DISCLAIMER

Care has been taken to confirm the accuracy of the information present and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: <http://www.lww.com>. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6:00 pm, EST.

DEDICATION

This third edition of Foundations of Osteopathic Medicine is dedicated to two individuals who made very significant contributions to the development of osteopathic medical research. Common threads bound their careers together: dedication to better understanding of the scientific basis of osteopathic medicine; complementary relationship in Basic Science and Clinical Science research; and sustained support of the research effort of the American Academy of Osteopathy, an affiliate body of the American Osteopathic Association. Their respective years of passage span the time between the release of the second and third editions of this text.

WILLIAM L. JOHNSTON, DO, FAAO

February 17, 1921–June 10, 2003

It is with sadness that I announce the passing of William L. Johnston, DO, and commemorate his numerous achievements. As Editor-in-Chief of the American Osteopathic Association (AOA) and having served on the AOA Bureau of Research, I have had the opportunity to work with truly outstanding people. Dr Johnston, with whom I collaborated for more than 20 years, was certainly one of those individuals.

I consider Dr Johnston a mentor in the truest sense of the word. He introduced me to research involving osteopathic principles and practice in a meaningful way. I met Dr Johnston at the Michigan State University College of Osteopathic Medicine (MSU–COM), East Lansing, when I was a young physician assuming a new role as vice chairman of the Bureau of Research. I was thoroughly impressed with the breadth and depth of his understanding of osteopathic medicine, particularly the focus he believed was needed in future research.

An outstanding teacher and, more important, an original and profound thinker, Dr Johnston was a professional who got things done. Truly, he was an original and special man who deserves every accolade that can be applied to such a professional. I am sure I am but one individual who will write a memoriam about Dr Johnston.

When I became the AOA's Editor-in-Chief, I decided to name new members to *JAOA's* Editorial Advisory Board. I needed a mentor to guide my choices. I wanted someone who had the respect of the profession and who understood what is meant by osteopathic principles and practice at the deepest level.

I found that the individual I needed was already on the Editorial Advisory Board. He was a go-to individual for many of my questions concerning osteopathic medicine. When he spoke at our Editorial Advisory Board meetings, the room became quiet and all attention was directed toward him. Everything Dr Johnston said was meaningful and important and sometimes enormously funny in the way he had of bringing reality to the table.

All in the osteopathic medical profession will miss Dr Johnston. I know that the faculty and students at MSU–COM will deeply miss him. And I will personally feel the void left by one so large in knowledge and personal responsibility.

Dr Johnston's family was blessed to have had his loving presence. I am sure that he will remain firmly in their minds and deep in their hearts for the remainder of their lives and will most likely live on for generations to come. A finer, more dedicated osteopathic physician committed to this profession, its research, and education would be difficult to find.

ALBERT F. KELSO, PHD, DSCI (HON)

November 19, 1917–January 29, 2009

It was with a great sense of loss that we inform you of the death of Albert F. Kelso, PhD. Dr. Kelso was more than just a colleague and fellow Academy member. Dr. Kelso received a Doctor of Philosophy degree from Loyola University Graduate School in 1959 and later received a Doctor of Science (Hon) from Kirksville College of Osteopathic Medicine in 1970. Dr. Kelso was also a student at the Institute of Medicine in Chicago as well as the University of Chicago.

Beginning in the mid-40s, Dr. Kelso worked as a biology and physiology instructor, professor, and department chair at George Williams College and the Chicago College of Osteopathic Medicine. By 1975, he was involved in research serving as the director of research affairs as well as a research professor in osteopathic medicine. It was in 1974 when he first became a research consultant on the AAO's Louisa Burns Clinical Observation Committee where he still gave counsel until his passing. He was awarded the American Osteopathic Association's 1981 Louisa Burns Memorial Lecture, "Planning, Developing and Conducting Osteopathic Clinical Research." Dr. Kelso was honored as the 2005 recipient of the ACADEMY AWARD in recognition of his outstanding commitment to the osteopathic medical profession, supporting its philosophy, principles, and practices.

As a representative of the Association of Colleges of Osteopathic Medicine, Dr. Kelso served on the National Society of Medical Research in addition to serving as a representative to the Medical Legal Council of the Illinois State Medical Society, Medical Records and Right to Privacy through 1982. Dr. Kelso was an educational consultant for the AOA's Committee on Colleges and served on their Council of Osteopathic Educational Development. Since 1981, he served as an editorial referee for the Journal of the AOA, and he was an associate editor of the definitive textbook, *Foundations of Osteopathic Medicine*, which was published in 1997.

Dr. Kelso was author or contributing author on several publications and has many abstracts and papers printed in a variety of medical journals. He was a member of many notable professional societies such as the American Academy of Osteopathy, American Osteopathic Association, American Physiologic Society, and the Illinois Society for Medical Research.

We know that his passing will leave a void not only in our lives but also in the hearts of all those who knew him.

Section 3**Osteopathic Manipulative Treatment** 669

TRADITIONAL APPROACHES

45. **Thrust (High Velocity/Low Amplitude) Approach; “The Pop”** 669
Hohner, Cymet
46. **Muscle Energy Approach** 682
Ehrenfeuchter
47. **Myofascial Release Approach** 698
O’Connell
48. **Osteopathy in the Cranial Field** 728
King
49. **Strain and Counterstrain Approach** 749
Glover, Rennie
50. **Soft Tissue/Articulatory Approach** 763
Ehrenfeuchter
51. **Lymphatics Approach** 786
Kuchera

CONTEMPORARY APPROACHES

52. **Representative Models** 809
Dowling
- A. **Balanced Ligamentous Tension and Ligamentous Articular Strain** 809
Crow
- B. **Facilitated Positional Release** 813
Dowling

- C. **Progressive Inhibition of Neuromuscular Structures** 820
Dowling
- D. **Functional Technique** 831
Johnston
- E. **Visceral Manipulation** 845
Lossing
- F. **Still Technique** 849
Van Buskirk
- G. **Chapman’s Approach** 853
Fossum, Kuchera, Devine, Wilson
- H. **Fulford Percussion** 866
Yadava

PART IV: APPROACH TO OSTEOPATHIC PATIENT MANAGEMENT

Section Editors: Jane E. Carreiro, DO, Anthony G. Chila, DO, FAAO dist, FCA., and John C. Glover, DO, FAAO

53. **Elderly Patient with Dementia** 873
Bates, Gugliucci
54. **Uncontrolled Asthma** 883
Morelli, Sanchez
55. **Adult with Chronic Cardiovascular Disease** 889
Kaufman
56. **Adult with Chronic Pain and Depression** 903
Kuchera, Jerome
57. **Dizziness** 910
Shaw, Shaw
58. **Child with Ear Pain** 918
Steele, Mills
59. **Difficulty Breathing** 931

PREFACE

This third edition of *Foundations of Osteopathic Medicine* (FOM3) is built on a years-long commitment by members of the osteopathic medical profession and the American Osteopathic Association (AOA). An informal proposal for a textbook began 30 or more years ago by the Educational Council on Osteopathic Principles (ECOP). The effort at that time was directed toward development of a longitudinal curriculum in Osteopathic Principles and Practice (OPP). Historically, other such forums had also discussed additional alternatives. The concept and plan for the text as it emerged were developed within the Bureau of Research of the AOA. It was the Bureau's decision to term this activity the "Osteopathic Principles Textbook Project". The Board of Trustees and House of Delegates of the AOA provided financial support for its development, and the project was launched in July 1990. Under the pioneering leadership of Executive Editor Robert C. Ward, DO, FAAO, the first and second editions of this text appeared in 1997 and 2003, respectively. Doctor Ward's decision not to continue led to search and selection of a new executive editor. It was with some trepidation that I accepted this great responsibility in late 2006. Personal friendship with Dr. Ward over many years helped to assuage concern, and transitioning in responsibility occurred between Dr. Ward and I began in November 2006. Formal meetings with Lippincott Williams & Wilkins (LWW) personnel and section editors for FOM3 occurred at Philadelphia, PA (LWW corporate offices) in January 2007 and Chicago, IL (AOA Headquarters) in October 2008. The remainder of work to conclusion of the FOM3 project was carried out via a series of teleconferences and ongoing electronic communication.

The process of review and revision was carried out in a careful and thoughtful manner. Particular attention was given to change in the construct and delivery of health care in recent years. From this viewpoint, the traditional and present positions of the osteopathic medical profession were analyzed. Also factored into discussions was the rapid growth in numbers and student bodies of colleges of osteopathic medicine. This entailed consideration of contemporary curricular tendencies in the numerous institutions. The overall decision reached was that FOM3 should be prepared and viewed as a resource applicable to all phases of osteopathic medical education. As in previous editions, recognition is given to addressing the needs of students and practitioners. The format chosen emphasizes the approach to the patient. The organization of the text is given in the following overview.

PART I: FOUNDATIONS

Section 1: Overview of the Osteopathic Medical Profession

The number of chapters in this section is doubled from previous editions. The role of the ECOP in developing the Osteopathic Five Models is elaborated in *Osteopathic Philosophy*. This effort considers the manifestation of the models (Biomechanical; Respiratory-Circulatory; Metabolic; Neurological; Behavioral) in three components of a philosophy of medicine (Health, Disease, Patient Care). New chapters are *Osteopathic Education and Regulation* and *International Osteopathic Medicine and Osteopathy*.

Section 2: Basic Sciences

Two major changes characterize this section: The five models of patient diagnosis, treatment, and management frequently used by osteopathic physicians provide the background for this section. As a result, all but three of the chapters in *Basic Science and Behavioral Science* (FOM2) have been completely rewritten or replaced by new material. In addition, consolidation into one section reflects a strong belief that integration of body and mind lies at the heart of osteopathic medicine.

A complete explanation of the significance of these changes is provided in Chapter 5.

PART II: THE PATIENT ENCOUNTER

A completely new emphasis is found in this contribution to FOM3. Authors point out that in the initial patient encounter, patient rapport is as important as the gathering of historical information. It is acknowledged that several clinical issues represent public health problems of such magnitude that all physicians must participate in detection and treatment (e.g., cancer, hypertension, hypercholesterolemia). Effective patient management occurs best within the largest possible context, including cultural, socioeconomic, and religious/spiritual issues.

PART III: APPROACH TO THE SOMATIC COMPONENT

A reorganization of concept characterizes the change represented in PART III. Fundamental methods remain, as do osteopathic considerations for the various regions of the body. Methods, however, receive a very different perspective. Designation as *Traditional Approaches* or *Contemporary Approaches* portrays the present-day teaching emphases in the various colleges of osteopathic medicine. Patient Vignettes are found throughout. These are presented as commonly encountered clinical complaints and serve as a means of reinforcing the value of skillful palpation, establishment of an appropriate palpatory diagnosis, and a rationale for the selection of osteopathic manipulative intervention.

Section 1: Basic Evaluation

Palpation, Screening Examination, Segmental Motion Testing, and Posture continue to define fundamental approaches to patient assessment.

Section 2: Osteopathic Considerations of Regions

Following precedents from FOM1 and FOM2, the various body regions are discussed with a view to facilitating the use of contemporary medical information in the establishment of an osteopathic medical approach to diagnosis, treatment, and management of clinical presentations.

Section 3: Osteopathic Manipulative Treatment

Traditional Approaches

Represented here are the methods of osteopathic manipulative intervention uniformly taught at all colleges of osteopathic

medicine: *Thrust (HV/LA)*; *“The Pop”*; *Muscle Energy*; *Myofascial Release*; *Osteopathy in the Cranial Field*; *Strain/Counterstrain*; *Soft Tissue/Articulatory*; *Lymphatics*.

This group of methods was determined during various consultations and discussions held with the ECOP during its meetings, 2007–2009.

Contemporary Approaches

In the broader perspective of osteopathic theory and practice, various other methods are being developed, refined, and taught. Not all are regularly taught at colleges of osteopathic medicine. Representatives of this group of methods are *Balanced Ligamentous Tension/Ligamentous Articular Strain*; *Facilitated Positional Release*; *Progressive Inhibition of Neuromuscular Structures*; *Functional Technique*; *Visceral Manipulation*; *Still Technique*; *Chapman’s Approach*; *Fulford Percussion*.

Whether *Traditional* or *Contemporary*, all approaches described in FOM3 reflect the components of the osteopathic medical profession’s definition of *Somatic Dysfunction*: Impaired or altered function of related components of the somatic (body framework) system: skeletal, arthrodiagonal, and myofascial structures, and related vascular, lymphatic, and neural elements. The systematic use of palpation in the process of palpatory diagnosis remains the hallmark expression of osteopathic medical practice.

PART IV: APPROACH TO OSTEOPATHIC PATIENT MANAGEMENT

Another completely new emphasis is found in this contribution to FOM3. It is well recognized that the curricula of many colleges of osteopathic medicine utilize case-based learning modules, which may employ various formats. Represented here is a selection of commonly encountered clinical presentations found in individuals from the young to the elderly. The entities chosen for presentation do not constitute a comprehensive listing, but serve as guides to the development of the thought processes of the osteopathic medi-

cal student and practitioner. Patient Vignettes are used to demonstrate an osteopathic medical approach to diagnosis, treatment, and management of each situation. Further, the applicability of the five models of patient diagnosis, treatment, and management is given specific attention within the context of the clinical presentation.

PART V: APPROACHES TO OSTEOPATHIC MEDICAL RESEARCH

Continued refinement of the focus for osteopathic medical research has defined five components: *Foundations*; *Priorities*; *Development/Support*; *Biobehavioral*; *Future*. The osteopathic medical profession has made many original contributions to the study of its premises. There is, in society at large, generous recognition of such. More effort is needed in validation of Osteopathic Manipulative Treatment (OMT). With pending changes in the health care delivery system in coming years, documentation of efficacy of OMT in promoting and maintaining health would be a most welcome contribution. Although not the exclusive expression of osteopathic medical practice, elucidation of knowledge about efficacy would significantly enhance the appreciation of this approach in attaining and maintaining health. This, after all, was the vision of Andrew Taylor Still.

The goal of the editorial team of FOM3 has been to continue to build on the work of our predecessors in FOM1 and FOM2. Change as introduced in this text seeks to acknowledge present trends in the educational formats and styles used in colleges of osteopathic medicine and their various programs. In doing so, it is hoped that the result offers the contemporary expression of osteopathic medical practice. It can only be certain that, with pending changes in health care delivery, future editions of this text will also seek to improve upon this effort.

It has been a privilege to serve.

ANTHONY G. CHILA, DO, FAAO *dist*, FCA
Executive Editor

FOREWORD

As Editor-in-Chief of the American Osteopathic Association, I again have the pleasure to present another edition of *Foundations of Osteopathic Medicine*. This third edition has uniqueness. It is a robust revision of an already strong textbook that has embraced the guiding principle and goal of teaching osteopathic medical students to think like osteopathic physicians. So instead of trying to create an “encyclopedic cookbook” that educates students on how to treat patients for every conceivable illness, this textbook concentrates on providing a solid foundation and clear examples that illustrate how osteopathic physicians think through patients’ problems.

To that end, we replaced the section on individual specialties with 17 new chapters in Part IV on problem-based learning. It is not intended for these chapters to be all-encompassing. Instead, each chapter involves a case example of how osteopathic principles and practice can be applied to patient care using existing osteopathic evidence and experience. We hope that faculty at osteopathic colleges and universities use and build on these chapters to provide their students with solid examples on how to apply the fundamentals of osteopathic medicine to daily patient care.

Additionally, the third edition has been strengthened with revisions made to the chapters on osteopathic manipulative treatment techniques (Part III) to concentrate on the techniques that are universally taught at osteopathic medical schools. However, there has been a preservation of the second edition’s effort to expose osteopathic medical students to as many OMT techniques as possible by placing eight lesser used treatments in Chapter 52, which is titled “Contemporary Approaches.”

Also central to this textbook are osteopathic medicine’s five models of treatment, which are introduced in Chapter 5 and applied throughout Part IV. Equally critical to understanding and appreciating the Foundation’s major themes are Chapter 1 on osteopathic philosophy and Part II on the patient encounter. Together, these chapters will lead students to understand how to think and practice osteopathically and use the rest of the textbook more effectively.

One can not help but to believe that all physicians may benefit from various sections in this textbook. I have expressed before how I have uncovered both scientific and clinical information that has helped me understand and practice pulmonary and critical care medicine using osteopathic principles and practices.

Importantly, the American Association of Colleges of Osteopathic Medicine’s Educational Council on Osteopathic Principles

(ECOP) was consulted throughout the process of revising this textbook. As with the first two editions of *Foundations*, ECOP’s glossary of terminology is included as an appendix to the third edition.

The *Foundations* textbook was the vision of Howard M. Levine, D.O., and the first two editions that were edited by Robert C. Ward, D.O. Through their persistent commitment to the osteopathic medical profession, this textbook came to life and flourished. This third edition would not have been possible without its executive editor, Anthony G. Chila, D.O., who dedicated four years of his life to planning and executing this revision. He has been a model of diligence and diplomacy, working with 10 dedicated section editors, all highly accomplished within the osteopathic medical profession, nearly 80 authors and numerous peer reviewers. To ensure that he could devote the necessary time and concentrated effort to this edition, Dr. Chila made such sacrifices as passing on the reins of the editorship of the *American Academy of Osteopathy Journal*. Combining his skills as a leader with his expertise in osteopathic medicine, Dr. Chila commanded and received the respect of the numerous contributors to *Foundations* and pulled them together to work as a team.

More than anyone else, Dr. Chila identified the new and guiding vision for the third edition. He inspired the other leaders and contributors, and he kept the entire complex process on track and on time. Dr. Chila paid careful attention to the needs of the faculty at our colleges and universities, making sure that he received feedback from ECOP on the plans and outcome of this edition.

On a personal note, I have known Tony for nearly thirty years, and I have admired him for the countless contributions he has made to osteopathic medicine. When I asked him to take this challenge on, he accepted without hesitation. As his colleague and as Editor-in-Chief of AOA Publications, I view the third edition of *Foundations of Osteopathic Medicine* as among Tony’s greatest legacies to the osteopathic profession and to medicine in general. I am proud of what he has done to make this edition even more relevant than previous editions for educating both current and future DOs to think like osteopathic physicians.

GILBERT E. D’ALONZO, D.O.
Editor-in-Chief, AOA Publications
American Osteopathic Association

ACKNOWLEDGMENTS

The work involved in preparation of this third edition of *Foundations of Osteopathic Medicine* (FOM3) was a dedicated effort by many individuals. In accomplishing their various tasks, all contributed to a cohesive product representing another level of development for this text. Grateful appreciation is extended to the following:

SECTION EDITORS

Jane E. Carreiro, DO
Anthony G. Chila, DO, FAAO *dist*, FCA
Dennis J. Dowling, DO, FAAO
Russell G. Gamber, DO, MPH
John C. Glover, DO, FAAO
Ann L. Habenicht, DO, FAAO
John A. Jerome, PhD, BCFE
Michael M. Patterson, PhD
Felix J. Rogers, DO, FACOI
Michael A. Seffinger, DO, FAAFP
Frank H. Willard, PhD

In establishing a new direction for FOM3, the *Section Editors* readily acknowledged the accomplishments and effort of contributors to the second edition of this text (FOM2). Specific recommendation was made to allow for online access to Section VI of FOM2 (*Clinical Specialties*). This offers demonstrable continuity between the second and third editions of this text.

In the matter of reformulating the content approach of this third edition of FOM3, the *Section Editors* also sought to express appreciation to former authors whose contributions helped shape the conceptual expression of the text:

David A. Baron, MEd, DO	David A. Patriquin, DO, FAAO
Ronald H. Bradley, DO, PhD	Ronald P. Portanova, PhD
Boyd R. Buser, DO	Bernard R. Rubin, DO
Thomas A. Cavaliere, DO	Mark Sandhouse, DO
Shawn Centers, DO	Stanley Schiowitz, DO, FAAO
Eileen L. DiGiovanna, DO, FAAO	Richard J. Snow, DO, MPH
Norman Gevitz, PhD	Harvey Sparks Jr., MD, PhD
Philip E. Greenman, DO, FAAO	Sarah A. Sprafka, PhD
Deborah M. Heath, DO, MD(H)	Robert J. Theobald Jr., PhD
James B. Jensen, DO	Terri Turner, DO
Lauritz A. Jensen, DO	Colleen Vallad-Hix, DO
H. James Jones, DO	Elaine M. Wallace, DO
Edna M. Lay, DO, FAAO	Mary C. Williams, DO
John C. Licciardone, DO, MS, MBA	John M. Willis, DO
Alexander S. Nicholas, DO, FAAO	Robert D. Wurster, PhD
Donald R. Noll, DO

EDUCATIONAL COUNCIL ON OSTEOPATHIC PRINCIPLES (ECOP)

This Council is comprised of the Departmental Chairpersons of the various Colleges of Osteopathic Medicine. During the years 2007–2010, support of the FOM3 Project was generously given by members of ECOP and its subgroups. Presentations on behalf of FOM3 were facilitated by Chairpersons John C. Glover, DO, FAAO (2007–2009) and David C. Mason, DO, FACOFP (2009–2010).

During the life of the project, at different times, members of ECOP were presented material in preparation and asked for their comment and critique. Special thanks for her initiative and leadership in this activity is given to Kendi Hensel, DO, PhD.

LIPPINCOTT WILLIAMS & WILKINS

SPECIAL THANKS

Special thanks to Samantha D. Dutrow and Cathy J. Bledsoe for their contributions to Chapter 30, "Health Promotion and Maintenance"

The Arizona College of Osteopathic Medicine—Midwestern University supported the *Chapman's Think Tank Retreat* which was held at Glendale, AZ in September, 2006. Contributors to this effort were Loren H. Rex, DO and Linos Cidros, ATC. Proofreading and critical suggestions were provided by Gary A. Fryer, PhD, BSc (Osteo) and Eliah Malka. These contributors helped pave the way for publication of FOM3 PART III, Chapter 52G; *Chapman's Approach*.

*Our website provides a **consolidated set of easy-to-use resources** to help you excel in your coursework, ace your exam, and launch your professional career. Whether you want to **access Student Resources** or **search online content**, thePoint gives you the edge by helping you find the right tools for your learning needs.*

Step 1: Get the Resources for Your Title

Your VitalBook comes with immediate access to the companion resources on thePoint.

No need to enter an access code! Simply click the link below, and you will be taken to the product page at thePoint, with live links to all the student resources*.

<http://thePoint.lww.com/vitalsource/ebook/9780781766715>

Step 2: Accessing Student Resources

Follow the instructions on the screen to login to thePoint. (First time users of thePoint will have to register an account.) Once you have signed in you will not need to do so again**.

Click the link above to go to the product page on thePoint, then click on the **Student Resources** tab for that title.

After clicking on **Student Resources**, you'll see an extensive list of available materials associated with that title. Certain resources (such as videos and image banks) should be viewed on screen, while other resources (such as Microsoft Word and PowerPoint files) may be downloaded to your computer. The drop-down menu on each title's product information page makes it simple and intuitive for you to locate and access the resources you want.

