the entire person because the inherent force that manifests from within the head region functions throughout the body. Therefore, this form of diagnosis and treatment affects the whole person rather than being limited to the cranium. Furthermore, the position of the head atop the vertebral column affects the postural balance of the entire neuromusculoskeletal system. For example, if the cranial bone structures have been brought into a state of imbalance through trauma, the cranium will cause compensatory changes throughout the neuromusculoskeletal system in order to keep the equilibrium apparatus efficient in its function.

Progression and Integration of OCF in Medical Education and Clinic Practice

The teaching and practice of OCF was continued after Sutherland’s death by the Sutherland Cranial Teaching Foundation (SCTF) and The Cranial Academy. In the past 55 years of teaching and practice of OCF, there emerged a number of leaders who have preserved and advanced Sutherland’s cranial concept through their teachings sponsored by these organizations. Magoun, D.O., wrote *Osteopathy in the Cranial Field* (6), a text that for many years has been a primary reference for those studying OCF. Howard Lippincott, D.O., and his wife Rebecca Lippincott, D.O., taught with Sutherland for many years and published the first work on ligamentous articular strain based on Sutherland’s teaching (7,8). Rollin E. Becker, D.O., succeeded Lippincott, D.O., as President of the SCTF and was considered the leading teacher of OCF for many years. His writings are also a primary reference for those studying OCF (9,10). Robert C. Fulford, D.O., was a contemporary of Becker and also studied with Sutherland; his writings elaborate many cranial principles and elucidate many of the subtle aspects of OCF (11–13). Anne L. Wales, D.O., along with her husband Chester Handy, D.O., taught OCF with Dr. Sutherland and she brought into print many of Sutherland’s recorded lectures (14). Beryl E. Arbuckle, D.O., was a pediatrician and researcher who, as part of her research on OCF, attended hundreds of autopsies at the hospital of Philadelphia College of Osteopathic Medicine. These autopsies involved gross or microscopic study of the skull. Dr. Arbuckle was noted for her application of OCF on special needs children, particularly those with cerebral palsy (15). Viola M. Frymann, D.O., F.A.A.O., was also a student of Sutherland and has championed OCF with children (16). She has been instrumental in teaching and research on OCF internationally as well as in the USA (17,18). Edna M. Lay, D.O., F.A.A.O., has also been a leader in teaching OCF and working with children, and her writings have shaped the form of this very chapter in previous editions (19).

The insights and techniques derived by Dr. Sutherland’s expansion of basic osteopathic principles are increasingly integrated into osteopathic teaching and clinical care (20–22). *The International Classification of Disease, Ninth Revision (ICD-9-CM)*, delineates coding for somatic dysfunction of the cranium, and *Current Procedural Terminology* provides coding for OMT of the head. In recent years, the American Osteopathic Association (AOA) has received numerous research grant proposals from both clinicians and basic scientists to study the mechanisms and/or efficacy of this approach; the AOA has funded several of these projects (23–26).

Instruction in OCF, also commonly referred to as cranial osteopathy (CO), has been a part of standard training in departments

of osteopathic principles, practice, and manipulative medicine in all osteopathic medical schools. Concepts and terminology pertaining to OCF/CO have been developed and defined by the Educational Council on Osteopathic Principles of the American Association of Colleges of Osteopathic Medicine. They have been published in the Glossary of Osteopathic Medical Terminology, which is updated annually and is easily accessed online (27).

As the federally recognized accrediting body for residency training programs within the osteopathic medical profession, the AOA has approved the *Basic Standards for Residency Training in Neuromusculoskeletal Medicine and Osteopathic Manipulative Treatment*. OCF/CO is one of the OMT models within these basic standards. The AOA also is the federally recognized body charged with approval of certifying boards within the osteopathic medical profession. The AOA has chartered the American Osteopathic Board of Neuromusculoskeletal Medicine. This certifying board administers written, oral, and practical examinations that include items relating to OCF/CO. Questions pertaining to principles of OCF/CO appear on the written portions of the Comprehensive Osteopathic Medical License Examination (COMLEX-USA) administered by the National Board of Osteopathic Medical Examiners, and COMLEX-USA results are accepted for medical licensure in all 50 of the United States.

PRIMARY RESPIRATORY MECHANISM

Central to Sutherland's cranial concept is his integration of anatomic structure and physiologic processes into the PRM model. Many components of this model have garnered scientific verification over the last 3 decades while the rest, though plausible, await empirical demonstration.

Primary refers to first in importance and precedes thoracic respiration in importance. Dr. Sutherland posited that physiologic centers, located in the floor of the fourth ventricle, which regulate pulmonary respiration, circulation, digestion, and elimination, and depend on the function of the CNS, were primary in the maintenance of life (6) Respiratory refers to the exchange of gases and other metabolites at the cellular level. Mechanism implies an integrated machine, each part in working relationship to every other part. The PRM is described as having five anatomic-physiologic components, also often referred to as the five phenomena of OCF. These five components or phenomena are described in the following sections and include:

1. The Inherent Rhythmic Motion of the Brain and Spinal Cord
2. Fluctuation of Cerebrospinal Fluid
3. Mobility of Intracranial and Intraspinous Membranes
4. Articular Mobility of Cranial Bones
5. Involuntary Mobility of Sacrum Between Ilia

The Inherent Rhythmic Motion of the Brain and Spinal Cord

The inherent motion of the CNS is a subtle, slow, pulse-wavelike movement. It is described as having a biphasic cycle, which may have a rhythmic nature. The entire CNS shortens and thickens during one phase and lengthens and thins during the other (6). In words still relevant today, Lassek described the brain as being "vibrantly alive ... incessantly active ... dynamic ... highly mobile, able to move forward, backward, sideward, circumduct and to rotate." He further stated, "The normal, human brain is a wondrous, enormously complex, master organ which can be only made by nature. There are probably approximately twenty billion neurons

in the CNS of man and it runs on a mere 25 W of electrical power" (6, p. 23). As the cerebral hemispheres develop in fetal life, they grow, lengthen, and curl or coil within the developing cranium in the shape of a pair of ram's horns. Specific motion characteristics of cranial palpation are attributed to this configuration of brain structures.

Since the publication of Magoun's text, the delineation of embryological development principles by Jealous (28), based in large measure on the work of Blechschmidt(29,30), has increased the understanding of Sutherland's formulation of the PRM and enhanced the detailed application of OCF in clinical practice through the appreciation of the anatomic positional changes of human structures as they develop from embryonic to adult human configuration and location.

Fluctuation of Cerebrospinal Fluid

The CSF is formed by the choroid plexuses and circulates through the ventricles, over and around the surface of the brain and spinal cord through the subarachnoid spaces and cisternae and is reabsorbed in the choroid plexus. Thus, the CSF is inside and outside of the CNS, bathing, protecting, and nourishing it. Fluctuation is defined as a wavelike motion of fluid in a natural or artificial cavity of the body observed by palpation or percussion (31). From the perspective of Sutherland's concept of the PRM, as the CNS shortens and lengthens in a biphasic rhythmic motion, the ventricles of the brain change shape slightly and the fluid moves concurrently. Furthermore, the combined motility of the CNS and the fluctuation of CSF manifests as a hydrodynamic activity as well as a bioelectric interchange throughout the body. Stated simply, this combined activity of the CNS and CSF functions both as a pump and as a bioelectric generator. Recording of the bioelectric flow in fascia and connective tissue is in the piezoelectric range (32).

Mobility of Intracranial and Intraspinous Membranes

The meninges surround, support, and protect the CNS. The dura mater, the outermost of the three meningeal coverings, is composed of two layers of tough fibrous tissue. The outer layer of dura mater lines the cranial cavity, forming a periosteal covering for the inner aspect of the bones, and extends through the sutures of the skull to become continuous with the periosteum on the outer surface of the skull.

The inner layer of dura mater covers the brain and spinal cord and has reduplications named the falx cerebri and the tentorium cerebelli. These sickle-shaped structures arise from a common origin along the straight sinus and invest the various bones of the cranium. The two layers of dura mater are blended or fused in certain areas and are separated in other areas, forming the intradural venous sinuses.

The dura mater extends down the spinal canal with firm attachment around the foramen magnum and in the spinal canal of the sacrum at the level of the second sacral segment. There are also occasional attachments at C2 and C3 and the lower lumbar. The falx cerebri arises from the straight sinus, attaching to the occiput, parietals, frontals, and the crista galli of the ethmoid. The two halves of the tentorium cerebelli arise or originate at the straight sinus and attach to the occiput, temporals, and sphenoid bone.

The spinal and cranial dura with its reduplications respond to the inherent motion of the CNS and fluctuation of CSF and move through the biphasic cycle, influencing the bones of the cranium and the sacrum. Sutherland named this functional anatomic unit, consisting of the dura mater within the cranium and spinal canal,

the reciprocal tension membrane (RTM) (6). It has also been referred to as the “core link” (6) because of the potential to transmit biomechanical forces by linking the cranium to the sacrum. Influences such as trauma and postural strains that affect one part of the mechanism have been clinically observed to affect other parts of the body via this “core link.”

Articular Mobility of Cranial Bones

The most dramatic and debated phenomenon of the PRM has been the articular mobility of the cranial bones. Careful study of the design of the various articulations of the cranium and face and the RTM and its influence on the motion of the bones led Sutherland to an appreciation of the mechanical design of this anatomy and their relationship of the inherent motility of the CNS and CSF. At birth, the cranial bones are smooth-edged osseous plates with membrane and/or cartilage between them. With normal growth and motion of intracranial structures, the edges of the cranial bone plates develop and come together with sutures (joints) between them. These sutures allow for a minimal amount of motion while still providing protection for the brain. The remaining debate on the PRM model and research in support of the model are reported below.

Involuntary Mobility of Sacrum Between Ilii

The cranial dura is continuous with the spinal dura; the spinal dura extends through the vertebral canal into the sacral canal, attaching at the level of some cervical and lumbar segments and the second sacral segment. Careful study of the design of the articular surfaces reveals that the sacrum may move on one or several postural axes in relation to the ilia (pelvic bones). In addition to these voluntary or postural movements, the sacrum also responds to the inherent mobility of the CNS, to the fluctuation of the CSF, and to the pull of the intracranial and intraspinal membranes with an involuntary movement that can be observed by palpation in the living body. This slight rocking motion occurs around a transverse axis (called the respiratory axis). Normally, the involuntary motion of the sacrum is synchronous with the involuntary motion of the occiput, each bone being influenced by the rhythmic pull of the spinal and cranial dura mater.

Appreciation of the five phenomena of the PRM in theoretical and practical terms requires an integration of the anatomic and physiologic factors substantiated by empirical research, and experience-derived applications are discussed subsequently. It may help to visualize this physiologic unit of function with all five components moving slightly but steadily in the living body from before birth until death. Becker (33, p. 57) summarizes its influence on the total body economy as follows, “Health requires that the PRM have the capacity to be an involuntary, rhythmic, automatic, shifting suspension mechanism for the intricate, integrated, dynamic interrelationships of its five elements. It is intimately related to the rest of the body through its fascial connections from the base of the skull through the cervical, thoracic, abdominal, pelvic, and appendicular areas of the body physiology. Since all of the involuntary and voluntary systems of the body, including the musculoskeletal system, are found in fascial envelopes, they, too, are subjected to the 10 to 14 cycle-per-minute rhythm of the craniosacral mechanism in addition to their own rhythms of involuntary and voluntary activity. The involuntary mobility of the craniosacral mechanism moves all the tissues of the body minutely into rhythmic flexion of the midline structures with external rotation of the bilateral structures and, in the opposite cycle, extension of the midline structures

with internal rotation of the bilateral structures 10 to 14 times/min throughout life.”

RESEARCH INDICATIVE OF THE PRIMARY RESPIRATORY MECHANISM

The Inherent Rhythmic Motion of the Brain and Spinal Cord

Much of the support for this phenomenon of the PRM derives from research done in basic science and medical laboratories outside the osteopathic profession. That the CNS anatomy moves has been proven and is not a matter of controversy. Representative studies demonstrating brain and spinal cord motion characteristics are presented next.

Greitz et al. (34), utilizing magnetic resonance imaging (MRI) technology, demonstrated brain tissue movement characterized by a caudal, medial, and posteriorly directed movement of the basal ganglia, and a caudad and anterior movement of the pons during cardiac systole. The resultant movement vectors created a “funnel shaped” appearance to the brain resulting in a “piston-like” remodeling of the brain. The authors felt that this “piston-like” action of the brain during cardiac systole was the driving force responsible for compression of the ventricular system and thus the driving force for the intraventricular flow of cerebral spinal fluid.

Enzmann and Pelc (35) demonstrated brain motion during the cardiac cycle utilizing a similar MRI technology. Peak displacement of the brain ranged from 0.1 to 0.5 mm, except the cerebellar tonsils that demonstrated a displacement of 0.4 mm.

Poncelet et al. (36), using echo-planar MRI, were able to demonstrate pulsatile motion of brain parenchyma. Brain motion in Poncelet’s study appeared to consist of a single displacement during systole and a slow return to baseline configuration during diastole. This displacement includes a descent of midbrain and brainstem toward foramen magnum with velocities ≤ 2 mm/s and medial compression of thalami onto the third ventricle with a velocity of ≤ 1.5 mm/s.

Feinberg and Mark (37) postulated that the pulsatile nature of CSF flow and brain motion was driven by the force of expansion of the choroid plexus. In their study, which involved observations of pulsatile brain motion via MRI, ejection of CSF into the ventricles occurred simultaneously with reversal of CSF flow in the basal cisterns. These observations suggest that the pumping force for CSF circulation may be a vascularly driven mechanism. They reported the velocity of anterior cortex and corpus callosum movement is 0.4 ± 0.25 mm/s and motion velocity of the basal ganglia and foramen of Monro is 0.63 ± 0.5 mm/s.

Maier et al. (38) demonstrated periodic brain and CSF motion associated with periodic squeezing of the ventricles due to the compression of the intracranial vasculature. They reported peak velocities up to 1 mm/s followed by a slower recoil. Having the subject do a Valsalva maneuver (exert pressure as if trying to defecate), the brain stem showed initial caudal and subsequent cranial displacement of 2 to 3 mm. Coughing produced a short swing of CSF in the cephalic direction.

Mikulis et al. (39) demonstrated movement of the cervical spinal cord in an oscillatory manner, conducted in a craniocaudal direction during cardiac systole. They also reported maximum rate of oscillation as 7.0 mm/s ± 1.4 .

These dimensions of motion of cranial and spinal CNS structures suggest that the intracranial structures may not move as far or as fast as spinal cord structures, but these structures do all manifest motion of a precise measurable nature. This motion appears to be

related to the vascular dynamics of the circulatory system and the cardiac cycle. This element of the PRM is not controversial as such motion has been well studied and established.

The PRM also postulates a deep cellular level, life-sustaining respiratory function that contributes to the rhythmicity of the PRM. Rhythmic motion suggestive of such a phenomenon has been identified in animals and possibly humans. As long ago as 1951, oligodendrocyte tissue from rat corpus callosum was placed in tissue culture medium and photographed by ciné-photomicrography (40). The authors state, "These cells show a characteristic rhythmic pulsatility apparently identical with that described in 1935 by Canti et al. (41) in the case of oligodendrocytes obtained from in culture from oligodendroglioma of the human brain. We believe also that we have seen similar cells in a few tissue culture preparations from the cortex of the normal human brain." (41, p. 114) In 1957, Wolley and Shaw (42) reported rhythmic contractions of the oligodendroglial cells of brain and spinal cord. In the early 1960s, Hyden (43) reported that glial cells, grown in a culture, pulsate continuously.

Using more modern technology, Vern et al. (44) were able to measure rhythmic oscillatory patterns related to intracellular oxidative metabolism in the cat and rabbit. They demonstrated a synchronous rhythm at about 7 cycles/min for the creation and then utilization of cytochrome oxidase within the cells of the cortex of the test animal subjects. Dani et al. (45) showed active waves of astrocytic Ca^{2+} in the rat hippocampus in response to neural activity. Propagation of the calcium wave was usually within 5 to 6 seconds from the beginning of neural stimulation, and under constant stimulation produced waves at the rate of 2/min. The findings of these studies are indicative of a regular periodicity propagated by biochemical activity of astroglia.

Whether or not there is any biomechanical impetus to the palpable characteristics of the PRM by cellular and intracellular activity, motility as well as mobility possibly associated with a primary respiration process has been identified.

Fluctuation of Cerebrospinal Fluid

That the CSF moves in a fluctuant flow pattern through the ventricles of the brain and within the subarachnoid space around the brain and spinal cord is also a noncontroversial and well-established phenomenon. In fact, much of research cited above, which demonstrated the motion of the brain and spinal cord, also identified features of the CSF fluctuant flow.

Summarizing over a century of research DuBelay et al. (46, p. 497) stated, "The majority of workers throughout these seven decades have become convinced that the 'cardiac' CSF pressure rise measured in the ventricles, at the cisterna magna and in the lumbar theca, is caused by the rhythmic arterial input of blood to the cranial cavity." DuBelay further states, "Most authors, e.g., Becher (47), had envisaged the arterial inflow to the head as causing an expansion of the brain and of the vessels within the basal cisterns. O'Connell (48) suggested that the brain's expansion, by compressing the third ventricle, might constitute a CSF pump."

Of particular interest to the OCF practitioner is the effect of spinal dural membranes (the third listed phenomenon of the PRM discussed below) on the flow of CSF. Levy et al. (49) reported that in healthy people the spinal CSF flow rate was 12.4 ± 2.92 mm/s. In patients with spinal dysraphism (conditions like spina bifida), the rate is much slower at 2.12 ± 1.69 mm/s. In patients with spinal cord compression (such as from traumatic injury or tumors), the rate was also slowed at 1.87 ± 1.4 mm/s. They concluded further that, "The origin of cord pulsations is compatible with a direct transfer of motion from brain pulsations."

Anatomic connection between CSF flow and the lymphatic system, a long-held hypothesis in OCF practice, appears to have been established. Research by Walter et al. (50) in which india ink particles injected into rat subarachnoid space were found distributed around the olfactory nerves and within the lymphatic vessels. The authors state, "This anatomical communication, thus, allows the CNS to connect with the lymphatic system. The presence of the route may play an important role in the movement of antigens from the subarachnoid space to the extracranial lymphatic vessels, resulting in inducement of an immune response of the CNS" (50, p. 388).

Based on the widely accepted nature of the fluctuant flow of CSF as demonstrated by decades of research and clinical application, this phenomenon of the PRM appears to be supported by the evidence and is not controversial.

Mobility of Intracranial and Intraspinial Membranes

The existence of the dura mater membrane around the brain and spinal cord is well documented and utilized in anatomic research and medical practice. Every medical student and anatomist who has dissected the central nervous system has seen this membrane. Every physician who has done a lumbar puncture (or spinal tap) has felt the "pop" as the needle penetrates the dura in the procedure to obtain a sample of CSF. Those who practice OCF utilize this anatomy to treat cranial and cervical malalignment from the sacrum, or sacral malalignment from the base of the skull. These types of treatment are believed to be possible because of the hypothesized direct connection between the cranium and sacrum in the form of the dural membranes.

As a phenomenon of the PRM, the RTM anatomy has been proven useful by many clinicians in practice, but has received critical review even by cranial practitioners (51,52). Norton reported insignificant correlation between PRM rates palpated simultaneously at the cranium and sacrum (51). Chaitow (52) reported different length measurements for the spinal canal when a person was forward bent versus backward bent. While these reservations raise questions yet to be answered, other experimental and anatomic findings tend to lend support to the concept that dural membrane linkage between the sacrum and cranial base may be correct and have clinical value.

Kostopoulos and Keramidas (53) utilized a novel approach to anatomic research on a male cadaver that had been embalmed for 6 months. The brain tissue was removed through two cut windows, leaving intact the intracranial dural membranes. The measurement used was a piezoelectric element attached to the falx cerebri with the motion recorded by oscilloscope. Application of the frontal lift cranial treatment maneuver then produced a 1.44-mm elongation of the falx cerebri and a parietal lift maneuver produced a 1.08-mm elongation. Even on embalmed tissue, application of the sphenobasilar compression maneuver produced a -0.33 mm movement, and the sphenobasilar decompression maneuver a $+0.28$ mm movement of the falx cerebri. The Kostopoulos and Keramidas data suggest that for cranial structures there is an identifiable association between cranial maneuvers applied to the cranium and the movement of cranial dural membranes.

Based on MRI imagery of *in vivo* kinematic analysis of head and neck position in extension and flexion positions, Zhu et al. (54) reported relative displacements of brain with respect to skull as the head position changes. The displacements were on the order of 1 to 2 mm when the head changed positions voluntarily. The authors state, "These displacements over the normal range of head/neck flexion suggest free interfacial conditions between brain and skull" (54, p. 2).

A possible connection between the cranial structure motion and sacral motion was identified by Zanakis et al. (55). Utilizing infrared surface skin markers positioned over the subject's parietal and frontal bones, cranial bone motion was observed utilizing a three-dimensional kinematic motion sensitive system. During the study, there was simultaneous palpation of the sacrum by an experienced examiner. The findings reported a 92% correlation between the examiner who signaled perception of the flexion phase of sacral movement via a foot-activated switch and the movement of the cranial bone markers.

Given the relatively small numbers of subjects in both of the empirical studies (51,55) and the difficulties inherent in ascertaining reliable palpatory data (56), it appears that indeed further study is needed before the RTM concept can be established empirically. The implications of anatomy-based, spinal canal length differences in forward versus backward bending are also in need of further study.

Therefore, while there is no doubt as to the existence of the continuity of dural membranes around the CNS, the clinical applications of this anatomy, as postulated by the concept of the PRM, are in need of further validation. However, from the perspective of OCF practitioners who report treatment success using this particular formulation of OCF, there is little doubt of the clinical applicability of the cranial to sacral connection of the dural membranes.

Articular Mobility of Cranial Bones

The most controversial phenomenon of the PRM from a scientific perspective is the concept of palpable cranial bone motion. Misgivings have been expressed based primarily on the assumed anatomic impossibility of such motion (57,58). However, cranial sutures are constructed in such a way that motion is possible beyond simple bony compliance (Fig. 48.1). The basis of the traditional anatomic concept of cranial bone immobility is derived primarily from forensic anthropology research done to estimate the age of skeletal remains. However, there is a growing body of literature that brings into question this long-held anatomically based perspective. The challenge to the position that cranial bones are incapable of motion is based on examination of the basis for this conclusion in the first place and empirical evidence of cranial bone motion in the second place.

To appreciate the conceptual challenge implied by the concept of cranial bone motion, it is important to know that in the last century respected scientists, anatomists, and anthropologists posited

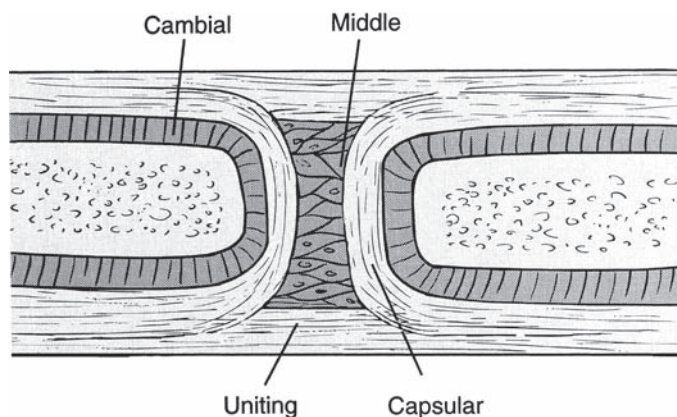

Figure 48-1 Histology of cranial sutures. (From Magoun HI. *Osteopathy in the Cranial Field*. 2nd Ed. Kirksville, MO: Journal Printing Company, 1966, with permission.)

the fusion and inherent immobility of cranial bones. Most often cited are the works of Bolk (59), Melsen (60), Perizonius (61), Cohen (62), and Sahni et al. (63) all of whom state or are reported to have held the view that cranial sutures were fused and immobile. Based on thorough examination of this debate, it may turn out that this view has been an anatomic version of “the world is flat” debate of the last millennium.