Instructors, these instructions are for the **student resources only. To gain access to the instructor's resources, you will need to use an access code, which you can request by clicking the "Request Access to Online Resources" link for this title on thePoint, or through your local sales representative.*

***Users will only need to register once, but if you delete the cookies on your computer or terminate your session on thePoint, you will have to login again.*

Need More Help?

We'll make sure you get the answers you need fast.

We're here to help, so be sure to select the **Help** tab in the upper right corner of every page any time you have questions or need assistance during your experience at thePoint.

You can also contact **thePoint Online Support at 1-800-468-1128** or **by email at techsupp@lww.com** if you're experiencing technical problems with the site.

Thank you for choosing Lippincott Williams & Wilkins and thePoint, your partners in education and practice.

Osteopathic Philosophy

MICHAEL A. SEFFINGER, HOLLIS H. KING, ROBERT C. WARD, JOHN M. JONES, III, FELIX J. ROGERS, AND MICHAEL M. PATTERSON

KEY CONCEPTS

- Osteopathic philosophy forms the foundation for the practice of osteopathic medicine, which is a comprehensive and scientifically based school of medicine.
- Classic osteopathic philosophy was articulated by the founder of the profession, Dr. Andrew Taylor Still, and his direct students.
- Classic osteopathic philosophy expresses Dr. Still's understanding of health and disease and his approach to patient care.
- Various aspects of osteopathic philosophy and principles have ancient historical roots, but, as a unified set of concepts, the philosophy represents a unique approach to health and patient care.
- The expression and emphasis of osteopathic philosophy and its tenets continue to evolve over time.
- Irvin M. Korr, Ph.D., eloquently expressed the tenets of osteopathic philosophy to generations of osteopathic students, physicians, and scientists as a professor at several osteopathic colleges throughout the latter half of the 20th century.
- The Educational Council of Osteopathic Principles of the American Association of Colleges of Osteopathic Medicine developed a Glossary of Osteopathic Terminology and identified the fundamental osteopathic approaches to patient care.
- Osteopathic principles guide osteopathic physicians toward a health-oriented, patient-centered approach to health care.

INTRODUCTION

Osteopathic philosophy, deceptively simple in its presentation, forms the basis for osteopathic medicine's distinctive approach to health care. The philosophy acts as a unifying set of ideas for the organization and application of scientific knowledge to patient care. Through the philosophy, this knowledge is organized in relation to all aspects of health (physical, mental, emotional, and spiritual). A patient-centered focus, using health-oriented principles of patient care and unique skills, including hands-on manual diagnosis and treatment, guide the application of that knowledge. These concepts form the foundation for practicing osteopathic medicine.

Viewpoints and attitudes arising from osteopathic principles give osteopathic physicians an important template for clinical problem solving, health restoration and maintenance, and patient education. In the 21st century, this viewpoint is particularly useful as practitioners from a wide variety of disciplines confront increasingly complex physical, psychological, social, ethical, and spiritual problems affecting individuals, families, and populations from a wide variety of cultures and backgrounds.

THE EDUCATIONAL COUNCIL ON OSTEOPATHIC PRINCIPLES

In the contemporary era, the evolution, growth, and teaching of osteopathic philosophy have been coordinated through the Educational Council on Osteopathic Principles (ECOP) of the American

Association of Colleges of Osteopathic Medicine. This organization consists of the chairs of the departments of osteopathic principles and practice from each osteopathic medical school. It is the "expert panel" in the osteopathic medical profession in regard to osteopathic manipulative medicine and osteopathic philosophy and principles. These osteopathic physicians are considered leading-edge thinkers in terms of osteopathic philosophy and principles.

One of ECOP's charges is to obtain consensus on the usage of terms within the profession. *The Glossary of Osteopathic Terminology* was first published in 1981 (1) and is updated annually. The latest edition is available through the American Association of Colleges of Osteopathic Medicine and the American Osteopathic Association (AOA) websites; the 2009 edition is reprinted in the appendix to this textbook. The 2009 Glossary includes the following definition of osteopathic philosophy:

A concept of health care supported by expanding scientific knowledge that embraces the concept of the unity of the living organism's structure (anatomy) and function (physiology). Osteopathic philosophy emphasizes the following principles:

1. The human being is a dynamic unit of function
2. The body possesses self-regulatory mechanisms that are self-healing in nature
3. Structure and function are interrelated at all levels
4. Rational treatment is based on these principles

One of the products of ECOP's work was the development of a uniquely osteopathic curriculum for medical education that was founded upon a health-oriented, patient-centered

perspective and focused on restoration, enhancement, and maintenance of normal physiologic processes (2). When utilizing a health-oriented perspective, it is crucial to restrain from focusing solely on that which is dysfunctional or impeding function, but to also acknowledge the physiologic adaptive response pattern that can be facilitated to enhance the patient's capacity to maintain or restore optimal function and health. Physiology texts (e.g., Vander) describe ten basic coordinated body functions, namely:

1. Control of posture and body movement
2. Respiration
3. Circulation
4. Regulation of water and electrolyte balance
5. Digestion and absorption of nutrients and elimination of wastes
6. Metabolism and energy balance
7. Protective mechanisms
8. The sensory system
9. Reproduction
10. Consciousness and behavior

The ECOP group combined these into five basic integrative and coordinated body functions and coping strategies that were considered in a context of healthful adaptation to life and its circumstances:

1. Posture and motion, including fundamental structural and biomechanical reliability
2. Gross and cellular respiratory and circulatory factors
3. Metabolic processes of all types, including endocrine-mediated, immune-regulatory, and nutritionally related biochemical processes
4. Neurologic integration, including central, peripheral, autonomic, neuroendocrine, neurocirculatory, and their reflex relationships
5. Psychosocial, cultural, behavioral, and spiritual elements

USING THE FIVE MODELS IN PATIENT ASSESSMENT AND TREATMENT

These five coordinated body functions have been referred to as "five models," referring to the fact that they represent particular approaches to the patient. The conceptual models are perspectives by which one might view the patient. This is analogous to viewing a patient through a lens; by altering the focal length of the lens one could view different aspects of the patient and gain various perspectives on the patient's struggle to maintain health. This would open many avenues for diagnosis, treatment, and management, including the use of palpatory diagnosis and osteopathic manipulative treatment (OMT). It is important to keep in mind that the five models are merely expressions of our physiological functions that maintain health and play key roles in adaptation to stressors as well as in recovery and repair from illness and disease.

The musculoskeletal system can be viewed as the core that links these five coordinated body functions.

Figure 1.1 depicts the musculoskeletal system as the core or hub of a five-spoked wheel. Careful observation and educated palpation help make the musculoskeletal system a natural entry point for both diagnosis and treatment. Importantly, the musculoskeletal system often reflects numerous signs relating to internal diseases. The models provide a framework for interpreting the significance of somatic dysfunction within the context of objective and subjective clinical information. These models therefore guide the osteopathic

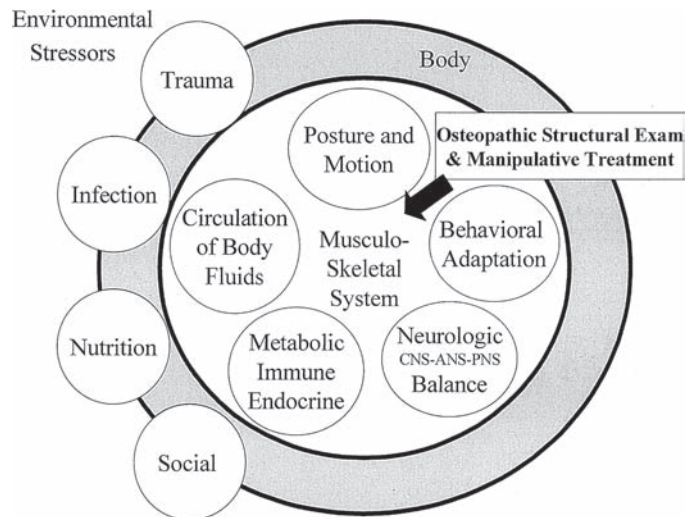

Figure 1-1 Osteopathic philosophy of health displayed as the coordinated activity of five basic body functions, integrated by the musculoskeletal system, adapting to environmental stressors. Evaluation and treatment of the musculoskeletal system is performed in light of its ability to affect not only the five functions but also ultimately the person's own ability to adapt to internal and external stressors.

practitioner's approach to diagnosis and treatment. Typically, a combination of models will be appropriate for an individual patient. The combination chosen is modified by the patient's differential diagnosis, comorbidities, and other therapeutic regimens.

The five-model concept has been used in osteopathic postgraduate manual medicine courses for over 35 years (3), in osteopathic manual medicine texts (4), and in osteopathic postgraduate education journals (5,6). In 2006, the World Health Organization recognized the osteopathic five-model concept as a unique osteopathic contribution to world health care (Personal Communication, Jane Carreiro, DO, AOA representative to the World Health Organization, 2006). The five models are:

- Biomechanical model
- Respiratory-Circulatory model
- Neurological model
- Metabolic-Energy model
- Behavioral model

Regional anatomical approaches to the patient were presented initially in the writings of Dr. Andrew Taylor Still, MD, DO. In considering an osteopathic visual and palpatory structural evaluation and treatment approach to the various body regions, ECOP considered that as the muscles and joints of the trunk and extremities are primarily involved in posture and motion, addressing them would be within the perspective of the Biomechanical model; addressing the costal cage and diaphragms, being that they are responsible for the movements associated with thoracic respiration and return of venous and lymph to the heart for recirculation, are considered as part of the Respiratory-Circulatory model; assessment and treatment of the abdominopelvic regions represent the Metabolic-Energy model as this is where our internal organs that process food, convert it to usable energy, and discard metabolic by-products (waste) reside; assessing and treating the head and spinal regions represent the Neurological model; addressing the patient's lifestyle, environmental stressors, values, and choices represents the Behavioral model. Table 1.1 outlines the five models as applied to assessment and treatment.

TABLE 1.1

Osteopathic Approaches to Patient Care

Model	Anatomical Correlates	Physiological Functions
Biomechanical	Postural muscles, spine, and extremities	Posture and motion
Respiratory-Circulatory	Thoracic inlet, thoracic and pelvic diaphragms, tentorium cerebelli, costal cage	Respiration, circulation, venous, and lymphatic drainage
Metabolic-Energy	Internal organs, endocrine glands	Metabolic processes, homeostasis, energy balance, regulatory processes; immunological activities and inflammation and repair; digestion, absorption of nutrients, removal of waste; reproduction
Neurological	Head (organs of special senses), brain, spinal cord, autonomic nervous system, peripheral nerves	Control, coordination, and integration of body functions; protective mechanisms; sensation
Behavioral	Brain	Psychological and social activities, e.g., anxiety, stress, work, family; habits, e.g., sleep, drug abuse, sexual activities, exercise; values, attitudes, beliefs

Biomechanical Model

The Biomechanical model views the patient from a structural or mechanical perspective. Alterations of postural mechanisms, motion, and connective tissue compliance, regardless of etiology, often impede vascular, lymphatic, and neurologic functions. As the structural integrity and function of the musculoskeletal system is interactive and interdependent with the neurologic, respiratory-circulatory, metabolic, and behavioral structural components and functions of the patient, this model considers that a structural impediment causing, or being caused by, a dysfunction of muscles, joints, and/or connective tissue, can compromise vascular or neurologic structures and therefore affect associated metabolic processes and/or overt behaviors. Depending on the person's adaptive capabilities, this can lead to disturbances in various body functions, including mental functions, as well as decrease the patient's homeostatic capacity. The person's ability to adapt to, or recover from, insults and stressors, or prevent further breakdown, becomes further compromised. Social activity is often adversely affected and economic consequences follow. The biomechanical perspective leads the osteopathic physician to assess the patient for a structural impediment, and upon removal of the impediment, that is, by correction of somatic dysfunction through application of OMT, enable the patient to regain associated structural, vascular, neurologic, metabolic, and behavioral functions. The objective is to optimize the patient's adaptive potential through restoration of structural integrity and function.

For example, a patient who is in an automobile accident often sustains a whiplash-type injury and subsequently has difficulty moving her neck, shoulders, and low back. If there is trauma to the costal cage, rib motion is impeded and breathing becomes difficult as well. Due to the lack of motion and muscle spasms, the patient begins to feel shooting pains into her arms, or pins and needles in her thumb and index fingers. She gets lightheaded and dizzy upon standing, loses her appetite, cannot maintain her exercise routine, has difficulty sleeping, and therefore cannot concentrate on studying or doing her work very well. Her structural problems have caused motion restrictions that have affected her four other main physiological functions, that is, the other four domains of health. Alleviation of her somatic dysfunction enables restoration of her normal posture and motion and improvement in her breathing and blood circulation; she begins to eat well again, restarts her exercise program, and sleeps through the night to awaken refreshed, energetic, and able to concentrate. She can study and do her work once again.

Respiratory-Circulatory Model

Approaching the patient from the perspective of the Respiratory-Circulatory model entails focusing on respiratory and circulatory components of the homeostatic response in pathophysiological processes. This includes central as well as peripheral processes that are involved in the dynamic interaction between these two paramount functions, that is, central neural control, cerebral spinal

fluid flow, arterial supply, venous and lymphatic drainage, as well as pulmonary and cardiovascular function. Additionally, this model views the interaction between respiratory-circulatory functions and musculoskeletal, neurologic, metabolic, and behavioral functions as they affect the patient's adaptive response and total homeostatic or health potential. Evaluation and treatment is geared toward maximizing the capacity and efficiency of respiratory-circulatory functions in order to maximize the patient's health potential. The respiratory-circulatory model concerns itself with the maintenance of extra- and intracellular environments through the unimpeded delivery of oxygen and nutrients and the removal of cellular waste products. Tissue stress interfering with the flow or circulation of any body fluid can affect tissue health. OMT within this model addresses dysfunction in respiratory mechanics, circulation, and the flow of body fluids.

A case in point is the patient with pneumonia. In this condition, an infection occurs in the lung, there is congestion of fluids in the lungs, and respiration is compromised. Often, each breath causes pain. The nervous system communicates this information to the musculoskeletal system that accommodates and responds by decreasing respiratory motion in the costal cage and upper back in the area of the infected lung tissue and irritated pleura. These changes in the musculoskeletal system can be palpated and treated with osteopathic manipulation to relax the tense muscles and provide some comfort, as well as helping to mobilize the congested fluids in the lungs. The pneumonia also affects the patient's metabolism and energy level. Fighting an infection such as this is exhausting and the patient complains of fatigue, loss of appetite, and has increased need for sleep. Social interactions are adversely affected. So, all five domains of health are affected and need to be addressed as part of the management plan for this patient. Getting the patient's respiration and circulation of fluids back into normal order is the primary goal, which will improve function of all of the other body functions in a coordinated fashion. Thus, the osteopathic physician would focus on treating the pneumonia with antibiotics, rehydrating the patient with intravenous fluids and restoring normal motion and function of the costal cage, diaphragm, and thoracic and cervical spine with OMT as appropriate.

Neurological Model

The Neurologic model views the patient's problems in terms of aberrancies or impairments of neural function that are caused by or cause pathophysiologic responses in structural, respiratory-circulatory structures and functions, metabolic processes, and behavioral activities. More specifically, the Neurological model considers the influence of spinal facilitation, proprioceptive function, the autonomic nervous system, and activity of nociceptors (pain fibers) on the function of the neuroendocrine immune network. Of particular importance is the relationship between the somatic and the visceral (autonomic) systems. Therapeutic application of OMT within this model focuses on the reduction of mechanical stresses, balance of neural inputs, and the elimination of nociceptive drive. The goal of treatment in this model is to re-establish normal (optimal) neural function. Restoration or optimization of neural integrative and regulatory functions will improve efficiency in associated structural, vascular, metabolic, and behavioral functions. This will help to maximize the patient's adaptive potential and regain optimal health.

An example patient for whom using a neurological focus for evaluation and management would be advantageous is one with peristalsis, or lack of intestinal motion, after general anesthesia and abdominal surgery. Through neurological reflexes, the paraspinal

back and neck muscles tighten. The intestines fill with gas, which, due to lack of intestinal motility, expand within the abdominal cavity causing distension, pain, and sometimes nausea and vomiting. The patient is not able to eat or pass the gas through the rectum, cannot sleep, ambulate, or take full breaths. The lungs partially collapse and breathing becomes difficult. All five domains of health are compromised. Treatment entails OMT to release the paraspinal tensions and spasms that decreases sympathetic hyperactivity and increases parasympathetic activity, ultimately restoring normal intestinal motility. Sometimes, nasogastric suction is helpful as well. Intravenous fluids may be needed to hydrate the patient. Once the nervous system functions normally once again, metabolic, respiratory, and motion functions return to normal as well. The patient returns to normal activity, and normal diet and sleep cycles also are restored.

Metabolic-Energy Model

In viewing the patient from the perspective of the Metabolic-Energy model, focus is placed upon the metabolic and energy-conserving aspects of the homeostatic adaptive response. This includes evaluation and treatment of cellular, tissue, and organ systems as they relate to each other's energy demand and consumption as well as production of work or products. The role of the musculoskeletal system and the connective tissues of the body in pathophysiological processes are important as they are accessible to palpation and manipulation. Efficient posture and motion, arterial supply, venous and lymphatic drainage, CSF fluid mechanics, neurologic, endocrine and immune functions, and prudent behaviors, balanced emotions, and proper nutrition are the keystones of energy conservation and efficiency of metabolic functions. Improving the functions of any of these components will aid the total body energy economy. This will maximize the patient's adaptive resources and ability to successfully respond and adapt to stressors.

The Metabolic-Energy model recognizes that the body seeks to maintain a balance between energy production, distribution, and expenditure. This aids the body in its ability to adapt to various stressors, including immunological, nutritional, and psychological types. The body's ability to restore and maintain health requires energy-efficient response to infectious agents and repair of injuries. Proper nutrition enables normal biochemical processes, cellular functions, and neuromusculoskeletal activity. Additionally, injuries to the musculoskeletal system tax the body's energy economy. Physical activity promotes optimum cardiovascular function, but an inefficient musculoskeletal system increases the body's allostatic load or burden. Therapeutic application of OMT within this model addresses somatic dysfunction that has the potential to dysregulate the production, distribution or expenditure of energy, increase allostatic load, or interfere with immunological and endocrinological regulatory functions. Another therapeutic application using this model includes prescribing medications to improve and stabilize metabolic and systemic functions.

A patient with congestive heart failure has to conserve energy so as not to further strain the heart. Any compromise of efficient posture and motion will place too high of an energy demand on the failing heart, increasing the congestion in the lungs and edema in the feet. So, if the patient stumbles and sprains his ankle, the difficulty in ambulating with only one good leg can cause significant worsening of the congestive heart failure. Breathing becomes more difficult and appetite becomes decreased. The nervous system relays information from the struggling heart to the surrounding musculoskeletal system, which creates muscle tensions and stiffness in the costal cage and cervical and thoracic spinal joints. The patient is

unable to lie down or sleep well. Again, all five domains of health are affected. The primary goal of treatment is to relieve the burden on the failing heart, that is, fix the sprained ankle and support the patient's motion needs in the meantime. Fluid and salt intake need to be closely controlled. Medications that help to excrete the excess fluids from the body and strengthen the heart contractility are typically needed as well as bed rest until the heart regains its strength. Once the metabolic-energy expenditure needs are addressed, respiration-circulation, posture and motion, neurological function, and behavioral activities are subsequently restored.

Behavioral Model

The Behavioral model recognizes that the assessment of a patient's health includes assessing his or her mental, emotional, and spiritual state of being as well as personal lifestyle choices. Health is often affected by environmental, socioeconomic, cultural, and hereditary factors and the various emotional reactions and psychological stresses with which patients contend. Environmentally induced trauma and toxicities, inactivity and lack of exercise, use of addictive substances, and poor dietary choices all serve to diminish a patient's adaptive capacity, rendering the patient vulnerable to opportunistic organisms and/or organ and system failure.

The osteopathic physician uses the behavioral perspective to consider that the musculoskeletal system expresses feelings and emotions, and stress manifests in increased neuromuscular tension. Somatic dysfunction affects the musculoskeletal system's reaction to biopsychosocial stressors. OMT is employed within this model with the goal of improving the body's ability to effectively manage, compensate, or adapt to these stressors. The osteopathic physician utilizes compassionate, caring, and education skills to help patients maximize their coping capabilities and improve healthy lifestyle and behavioral choices. The whole person—body, mind, and spirit—is considered in the individualized management plan. Psychological, social, cultural, behavioral, and spiritual elements are addressed within the management plan as needed. In addition to providing care for the cause of diseases, the patient's perspective of needing palliative and remedial care is also addressed. In addition, the Behavioral model entails providing patient education on health, disease and lifestyle choices, mental outlook, and preventive care.

A patient with chronic obstructive pulmonary disease (emphysema) from tobacco abuse is a patient for whom the behavioral perspective plays a primary role in osteopathic management. After decades of smoking at least one pack of cigarettes per day, the lungs undergo anatomical change and can no longer exchange carbon dioxide for oxygen appropriately. This alters many metabolic processes throughout the body that rely on this gas exchange. Vascular functions are compromised since oxygen is not delivered appropriately to the tissues and carbon dioxide builds up creating an acidic environment that is toxic to normal cells. Neurologic functions, that is, brain activity, suffer from this altered metabolic milieu. Musculoskeletal structures and functions throughout the body undergo adaptation, that is, the barrel-shaped costal cage formed by patients with emphysema due to retained air in the lungs. There are further changes in the behavioral realm. The patient who cannot breathe efficiently becomes short of breath, anxious, and agitated easily, insecure, and loses self-confidence. He or she cannot tolerate exercise or exertion. Sleep is disturbed and difficult as the patient can only get rest in the seated position, or propped up on two or more pillows in bed, which is not comfortable for the low back after several hours. Work and social relations are compromised, often leading to disability and isolation. Smoking is an addictive behavior that requires the

patient to exert considerable willpower, courage, and perseverance in order to overcome the habit. Medications may be needed to help the patient gain control over the addiction. The osteopathic physician and the entire professional health care team, including family and friends, need to encourage the patient to work toward the goal of restoration of health by removal of the offending agent (tobacco and its related chemicals), offering medications to improve lung function, and providing much-needed psychological support. The primary treatment for the disease is for the patient to stop smoking and allow the body to heal itself. OMT to improve compliance of the costal cage can reduce the physical burden of breathing that is typically labored and exhausting to the muscles of respiration. The cervical paraspinal muscles become hypertonic and painful, which can be relieved with OMT. In this instance, OMT is an adjunct to the primary treatment, which is behavioral in nature. Often, OMT enables the physician to obtain trust and build rapport with the patient, enabling a partnership that facilitates the achievement of the mutual goal of ridding the patient of the smoking habit.

OSTEOPATHIC PRINCIPLES AS PRACTICE GUIDELINES

The contributions of A.T. Still and the osteopathic medical profession affect many aspects of general patient care. First, irrespective of diagnoses or practitioner, the patient is of central importance. Second, a competent differential diagnosis is essential. This includes all aspects of the person (body, mind, and spirit), as shown in Box 1.1. Third, clinical activities integrate realistic expectations with measurable outcomes. Finally, and ideally, patient-oriented educational efforts pragmatically address both personal and family-related concerns. The patient is ultimately responsible for long-term self-health care. Emphasis is on health restoration and disease prevention.

Irvin M. Korr, Ph.D., a prominent and well-respected scientist, philosopher, and educator reasoned (7):

[There are] three major components of our indwelling health care system, each comprising numerous component systems. In the order in which humans became aware of them, they are (a) the healing (remedial, curative, palliative, recuperative, rehabilitative) component; (b) the component that defends against threats from the external environment; and (c) the homeostatic, health-maintaining component. These major component systems, of course, share subcomponents and mechanisms.

Health Restoration and Disease Prevention

Although osteopathically oriented medical care emphasizes competent comprehensive patient management, it also places importance on restoration of well being appropriate for the patient's age and health potential. This includes addressing:

- Physical, mental, and spiritual components
- Personal safety, such as wearing seat belts
- Sufficient rest and relaxation
- Proper nutrition
- Regular aerobic, stretching and strengthening exercises
- Maintaining rewarding social relationships
- Avoidance of tobacco and other abused substances
- Eliminating or modifying abusive personal, interpersonal, family, and work-related behavior patterns
- Avoidance of environmental radiation and toxins

When the internal health care system is permitted to operate optimally, without impediment, its product is what we call health. Its natural tendency is always toward health and the recovery of health. Indeed, the personal health care system is the very source of health, upon which all externally applied measures depend for their beneficial effects. The internal health care system, in effect, makes its own diagnoses, issues its own prescriptions, draws upon its own vast pharmacy, and in most situations, administers each dose without side effects. Health and healing, therefore, come from within. It is the patient who gets well, and not the practitioner or the treatment that makes [him or her] well.

In caring for the whole person, the well-grounded osteopathic physician goes beyond the presenting complaint, beyond relief of symptoms, beyond identification of the disease and treatment of the impaired organ, malfunction, or pathology, important as they are to total care. The osteopathic physician also explores those factors in the person and the person's life that may have contributed to the illness and that, appropriately modified, compensated, or eliminated, would favor recovery, prevent recurrence, and improve health in general.

The physician then selects that factor or combination of factors that are readily subject to change and that would be of sufficient impact to shift the balance toward recovery and enhancement of health. The possible factors include such categories as the biological (e.g., genetic, nutritional), psychological, behavioral (use, neglect, or abuse of body and mind; interpersonal relationships; habits; etc.), sociocultural, occupational, and environmental. Some of these factors, especially some of the biological [ones], are responsive to appropriate clinical intervention, some are responsive only to social or governmental action, and still others require changes by patients themselves. Osteopathic whole-person care, therefore, is a collaborative relationship between patient and physician.

It is obvious that some of the most deleterious factors are difficult or impossible for patient and physician to change or eliminate. These include (at least at present) genetic factors (although some inherited predispositions can be mitigated by lifestyle change). They include also such items as social convention, lifelong habits (e.g., dietary and behavioral), widely shared beliefs, prejudices, misconceptions and cultural doctrines, attitudes, and values. Others, such as the quality of the physical or socioeconomic environments, may require concerted community, national, and even international action.

Focus falls, therefore, upon those deleterious factors that are favorably modifiable by personal and professional action, and that, when appropriately modified or eliminated, mitigate the health-impairing effects of the less changeable factors. Improvement of body mechanics by osteopathic manipulative treatment is a major consideration when dealing with these complex interactions.

Korr explored the implications of what he called "our personal health care systems" and how that concept guides the doctor-patient relationship:

This principle has important implications for the respective responsibilities of patient and physician and for their relationship. Since each person is the owner and hence the guardian of his or her own personal health care system, the ultimate source of health and healing, the primary responsibility for one's

health is each individual's. That responsibility is met by the way the person lives, thinks, behaves, nourishes himself or herself, uses body and mind, relates to others, and the other factor usually called lifestyle. Each person must be taught and enabled to assume that responsibility.

It is the physician's responsibility, while giving palliative and remedial attention to the patient's immediate problem, to support each patient's internal health care system, to remove impediments to its competence, and above all, to do it no harm. It is also the responsibility of physicians to instruct patients on how to do the same for themselves and to strive to motivate them to do so, especially by their own example.

The relationship between patient and osteopathic physician is therefore a collaborative one, a partnership, in maintaining and enhancing the competence of the patient's personal health care system. The maintenance and enhancement of health is the most effective and comprehensive form of preventive medicine, for health is the best defense against disease (7).

In 2002, an ad hoc interdisciplinary task force of osteopathic educators, philosophers, and researchers proposed osteopathic principles for patient care (8):

1. **The Patient Is the Focus for Health Care**—All osteopathic physicians, irrespective of the specialty of the practitioner, are trained to focus on the individual patient. The relationship between clinician and patient is a partnership in which both parties are actively engaged. The osteopathic physician is an advocate for the patient, supporting his or her efforts to optimize the circumstances to maintain, improve, or restore health.
2. **The Patient Has the Primary Responsibility for His or Her Health**—While the physician is the professional charged with the responsibility to assist a patient in being well, the physician can no more impart health to another person than he or she can impart charm, wisdom, wit, or any other desirable trait. Although the patient-physician relationship is a partnership, and the physician has significant obligations to the patient, ultimately the patient has primary responsibility for his or her health. The patient has inherent healing powers and must nurture these through diet and exercise as well as adherence to appropriate advice in regard to stress, sleep, body weight, and avoidance of abuse.
3. **An Effective Treatment Program for Patient Care**—An effective treatment program for patient care is founded on the above tenets and incorporates evidence-based guidelines, optimizes the patient's natural healing capacity, addresses the primary cause of disease, and emphasizes health maintenance and disease prevention. The emphasis on the musculoskeletal system as an integral part of patient care is one of the defining characteristics of osteopathic medicine.

When applied as part of a coherent philosophy of the practice of medicine, these tenets represent a distinct and necessary approach to health care. Evidence-based guidelines should be used to encourage those treatments with proven efficacy and to discourage those that are not beneficial, or even harmful. Osteopathic medicine embraces the concept of evidence-based medicine as part of a valuable reformation of clinical practice.

Andrew Taylor Still told his students “the object of the doctor is to seek health; anyone can find disease.” This precept provides a useful orientation in patient care. An emphasis on health rather than disease helps to promote optimism. It may facilitate efforts to engage the patient as an active participant in recovery from illness. It may also encourage the realization that no single treatment approach is successful for every patient. Rather, optimal approaches will use diet, exercise, medications, manipulative treatment, surgery, or other modalities according to the needs and wishes of the patient and the skill and aptitude of the practitioner (8).

In end-stage conditions, it is recognized that treatment may be only palliative, remedial, and supportive. The AOA position paper on end-of-life care promotes compassionate and humanistic care tailored to the needs of each individual patient and his or her family.

Osteopathically oriented problem solving and treatment plans help guide the application of osteopathic principles in medical, behavioral, and surgical care. In 1987, ECOP developed guidelines for use by osteopathic physicians in developing an osteopathic management plan (2). The extent to which palpatory diagnosis and manipulative treatment are specifically useful interventions for a wide variety of neuromusculoskeletal problems remains to be seen through research. However, since many clinical presentations commonly interfere with a patient’s ability to meet the requirements of normal daily activities (including appropriate exercise), it stands to reason that improving the efficiency of the neuromusculoskeletal system would benefit each patient. “There is a somatic component in all clinical situations. The somatic component is addressed to the extent that it influences patient well-being. Conceptually, osteopathic manipulative treatment is designed to address both structural abnormalities and self-regulatory capabilities” (2).

HOW IT ALL BEGAN

Andrew Taylor Still, M.D., D.O. (Fig. 1.1) (1828–1917), was an American frontier doctor who was convinced that 19th century patient care was severely inadequate. This resulted in an intense desire on his part to improve surgery, obstetrics, and the general treatment of diseases, placing them on a more rational and scientific basis.

As his perspectives and clinical understanding evolved, Still created an innovative system of diagnosis and treatment with two major emphases. The first highlights treatment of physical and mental ailments (i.e., diseases) while emphasizing the normalization of body structures and functions. Its hallmark was a detailed knowledge of anatomy that became the basis for much of his diagnostic and clinical work, most notably palpatory diagnosis and manipulative treatment. The second emphasizes the importance of health and well being in its broadest sense, including mental, emotional, and spiritual health, and the avoidance of alcohol and drugs and other negative health habits.

ORIGINS OF OSTEOPATHIC PHILOSOPHY

Historically, Still was not the first to call attention to inadequacies of the health care of his time; Hippocrates (c. 460–c. 377 B.C.E.), Galen (c. 130–c. 200), and Sydenham (1624–1689) were others. Each, in his own way, criticized the inadequacies of existing medical practices while focusing contemporary thinking on the patient’s natural ability to heal.

In addition, Still was deeply influenced by a number of philosophers, scientists, and medical practitioners of his time. There is also evidence he was well versed in the religious philosophies

and concepts of the Methodist, Spiritualist, and Universalist movements of the period (9).

Following the loss of three children to spinal meningitis in 1864, Still immersed himself in the study of the nature of health, illness, and disease (10). His goal was to discover definitive methods for curing and preventing all that ailed his patients. He implicitly believed there was “a God of truth,” and that “All His works, spiritual and material, are harmonious. His law of animal life is absolute. So wise a God had certainly placed the remedy within the material house in which the spirit of life dwells.” Furthermore, he believed he could access these natural inherent remedies “... by adjusting the body in such a manner that the remedies may naturally associate themselves together, hear the cries, and relieve the afflicted” (10). In this quest, he combined contemporary philosophical concepts and principles with existing scientific theories. Always a pragmatist, Still accepted aspects of different philosophies, concepts, and practices that worked for him and his patients. He then integrated them with personal discoveries of his own from in-depth studies of anatomy, physics, chemistry, and biology (9). The result was the formulation of his new philosophy and its applications. He called it “Osteopathy.”

Still’s moment of clarity came on June 22, 1874. He writes, “I was shot, not in the heart, but in the dome of reason” (10). “Like a burst of sunshine the whole truth dawned on my mind, that I was gradually approaching a science by study, research, and observation that would be a great benefit to the world” (10). He realized that all living things, especially humans, were created by a perfect God. If humans were the embodiment of perfection, then they were fundamentally made to be healthy. There should be no defect in their structures and functions.

Since he believed that “the greatest study of man is man,” he dissected numerous cadavers to test his hypothesis (10). He believed that if he could understand the construction (anatomy) of the human body, he would comprehend Nature’s laws and unlock the keys to health. Still found no flaws in the concepts of the body’s well-designed structure, proving to himself that his own hypothesis was correct.

A corollary to Still’s revelation was that the physician does not cure diseases. In his view, it was the job of the physician to correct structural disturbances so the body works normally, just as a mechanic adjusts his machine. In *Research and Practice* he wrote,

The God of Nature is the fountain of skill and wisdom and the mechanical work done in all natural bodies is the result of absolute knowledge. Man cannot add anything to this perfect work nor improve the functioning of the normal body.... Man’s power to cure is good as far as he has a knowledge of the right or normal position, and so far as he has the skill to adjust the bones, muscles and ligaments and give freedom to nerves, blood, secretions and excretions, and no farther. We credit God with wisdom and skill to perform perfect work on the house of life in which man lives. It is only justice that God should receive this credit and we are ready to adjust the parts and trust the results (11).

While Still practiced the orthodox medicine of his day from 1853 to 1879, including the use of oral medications such as purgatives, diuretics, stimulants, sedatives, and analgesics, and externally applied salves and plasters, once he began using his new philosophical system he virtually ceased using drugs. This occurred after several years where he experimented with combinations of drugs and manipulative treatment. In addition, he compared his results with those of patients who received no treatment at all (10). After several years’ experience, he became convinced that his mechanical corrections consistently achieved the same or better results without using medications.

It was at that point that Still philosophically divorced himself from the orthodox practices of 19th century medicine (10). He writes, “Having been familiar myself for years with all their methods and having experimented with them I became disheartened and dropped them” (11). His unerring faith in the natural healing capabilities of the mechanically adjusted body formed the foundation for his new philosophy.

Unsure of what to call his new hands-on approach in the early years, Still at times referred to himself as a “magnetic healer” and “lightning bone-setter” (9,12). In the 1880s, Still began publicly using the term “osteopathy” as the chosen name for his new profession (5,9,13). He writes, “Osteopathy is compounded of two words, osteon, meaning bone, (and) pathos, (or) pathine, to suffer. I reasoned that the bone, ‘Osteon,’ was the starting point from which I was to ascertain the cause of pathological conditions, and so I combined the ‘Osteo’ with the ‘pathy’ and had as a result, Osteopathy” (10).

As the name osteopathy implies, Still used the bony skeleton as his reference point for understanding clinical problems and their pathological processes. On the surface, he was most interested in anatomy. On the other hand, he taught that there is more to the skeleton than 206 bones attached together by ligaments and connective tissue. In his discourses, Still would describe the anatomy of the arterial supply to the femur, for example, trace it back to the heart and lungs, and relate it to all of the surrounding and interrelated nerves, soft tissues, and organs along the way (Fig. 1.2). He would

Still National Osteopathic Museum, Kirksville, Missouri [PH 446]

Figure 1-2 A.T. Still analyzing a human femur as he ponders the principles of osteopathy. (Still National Osteopathic Museum, Kirksville, MO.)

then demonstrate how the obstruction of arterial flow anywhere along the pathway toward the femur would result in pathophysiologic changes in the bone, producing pain or dysfunction.

He writes of his treatment concepts: “Bones can be used as levers to relieve pressure on nerves, veins and arteries” (10). This can be understood in the context that vascular and neural structures pass between bones or through orifices (foramina) within a bone. These are places where they are most vulnerable to bony compression and disruption of their functions. In addition, fascia is a type of connective tissue that attaches to bones. Fascia also envelops all muscles, nerves, and vascular structures. When strained or twisted by overuse or trauma myofascial structures not only restrict bony mobility, but also compress neurovascular structures and disturb their functions. By using the bones as manual levers, bony or myofascial entrapments of nerves or vascular structures can be removed, thus restoring normal nervous and vascular functions.

As Korr explained, “Even at the time of the founding of the osteopathic profession in 1892, the available knowledge in the sciences of physiology, biochemistry, microbiology, immunology, and pathology was meager. Indeed, immunology, biochemistry, and various other neurosciences and biomedical sciences had yet to appear as distinct disciplines. Therefore, these principles could only be expressed as aphorisms, embellished perhaps with conjectures about their biological basis” (7).

Beyond Neuromusculoskeletal Diagnosis and Treatment

The osteopathic medical profession is not only a neuromusculoskeletal-oriented diagnostic and treatment system, it is also a comprehensive and scientifically based school of medicine that embraces a philosophy. In answer to the question, “What is osteopathy?” Still stated, “It is a scientific knowledge of anatomy and physiology in the hands of a person of intelligence and skill, who can apply that knowledge to the use of man when sick or wounded by strains, shocks, falls, or mechanical derangement or injury of any kind to the body” (14) (Fig. 1.3).

Furthermore, osteopathy had a greater calling. In what could be considered a mission statement, Still wrote, “The object of Osteopathy is to improve upon the present systems of surgery, midwifery, and treatment of general diseases” (10).

The primary ideological components that distinguish one philosophy of healing from another are that system’s concepts of what constitutes health, disease, and patient care. The following sections delineate how osteopathic philosophy has evolved and expressed itself in regards to these three concepts.

Classical osteopathic philosophy is described in Box 1.2.

CLASSIC OSTEOPATHIC PHILOSOPHY OF HEALTH

Health Is a Natural State of Harmony

Still believed health to be the natural state of the human being. In his own words:

Osteopathy is based on the perfection of Nature’s work. When all parts of the human body are in line we have health. When they are not the effect is disease. When the parts are readjusted disease gives place to health. The work of the osteopath is to adjust the body from the abnormal to the normal, then the abnormal conditions give place to the normal and health is the result of the normal condition (11).

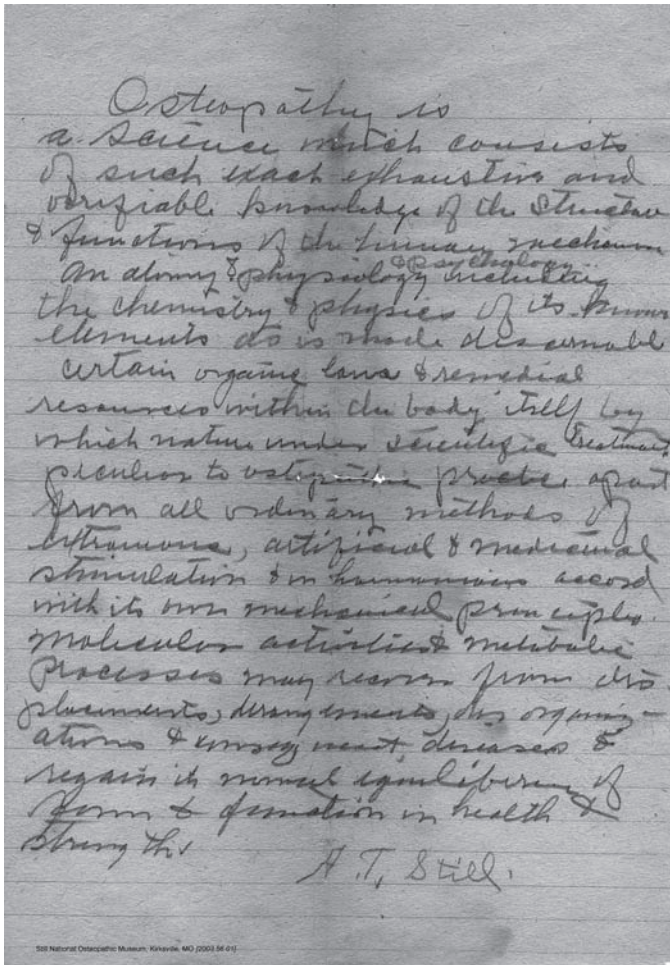

Figure 1-3 Handwritten definition of osteopathy by A.T. Still, M.D., D.O. (Still National Osteopathic Museum, Kirksville, MO.)

Mechanics and Health

Still's concept of a healthy person is insightful. It places his belief of the importance of structural and mechanical integrity within the perspective of a comprehensive view of a human being within society:

When complete, he is a self-acting, individualized, separate personage, endowed with the power to move, and mind to direct in locomotion, with a care for comfort and a thought for his continued existence in the preparation and consumption of food to keep him in size and form to suit the duties he may have to perform (14).

Still believed that life exists as a unification of vital forces and matter. Since the body is controlled by the mind to exhibit purposeful motion in attaining the needs and goals of the organism, he stated that "Osteopathy ... is the law of mind, matter and motion" (10). Once Still accepted that motion is an inherent quality of life itself, it was a small step to inquiring into what is moving and how it moves. Through his in-depth study of anatomy, he could see the interdependent relationships among different tissues and their component parts. He observed that each part developed as the body was moving, growing, and developing from

Classical Osteopathic Philosophy

A.T. Still's fundamental concepts of osteopathy can be organized in terms of health, disease, and patient care.

Health

1. Health is a natural state of harmony.
2. The human body is a perfect machine created for health and activity.
3. A healthy state exists as long as there is normal flow of body fluids and nerve activity.

Disease

4. Disease is an effect of underlying, often multifactorial causes.
5. Illness is often caused by mechanical impediments to normal flow of body fluids and nerve activity.
6. Environmental, social, mental, and behavioral factors contribute to the etiology of disease and illness.

Patient Care

7. The human body provides all the chemicals necessary for the needs of its tissues and organs.
8. Removal of mechanical impediments allows optimal body fluid flow, nerve function, and restoration of health.
9. Environmental, cultural, social, mental, and behavioral factors need to be addressed as part of any management plan.
10. Any management plan should realistically meet the needs of the individual patient.

embryo to fetus to newborn and throughout life. Thus, each tissue, organ, and structure is designed for motion. "As motion is the first and only evidence of life, by this thought we are conducted to the machinery through which life works to accomplish these results" (15).

If "life is matter in motion" (14), then what is the effect on a body part that is not moving? Still reasoned that a lack of motion is not conducive to life or health. "[The osteopath's] duties as a philosopher admonish him that life and matter can be united, and that that union cannot continue with any hindrance to free and absolute motion" (14). Further, he boldly states that the practice of osteopathy "covers all phases of disease and it is the law that keeps life in motion" (10).

Normal Nerve Activity and Flow of Body Fluids

A machine cannot run without proper lubrication, fuel, and mechanisms to remove the by-products of combustion. In teaching his students, Still identified each component of the body's intricate mechanisms as he knew them. In the process, he discussed various forces that he reasoned create motion and maintain life. He explained how lubricating and nourishing fluids flow through the arteries, veins, lymphatics, and nerves. He also noted that they turn over by-products of metabolism through the venous and lymphatic systems. "The human body is a machine run by the unseen force called life, and that it may be run harmoniously it is necessary that there be liberty of blood, nerves and arteries from their generating point to their destination" (10).

Another component of Still's machine concept was the power source. He identified the brain as the dynamo, the electric battery that keeps the body moving and working:

The brain furnishes nerve-action and forces to suit each class of work to be done by that set of nerves which is to construct forms and to keep blood constantly in motion in the arteries and from all parts back to the heart through the veins that it may be purified, renewed, and re-enter circulation (14).

CLASSIC OSTEOPATHIC PHILOSOPHY OF DISEASE

Disease Is an Effect of an Underlying Cause or Causes

From the time of Hippocrates through the first half of the 20th century, diseases were identified primarily through simple and complex descriptions of symptoms and signs. Many afflictions were without clear etiology. In spite of our current greater levels of knowledge and understanding, this is still true in many cases.

Still taught that disease is the effect of an abnormal anatomic state with subsequent physiologic breakdown and decreased host adaptability. Germs were first discovered in the 17th century with the invention of the microscope, but the germ theory of disease was not accepted until Pasteur provided convincing scientific evidence in the mid-19th century. However, experienced clinicians like Still, as well as an emerging group of laboratory scientists, saw germs as opportunists to decreased host function, not as primary causes of disease in themselves. They speculated that infections resulted from an interaction between the degree of virulence and quantity of the infecting agent and the level of host immunity.

Still also realized that there were multifactorial components to disease processes (16,17). He believed that disease was a combination of influences arising from decreased host adaptability and adverse environmental conditions. He recognized that symptoms often were a manifestation of nerves irritated by pathophysiologic processes commonly created by an accumulation of fluids (congestion and inflammation). This diminished the patient's ability to adapt to the environment (10). Additionally, Still was keenly aware of the deleterious effects of environmentally induced trauma, or abrupt changes in the atmosphere, causing physical or emotional "shock" or inertia, and therefore obstructing normal metabolic processes, body fluids, and nerve activity (11).