With the exception of Bolk (59), all of the aforementioned anthropologists and anatomists cite as precedent for their work, that of Todd and Lyon (64,65) as central to the idea that cranial bones fuse and therefore are immobile. There is reason to question Todd and Lyon's conclusions based on a close reading of their lengthy manuscripts. Paul Dart, M.D. (66) states, “In interpreting this data, it must be noted that Todd and Lyon were attempting to establish ‘modal’ norms for sutural closure, and they discounted data that was clearly out of the modal pattern before creating their summary. 11.7% of their 307 white male specimens and 25.8% of their 120 negro male specimens were excluded from the data due to prolonged sutural patency.”

Further reason to question the concept of universal sutural fusion was given by Singer (67). He found a high percentage of specimens with much less closure than Todd and Lyon's norms, including a 64-year-old specimen with no closure at sagittal, lambdoid, or left coronal sutures and three specimens aged early 40s with virtually no sutural closure in the coronal, lambdoid, or sagittal sutures. Also in the 1950s, Pritchard et al. commented to the effect that “Obliteration of sutures and synostosis of adjoining bones, *if it happens at all* (italics added), occurs usually after all growth has ceased. In great apes synostosis of all sutures occurs immediately after growth has ceased, but in man and most laboratory animals sutures may never completely close. These differences have been attributed to the differences in the degree of development of the masticatory apparatus” (68, p. 81).

A recent article by Sabini and Elkowitz (69) gives pictorial and systematic review of 36 human cadaver skulls ranging in age from 56 to 101 years, all well above the age when bone growth is complete. Twenty-six of the skulls showed more than 100% obliteration of the coronal suture, 31 of the skulls had unobliterated lambdoidal sutures, and 24 of the skulls had unobliterated sagittal sutures. The lambdoidal suture was the least fused on a majority of the skulls and the attachment of musculature on the occipital bone was cited as the probable cause of maintaining sutural patency. Similar to Pritchard et al. (68) Sabini and Elkowitz speculated that the chewing motion contributes to muscular tension on the bones, maintaining some degree of sutural patency. The endocranial (inner) surface of the skull was not evaluated so that no estimate of through and through fusion of each suture could be made. However, the finding of a significant amount of sutural patency (nonfusion) certainly brings into question the idea that all cranial sutures are fused and therefore cannot move.

Prior to the Sabini and Elkowitz publication, the work of Retzlaff and associates dealt directly with the nature of cranial suture morphology and cranial bone motion. Retzlaff et al. (70, p. 663) state, “Gross and microscopic examination of the parieto-parietal and parieto-temporal cranial sutures obtained by autopsy from 17 human cadavers with age range of 7 to 78 years shows that these sutures remain as clearly identifiable structures even in the oldest samples.” Retzlaff et al. (71) identified sutural elements contradicting ossification and demonstrated the presence of vascular and neural structures in the sutures. These studies also showed the presence of nerve and vascular tissue substantial enough to supply the needs of connective tissue activated beyond mere bony sutural adhesions and ossification. Additionally, Retzlaff et al. (72) traced nerve endings

from the sagittal sinus through the falx cerebri and third ventricle to the superior cervical ganglion in primates and mammals. That such structures were found in cranial sutures brings further doubt to the idea that these sutures fuse and are immobile.

Empirically demonstrated cranial bone motion in animals is well documented. Michael and Retzlaff (73) demonstrated cranial bone (parietal) mobility in the squirrel monkey. In cats, parietal bone motion in the range of 200 to 300 μm was induced by laboratory-controlled changes in the CSF volume (74–76). Jaslow (77) demonstrated in goat skulls (*Capra hircus*) that patent cranial sutures in adult animals may play a role in shock absorption and redistribution of forces directed against the skull (e.g., ballistic forces directed against the goat's skull) and during chewing movements. Thus, a compliant skull is a stronger, more resilient skull in that it is capable of absorbing and redistributing forces directed against it.

Research involving assessment of human cranial bone motion has been done by neurologists, space physiologists, osteopathic medical profession physicians, and basic scientists. In work later cited by NASA scientists, Frymann (78) developed a noninvasive apparatus for mechanically measuring the changes in cranial diameter. Cranial motion was recorded simultaneously with thoracic respiration. On the basis of her extensive recordings on one human subject, she concluded that a rhythmic pattern of cranial bone mobility exists and moves at a rate that is different than that of thoracic respiration.

In a 1981 study on two comatose patients, Heifetz and Weiss (79) used a strain gauge device that demonstrated cranial vault expansion associated with an artificially induced rise in intracranial pressure (ICP). Utilizing a head-holding device similar to Gardner-Wells tongs, accompanied by a strain gauge meter, the skull device was inserted into the calvaria above the external auditory canal. The strain gauge device employed a "Wheatstone Bridge," which was designed to detect any expansion of the skull of about 0.0003 mm or greater, which when it occurred, would produce a voltage change of 1 μV . They performed 19 trials and each time ICP was artificially elevated, there was a voltage change. This voltage change indicated that the skull tong pins were being spread apart. This could only occur with expansion of the cranial vault.

A promising approach to assessing cranial bone motion before and after cranial manipulation was carried out utilizing x-rays (Dental Orthogonal Radiographic Analysis) on 12 subjects (80). The before to after changes in cranial bone position measured in degrees ranged from 0 to 8 degrees for atlas, mastoid, malar, sphenoid, and temporal bone position. The percentage of subjects with identifiable changes ranged 66.6% with the mastoid to 91.6% for the atlas, sphenoid, and temporal bones. There are plans to expand this research utilizing a larger number of subjects.

Russian and United States Space Research

One of the strongest areas of research, which involved assessment of cranial bone motion, has been that carried out by the Russian and U.S. astronaut programs. The concerns that led to this research had to do with the nature of human response to prolonged weightlessness in space. Without gravity, would the human circulatory and CNSs function normally? In the process of assessing intracranial fluid dynamics, various types of radiographic and ultrasound equipment have been used to measure intracranial volume as well as cranial bone dimensions, and changes in these dimensions have been observed.

Yuri Moskalkenko, Ph.D. (81,82), first published research on cats in space that described "third order waves" similar to that

described above in glial cells. After being introduced to OCF by Frymann, D.O., Moskalkenko and associates carried out several studies that showed cranial bone motion. One utilizing NMR tomograms, showed cranial bone motion between 380 μm to 1 mm, and cranial cavity volume increases by 12 to 15 mL, with a rhythmicity of 6 to 14 cycles/min (83). This work was followed by a study utilizing bioimpedance measures and transcranial ultrasound Doppler echography to demonstrate slow oscillations of the cranial bones at 0.08 to 0.2 Hz (84). Moskalkenko demonstrated that these oscillations, "...were of intracranial origin and were related to the mechanisms of regulation of the blood supply to and oxygen consumption by cerebral tissue, as well as with the dynamics of CSF circulation" (84, p. 171). Moskalkenko and Frymann have carried this work into a formulation of a theory that explains the physiology of the PRM (85).

In the mid-1990s, NASA was also concerned about intracranial fluid volume changes in astronauts in space. NASA carried out research and developed an ultrasound device, pulse-phase locked loop (PPLL), with sensitivity to 0.1 μm , to more precisely assess intracranial anatomy and physiology (86). This NASA team at the Ames Research Center carried out a series of studies (87–90).

On two fresh cadavera (<24 hours post mortem), female 83 and male 93, ICP pulsations were generated manually by infusing saline into the intracranial ventricular system at a rate of 1 cycle/s (1 Hz) (87). In this study, an increase in ICP of 15 mL Hg caused a skull expansion of 0.029 mm, and this was interpreted by the authors as similar to that found by Heisey and Adams (74), Frymann (78), and Heifetz and Weiss (79).

In another study, seven healthy volunteers fitted with the PPLL device were placed in 60 degree, 30 degree head-up tilt, supine, and 10 degree head-down tilt positions. The average path length from forehead to occipital bone increased 1.038 ± 0.207 mm at 10 degree head down tilt relative to 90 degree upright. "In other words, when intracranial pressure increases, arterial pulsation produces a higher amplitude ICP pulsation. Increased amplitude of ICP pulsations will be manifested by larger fluctuations in distance across the skull" (88, p. 3).

Summarizing their work to a certain point, the NASA research team stated, "Although the skull is often assumed to be a rigid container with a constant volume, many researchers have demonstrated that the skull moves on the order of a few micrometers in association with changes in intracranial pressure" (89, p. 66). In their last publication in this series, they state, "...analysis of covariance revealed that there was a significant effect of tilt angle on amplitude of cranial diameter pulsation ($p < 0.001$). . . . As a result, amplitudes of cranial distance pulsation increased as the angle of tilt decreased. The observed changes in cranial diameter pulsation are considered to be statistically significant" (90, p. 883).

Contemporary Osteopathic Research on Cranial Bone Motion

Research comparing palpatory assessment of cranial bone motion with simultaneous assessment by laser Doppler flowmetry technology has been done. Striking correlations have been found between cranial palpation reports and the technologically measured physiologic motion phenomena identified by the laser Doppler flowmetry. Nelson et al. (91–94) posit that it is the Traube-Hering and Meyer oscillations that they have identified. Based on laser Doppler flowmetry electronically recorded on humans, they described oscillations that occur about 4 to 6 cycles/min. In their studies, these oscillations have been shown to correlate with reports of phases of cranial bone motion as reported by osteopathic cranial practitioners.

These investigators proposed that Traube-Hering and Meyer oscillations comprise all or account for most of the cranial bone motion palpated by cranial practitioners. To have instrumented recordings of physiologic activity correlated to the palpatory experience of OCF practitioners constitutes support for the PRM and the concept of cranial bone motion.

Another approach to examining cranial bone motion was carried out by Crow et al. (95,96) This group utilized MRI imagery of eight slices each through the same calvarial plane on the heads of 20 healthy subjects. ImageJ (97) analysis from the National Institutes of Health showed that there were significant differences ($p < 0.003$) between the means for largest and smallest cranial bone dimensions for area. The mean difference was 122.69 mm² for the area analyzed on the outer table of the cranial bones. The significant differences in this intracranial dimension would not be possible if cranial bones were not capable of motion. The authors suggested the intracranial area change may be related to intracranial fluid volume changes.

The evidence for cranial bone motion is increasing in number and quality, but the nature of the motion has more questions to be answered. Commentary that holds to the “cranial bones are fused” perspective is particularly critical of the sphenobasilar junction mobility model (98). In answer, Cook (99), an OCF practitioner with a background in engineering and computational fluid mechanics, presents a plausible model based on cranial bone compliance and flexibility that would explain the palpatory experience of OCF practitioners.

Involuntary Mobility of Sacrum Between Iliia

That the sacrum moves in its position between the ilia is an anatomical fact. It would not be possible for humans to walk or run if the iliosacral joints did not allow motion. It is hard to imagine, but for centuries it was believed by scientists of the day that the pelvis was a solid array of bone and that there was no independent motion of the sacrum.

The biomechanical dimensions of iliosacral joint motion were delineated by Weisl in the mid-1950s (100). Elaboration on iliosacral motion characteristics was done by Kissling (101) who has subjects perform flexion and extension movements of the spine as well as one-legged stance to induce sacroiliac motion. The range of motion was 0.2 to 1.6 mm, with an average of 0.7 mm for males and 0.9 mm for females. Other research describes a number of different axes of sacral motion, a concept already well integrated into OMT training programs, with motion noted to be in the range of 1 to 3 mm (102).

As seen in the now-settled debate over sacroiliac joint motion, history may be repeating itself in the debate over cranial bone motion. It is unfortunate that today there is doubt about cranial bone motion despite the growing evidence for the reality of this phenomenon.

The controversy of sacral motion from the perspective of the PRM has to do with the nature of the impetus for the sacral motion. There is some evidence to support the contention of *involuntary active motion* of the sacrum between the ilia. Mitchell and Pruzzo (103–105) demonstrated a horizontal axis for sacral motion located anterior to the second sacral segment. Movement around this axis was measured at 0.9 to 4.7 mm at the sacral apex, and the impetus for this motion was simply breathing, which associated sacral motion with the normal respiratory excursion (103). While this research establishes normal respiratory motion as one impetus for sacral motion, other research describes the sacral motion induced by the PRM as separate and distinct from motion caused by respiratory excursion (78).

Furthermore, the correlation of sacral motion with cranial bone motion has not been established empirically (51), and may be related to the apparent differences in spinal canal length previously mentioned by Chaitow (52) who cites the work of Butler (106).

OCF Research Status

Evidence-based research appears to support the vast majority of the PRM phenomena and the palpatory experience of osteopathic practitioners who utilize OCF in medical practice. However, more questions need to be answered and these questions are subjects of ongoing research. Based on the preponderance of evidence supportive of OCF, the succeeding sections will elucidate the classic OCF concepts taught in osteopathic medical schools and osteopathic training programs worldwide.

MECHANICS OF PHYSIOLOGIC MOTION

The overall shape of the skull is that of a relative sphere with its inferior surface indented. The sphenoid and occiput meet to create this indentation, which is slightly convex on its superior surface. These two midline bones form the key articulation of cranial bone motion at the sphenobasilar symphysis (or synchondrosis) in the base of the skull. This is a cartilaginous union up to the age of 25 years and thereafter has the resiliency of cancellous bone (107).

The overall motion of the cranium is similar to the motion of the chest during respiration, but the two do not occur simultaneously. Thoracic respiration occurs 12 to 16 cycles/min in adults and up to 44 cycles/min in newborns (108); the most frequently encountered motion of the PRM normally occurs 10 to 14 cycles/min (6).

The terminology used to describe the directions of motion of the various bones is similar to that for the motions of the spine and extremities. Midline bones (the sphenoid, occiput, ethmoid, vomer, and sacrum) move through a flexion phase and an extension phase around a transverse axis, while paired bones move through external and internal rotation. They are moved through this biphasic cycle in response to the pull or influence of the dural membranes, which are influenced by the coiling and uncoiling of the CNS and the fluctuation of the CSF. This motion, initiated from within the living body, is referred to as inherent motion or involuntary motion.

With flexion of the sphenobasilar symphysis, there is slight increase in the convexity of the superior surface of the joint. At the same time, the area where the coronal and sagittal sutures join, called bregma, descends. Palpation in the flexion portion of the biphasic cycle senses that the head widens slightly in its transverse diameter and shortens slightly in its anteroposterior (AP) diameter as the paired bones move toward external rotation. With extension of the midline bones, the head narrows and lengthens slightly as the bregma ascends, and all paired bones move toward internal rotation.

During the biphasic cycle, the osseous cranium changes shape slightly but allows some intracranial fluid volume change. The research of Heisey and Adams (74) and Moskalenko (83) suggests there is enough cranial bone compliance and “sutural stretch” to allow as much as a 15-mL intracranial fluid volume change.

During flexion, the sacrum is influenced by the spinal dura and core link and moves posterosuperiorly at its base while the apex moves anteriorly toward the pubes. During extension, the base moves anteriorly and the apex moves posteriorly. This motion occurs around a transverse axis in the area of the second sacral segment posterior to the sacral canal and is called the respiratory axis of the sacrum. The other axes of sacral motion are postural axes (Fig. 48.2).

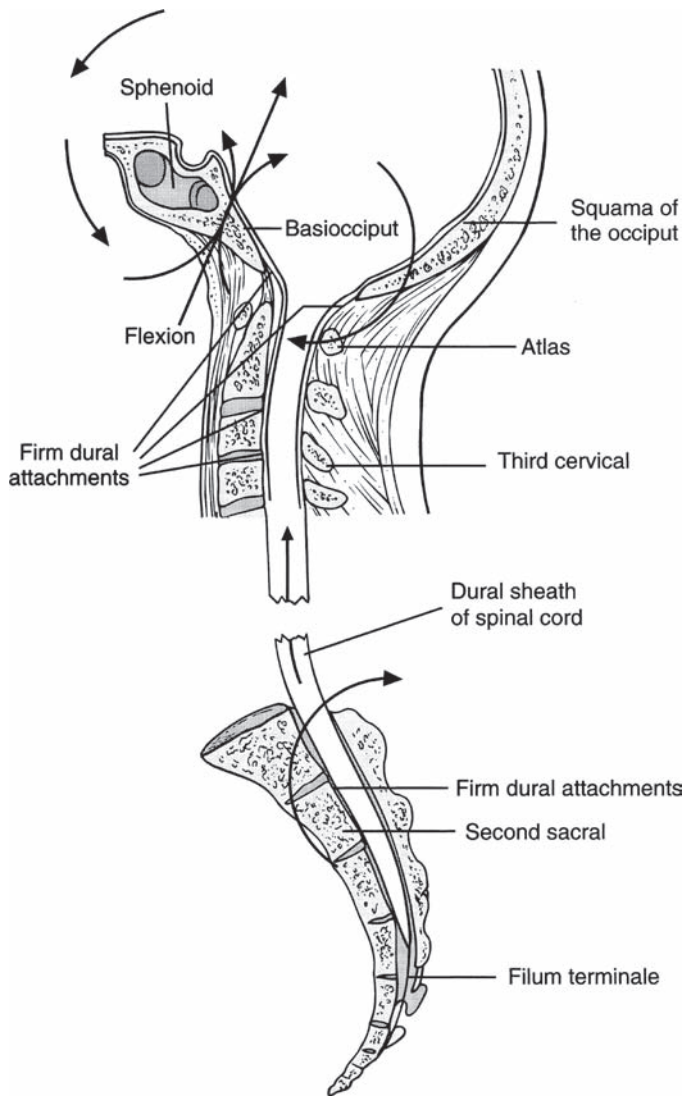

Figure 48-2 Craniosacral mechanism with arrows indicating direction of motion during flexion phase of physiologic motion. (From Magoun HI. *Osteopathy in the Cranial Field*. 2nd Ed. Kirksville, MO: Journal Printing Company, 1966, with permission.)

PALPATION OF THE PRIMARY RESPIRATORY MECHANISM

The inherent motion of the cranium is not visible but it is palpable. This motion is perceived as a subtle, soft, slight movement of fluid (CSF) and semifluid (CNS) inside an osseous case. The first attempts at this palpatory exercise may not reveal anything, or you may feel the subject's thoracic respiration transmitted through the neck to the head. If the breathing is a distraction, ask the patient to hold their breath for a moment. If you can still sense the rhythmic motion in the head, the inherent motion is coming from within the cranium. With palpatory experience, one learns to distinguish between these different motions.

Follow these steps to palpate this rhythmic motion:

1. Position the patient supine, with the head 8 to 10 in from the head of the table
2. Sit comfortably at the head of the table with your forearms resting on the table and your hands placed on the sides of the

3. Contact the patient's head lightly, allowing the fingers and part of the palms to gently conform to the curvature of the head. (It is essential that the palmar surface of all the fingers, but not the thumbs, contact the head because the nerve endings that sense the subtle cranial motion are proprioceptors located in tendons and around joints. The numerous tactile sensors in the fingerpads are not as receptive to this motion. Even though a gentle and light contact is essential, it is not a fingertip contact.)
4. Allow your mind to become quiet and direct your attention to the space between your hands, allowing what is sensed by your proprioceptors to be perceived by your brain. Continue to stay relaxed; do not try to feel something. If the patient's head has fairly normal motion, you may feel a slow, rhythmic swelling or widening followed by a receding or narrowing. This constitutes one cycle of inherent motion. This cycle is usually steadily repeated. The motion is so mild and subtle that it may actually feel as if the head is breathing

Subtle motion is easier for some physicians to palpate than for others. Some find this difficult to sense because they try too hard. Their intensity is so set, their effort so strong, that they block their own sensorium. It is essential to be relaxed, physically, mentally, and emotionally. Your attitude should be similar to one who is trying to hear a minor sound—complete attention is given to listening.

Keep the hand contact light. Pressure by the hands will suppress the inherent motion and/or distract the sensors (proprioceptors) in the hands. If excessive hand pressure is continued, the patient may get a headache.

If you have difficulty perceiving the motion in one patient, try other patients. The cyclic characteristics of the motion and its amplitude (strength or power) usually vary from one individual to another. The biphasic cycle of motion of the PRM most often encountered occurs 10 to 14 times/min, although it can occur at somewhat faster or slower rates. When observing the rate, allow one full minute and count the number of cycles (one flexion phase plus one extension phase equals one complete cycle).

Evaluating the amplitude, or quality rather than rate, of the PRM in patients who have clinical problems requires experience but has been found to be statistically possible (109) and may reveal the most useful clinical data about the patient. After palpating five or ten individuals, one can determine that the strength or vitality of the rhythm is stronger in one or two individuals, fair or medium in some, and weak or poor in others. Experience with palpation has shown that the rate and amplitude of the PRM, when considered in addition to clinical knowledge of the patient's history and symptoms, becomes an additional diagnostic indication of their state of health and is helpful in determining a prognosis.

There are many scenarios in which the rate and quality of the PRM may be increased slightly:

- Following vigorous physical exercise
- With systemic fevers
- Following effective OMT of the craniosacral mechanism

The rate and quality of the PRM may be decreased in the following situations:

- Stress (mental, emotional, physical)
- Chronic fatigue
- Chronic infections
- Mental depression and other psychiatric conditions (110)
- Chronic poisoning
- Other debilitating conditions

The cyclic, biphasic motion originating within the PRM, is most evident to palpation in the head region but is palpable in every part of the body. The impulse moves longitudinally through the body and extremities, with midline structures moving through flexion/extension and paired structures moving through external/internal rotation. Its presence or absence and its deviation from normal direction are useful diagnostic signs.

The body is subject to stresses and strains from before birth until death. Pressures and forces affect the developing fetus, the neonate during birth, and the individual through childhood, adolescence, and adulthood. These forces cause minor to major distortions of the cranium that result in strains of the sphenobasilar synchondrosis (SBS). With induced strain, the efficiency of the PRM is compromised. The compromise may be minor to major in its effect on the health of the individual.

STRAINS

Several types of strains of the SBS are known and frequently encountered in the practice. In order to understand a discussion of strain patterns, it is necessary to know some terminology and to recall some basic principles of anatomy. The portion of the occiput that is at the base of the skull and is part of the SBS is called the basiocciput. Likewise, the part of the sphenoid that lies at the base of the skull and is part of the SBS is the basisphenoid. When we discuss motion of these bones, we name the motion for what is occurring at the most anterior and superior portion of the structure. However, the major articulation that concerns us in the following discussion of strain patterns is composed of the anterior portion of one bone (the occiput) and the posterior portion of another bone (the sphenoid). So, when motion occurs in the same direction in the two bones, the two bones appear to move in opposite directions at the SBS. Keeping these principles in mind will help you understand the following discussion of strain patterns.

Torsion occurs around an AP axis of the skull that extends from nasion through the symphysis to opisthion (Fig. 48.3A). The sphenoid and related structures of the anterior cranium rotate in one direction about this axis; the occiput and related structures of the posterior cranium rotate in the opposite direction, producing a twist or torsion at the SBS. This strain is named for the side of the high wing of the sphenoid, right torsion (RT), or left torsion (LT).

Side bending/rotation (SBR) at the SBS occurs around an AP axis and around two parallel vertical axes. The AP axis is the same as the axis around which torsions occur. The vertical axes are through the body of the sphenoid and through the foramen magnum, perpendicular to the physiologic transverse axes and the AP axis (Fig. 48.3B). This is a compound movement similar to physiologic motion in the spine when rotation and side bending are concomitant movements. Because the sphenobasilar symphysis is slightly convex upward, as the two bones side bend away from each other (around the two parallel vertical axes), both bones rotate inferiorly on the convex side (around the AP axis) and superiorly on the concave side. This strain pattern is named for the side of the convexity, SBR right (SBR_R) or SBR left (SBR_L). These four strain patterns (RT, LT, SBR_R, SBR_L) are common and are considered physiologic if their presence does not interfere with the flexion-extension motion of the mechanism.