Mechanical Impediments to Flow of Body Fluids and Nerve Activity

Still's study of pathology found that in all forms of disease there is mechanical interruption of normal circulation of body fluids and nerve force to and from cells, tissues, and organs (11). "Sickness is an effect caused by the stoppage of some supply of fluid or quality of life" (10). He understood that it is the combination of free circulation of wholesome blood and motor, nutrient, and sensory nerve activity that creates tissues and organs, and facilitates their growth, maintenance, and repair. Through cadaver dissection studies he reasoned that strains, twists, or distortions in fascia, ligaments, or muscle fibers surrounding the small capillaries and nerve bundles could very well be the cause of ischemia and congestion by mechanical obstruction, interruption, or impediment to normal flow of vital fluids.

Still understood that the flow of body fluids was under the control of the nerves that innervated the blood vessel walls, adjusting the diameter of the vessels and thus controlling the amount and rate of blood flow to the tissues and organs. "While the vascular

and nervous systems are dependent upon each other, it must be remembered that the bloodstream is under the control of the nervous system, not only indirectly through the heart, but directly through the vasoconstrictor and vasodilator nerve fibers, which regulate the caliber and rhythm of the blood vessels" (17). Still writes, "All diseases are mere effects, the cause being a partial or complete failure of the nerves to properly conduct the fluids of life" (10). Although he emphasized that "the rule of the artery is absolute, universal, and it must be unobstructed, or disease will result" (10), he also pointed out the importance of unimpeded flow of lymphatics: "[W]e must keep the lymphatics normal all the time or see confused Nature in the form of disease. We strike at the source of life and death when we go to the lymphatics" (14). However, even if the blood and the lymph are flowing normally, Still pointed out that "the cerebro spinal fluid is the highest known element that is contained in the human body, and unless the brain furnishes this fluid in abundance a disabled condition of the body will remain. He who is able to reason will see that this great river of life must be tapped and the withering field irrigated at once, or the harvest of health be forever lost" (15).

Holistic Aspects—Environmental and Biopsychosocial Etiologies

For the most part, Still described the origins of disease and illness as a result of "anatomic disturbances followed by physiologic discord." However, at the same time, he acknowledged the potential detrimental influences of heredity, lifestyle, environmental conditions, contagious diseases, inactivity and other personal behavior choices, and psychological and social stress on health (14,16,17).

Still also recognized that substance abuse (e.g., alcohol and opium) as well as poor sanitation, personal hygiene, and dietary indiscretion, lack of exercise or fitness all contributed to illness and disease. He lectured passionately against the social forces that promulgated these deleterious behaviors and social situations, including slavery and economic inequities. Indeed, he spoke from personal experience as he and his family members suffered from these challenging social circumstances during the pioneer days of the 19th century Midwest.

CLASSIC OSTEOPATHIC PHILOSOPHY AND PATIENT CARE

The Body Provides Its Own Drug Store

Like many others, Still observed that some people are more susceptible to epidemic diseases than others. It was also recognized that host resistance to disease is more apparent in certain individuals (18) who have so-called natural immunity that is either inherited or acquired (19,20). Still believed that promoting free flow of arterial blood to an infected area would enable "Nature's own germicide" to eradicate the infectious agent (11). Still's philosophy places complete trust in the innate self-healing ability of the body. Removing all hindrances to health was not enough, however, as it was incumbent upon the physician to ensure that the body's natural chemicals were able to work effectively in alleviating any pathophysiologic processes (10).

Medications

I was born and raised to respect and confide in the remedial power of drugs, but after many years of practice in close conformity to the dictations of the very best medical authors and in consultation with representatives of the various schools, I failed to get from drugs

the results hoped for and I was face to face with the evidence that medication was not only untrustworthy but was dangerous (11).

Initially, Still conceived of the osteopathic medical profession as “a system of healing that reaches both internal and external diseases by manual operation and without drugs” (10). Although he stated, “Osteopathy is a drugless science,” he clarified this statement by explaining that he believed that drugs “should not be used as remedial agents,” since the medications of his era only addressed symptoms or abnormal bodily responses to an unknown cause. In osteopathy, there is no place for injurious medications, whose risks outweigh their benefits, especially if safer and equally effective alternatives exist.

Specifically, Still was against the irrational use of drugs that (a) showed no benefit, (b) had proven to be harmful, and (c) had no proven relationship to the cause of disease processes. He accepted anesthetics, poison antidotes, and a few others that had proven beneficial. “Osteopathy has no use for drugs as remedies, but a great use for chemistry when dealing with poisons and antidotes” (21). Still supports his reasons by listing the life-threatening risks of using drugs commonly employed in the late 19th century, namely: calomel, digitalis, aloe, morphine, chloral hydrate, veratrine, pulsatilla, and sedatives (10). Still persuasively argued that a detailed physical examination, with focus on the neuromusculoskeletal system, followed by a well-designed manipulative treatment, often removes impediments to motion and function. Where he differed from others was his view that manipulative treatment should always be used before deciding that the body had failed in its own efforts.

Vaccinations

Jenner introduced the smallpox vaccine in the 17th century with considerable success. Still acknowledged this by stating, “I believe the philosophy of fighting one infection with another infectious substance that could hold the body immune by long and continuous possession is good and was good” (14). Without disrespect to Jenner, he described shortcomings of Jenner’s methods, pointing out that there were many patients on whom the vaccine did not work or who became disabled or fatally ill. He stated his belief that there is a less harmful method of vaccination and requested that Jenner’s methods be improved.

Still’s rejection of drugs and vaccinations showed up in the initial mission statement for the American School of Osteopathy (ASO) (11). However, in 1910, even while he was president, the school changed its stance and accepted vaccinations and serums as part of osteopathic practices.

First and foremost, Still clearly believed that the osteopathic physician should strive to help the patient’s body release its own medicine for a particular problem. He writes:

The brain of man was God’s drug store, and had in it all liquids, drugs, lubricating oils, opiates, acids, and antacids, and every quality of drugs that the wisdom of God thought necessary for human happiness and health (21).

The Mechanical Approach to Treating the Cause of Disease

Still reasoned that the cause of most diseases was mechanical; therefore, treatment must follow the laws of mechanics. As a consequence, he used manipulative approaches designed to release bony and soft tissue barriers to nervous and circulatory functions in order to improve chances for healing. He claimed that mobilization of these structures improved the outcomes of his patients (11). However, manipulation procedures were not

only applied to relieve musculoskeletal strains and injuries, but to treat internal organ diseases as well. For example, he found characteristic paraspinal muscle rigidity and other abnormal myofascial tensions in patients with infectious diseases. He noted improvement in the health of these patients as well when the musculoskeletal and myofascial impediments to normal physiologic processes were alleviated. In a majority of cases, the patient’s condition was seemingly cured, leading him to believe that the mechanical aspects of dysfunction or disease were vitally important (11). Still thus proposed that in all diseases, mobilization of all the spinal joints not in their proper positional and functional relationships was necessary to ensure proper nerve activity and blood and lymph flow throughout the body. This included everything from the occiput to the coccyx, and indicated adjustment of the pelvis, clavicles, scapulae, costal cage, and diaphragm.

Comprehensive Treatment

While heavily committed to the use of palpatory diagnosis and manipulative treatment, Dr. Still continued many other aspects of patient care. He practiced surgery and midwifery (obstetrics), although little is documented about specific activities.

His patient education strategies highlighted moderation. He included advice for removing noxious or toxic substances from the diet and environment and behavioral adjustments such as adding exercises and stopping smoking. He also admonished his patients for abusing alcohol, opium, and heroin.

Mental illness and stress-related problems were also important to Still (10,11). He wrote about the role the physician can take in providing emotional support and encouragement to patients with end-stage medical problems. He described the importance of giving hope to patients and, at the same time, providing them with a realistic approach to managing their clinical condition (11).

Individualized Treatment

Each person is treated as a unique individual, not as a disease entity. Still taught that the history and physical evaluation of each person would turn up unhealthy self-care behaviors or circumstances and parts of the body not moving normally; the combination interferes with the body’s natural ability to heal itself. The treatment would need to be tailored specifically for each patient’s particular needs.

The classical philosophy of osteopathic medicine formed the foundation upon which contemporary osteopathic patient care is based. The contemporary “five models of osteopathic care” can be understood in the context of the classical osteopathic philosophy of health, disease, and patient care, as depicted in Table 1.2.

HISTORICAL DEVELOPMENT OF OSTEOPATHIC CONCEPTS

Exactly how much influence previous or contemporary philosophies and practices had on Still is purely speculative, since he never discussed specific attachments for any particular philosopher or scientist. The writings of contemporary philosophers of science and biology, like Herbert Spencer (1820–1903) and Alfred Russel Wallace (1823–1913), resonated with those of Still (9). They promoted the theories of evolution and the interdependence of the environment and the organism in all biologic processes, including the origins of disease. They also promoted the concepts of

TABLE 1.2

Osteopathic Five Models in the Context of the Three Domains of a Philosophy of Medicine

Models	Health	Disease	Patient Care ^a
Biomechanical	Efficient and effective posture and motion throughout the musculoskeletal system	Somatic dysfunction; inefficient posture; joint motion restrictions or hyper mobility; instability	Alleviate somatic dysfunction utilizing osteopathic palpatory diagnosis and OMT to restore normal motion and function throughout the body
Respiratory-Circulatory	Efficient and effective arterial supply, venous and lymphatic drainage to and from all cells; effective respiration	Vascular compromise, edema, tissue congestion; poor gas exchange	Remove mechanical impediments to respiration and circulation and relieve congestion and edema by improving venous and lymphatic drainage
Neurological	Efficient and effective sensory processing, neural integration and control, autonomic balance, central and peripheral nervous functions	Abnormal sensation, imbalance of autonomic functions, central and peripheral sensitization/malfunction; pain syndromes	Restore normal sensation, neurological processes and control; alleviate pain
Metabolic-Energy	Efficient and effective cellular metabolic processes, energy expenditure and exchange, endocrine and immune regulation and control	Energy loss, fatigue, ineffective metabolic processes, toxic waste buildup, inflammation, infection, poor wound healing, poor nutrition; adverse response to medication; loss of endocrine control of vital functions	Restore efficient metabolic processes and bioenergetics, alleviate inflammation, infection, restore healing and repair functions and endocrine control
Behavioral	Efficient and effective mental, emotional and spiritual functions, healthy lifestyle choices and activities, good social support system	Ineffective function due to drug abuse, environmental chemical exposure or trauma, poor lifestyle choices (i.e., inactivity, dietary indiscretions); inability to adapt to stress or environmental challenges	Assess and treat the whole person—physical, psychological, social, cultural, behavioral and spiritual aspects; collaborative partnership; individualized patient care and self-responsibility for healthy lifestyle choices

^aUtilizing combinations of osteopathic manipulative medicine, medications, surgery, and education as appropriate.

the interdependence of structure and function, the importance of differentiating cause and effect, and emphasized the unity of the organism and interrelatedness of its parts. Throughout his life, however, Still maintained that his discoveries and thoughts were based on personal observation, experimentation, applications of factual knowledge, and the power of reasoning. After nearly 50 years of developing his concepts, he stated:

I have explored by reading and inquiry much that has been written on kindred subjects, hoping to get something on this great law written by the ancient philosophers, but I come back as empty as I started (10).

A number of scholars and educators have attempted to trace both the historical development and the evolution of thoughts and

practices that may have influenced Still's thinking (18–20,22–26). In general, the authors compare Still's ideas with well-known discourses passed on principally through Western cultural ideas. In 1901, Littlejohn, one of Still's students who became a faculty member at the ASO and founder of two osteopathic colleges, wrote, "Osteopathy did not invent a new anatomy or physiology or construct a new pathology. It has built upon the foundation of sciences already deeply seated in the philosophy of truth, chemistry, anatomy and physiology, a new etiology of diseases, gathering together, adding to and reinforcing natural methods of treating disease that have been accumulating since the art of healing began" (18). However, other students of A.T. Still disagreed with this perspective. C.M.T. Hulett, emphatically stated that "Osteopathy is a new system of thought, a new philosophy of life" (27). Whereas Littlejohn (22) finds the foundation of osteopathy in Greek and

Roman medicine, G.D. Hulett (20) and Downing (23) trace the origins of various osteopathic concepts to the philosophy and practice of medicine found in other ancient writings, such as those of the Ptolemies, Brahmins, Chinese, and Hebrews. All agree on the further development of medicine throughout Europe as a precursor to American osteopathic medical practice. Northrup compares osteopathy to the concepts of Hippocrates and the Cnidian schools (26). Korr contrasts the contributions of Asclepian and Hygeian roots (25). Whereas G.D. Hulett (20) and Korr (25) describe osteopathy as part of an *evolution* of the philosophy of medicine, Lane (19) and Northrup (26) consider it a *reformation* of medical theory and practice.

Still's use of spinal manipulation had many precedents. Schiötz and Cyriax (28) and Lomax (29), among many, document the use of manual treatments for millennia. Hippocrates discussed "subluxations" or minor displacements of vertebra in his treatise "On the Articulations" and the manual adjustments used to correct them (30). In the 18th and 19th centuries, many American and European practitioners acknowledged that there are relationships among displaced or "subluxed" vertebrae and "irritated" spinal nerves in relation to both musculoskeletal and visceral disorders (31).

EVOLUTION OF OSTEOPATHIC PHILOSOPHY

In his unique way, Still integrated many of these concepts into his new system and molded it into a distinctive medical school curriculum that continues to evolve to this day. Still was adamant that he did not expect his students and colleagues to take what he advocated as dogma. He taught, "You must reason. I say reason, or you will finally fail in all enterprises. Form your own opinions, select all facts you can obtain. Compare, decide, then act. Use no man's opinion; accept his works only" (14). He urged his students to study, test, and improve upon his ideas.

An example of this evolution is a shift from Still's early, and virtually exclusive, emphasis on anatomy to a more inclusive stress on primary physiologic functions that strengthen his concepts. Initially, Littlejohn (22), and later, Burns (32), Cole (33,33a), Denslow (34), and Korr (35,36), promoted integrative neurophysiologic and neuroendocrine concepts.

Whereas Littlejohn interpreted Still's concepts in light of 19th century physiologic theories, Burns, Cole, Denslow, and Korr pioneered distinctive osteopathic approaches to physiologic investigations, making significant scientific contributions. Korr was particularly influential in interpreting osteopathic concepts in light of the rapidly developing science of physiology in the 20th century (Box 1.3). He has been referred to as "the second great osteopathic philosopher" (37) (Figs. 1.4 and 1.5).

Korr's Explication of Osteopathic Principles

For the first edition of this text, Korr wrote an "Explication of Osteopathic Principles," which was his last published work. It is included here to demonstrate how he was able to use the osteopathic philosophy and tenets to organize and apply 20th century scientific knowledge to patient care:

At this stage of your medical training, you have become familiar with osteopathic principles and can recite them in their usual brief, maxim form. The purpose of this section is to explore more fully the meaning, biological foundations, and clinical implications of the founding principles of osteopathic medicine.

Irvin Korr, Ph.D.

Irvin Korr, Ph.D., received his physiology degree from Princeton University. Most of his teaching and research career was spent at the Kirksville College of Osteopathic Medicine in Missouri, with later appointments at both Michigan State University College of Osteopathic Medicine and The Texas College of Osteopathic Medicine (University of North Texas). A multitalented individual, Korr was an accomplished violinist, sometimes playing chamber music with Albert Einstein, who was in residence at the time of his postgraduate training. He published extensively with several colleagues, including J.S. Denslow, A.D. Krems, Martin J. Goldstein, Price E. Thomas, Harry M. Wright, and Gustavo S.L. Appeltauer. In 1947, Korr's initial publication, with Denslow and Krems, focused on facilitation of neural impulses in motoneuron pools. Original research papers followed this on dermal autonomic activity, electrical skin resistance, and trophic function of nerves (36). As Korr gained insight into Still's concepts, he lectured widely and published a number of important treatises tying osteopathic concepts together with proven physiologic models that emphasized the important roles played by the neuromusculoskeletal system. Whereas Still emphasized a focus on bones as the starting place from which he was to discern the cause of pathology, Korr expanded this concept to include the integrative activity of the spinal cord and its relationships with the musculoskeletal and the sympathetic nervous systems (36). Similar to Still, however, Korr often referred to the neuromusculoskeletal system as the "Primary Machinery of Life."

For 50 years, Irvin M. Korr, scientist, philosopher, and humanist, has led and inspired several generations of osteopathic physicians and educators. His final treatise on osteopathic philosophy was written for the first edition of this text published in 1997. Upon reflection on the osteopathic principles, Korr stated "It is to the credit and honor of the osteopathic profession that it contributed cogent elaboration of the principles, developed effective methods for their implementation, built a system of practice upon those principles, and disclosed much about their basis in biological mechanisms through research (7)."

Remember that these principles began to evolve centuries ago, even before the time of Hippocrates. However, their basis in animal and, more specifically, human biology did not begin to become evident through research until late in the 19th century. The origin of these principles, therefore, was largely empirical; that is, they were the product of thoughtful and widely shared observations of ill and injured people. For example, it could hardly escape notice, even in primitive societies, that people (and animals) recovered from illness and wounds healed without intervention and, therefore, some natural indwelling healing power must be at work.

Even at the time of the founding of the osteopathic profession in 1892, the available knowledge in the sciences of physiology, biochemistry, microbiology, immunology, and pathology was meager. Indeed, immunology, biochemistry, and various other neurosciences and biomedical sciences had yet to appear as distinct disciplines. Therefore, these principles could only be expressed as aphorisms, embellished perhaps with conjectures about their biological basis. It is to the credit and honor of the osteopathic profession that it contributed cogent elaboration of the principles, developed effective methods for their implementation, built a system of practice upon those principles, and

Figure 1-4 Irwin M. Korr, Ph.D. (1909–2004), “The second great osteopathic philosopher.”

disclosed much about their basis in biological mechanisms through research.

In view of the enormous amount of biomedical knowledge recorded throughout the 20th century, it is timely to examine the principles that guide osteopathic practice in the light of that knowledge and to explore their relevance to clinical practice and to current and future health problems. What follows is an effort in that direction, without detailed reference to individual research.

THE PERSON AS A WHOLE

The Body

The principle of the unity of the body, so central to osteopathic practice, states that every part of the body depends on other parts for maintenance of its optimal function and even of its integrity. This interdependence of body components is mediated by the communication systems of the body: exchange of substances via circulating blood and other body fluids and exchange of nerve impulses and neurotransmitters through the nervous system.

The circulatory and nervous systems also mediate the regulation and coordination of cellular, tissue, and organ functions and thus the maintenance of the integrity of the body as a whole. The organized and integrated collaboration of the body components is reflected in the concept of homeostasis, the maintenance of the relative constancy of the internal environment in which all the cells live and function.

In view of this interdependence and exchange of influences, it is inevitable that dysfunction or failure of a major body component will adversely affect the competence of other organs and tissues and, therefore, one’s health.

Figure 1-5 I.M. Korr, Ph.D., like A.T. Still, M.D., D.O., emphasized the role of the musculoskeletal system as The Primary Machinery of Life. This is a drawing by the renowned anatomist, Vesalius (1514–1564), depicting the muscles of the body in a dramatic pose. (Vesalius, *Andreas De humani corporis fabrica* plate 25 (Liber I) Basileae, [Ex officina Joannis Oporini, 1543]. Courtesy of the National Library of Medicine.)

The Person

Important and valid as is the concept of body unity, it is incomplete in that it is, by implication, limited to the physical realm. Physicians minister not to bodies but to individuals, each of whom is unique by virtue of his or her genetic endowment, personal history, and the variety of environments in which that history has been lived.

The person, obviously, is more than a body, for the person has a mind, also the product of heredity and biography. Separation of body and mind, whether conceptually or in practice, is an anachronistic remnant of such dualistic thinking as that of the 17th century philosopher-scientist, René Descartes. It was his belief that body and mind are separate domains, one publicly visible and palpable, the other invisible, impalpable, and private. This dualistic concept is anachronistic because, while it is almost universally rejected as

a concept, it is still acted out in much of clinical practice and in biomedical research.

Clinical and biomedical research (as well as everyday experience) has irrefutably shown that body and mind are so inseparable, so pervasive to each other, that they can be regarded—and treated—as a single entity. It is now widely recognized (whether or not it is demonstrated in practice) that what goes on (or goes wrong) in either body or mind has repercussions in the other. It is for reasons such as these that I prefer unity of the person to unity of the body, conveying totally integrated humanity and individuality.

The Person as Context

Phenomena assigned to mind (consciousness, thought, feelings, beliefs, attitudes, etc.) have their physiological and behavioral counterparts; conversely, bodily and behavioral changes have psychological concomitants, such as altered feelings and perceptions. It must be noted, however, that it is the person who is feeling, perceiving, and responding not the body or the mind. It is you who feels well, ill, happy, or sad, and not your body or mind. What goes on in body and mind is conditioned by who the person is and their entire history.

In short, the person is far more than the union of body and mind, in the same sense that water is more than the union of hydrogen and oxygen. Nothing that we know about either oxygen or hydrogen accounts for the three states of water (liquid, solid, and gas), their respective properties, the boiling and freezing points, viscosity, and so forth. Water incorporates yet transcends oxygen and hydrogen. To understand water, we must study water and not only its components. In the same way, at an enormously more complex level, the person comprises yet transcends body and mind.

Moreover, once hydrogen and oxygen are joined to form water, they become subject to the laws that govern water. In the same but infinitely more complex sense, it is you who makes up your mind, changes your mind, trains and enriches your mind, and puts it to work. It is you who determines from moment to moment whether and in what way you will express, through your body, what is in or on your mind.

Thus the person is the context, the environment, in which all the body parts live and function and in which the mind finds expression. Everything about the person—genetics, history from conception to the present moment, nutrition, use and abuse of body and mind, parental and school conditioning, physical and sociocultural environments, and so on—enters into determining the quality of physical and mental function. The better the quality of the environment provided by the person for the mental and bodily components, the better they will function. For example, someone who has a peptic ulcer is not ill because of the ulcer. The ulcer exists because of an unfavorable internal environment.

In conclusion, just as the proper study of mankind is man (Alexander Pope), so is the study of human health and illness also man. As will become evident, the principle of the unity of the person leads us naturally to the next principle.

THE PLACE OF THE MUSCULOSKELETAL SYSTEM IN HUMAN LIFE

The Means of Expression of Our Humanity and Individuality

Structure determines function, structure and function are reciprocally interrelated, and similar aphorisms have traditionally represented another osteopathic principle. That principle recognizes the special place of the musculoskeletal system among the body

systems and its relation to the health of the person. We examine now the basis for the osteopathic emphasis on the musculoskeletal system in total health care.

Human life is expressed in human behavior, in humans doing the things that humans do. And whatever humans do, they do with the musculoskeletal system. That system is the ultimate instrument for carrying out human action and behavior. It is the means through which we manifest our human qualities and our personal uniqueness—personality, intellect, imagination, creativity, perceptions, love, compassion, values, and philosophies. The most noble ethical, moral, or religious principle has value only insofar as it can be overtly expressed through behavior.

That expression is made possible by the coordinated contractions and relaxations of striated muscles, most of them acting upon bones and joints. The musculoskeletal system is the means through which we communicate with each other, whether it be by written, spoken, or signed language, or by gesture or facial expression. Agriculture, industry, technology, literature, the arts and sciences—our very civilization—are the products of human action, interaction, communication, and behavior, that is, by the orchestrated contractions and relaxations of the body's musculature.

Relation to the Body Economy

The musculoskeletal system is the most massive system in the community of body systems. Its muscular components are collectively the largest consumer in the body economy. This is true not only because of their mass, but because of their high energy requirements. Furthermore, those requirements may vary widely from moment to moment according to what the person is doing, with what feelings, and in what environments.

The high and varying metabolic requirements of the musculoskeletal system are met by the cardiovascular, respiratory, digestive, renal, and other visceral systems. Together, they supply the required fuels and nutrients, remove the products of metabolism, and control the composition and physical properties of the internal environment. In servicing the musculoskeletal system in this manner, these organ systems are at the same time servicing each other (and, of course, the nervous system).

The nervous system is also, to a great degree, occupied with the musculoskeletal system, that is, with behavior and motor control. Indeed, most of the fibers in the spinal nerves are those converging impulses to and from the muscles and other components of the musculoskeletal system. In addition, the nervous system, its autonomic components, and the circulatory system mediate communication and exchange of signals and substances between the soma and the viscera. In this way, visceral, metabolic, and endocrine activity is continually tuned to moment-to-moment requirements of the musculoskeletal system, that is, to what the person is doing from moment to moment.

Consequences of Visceral Dysfunction

Impairment or failure of some visceral function or of communication between the musculoskeletal system and the viscera is reflected in the musculoskeletal system. When the resulting dysfunction is severe and diffuse, motor activity and even maintenance of posture are difficult or impossible and automatically imposed.

The Musculoskeletal System as Source of Adverse Influences on Other Systems

In view of the rich afferent input of the musculoskeletal system into the central nervous system and its rich interchange of substances

with other systems through the body fluids, it is inevitable that structural and functional disturbances in the musculoskeletal system will have repercussions elsewhere in the body.

Such structural and functional disturbances may be of postural, traumatic, or behavioral origin (neglect, misuse, or abuse by the person). Further, it must be appreciated that the human framework is, compared with other (quadruped) mammals, uniquely unstable and vulnerable to compressive, torsional, and shearing forces, because of the vertical configuration, higher center of gravity, and the comparatively small, bipedal base.

The human musculoskeletal system, therefore, is the frequent source of aberrant afferent input to the central nervous system and its autonomic distribution, with at least potential consequences to visceral function. Which organs, blood vessels, etc. are at risk is determined by the site of the musculoskeletal dysfunction and the part(s) of the central nervous system, (e.g., spinal segments) into which it discharges its sensory impulses.

When a dysfunction or pathology has developed in a visceral organ, that disturbance is reflected in segmentally related somatic tissues. Viscus and soma become linked in a vicious circle of afferent and efferent impulses, which sustain and exacerbate the disturbance. Appropriate treatment of the somatic component reduces its input to the vicious circle and may even interrupt that circle with therapeutic effect.

Importance of the Personal Context

Whether or not visceral or vasomotor consequences of somatic dysfunction occur, and with what consequences to the person, depends on other factors in the person's life, such as the genetic, nutritional, psychological, behavioral, sociocultural, and environmental. As research has shown, however, the presence of somatic dysfunction and the accompanying reflex and neurotrophic effects exaggerate the impact of other detrimental factors on the person's health. Effective treatment of the musculoskeletal dysfunction shields the patient by reducing the deleterious effects of the other factors. Such treatment, therefore, has preventive as well as therapeutic benefits.

Such treatment directed to the musculoskeletal system assumes even greater and often crucial significance when it is recognized that the other kinds of harmful factors, such as those enumerated above, are not readily subject to change and may even require social or governmental intervention. The musculoskeletal system, however, is readily accessible and responsive to OMT. I view these considerations as the rationale for OMT and its strategic role in total health care.

Finally, the osteopathic philosophy and the unity of the person concept enjoin the physician to treat the patient as a whole and not merely the affected parts. Hence, appropriate corrective attention should also be given to other significant risk factors that are subject to change by both patient and physician.

OUR PERSONAL HEALTH CARE SYSTEMS

The Natural Healing Power

Appreciation, even in ancient times, of our inherent recuperative, restorative, and rehabilitative powers is reflected in the Latin phrase, *vis medicatrix naturae* (nature's healing force). We recover from illnesses, fevers drop, blood clots and wounds heal, broken bones reunite, infections are overcome, skin eruptions clear up, and even cancers are known to occasionally undergo spontaneous remission. But miraculous as is the healing power (and appreciated

as it was until we became more impressed by human-made miracles and breakthroughs), the other, more recently revealed components of the health care system with which each of us is endowed are no less marvelous.

The Component System That Defends against Threats from Without

This component includes, among others, immune mechanisms that defend us against the enormous variety and potency of foreign organisms that invade our bodies, wreaking damage and even bringing death. These same immune mechanisms guard us against those of our own cells that become foreign and malignant as the result of mutation. Included also are the mechanisms that defend against foreign and poisonous substances that we may take in with our food and drink or that enter through the skin and lungs, by disarming them, converting them to innocuous substances, and eliminating them from the body. They defend us (until overwhelmed) even against the toxic substances that we ourselves introduce into the atmosphere, soil, water, or more directly into our own bodies.

Mechanisms That Defend against Changes in the Internal Environment

We humans are exposed to, and adapt to, wide variations in physical and chemical properties of our environment (e.g., temperature, barometric pressure, oxygen, and carbon dioxide concentrations) and sustain ourselves with chemically diverse food and drink. But the cells of our body can function and survive only in the internal environment of interstitial fluids that maintain body functions within relatively narrow limits as regards variations in chemical composition, temperature, tissue, osmotic pressure, pH, etc.

This phenomenon, called homeostasis, is based on thousands of simultaneously dynamic equilibria occurring throughout the body. Examples include rates of energy consumption and replenishment by the cells. Homeostasis constancy and quick restoration of constancy must be accomplished regardless of the variations in the external environment, composition of food and drink, and the moment-to-moment activities of the person. It is accomplished by an enormously complex array of regulatory mechanisms that continually monitor and control respiratory, circulatory, digestive, renal, metabolic, and countless other functions and processes. Maintenance of optimal environments for cellular function is essential to health. The homeostatic mechanisms may, therefore, be viewed as the health maintenance system of the body.

Commentary

These, then, are the three major components of our indwelling health care system, each comprising numerous component systems. In the order in which humans became aware of them, they are (a) the healing (remedial, curative, palliative, recuperative, rehabilitative) component; (b) the component that defends against threats from the external environment; and (c) the homeostatic, health-maintaining component. These major component systems, of course, share subcomponents and mechanisms.

When the internal health care system is permitted to operate optimally, without impediment, its product is what we call health. Its natural tendency is always toward health and the recovery of health. Indeed, the personal health care system is the very source of health, upon which all externally applied measures depend for their beneficial effects. The internal health care system, in effect,

makes its own diagnoses, issues its own prescriptions, draws upon its own vast pharmacy, and in most situations, administers each dose without side effects.

Health and healing, therefore, come from within. It is the patient who gets well, and not the practitioner or the treatment that makes them well.

THE THREE PRINCIPLES AS GUIDES TO MEDICAL PRACTICE

The Unity of the Person

In caring for the whole person, the well-grounded osteopathic physician goes beyond the presenting complaint, beyond relief of symptoms, beyond identification of the disease and treatment of the impaired organ, malfunction, or pathology, important as they are to total care. The osteopathic physician also explores those factors in the person and the person's life that may have contributed to the illness and that, appropriately modified, compensated, or eliminated, would favor recovery, prevent recurrence, and improve health in general.

The physician then selects that factor or combination of factors that are readily subject to change and that would be of sufficient impact to shift the balance toward recovery and enhancement of health. The possible factors include such categories as the biological (e.g., genetic, nutritional), psychological, behavioral (use, neglect, or abuse of body and mind; interpersonal relationships; habits; etc.), sociocultural, occupational, and environmental. Some of these factors, especially some of the biological, are responsive to appropriate clinical intervention, some are responsive only to social or governmental action, and still others require changes by patients themselves. Osteopathic whole-person care, therefore, is a collaborative relationship between patient and physician.

The Place of the Musculoskeletal System in Human Biology and Behavior: The Strategic Role of Osteopathic Manipulative Treatment

It is obvious that some of the most deleterious factors are difficult or impossible for patient and physician to change or eliminate. These include (at least at present) genetic factors (although some inherited predispositions can be mitigated by lifestyle change). They include also such items as social convention, lifelong habits (e.g., dietary and behavioral), widely shared beliefs, prejudices, misconceptions and cultural doctrines, attitudes, and values. Others, such as the quality of the physical or socioeconomic environments, may require concerted community, national, and even international action.

Focus falls, therefore, upon those deleterious factors that are favorably modifiable by personal and professional action, and that, when appropriately modified or eliminated, mitigate the health-impairing effects of the less changeable factors. Improvement of body mechanics by OMT is a major consideration when dealing with these complex interactions.

OUR PERSONAL HEALTH CARE SYSTEMS

This principle has important implications for the respective responsibilities of patient and physician and for their relationship. Since each person is the owner and hence the guardian of his or her own personal health care system, the ultimate source of health and healing, the primary responsibility for one's health is each individual's. That responsibility is met by the way the person lives, thinks,

behaves, nourishes himself or herself, uses body and mind, relates to others, and the other factor usually called lifestyle. Each person must be taught and enabled to assume that responsibility.

It is the physician's responsibility, while giving palliative and remedial attention to the patient's immediate problem, to support each patient's internal health care system, to remove impediments to its competence, and above all, to do it no harm. It is also the responsibility of physicians to instruct patients on how to do the same for themselves and to strive to motivate them to do so, especially by their own example.

The relationship between patient and osteopathic physician is therefore a collaborative one, a partnership, in maintaining and enhancing the competence of the patient's personal health care system. The maintenance and enhancement of health is the most effective and comprehensive form of preventive medicine, for health is the best defense against disease. As stated by Still, "To find health should be the object of the doctor. Anyone can find disease."

Relevance to the Current and Future Health of the Nation

The preventive strategy of health maintenance and health enhancement, intrinsic to the osteopathic philosophy, is urgently needed by our society today. One of the greatest burdens on the nation's health care system and on the national economy is in the care of victims of the chronic degenerative diseases, such as heart disease, cancer, stroke, and arthritis, which require long-term care.

The incidence of these diseases has increased and will continue to increase well into the next century as the average age of our population continues to increase. The widely accepted (but usually unspoken) assumption that guides current practice (and national policy) is that the chronic degenerative diseases are an inevitable aspect of the aging process; that is, that aging is itself pathological. It is now increasingly apparent, however, that the increase of their incidence with age is because the longer one lives, the greater the toll taken by minor, seemingly inconsequential, inconspicuous, treatable impairments, and modifiable contributing factors in and around the person. They are, therefore, largely the natural culmination of less-than-favorable lifestyles, and, hence, they are largely preventable.

The great national tragedy is that, while the nation's health care system is so extensively and expensively absorbed in the care of millions of older adult victims of chronic disease (at per capita cost 3.5 times that of persons under the age of 65 years), tens of millions of younger people and children are living on and embarking on life paths that will culminate in the same diseases. The health care system simply must move upstream to move people from pathogenic to salutary paths. And the osteopathic profession can show the way.

The osteopathic profession has a historic opportunity to make an enormous contribution to the enhancement of the health of our nation. It can do this by giving leadership in addressing this great tragedy by bringing its basic strategy of whole-person, health-oriented care to bear on the problem and demonstrating its effectiveness in practice.

Having reviewed and enlarged on the principles of osteopathic medicine, their meaning, biological foundations, and clinical implications, it seems appropriate to propose a definition of osteopathic medicine. The author offers the following: Osteopathic medicine is a system of medicine that is based on the continually deepening and expanding understanding of (a) human nature; (b) those components of human biology that are centrally relevant to health, namely the inherent regulatory, protective,

regenerative, and recuperative biological mechanisms, whose combined effect is consistently in the direction of the maintenance, enhancement, and recovery of health; and (c) the factors in and around the person that both favorably and unfavorably affect those mechanisms.

The practice of osteopathic medicine is, essentially, the potentiation of the intrinsic health-maintaining and health-restoring resources of the individual. The methods and agents employed are those that are effective in enhancing the favorable factors and diminishing or eliminating the unfavorable factors affecting each individual. Osteopathic medical practice necessarily includes the application of palliative and remedial measures, but always on the condition that they do no harm to the patient's own health-maintaining and health-restoring resources. This stipulation governing the choice of methods and agents is based on the recognition that all therapeutic methods depend on the patient's own recuperative power for their effectiveness and are valueless without it and that health and the recovery of health come from within.

The art and science of osteopathic medicine are expressed in the identification and selection of those factors in each individual that are accessible and amenable to change and that, when changed, would most decisively potentiate the person on health-supporting resources.

Osteopathic physicians give special emphasis to factors originating in the musculoskeletal system, for the following reasons:

1. The vertical human framework (a) is highly vulnerable to compressive (gravitational), torsional, and shearing forces, and (b) encases the entire central nervous system.
2. Since the massive, energy-demanding system has rich two-way communication with all other body systems, it is, because of its vulnerability, a common and frequent source of impediments to the functions of other systems.
3. These impediments exaggerate the physiological impact of other detrimental factors in the person's life, and, through the central nervous system, focus it on specific organs and tissues.
4. The musculoskeletal impediments (somatic dysfunctions) are readily accessible to the hands and responsive to the manipulative and other methods developed and refined by the osteopathic medical profession.

The Definition of Osteopathy

Osteopathic philosophy has been defined various ways over the years. To get a better sense of the evolution of the osteopathic philosophy since its inception, it is instructive to follow how it has been defined over time. In his autobiography, Still gave a "technical" definition as follows:

Osteopathy is that science which consists of ... knowledge of the structure and functions of the human mechanism ... by which nature under the scientific treatment peculiar to osteopathic practice ... in harmonious accord with its own mechanical principles, ... may recover from displacements, disorganizations, derangements, and consequent disease and regain its normal equilibrium of form and function in health and strength. (10)

Besides Still, several other American osteopathic scholars wrote treatises on osteopathic philosophy and principles (19,20,23,24,33,33a,38-44). Each author had his or her own definition and explanation of osteopathic philosophy. There have been several attempts over the past century to obtain consensus, or agreement,

on a unifying definition and clearly stated tenets or principles that govern the practice of osteopathic medicine.

According to Littlejohn, the first consensus definition of osteopathy, among multiple faculty members representing several osteopathic medical schools, was published in 1900 (18). After Still passed away in 1917, the AOA House of Delegates passed a resolution that the A.T. Still Research Institute, under the direction of Louisa Burns, D.O. at the time, would publish an updated version of the most popular textbook on osteopathic principles in print, adding current scientific knowledge in support of the philosophy. The book was passed around to all the osteopathic colleges for input and consensus. In 1922, this consensus based textbook was published by the A.T. Still Research Institute as a revised edition of the classic textbook by G.D. Hulett initially written at the turn of the 20th century (20). By this time in medical thought, it was widely accepted that cellular level activity was a strong determinant of health or disease states. In an attempt to update osteopathic philosophy in light of emerging concepts in cellular biology, the authors applied Still's mechanistic viewpoint to cellular physiology. The following passage not only illustrates this approach but also demonstrates the desire of the profession to state osteopathic philosophy and principles in terms of concise tenets based on contemporary scientific knowledge:

The osteopathic view of the cell ... is largely covered by the following statements:

- Normal structure is essential to normal function.
- Normal function is essential if normal structure is to be maintained.
- Normal environment is essential to normal function and structure, though some degree of adaptation is possible for a time, even under abnormal conditions.

In the human body, with its diversified functions, we may add also:

- The blood preserves and defends the cells of the body.
- The nervous system unifies the body in its activities.
- Disease symptoms are due either to failure of the organism to meet adverse circumstances efficiently, or to structural abnormalities.
- Rational methods of treatment are based upon an attempt to provide normal nutrition, innervation, and drainage to all tissues of the body, and these depend chiefly upon the maintenance of normal structural relations (20).

The addition of medications in the practices of osteopathic physicians and surgeons over the years affected how the philosophy was stated. For example, in 1948 the faculty at the College of Osteopathic Physicians and Surgeons in Los Angeles added the following phrase to their basic osteopathic principles statement: "Like a machine, the body can function efficiently only when in proper adjustment and when its chemical needs are satisfied either by food or medical substances" (45). Further evolution occurred in 1953 when the faculty of the Kirksville College of Osteopathy and Surgery agreed on the following:

Osteopathy, or Osteopathic Medicine, is a philosophy, a science, and an art. Its philosophy embraces the concept of the unity of body structure and function in health and disease. Its science includes the chemical, physical, and biological sciences related to the maintenance of health and the prevention, cure, and alleviation of disease. Its art is the application of the philosophy and the science in the practice of osteopathic medicine and surgery in all its branches and specialties.

Health is based on the natural capacity of the human organism to resist and combat noxious influences in the environment and to compensate for their effects—to meet, with adequate reserve, the usual stresses of daily life, and the occasional severe stresses imposed by extremes of environment and activity. Disease begins when this natural capacity is reduced, or when it is exceeded or overcome by noxious influences.

Osteopathic medicine recognizes that many factors impair this capacity and the natural tendency toward recovery, and that among the most important of these factors are the local disturbances or lesions of the musculoskeletal system. Osteopathic medicine is therefore concerned with liberating and developing all the resources that constitute the capacity for resistance and recovery, thus recognizing the validity of the ancient observation that the physician deals with a patient as well as a disease (46).

They then combined several concepts and restated them as four principles:

The osteopathic concept emphasizes four general principles from which are derived an etiological concept, a philosophy and a therapeutic technic that are distinctive, but not the only features of osteopathic diagnosis and treatment.

1. The body is a unit.
2. The body possesses self-regulatory mechanisms.
3. Structure and function are reciprocally inter-related.
4. Rational therapy is based upon an understanding of body unity, self-regulatory mechanisms, and the inter-relationship of structure and function (46).

Over the ensuing 40 years, advances in the biologic sciences elucidated many mechanisms in support of the concept that optimal health calls for integration of countless functions ranging from the molecular to the behavioral level. When this integration breaks down, dysfunction and disease commonly follow. Infectious and metabolic diseases, as well as diseases of aging and genetics, are frequent examples. Interdisciplinary fields of study have been developed to investigate and delineate the complex interactions of numerous coordinated body functions in health and disease. Psychoneuroimmunology, for example, provides substantial evidence linking mind, body, and spiritual activities with a wide variety of biologic observations (47–50).

Clinical applications of the advances in molecular, cellular, neurologic, and behavioral sciences, combined with the decreased emphasis on mechanical factors within osteopathic medical practice, demanded a new consensus statement. Using the 1953 Kirksville faculty statement as a beginning, the associate editors of the first edition of this text (1997) stated

Health is the adaptive and optimal attainment of physical, mental, emotional, and spiritual well-being. It is based on our natural capacity to meet, with adequate reserves, the usual stresses of daily life and the occasional severe stresses imposed by extremes of environment and activity. It includes our ability to resist and combat noxious influences in our environment and to compensate for their effects. One's health at any given time depends on many factors including his or her polygenetic inheritance, environmental influences, and adaptive response to stressors (51).

The editors modified the four key principles of osteopathic philosophy as follows:

1. The body is a unit; the person is a unit of body, mind, and spirit.

2. The body is capable of self-regulation, self-healing, and health maintenance.
3. Structure and function are reciprocally interrelated.
4. Rational treatment is based upon an understanding of the basic principles of body unity, self-regulation, and the inter-relationship of structure and function (51).

In July 2008, the AOA House of Delegates adopted a policy statement accepting these four tenets as stated.

In order to represent an increasingly diverse group of osteopathic physicians, the AOA adopted a general statement regarding osteopathic medicine. Since 1991, the official AOA definition of *osteopathic medicine* has been reviewed periodically. The latest rendition defines Osteopathic Medicine.

A complete system of medical care with a philosophy that combines the needs of the patient with current practice of medicine, surgery and obstetrics; that emphasizes the interrelationship between structure and function; and that has an appreciation of the body's ability to heal itself.

SUMMARY

Based on a health-oriented medical philosophy, osteopathic medicine uses a number of concepts to implement its principles. The neuromusculoskeletal system is used as a common point of reference because it directly relates the individual to the physical environment on a day-to-day basis. The practitioner's primary roles are to:

- Address primary cause(s) of disease using available evidence-based practices
- Enhance the patient's healing capacity
- Individualize patient management plans with an emphasis on health restoration and disease prevention
- Use palpatory diagnosis and manipulative treatment to focus on and affect somatic signs of altered structural, mechanical, and physiologic states

Osteopathic philosophy is meant to guide osteopathic physicians in the best use of scientific knowledge to optimize health and diminish disease processes. Upon founding his profession and school, Still expressed the hope that “the osteopath will take up the subject and travel a few miles farther toward the fountain of this great source of knowledge and apply the results to the relief and comfort of the afflicted who come for counsel and advice” (14). It is the intention of the authors to organize current medical knowledge and place it on a foundation of osteopathic philosophy. We do this in order to provide the osteopathic medical student with a road map that will lead to the further study of the science of osteopathy and the practice of the highest quality patient-centered health care possible.

Major Events in Osteopathic History

BARBARA E. PETERSON

KEY CONCEPTS

- The origin of osteopathic medicine is the story of a search for improvement in the system of health care.
- Growth of the osteopathic profession followed a philosophy enunciated by Andrew Taylor Still.
- The establishment of an osteopathic educational process was influenced by individuals not only in the United States but also from other countries.
- Andrew Taylor Still did not intend to establish a separate profession for the practice of medicine but sought acceptance of his ideas within teaching programs of traditional medicine.
- The growth of osteopathic professional organizations was made necessary by concerted resistance from the organizations of traditional medicine.
- The continued demonstration of strength and growth by the osteopathic profession led to recognition by state and federal governments.
- The need to provide expanded teaching of osteopathic theory, methods, and practice led to the development of hospitals, primary care emphasis, and the implementation of specialty training programs.

INTRODUCTION

Osteopathic medicine has from its beginning been a profession based on ideas and tenets that have lasted through all sorts of adversity and have been credited with bringing the profession to its present level of success. The previous chapter outlines in some detail the growth of these ideas. It is perhaps significant that the profession's founder never wrote clinical manuals, only books of philosophy (1–4).

It is striking that these ideas, still quoted extensively today (5), came not from universities or medical centers but from the creative problem solving of an informally educated American frontier doctor named Andrew Taylor Still. Looking back more than a century, it seems surprising that his ideas were so controversial when first put forward. But perhaps history has caught up with this eccentric, inventive man.