Extreme or exaggerated flexion with decreased extension of the SBS is considered a strain pattern. Conversely, marked or exaggerated extension with decreased flexion is considered a strain pattern. Normally, the PRM moves through the flexion and extension phases equally and fully.

Figure 48-3 Schematic patterns of sphenobasilar junction. In torsion and SBR, sphenoid and occiput rotate in opposite directions about axes indicated. **A.** Torsion with great wing high on the right. Occiput is lower on the side of high great wing. **B.** SBR with convexity to the left. Both great wings of sphenoid and occiput are lower on the side of convexity. (From Sutherland WG, Wales AL. *Teachings in the Science of Osteopathy*. Portland, OR: Rudra Press, 1990, with permission.)

Vertical and lateral strains or displacement occur at the SBS and can be superimposed on the above strains. Vertical strain at the SBS is present when the sphenoid and the occiput rotate in the same direction around their own transverse axes (Fig. 48.4A). This creates a superior or inferior strain at the SBS and disrupts normal flexion-extension. Vertical strain is named for the position of the basisphenoid relative to the occiput, superior, or inferior.

Lateral strain at SBS occurs when both bones rotate in the same direction, clockwise, or counterclockwise, around two parallel

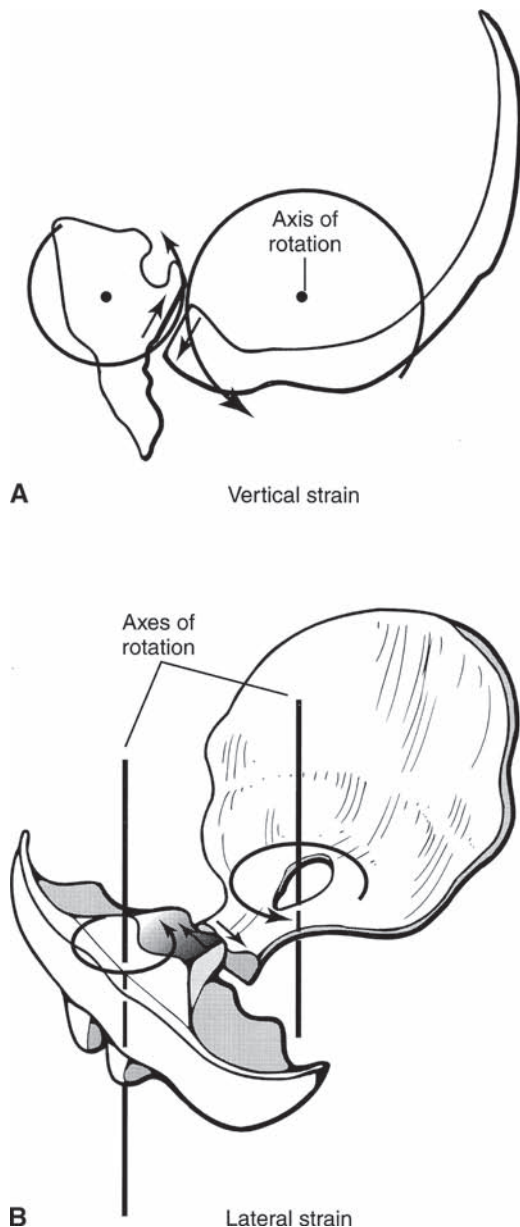

Figure 48-4 Schematic patterns of sphenobasilar junction. In vertical and lateral strain patterns, sphenoid and occiput rotate in the same direction around parallel axes. **A.** Superior vertical strain. As a result of rotation of the bones, the base of the sphenoid is relatively elevated with the base of the occiput relatively depressed. **B.** Right lateral strain. As a result of rotation of the bones, the base of the sphenoid is relatively displaced to the right with the base of the occiput relatively displaced to the left. (From Sutherland WG, Wales AL. *Teachings in the Science of Osteopathy*. Portland, OR: Rudra Press: 1990, with permission.)

vertical axes (Fig. 48.4B). Basisphenoid and basiocciput veer in opposite directions, producing a shearing type of motion. When this strain occurs *in utero* or during the birth process, it results in a parallelogram-shaped head in the infant. Lateral strain is named for the direction the basisphenoid shifts, right or left.

SBS compression is a strain in which the sphenoid and occiput have been forced together to such a degree that physiologic flexion-extension is impaired. Compression varies from mild to moderate to severe and occurs from a force to the back of the head, to the

front of the head, or from a circumferential compression (as during birth) that exceeds the resiliency of the tissues.

Strains of the SBS involve the entire cranial and facial structure and influence the position and motion of the sacrum by way of the RTM. The midline bones and paired bones accommodate to the strain(s) in the base of the skull. Trauma to the head, face, spine, sacrum, pelvis, or lower extremities is a common strain-producing factor. Pelvic function is affected by a strain in the base of the skull. Likewise, the function of the cranial bones is affected by strain in the pelvis. The body, including the head, truly functions as a unit.

PRINCIPLES OF DIAGNOSIS

The diagnosis of a pathologic condition or malfunction of the PRM is based on the history, observation, and palpation. Palpation by a well-trained and sensitive operator is the most reliable source of information.

Patient History

Taking the patient's history includes asking leading and pertinent questions to encourage the patient to recall relevant past events and to describe the complaint in some detail. In addition to the usual questions pertaining to heredity, childhood diseases, adult diseases, and surgeries, two other areas for questioning are pertinent to dysfunction of the cranosacral mechanism: trauma history and information about the delivery and newborn recovery period.

Trauma

Obtain the following information about trauma:

1. Age at which the trauma occurred; this includes birth trauma.
2. Type of force as well as amount, velocity, direction, and the area of impact; vehicular accidents, blows to the face or head, and falls on the tailbone or buttocks are common
3. Dental history including extractions, orthodontia, malocclusion, bruxism, and temporomandibular joint problems
4. Fractures, concussions, inertial injuries, coma
5. Habitual head pressures, such as sleeping positions, thumb sucking, ear phones, orthodontic head gear, new dentures, etc
6. Extremes of temperature: chilling of the face or head may precede Bell palsy; heatstroke or sunstroke may be related to headache
7. Surgical procedures involving the head such as the mouth gag, the bite block, the bronchoscope or gastroscope, or the anesthetic mask held over the nose-mouth for prolonged periods with a tight headband to keep it in place
8. Changes in appearance or personality following severe trauma

Adult patients tend to recall only injuries of the recent past. They believe that injuries from infancy, childhood, or adolescence are of no importance and tend to forget past trauma. They may need leading questions to elicit this information. Some patients have amnesia related to trauma to the head and cannot relate accurate information. A family member may be able to give additional history.

History of Delivery and Newborn Period

If the patient is an infant or child, a more detailed history from the parent(s) is essential. Questions concerning the health of the mother during pregnancy, the number and character of pregnancies, the details of the delivery, the appearance and action of the newborn, and the development of the infant should be asked. Signs and symptoms compatible with severe forces of labor and delivery

are an indication for considering OMT in the care of these patients. Following is a list of signs and symptoms that might indicate that a newborn has experienced severe forces during labor and delivery:

- Distortion of the cranium
- Excessive molding
- Ridging or overriding along any suture
- Difficulty in suckling or swallowing
- Vomiting
- Respiratory distress
- Bradycardia
- Tachycardia
- Abnormal crying
- Strabismus
- Nystagmus
- Spasticity or flaccidity of the limbs
- Opisthotonos
- Drowsiness
- Cyanosis
- Convulsions
- Fever
- Tremors

Abnormal habits such as lying with the head turned to one side only, head banging, or constant rubbing of the back of the head against the sheet are indicative of strains of the cranium.

Diagnosis by Observation

Look for symmetry or distortion of the osseous structure beneath the soft tissues. Observe the face and head: the shape and contours of the head and face show hereditary influences as well as the combined effect of the forces of labor on the bones. At birth, the sphenoid, temporals, and occiput are made up of several osseous parts with cartilage between parts and between bones to allow for compression and molding of the head during birth. Strains within a bone may occur and are called intraosseous strains.

The flexion type of skull is round in shape with a wide transverse and a shortened AP diameter, with the temporals in relative external rotation (flared laterally). In this type of skull, the frontals are wide and sloping upward, the cheek bones are wide, and an open mouth view of the maxillary region of the hard palate reveals it to be wide and with a low arch to the vault. All paired structures are in a position of relative external rotation.

The extension type of skull is long and narrow with temporals in relative internal rotation, frontals narrow with the brow appearing more vertical, orbits and face narrow, and maxillae (hard palate) narrow with a high arched vault. All paired structures are in a position of relative internal rotation.

Note the positioning of the bones. The position of the sphenoid bone influences the position of the peripheral bones of the anterior cranium, which includes the frontals and all bones of the face except the mandible. The position of the occiput influences the position of the bones of the posterior cranium (the parietals and temporals) and in turn influences the position of the mandible.

With torsion and SBR of the SBS, the facial structures tend to appear asymmetric as they assume a position of relative external rotation on the side of the high wing and a position of relative internal rotation on the side of the low wing. If the sphenoid is rotated on an AP axis, the eyes and orbits will appear unlevelled, as will the cheekbones and the maxillae.

Note the relative positioning of landmarks. It is sometimes difficult to determine if the occiput has rotated on the AP axis because it is hidden by hair. As the occiput tilts on this axis, it carries the

temporals with it. The temporal on the low side of the occiput is positioned toward relative external rotation, and the temporal on the high side of the occiput is positioned toward relative internal rotation. Therefore, the relative position of the ears gives an indication of the tilt of the occiput. Compare right and left ear lobes to see if they are level; note flaring of the ears. A temporal positioned toward external rotation tends to be more flared; a temporal positioned toward internal rotation tends to be more flat. By combining the findings of the anterior and posterior cranium, the observer is able to arrive at a tentative or working diagnosis of torsion or SBR of the SBS.

Viewing the midline of the face, noting the nose, mouth, and center of the chin, provides additional information. Nasal deviation may indicate the relative position of the maxillae and sphenoid or may indicate past trauma or fracture. The chin (mandible) tends to deviate to the side of the externally rotated temporal bone. Heredity also influences facial characteristics and is a significant consideration for establishing a prognosis.

Strains of the cranial base occur during birth or from trauma. If trauma is induced into a prior strain pattern, the findings of observation are not reliable for diagnosis.

Diagnosis by Palpation

To become an expert at the art of palpation for diagnosis and treatment requires repeated experience, patience, and perseverance. These guidelines help improve palpatory skill:

1. Use a light hand contact. If your contact is stronger than the force of the inherent motion, you interfere with the mechanism you are attempting to diagnose or treat. Do not interject yourself into the patient's PRM.
2. Have a clear visualization of the structure(s) beneath your hands. This requires a detailed study of the anatomy and physiologic motion of each of the bones of the body, including the cranium and face. The design of the articulations between bones and their mechanical and physiologic relationship is a complex study, but it is essential to providing accurate diagnosis and successful treatment.
3. Understand that the job of the physician is to assist the patient to obtain or maintain optimal health. The physician does not do the healing; healing comes from within the patient. With knowledge and experience, one learns to tune into and be guided by the PRM of the patient to facilitate this healing process, assisting the patient's own inherent healing capacity to release biomechanical impediments. The automatic processes that promote healing are much more intelligent and efficient in the management of the health of the individual than any external force or person can be.

CLINICAL CONSIDERATIONS

Neonatal

OMT of infants and children can be a rewarding experience for the patient and the doctor, because children respond to treatment faster than adults and because treatment in this stage of life can prevent dysfunction later in life.

Compromised function of the PRM is a cumulative process beginning *in utero* or during birth, combined with the various traumatic incidents of growing up, as well as one or more traumatic events sustained as an adult. The physician must keep this in mind when taking the history.

Consideration of the trauma of the birth process deserves further explanation. The base of the skull is formed in cartilage and

Figure 48-5 Sphenoid at birth in three parts. Cartilage intervenes between body-lesser wing unit and greater wing-pterygoid units. (From Sutherland WG, Wales AL. *Teachings in the Science of Osteopathy*. Portland, OR: Rudra Press, 1990, with permission.)

the vault is formed in membrane. At birth, the sphenoid is in three parts, the temporal is in three parts, and the occiput is in four parts, with cartilage intervening between the osseous elements (14). The frontal and mandible are in two parts and each maxilla is in two parts. This is nature's way of protecting the CNS and providing for compressibility of the head as it passes through the birth canal. The bones of the vault are osseous plates that overlap at the edges. The cartilaginous base tends to compress, bend, twist, or buckle depending on the amount and direction of compression and rotational forces of labor and birth. These various parts are vulnerable to misalignment; the brain, cranial nerves, and intracranial membranes are subject to possible injury or malfunction. One or more of the strain patterns of the SBS generally has its beginning during the birth process (Figs. 48.5 and 48.6).

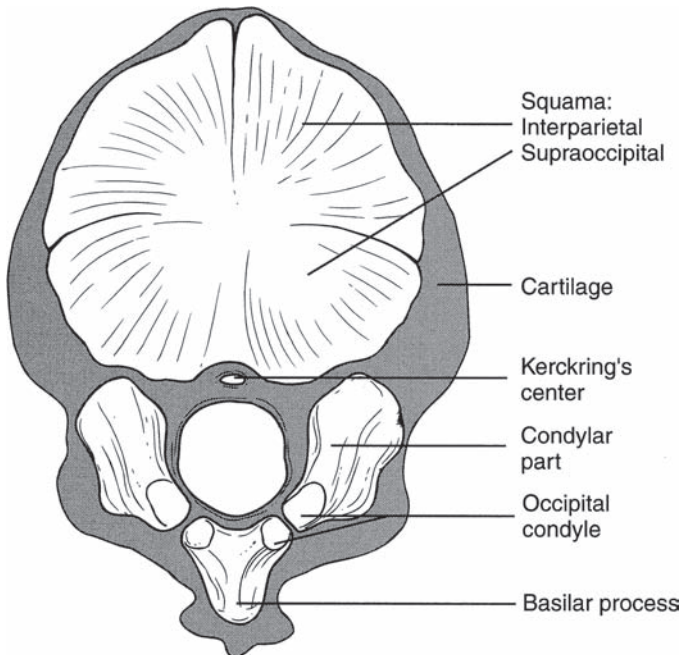

Figure 48-6 Occiput at birth in four parts within a cartilaginous matrix. Articular condyles receive contributions from both condylar and basilar parts of the occiput. (From Sutherland WG, Wales AL. *Teachings in the Science of Osteopathy*. Portland, OR: Rudra Press, 1990, with permission.)

The infant's first breath and subsequent crying with deep breathing, kicking, squirming, and suckling assist with decompression of the cranium, face, and pelvis (14). Decades of clinical experience have shown that if the activities of the neonate are not strong enough to open up the entire PRM to its optimal function, these neonates benefit from the assistance of an osteopathic physician trained in the cranial concept and in treatment procedures. Examination and treatment are best given during the first few days of life, at which time a great deal is accomplished by releasing the compressive forces of birth. If no treatment is provided, as time passes and growth progresses, the strains become more established. In time, the formative parts of the various bones of the base change from cartilage to osseous tissue. If overlapping of the osseous plates of the vault is allowed to remain, the plates grow together, forming a synostosis. Osteopathic physicians utilizing OCF have found that when synostosis pervades the vault, the osseous case cannot grow and expand at the same rate as the brain inside, and the brain function of that individual appears to be compromised. Expert treatment given early in the life of an individual can be one of the most important therapeutic measures in preventive medicine. Treatment given later is beneficial, but more can be accomplished in less time and with less effort and expense if treatment is given soon after the stresses and strains occur.

An example of disturbance of function directly related to the compressive forces of birth concerns the posterior part of the cranial base. There are four parts to the developing occiput:

- The basilar process
- Two condylar parts along the lateral sides of foramen magnum
- Squama extending from the posterior border of the foramen magnum to the lambdoid suture

The medulla oblongata rests on the basilar part, and the spinal cord extends through the space within the four parts. Cranial nerves IX, X, and XI and the jugular veins pass through the jugular foramina at the anterolateral border of each condylar part. Cranial nerve XII passes through the anterior condylar canals located within the condylar parts near the junction between the condylar parts and the basilar part. Compression with rotation of the posterior cranium during birth with distortion, displacement, and jamming of these four osseous plates and intervening cartilage is easily visualized (see Fig. 48.6). Knowing the function of these cranial nerves and their intimate relationships with the bones of the cranial base makes it easy to see how distortion of the cranial base could lead to symptoms such as vomiting, torticollis, or respiratory distress.

This abnormal mechanical stress on the brainstem, cranial nerves, and venous drainage is treated by gentle application of mild, sustained spreading of the formative parts of the base of the skull by a physician trained to apply OMT in this manner.

The relative position and motion of the temporal bones affect drainage from the middle ear through the pharyngotympanic tube; their somatic dysfunction is clinically capable of resulting in tinnitus, dizziness, and decreased auditory acuity. Treatment is aimed at releasing membranous strains of the cranial base, temporal bones, and upper cervical spine to help reestablish equal and synchronous motion to the temporals as well as the entire PRM. Consider these factors:

1. Without normal motion present, stasis of fluids and lack of oxygen provide an ideal medium for proliferation of microorganisms
2. When the inherent motion throughout the cranium and face is optimal, the movement of fluids and mucus is enhanced (a provision of nature for emptying the ethmoid, sphenoid, and maxillary sinuses)

3. The autonomic nerve supply to the nasal mucosa by way of the sphenopalatine ganglion is vulnerable to impingement by malaligned adjacent bony structures
4. Middle ear infections, sinusitis, pharyngitis, and other acute inflammatory processes are often associated with altered cranial functions (111)

Trauma

Trauma is by far the major cause of disruption and malfunction of the PRM. The force of trauma is extreme in vehicular accidents. The force from a fall is transmitted from the feet or ischial tuberosities upward through the body into the base of the skull. The vector of force established through the body or head is palpable (112,113) and is an important diagnostic sign. The direction of motion of the CSF and CNS is disrupted, and the function of the PRM is mildly to severely impaired, depending on the severity of the trauma and the response of the patient.

Trauma to the PRM can occur from mild, sustained force such as wearing a spring type of headset or from orthodontic appliances on the teeth (114). Also, wearing a tight hat or swim cap will augment or create or alter existing patterns. Trauma occurs in various degrees and in innumerable forms.

The PRM functions as a unit; trauma to one area affects the entire RTM. The PRM does its best to continue to function, but the quality of that function decreases with the passage of time and additional trauma. The rate and amplitude of the PRM is a most valuable diagnostic and prognostic indicator of the severity of the compromise and response to treatment (9). A slow rate and a low amplitude are dependable indicators of a longstanding and/or overwhelming problem during which the patient's vitality has been depleted, indicating more treatment over a longer period of time will be required (9). The reciprocal is also true. In the course of treatment, improvement is associated with a rate and amplitude increase toward a more normal pattern.

CLINICAL RESEARCH

The foregoing discussion of the types of conditions that benefit from application of OCF and the principles of treatment is based on the consensus of teachers of OCF with many years of successful clinical practice.

The development of clinical research on OCF has grown as resources for such research have become more available, but there has always been a scientific, systematic observational discipline applied by those who used OCF in the medical practice. Over the years, there have been a number of reports of the clinical applications of OCF. Some of the earliest appeared in the OCF text by Magoun (6, p. 112) with charts done by G. A. Laughlin, D.O., which showed an apparently reduced sweat production before and after application of the technique known as the compression of the fourth ventricle (CV₄). This appeared to reflect a decrease in sympathetic nervous system activity, which has also been demonstrated in more recent research (115). Also in the Magoun text are illustrations documenting, in a group of five patients, substantial lowering of blood sugar and white blood cell counts before and after application of the CV₄ (6, p. 113).

The Magoun text devotes a chapter to the "Practical Application of the Cranial Concept," and reports on a number of conditions in which application of OCF techniques has proven beneficial for the individuals involved. A number of these applications of OCF are amplified in other publications (116–118).

It is significant to note that OCF treatment is like any other modality of OMT in the hands of a capable osteopathic physician.

It is the specific attention to the anatomy of the particular part of the body being manipulated that facilitates the OMT and enhances the probability of benefit. Furthermore, it is the knowledge of anatomy and especially neuroanatomy in the cranial area that provides the basis for a strong rationale for how OCF might be beneficial. This point is exceedingly well illustrated in a series of articles by Magoun on the theme of entrapment neuropathy in the cranium (111,119,120). That is, if cranial bone motion exists and OCF maneuvers can affect cranial bone and intracranial structures such as cranial nerves, then there may be great utility in applying such technique in clinical practice.

From a philosophy of science perspective, appropriate application of OCF based on systematic observation of anatomic relationships palpated by the osteopathic physician and correlated with changes in the patient's symptoms is indeed scientific procedure. It remains for the osteopathic medical profession to develop documentation procedures that will facilitate collection of this type of data from many physicians utilizing OCF and thereby obtain large-scale population data appropriate for analysis. In the meantime, those who utilize OCF in clinical practice are following a tried and true scientific methodology in the application of OCF: practice based on proof of benefit to patients as reported by many clinicians on many patients. This is the principle of appeal to authority and precedence of success by practice. Gradually, empirical clinical practice studies are being carried out and published. Many of the clinical observations made at the time of Sutherland and the early cranial osteopaths have begun to receive scientific support.

Otitis Media

The location of the eustachian tube within the temporal bone and the possible derangement of the temporal bone during a difficult labor and delivery comprise the anatomy and life circumstance that have been described as the basis for the application of OCF to the treatment of otitis media. The clinical success reported by OCF clinicians has been validated by positive results in several studies and has resulted in plans for a multisite clinical trial (121–123). These studies showed improvement in health as measured by fewer ear tubes, improved tympanography assessment, and generally reduced need for antibiotics in children suffering from recurrent ear infections (otitis media).

Pregnancy, Labor, and Delivery

The prenatal application of OMT has been a staple of the osteopathic medical profession since its inception (124). Clinical research on the application of OMT in prenatal care has a long history too. As early as 1911, studies on 100 of women who received prenatal OMT were published, and benefits such as shorter durations of labor and fewer complications were reported (125). In a study where the application of OCF was not the only OMT modality applied in prenatal care, but was included in OMT delivered to virtually every patient, the results were statistically significant ($N = 321$ patients) for fewer preterm deliveries and fewer cases of meconium-stained amniotic fluid (126).

A promising pilot study that awaits a larger follow-up was done by Gitlin and Wolf (127) on women who were overdue to deliver and had not yet perceived uterine contractions. Eight women were treated using only the CV₄. Two were eliminated due to disruption during the posttreatment monitoring, while the other six all began uterine contractions within 34 minutes with an average of 17.5 minutes. The theory underlying the use of the CV₄ is that this maneuver "helps nature take its course." It is probably incorrect to

be concerned about the use of the CV₄ in pregnant women out of fear of inducing contraction, as the women in this study were “over due” and the OCF only facilitated a normal gestational phase.

Pediatric Applications

Besides the previously mentioned research on otitis media, the general concern for the effects of a difficult labor and delivery involves many unfortunate outcome possibilities. Frymann (128) evaluated the cranial bone mechanics of 1,250 newborns and found that 88% had identifiable malalignment in the form of cranial bone strain patterns. Frymann (129) has gone on to present data indicating benefit of OCF in the treatment of children with learning problems, children with neurological deficits (130), and seizure disorders (131).

Inspired by Frymann's work, research was done in Russia by Lassoetskaia (132) on children with language and learning problems. In this study, 96 children undergoing neuropsychological tutoring in a large school program due to delayed academic performance were selected and compared to the performance of the rest of the children before and after receiving OCF for 6 to 12 weeks. The children who received the OCF were significantly higher in virtually all categories of academic performance compared to the comparable population of children who did not receive OCF.

As with all OMT, OCF is described as an effective means to correct anatomic malalignment and restore optimal physiologic function by improving the anatomic structures associated with those functions. For example, in the treatment of colic, the commonly found impingement of the tenth cranial nerve (which coordinates the peristaltic wave action of the gastrointestinal tract) as it passes through the jugular foramen, caused by compression of the nerve during the birth process, between the occipital and temporal (mastoid area) bones, can be relieved by gentle OCF to decompress and relieve the obstructed flow of coordinated nerve supply to its intended destination. In fact, a recent pilot study found that the OCF applied to infants with colic did significantly reduce the symptoms of colic (134). Obstructive sleep apnea in infants may also be reduced by osteopathic treatment employing OCF (135). Mobility in children with cerebral palsy has been improved with OMT including OCF (136).

Dental Applications

Because the teeth are cranial bones that move within their sockets, which are in turn housed in cranial bones, application of OCF for treatment of dental conditions can and has been used successfully in practice. In a series of articles, Magoun (137–139) gives case studies and specific technique for OCF treatment of individuals whose cranial malalignment involves dentition. Lay carried on this work on dental applications and described more case studies utilizing OCF with an emphasis on temporomandibular joint dysfunction (114). With the publication of these articles, many dentists have been attracted to study and even apply OCF in their practices. There is even a special membership section within The Cranial Academy for dentists.

Empirical research was done by Baker (140) who demonstrated measurable changes in the dental arch of a patient receiving OCF. Serially measured models of maxillary teeth over six months showed overall lateral dimensional changes between permanent second molars of 0.0276 of an inch. It is common in the practice of orthodontics today to move the maxillary arch this much and more, up to 2 mm by dental appliances, but in the case reported by Baker, the changes were brought about by OCF alone.

It is worthy of note that musculoskeletal deformities, specifically scoliosis and pronounced kyphosis dorsalis (Scheuermann disease), have now been associated with malocclusion (141). This finding substantiates emphasis on early childhood treatment and prevention championed by practitioners of OCF.

Effects of OCF on Vascular and Autonomic Nervous System Functions

A commonly applied OCF technique called the “venous sinus technique” has been reported by many who practice OCF to be successful in the relief of headache and sinus congestion symptoms. A study by Huard (142) suggests that the efficacy of this technique may be in the restoration of optimal intracranial vascular flow. Huard applied the venous sinus technique to 39 subjects, with 39 others receiving light touch only, and another group of 39 subjects received no touch at all. The outcome measure was a radiology procedure called the encephalogram, which utilizes ultrasound technology to record blood flow. Huard's results showed that the subjects receiving the OCF venous sinus technique had demonstrably improved blood flow in the area of the cranial base.

A study by Cutler et al. (115) showed statistically significant effects of application of the CV₄ on sleep latency and the reduction of sympathetic nerve activity. In a controlled environment, healthy subjects who received the CV₄ treatment went to sleep faster than subjects who received only a light touch control protocol or no touch at all. Sympathetic nerve activity, measured at the peroneal nerve in the popliteal fossa using standard microneurographic technique, was also significantly reduced in the CV₄ group compared to control or no treat groups.

Further evidence of the impact of OCF on physiological function is the work on healthy humans that showed a statistically significant improvement in heart rate variability. In this study, Giles et al. (143,144) used soft tissue manipulation to the cervical spine with emphasis on the occipitoatlantal decompression maneuver, a commonly OCF technique. With an $N = 24$ in a crossover design, heart rate variability was best when the OCF was applied compared with sham and time control conditions. Using a similar design, Henley et al. (145) also found alterations in heart rate variability as a result of OMT that utilized several OCF maneuvers. A study done in Israel evaluated the impact of cranial manipulation on urinary tract function and quality of life in outpatients with multiple sclerosis (146). Results showed statistically significant reductions in postvoiding residual volume, urinary frequency, urinary urgency, and improvement in quality of life. The nature of OCF suggests impact on parasympathetic centers in the lower brain stem and in the sacral spinal cord may be the likely mechanism of action in this study.

Clinical Research—Summary

OCF clinical research compares favorably with the amount of clinical research done on the other commonly used OMT modalities. From a technical perspective, the application of OCF takes longer than other OMT modalities and is often not applied due to time restraints. Critics of OCF cite lack of clinical evidence for benefits thereof and raise the question of risk-benefit ratio. However, there has been only one report of an adverse event from the application of OCF, and the teaching and practice of OCF have been modified to take into account factors that may cause adverse events (147). On the other hand, improvement reported in the reviewed clinical articles on OCF is certainly suggestive, if not compelling, evidence of benefit for OCF.

PRINCIPLES OF TREATMENT

The aim of treatment with OCF, as with any osteopathic procedure, is to normalize structure and function. The optimal function of the PRM affects not only the CNS but also every cell and tissue in the body. Regardless of which method or procedure a physician elects to use, this constant cyclic motion is at work behind the scenes every minute of every hour of every day of every year of an individual's life.

Goals of Treatment

The goals of treatment include:

- Normalizing nerve function, including all cranial and spinal nerves as well as the autonomic nervous system
- Counteracting stress-producing factors by normalizing function of the cerebrum, thalamus, hypothalamus, and pituitary body
- Eliminating circulatory stasis by normalizing arterial, venous, and lymphatic channels
- Normalizing CSF fluctuation
- Releasing membranous tension
- Correcting or resolving cranial articular strains
- Modifying gross structural patterns

Some hindrances to treatment are myofascial strains from below the cranium or from the sacrum, local or general infections, nutritional deficiencies, and organic poisons (6). For optimal management of the patient's health problems, the physician must address nonstructural hindrances to health, in addition to applying OMT. To use the power or potency of the inherent activity of the PRM within the patient to assist with the release of strains (somatic dysfunctions), it is necessary to understand balanced ligamentous tension and balanced membranous tension. Balanced ligamentous tension is used in treating any articulation supported and protected by ligaments. Balanced membranous tension refers to the dura mater (RTM) and is used to treat the articulations of the cranium, face, and sacrum.

The point of balanced membranous tension is defined as that point in the range of motion of an articulation where the membranes are poised between the normal tension present throughout the free range of motion and the increased tension preceding the strain or fixation that occurs as a joint is carried beyond its normal physiologic range (6). Thus, it is the most neutral position possible under the influence of all the factors responsible for the existing pattern. That is, all attendant tensions having been reduced to the absolute minimum.

This point is unique for each strain that occurs. It is the point at which the inherent force can move through the involved tissues at its maximum efficiency. The operator seeks to position the bones making up the articulation at the point of balanced membranous tension by keen, sensitive, knowledgeable palpation. Dr. Sutherland expressed this as palpating with seeing, feeling, thinking, knowing fingers.

Figure 48.7 illustrates arriving at the point of balanced membranous tension by positioning the components. The squares indicate two bones making up an articulation, and the arrows represent the directions the operator employs for positioning (6).

Figure 48.7A illustrates indirect action or exaggeration. This procedure is commonly employed from the age of 5 through adulthood. It is not used in acute trauma to the head when exaggeration of misalignment may produce or increase intracranial hemorrhage. To employ this method, increase the abnormal relationship at the joint by moving the articulation slightly further in the direction of malalignment.

Figure 48-7 Methods for arriving at the point of balanced membranous tension. **A.** Indirect action (exaggeration). **B.** Direct action. **C.** Disengagement. **D.** Opposite physiologic motion. (From Magoun HJ. *Osteopathy in the Cranial Field*, 2nd Ed. Kirksville, MO: Journal Printing Company, 1966, with permission.)

Figure 48.7B illustrates direct action. This treatment method is employed when exaggeration is not desirable, as in acute trauma and in young children in whom the sutural pattern has not yet developed. This treatment is also used when there are overriding sutures. The components are gently guided back toward their normal position.

Figure 48.7C illustrates disengagement. This treatment method is used when force or excessive membranous tension impacts the osseous components. Disengagement technique merely separates the opposing surfaces within the anatomic and physiologic limits of permitted motion.

Figure 48.7D illustrates opposite physiologic motion. This method is seldom used, but when needed it is employed to release a strain when a traumatic force has severely violated the physiologic pattern. One component is influenced by direct action; the other is influenced by indirect action.

The physician selects the method of choice according to the patient's age and history, as well as by palpatory diagnosis.

Respiratory cooperation may be used to enhance the effort of inherent motion. The patient is asked to hold their breath in full inhalation or exhalation after the physician has positioned the articulation at balanced ligamentous or membranous tension. Holding the breath at full inhalation is more commonly used, but if the articulation is held toward extension or internal rotation, holding the breath at full exhalation is more effective.

Example 1

An example would be a case in which the patient reports a history of a fall on their rear end, possibly from a slip on a banana peel.

Diagnosis

Somatic dysfunction of the lumbosacral junction (L5-S1 compression).

Treatment

Treatment is indirect method, using balanced ligamentous tension, exaggeration, and inherent force.

Procedure

1. Position the patient supine
2. Sit at the side of the table so that the operator's dominant hand (assume right hand) can be placed under the patient's sacrum
3. Place the right hand under the sacrum so that the patient's coccyx rests between the operator's thenar and hypothenar eminences. The finger tips should be placed at the sacral base with the 3rd and 4th digits just below L5
4. Place the left hand perpendicular to the right hand with the hypothenar eminence barely touching right hand fingers and in firm comfortable palpatory contact with L5

5. Maintain this position and allow the inherent force to work. Keep your sensing apparatus alert so that it perceives the slow cyclic movement of the PRM. This movement feels like a longitudinal ebb and flow or a subtle pumping effect up and down the spine
6. Continue to maintain the positioning and to observe this cyclic motion; the inherent force is working through the tissues that are maintaining the somatic dysfunction. As they accomplish their task for this articulation at this time, the amplitude of the inherent rhythm lessens and the pumping decreases, and the tissues beneath your palpating fingers seem to soften or melt. Once the tissues have softened, the flexion and extension motion of the sacrum begins to increase. As flexion and extension motion of the sacrum increases toward normal, it may be necessary to gently pull caudad on the sacrum before full motion is restored
7. At this time, cease to hold the articulation in the treatment position. Gently recheck the motion of the articulation to ascertain the therapeutic response. Physiologic motion is restored to varying degrees

A strain of the sacral base can be treated using the inherent forces and positioning for balanced membranous tension of the RTMs. This technique is applicable for an uncomplicated strain of the sacral base. If a strain of the sacral base is complicated by additional traumatic strains such as a compression in either sacroiliac (SI) joint, the technique as described will probably not be successful.

If SI joint compression is present, treatment position will vary slightly. If, for example, the patient's left SI joint is compressed, the doctor's left hand will be under the sacrum. This hand maintains the same position as for treatment of sacral base compression. However, the operator's other hand (in this case the right hand) would be placed under the ilium, perpendicular to the fingers of the left hand. The fingertips of the right hand would be at the medial border of the left ilium and would barely touch the 5th digit and hypothenar eminence of the left hand. As in step 6, maintain this position while observing the cyclic motion of the PRM. In this case, rather than providing caudad traction, it may be necessary to provide gentle lateral traction until normal balance between the motion of the sacrum and the motion of the ilium is restored.

Example 2

Another case is a patient who has been struck on the side of the head, possibly by a baseball bat or fist.

Diagnosis

Somatic dysfunction of the sphenobasilar symphysis is SBR right (SBS is SBR_R).

The sphenoid and occiput have rotated on an AP axis so that the right side of the cranium is relatively inferior (caudad) and the left side is relatively superior (cephalad). Concomitant with that position, the greater sphenoid wing and the lateral angle of the occiput on the right side are slightly spread and the greater sphenoid wing and the lateral angle of the left occiput are slightly approximated.

Treatment

Treatment is indirect method, balanced membranous tension, with exaggeration and inherent forces to balance the RTM.

Procedure

1. Position the patient supine
2. Sit at the head of the table

Figure 48-8 "Vault hold" for contact of the cranium. (From Hruby R. *Craniosacral Osteopathic Technique: A Manual*. 2nd Ed. Okemos, MI: The Institute for Osteopathic Studies, 1996:331, with permission.)

3. Place your hands on the lateral sides of the patient's head with the index fingers contacting the greater wings of the sphenoid and the little fingers contacting the lateral angles of the occiput (vault contact) (Fig. 48.8)
4. Gently palpate the rhythmic activity of the patient's PRM and RTM
5. The right hand slowly moves slightly caudad with index and fifth fingers spreading slightly, while the left hand moves slightly cephalad as the fingers approximate slightly. This positioning is slight and must be accurate, being guided by the ease of tension in the membranes within the cranium. With the ease of membranous tension, the inherent forces begin to manifest with increased vigor. The amplitude of the PRM automatically increases
6. Maintain the positioning and carefully and continuously observe the increased activity of the inherent forces at work within the patient's mechanism. As the inherent forces work through the membranous strain, they gradually cease the increased activity and become quiet. This cessation of the inherent rhythm is called a still point (14)
7. After the still point occurs, cease to maintain the positioning of the bones and membranes and continue to observe the fluctuant activity by light palpation. The quiet period passes, the rhythmic fluctuation resumes, increasing slowly and steadily in amplitude until it has returned to a more normal flexion-extension of the SBS
8. Gently remove your hands

There is no substitute for thorough training and practice in the development of skill in OMT based on the principles of OCF/CO. Well-known and typically utilized treatment procedures based on the principles of OCF/CO are the compression of the fourth ventricle (CV₄) and the V-spread procedures.

The CV₄ (Fig. 48.9 A,B) is typically used to stimulate the body's inherent therapeutic capacity to deal with whatever dysfunction is present. By inducing extension (or internal rotation) of the PRM, the inherent capacity for self-regulation and healing is facilitated by a stimulation of CSF flow.

The technique is as follows:

1. Operator at head of table
2. Patient supine

Figure 48-9 Compression of fourth ventricle (CV_4). **A.** Hand position for CV_4 technique. **B.** CV_4 technique. (From Hruby R. *Craniosacral Osteopathic Technique: A Manual*, 2nd Ed. Okemos, MI: The Institute for Osteopathic Studies, 1996, with permission.)

3. With both hands palm up, place one hand in the palm of the other so that the thenar eminences lie parallel to one another. Then slip the hands under the head, permitting the lateral angles of the occiput medial to the occipitomastoid suture to rest on the thenar eminences. The thenar eminences provide a cushion for the occiput that should be comfortable for the patient and operator. The fingers are free and not pressing on the neck. The weight of the head rests on the thenar eminences and thereby gently compresses the lateral angles
4. Become aware of the cyclic motion of the occiput. Follow it toward extension (i.e., as the hands rock gently toward the operator). Discourage flexion (hands moving away). The amplitude of the motion will get progressively smaller until the still point is reached. The still point may be difficult to detect because it passes so swiftly. However, it is followed by a sense of softening and warmth in the occiput and the gentle rocking motion of flexion and extension that should be more easily detectable. At the same time, thoracic respiration should become primarily diaphragmatic and approximate the same cycle as the PRM
5. Observe the cranial activity to be sure that it remains quiet and then very gently remove your hands and put the patient's head on the table. Figure 48.9 demonstrates the CV_4 via the occiput, but it is also possible to accomplish a CV_4 via the temporals, parietals, and sacrum

Figure 48-10 V-spread of occipitomastoid suture. (From Hruby R. *Craniosacral Technique: A Manual*. 2nd Ed. Okemos, MI: The Institute for Osteopathic Studies, 1996, with permission.)

The V-spread (Fig. 48.10) is a very simple, safe technique for releasing any peripheral suture such as frontonasal, nasomaxillary, or occipitomastoid. The technique is as follows:

1. Place the index and middle fingers of the ipsilateral hand on either side of the suture. For a linear suture like the occipitomastoid, use the palmar surface of the length of two fingers. For a small suture like the frontonasal, use the fingertips
2. Place the palm of the other hand on the patient's head at the other end of the longest diameter of the head from the suture (e.g., for the left occipitomastoid), place the hand on the right frontal only. You will soon perceive a gentle impulse coming into the palm of this hand. Now cluster the fingers at the site of that impulse. You have thereby localized the optimum place from which to direct a palpatory sensation of a "fluid wave" to the restricted suture. As long as the suture is restricted, the fluid sensation will "bounce" back, but as soon as it releases, you will feel a gentle, easy motion between your hands

Treatment procedures of the cranium should be used only by physicians experienced with palpation of the subtle activity of the PRM. Guidance by a physician experienced with the function of the PRM and the inherent forces is essential to learning this technique.

SUMMARY

Much research remains to be done in order to demonstrate the exact mechanisms involved in craniosacral dysfunction and recovery. However, more than 55 years of clinical experience has indicated that the use of OCF/CO has given relief to many patients in whom no other treatment was effective.

KEY CONCEPTS

- Astute clinical observation (Jones) followed by progressive exploration of a line of thought represents the development of this approach.
- Treatment of somatic dysfunction can be enhanced by placing the patient's body in a position of maximum comfort. Effective use of this approach requires exploration of anterior and posterior body areas for appropriate diagnosis(es).
- Correlations between symptoms, history and physical examination, structural findings and associated tender points are necessary preparation for utilization of this approach.
- Tender points described and utilized in this approach are most commonly found in muscle tissue. Explorations of muscle involvement through research activity continue to elaborate the involvement of various body systems.

CASE STUDY

A 45-year-old male presents to the office with a complaint of non-radiating low back pain of 2 weeks' duration. The pain is described as an intense deep pain at times and achy at other times. It is worse when he tries to stand upright. The problem began 2 weeks ago when he spent a day cleaning out his garage. After working most of the day bending and lifting to go through boxes and move them into a storage cabinet, he lifted a very heavy box of books. He was bent over at the waist and had barely lifted the box off the ground when he felt a sharp pain in his low back. He dropped the box and, as a reflex reaction, stood up quickly. He went inside to sit down to rest, and when he tried to stand up from the chair, he had a low back spasm and could not stand upright. Over the course of the last 2 weeks, he has tried hot showers, a heating pad, a topical analgesic cream, and Extra Strength Tylenol, all without much benefit. The patient denies any change in bladder or bowel function.

Physical examination:

Vital signs within normal limits (P: 72, R: 14, BP: 118/74, T: 98°F), HEENT, cardiovascular, pulmonary and abdominal exams are within normal limits. Neurological exam: normal lower extremity DTRs (2+/4+ bilaterally) and normal sensation in the lower extremities. Straight leg raising test is negative. Structural exam reveals a discrete area of intense tenderness to palpation and tissue texture abnormalities at the level of the anterior superior iliac spine (ASIS), one-third the distance to midline and deep in the abdomen bilaterally over the iliopsoas muscles with the left more tender than the right.

Diagnosis:

1. Lumbar strain, left greater than right
2. Somatic dysfunction—lumbar spine and abdomen

Plan:

Osteopathic manipulative treatment using counterstrain with good results and well tolerated by the patient.

Discussion:

The initial injury occurred when the patient used the erector spinae muscles from a stretched position as the agonist to lift a

heavy load. Due to muscle fatigue from lifting and bending all day and the heavy load, he strained the erector spinae muscles that produced the pain. When he stood up rapidly to protect the strained erector spinae muscles from further damage, the rapid lengthening of the shortened antagonist iliopsoas muscles reported a strain to the central nervous system before an actual strain occurred. This resulted in hypershortened iliopsoas muscles containing Jones tender points. The lumbar strain (erector spinae) will heal, but the Jones tender points will remain in the muscles until the somatic dysfunction is treated.

INTRODUCTION

Initially, Lawrence H. Jones, D.O., F.A.A.O., referred to his new treatment approach as *spontaneous release by positioning* (5) but found this term to be cumbersome. Dr. Jones decided to use a shorter term, *strain-counterstrain*, describing what he believed was more descriptive of the underlying physiologic mechanism he used to treat somatic dysfunction. Jones, once he formalized its teaching, always referred to the manipulative treatment model he developed as strain-counterstrain. In this chapter, we refer to this method as *counterstrain*, the terminology used in the Glossary of Osteopathic Terminology (Educational Council on Osteopathic Principles, 2009) and by most practitioners.

Manipulative treatment models are divided into two primary divisions: direct and indirect, based on the initial positioning of the patient relative to the restrictive barrier. Counterstrain is an indirect model with the initial positioning away from the restrictive barrier. It has a unique advantage over other manipulative treatment models in that the patient can provide feedback to the physician to indicate when they are in the correct position for treatment. The model is also highly accessible to the student who has limited palpation skills and treatment experience. In fact, counterstrain is often taught early in an osteopathic curriculum because it is a treatment model that novice students can use and experience success. Additionally, if the student pays attention to the tissue changes under their monitoring hand, they will learn to palpate the more subtle tissue changes needed to be effective in applying other manipulative

treatment models. While counterstrain can be learned early in manual skills development, it can continue to be used effectively as the sole manipulative treatment model by experienced physicians and is also used in combination with other models.

HISTORY

Counterstrain began as an unexpected discovery in 1955. A young, athletic-looking man visited Lawrence H. Jones, D.O., F.A.A.O. (Jones, 1981), because he had developed a psoasitis 2½ months before seeking treatment that left him in pain and unable to stand erect. The injury was not caused by trauma, but it gradually worsened over the 2½ months. Since the onset, the man had received treatment by two chiropractors with no substantial improvement. Jones treated the man several times with thrust-type treatment over the course of 6 weeks with no better results.

At one visit, the man reported difficulty sleeping due to pain. Jones worked with the patient for 20 minutes to find a comfortable sleeping position. After finding the position, Jones left the young man in the position and went to treat another patient. When Jones returned, he assisted the young man to a standing position and to their mutual surprise, the patient stood erect and pain free for the first time in 4 months. Jones was impressed by the results and decided to investigate these findings.

Jones experimented by treating patients with whole-body positions of comfort. He had frequent success and wanted to shorten the time in the treatment position. He observed that there were discrete tender paravertebral areas prior to treatment that became pain free after time in the position of comfort. Dr. Jones then began positioning only the affected region of the body, and this reduced the time in the treatment position. He experimented with reducing the amount of time needed for treatment. Ninety seconds in the position of comfort proved to be the optimal time required to benefit the patient. Shorter periods of time did not always produce lasting relief, and longer periods did not necessarily yield greater benefit. He also began mapping the discrete areas of tenderness and correlating them to specific somatic dysfunctions identified by the traditional methods he learned in osteopathic medical school.

Jones found that he could only find the discrete paravertebral areas of tenderness in half of his patients. More answers came when Jones saw another patient he was treating for psoasitis who thought he developed a hernia from an accident in his garden. Although the physical examination revealed no inguinal hernia, there was a

discrete area of tenderness. Jones placed the man in a position of comfort to treat the psoasitis and then palpated the tender area from the groin injury. To their mutual surprise, the tissue was no longer tender. Jones slowly returned the patient to a neutral position and palpated the area again. He found no evidence of tenderness.

Jones had discovered that there were anterior as well as posterior tender points. He began to search for tender points on the front of the body (Jones, 1966). This observation is consistent with the osteopathic principle of the body is a unit. The emphasis on spinal function and posterior diagnostic evaluation had eclipsed this connection.

Other treatment approaches to the musculoskeletal system have identified discrete areas of tense tender tissue. Travell (Travell and Simons, 1999) developed an approach and used the term *trigger point* to describe tense areas. Jones et al. (1995) initially used the same term, but later referred to these areas as *tender points*. Jones described over 300 specific tender points, and new tender points continue to be found. Through correspondence, Travell and Jones identified similarities and differences between their points. Table 49.1 provides a comparison of trigger and tender points.

Jones' theory for the mechanism of action in counterstrain is that the initial injury produces a sudden "panic" lengthening of the antagonist muscle to the originally strained and painful agonist muscle. Jones treated the tender point associated with the asymptomatic antagonist muscle by shortening this muscle, which also places the originally strained and painful muscle back into a stretched position, the position of the original strain, thus producing a counter to the strain.