ANDREW TAYLOR STILL

The story of Andrew Taylor Still is worth knowing in detail but must be told superficially. He was born in a log cabin in Virginia in 1828, the year Andrew Jackson was elected president (Fig. 2.1). Still's family were farmers, as most people were then; his father was also a Methodist circuit rider who preached and treated people's ills. He later would teach his five sons to be doctors in the usual frontier apprentice system of the time.

Still's mother came from a family that was nearly all wiped out by a Shawnee Indian massacre (6), and it must have seemed a supreme irony when in 1851 she and her husband moved to Kansas as missionaries to the descendants of these same Indians. However, the family course first took them to Tennessee and then to Missouri, where they also were frontier missionaries.

Still had the sketchy education of a frontier child (3) but he was an inventive person and liked to read. Eventually, he would become familiar with many of the major practical and ideological trends

of his time. But learning to survive had to come first; Missouri and Kansas were true frontiers. The Stills first eked out a living by hunting for food and making some of their clothes from animal skins. The family also plowed their land claim and established a farm while the father rode a circuit among scattered settlers, ministering to minds and bodies. It was a lifestyle that gave substance to the word “survivor” (7).

Still would later say how important animal dissection had been as a preparation for study of human anatomy. He also recorded another prophetic childhood experience in his *Autobiography*:

One day, when about ten years old, I suffered from a headache. I made a swing of my father's plow-line between two trees; but my head hurt too much to make swinging comfortable, so I let the rope down to about eight or ten inches of the ground, threw the end of a blanket on it, and I lay down on the ground and used the rope for a swinging pillow. Thus I lay stretched on my back, with my neck across the rope. Soon I became easy and went to sleep, got up in a little while with the headache gone. As I knew nothing of anatomy at this time, I took no thought of how a rope could stop headache and the sick stomach which accompanied it. After that discovery I roped my neck whenever I felt one of those spells coming on (3).

To the end of his life, Still continued to “rope his neck” (Fig. 2.2). In his old age, he would lie down daily with his neck on a version of a Chinese pillow, known among country folk as a “saint's rest”—a wooden frame with a leather strap suspended across it—giving the same effect as a plow rope suspended between two trees. In his middle years, he discovered other crude but effective methods for self-treatment, notably a croquet ball upon which he would lie down at the correct point when the problem was in his back rather than his neck (Mrs. J.S. Denslow [Dr. Still's granddaughter], personal communication, 1972).

In the 1840s, the issue of slavery divided the Methodist church and the Stills stayed with the northern (abolitionist) branch.

Figure 2-1 A.T. Still's birthplace: a one-room log cabin near Jonesville, Virginia. Preserved and displayed at the A.T. Still Museum on the campus of A.T. Still University in Kirksville, MO. (Still National Osteopathic Museum, Kirksville, MO.)

By the early 1850s, most of the family had moved to Kansas, including Still and his young wife. At that time Still began seriously to read and practice medicine with his father. They gave the Indians “such drugs as white men used [and] cured most of the cases [they] met” (3).

In 1855, the government forced the Shawnees farther west, and Kansas became a virtual war zone as both abolitionist and proslavery settlers rushed in. The fate of Kansas as a free state depended on a popular vote. The Stills chose to be active abolitionists. Still recalled:

I could not do otherwise, for no man can have delegated to him by statute a just right to any man's liberty, either on account of race or color. With these truths before me I entered all combats for the abolition of slavery at home and abroad, and soon had a host of bitter political enemies, which resulted in many thrilling and curious adventures (3).

The Stills met John Brown and fought, under the command of Jim Lane, two of the abolitionist leaders active on the western frontier. There are numerous stories of “abolitionist encounters” during the pre-Civil War days (8–10). The struggle lasted, said Still, until Abraham Lincoln “wrote the golden words: ‘Forever free, without regard to race or color.’ I will add—or sex” (3).

The territorial political situation was volatile and confusing, with even the elections seemingly decided by gun battles. There are many accounts of “bloody Kansas” in the pre-Civil War period, including those in early osteopathic writings. But somehow a free state legislature was elected in 1857, and Still was a proud member of that group (11).

Still's first wife, née Mary Margaret Vaughn, died in 1859, leaving three children. In late 1860, Still married a young schoolteacher who had learned to mix prescriptions for her physician father and who was prepared by her background to accept Still's medical and spiritual speculations (8). It was a most important partnership; Mary Elvira Turner Still was to support her husband and family through the long period of doubt and disgrace that preceded successful establishment of the osteopathic profession and again through the heady days of unexpected success. But all this was in the future.

When the Civil War officially began, Still enlisted first in a cavalry division of a force assigned to Jim Lane. Later, he organized a company of Kansas militia, which was in turn consolidated with other militia battalions. He was commissioned a major and saw active combat; some experiences are recounted in his *Autobiography* (3). He also served as a military surgeon, though he had been listed as a hospital steward on the official record (12). His unit was disbanded in October 1864, and Still went home to resume normal civilian life.

It was not exactly a joyful homecoming. In February 1864, his three children had died of cerebrospinal meningitis, despite the best efforts of the physicians called to help. All around him, Still saw people who had become addicted to alcohol or morphine, and he considered that these were “habits, customs, and traditions no better than slavery in its worst days” (3).

Mainstream Civil War medicine still depended heavily on purging, bloodletting, and an armamentarium of medicines that could only be characterized as violent. On both sides, there were

Figure 2-2 Like many physicians before and after him, Dr. A.T. Still applied his new philosophy first to himself and then to his patients. In a famous early anecdote, he stopped a headache by suspending his neck across a low-lying rope swing. He later applied self-adjustments of spinal joint dysfunction to abate an attack of “flux” (bloody dysentery). After he was successful at curing 17 children of the same affliction by adjusting their spinal joint dysfunctions, he realized he was onto something worthwhile. (From Still AT. *Autobiography of Andrew T. Still*. Rev Ed. Kirksville, MO: Published by the author, 1908. Distributed, Indianapolis: American Academy of Osteopathy.)

many more casualties from sickness than from battle injuries (13). A history of American medicine recounts:

Even the most erudite and experienced physician had few effective medicines at his command. Some of those which were effective were unknown to the poorly educated practitioner; others he knew not how to use. The short list of effective agents in the 1870s included the anesthetics (ether, chloroform, and nitrous oxide); opium and its alkaloids (morphine was first used extensively during the Civil War to ease the pain of the wounded); digitalis, which was used chiefly for cardiac edema [congestive heart failure]; ergot, to stimulate uterine contractions and to control postpartum hemorrhage; mercury in the form of an inunction for syphilis and in the form of calomel to purge and salivate; various cathartics of botanical origin; iron, usually in the form of Bland's pills for anemia; quinine for malaria; amyl nitrite, which was first recommended for the relief of angina pectoris by Sir Thomas Lauder Brunton in 1867 but was still not well known in 1876; sulfur ointment for the itch (scabies); green vegetables or citrus fruit for the prevention or treatment of scurvy. These various medicines were administered either by mouth, by rectum, by inhalation, or by application to the skin. The hypodermic syringe had been introduced by the French surgeon Pravaz in 1851. He employed it to inject "chloride of iron" into vascular tumors to coagulate their contents. Although it was subsequently used for other restricted purposes, the danger of infection limited its use until the physician had learned how to prevent infections by the preparation of sterile solutions (14).

This description of the *best* of the armamentarium available was recorded about a decade after the Civil War. The urban populations certainly benefited most from these breakthroughs; frontier doctors and their patients were very much worse off. Still agonized over the situation:

My sleep was well nigh ruined; by day and night I saw legions of men and women staggering to and fro, all over the land, crying for freedom from habits of drugs and drink.... I dreamed of the dead and dying who were and had been slaves of habit. I sought to know the cause of so much death, bondage, and distress among my race.... I who had had some experience in alleviating pain found medicine a failure. Since my early life I had been a student of nature's book. In my early days in windswept Kansas I had devoted my attention to the study of anatomy. I became a robber in the name of science. Indian graves were desecrated and the bodies of the sleeping dead exhumed in the name of science. Yes, I grew to be one of those vultures with the scalpel, and studied the dead that the living might be benefited. I had printed books, but went back to the great book of nature as my chief study (3).

He also wrote that he attended a course of lectures at a Kansas City medical school that was long defunct at the time of writing (15).

The next decade of Still's life was devoted to a search for a better way. He farmed, and he invented a butter churn and a version of a grain reaper. More children were born, the sons and daughter who would eventually become prominent in the profession their father was soon to found.

The search for a better way had many potential bypaths. The post-Civil War period was a time of great diversity in the healing professions, both in terms of how one became identified as a physician and how one approached the practice (16). In the mid-19th century, there were no licensing boards and only scattered state laws governing medical practice. There were a few medical schools

but there were no standard curricula. Most physicians, especially on the frontiers, were trained as apprentices, doing some reading and serving as a physician's assistant for an unstated length of time.

A majority of physicians followed a standard pattern, heavily influenced by the "heroic medicine" of Benjamin Rush, who said that "there is but one disease in the world" and that it was treatable by "depletion," which translated as bloodletting, blistering, and purging. One influential textbook writer, John Esten Cooke, wrote that:

All diseases, particularly fevers, arose from cold or malaria, which weakened the heart and thus produced an accumulation of blood in the vena cavae and in the adjoining large veins of the liver. Consequently, calomel and other cathartics which acted on that organ were the cure. "If calomel did not salivate and opium did not constipate, there is no telling what we could do in the practice of physic" (17).

Calomel and other mercury compounds were still listed as late as 1899 in the first Merck's manual, along with opium and morphine and many alcohol-based compounds (18). The practice of "heroic" dosing was well established and well defended. By the time of the Civil War, the system was also called "allopathy," now defined as "that system of therapeutics in which diseases are treated by producing a condition incompatible with or antagonistic to the condition to be cured or alleviated" (19).

The damage caused by the "heroic" techniques was obvious to thinkers before Still, and there were alternative systems of medicine available for consideration. Home remedies and Indian herbal preparations were a basic choice, and this lore was substantial and widely used (17). Numerous resources for botanic preparations were available as well; many of these manuals were widely circulated.

Homeopathy was a major influence in the 19th century. Articulated by Samuel Hahnemann (1755–1843), it was a system of therapy in which "diseases are treated by drugs which are capable of producing in healthy persons symptoms like those of the disease to be treated, the drug being administered in minute doses" (19,20). Eclecticism was another choice, described as "a once popular system of medicine which treats diseases by the application of single remedies to known pathologic conditions, without reference to nosology, special attention being given to developing indigenous plant remedies" (16). Magnetic healing, which "combined spiritualism and healing by seeking to restore the balance of an invisible magnetic fluid circulating throughout the body" (16), and its variants that attempted to use electrical current to restore health were employed. The water cure, movements emphasizing hygiene, antialcoholism or temperance, fresh air and sunlight, nutritional programs, and physical education and popular versions of mental healing, including hypnotism, spiritualism (table rapping), and phrenology, were additional alternatives. And, there were the bonesetters.

At least two of these methods attracted Still and he linked his name to each for a time. A professional card in the Still Museum in Kirksville, Missouri, identifies Still as a "lightning bone-setter." In 1874, he advertised himself in Kirksville as a "magnetic healer," possibly because he was persuaded by "the metaphor of the harmonious balance of the interaction of body parts and the unobstructed flow of body fluids" (16).

After a decade of study, in 1874, Still "flung to the breeze the banner of osteopathy" (3). He did not say precisely what that meant—perhaps a decision, perhaps a sudden coming together of creative thought—but it was followed by attempts to present his findings at Baker University, an institution his family had helped to found (21). He could not get a hearing. Furthermore, he was ejected from the Methodist church on the basis that only Christ

was allowed to heal by the laying on of hands. Still's description of that experience makes it clear that his "laying on of hands" was therapeutic manipulation.

During the next year, Still spent some time with his brother, who had become addicted to morphine through medical treatment. This experience, added to the uselessness of medications in saving his family and others, roused in Still a hatred for the drugs of the day. This enmity sometimes appeared to be nearly absolute, even when the armamentarium of drugs began to move from harmful toward helpful (1–4,22). However, there is evidence in his own writings that he sometimes used topical medications. For example, for snakebites, he washed the wounds with spirits of ammonia, and washed areas bitten by a dog with hydrophobia/rabies with a diluted sulfuric acid solution, and used alcohol to wash a spasmodic tetanic joint (4).

Late in 1875, Still moved from Kansas to Kirksville, Missouri, where he spent the rest of his life. For several years, Still used Kirksville as a base to conduct a marginal itinerant practice (23). His practice evolved as he gained experience, so that the main treatment modality became manipulation. Although this treatment included some of the traditions of magnetic healing and bone setting, it emphasized detailed knowledge of anatomy and body mechanics so that treatment could be said to restore normal function. He held that the body is an efficient chemical laboratory that, in health, makes all the "drugs" it naturally needs. The object of treatment was to discover what caused the sickness and remove the interference so that the body could heal itself (2).

By 1887, enough patients came to Kirksville so that Still could stop his itinerant practice. Word of dramatic successful outcomes

Figure 2-4 The first class of the American School of Osteopathy had five women (1892). (Still National Osteopathic Museum, Kirksville, Mo.)

began to spread via the newspapers and word of mouth, and once that happened, the burden of practice quickly became heavy. Still began to think about teaching others his methods; unlike many alternative practitioners of his day, he never intended to keep therapeutic secrets to himself or to grow rich from his methods. There were abortive attempts first to train apprentices and then to teach a class of operators to assist in the practice of osteopathy. The attempts were unsuccessful largely because the students lacked Still's detailed knowledge of anatomy and bodily function.

The term "osteopathy" was coined by Still in about 1889. The story is told (24) that, when challenged because this word was not in the dictionary, Still replied, "We are going to put it there." The word became for Still and his followers a symbol for medical reform, for a science that would refocus medicine on the restoration of normal function. Osteopathy aimed to work with and facilitate the natural machinery of the body for normal and reparative function, rather than working against it, as seemed to be the case with purgatives, emetics, bloodletting, and addictive drugs.

PROFESSIONAL EDUCATION AND GROWTH

First School

The first successful school where osteopathy was taught, the American School of Osteopathy, was chartered in May 1892 and opened that fall with a class of about 21 men and women, including members of Still's family and other local people (Figs. 2.3 and 2.4). The faculty consisted of Still and Dr. William Smith, a physician

Figure 2-5 A.T. Still, M.D., (left) and William Smith, M.D., were the inaugural faculty of the newly founded American School of Osteopathy in 1892. (Still National Osteopathic Museum, Kirksville, MO.)

trained in Edinburgh, Scotland, who taught anatomy in exchange for learning osteopathy (Fig. 2.5)

The goal, as stated in the revised (1894) charter for the school, was “to improve our present system of surgery, obstetrics, and treatment of diseases generally, and [to] place the same on a more rational and scientific basis, and to impart information to the medical profession.” The charter would have permitted granting the doctor of medicine (MD) degree, but Still insisted on a distinctive recognition for graduates, DO, for diplomate in osteopathy (later doctor of osteopathy) (25).

The first course was just a few months long; most of the students voluntarily returned for a second year of additional training. By 1894, the course was 2 years long, two terms of 5 months each. In addition to their study of anatomy, students worked in the clinic under experienced operators, at first only under Still but later under graduates as well.

During the last 5 years of the 19th century, the growth of both the clinic and the school was spectacular. Patients came from near and distant places, having heard by word of mouth or by printed accounts of near-miraculous cures. There were enough such “miracles” that the osteopathic profession was widely promoted by grateful patients. A significant number of early DOs were either former patients or family members of patients who came to their studies with a kind of evangelical fervor. The town of Kirksville prospered and came to regard Still, who once was ridiculed, as a citizen of immense importance. He was lavishly praised, and he lived to see his statue, with the inscription “The God I Worship Demonstrates All His Work,” erected in the town square (26,27) (Fig. 2.6).

Data on numbers of enrolled students illustrate the school’s dramatic growth. In October 1895, there were 28 students. By the following summer, there were 102. By 1900, there were over 700 students, with a faculty of 18 (25) (Fig. 2.7). By the turn of the century, there were also more than a dozen “daughter” schools founded by graduates of the original school (28). Some of the schools were well organized under the model established by Still; others were established as diploma mills with the anticipation of generating large incomes for the persons establishing them. Still considered many of these to be for training “engine wipers” who were incapable or inexperienced in the practice of osteopathy. Many of these closed as standards were established by the American Osteopathic

Association (AOA) and by state licensure; by 1910, only eight remained.

Conflict with the American Medical Association

Medical education in the late 19th century was not well regulated. Many schools—allopathic, eclectic, homeopathic, and osteopathic—had virtually no entrance requirements except tuition payments, and many schools were for-profit institutions. Licensing laws had not yet reached a stage where they were effective in setting educational standards. The American Medical Association (AMA), founded in 1847 and later a powerful influence on raising educational standards, was weak and in need of reorganization in the 1890s.

A new, reorganized AMA, observing that there were too many doctors, made its first order of business, under a revised constitution, the regulation of medical education. Its Council on Medical Education was formed in 1904, with a charge (among others) to improve the academic requirements for medical schools. This was fulfilled by rating all medical schools as class A (approved), B (probation), or C (unapproved) and making the findings available to state licensing boards (29).

Even before the AMA formed its Council on Medical Education, the young AOA had adopted standards of its own for approval of osteopathic colleges (1902) and began inspections (1903) (30). This caused many small osteopathic colleges to close or merge with larger institutions.

Osteopathic schools were not included in the first AMA survey but they were included in the influential Flexner Report,

published in 1910 (31). After this report, which harshly condemned osteopathic schools along with many medical schools, more marginal schools closed, and the surviving ones converted to a not-for-profit status. Few of the schools established for teaching black physicians survived this period (32) and all but two or three of the schools for women closed (33,34). State licensing boards began to enforce stricter requirements; this probably was a more decisive influence than the Flexner Report (16, 35).

Curriculum

Many medical schools formed affiliations with universities; by doing so, they gained both experienced science faculty and stable funding. This was not an option for osteopathic institutions at that time, and they faced a difficult dilemma: raise entry standards and lose major portions of tuition payments, which represented their only income, or adopt a “go slow” attitude. They chose the latter, which meant that they were perhaps 2 decades behind in the educational reforms that many agreed were desirable (36). AOA standards did increase the required length of osteopathic curricula to 3 years in 1905 and to 4 years in 1915 (30).

The profession responded officially to external criticism by pointing out the differences between osteopathic and orthodox medical education. However, when there was an opportunity to raise general standards, as came about in the 1930s, the profession did so. By the mid-1930s, osteopathic colleges were requiring at least 2 years of college before matriculation; in 1954, 3 years were required; by 1960, over 70% of students had either baccalaureate

Figure 2-7 The faculty of the American School of Osteopathy in 1899. Several soon thereafter became leaders in the profession and founded new osteopathic colleges. (Still National Osteopathic Museum, Kirksville, MO.)

or advanced degrees prior to entry (36). At present, virtually all students enter colleges of osteopathy with at least baccalaureate degrees; many have advanced degrees as well.

Curriculum content similarly grew and changed with the times. An 1899–1900 Kirksville catalogue describes the school's course of study as follows (37):

The course of study extends over two years and is divided into four terms of five months each, as shown in Table 2.1.

The major difference between this 1899–1900 curriculum and that of an allopathic medical school of the same period, in addition to the distinctive osteopathic content, was the exclusion of *materia medica* (pharmacology).

Early in osteopathic history, a difference appeared between so-called lesion osteopaths and broad osteopaths: those who limited their therapeutic practice essentially to manipulation and those who used all the tools available to medicine, including *materia medica*.

Still practiced midwifery (obstetrics) and surgery; both were taught under his guidance. Indeed, when the issue of surgery became controversial among later DOs, Still's son provided an affidavit

TABLE 2.1

Description of Course of Study by Term

Term	Topics
1	<ul style="list-style-type: none"> • Descriptive anatomy, including osteology, syndesmology, and myology • Lectures on histology, illustrated by microstereopticon • Principles of general inorganic chemistry, physics, and toxicology
2	<ul style="list-style-type: none"> • Descriptive and regional anatomy with demonstrations • Didactic and laboratory work in histology • Physiology and physiological demonstrations • Physiological chemistry and urinalysis • Principles of osteopathy • Clinical demonstrations in osteopathy
3	<ul style="list-style-type: none"> • Demonstrations in regional anatomy • Physiology and physiological demonstrations • Lectures on pathology illustrated by microstereopticon • Symptomatology • Bacteriology • Physiological psychology • Clinical demonstrations in osteopathy and osteopathic diagnosis and therapeutics
4	<ul style="list-style-type: none"> • Symptomatology • Surgery • Didactic and laboratory work in pathology • Psychopathology and psychotherapeutics • Gynecology • Obstetrics • Hygiene and public health • Venereal diseases • Medical jurisprudence • Dietetics • Clinical demonstrations • Osteopathic and operative clinics

concerning his father's practice (38). As already noted, Still remained skeptical about using or teaching any form of pharmaceutical therapy.

Still's general opposition to drugs did not prevent some early DOs from using them for treatment. Quite a few had been trained as MDs before they came to osteopathic schools; others went on to earn MD degrees after they became DOs; still others simply decided to use all the adjunctive treatments available. Most "broad" osteopaths felt that after new safer medications were developed it was consistent with being a completely trained physician to incorporate them into osteopathic practice. The most direct early confrontation came in 1897 when a DO-MD opened the short-lived Columbian School of Osteopathy in Kirksville, with the announced intention of offering DO and MD degrees upon graduation from a course in manipulation, surgery, and *materia medica*. The competitive and personal issues in this case extended beyond the academic questions and the school closed after graduating only three classes (25). The issue was professionally divisive for many years thereafter.

Adjunctive treatments became a major subject of debate within the AOA and the Associated Colleges of Osteopathy (now the American Association of Colleges of Osteopathic Medicine) for many years. The question finally was resolved in favor of the "broad" osteopaths, not by consensus over the idea but by recognizing that state licensing laws required fuller training. In 1916, against the direct protest of Still (39), the trustees revoked a previous year's action condemning individuals and colleges that taught drug therapy, effectively opening the way for the colleges to form their own curricula. The profession's great success in using manipulative treatment during the 1918 influenza epidemic (40) probably slowed the integration of *materia medica* into the osteopathic curriculum. However, by the late 1920s, it became officially permissible to institute courses in "comparative therapeutics," of which pharmacology was one subheading (36). By the mid-1930s, the integration was complete. The change was validated as drugs were greatly improved, making it possible to offer pharmaceutical treatment where benefits outweighed risks.

Curricular improvement continued as clinical teaching facilities grew and as budgets permitted the hiring of full-time faculty, particularly in the basic sciences. While instruction by physicians in active practice was an advantage for students who were developing clinical skills, the basic sciences and laboratory-based research required faculty who could give these interests their full attention. All the colleges had full-time basic science faculty by the time the first osteopathic medical school became affiliated with a major American university; such affiliations had been the route by which allopathic schools had strengthened their basic science teaching earlier in the 20th century.