Dr. Jones made two important discoveries:

1. Placing the body into a position of maximum comfort can treat somatic dysfunction
2. The anterior aspect of the patient must be evaluated, as well as the posterior, to effectively diagnose and treat somatic dysfunction

THEORETICAL PHYSIOLOGIC BASIS OF COUNTERSTRAIN

Physicians have demonstrated the clinical benefits of counterstrain for over 50 years (Anonymous, 1989; Bailey and Dick, 1992; Brandt and Jones, 1976; Cisló et al., 1991; Jacobson, 1989; Jones, 1973; Radjieski et al., 1998; Ramirez et al., 1989; Schwartz, 1986). Counterstrain basic research has been limited to only a few studies. (Howell et al., 2006; Luckenbill-Edds and Bechill, 1995; Wynne

TABLE 49.1

Comparison of Trigger Points and Tender Points

Trigger Point	Tender Point
Patient presents with characteristic pain pattern	Typically no characteristic pain pattern
Located in muscle tissue	Located in muscle, tendons, ligaments, and fascia
Locally tender	Locally tender
Elicits jump sign when pressed	Elicits jump sign when pressed
Elicits a radiating pain pattern when pressed	No radiating pattern when pressed
Present within a taut band of tissue	Taut band not present
Elicits twitch response with snapping palpation	Twitch response not present
Dermographia of skin over point	Dermographia not present

et al. 2006). One study showed a change in the muscle spindle following counterstrain treatment, supporting Dr. Jones hypothesis (Howell et al., 2006). More studies need to be done, especially electromyography studies of tissues containing the tender points, to demonstrate the specific muscles, ligaments, etc. associated with the somatic dysfunction.

Understanding muscle physiology provides some answers because tender points are most commonly found in muscle tissue. The neural system is another key component in the development and maintenance of somatic dysfunction. A third element important to understanding counterstrain is the role of the circulatory system.

At the time Jones was formulating his ideas about counterstrain, Korr (1974) published an article on proprioceptors and somatic dysfunction, which helped to explain the role of the proprioceptors in muscle tone and the response to injury. Another important part of the model is the gamma system and its role in muscle tone. Van Buskirk (1990) described the important role of nociception in somatic dysfunction. The role of the circulatory system has been described (Rennie et al., 2004) and needs further exploration and has not yet been adequately explained.

One of the most important characteristics of the counterstrain model is the relationship between tender points and somatic dysfunction. The location of a specific tender point is constant from one patient to another. This suggests a strong anatomic basis for their location. Different myofascial structures including tendons, ligaments, fascia, and muscle bellies have all been found to contain tender points. Myotomal, dermatomal, and sclerotomal relationships have been proposed to explain the relationship between a specific anatomic segment and the related tender points (Beal, 1985; Yates and Glover, 1994; Rennie et al., 2004). Another interesting anatomic correlation is the close location of tender points in areas where *motor points* are found (Rennie et al., 2004). A motor point is the site where the motor nerve pierces the investing fascia and enters the muscle it innervates.

Mapping the pathways of afferent nerves and the central system is important to understanding the role of the afferent nervous system. The bulk of afferent input comes from the soma (as opposed to the viscera). This difference is so great that nociceptive messages from the viscera are typically interpreted as being of somal origin. This unequal distribution can also be seen with the illustration of the homunculus in the cerebral cortex. The homunculus illustrates the proportional area in the cortex devoted to sensing and interpreting afferent input from different locations in the periphery. The neuronal "crosstalk" in the central nervous system between sensory and motor nerves is the source of the various reflexes between the viscera and the soma. It also provides an explanation for the effect counterstrain treatments have on visceral function and circulatory flow.

Normal function of the gamma efferent system is partly responsible for the change in muscle tone with changing demand. Jones proposed that the gamma system is responsible for the development of an inappropriate proprioceptive reflex associated with somatic dysfunction. A rapid lengthening of the myofascial tissue sets up the inappropriate reflex. An event occurs that produces rapid lengthening of a muscle. Afferent feedback indicates possible myofascial damage from a strain. The body tries to prevent the myofascial damage by rapidly contracting the myofascial tissue that may be strained. This produces a rapid lengthening in the antagonist muscle. It is proposed that the rapid lengthening of the antagonist produces the inappropriate reflex, which is manifest as a tender point. The theory is that the nociceptive feedback from the antagonist is interpreted as a muscle strain (although a strain

has not occurred). The end result is hypertonic myofascial tissue and restricted motion. A guarding reflex by the patient, without actual mechanical trauma, can also produce the inappropriate reflex. Although this model does explain the development of tender points in muscle tissue, it does not explain tender points in other types of tissue.

Trauma produces change in myofascial tissues at microscopic and biochemical levels (Mense, 1997). The force of the trauma causes damage to myofibrils and their microcirculation. Myofibril damage interferes with the actin-myosin bridges and changes the chemistry around them. Nociceptive information is carried to the central nervous system to alert the body to the tissue damage. The tissue disruption and subsequent chemical changes cause the tissue to become more sensitive to touch and may be part of the reason for the formation of a tender point. The damage to the microcirculation changes intramuscular pressure and muscle function. A small increase in intramuscular pressure can produce muscle fatigue due to decreased cellular metabolism (Mense, 1997). This change in metabolism changes the chemical matrix around the myofibrils and can produce nociceptive activity resulting in tenderness (Mense, 1997).

A tender point is sensitive to palpation and therefore must be related to nociceptive activity. The position of comfort used to treat a somatic dysfunction with counterstrain is a very specific three-dimensional position in space. When the optimal position of comfort is established, the tenderness of the tender point disappears or becomes insignificant. This seems to indicate a neural relationship between the tender point and the somatic dysfunction. Neural messages are rapidly transmitted and used by the body when quick responses are needed. Palpation of changes at the tender point and in the surrounding tissue suggests that in addition to the neural component, the position of comfort also produces changes in the myofascial tissue and small circulatory vessels.

A clue for the treatment time comes from the palpation of a pulsation, the *therapeutic pulse*, at a tender point location. The frequency of the pulsation is the same as the cardiac rate and would therefore suggest a circulatory relationship. Another important element is that the pulsation is not present before positioning; it develops only when the patient is moved close to the position of comfort and disappears after myofascial tissue relaxation. This process takes approximately 90 seconds to occur. The pulsation phenomenon does not occur with every tender point; however, when it is palpated, it does correlate with markedly improved treatment response.

Indications

Identification of the presence of a tender point is an indication for counterstrain. Tender points can be found in acute and chronic musculoskeletal conditions. They may also be found in association with a viscerosomatic reflex. The tender points may be the primary indication of somatic dysfunction or develop secondary to another primary cause for somatic dysfunction such as a joint restriction. Counterstrain is indicated for any patient who is hesitant about the forces used in other forms of manipulative treatment, a frail patient or a trial of manipulative treatment to access a patient's tolerance. Tender points have been identified in every region of body.

Contraindications

Absolute contraindications are rare when considering the use of counterstrain. The presence of a fracture in the area used to treat the somatic dysfunction would be a contraindication. Another

would be the treatment of a patient with a torn ligament in the area to be treated where positioning for treatment would risk further tearing. All other contraindications for not using counterstrain are relative. Patients who cannot voluntarily relax are not good candidates for counterstrain. Children who cannot remain passive are poor candidates. Some of the elderly who confuse not moving with relaxation and cannot be taught the difference do not respond well to counterstrain. Severe osteoporosis where positioning the patient for treatment may risk a fracture is contraindicated, although this is typically not a problem because the position for treatment is within a patient's range of motion and therefore should not cause a problem. Treatment of the cervical spine in patient with vertebral artery disease may be contraindicated with severe disease. This applies especially to positions with marked rotation and/or hyperextension. In addition, severely ill patients who may not tolerate a treatment reaction are not good candidates although counterstrain has been used very effectively in the hospital setting, including intensive care units. An example of this situation is in the case of a patient who is having a myocardial infarction. A classic presentation with all the signs and symptoms would cause the physician to get the patient to a hospital for treatment, but if the signs and symptoms are not classic, a viscerosomatic reflex associated with the myocardial infarction may be treated, reducing the discomfort and delay getting prompt treatment for the myocardial infarction.

PHASES OF PALPATORY DEVELOPMENT

There are two basic phases in the development of palpatory and treatment skills used to treat patients with counterstrain. The first is to identify the various locations where tender points may be found by following the descriptions given in a counterstrain text, pressing the location, and asking the patient if it is tender. Initially, many students are unable to identify the tissue texture abnormalities associated with the presence of a tender point and rely on the patient's response to their pressing the tender point location. This same method is used to position the patient. The novice practitioner moves the patient in a direction that should shorten the dysfunctional myofascial tissue (or that reproduces the treatment position given in a text) and relies on the patient response of the level of tenderness to indicate if the treatment position is being approached. This method is effective, but time consuming.

A patient who does not perceive tenderness of a tender point despite the presence of a tender point is referred to as a *stoic* patient. Counterstrain is not effective on these patients if the student relies totally on the patient's response because the patient is incapable of providing an accurate response. The second phase of learning begins when the student can perceive the tissue texture abnormalities characteristic of a tender point. These tissue texture abnormalities will alert a student to the presence of a tender point before the patient experiences tenderness as the student presses the tender point.

Another important step for the student is the ability to palpate changes in the tissue texture abnormality of the tender point during treatment. A change of position of the patient toward the position of maximal comfort will cause decreased tension or softening of the tissue of the tender point. This allows the student to know immediately if they are moving the patient in the correct direction for treatment. Experience will also allow the student to correlate the degree of tissue change with the amount of positional change needed. The changes in tissue texture can also be used to determine when the time needed in the treatment position is sufficient.

DIAGNOSIS

Several different approaches can be used. History and observation can be an indicator of tender point location. If the patient can recount accurately the mechanism of the injury, it can lead the physician to the tender point. For example, a patient whose injury occurred in a flexed position typically has a tender point on the anterior aspect of the body and the treatment position is to approximate the position of injury. Observation of the patient's habitus provides valuable clues to the location of significant tender points. A patient who has difficulty standing upright and is more comfortable in a forward bent position typically has tender points on the anterior aspect of the body. The more forward or backward bend without sidebending and rotation the more likely the tender point will be located close to the midline. If the patient is most comfortable with a sidebent and/or rotated position, then the tender points are more likely to be located lateral to the midline. The report of pain patterns by the patient can be used to identify specific muscle groups that may contain tender points (Myers, 2006).

Another method is to do a neuromusculoskeletal exam and after segmental diagnosis is made to look for the tender points associated with the segment. If the segment is flexed, rotated, and sidebent to the right, there is commonly a tender point on the anterior aspect of the body on the left side, but there also may be tender points on the right anterior or either the right or left side on the posterior aspect of the body.

Still another method is to scan the tender points in the region of the complaint and one region above and below the area of the complaint. A thoracic complaint may yield significant tender points in the thoracic, cervical, lumbar, or costal regions as well as the upper extremities. It is always important not to narrow the evaluation of a patient just to the area of the complaint.

TREATMENT

Counterstrain is a very gentle technique that is well tolerated by most patients. The patient is not subjected to any external force other than gentle positioning. In addition, patients do not generate force from their own muscle contraction to produce effective treatment. It is an indirect technique, with positioning away from restrictive barriers; therefore, it is tolerated in both acute and chronic problems.

Counterstrain is based on identifying tender points associated with somatic dysfunction and positioning the patient to eliminate the tenderness of the point. Counterstrain is easy to understand and apply; however, mastery requires time to learn the location of tender points; skill in fine-tuning the treatment position for maximum results; and the clinical experience to understand the correlations between symptoms, structural findings, and associated tender points. The basic steps for treating somatic dysfunction with counterstrain after a relevant osteopathic neuromusculoskeletal exam are as follows:

1. Find the most significant/relevant tender point
2. Establish a tenderness scale
3. Continuously monitor tender point tenderness and tissue texture
4. Place the patient passively in a position that results in the greatest reduction of tenderness and tissue texture abnormality at the tender point (position of comfort/ease)
 - (a) Slowly position the patient towards a position of comfort/ease, with large movement initially, while the patient remains passive
 - (b) Then, fine-tune the position through small arcs of movement in multiple planes of motion to find the greatest position of comfort/ease

5. Maintain this position for 90 seconds while the patient remains passive
 - (a) Continuously monitor the tender point for tissue texture changes
 - (b) Periodically retest for tenderness
6. Slowly return the patient passively to the pretreatment position while maintaining contact with the tender point
7. Reevaluate for resolution of tenderness and tissue abnormality at the tender point

Step 1: Find the Most Significant/Relevant Tender Point

Tender points are typically located in tendinous attachments or in the belly of a muscle. Additional tender points are found in other myofascial tissues (tendons, ligaments, and myofascial sheets) associated with the joint dysfunction. Tender points are typically discrete, small, tense, and edematous. The areas are typically smaller than a fingertip, and they are exquisitely tender. A significant tender point is about four times more tender than the adjacent tissue. Tender point tissue changes may range from several inches to almost nothing. The tissue of the tender point is found to be more tense than the surrounding tissue.

It is essential to identify the most significant tender point associated with the somatic dysfunction rather than just finding a point that is tender. Due to the exquisite tenderness of significant tender points, a patient will typically jump, wince, guard, or push your hand away when you press the tender point. Patients are often surprised with the amount of tenderness, especially when they were unaware of the existence of the tender point. In rare cases, a patient does not perceive tenderness when a tender point is pressed, but they still can be treated with counterstrain by monitoring tissue changes, rather than the patient's reactions, that occur during treatment.

Palpate for a tender point with the pad of your finger or thumb. The pads of the fingers are profoundly more sensitive to tactile input and are better at identifying the location of tender points. Avoid using the fingertips, especially if you have long fingernails. Fingertips are less sensitive and can elicit iatrogenic tenderness.

Palpation should be slow and firm but gentle. The pressure used to elicit a tender point is typically a few ounces and not strong enough to elicit tenderness in normal tissue. Jones recommended using the amount of force needed to blanch under the fingernail of the palpating finger. The vector of pressure is also important. Typically, the tissue of the tender point is pressed onto more rigid tissue like bone or cartilage. Do not forget to check for other pathology that might produce tenderness that is not related to neuromusculoskeletal tender points, such as infection, inflammation, or pathology of visceral origin.

Before the physician begins palpating for tender points, ask the patient to report any tenderness as you palpate. The physician is palpating for tissue texture abnormalities, especially edema and tension before the patient experiences tenderness. Verify the presence of a tender point by asking the patient if the area is tender while the potential tender point is pressed briefly. The tenderness of a tender point is an objective sign elicited by physically palpating the dysfunctional area. In contrast, pain is a subjective symptom that the patient may experience without palpation. Jones found that tender points are often found in nonpainful areas.

One method to determine where tender points may be found is to perform an osteopathic structural examination noting any alteration of movement, asymmetry of paired landmarks, or tissue texture abnormalities. Palpating these areas for tender points is how Jones

originally found many of the tender points he described. Evaluate the patient for variations from ideal posture and palpate those areas for tender points. For example, a patient presenting with flattening of the normal thoracic kyphotic curve is likely to have one or more posterior thoracic tender points associated with the extension in this region. Tender point locations can also be suggested based on clinical history and presenting complaints. By knowing the position in which the original injury occurred, the most likely places for significant tender points can be deduced. Many myofascial pain patterns have been described by Travell and may provide additional correlation.

The presence of a significant tender point will result in the patient attempting to obtain a comfortable posture to alleviate the functional distress. This is an unconscious attempt by the patient to shorten and relieve tense myofascial tissues. Patients tend to bend around a tender point. That is, tender points tend to be at the focal point of the concavity of the postural adaptation. If the patient is forward bent, tender points tend to be anterior. If a patient is backward bent, tender points tend to be posterior. Jones found that a patient who presents sidebent to one side usually has a tender point on the opposite side of the spine (L.H. Jones, *personal communication*, 1993).

Tender points are frequently found in areas other than the area of pain or discomfort. The primary or key strain may induce a secondary or compensatory strain elsewhere, which may be more symptomatic. For example, when the psoas muscle chronically stays in spasm, patients seldom complain of abdominal or anterolateral hip pain. Instead, they complain of pain in the lumbosacral or sacroiliac regions, due to the strain and compensation of those regions by the psoas spasm. Tender points may be 180 degrees around the body from the site of the presenting pain. For example, in a patient with pain between the shoulder blades, the tender point is often on the sternum. It is also possible to have both anterior and posterior or right and left tender points associated with the same anatomic segmental level. This is because tender points are mediated through the nervous system and can result in multiple points for a single somatic dysfunction. If there are multiple tender points in a given area, ask the patient which is the most tender. Then, treat the most severe tender point first. Associated but less significant tender points often disappear after successful treatment of the tender point.

If the tender point results from a viscerosomatic reflex, tenderness returns within minutes or hours, not days. When this is found, a thorough review of the patient's medical history and more careful physical examination are needed. Be sure all of the possible causes of the original tenderness have been considered. (For more information about viscerosomatic reflexes, refer to the discussion of viscerosomatic reflexes in the basic science section of this book, or read Beal's article (1985)). This information is also important when treating patients in the hospital. (Refer to the article by Schwartz (1986) on the treatment of hospital patients with counterstrain.)

Initially, the physician will palpate the anatomical location of a tender point as described by Dr. Jones and others and then test for the presence of a tender point. As the physician's skill grows, tissue texture abnormalities, typically increased tension, will become evident well before the patient reports any tenderness. The skilled palpating hand will zero in on the area of greatest tissue change and then confirm the identification of a significant tender point by pressing on the tissue to elicit tenderness from the patient. This ability to palpate the tissue changes associated with the tender point will also be used for more accurate positioning and will allow the physician to treat a stoic patient.

Step 2: Establish a Tenderness Scale

To facilitate the communication between physician and patient, it is important to establish a means of monitoring the level of tenderness of the tender point. Physicians typically use a tenderness scale to enhance verbal feedback with the patient. Several scales have been used effectively. The one most commonly used is a 0-to-10 scale, with 10 being equal to the level of tenderness prior to positioning for treatment and 0 representing the absence of tenderness. The scale represents a continuous range from the pretreatment tenderness (a 10) to the elimination of tenderness (a 0). The number does not represent a fixed quantity of tenderness. The 10 of one tender point is different to the 10 of another tender point. The scale allows the patient to communicate changes in tenderness and is correlated with palpatory changes. The same amount of pressure should be used each time the physician attempts to elicit tenderness of a specific point although different pressures are needed for different tender points due to different amounts of tissue over the tender points. It should be emphasized to the patient that this is not acupressure or a form of massage. Firm pressure is applied only when trying to determine the level tenderness. At other times, only light contact is maintained. This feedback provides a means for monitoring the effectiveness of positioning and treatment for both patient and physician.

Step 3: Monitor Tender Point Tenderness and Tissue Texture

It is important to maintain contact with the tender point throughout treatment. This allows the physician to palpate the tissue changes that occur at the tender point when establishing the optimal treatment position as well as the end point of treatment. The pressure used to monitor the tender point is less than what is used to test for tenderness. Monitoring pressure allows enough force to maintain contact with the myofascial tissues of the tender point without causing tenderness in the patient. A patient in pain does not relax well and therefore is more difficult to treat.

After a significant tender point is selected for treatment, it is monitored as the physician begins to move the patient toward the position of comfort described by Dr. Jones and others. The myofascial tissues of the tender point will begin to relax as the patient is moved toward the correct treatment position. About half way to the described treatment position, the physician stops and tests the level of tenderness. The pressure used to test for the level of tenderness is increased to the firm pressure used initially to test for the presence of a tender point. Jones found it requires about four times the pressure on normal tissue to produce tenderness as it does to elicit tenderness of a tender point (Jones et al., 1995). The pressure should be applied as a short quick push, not a long slow sustained amount of pressure. If the physician is moving the patient in the correct direction, the tenderness will decrease. The closer to the optimal position, the less tenderness is present. Once the physician is able to palpate changes in tissue texture, the changes can be used to determine if the patient is being positioned correctly. For example, if the physician is moving the patient toward the optimal position, the tissues typically relax. If the patient is moving away from the optimal position, the tissue tension typically increases. Experience will teach the physician the correlation between tissue changes and the level of tenderness. This is then used to find the optimal position of comfort more efficiently by taking less time to find the optimal position. Each new position is accompanied by retesting the tenderness of the tender point.

Step 4: Place Patient Passively in Position of Comfort

One of the advantages of counterstrain is that treatment is always in a position of comfort or ease. By placing the patient in a position of comfort, discomfort is avoided and further injury is unlikely to occur. Counterstrain can be used for patients with a wide variety of medical conditions, unless gently moving the patient into the specific treatment position is contraindicated. A word of caution: medical judgment must always be used to determine the appropriateness of any treatment. Every patient needs to be evaluated thoroughly on an individual basis. The only absolute requirement is that the patient must be relaxed while the physician places the dysfunctional area of the body into the position of comfort and maintains it during treatment.

The optimal position of comfort is a very specific position in space. The position is similar for the same tender point in different patients, but the exact position is unique for each patient. To find the optimal position, the physician uses a combination of palpation and feedback from the patient. Maintaining continuous light contact with the tender point during treatment is important for maximum effectiveness and efficiency.

The first step in positioning is to approximate the position expected. The expectation may be from previous clinical experience, patient history, or from looking at an illustration of the positioning in a counterstrain book. The purpose of the positioning is to reduce the tension on the dysfunctional myofascial structures. As a rule, the closer tender points are to the midline, the more flexed or extended is the patient's presenting posture, and more flexion or extension is required for the treatment position. With tender points more lateral to the midline, more sidebending and rotation are usually required for treatment. Sidebending and/or rotation of the body away from the tender point are the most common positions needed for effective treatment.

Slowly move the patient toward the described or expected position of comfort while monitoring the tender point for relaxation of the tissue. When marked relaxation of the tender point is palpated, stop moving the patient. Press the tender point and ask for the level of tenderness. If the level of tenderness is greater than 3 on the 10-point scale, continue to move the patient in the same direction. Then, as significant relaxation is palpated, stop movement and test again. Repeat this process until the tenderness level is three or less. If the number increases, return in the direction just traveled and retest. It may be necessary to change direction or add other directions to find the correct position. Figure 49.1 shows the changes in tenderness as the patient is moved from a neutral starting position to the position of comfort and beyond.

From the beginning of positioning to about half way to the position of comfort, large movements are typically used because the reduction in tenderness is small for the distance traveled. As you get close to the optimal position, fine-tuning the position with small motions is required. A small change in position at this point in the treatment markedly reduces tenderness. For example, several inches of movement close to the neutral position may reduce the tenderness by one on the scale, whereas it may take only one quarter inch of movement close to the optimal position to reduce the tenderness the same amount. Slow, small movements, constant light contact of the tender point for monitoring, and retesting the tender point for reduction of tenderness with each new position all allow the practitioner to find the precise position of optimal comfort. If the optimal position is overshoot, the level of tenderness will increase. Fine-tune the position until the tenderness has been reduced by at least 70% (3 on the scale), preferably 100%. The

Figure 49-1 Tenderness scale-distance graph.
(Courtesy of Johannes Liedtke)

position of comfort must be at least 70% improved over the initial tenderness, or the technique is ineffective. Jones recommended a reduction of two thirds, and other practitioners have suggested three fourths. An effort should be made to maximally reduce the tenderness. The extra time spent trying to eliminate the tenderness will significantly increase the effectiveness of the treatment.

A common mistake is to use constant firm pressure on the tender point throughout the treatment sequence. Instead, constant light contact should be maintained. Once the optimal treatment position has been determined, be sure to maintain only light contact with the myofascial tissue of the tender point. There are three important reasons for maintaining contact:

1. Tissue changes that occur in the tender point can be monitored more easily and aid in determining the end point of treatment
2. The tender point can continue to be fine-tuned while maintaining the optimal position of comfort, because the position may change slightly during treatment
3. Both the patient and the practitioner can be confident of the location of the tender point

The third reason may seem unimportant, but when contact with the tender point is lost, the patient may question whether the same point is being pressed. Also, the practitioner may have difficulty reestablishing contact with the point with enough confidence to allow an accurate recheck.

At times, a pulsation in the tender point may be palpated. This is referred to as the therapeutic pulse. Although its intensity may vary, it is often close to the intensity of the radial pulse. In fact, palpating the patient's radial artery with the other hand typically shows it to be synchronous with the therapeutic pulse. For this reason, it is postulated that the position of release results in a sympathetic vasodilation of the small arterioles in the myofascial tissue. At times, the therapeutic pulse can be palpated while attempting to find the optimal position of comfort, enabling the practitioner to establish the position more accurately. At other times, the therapeutic pulse will not be palpated until the treatment position has been maintained for a period of time. In either case, the appearance of the therapeutic pulse can be used to enhance the treatment.

Step 5: Maintain Position for 90 Seconds While Patient Remains Passive

Once the position of comfort has been established, hold it for 90 seconds. It is important to remember that the patient must remain

relaxed without contracting the dysfunctional myofascial tissue. The 90 seconds does not begin until the patient is completely relaxed. It may be necessary to remind the patient to stay relaxed several times during the 90 seconds, because often the patient contracts muscles unconsciously. An apparent decrease in the patient's weight as you support them in the treatment position is an indication that the patient is contracting muscles. Patients who are not comfortable will not be able to relax for the entire 90 seconds. Also, if the practitioner is not comfortable, it is difficult to hold the patient in the treatment position for 90 seconds. You may need to experiment to find the best way to remain comfortable during treatment. Each patient and clinical setting offers different challenges. It may be necessary to invent a new treatment position to enable both the patient and yourself to remain comfortable. This is especially true with pregnant patients, patients with some degree of paralysis, hospitalized patients, and with physician-patient size mismatches.

Dr. Jones used 120 seconds to treat rib dysfunctions. When asked if these tender points were different in some way to all the other tender points, Dr. Jones said they were not different. His stated reason for increasing the time to 120 seconds was purely behavioral. He felt that most patients were a little uncomfortable leaning up against the physician, so he gave them an additional 30 seconds to relax. Once the patient is in the position of maximal comfort for the rib tender point, the same 90 seconds is all that is needed to treat the dysfunction. The tender points are not different, but the physician must be aware of the patient's state of relaxation and comfort being close to the physician. This is critical in all areas of the body and a common reason for failure of a physician to get a good response using counterstrain.

Feel for tissue changes in the tender point and surrounding tissue. As time in the treatment position increases, the tissue relaxes and you should feel a softening. The myofascial tissue around the tender point may begin to move in a seemingly random pattern. This sensation is due to the relaxation of myofascial tissue in different planes. Although treatment time may not always be exactly 90 seconds, it is important to maintain the treatment position for 90 seconds when beginning to learn counterstrain. The ability to palpate myofascial release patterns enhances counterstrain treatment and can also be used to improve palpatory skills needed for myofascial release techniques. As discussed earlier, you may also feel the therapeutic pulse. Once the random motion becomes symmetrical or the therapeutic pulse disappears, it is time to move the patient back to the starting position. Once the tissue changes that signal the end of treatment can be palpated with confidence; watching a clock is no longer necessary.

Step 6: Passive Slow Return While Maintaining Tender Point Contact

After maintaining the position of comfort for 90 seconds, it is time to slowly return the patient to the starting position while monitoring the tender point. Before starting to move, ask the patient to remain passive and not assist you by actively moving. Patients may unconsciously try to help. If the patient starts to help or move, stop the return and remind the patient not to help. When the patient has relaxed, start moving again, more slowly. An apparent decrease in the patient's weight as you move them is another indication that the patient is contracting muscles. A common error when learning counterstrain is to move the patient too quickly. A slow return is critical. The first few degrees of motion during return are the most critical. Watch the patient for signs of flinching or other guarding gestures. Palpating for muscle contraction could also provide a sign that the patient is being moved too quickly.

Step 7: Reevaluate Tenderness and Tissue Texture

Once the patient has been returned to a relaxed position, reevaluate the tenderness and tissue texture of the tender point. To consider the treatment successful, no more than 30% (3 on the 10-point scale) of the original tenderness should remain. Ideally, all of the tenderness will have resolved. If more than 30% of the tenderness remains, several possible reasons may exist. The patient may not have been optimally positioned, the physician may have let the position change during treatment, the patient may have contracted the muscle being treated, or the physician may have lost contact with the tender point. Repeat the positioning, with particular attention to obtaining and maintaining the optimal position with the patient completely relaxed.

Another cause for failure may be that another tender point is the primary problem and, therefore, the most significant point was not treated. Evaluate the tender points in the area near the tender point just treated and the corresponding area on the opposite side of the body to see if another, more significant tender point is present. This is especially true if the point treated was part of a sequential line of tender points. Consider the possibility that the primary tender point is distant from the area evaluated or on the opposite side of the body from the reported problem. More than one treatment session may be necessary to completely resolve a tender point. Also, failure to completely resolve the tenderness does not necessarily indicate an ineffective treatment. Some of the most challenging tender points to treat are when both anterior and posterior tender points are present at the same level (e.g., AT4 and PT4).

Reevaluate the original structural findings to evaluate the effectiveness of the treatment. You are treating a somatic dysfunction, not just a tender point, so reevaluating cannot be overstated. Motion restrictions, asymmetry, and tissue texture abnormalities should improve or disappear after effective treatment. With chronic somatic dysfunction, the tissue changes may be slower to return to normal.

Clinical tips for providing strain and counterstrain techniques are found in Box 49.1.

PATIENT EDUCATION

It is important to start instructions before the patient gets off the treatment table. Patients are curious to see if the treatment eliminated the presenting complaint. Warn the patient not to test previously restricted motions and to avoid extremes of motion for

several days. This is especially true if the movement approximates the original position of injury, because it may reproduce the inappropriate reflex just treated. Active movement that reproduces the position of injury is different from the careful positioning performed by the physician while the patient is passive.

The patient should stay well hydrated for several days after treatment. This helps with the elimination of increased metabolic waste products that may be released into circulation after relaxation of the tense myofascial tissue. Water is recommended over other fluids, which may contain sugar and other dissolved substances. The patient is especially recommended to avoid consuming alcoholic beverages for about 3 days.

Although counterstrain techniques are well tolerated, a post-treatment reaction may occur. Approximately 30% of patients experience a generalized soreness or a flu-like reaction 1 to 48

Clinical Tips

- A single somatic dysfunction may have more than one associated tender point
- Test for tenderness of a specific tender point with the same amount of pressure each time
- Use less pressure to monitor a tender point than to test it
- Physician's palpatory abilities are more reliable than a patient's report of tenderness
- Anterior points typically require flexion and posterior points typically require extension
- Midline points typically require pure flexion (if anterior) or pure extension (if posterior), whereas the more lateral a point is from midline, the more rotation and/or sidebending is required
- If there are multiple tender points in an area, usually the most tender one is the most significant and should be treated first
- If several tender points of equal tenderness occur in a row, treat the middle one first
- Spend a little extra time to fine-tune and completely eliminate the tenderness of a tender point
- The optimal position of comfort is obtained when the tender point is no longer tender and the tissue tension is maximally reduced
- Monitor changes in myofascial tension and adjust the treatment position to decrease the tension for maximum results
- Monitor the myofascial tissue of the tender point throughout the treatment
- For maximum results, the patient must be completely relaxed (passive) during treatment
- Recheck the tenderness of a point several times while in the treatment position
- Causative factors and mechanism of injury are unique to each patient. Therefore, the exact position of ease will vary depending on the response of the tissue during positioning
- Scan for both anterior and posterior tender points within a region/functional unit to determine the most significant
- Aim for a reduction of tenderness of less than or equal to 70% with a goal of 100%
- Use both tenderness and tissue texture abnormalities to find the best treatment position
- The presence of a therapeutic pulse indicates good myofascial relaxation
- If difficulty reducing the tenderness to zero is experienced, there usually is another more significant tender point that needs to be treated first or the patient is contracting muscles near the tender point

hours after treatment. This usually is experienced by the patient on the morning after treatment and may last 1 to 5 days, although 1 day is most typical. The reaction usually occurs only after the first treatment, but may be experienced after other treatments. The cause of the reaction is unclear, but may be related to the washout of metabolic waste products from the dysfunctional myofascial tissue. There also is a correlation with treating dysfunctions where the therapeutic pulse is palpated during treatment. In any case, the patient should be alerted to the possibility of a posttreatment reaction. Prescribing an analgesic for 1 or 2 days may help reduce the discomfort. This possibility of a posttreatment reaction also provides a reason for caution in using counterstrain to treat some gravely ill patients.

Patients want to know how often they need to be treated and how long it will take to resolve the complaint. As with all forms of manipulative treatment, there is no single, definitive answer. One treatment may eliminate the somatic dysfunction, although other dysfunctions require treatment over a more extended period of time. Jones had patients return in 3 to 7 days after the initial treatment, although 1 to 2 weeks may be more practical for many physicians. As the somatic dysfunction resolves, the time between treatments is increased. The end point of treatment depends on the cause of the problem, the underlying tissue damage, preexisting medical problems, the response of the patient, cooperation by the patient to avoid painful positions, and the skill of the physician.

EVOLUTION OF THE COUNTERSTRAIN MODEL

It is not the nature of an osteopathic physician to learn a manipulative model by memorizing a group of techniques and repeating them over and over. Andrew Still did not write a technique manual. Instead, he emphasized learning anatomy and concepts that can be applied to meet the unique needs of each patient. Therefore, it is no surprise that osteopathic physicians have modified Larry Jones' model. Classical counterstrain involves maintaining the position of release for 90 seconds, but this is not always necessary or the best option. Just as each patient is an individual, the time needed for treatment is not a constant. The physician's ability to accurately position the patient and the patient's ability to remain completely passive are two critical factors that affect the time needed. The best indicator that the treatment is complete is the palpatory response gained by monitoring the tender point. The tissues relax and rhythmic motion of the surrounding myofascial tissues returns, indicating the treatment is finished. If the myofascial tissues in the region being treated begin to unwind, the physician may choose to change from counterstrain to myofascial release to treat the somatic dysfunction. Counterstrain is classically a positional release model, but it is the physician's experience and choice whether remaining in one position or moving the dysfunctional area offers the best option for treatment.

Instead of treating a single tender point with a position of ease, Ross Pope, D.O., F.A.A.O., found stacking several regional tender points at once allows him to use a single position for treatment. This allows treatment of a region with a single position and greatly increases his efficiency. Paul Rennie, D.O., F.A.A.O., has found combining counterstrain with exercise is another approach that increases the efficiency of treatment and improves patient recovery. Specific exercises are combined with the treatment of specific tender points (Rennie et al., 2001).

Other alternatives may be used to speed up the time for the release to occur. With the patient in the counterstrain treatment position, the patient may contract the antagonist to the muscle being treated and attempt to move out of the treatment position. The contraction used is an isometric contraction commonly

utilized with muscle energy technique and has been shown to be effective. Another option to decrease the time needed is to use a facilitating force applied by the physician. Compression is most commonly used, but distraction or a torque force can also be used. This approach blends well with Dr. Schiowitz' Facilitated Positional Release model. Dr. Van Buskirk used Jones' tender points as he worked on redeveloping the Still technique. He would identify a somatic dysfunction, find an associated tender point, position to eliminate the tenderness, add a compressive force, and then bring the joint from its indirect position in a continuous arc past neutral and through the restrictive barrier. He also uses distractive and torque forces as in Facilitated Positional Release. A number of osteopathic physicians, including Larry Jones, studied Janet Travell's myofascial pain syndromes and the associated trigger points described. A number of the trigger point locations described were identical to the tender point locations, so it was natural for physicians to try to treat trigger points with a counterstrain positional release approach and it was found to be quite effective (Myers, 2007; Ravin et al., 2008).

One component of the counterstrain model that has been a source of confusion for students is the nomenclature used for the tender points. Dr. Jones identified and named the points he found in several ways over a number of years. Some were named for the dysfunctional segment, others for a nearby landmark, some for an associated diagnostic finding, and a number for a muscle in which the point was located. Jones changed the names of a number of points between the publication of his two books (Jones, 1981; Jones et al., 1995), and in most cases, the change was to identify the muscle he felt was associated with the somatic dysfunction. It is time for an overall review of Jones tender points nomenclature to produce a more uniform standard for the tender point names. The basis of the system should be based on anatomy, predominately muscles. This will help students learn both the names and treatment positions more effectively.

DIAGNOSES AND TREATMENTS BY BODY REGION

The treatment illustrations that follow are intended as an introduction to the counterstrain technique model. An example from each of the 10 codable regions of the body has been chosen to illustrate a variety of treatment options. More in-depth counterstrain reference texts are available for more complete coverage of the body regions (Jones, 1981; Jones et al., 1995; Myers, 2007; Ravin et al., 2008; Rennie et al., 2004).

The treatment positions presented may be modified for the needs of the physician and the patient. Therefore, knowledge of the three-dimensional position that is typically used to treat a tender point is helpful to change the position from that described in a text. For example, a change to seated, supine, or sidelying may be preferred by either the physician or the patient. Certain conditions may necessitate changing a preferred position of treatment. For example, a pregnant patient in the third trimester may need to be treated in a side-lying position. As long as the treatment can be successfully performed, modifications may be helpful adaptations to these techniques. If you can position the patient and reduce the tenderness to zero it should be an effective treatment position.

Head (739.0): Head Region, Occipitocervical Region

Dr. Jones described a number of tender points on the head, many associated with cranial dysfunctions and the reader should refer

to a counterstrain text for a description of these tender points. In addition, several of the cervical tender points are located on the skull. Two very common tender points found on the head are the anterior first cervical and posterior second cervical tender points.

Anterior First Cervical (AC1)

Tender Point Location

Found on the posterior surface of the ascending ramus of the mandible approximately 1 cm from the angle of the jaw pressing anteriorly (Fig. 49.2).

Treatment Position (Patient Supine)

Slight *flexion* of the head and upper neck, *rotation* away from the side of the tender point close to the end range of motion, and slight *sidebending* away from the side of the tender point.

Cervical Spine (739.1): Cervical Region, Cervicothoracic Region

The cervical spine has several maverick tender points (points where the position of comfort is different from what might be expected). Anterior tender points are typically located on the most anterolateral aspect of the anterior tubercles of the cervical vertebra. Posterior tender points are found on the occiput or associated with the tip of the spinous processes or lateral to the spinous processes.

Anterior Fourth Cervical (AC4)

Tender Point Locations

Found at the anterior-lateral surface of the anterior tubercle of the fourth cervical vertebrae pressing anterolateral to posteromedial (Fig. 49.3).

Treatment Position (Patient Supine)

Flexion of the head and upper neck to the fourth cervical vertebra (approximately 45 degrees). *Sidebend* and *rotate* the head and upper neck away from the side of the tender point.

Thoracic Spine (739.2): Thoracic Region, Thoracolumbar Region

Anterior thoracic spine tender points are located in two major areas. The first group of tender points, AT1-6, are located midline

Figure 49-2 Anterior first cervical (AC1).

Figure 49-3 Anterior fourth cervical (AC4).

on the sternum. They can be located by palpating for tense, tender tissue overlying the sternum. The second group is located in the abdominal wall. Most are located in the rectus abdominis muscle and can be found an inch or two lateral to midline on the right or left. Posterior thoracic tender points are found on two parts of each vertebra. One location is associated with the spinous process, and is more tender on either the left or right side. The second location is on either transverse process.

The treatment described here is given for different spinal levels but are not hard and fast requirements. Extension, sidebending, and rotation to any level can be introduced either from above or below the segment. The physician's choice is based on the flexibility of the patient, patient comfort, and the relative size of the patient and physician.

Posterior Fifth Thoracic (PT5)

Tender Point Location

On the inferolateral side of the spinous process of the fifth thoracic vertebra pressing anteriorly (Fig. 49.4). Even though the spinous process is a midline structure, there will be more tenderness on one

Figure 49-4 Posterior fifth thoracic (PT5).

side more than the other and also look for deviation of the spinous process.

Treatment Position (Patient Prone)

Sidebend the trunk away from the deviated side of the spinous process by pulling the opposite shoulder in a caudal and posterior direction. This creates extension with rotation and sidebending away from the deviated side.

Ribs (739.3): Rib Cage, Costochondral, Costovertebral, Sternochondral Regions

Jones used the terms “depressed” and “elevated” to refer to the tender points associated with rib somatic dysfunction. This was done to emphasize what was done with the patient to find a position of maximum comfort. The convention in current use is to name the tender points for their location on the body. In the example used here, both conventions have been combined.

Anterior tender points correspond to Jones depressed ribs and posterior tender points correspond to Jones elevated ribs. The anterior rib tender points start just below the medial end of the clavicle where the first rib attaches to the sternum and move laterally in an arc to the anterior axillary line. Most of the anterior rib tender points are on the ribs along the anterior axillary line. It is not common to find tender points below the sixth rib, but they do occur. The posterior tender points, with the exception of the first rib, are located on the angle of the ribs.

Anterior (Depressed) Third Rib (AR3)

Tender Point Location

On the third rib in the anterior axillary line, pressing from anterolateral to posteromedial (Fig. 49.5).

Treatment Position (Patient Seated)

Depression of the ipsilateral costal cage by *sidebending* that side, *flexion* of the thoracic cage, head, and neck with elevation of the contralateral shoulder and translation away from (sidebend toward) the tender point. Fine-tune with *rotation* of the body, usually toward the tender point. Sidebending can be increased with patients legs placed on the table opposite the elevated shoulder. The elevated shoulder is usually supported on the physician's thigh.

Figure 49-5 Anterior third rib (AR3).

Lumbar Spine (739.4): Lumbar Region, Lumbosacral Region

Anterior lumbar spine tender points are mostly located around the rim of the pelvis anteriorly. They can be found in association with the ASIS, anterior inferior iliac spine, and anterior surface of the pubic rami. Posterior lumbar tender points are found mostly in the same places as in the thoracic spine, although the tender points found on the tips of the transverse processes need to be approached by pressing anteromedially at about a 45-degree angle.

The naming convention used for describing spinal dysfunction in the osteopathic profession is to describe the dysfunctional segment relative to the segment below it. If motion is introduced from below the dysfunctional segment, the vertebral segment below it moves first, producing a position relative to the dysfunctional segment that can seem confusing. As an example, if the vertebra below the dysfunctional segment is rotated to the right, then the relative position of the dysfunctional segment to the vertebra below is described as rotated left. This is important to understand when reading the treatment descriptions for this section.

Posterior Fifth Lumbar (PL5)

Tender Point Location

On the tip of the spinous process, testing right and left sides of the spinous process to identify the most tender side pressing anteriorly (Fig. 49.6).

Treatment Position (Patient Prone)

Extend the trunk on the ipsilateral side of the spinous process by lifting the pelvis in a posterior direction. This creates extension with the needed rotation of the lower vertebrae toward the tender point side.

Pelvis (739.5): Pelvic Region, Hip Region, Pubic Region

There are several anterior tender points and several posterior tender points that are important for diagnosis and treatment of pelvic somatic dysfunction. The anterior points typically require flexion. Rotation of varying amounts is also needed and, to a lesser degree, sidebending. Posteriorly, tender points are associated with sacral problems and muscles of the pelvis. Extension is the predominant motion associated with the posterior tender points, although several points require some degree of flexion.

Figure 49-6 Posterior fifth lumbar (PL5).

Piriformis (PIR)**Tender Point Location**

In the middle of the piriformis muscle, half way between the greater trochanter and where it attaches to the lateral side of the sacrum pressing posterolateral to anteromedial (Fig. 49.7).

Treatment Position (Patient Prone)

Marked flexion of the ipsilateral hip to about 135 degrees and marked *abduction*. *Lateral rotation* of the hip may also be required, particularly if tenderness is found more lateral on the piriformis muscle.

Pelvis (739.6): Sacral Region, Sacrococcygeal Region

A number of tender points are located on the sacrum and associated with the musculature of the posterior pelvis. The tender point locations and treatment demonstrate the counterstrain approach to the sacrococcygeal region. Because there are many tender points in the sacrococcygeal region, it is recommended that a text devoted to counterstrain is consulted for more extensive discussion of the tender points associated with this body region.

High Ilium Sacroiliac (HISI)**Tender Point Location**

Found just lateral to the PSIS of the ilium, pressing lateral to medial (Fig. 49.8).

Treatment Position (Patient Prone)

Extension of the ipsilateral hip. Slight *external rotation* and *abduction* of the hip is also added.

Upper Extremity (739.7): Upper Extremities, Acromioclavicular, Sternoclavicular Regions

The tender point location and treatment demonstrates the counterstrain approach to the upper extremity. Because there are many tender points in the upper extremity, it is recommended that a text devoted to counterstrain is consulted for more extensive discussion of the tender points associated with this body region. Tender points may be found at attachment points for muscles or ligaments as well as in the belly of a dysfunctional muscle.

Figure 49-7 Piriformis (PIR).

Figure 49-8 High ilium sacroiliac (HISI).

Supraspinatus (SPI)**Tender Point Location**

In the middle of the supraspinatus muscle, superior to the spine of the scapula pressing cephalad to caudad (Fig. 49.9).

Treatment Position (Patient Supine)

Flexion and *abduction* to about 45 degrees and *external rotation* of the humerus.

Lower Extremity (739.8): Lower Extremities

The tender point location and treatment demonstrates the counterstrain approach to the lower extremity. Because there are many tender points in the lower extremity, it is recommended that a text devoted to counterstrain is consulted for more extensive discussion of the tender points associated with this body region. Tender points may be found at attachment points for muscles or ligaments as well as in the belly of a dysfunctional muscle.

Figure 49-9 Supraspinatus (SPI).

Figure 49-10 Extension ankle (EXA).

Figure 49-11 Iliacus (ILA).

Extension Ankle (EXA)

Tender Point Location

Within the two bellies of the gastrocnemius just below the lower popliteal margin, pressing posterior to anterior (Fig. 49.10).

Treatment Position (Patient Prone)

Marked *plantar flexion* of the ankle. This is usually accomplished with the patient prone and the dorsum of the involved foot supported on the physician's thigh. Pressure is put on the calcaneus to produce plantar flexion.

Abdomen (739. 9): Abdomen Region and Other

A number of tender points are found in the abdomen. These include anterior thoracic 7 to 11, iliacus and anterior lumbar 1 through 4. These tender points may also be related to viscerosomatic reflexes.

Iliacus (ILA)

Tender Point Location

At the level of the ASIS, one third of the way toward midline from the ASIS deep in the abdomen over the iliacus pressing anterior to posterior (Fig. 49.11).

Treatment Position (Patient Supine)

Marked *flexion* of the hips bilaterally to shorten the iliacus muscles. Both hips are *laterally rotated* with the knees *abducted* from the center of the body.

KEY CONCEPTS

- Soft tissue techniques are directly applied to the muscular and fascial structures of the body and affect the associated neural and vascular elements.
- Soft tissue preparation facilitates improvement of articular motion. This basic tenet of manipulative intervention has been consistent in the history of osteopathic medicine.
- Articulatory techniques involve gentle and repetitive motions through the restrictive barrier. Many techniques use long lever forces in achieving effects.
- Soft tissue and articulatory techniques span a wide range of applications of force. It is this characteristic that makes them two of the most versatile treatment forms available.

CASE STUDY

A 54-year-old man presents to the office with a sore throat and dry cough. He complains of an ulcer on the buccal surface of his left cheek. He admits to having similar ulcers around his mouth in the past. He denies other complaints.

Physical examination:

Vital signs are normal. Exam of the buccal mucosa reveals a shallow ulcer with a red border approximately 2 mm in diameter; tongue is in the midline; there is no tonsillar hypertrophy or erythema; teeth in good repair. Small left submental node is palpable. CV, pulmonary, abdominal, and neurologic exams are noncontributory. Structural exam reveals rigid, tender, hypertonic paravertebral musculature from the C5 to T2 spinal levels bilaterally. Rib 4 on the left is held in exhalation.