One other curricular improvement deserves mention. For many years, teachers of osteopathic principles and practice developed courses in their area of expertise as traditions within their individual schools, sometimes jealously guarded and always zealously defended. In 1968, a small intercollegiate group of osteopathic principles professors met for the first time. The initial agenda was a response to the new initiative of uniform medical coding, in light of a movement to change the term "osteopathic lesion" to "somatic dysfunction." This change had to be discussed and agreed upon as part of preparation for diagnostic coding. The group continued to meet and it became known as the Educational Council on Osteopathic Principles; later, it became affiliated with the American Association of Colleges of Osteopathic Medicine. Its agenda grew to include a uniform glossary of osteopathic terminology (a current edition is included at the back of this text); systematic development of agreement about the content of a multidisciplinary, problem-based,

and patient-oriented osteopathic principles curriculum; and finally, this textbook, *Foundations of Osteopathic Medicine*. Its continuing role also includes development of osteopathic-oriented questions for national board/licensure and specialty board examinations.

Research

On one level, since its earliest days, osteopathic medicine has been a profession based on a research question: “Can we find a better way?” Osteopathic manipulation developed as an experimental approach to clinical conditions that did not respond to the conventional treatments of the time, and its practical success became the empirical research results that led to another level: the questions of “why” and “what if” appropriate to laboratory study. Medical research, in parallel with medical education, underwent a process of developing new traditions and controls, as well as better equipment, all of which would shape future clinical studies.

Laboratory studies began among osteopathic physicians almost as soon as there was an organized osteopathic school (41). Study of the scientific questions raised by osteopathic manipulative practice has never been easy; the difficulty can be illustrated by one obvious clinical question: “What is a manipulative placebo?” In spite of these and other difficulties, a number of significant accomplishments have been recorded (42). Part V of this book offers an extensive survey of osteopathic research efforts from past to present.

Growth of the Profession’s Schools

Enthusiastic graduates of the first osteopathic college—for reasons evangelistic or pecuniary—quickly began to establish new schools throughout the country. Some of these were short-lived because they were unable to meet the rising standards of the AOA. Others merged with stronger institutions and survived in a new organization. Still others strengthened their positions and survived. This was the general trend for medical education in the 19th century, and the smaller schools, whether allopathic, osteopathic, or homeopathic, had similar closures, consolidations, or rebuilding.

As noted previously, by 1910 only eight of the early osteopathic schools were still in operation. Six of these have survived into the new millennium; all have had complicated histories of name changes, relocations, charter changes, mergers, and affiliations with other educational institutions. The five original schools still accredited (28) are

- Kirksville College of Osteopathic Medicine, successor to the first school (1892)
- Philadelphia College of Osteopathic Medicine (1898)
- Chicago College of Osteopathic Medicine at Midwestern University (1900)
- University of Health Sciences, College of Osteopathic Medicine, Kansas City (1916)—there had been an osteopathic college in Kansas City as early as 1895
- Des Moines University, College of Osteopathic Medicine and Surgery (1905)—there had been a school in Des Moines as early as 1898

One school, the College of Osteopathic Physicians and Surgeons, Los Angeles, has survived as a medical school (University of California at Irvine School of Medicine). The California conflict and merger in the 1960s, described briefly under “State Licensure,” resulted not only in the change of an osteopathic college to an allopathic college but also in a revival of interest in osteopathic education in the profession. The first new educational focus was in Michigan, and it began not only a new tradition in osteopathic

education but also became an impetus for nationwide growth that continues to this day (43).

In 1964, the Michigan Association of Osteopathic Physicians and Surgeons committed itself to develop a new, independently funded college of osteopathic medicine. This initiative occurred because more than 1,000 osteopathic physicians practiced in the state, representing about 5% of the state’s physician total and providing care for about 20% of the state’s patients. None of these DOs had received their education in the state. In 1969, 18 students enrolled in the first class at a new campus in Pontiac, Michigan. Within 2 years, it was clear that a program of such complexity could not survive financially as a freestanding institution. A number of strong supporters in the Michigan legislature, and Michigan’s governor, were willing to support a bill for state funding with one major stipulation: the college had to be integrated with an existing, accredited university program. After complex negotiations, the program transferred to the campus of Michigan State University in 1971, where it became the first university-based osteopathic college.

After this affiliation proved successful, 20 more osteopathic schools (some public, some private) were developed over the next 38 years. In 2009, 26 colleges were accredited by the AOA for predoctoral osteopathic education (28). See Table 4.2 for a list of these colleges and Chapter 4 in this section for the current scope and status of osteopathic education and regulation.

STATE LICENSURE

Closely related to the issue of educational standards was licensure under increasingly strict state laws.

The first legislative recognition of osteopathic practice came from Vermont in 1896 (44), where graduates of the American School of Osteopathy, Kirksville, were accorded the right to practice in that state. Missouri had a successful bill as early as 1895, but it was vetoed by the governor; what was hailed as a better bill was passed and signed into law in March 1897 (22,45).

Such laws as these, greeted with much rejoicing, made tremendous growth possible in the osteopathic profession in states where legislation provided a friendly welcome. Osteopathic history includes numerous stories about legal action against DOs for practicing without a valid license, David-and-Goliath encounters of DOs with MD-dominated legislatures, and testimony or influence offered by prominent people who were osteopathic patients. These colorful tales were the war stories of an energetic first generation of DOs, who managed to secure legislative rights to at least limited practice in a majority of states.

Registration and licensure were related (but often different) matters. Some states provided for the formation of separate osteopathic licensing boards, some permitted the addition of an osteopathic representative to an existing or composite board, and a few permitted DOs to apply through a medical board without osteopathic representation.

The roles of these boards were not immediately clear at the time of their formation. There was opposition on ideological grounds even to the idea of licensure. Some populists, not partisan to either osteopathic or allopathic physicians, said that medical licensure was in itself discriminatory. Others said that licensing would interfere with freedom of medical research. Some social Darwinists went so far as to say that if the poor died of their own foolishness in choosing bad medical practitioners, the species would improve (32).

By 1901, however, every state had some form of legislation requiring at least registration, with a diploma from an accepted school, or a state examination of some type. When the Missouri board began to function in 1903, the first certificate it issued was to Still (46).

Licensure to practice a full scope of medicine was another matter, and in most places, it was related first to the content of the osteopathic curriculum and later to the results of examinations. Again using Missouri as an example, by 1897, the subjects taught had expanded to include anatomy, physiology, surgery, midwifery, histology, chemistry, urinalysis, toxicology, pathology, and symptomatology. Everything was included except *materia medica* and academic consciences were temporarily satisfied. By 1937, however, only 26 states had any provision to provide unlimited licenses to DOs.

In some states, DOs were ineligible to apply because their education did not meet specific criteria. As late as 1937, osteopathic standards did not meet preprofessional college requirements in 16 states; in 8 states, a year's internship was needed. Originally, DOs who took examinations under medical or composite boards showed a much lower pass rate. Whether this was a difference in osteopathic curricula or an educational deficiency, as it was argued, in due course, the curricula were altered and the pass rates increased. The major changes were addition of more basic science courses, more faculty, and larger clinical facilities (36).

After World War II, a major effort was made to change the old limited practice laws. These efforts, along with major changes in osteopathic education, enabled the enactment of new practice laws for all 50 states (47).

A final dramatic chapter in the American licensing story of the osteopathic professional came when the California Osteopathic Association agreed in 1961 to merge with the California Medical Association, and the College of Osteopathic Physicians and Surgeons, Los Angeles, became the California College of Medicine. Qualified and consenting DOs were conferred MD degrees as a preparation for a referendum approved by voters in 1962, which discontinued new licensure of DOs in that state (36,43).

A new state osteopathic group, Osteopathic Physicians and Surgeons of California, was chartered by the AOA. This group fought against the referendum but lost; they then began a long legal battle that culminated in a 1974 decision by the California Supreme Court that licensure of DOs must be resumed (36,43,48). A new college was chartered in that state, and professional continuity was restored (43).

By the end of the 20th century, state licensure could be attained in various ways: through the standard national osteopathic licensing examination and/or through the standard national medical licensing examination, depending on state requirements. Some states maintained separate osteopathic and allopathic licensing boards; many were composite boards. Graduate education required for new licenses still varied from state to state. In every state, however, as well as in a number of foreign countries, it was possible for DOs to be licensed for unlimited practice.

OSTEOPATHIC ORGANIZATION

The AOA began as a student organization in Kirksville, under the name American Association for the Advancement of Osteopathy, in 1897. Its present name was adopted in 1901 (49). The second national association was the Associated Colleges of Osteopathy (now the American Association of Colleges of Osteopathic Medicine), formed in 1898. Both groups sought to protect and raise standards for education and practice of DOs. The AOA became the regulatory group, no longer under student control; the Associated Colleges became a discussion and consensus group for faculty and officers of the schools.

In 1907, the first organization devoted to osteopathic research began, though the first recorded osteopathic research was done almost a decade earlier (41). The AOA played a vital role in encouraging and

supporting osteopathic research. Money for research has never been plentiful; a major portion of the support for osteopathic research, especially in earlier days, had come from financial contributions by DOs themselves. More recently, qualified researchers have been recipients of public grant funds, but the role of AOA-affiliated research organizations has been essential for start-up projects.

State (divisional) and local (district) osteopathic organizations were established to serve DOs in their own localities. When the AOA grew too large for general membership meetings, state societies began (in 1920) to name representatives to serve in an AOA House of Delegates. That body, thereafter, became the chief policy-making group for the osteopathic profession. A board of trustees, elected by the house, oversaw the implementation of those policies, a role it still fills. Students participate as voting members of delegations from the states in which their schools are located; are appointed to AOA boards, bureaus, and committees; and also have a number of organizations of their own.

A major early effort of the AOA was to produce a code of ethics; this was accomplished in 1904. A participant in those deliberations observed that the problem was not because anyone really wished to practice unethically, but rather that on some points it was difficult to agree upon what was ethical (50). To put this in perspective, the issue of advertising was a hard-fought question among all professionals at that time. The question was resolved by declaring advertising unethical except for brief professional card listings. By the 1990s, advertising by professionals was ultimately considered ethical, though not of course to condone unfounded claims.

Over time, many osteopathic organizations grew from starting points as various as special tasks, geographic or school affinity, and practice interest. A current guide to all AOA-recognized osteopathic organizations is available online, which is updated annually (51). These include state and regional osteopathic medical associations, specialty groups, osteopathic colleges, nonpractice affiliates, accredited hospital and health care facilities, and AOA-supported programs.

The AOA has always been the umbrella group that recognizes and coordinates its efforts on behalf of the profession. The AOA itself has many important functions. Through its bureaus, councils, and committees, it is the osteopathic accrediting organization for undergraduate, graduate, and continuing medical education and for health care facilities. It certifies specialists in all fields, through a network of specialty boards and its own central bureau. Research grants and related projects, as well as educational meetings, are arranged through AOA bureaus and councils.

Staff, directed by elected officers and trustees, provide professional services including maintenance of central records on all DOs, public and legislative education, member services, educational activities including publications and conventions, and coordinated special efforts on a variety of concerns. Position papers on various topics are approved by the House of Delegates and presented as the profession's position on questions of public health and professional interest.

In addition to activities of the AOA itself, a network of divisional and affiliate societies is recognized by the AOA. Certain major "subumbrella" organizations have networks of their own: the associations of osteopathic colleges, health care organizations, licensing groups, and foundations.

Specialty colleges, distinct from the certifying boards, conduct educational affairs and recognize their own members' achievements through fellowships and other awards. State (divisional) and local (district) societies typically deal with state legislative and regulatory affairs, conduct educational programs, and provide a variety of member services.

Colleges typically have student and alumni groups, student chapters of certain specialty organizations, fraternities and sororities, and a variety of special interest groups. Many of the physicians' and students' organizations have auxiliary organizations for spouses.

All organizations recognized by the AOA accept such ongoing controls as approval of any changes in basic documents and designation of how many representatives (if any) are sent to the AOA House of Delegates for voice and vote in professional policy affairs.

FEDERAL GOVERNMENT RECOGNITION

The first major attempt by the AOA to obtain federal government recognition was during World War I when it tried to gain commissions for DOs as military physicians (40). This effort was unsuccessful in spite of active support by such prominent advocates as the former president of the United States, Theodore Roosevelt (52).

At that time, an examination was set, and it was understood that if DOs (along with MDs) took this and passed it, they could be commissioned as medical officers. About 25 DOs took the examination and were recommended for commissions. The surgeon general unilaterally ruled that only MDs were eligible. Bills were then introduced (1917) in both the House of Representatives and the Senate to correct this inequity. The bills were referred to the Military Affairs Committees, and hearings were held. The committee then referred the issue to the surgeon general, who in his statement of opposition claimed that regular physicians would withhold their services if DOs were allowed to serve. The bills remained in committee without resolution until the end of the war. Meanwhile, DOs served as regular soldiers, unable to use their medical training.

The situation remained uncorrected when World War II began. Again there were efforts to obtain commissions for DOs, this time emphasizing regulatory rather than legislative barriers (40,53). DOs were deferred rather than drafted, waiting for the possibility to serve in a medical capacity that never came. Ironically, the DOs left behind became family physicians to the thousands of the patients left by the MDs in military service, which enhanced the public's view of DOs as full-service physicians.

The pressure for federal recognition continued after World War II ended and in 1956 a new law specifically provided for the appointment of DOs as commissioned officers in the nation's military medical corps. However, implementation of that law was blocked for another 10 years until the Vietnam conflict created another special need for military physicians. The first DO was finally commissioned in May 1966. The next year the AMA withdrew its long-standing opposition and DOs were included in the doctor draft. It was another 16 years, in 1983, before the first DO was promoted to be a flag officer in the U.S. military medical corps (30).

Acceptance of DOs as medical officers in the U.S. Civil Service was accomplished in 1963. Careers in this field became possible after that date. Nearly every federal recognition for DOs came after a long and difficult fight. Among the important federal recognitions were the following (30,36):

- 1951: The U.S. Public Health Service first awarded renewable teaching grants to each of the six osteopathic colleges.
- 1957: The AOA was recognized by the U.S. Office of Education, Department of Health, Education and Welfare (DHEW), as the accrediting body for osteopathic education.
- 1963: The Health Professions Educational Assistance Act included a provision for matching construction grants for osteopathic colleges and loans to osteopathic students.

1966: The AOA was designated by the DHEW (now the Department of Health and Human Services [DHHS]) as the official accrediting body for hospitals under Medicare.

1967: The AOA was recognized by the National Commission on Accrediting as the accrediting agency for all facets of osteopathic education.

1983: The first osteopathic flag officer in the U.S. military was appointed.

1997: The first osteopathic surgeon general of the army was appointed.

The U.S. Postal Service commemorated a stamp in 1972 in honor of the 75th anniversary of the founding of the AOA; it was also the 80th anniversary of the first osteopathic medical school and nearly a century since Still "flung to the breeze the banner of osteopathy" in 1874 (Fig. 2.8).

The AOA continues to maintain a presence in Washington, DC, where it attempts to ensure inclusion of DOs and osteopathic institutions as active partners in all legislative and regulatory initiatives.

SPECIALTIES AND HOSPITALS

Perhaps the first osteopathic activity in what now is called a medical specialty began only 3 years after Wilhelm Roentgen announced the discovery of radiographs. The second x-ray machine west of the Mississippi was installed in Kirksville in 1898. With it, Dr. William Smith formulated a method to inject a radiopaque substance in cadaveric veins and arteries to demonstrate the normal pattern of circulation. Two articles were published late that year, one in the *Journal of Osteopathy*, a Kirksville journal associated with the American School of Osteopathy, and the other in the fledgling *American X-Ray Journal*. These were reprinted for modern reference in AOA publications in 1974 (54). When formal certifying boards for osteopathic specialties were organized, radiology was the first (1939) (30).

Along with these events came the long story of the development of osteopathic hospitals, internships, residencies, specialty organizations, specialty standards, examinations, and recognition for those standards. By the 1990s, a full complement of specialties, training programs, and certifying boards were well established in the osteopathic profession, including a board recognizing osteopathic manipulative medicine, now referred to as neuromusculoskeletal medicine. At the same time, the profession was unknowingly developing what would come to be the most needed type of practice for the 1990s: primary care.

Figure 2-8 In 1972, an osteopathic medicine commemorative stamp was issued by the U.S. Postal Service. (Still National Osteopathic Museum, Kirksville, MO.)

Throughout its history, osteopathic clinical education has taken place in primary care settings: community hospitals and clinics. The profession has supported very few academic medical centers. By the 1990s, this disadvantage became an advantage because of the profession's success in producing primary care physicians, including many willing to work in underserved communities.

Many factors have been cited as influential in the choice of practice type and venue, but the chief ones seem to be undergraduate experiences and role models (55). Students trained in academic medical centers tend to have only subspecialists as role models and their clinical contacts tend to be cases typically referred to tertiary medical centers. Meanwhile, osteopathic students have continued to have regular contact with community clinics and hospitals and have many faculty role models who are primary care physicians.

For instance, rural clinics, long a mainstay of clinical education for the Kirksville college and later for other osteopathic schools, have become a model for primary care education (56). In the last decade of the 20th century, the osteopathic profession found itself in the enviable role of adviser on how to replicate its educational processes in other places.

As with medicine in general, hospitals had their share of developmental problems in the 19th century. Inadequate facilities and staff, infection, disagreement over who should get patient fees, social stigma, and hospital ownership all entered the picture. By about 1900, however, with the growth of an educated nursing profession and a new sense of sanitation, hospitals began to be—at the very least—safe. Many small institutions were privately owned by surgeons who furnished hotel services and nursing for their own patients. New general hospitals began to appeal to patients other than the poor, and patient fees began to help with hospital development (35).

There were osteopathic hospitals early in the 20th century; at the time of Flexner's inspection, Kirksville had the largest, with 54 beds. Chicago had 20 beds; the Pacific College, 15; Boston, 10; and Philadelphia, 3. No others were listed in that report (36). Eventually, the numbers and size of osteopathic hospitals grew, but few reached the size and diversity of specialties that characterized the academic medical centers associated with university medical schools. However, the osteopathic profession did set hospital standards, first for the training of interns and residents and then for accreditation of the institutions themselves.

The growth of osteopathic hospitals was especially marked in the period during and after World War II when MD-run hospitals did not permit DOs to join their medical staffs. When U.S. government programs were approved to help with construction of hospitals, osteopathic institutions participated along with MD-run institutions. Many community teaching hospitals were constructed during those years.

In 1954, a landmark court decision in Audrain County, Missouri, made it illegal for public hospitals to deny staff membership and admitting privileges to qualified DOs. This initiated a series of changes in areas outside California, where DOs had been in charge of a segregated building at the Los Angeles County Hospital since 1928 (43). By the 1960s, most public hospitals were open to DOs; by the 1980s, most private hospitals were open as well.

By the 1990s, with medical residencies open to both MDs and DOs, the need for a network of osteopathic hospitals for training purposes was much reduced. Mechanisms were adopted to recognize training that took place in allopathic institutions as acceptable for osteopathic board certification. This is now possible either by affiliation of the MD institution with an accredited osteopathic college or by direct AOA accreditation of the training institution (51).

By 1999, osteopathic graduate training institutes were the standard, linking resources through hospital–college consortiums.

Reorganization of the health care system itself made these changes necessary. Payment mechanisms led to the formation of large networks of health care providers, including hospitals, outpatient facilities, home care, extended and long-term care, and multiple independent contractors and physician organizations. Community hospitals, including many osteopathic institutions, were merged with larger groups or simply closed. The lines between osteopathic and allopathic hospitals blurred as both came under the umbrella of managed care organizations.

In a case of history repeating itself, economic factors control health care delivery, and the profit motive is once again a respectable part of medical practice. This is placed against a call for serious reform of medical education and better distribution of primary care physicians. The goal is to provide excellence in patient care and in physician education while seeking through corporate management tools the funds to survive in a competitive environment.

SUMMARY

At the start of the 21st century, the “parallel and distinctive” osteopathic profession is respected in many quarters for a variety of reasons. First and foremost is the osteopathic emphasis on primary care. This arose not only from the earlier circumstances of training opportunities and role models but also from the profession's traditional whole-person philosophy.

Additionally, there has been a rebirth of interest in manual medicine and other osteopathic methods. In most osteopathic colleges and graduate education programs, there is increased emphasis on historic tenets and clinical skills. The profession's horizons have been expanded by a global emphasis of its own and an interest in international groups devoted to manual medicine (57–60).

Osteopathic physicians have gained a positive voice in public affairs. In the public arena, DOs are regarded as “parallel and distinctive” in regulatory and legislative affairs, and the profession is consulted on most matters of public health policy. The profession has also launched clinical initiatives in such categories as women's health, minority health care, and pediatric end-of-life care. Continued emphasis on preventive care and health maintenance is in line with traditional osteopathic values. An ambitious strategic plan launched in 2001 by the AOA formalized some of these emphases and added others, including international recognition of United States-trained DOs, an AOA Center for International Affairs, and a new World Osteopathic Medical Association (61).

One of the dedicatees of this volume, George W. Northup, wrote in 1988:

Today, the practice of medicine needs as never before the guiding light of a fundamental philosophy. It needs to recognize the action and interaction of all body systems. It should apply known truths and explore new frontiers founded on the osteopathic profession's basic philosophy.... Dr Still did not say he was giving the world a philosophy that should act as a guide to the future. Rather, in his book, *The Philosophy of Osteopathy*, he stated his desire was “... to give the world a start in a philosophy that may be a guide to the future” (62).

The purpose of medical history has long been a subject for discussion. At its best and fullest, it can be said to “provide a wonderful schooling in prudence” (63). The caution follows that the historical record must be “considered in terms of its own circumstances and standards. This demands insight into the viewpoints, thoughts,

emotions, reactions, and likes and dislikes of people of the past.” Such insight requires a more thorough study than an introductory chapter can offer.

Some care has been taken to offer to the interested student a list of references that can facilitate deepened insights. But beyond these readings, there is much more to explore and understand.

Osteopathic Education and Regulation

BRUCE P. BATES

KEY CONCEPTS

- Characteristics of preparation for osteopathic medical school include personality development, experience in health care and service, knowledge of osteopathic philosophy and history, presence of a good support system, and a college degree.
- The osteopathic medical school application and selection process views the applicant as a whole person and considers personal and professional attributes in addition to grades and test scores.
- The Colleges of Osteopathic Medicine are accredited by the Commission on Osteopathic College Accreditation of the American Osteopathic Association.
- Osteopathic medical school curriculum entails preclinical basic science education and clinical skill development, including training in osteopathic palpatory diagnosis and manual treatment.
- Osteopathic clinical training includes experiential learning in accredited hospitals and clinics associated with the colleges.
- Osteopathic education engenders lifelong learning and professional commitment.

Preparation to appreciate and utilize the knowledge, attitude, and skills to be an osteopathic physician begins well before entry into an osteopathic medical school. An appreciation for the philosophical basis and key tenets of the profession noted in Chapter 1 is an obvious base. An understanding of the major historical events recounted previously allows one to appreciate the challenges that the profession has overcome to achieve its current professional standing. These underpinnings set the stage for the growth and development of individuals desirous of becoming osteopathic physicians.