Diagnosis

1. Acute herpetic stomatitis
2. Somatic dysfunction—cervical, thoracic, rib

Plan

1. Treatment with antiviral medication
2. Soft tissue technique on the hypertonic cervicothoracic musculature
3. Articulatory technique on the rib dysfunction

SOFT TISSUE TECHNIQUE (INHIBITION-VIDA INFRA)

Treatment Position

Patient: Supine

Physician: Seated at the head of the table

Procedure

1. You place the pads of the fingers of both hands beneath the cervicothoracic junction, just lateral to the spinous processes (Fig. 50.1)
2. You extend the cervicothoracic junction until you feel the musculature relax under your fingers
3. You then maintain a deep sustained pressure over these muscles until they are further felt to soften (release). This may take anywhere from 30 seconds to several minutes
4. Success of the technique is determined through palpation to reassess the characteristics of the soft tissues that prompted

the selection of the technique to begin with. Success may also be determined in part by reassessing the patient's symptomatology (sore throat and cough)

ARTICULATORY TECHNIQUE

Dysfunction

Position: Rib 4 held in exhalation

Restriction: Rib 4 is restricted in inhalation

Treatment Position

Patient: Lateral recumbent—lying on the right side

Physician: Standing behind the patient at the side of the treatment table

Procedure

1. Place your caudad hand posterior to the left iliac crest to stabilize the body (Fig. 50.2)
2. Place your caudad knee against the angle of rib 4 on the left and maintain a firm steady pressure (a folded towel or small pillow may be needed between your knee and the rib to minimize patient discomfort) (Fig. 50.3)
3. With your cephalad hand, grasp the patient's left arm just proximal to the wrist
4. Smoothly carry the left shoulder into a combination of flexion and abduction in order to place the pectoralis minor muscle on passive stretch (Fig. 50.4). It is the tension on this muscle combined with the gapping force provided by the knee that allows the rib to easily articulate (Fig. 50.5)
5. Success of the technique is determined by reassessing respiratory motion of rib 4. Success may also be determined in part by reassessing the patient's symptomatology (sore throat and cough) (1)

INTRODUCTION

Soft Tissue Technique

Definition

Soft tissue techniques are defined as direct techniques that address the muscular and fascial structures of the body and associated neural and vascular elements.

Figure 50-1 Cervicothoracic inhibition technique.

Figure 50-2 Articular technique. Upper rib: exhalation dysfunction, step 1.

Figure 50-3 Articular technique. Upper rib: exhalation dysfunction, step 2.

Figure 50-4 Articular technique. Upper rib: exhalation dysfunction, step 4.

History

Preparation of the soft tissues in order to achieve improved articular motion has been one of the basic tenets of the manipulative approach since the early days of A.T. Still. Based on descriptions provided by his students, it is believed that Dr. Still made extensive use of the soft tissue style—direct inhibitory pressure.

Indications

Soft tissue techniques may be applied in a number of different ways to:

- Relax hypertonic muscles and reduce spasm
- Stretch and increase the elasticity of shortened fascial structures
- Enhance circulation to local myofascial structures
- Improve local tissue nutrition, oxygenation, and removal of metabolic wastes

- Improve abnormal somato-somatic and somato-visceral reflex activities, thus improving circulation in areas of the body remote from the area being treated
- Diagnostically to identify areas of restricted motion, tissue texture changes, and sensitivity

Figure 50-5 Articular technique. Upper rib: exhalation dysfunction, step 4.

- Observe tissue response to the application of manipulative technique
- Improve local and systemic immune response
- Provide a general state of relaxation
- Provide a general state of tonic stimulation by stimulating the stretch reflex in hypotonic muscles

Other techniques used on more superficial soft tissue structures include variations on techniques developed in the European massage movement. These include:

- Effleurage—a light stroking movement
- Petrissage—kneading of the muscles
- Tapotement—striking with the side of the hand
- Skin rolling—lifting the skin away from the deeper structures and “rolling” the skin fold along the body

Contraindications

Relative Contraindications

Individual techniques may be contraindicated in specific situations such as; in a patient with severe osteoporosis, prone pressure techniques may be contraindicated in the thoracocostal region, but lateral recumbent techniques could be easily applied.

Direct techniques that stretch acutely injured muscles, tendons, ligaments, or joint capsules may do additional damage to these structures, or increase the amount of pain the patient experiences and are therefore contraindicated.

Articular Technique

Definition

Articular techniques have also been called springing techniques and are defined as direct techniques. In these techniques, the physician gently and repetitively carries the body part being treated through the restrictive barrier. This form of technique could also be called low-velocity/high-amplitude technique. Many of these techniques use long lever forces to achieve their effects.

History

Articular techniques are at least as old as the osteopathic profession itself. In fact, the only film clip that exists of A.T. Still performing a technique is 9 seconds long and appears to be a shoulder or clavicular articular technique.

Indications

Articular technique is indicated when the restrictive barriers to motion appear to be in a joint itself or in the periarticular tissues. It can be used to affect a single joint (e.g., the Glenohumeral joint) or for an entire region (e.g., the thoracic cage). It is well tolerated by arthritic patients, elderly or frail individuals, as well as critically ill or postoperative patients. Also infants and very young patients, as well as others who are unable to cooperate with instructions for other techniques often derive great benefit from articular techniques.

Contraindications

Relative Contraindications

In the upper cervical region, due to the possibility of vertebral artery compromise, it is wise to avoid the combination of repetitive rotation and extension.

Absolute Contraindications to Both Soft Tissue and Articular Techniques

Many techniques including soft tissue and articular techniques are contraindicated for use in the local region of any of the following conditions:

- Fracture or dislocation
- Neurologic entrapment syndromes
- Serious vascular compromise
- Local malignancy
- Local infection (e.g., cellulitis, abscess, septic arthritis, osteomyelitis)
- Bleeding disorders

BASIC TECHNIQUE PRINCIPLES

Soft Tissue Technique

1. The patient should be comfortable and able to relax
2. The physician should also be in a position of comfort to minimize energy expenditure and make use of body weight and leverage rather than having to exert muscular force
3. Initially, the applied forces are very gentle and of low amplitude. The force is applied rhythmically, typically 1 or 2 seconds of stretch followed by a similar time frame releasing that stretch
4. As the soft tissues are palpated responding to the technique, the applied forces can be increased to increase the amplitude of the technique. The rate of application typically remains the same
5. The applied forces should be comfortable for the patient. Some patients experience some discomfort, but it is recognized by the patient as a good discomfort
6. Do not allow your hands to create friction by sliding across the skin or rubbing it. The physician's hand should carry the skin with it as the activating force is applied. Do not compress the musculature directly against a bone
7. The technique is continued until the desired effect is achieved. This typically means that the amplitude of excursion of the soft tissues has reached a maximum and has plateaued at that level

Articular Technique

1. The patient should be comfortable and able to relax
2. The physician should also be in a position of comfort to minimize energy expenditure and make use of body weight and leverage rather than having to exert muscular force

3. The physician moves the affected joint or body part through its range of motion until the restrictive barrier is engaged
4. A gentle but firm force is applied carrying the body part a short distance through the restrictive barrier. The distance is limited by the tissues being treated and the patient's tolerance to pain or fatigue
5. This force is applied rhythmically, typically 1 or 2 seconds of stretch followed by a similar time frame releasing that stretch. The joint is permitted to return to a point just short of its restrictive barrier
6. As the patient responds to the technique, the restrictive barrier will shift position within the physiologic range of motion. For each cycle of the applied technique, reengage the restrictive barrier and carry the affected body part a short distance further through that new barrier to normal motion
7. The applied forces should be comfortable for the patient. Some patients experience some discomfort, but it is recognized by the patient as a good discomfort
8. The technique is continued until the location of the restrictive barrier reaches a plateau; that is, no further increase in range of motion can be achieved by continuing the technique, or until full physiologic range of motion has been restored to the joint(s) being treated
9. At no time is the anatomic barrier to joint motion exceeded

TYPES OF TECHNIQUES

Soft Tissue Technique

Parallel Traction

In this type of soft tissue technique, the forces being applied are parallel to the myofascial structures needing treatment. This may be done by separating the proximal and distal attachments of the muscle (both hands moving in opposite directions like a taffy pull) or by anchoring one end of the muscle and pulling on the other (one hand or structure serving as a stationary anchor, the other one mobile) (Fig. 50.6).

Example: Intermittent cervical traction

Diagnosis

1. Hypertonicity of the cervical musculature
2. Bulging cervical disc
3. Cervical degenerative disc disease

Treatment Position

Patient: Supine on the treatment table

Physician: Seated at the head of the table

Figure 50-6 The taffy pull.

Procedure

1. The physician's one hand cradles the occiput with the thumb and index finger spanning the region just caudad to the superior nuchal line
2. The physician's other hand cradles the chin. (In some patients, this will aggravate a preexisting temporomandibular joint or dental problem—for those cases, an alternative is to place this hand across the patient's forehead.) (Fig. 50.7)
3. The physician applies axial cephalad traction with both hands simultaneously, maintaining the head and neck in a neutral to slightly flexed position. The occipital hand must not squeeze the occiput or there is the risk of compressing the occipitomas-toid suture
4. This technique is applied slowly and rhythmically with gradually increasing amplitude (Fig. 50.8)
5. The technique is continued until the desired soft tissue or disc response is obtained. This may take anywhere from 2 to 5 minutes
6. Success of the technique is determined through palpation to reassess the characteristics of the soft tissues that prompted the selection of the technique to begin with. Success may also be determined in part by reassessing the patient's symptomatology

Figure 50-7 Intermittent cervical traction. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

Figure 50-8 Intermittent cervical traction. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

Perpendicular Traction

In this type of soft tissue technique, the myofascial structure being treated is contacted near its midpoint between the proximal and distal attachments, and a stretching force is applied at right angles to the muscle's longitudinal axis (e.g., similar to an archer stretching a bowstring) (Fig. 50.9).

Example: Contralateral traction

Diagnosis: Hypertonicity of the cervical paraspinal musculature

Treatment Position

Patient: Supine on the treatment table

Physician: Standing at the side of the head of the treatment table

Procedure

1. The physician's cephalad hand bridges the forehead to stabilize and control head motion (Fig. 50.10)
2. The physician's caudad hand reaches around the side of the neck to contact the cervical paraspinal musculature just lateral to the spinous processes
3. While keeping the caudad elbow locked in extension, the physician rotates his/her upper trunk to draw that arm upward, drawing the paraspinal musculature ventrally. Force must be exerted with the cephalad hand to control the head and ensure that minimal cervical extension occurs
4. Care must be taken not to apply too much pressure to the lateral aspect of the cervical region as this may provoke bradycardia and hypotension due to a reflex carotid body response
5. This technique is applied slowly and rhythmically with gradually increasing amplitude
6. The technique is continued until the desired soft tissue response is obtained. This may take anywhere from 2 to 5 minutes

Figure 50-9 The bowstring.

Figure 50-10 Contralateral traction. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*, Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

7. Success of the technique is determined through palpation to reassess the characteristics of the soft tissues that prompted the selection of the technique to begin with. Success may also be determined in part by reassessing the patient's symptomatology

Note: By increasing the rotational force, this technique may be converted to an articulatory technique. By adding more of an axial milking motion, it may be used to enhance lymphatic drainage in the cervical lymph node chains.

Inhibition

In this type of soft tissue technique, the myofascial structure being treated is contacted over the musculotendinous portion of the hypertonic muscle and a force is directed straight into the muscle. Pressing into a hypertonic muscle belly can be painful and may bruise the muscle; therefore, pressure should be directed to the musculotendinous junction.

Example: Suboccipital inhibition

Diagnosis: Hypertonic suboccipital musculature

Treatment Position

Patient: Supine

Physician: Seated at the head of the treatment table

Procedure

1. Places the pads of your fingers just inferior to the superior nuchal line in the suboccipital soft tissues (Fig. 50.11)

Figure 50-11 Suboccipital inhibition. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins with permission.)

- Lifts the head so that the weight of the patient's head is entirely supported on the pads of your fingers. The head is held slightly above, but not resting on, your palms
- Maintain this position until you achieve the desired relaxation of the suboccipital tissues. This may take anywhere from 30 seconds to several minutes
- Success of the technique is determined through palpation to reassess the characteristics of the soft tissues that prompted the selection of the technique to begin with. Success may also be determined in part by reassessing the patient's symptomatology

Note: This technique is similar in position to the method used by A.T. Still when he created a rope sling to relieve his own headaches.

Articulatory Technique

Regional

Articulatory techniques may be applied to entire regions of the spine to improve regional range of motion when the restriction to motion is perceived by the physician to have an articular component to it.

Example: Cervical sidebending

Diagnosis

Position: Cervical spine is sidebent left.

Restriction: Cervical region is restricted in right sidebending.

Treatment Position

Patient: Lateral recumbent, lying on the side of the positional diagnosis

Physician: Sitting on the side of the table in front of the patient, facing the patient's head

Procedure

- Take your left arm and place the patient's right shoulder in your left axilla (Fig. 50.12)
- Your left hand will grasp the spinous process of T1 to serve as an anchor and a reference for motion during this technique
- With your right hand, grasp the patient's head in the left occipitoparietal region and support it in a position neutral to the rest of the spine
- Lift the patient's head up toward the ceiling until you palpate motion occurring at the T1 level. This is your initial restrictive barrier

Figure 50-12 Cervical sidebending. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

- Stretch the cervical spine through this motion barrier, using your left hand to anchor T1
 - Hold this position briefly (<1 second), then return the neck to a position just away from the restrictive barrier
- Rhythmically repeat step 5 as many times as is necessary to achieve full physiologic range of motion for the cervical spine in regional sidebending
- If you are unable to reach full range of motion, continue the technique until there is no further advancement of the restrictive barrier toward the physiologic barrier
- Success of the technique is determined by retesting cervical regional sidebending range of motion

Segmental

Segmental articulatory techniques are applied to segmental motion restrictions that are perceived to be articular in nature in the vertebral column.

Example: Segmental somatic dysfunction—C4

Diagnosis

Position: C4 is rotated right and sidebent right.

Restriction: C4 is restricted in left rotation and left sidebending.

Treatment Position

Patient: Supine

Physician: Standing at the head of the treatment table

Procedure

- Cradle the patient's head between your two hands (Fig. 50.13)
- Place the pad of your right index or middle finger posterior to the articular process of C4. This is the articulating finger
- Place the pad of your left index or middle finger posterior to the articular process of C5. This finger will serve as an anchor and a reference to palpate segmental motion at this level
- Position the cervical spine so that the C4/5 motion segment is in neutral in the sagittal plane
- Use your hands to turn the head to the left until you palpate the motion reach the C5 palpating finger. This is your initial restrictive barrier. (Remember that sidebending and rotation are always coupled motions to the same side in the C2-6 region. You cannot produce one without producing the other.)
- Holding the head and neck stable, use your right articulating finger to exaggerate the rotation/sidebending of C4 to the

Figure 50-13 Segmental somatic dysfunction: C4. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

left. Hold this position briefly (<1 second) and then allow the return of the C4 segment to its position just before engaging the restrictive barrier

7. Rhythmically repeat step 6 as many times as is necessary to achieve full physiologic range of motion for C4
8. If you are unable to reach full range of motion, continue the technique until there is no further advancement of the restrictive barrier toward the physiologic barrier
9. Success of the technique is determined by retesting segmental motion at the C4 level

Peripheral

Articulatory techniques are especially useful in treating restriction of motion of the peripheral limb joints.

Example: Radiocarpal joint restriction

Diagnosis

Position: Radiocarpal joint extended

Restriction: Radiocarpal joint restricted in flexion

Treatment Position

Patient: Supine with dysfunctional arm extended toward the ceiling.

Physician: Standing at the side of the treatment table on the side of dysfunction.

Procedure

1. The physician clasps the hand from both sides with his/her hands. The first hand clasps the patient's hand in a fashion similar to a grip taken in arm wrestling (Fig. 50.14)
2. Steady traction is exerted upward toward the ceiling by the physician. The hand is held pointing vertically toward the ceiling throughout the technique (Fig. 50.15)
3. The patient's wrist is flexed to the restrictive barrier by carrying the patient's shoulder toward flexion (Fig. 50.16)
4. The radiocarpal joint is carried further into flexion through the restrictive barrier and held there for a brief period of time (less than a second). The radiocarpal joint is then allowed to return to a position just before the restrictive barrier by slightly extending the shoulder (Fig. 50.17)
5. Rhythmically repeat step 4 as many times as is necessary to achieve full physiologic range of motion for the radiocarpal joint
6. If you are unable to reach full range of motion, continue the technique until there is no further advancement of the restrictive barrier toward the physiologic barrier
7. The same techniques can be carried out in radial or ulnar deviation and circumduction (Fig. 50.18A and B)
8. Success of the technique is determined by retesting radiocarpal range of motion

TECHNIQUE EXAMPLES

739.0: Head and Suboccipital Somatic Dysfunction

Soft Tissue Technique

Temporalis Muscle

Diagnosis

Hypertonicity of the temporalis muscle

Type of Soft Tissue Technique

Parallel traction

Figure 50-14 A–C. Radiocarpal restriction.

Treatment Position

Patient: Supine with head turned to place dysfunctional temporalis muscle superiorly

Physician: Seated at the side of the table facing the patient.

Procedure

1. Place your cephalad hand beneath the patient's head to prevent excessive head movement (Fig. 50.19)
2. Take the thumb of your caudad hand and place it approximately 2 cm caudad to the temporal lines in the region of the temporalis muscle previously determined to be hypertonic. Your other fingers extend over the top of the skull

Figure 50-15 Radiocarpal joint restriction, step 2.

Figure 50-18 A-B. Radiocarpal joint restriction, step 9.

Figure 50-16 Radiocarpal joint restriction, step 3.

Figure 50-17 Radiocarpal joint restriction, step 4.

Figure 50-19 Temporalis muscle soft tissue.

- The one end of the temporalis muscle is anchored by its attachment to the coronoid process. Your thumb then exerts a force directly toward the skull until sufficient pressure to engage the musculature is achieved
- Exert a tractional force parallel to the muscle fiber direction toward the top of the skull
- Apply this force gently and rhythmically every 1 to 2 seconds. Note the softening of the soft tissue structures as you continue this technique for 1 to 2 minutes. (The time frame is shortened here because of the smaller size of the muscle being treated.)
- Success of the technique is determined by repalping the previously hypertonic temporalis muscle

Articulatory Technique Temporomandibular Joint

Diagnosis

Position: Mandible laterally translated to the right

Restriction: Mandible restricted in left lateral translation

Type of Articulatory Technique

Peripheral

Treatment Position

Patient: Supine with the head turned with the side to be treated superior.

Physician: Seated at the side of the head of the table facing the patient.

Procedure

- The physician's cephalad hand is placed under the patient's head, elevating it slightly (Fig. 50.20)
- The physician's caudad hand is positioned with the third, fourth, and fifth fingers along the posterior border of the ramus of the mandible and the hypothenar eminence along the body of the jaw
- The patient is instructed to open the mouth slightly
- The physician exerts pressure with the hand on the jaw so as to draw the jaw forward at the temporomandibular joint and deviate the jaw laterally to the left
- This traction on the jaw is applied and released in a slow rhythmic pattern, continuing the technique for 30 seconds to 2 minutes
- Success of the technique is determined by reassessing mandibular range of motion in lateral translation.

Figure 50-20 Temporomandibular joint articulatory technique. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

739.1 Cervical Somatic Dysfunction

Soft Tissue Technique

Cradling with Traction

Diagnosis

Hypertonicity of the cervical paraspinal musculature

Type of Soft Tissue Technique

Parallel traction

Treatment Position

Patient: Supine

Physician: Seated at the head of the table

Procedure

- The physician's fingers are placed under the patient's neck bilaterally, with the finger pads contacting the cervical paraspinal musculature overlying the articular pillars and just lateral to the spinous processes (Fig. 50.21)
- The physician exerts pressure ventrally of sufficient force to engage the soft tissues without extending the cervical spine
- The physician pulls the hands cephalad producing a longitudinal traction
- This traction is slowly released
- The physician's hands are repositioned along the cervical pillars and steps 2 to 4 are repeated in a gentle rhythmic manner
- This technique is continued for 2 to 5 minutes
- Success of the technique is determined by repalping the previously hypertonic cervical musculature

Articulatory Technique

Segmental Cervical Extension

Diagnosis

Position: C4 flexed (flexed dysfunctions are commonly found following whiplash injuries)

Restriction: C4 restricted in extension

Type of Articulatory Technique

Segmental

Treatment Position

Patient: Supine

Physician: Seated at the head of the treatment table

Figure 50-21 Cradling with traction soft tissue technique. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

Figure 50-22 Segmental cervical extension articular technique. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

Procedure

1. The physician's fingers are placed under the patient's neck bilaterally, with the finger pads contacting the C4 articular processes and lateral to the spinous processes (Fig. 50.22)
2. The physician exerts pressure ventrally of sufficient force to extend C4 on C5 to the initial restrictive barrier
3. C4 is carried through its restrictive barrier into further extension and held there for a brief period of time (less than a second). C4 is then allowed to return to a position just before the restrictive barrier by releasing the extension force
4. Rhythmically repeat step 3 as many times as is necessary to achieve full physiologic range of motion for C4
5. If you are unable to reach full range of motion, continue the technique until there is no further advancement of the restrictive barrier toward the physiologic barrier
6. Success of the technique is determined by retesting C4 segmental extension

739.2 Thoracic Somatic Dysfunction

Soft Tissue Technique

Prone Pressure with Counterpressure

Diagnosis

Thoracic paravertebral muscle hypertonicity

Type of Soft Tissue Technique

Parallel traction

Treatment Position

Patient: Prone with the head turned toward the physician

Physician: Standing at the side of the table facing the patient's thorax.

Procedure

1. Place your caudad hand on the far side of the spine; the heel of your hand is over the transverse process of the thoracic vertebra at the level of the hypertonic musculature. Your fingers are pointing cephalad (Fig. 50.23)
2. Place your cephalad hand on the near side of the spine, with the heel of your hand over the opposite transverse process of that same vertebral segment. Your fingers are pointing caudad
3. Exert sufficient pressure downward toward the table to engage the myofascial structures of the spine
4. Once this has been accomplished, exert a longitudinal force simultaneously with both hands

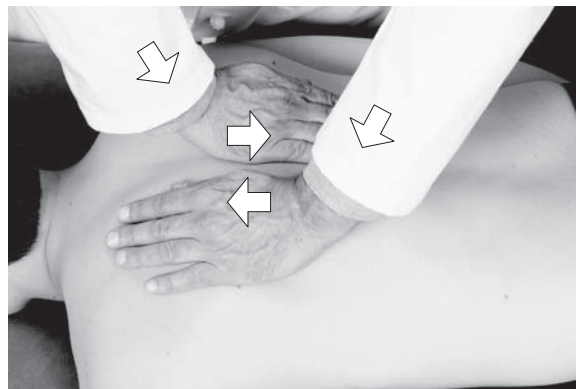

Figure 50-23 Prone pressure with counterpressure soft tissue technique. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

5. This pressure is slowly released

6. The hands are both repositioned together either a segment cephalad or caudad depending upon the needs of the patient
7. Steps 3 to 6 are repeated in a rhythmic fashion for 2 to 5 minutes
8. Success of the technique is determined by palpating the previously hypertonic thoracic paravertebral musculature

Articular Technique

Thoracic Sidebending

Diagnosis

Position: T8 sidebent left

Restriction: T8 restricted in right sidebending

Type of Articular Technique

Segmental

Treatment Position

Patient: Prone with the head turned toward the physician

Physician: Standing at the side of the table facing the patient's thorax

Procedure

1. Place your caudad hand on the far side of the spine, the heel of your hand is over the transverse process of T8. Your fingers are pointing cephalad (Fig. 50.24)

Figure 50-24 Thoracic sidebending articular technique. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

2. Place your cephalad hand on the near side of the spine, with the heel of your hand over the opposite transverse process of T8. Your fingers are pointing caudad
3. Exert sufficient pressure downward toward the table to produce articular motion of the spine
4. Once this has been accomplished, exert a longitudinal force simultaneously with both hands to carry T8 through its restrictive barrier and hold it there briefly (<1 second). This pressure is slowly released allowing T8 to return to a position just before engaging the restrictive barrier
5. Steps 3 and 4 are repeated in a rhythmic fashion until full physiologic motion has been restored to T8
6. If you are unable to reach full range of motion, continue the technique until there is no further advancement of the restrictive barrier toward the physiologic barrier
7. Success of the technique is determined by reassessing segmental sidebending at T8

739.3 Lumbar Somatic Dysfunction

Soft Tissue Technique

Lumbar Seated Technique for Paraspinal Tissues

Diagnosis

Hypertonicity of the left lumbar paraspinal musculature.

Type of Soft Tissue Technique

Perpendicular traction

Treatment Position

Patient: Seated, straddling the treatment table with his/her back to the end of the table.

Physician: Standing behind the patient toward the side opposite the side to be treated. Table height should be adjusted so that the physician stands roughly one head taller than the patient.

Procedure

1. Instruct the patient to place their left hand behind their neck. They are then instructed to grasp the left elbow with the right hand (Fig. 50.25)
2. Place the heel of your left hand on the patient's left paraspinal muscle mass, just lateral to the spinous processes
3. Take your right arm, pass it in front of the patient (under the right upper arm), and grasp the patient's left upper arm
4. Instruct the patient to lean forward and relax so that their weight will be carried by your right arm. The patient will have a natural tendency to rotate their trunk to the right

Figure 50-25 Lumbar seated technique for paraspinal tissues.

Figure 50-26 Lumbar seated technique for paraspinal tissues, step 6.

5. Carry the hypertonic paraspinal musculature laterally away from the spine with your left hand. Simultaneously turn your body to the right so that the rotation of the patient's trunk to the right is exaggerated
6. This traction and rotation is held for as short time and then it is released. The natural tension of the soft tissues will return the lumbar column to a position just inside the restrictive barrier (Fig. 50.26)
7. Reposition your left hand to engage a different portion of the lumbar paraspinal musculature
8. Repeat steps 5 to 7 in a rhythmic fashion for 2 to 5 minutes
9. Success of the technique is determined by palpating the previously hypertonic lumbar musculature

Articulatory Technique

Lumbar Regional Rotation: Seated Position

Diagnosis

Position: Lumbar region rotated left

Restriction: Lumbar region restricted in right rotation

Treatment Position

Patient: Seated, straddling the treatment table with his/her back to the end of the table.

Physician: Standing behind the patient toward the side opposite the side to be treated. Table height should be adjusted so that the physician stands roughly one head taller than the patient.

Procedure

1. Instruct the patient to place their left hand behind their neck. They are then instructed to grasp the left elbow with the right hand
2. Place the heel of your left hand to the left of the patient's spine, overlying the lumbar transverse processes
3. Take your right arm, pass it in front of the patient (under the right upper arm), and grasp the patient's left upper arm
4. Instruct the patient to lean forward and relax so that their weight will be carried by your right arm. The patient will have a natural tendency to rotate their trunk to the right
5. Turn your body to the right so that the rotation of the patient's trunk to the right is exaggerated. Simultaneously exert an anterior pressure with your left hand over the left lumbar transverse processes
6. This rotational force is held for as short time and then released. The natural tension of the soft tissues will return the lumbar column to a position just inside the restrictive barrier

7. Reposition your left hand to engage a different portion of the lumbar spine
8. Repeat steps 5 to 7 in a rhythmic fashion for 2 to 5 minutes
9. Success of the technique is determined by retesting lumbar regional range of motion in rotation

Note: This technique may be converted to a segmental lumbar rotation technique by isolating the forces of the left hand over a single transverse process and by limiting truncal rotation to that amount which specifically articulates that segment.

739.4 Sacral Somatic Dysfunction

Soft Tissue Technique

Bilateral Thumb Pressure: Sacral Region

Type of Soft Tissue Technique

Parallel traction

Diagnosis

Hypertonicity of the multifidus and erector spinae musculature overlying the sacrum

Treatment Position

Patient: Prone

Physician: Standing at the side of the treatment table at the level of the patient's thighs

Procedure

1. Place your thumbs on either side of the spinous process of S1 (Fig. 50.27)

Figure 50-27 A-B. Bilateral thumb pressure—sacral region.

2. Gently press down toward the table until sufficient pressure is in place to engage the sacral paravertebral musculature. *Note:* Care must be taken not to exert excessive pressure as this will compress the muscle against the bone. This causes the patient unnecessary pain and may bruise the soft tissues
3. To the extent permitted by the soft tissues, slide your thumbs cephalad carrying the skin and musculature with them. At the end of longitudinal glide, separate your thumbs slightly exerting a lateral traction. *Note:* Do not slide over the surface of the skin
4. Hold this position for a short period of time and then gradually release the tension
5. Reposition your thumbs half to one segment lower on the sacrum
6. Repeat steps 2 to 4 for 2 or 3 minutes
7. Success of the technique is determined by palpating the degree of tissue tension in the previously hypertonic postsacral musculature

Articulatory Technique

Sacral Rock

Diagnosis

Restriction: Sacral motion with respiration is restricted.

Treatment Position

Patient: Prone

Physician: Standing at the side of the patient at the level of the patient's pelvis

Procedure

1. Place your cephalad hand on the sacrum, heel of the hand at S1, fingers pointing toward the coccyx (Fig. 50.28)
2. Place your caudad hand on top of the other hand, heel of the hand at the S4/5 level, fingers pointing toward the lumbar spine (Fig. 50.29)
3. Instruct the patient to inhale deeply, and follow the sacrum into extension
4. At the end of inhalation, carry the sacrum slightly further into extension and hold it there for a second (Fig. 50.30)
5. Instruct the patient to exhale, and follow the sacrum into flexion
6. At the end of exhalation, carry the sacrum slightly further into flexion and hold it there for a second (Fig. 50.31)
7. Steps 3 to 6 are repeated for 2 or 3 minutes
8. Success of the technique is determined by reassessing sacral motion

739.5 Pelvic Somatic Dysfunction

Soft Tissue Technique

Piriformis Muscle

Type of Soft Tissue Technique

Inhibitory pressure

Diagnosis

Hypertonicity of the piriformis muscle

Treatment Position

Patient: Lateral recumbent with the hypertonic piriformis muscle away from the table.

Physician: Standing at the side of the treatment table, facing the patient at the level of the patient's pelvis.

Figure 50-28 A-B. Sacral rock, step 1.

Figure 50-29 A-B. Sacral rock, step 2.

Procedure

1. Flex the patient's hips to 45 degrees and knees to 90 degrees
2. The hypertonic muscle can be located at the superior posterior corner of the greater trochanter (Fig. 50.32)
3. Place the olecranon process of your cephalad elbow on top of this hypertonic fascicle of muscle (Fig. 50.33)
4. Press gently down ward toward the table for 2 to 5 minutes or until a softening (release) of the muscle is felt. *Note:* Care should be taken with this technique as the olecranon is less sensitive to pressure than the hands and neophytes often exert too much force
5. Success of the technique is determined by repalpating the previously hypertonic piriformis muscle and/or by testing hip range of motion in internal rotation with the hip held in a neutral position

Figure 50-30 Sacral rock, step 4.

Figure 50-31 Sacral rock, step 6.

Figure 50-32 Piriformis muscle, step 2.

Figure 50-33 Piriformis muscle, step 3.

Articulatory Technique

Posteriorly Rotated Innominate: Modified Sims Position

Diagnosis

Position: Posteriorly rotated innominate

Restriction: Innominate is restricted in anterior rotation

Treatment Position

Patient: Modified Sims position with the innominate to be treated away from the table (Fig. 50.34)

Physician: Standing behind the patient at the level of the patient's pelvis

Procedure

1. Place the heel of your cephalad hand posterior to the posterior superior iliac spine on the side of the dysfunction and exert a continuous firm force
2. With your caudad hand, grasp the patient's shin just distal to the knee (Fig. 50.35)
3. With a smooth continuous motion, perform the following motions:
 - Flexion of the hip to 100 to 120 degrees (Fig. 50.36)
 - Abduction of the hip to 25 to 30 degrees (Fig. 50.37)
 - Extension of the hip to 35 to 40 degrees (Fig. 50.38)
 - Adduction of the hip to 0 degrees (Fig. 50.39)

Figure 50-34 Posteriorly rotated innominate—modified Sims position.

Figure 50-35 Posteriorly rotated innominate—modified Sims position, step 2.

Figure 50-36 Posteriorly rotated innominate—modified Sims position, step 3.

Figure 50-39 Posteriorly rotated innominate—modified Sims position, step 3, adduction.

Figure 50-37 Posteriorly Rotated innominate—modified Sims position, step 3, abduction.

Figure 50-40 Plantar fascia soft tissue.

Figure 50-38 Posteriorly rotated innominate—modified Sims position, step 3, extension.

4. Repeat this series of movements three to five times
5. Success of the technique is determined by retesting iliosacral motion

739.6 Lower Extremity Somatic Dysfunction

Soft Tissue Technique

Plantar Fascia

Diagnosis

- Plantar fasciitis
- Rigid pes planus
- Need for general relaxation and sedation

Treatment Position

Patient: Supine

Physician: Seated at the foot of the treatment table

Procedure

1. Place your other hand beneath the patient's heel to stabilize the foot (Fig. 50.40)
2. Make a loose fist with your dominant hand, and position your fingers so that a smooth spiraling arc of a surface is created by the proximal phalanges of your fingers (Fig. 50.41)
3. Contact the sole of the foot just proximal to the heads of the metatarsals with the proximal phalanx of your little finger (Fig. 50.42)
4. Maintaining a firm pressure against the arch, slide your fingers down the sole of the foot toward the medial calcaneal tubercle. Your proximal phalanges of your fingers should make sequential contact (little finger, ring finger, middle finger, index finger) with the sole of the foot proximal to the heads of the metatarsals (Fig. 50.43)
5. Upon reaching the heel, remove your hand and repeat steps 3 and 4
6. This technique is continued for 3 to 5 minutes
7. Success of this technique is determined by palpating for reduced tension in the plantar fascia, or reassessing the mobility of the longitudinal arch, or by auscultating a snoring sound from your patient

Figure 50-41 Plantar fascia soft tissue, step 2.

Figure 50-44 Longitudinal arch springing.

Figure 50-42 Plantar fascia soft tissue, step 3.

Figure 50-43 Plantar fascia soft tissue, step 4.

Articulatory Technique Longitudinal Arch Springing

Diagnosis

Restriction: Rigidity or reduced motion of the longitudinal arch

Treatment Position

Patient: Patient lies supine

Physician: Seated at the foot of table

Procedure

1. Place both thumbs under the arch of the foot from the medial aspect with the fingers of each hand fanning out on the dorsal surface of the foot (Fig. 50.44)
2. With your more cephalad thumb, lift the arch with a force that wraps from medial to lateral across the top of the foot
3. With your more caudad thumb, lift the lateral aspect of the more distal portion of the arch; your hand wraps medially around the foot creating an arch raising counterforce
4. The two hands twist in opposite directions with a “wringing” motion, reestablishing the arch. After each wringing motion, the thumbs are shifted slightly more proximal or distal on the arch, not twisting the foot in exactly the same way each time (Fig. 50.45)
5. Success of the technique is determined by reevaluating the mobility of the longitudinal arch

739.7 Upper Extremity Somatic Dysfunction

Soft Tissue Technique

Rhomboid Muscles

Type of Soft Tissue Technique

Parallel traction

Diagnosis

Hypertonicity of the rhomboid musculature

Treatment Position

Patient: Lateral recumbent technique with the rhomboid to be treated away from the table

Physician: Standing facing the patient at the level of the patient’s shoulder

Figure 50-45 A-B. Longitudinal arch springing, step 4.

Procedure

1. Extend the patient's shoulder to 45 degrees and have the patient's hand rest on the lateral abdomen (Fig. 50.46)
2. Pass your caudad hand under the patient's arm, and with the pads of your fingers, grasp the medial border of the scapula
3. With your cephalad hand, contact the anterior portion of the shoulder to provide an effective counterforce
4. With your caudad hand, draw the medial border of the scapula laterally and caudad, parallel to the fibers of the rhomboid musculature, hold for a second, and slowly release the tension
5. This technique is applied slowly and rhythmically gradually progressing along the medial border of the scapula
6. Continue this technique for 3 to 5 minutes
7. Success of the technique is determined through palpation of the previously hypertonic rhomboid musculature. Success may also be determined in part by reassessing the patient's symptomatology

Figure 50-46 A-B. Rhomboid muscles.

Articulatory Technique Seven Stages of Spencer

Historical note: These techniques were developed by Charles H. Spencer, DO of Los Angeles, CA. They were first presented before the Section on Technic at the Portland Session of the American Osteopathic Association Convention, August 1915, and published in the *Journal of the American Osteopathic Association*. The original version of these techniques was largely forgotten; as were the photos and many personal modifications were developed by osteopathic physicians over the ensuing years. One of the common modifications of stage 5 was taught by Angus Cathie, DO, in Philadelphia, hence the division of stage 5 into parts 5-A and 5-B. Stage 5-A is the technique as Spencer performed it (2–5). Another commonly taught modification is the addition of a postisometric relaxation muscle energy technique performed in the same position for those stages that permit this sort of modification.

Indications

- Bursitis of the shoulder
- Tendinitis and tenosynovitis of the shoulder
- Fibrous adhesive capsulitis

Treatment Position

Patient: Lateral recumbent with the shoulder to be treated away from the table

Physician: Standing at the side of the table facing the patient at the level of the patient's chest

Procedure

Stage 1: Extension

1. Use your cephalad hand to stabilize the shoulder girdle by spanning with scapular and clavicle from the superior aspect with your thumb and fingers (Fig. 50.47).

Figure 50-47 Seven stages of Spencer—stage 1—extension. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

2. With your caudad hand, grasp the patient's forearm just distal to the elbow
3. Carry the shoulder into extension until you engage the restrictive barrier
4. Apply a gentle but firm force carrying the shoulder a short distance through its restrictive barrier. Hold for 1 or 2 seconds and release. Passive tissue tension will return the shoulder to a position just inside the restrictive barrier. Apply this force rhythmically, stretching 1 to 2 seconds, followed by a release of that stretch. This rhythmic stretching is continued until no further progress in shoulder extension can be appreciated
5. *Muscle energy modification:* The patient is instructed to flex the shoulder against the physician's unyielding resistance. This contraction is held for 3 to 5 seconds followed by a second of relaxation before the restrictive barrier is again engaged
6. Step 5 is repeated three to five times
7. Success of the technique is determined by retesting shoulder range of motion in extension. Success is determined in part by reassessing the patient's symptoms

Stage 2: Flexion

1. Draw the patient's arm across in front of their body toward flexion. At the same time, turn your body to face the head of the table, arm in front of you (Fig. 50.48)
2. Switch hands so that your hand farthest from the body grasps the patient's hand

Figure 50-48 Seven stages of Spencer—stage 2—flexion. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

3. Use your hand that is closest to the patient to anchor the shoulder girdle by placing the heel of your hand on the spine of the scapula and extending your fingers over the top of the shoulder to the clavicle
4. Carry the shoulder into flexion until you engage the restrictive barrier
5. Apply a gentle but firm force carrying the shoulder a short distance through its restrictive barrier. Hold for 1 or 2 seconds and release. Passive tissue tension will return the shoulder to a position just inside the restrictive barrier. Apply this force rhythmically, stretching 1 to 2 seconds, followed by a release of that stretch. This rhythmic stretching is continued until no further progress in shoulder flexion can be appreciated
6. *Muscle energy modification:* The patient is instructed to extend the shoulder against the physician's unyielding resistance. This contraction is held for 3 to 5 seconds followed by a second of relaxation before the restrictive barrier is again engaged
7. Step 5 is repeated three to five times
8. Success of the technique is determined by retesting shoulder range of motion in flexion. Success is determined in part by reassessing the patient's symptoms

Stage 3: Compression Circumduction

1. Return to your starting position for stage 1 (Fig. 50.49)
2. Abduct the patient's shoulder to approximately 90 degrees
3. Very gently compress the patient's elbow toward the glenoid fossa
4. Start making small clockwise circles, a circumduction motion. Gradually enlarge these circles creating larger and larger concentric circles as the patient's condition permits. This movement is continued for 15 to 30 seconds
5. Then reverse direction performing the same maneuver in a counterclockwise direction. There are occasions where a restriction may not be felt in one direction but may become quite evident in the reverse direction
6. It is not necessary to perform the entire circle every time. If an arc of motion is identified that is particularly restricted, movement can be limited to that restricted arc
7. *Muscle energy modification:* None for stage 3

Figure 50-49 Seven stages of Spencer—stage 3—compression circumduction. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

Figure 50-50 Seven stages of Spencer—stage 4—traction circumduction. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

- Success of the technique is determined by reassessing circumduction of the shoulder. Success is determined in part by reassessing the patient's symptoms

Stage 4: Traction Circumduction

- Upon completion of stage 3, extend the patient's elbow and grasp the patient's arm at the wrist by encircling it with your hand (take care not to compress any of the neural or vascular structures crossing the wrist joints) (Fig. 50.50)
- Place a gentle traction upward toward the ceiling on the wrist
- Start making small clockwise circles, a circumduction motion. Gradually enlarge these circles creating larger and larger concentric circles as the patient's condition permits. This movement is continued for 15 to 30 seconds
- Then reverse direction performing the same maneuver in a counterclockwise direction. There are occasions where a restriction may not be felt in one direction but may become quite evident in the reverse direction
- It is not necessary to perform the entire circle every time. If an arc of motion is identified that is particularly restricted, movement can be limited to that restricted arc
- Muscle energy modification:* None for stage 3
- Success of the technique is determined by reassessing circumduction of the shoulder. Success is determined in part by reassessing the patient's symptoms

Stage 5A: Adduction and External Rotation

- Return to the starting position for stage 1 (Fig. 50.51)
- Move your cephalad arm so that your forearm is at right angles to the long axis of the patient's body and parallel to the surface plane of the table
- Slightly flex the shoulder so that the arm may pass just in front of the body
- With your caudad hand, adduct the shoulder until the restrictive barrier is engaged

Figure 50-51 Seven stages of Spencer—stage 5A—adduction external rotation. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

- Apply a gentle but firm force carrying the shoulder a short distance through its restrictive barrier. Hold for 1 or 2 seconds and release. Passive tissue tension will return the shoulder to a position just inside the restrictive barrier. Apply this force rhythmically, stretching 1 to 2 seconds, followed by a release of that stretch. This rhythmic stretching is continued until no further progress in shoulder adduction can be appreciated
- Muscle energy modification:* The patient is instructed to abduct the shoulder against the physician's unyielding resistance. This contraction is held for 3 to 5 seconds followed by a second of relaxation before the restrictive barrier is again engaged
- Step 5 is repeated three to five times
- Success of the technique is determined by retesting shoulder range of motion in adduction. Success is determined in part by reassessing the patient's symptoms

Stage 5B: Abduction

- Return to your starting position for stage 5 (Fig. 50.52)
- With your caudad hand, abduct the shoulder until the restrictive barrier is engaged
- Apply a gentle but firm force carrying the shoulder a short distance through its restrictive barrier. Hold for 1 or 2 seconds and release. Passive tissue tension will return the shoulder to a position just inside the restrictive barrier. Apply this force rhythmically, stretching 1 to 2 seconds, followed by a release of that

Figure 50-52 Seven stages of Spencer—stage 5B—abduction. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

Figure 50-53 Seven stages of Spencer—stage 6—internal rotation. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

stretch. This rhythmic stretching is continued until no further progress in shoulder abduction can be appreciated

4. *Muscle energy modification:* The patient is instructed to adduct the shoulder against the physician's unyielding resistance. This contraction is held for 3 to 5 seconds followed by a second of relaxation before the restrictive barrier is again engaged
5. Step 5 is repeated three to five times
6. Success of the technique is determined by retesting shoulder range of motion in abduction. Success is determined in part by reassessing the patient's symptoms

Stage 6: Internal Rotation

Note: Patients with severely advanced fibrous adhesive capsulitis may not be able to be placed in position for this technique without significant modification (Fig. 50.53).

1. Abduct the patient's shoulder 45 degrees. Internally rotate the patient's shoulder 90 degrees (if possible). Place the dorsum of the patient's hand in the small of the back
2. Reinforce the anterior portion of the shoulder with your cephalad hand
3. Gently pull the patient's elbow forward until the restrictive barrier is engaged
4. Apply a gentle but firm force carrying the shoulder a short distance through its restrictive barrier. Hold for 1 or 2 seconds and release. Passive tissue tension will return the shoulder to a position just inside the restrictive barrier. Apply this force rhythmically, stretching 1 to 2 seconds, followed by a release of that stretch. This rhythmic stretching is continued until no further progress in shoulder abduction can be appreciated
6. *Muscle energy modification:* The patient is instructed to pull the elbow backward against the physician's unyielding resistance. This contraction is held for 3 to 5 seconds followed by a second of relaxation before the restrictive barrier is again engaged
7. Step 6 is repeated three to five times
8. Success of the technique is determined by retesting shoulder range of motion in internal rotation. Success is determined in part by reassessing the patient's symptoms

Stage 7: Traction with Inferior Glide

1. Turn and face the head of the table (Fig. 50.54)
2. Abduct the patient's arm and place the patient's hand and wrist on your shoulder closest to the patient
3. With fingers interlaced, place your hands just distal to the glenohumeral joint

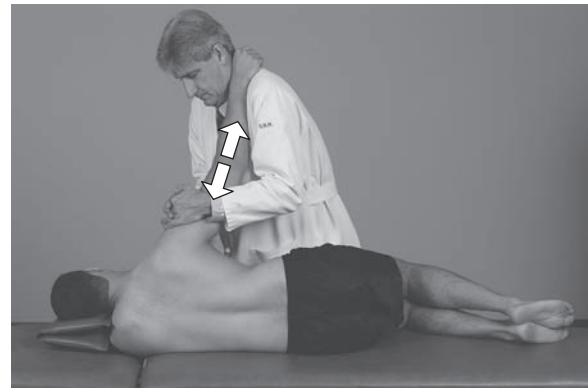

Figure 50-54 A & B. Seven stages of Spencer—stage 7—traction with inferior glide. (Used from Nicholas & Nicholas. *Atlas of Osteopathic Technique*. Philadelphia, PA: Lippincott, Williams & Wilkins, with permission.)

4. Scoop the patient's humeral head in a caudad direction parallel to the table, creating a translatory motion toward the inferior edge of the glenoid fossa
5. Apply a gentle but firm force carrying the shoulder a short distance through its restrictive barrier. Hold for 1 or 2 seconds and release. Passive tissue tension will return the shoulder to a position just inside the restrictive barrier. Apply this force rhythmically, stretching 1 to 2 seconds, followed by a release of that stretch. This rhythmic stretching is continued until no further progress in shoulder abduction can be appreciated
6. *Muscle energy modification:* While maintaining the caudad traction on the patient's arm, instruct the patient to press their hand down against your shoulder. This contraction is held for 3 to 5 seconds followed by a second of relaxation before the restrictive barrier is again engaged
7. Step 6 is repeated three to five times
8. Success of the technique is determined by retesting shoulder range of motion. Success is determined in part by reassessing the patient's symptoms

739.8 Rib Somatic Dysfunction

Soft Tissue Technique Scalene Stretching

Diagnosis

Hypertonicity of the scalene musculature maintaining ribs 1 and 2 in a position of inhalation on the left side of the neck

Type of Soft Tissue Technique

Parallel traction

Figure 50-55 Scalene stretching.

Treatment Position

Patient: Supine