ASPIRATIONS AND PREPARATION

Traditionally, men have sought careers in medicine, including osteopathic medicine, at rates greater than women. Since the 1990s, there has been a significant narrowing of that gap from less than 30% in the 1980s to 50/50 by 2004 (1) (Fig. 3.1). The aspirations for entering a career in medicine include sociodemographic factors (family income, parental careers, and parental education) and personality-career fit characteristics (2). Family role models and expectations have long been known to influence career choice in numerous professions. This is true of medicine as well. For example, having a parent of the same gender who was a doctor is as predictive of having medical career aspirations as is years of preparation in the biological sciences, math, and foreign languages (2). This is especially true for women. Men, unlike women, also need a social or altruistic personality in order to aspire to a medical career (2). Based on the Holland Personality—Occupation Typology, those aspiring to be physicians are best described by three personality types—investigative, artistic, and social. The investigative personality tends to be analytical, curious, methodological, and precise. The artistic individual tends to be expressive, nonconforming, original, and introspective; and the social individual enjoys working with and helping others.

Thus, it is not surprising that the characteristics expected of students seeking to enter the osteopathic profession mirror

Figure 3-1 As per tradition at the COM of the Pacific at Western University of Health Sciences graduation ceremonies, graduate Lynsey Drew, D.O. receives her doctor's hood from her family supporters, her husband and daughter, as Board of Trustees Vice-Chairman Richard A. Bond, D.O., DrPH, FAAFP, looks on from afar. Photo courtesy of Western University of Health Sciences.

these same elements. While particular details may vary between individual schools, all expect a strong grounding in the sciences such as Biology/Zoology, Chemistry, Physics, and English. Firm academic preparation is necessary to aspire to being an osteopathic physician. The 2006 application cycle saw MCAT scores for applicants averaging 8.02 verbal, 7.72 physical, and 8.30 biology with an average GPA of 3.38. Those actually selected for matriculation in 2007 scored slightly higher: MCAT averaging 8.52 verbal, 8.18 physical, 8.82 biology, with mean GPA of 3.45 (3).

While grades provide a convenient comparison score, and applicants must meet the minimums of preparatory education noted above, osteopathic schools also look for additional factors. Applicants should demonstrate additional challenging academic preparation, experience with the health care system, direct knowledge of the profession, awareness of the sociopolitical aspects of medical practice in general and the osteopathic medical profession specifically, and evidence of leadership in service. Osteopathic medical schools have a long tradition of accepting nontraditional students. These students bring a richness of experience and perspective to their class, classmates, and career choices. These students comprise approximately 25% of the osteopathic student body across the country (3).

Osteopathic physicians differ from allopathic physicians in their philosophical approach to patients. Beyond the use of manipulative treatments, patient-centered care has been the hallmark of osteopathic medicine since its inception. Such an approach is gaining popularity across the health professions. A recent study by the Maine Medical Assessment Foundation and the University of North Carolina noted that osteopathic physicians were easily distinguished from allopathic physicians by their verbal interactions with patients. Osteopathic physicians were more personal, likely to use the patient's first name, explain etiologic factors, and discuss social, family, and emotional impact of illnesses (4). Similar personality and behavioral characteristics are sought in applicants to osteopathic schools and expected throughout the professional development of the osteopathic physician.

APPLICATION PROCESS

The application process begins well before the submission of application documents to the osteopathic school of choice. The applicant begins with a well-designed course of study, contributions of leadership in service to community and others, experiences in health care settings, and participation in scholarly activities such as research and writing. If the applicant is a second career applicant, similar attributes are expected to complement the life experience as evidence of the pursuit of continued intellectual and academic rigor. All candidates should develop ongoing mentoring relationships with professors and osteopathic physicians to facilitate the candidate's understanding of the career they have chosen to seek and to allow the character and individualism of the candidate to be defined.

Twenty-five out of twenty-six osteopathic medical schools utilize the American Association of Colleges of Osteopathic Medicine Application Service (AACOMAS). This centralized service allows the applicant to file a single electronic application. AACOMAS then verifies, standardizes, compiles, and distributes the electronic application to each of the osteopathic schools designated by the applicant. Osteopathic medical schools utilize a holistic approach to the applicant and look beyond the GPA and MCAT scores submitted. Each school has a secondary application process to identify those applicants best suited to the mission and goals of the individual school. Letters of recommendation,

experiences in the health professions, and knowledge of and experience with osteopathic medicine are important features considered in the secondary application process. Personal statements and interviews may be vital considerations. The personal and professional fit for the applicant and the school are crucial to the attainment of mutual success.

Successful candidates demonstrate achievement in the required prerequisite course work including growth in meeting challenges of increasing academic rigor. The profession of osteopathic medicine focuses on the whole person and the prospective student must demonstrate the ability to relate to individuals and to society as well as being intellectually sound. Evidence of character traits such as honesty, reliability, and commitment is sought. Leadership in service-beyond-self is desired. Likewise, experience and knowledge with the health care system and osteopathic medicine in particular, within the context of the sociopolitical aspect of medical practice, complements a candidate's successful application (Table 3.1).

CURRICULUM

The American Osteopathic Association (AOA) Commission on Osteopathic College Accreditation (COCA) is the accrediting agency of predoctoral osteopathic education. It is recognized by the United States Department of Education. Accreditation means that a college or a school of osteopathic medicine has appropriately identified its mission, has secured the necessary resources to accomplish that mission, currently shows evidence of accomplishing that mission, and may be expected to continue to do so. Accreditation requires each school or college to undergo continuing self-study and periodic peer evaluation to ensure its continued performance within the standards established by the COCA. The president of the AOA appoints the members of the commission, but the COCA is otherwise self-determining as to the standards it defines and the assessment of achievement necessary to award accreditation status to an individual school. Once a school is accredited, ongoing reassessments are required to maintain accreditation status. Accreditation is a necessary step for a school's graduates to be eligible for residency training and licensure. COCA currently accredits 26 colleges of osteopathic medicine offering instruction at 32 locations in 23 states (Table 3.2).

AOA-accredited schools have met or exceeded standards determined by COCA in seven areas:

1. Organization Administration and Finance
2. Faculty and instruction
3. Curriculum
4. Student Services
5. Performance and evaluation
6. Research and Scholarly Activity; and
7. Facilities

Each of these areas has specific guidelines determined by COCA that are available online through the AOA predoctoral accreditation website (http://www.osteopathic.org/index.cfm?PageID=acc_predoc). The evaluation of compliance with these guidelines is determined through self-study reports and on-site reviews by members of the COCA registry of evaluators.

The standards for accreditation require each College of Osteopathic Medicine (COM) to have a clearly defined mission statement including goals and objectives appropriate to osteopathic medical education that address teaching, research, service, including osteopathic clinical service, and student achievement (5). The COM may implement its curriculum utilizing different curriculum models. The particular curriculum is the prerogative of the individual schools within the COCA guidelines. Two frequently used

TABLE 3.1

Characteristics of Applicants to Osteopathic Medical School

Requirements	Personal Qualities	Achievements
<ul style="list-style-type: none"> • At least 3 y of college education in biology, chemistry, physics, English 	<ul style="list-style-type: none"> • Honest, reliable, responsible 	<ul style="list-style-type: none"> • Demonstrated success in challenging academic college courses
<ul style="list-style-type: none"> • Medical College Admissions Test 	<ul style="list-style-type: none"> • Family support and encouragement 	<ul style="list-style-type: none"> • Most have at least a bachelor's degree
<ul style="list-style-type: none"> • Personal statement 	<ul style="list-style-type: none"> • Investigative, social and artistic personality 	<ul style="list-style-type: none"> • Experience with health care system
<ul style="list-style-type: none"> • Letters of recommendation, including at least one from an osteopathic physician 	<ul style="list-style-type: none"> • Second career (25%) 	<ul style="list-style-type: none"> • Direct knowledge of the osteopathic profession (e.g., shadowing a D.O.)
<ul style="list-style-type: none"> • Secondary college application 		<ul style="list-style-type: none"> • Awareness of the sociopolitical aspects of osteopathic medical practice
<ul style="list-style-type: none"> • Interviews 		<ul style="list-style-type: none"> • Evidence of leadership and community service • Research experience

models are the discipline-based and system-based models. The former is organized around specific academic and practice specialties such as internal medicine, obstetrics, and family medicine and the basic science disciplines, such as physiology and anatomy. The latter is organized around body systems such as the cardiovascular or reproductive systems and attempts to integrate the disciplines through the study of those body systems. Newer models include case-based, evidence-based, problem-based and independent study models. Each school may choose a variety of methods to achieve its specific mission and goals. Thus, schools may vary in the amount of emphasis placed on such teaching methods as small group exercises, problem-based learning, didactic lecturing or on particular elements of the curriculum such as research, rural medicine, or primary care, depending on the mission of the particular school (6).

Since each school may employ different methods in its curriculum, it is imperative that the student have a good understanding of his or her learning style and seek an environment that is conducive to that learning style. Independent and experiential learners may thrive in a problem-based environment, whereas traditional learners may do better in a discipline-based curriculum. In any event, the medical student will evolve a learning style that is increasingly driven by adult learning theory. One of the most difficult transitions that most medical students encounter is away from the teacher-driven academic learning and evaluation environment. In that environment, the instructor likely determines the student's more concrete assignments, readings, and testing parameters. As students progress through medical education, there is transition to adult learning methods in which the learner must assume increasing responsibilities for learning. This is often based on a case-oriented need-to-know basis but requires a discipline on the part of the learner to secure the best evidence for the query.

AACOM

The growth and acceptance of the profession has been impressive. As colleges developed, it became clear that a single avenue of advocacy for osteopathic education, development and integration educational paradigms, and a forum for collegial collaboration would benefit the profession. In 1898, the American Association of Colleges of Osteopathic Medicine was founded to lend support and assistance to the nation's osteopathic medical schools. This association serves as the unifying voice of the colleges through proactive advocacy. It fosters collaboration and innovation among its member colleges particularly with its membership councils that bring interest groups together on issues of professional education. It provides a centralized service for data collection and analysis including the online application service. The AACOM develops national initiatives to promote and raise awareness of osteopathic medical education.

Led by the Board of Deans that includes the dean of each Osteopathic school, the AACOM includes 11 councils to encourage interest groups ranging from information technology and library services to financial officers, student affairs personnel, development officers, researchers, and more. These include the following:

- Council of Development and Alumni Relations Professionals
- Council of Fiscal Officers
- Council for Information and Technology
- Council of Medical Admissions Officers
- Council of Osteopathic Librarians
- Council of Osteopathic Medical Student Services Officers
- Council of Osteopathic Student Government Presidents
- Council of Researchers
- Council of Student Financial Aid Administrators

TABLE 3.2

Osteopathic Medical Schools Accredited by the AOA COCA as of December 2009

Year Established	Name and Location	City, State	Type
1892	A.T. Still University of Health Sciences/Kirksville College of Osteopathic Medicine (ATSU/KCOM); A.T. Still University, School of Osteopathic Medicine in Arizona (ATSU-SOMA) ^a , founded in 2008	Kirksville, MO Mesa, AZ	Private
1898	Des Moines University-College of Osteopathic Medicine (DMU-COM)	Des Moines, IA	Private
1899	Philadelphia College of Osteopathic Medicine (PCOM) Philadelphia College of Osteopathic Medicine (Georgia-PCOM), founded in 2004	Philadelphia, PA; Suwanee, GA	Private
1900	Midwestern University/Chicago College of Osteopathic Medicine of (MWU/CCOM) Midwestern University/Arizona College of Osteopathic Medicine of (MWU/AzCOM), founded in 1995	Downers Grove, IL Glendale, AZ	Private
1916	Kansas City University of Medicine and Biosciences—College of Osteopathic Medicine (KCUMB-COM)	Kansas City, MO	Private
1966	University of North Texas Health Science Center at Fort Worth, Texas College of Osteopathic Medicine (UNTHSC)	Ft. Worth, TX	Public
1969	Michigan State University College of Osteopathic Medicine (MSUCOM)	East Lansing, MI	Public
1970	Oklahoma State University Center for Health Sciences College of Osteopathic Medicine (OSU-COM)	Tulsa, OK	Public
1974	West Virginia School of Osteopathic Medicine (WVSOM)	Lewisburg, WV	Public
1975	Ohio University College of Osteopathic Medicine (OU-COM)	Athens, OH	Public
1976	University of New England, College of Osteopathic Medicine (UNE/COM)	Biddeford, ME	Private
1976	University of Medicine and Dentistry of New Jersey, School of Osteopathic Medicine (UMDNJ-SOM)	Stratford, NJ	Public
1977	Western University of Health Sciences, College of Osteopathic Medicine of the Pacific (COMP)	Pomona, CA	Private
1977	New York College of Osteopathic Medicine (NYCOM), of the New York Institute of Technology	Old Westbury, Long Island, NY	Private
1979	Nova Southeastern University College of Osteopathic Medicine (NSU-COM)	Fort Lauderdale, FL	Private
1992	Lake Erie College of Osteopathic Medicine (LECOM) Lake Erie College of Osteopathic Medicine—Bradenton (LECOM-Bradenton), founded in 2003	Erie, PA Bradenton, FL	Private
1996	Touro University College of Osteopathic Medicine (TUCOM) Touro University College of Osteopathic Medicine—Nevada (TUCOM-NV), founded in 2003	Mare Island, Vallejo, CA; Las Vegas, NV	Private
1997	Pikeville College School of Osteopathic Medicine (PCSOM)	Pikeville, KY	Private
2000	Edward Via Virginia College of Osteopathic Medicine (VCOM)	Blacksburg, VA	Private
2006	Lincoln Memorial University DeBusk College of Osteopathic Medicine (LMU-DCOM) ^a	Harrogate, TN	Private
2007	Rocky Vista University College of Osteopathic Medicine (RVUCOM) ^a	Parker, CO	Private
2007	Pacific Northwest University of Health Sciences College of Osteopathic Medicine (PNWU-COM) ^a	Yakima, WA	Private
2008	Touro College of Osteopathic Medicine (TouroCOM) ^a	New York, NY	Private
2009	William Carey University College of Osteopathic Medicine (WCU-COM) ^a	Hattiesburg, MS	Private

^aProvisional Accreditation until the college graduates its first class.

- Educational Council on Osteopathic Principles (ECOP); and
- Marketing and Communication Advisory Council

Aided by the Board of Deans of AACOM, the Society of Osteopathic Medical Educators and its member councils, the AACOM promotes educational development, research initiatives, and membership services for students, educators and colleges, and professional advocacy for all the colleges of osteopathic medicine. (see AACOM web page at www.aacom.org)

ECOP, which was established in 1969 under the leadership of Ira Rumney, D.O., and Norm Larson, D.O., serves as the cooperative voice for the teaching of osteopathic principles and practices for the member colleges of AACOM. ECOP consists of the chairs, or designees, from the departments at the osteopathic colleges that oversee the teaching of the structural diagnosis and osteopathic manipulative treatment (OMT) portion of the curriculum. It develops and promotes the improvement of curricula in these areas as well as best practices across the continuum of education. As an initial publication of its work, the ECOP developed a *Glossary of Osteopathic Terminology* in 1981 which it updates and regularly publishes, and which is used worldwide. In 1987, the Council of Deans approved the ECOP consensus document: Core Curriculum in Osteopathic Principles Education for the AACOM colleges. ECOP was a critical impetus for the establishment of the *Foundations for Osteopathic Medicine* textbook, and its members perform vital roles as authors, editors, and peer reviewers for each edition.

SCHOLARSHIP AND RESEARCH

Osteopathic medical schools have always fostered research among the faculty of the schools and to a lesser extent the students and residents engaged in the programs of the colleges. However, the emphasis has always focused on patient care; research has not been as much of the focus as it is with allopathic schools. Scholarship and research are necessary for the advancement of the credibility and visibility of the profession. The profession also has an obligation to contribute to the fund of knowledge and application of research to the milieu of medical care. Therefore, the standards for colleges of osteopathic medicine, and osteopathic postgraduate training have increasingly emphasized research and scholarship skills as desired traits in applicants, students, faculty, and residents. Many schools seek students with research backgrounds, and a few offer value-added PhD and Masters level programs to complement the offerings available to students and practitioners of osteopathic medicine. Nowhere is this more important than in the fundamental research accorded to OMT. A firm evidence-based research track in this important modality and translational research into its effective implementation remains as a core challenge to the profession. Furthermore, it appears that competitive specialty and subspecialty training programs increasingly value residents with a firm understanding of research and a record of scholarly achievement. Even students without aspirations in a research career are well served by a basic understanding of research design and interpretation. The rapid advancements in the practice of medicine require the practitioner of the future to be able to critically appraise the voluminous literature to determine its validity and application to the patients who come under the care of an osteopathic physician. Evidence-based medicine—the practice of medicine according to the best available information—is a standard of practice expected by hospitals, insurance carriers, and patients. In the meantime, practicing physicians are confronted with a large amount of information

from various sources. Some of this is tainted by commercialism or self-promotion. Some is critical information that makes a significant contribution to the outcomes of care. Much of what appears in print or in online resources is irrelevant, inaccurate, or mediocre. The ability to successfully differentiate these to improve the delivery of patient-oriented care demands that the practitioners of osteopathic medicine attain a level of competency in this critical area.

PRECLINICAL CURRICULUM

Classically, osteopathic medical schools have viewed the curriculum in two parts—each dependent on the other. The first portion of the curriculum encompasses the acquisition of basic knowledge and skills in the sciences and the fundamental development of attitudes and skills in clinical practice. This is typically 2 years in length. While the emphasis is on securing a base of knowledge, most schools also work to expose students to fundamental patient care skills in physical examination and medical documentation during this phase of education. The AOA COCA requires the various colleges to stipulate the course of instruction designed to address the educational objectives, the resources and the faculty available for offering this instruction and for assessing the students' achievement of these objectives. This includes the integration of osteopathic philosophy, principles, and practices throughout the entire curriculum. Many osteopathic schools also include introductory exposure to patients in this first 2 years through observerships and limited practicums. This allows the emphasis to remain on acquiring the skills necessary for a focus on the person/the patient in addition to the acquisition of basic skills and knowledge.

CLINICAL CURRICULUM

Traditionally, the clinical curriculum of medical schools has included experiential learning in hospitals and clinics associated with the medical school. This has occurred largely during the last 2 years of the osteopathic medical school curriculum. Because of its emphasis in primary care and community-based care, the osteopathic profession has always utilized a number of community-based and affiliated sites to secure the best educational opportunities for its graduates. This diversity of training sites has served the profession to ensure exposure to a number of venues of care, from tertiary-care hospitals to rural clinics and private practices. While many allopathic schools have found the maintenance of a central academic medical center difficult, the osteopathic profession has reached out to community-based training as consistent with the mission and goals of most osteopathic medical schools. Many studies, including the GPEP (General Professional Education of the Physician) report and the Pew Foundation have noted that training in tertiary-care centers alone leads to a large percentage of students choosing to be tertiary-care doctors as they are exposed to those role models. Mentoring and role models in primary care can best be served in nontertiary care models including community hospitals and private practices. The AOA COCA standards recognize this and note that such training must be a cooperative venture between the training locales and the college. The college must define the educational objectives and appoint the faculty of the affiliated distant sites. Most important, the college must establish clinical core competencies to be acquired and a methodology to ensure they are being met in preparation for the graduates' entry into postdoctoral (residency) programs. This can be assessed through a variety of tools including

standardized patients, skills' testing clerkship exams, and clerkship training evaluation. The clinical experience curriculum is referred to as the clerkships curriculum. It is often divided into the core clerkship and the elective clerkship curriculum at the discretion of the college. The core clerkship includes the basic requirements designed and administered by the COM in such disciplines as family medicine, obstetrics, pediatrics, internal medicine, and surgery. This phase is usually offered during the third year. Students are frequently given latitude to select specialties and training locales on an elective basis with the permission of the COM in their fourth year. This allows the student an opportunity to pursue additional training in an area of interest, to supplement previous experiences, and to explore postgraduate opportunities for residency training.

COMLEX—USA

All osteopathic students must pass three of the four parts of the National Board of Osteopathic Medical Examiners, Inc. (NBOME) Comprehensive Osteopathic Medical Licensing Examination (COMLEX-USA) to graduate from an accredited osteopathic school. COMLEX-USA Level 1 concentrates on the assessment of basic science and clinical science knowledge through a variety of computer-accessed case-based questions. This is typically administered online at the end of the preclinical portion of the curriculum at the end of year two of the traditional curriculum. COMLEX-USA Level 2 CE (cognitive evaluation) similarly assesses case-based knowledge in clinical presentations and is typically administered online at the conclusion of the core clinical curriculum, usually at the end of the core clerkships of year three of the traditional curriculum. In addition, students must pass the COMLEX-USA PE (Performance Evaluation) wherein standardized patients are used to assess the student skills and competencies in two domains. The first domain is the humanistic domain concentrating on the physician-patient interaction emphasizing interpersonal and communication skills. The second is the biophysical domain concentrating on the skill of the patient interview, the physical examination, the selection and performance of OMT, and the writing of medical notes documenting the patient care encounter. In the COMLEX-USA level 2 PE process, communication and performance is emphasized, while in COMLEX-USA level 1 and

COMLEX-USA level 2 CE, knowledge acquisition and decision making is emphasized.

The USA COMLEX-USA offers a third exam at the end of the first year of postgraduate training (COMLEX-USA level 3 CE) that is the final step in meeting state examination requirements for licensure. This examination places an emphasis on case analysis, diagnostic choices, and patient management (Table 3.3).

The allopathic profession offers similar examinations entitled the United States Medical Licensing Exam (USMLE). This exam is divided into three sections like the COMLEX-USA. These may not be substituted for the COMLEX-USA requirements. Some students choose to also take the USMLE equivalent examinations believing that this may be advantageous to them in the pursuit of residency. Comparisons between allopathic and osteopathic education requirements are listed in Table 3.4.

POSTDOCTORAL

For many years, the osteopathic and allopathic professions had no requirement for additional training beyond the years of medical school. Only a few graduates apprenticed with experienced doctors. In the early 1950s, a formal program of additional training became commonplace as a 1-year internship through the general wards of care in a hospital. The young graduate was in place (interned) in the hospital for a year of intensive tutelage at the hands of a group of experienced physicians. Gradually becoming more formalized postgraduate training expanded to longer periods of time in areas of specialization. This often required the aspiring specialist to live at the hospital (thus the term resident) and to be available for service and learning at all times. Living quarters and perhaps a small stipend was provided if the resident was fortunate. As medicine grew even more complex, both the AMA and the AOA developed criteria and standards to govern the content and duration of these residencies. For the AMA, the oversight body for these residencies became the Accreditation Council for Graduate Medical Education (ACGME) and its Residency Review Committees. For the AOA, it became the Council on Postdoctoral Training (COPT) and its Program and Trainee Review Committee (PTRC) and the Committee on Osteopathic Postdoctoral Training Institutions Committee.

TABLE 3.3

Content Emphasis for each COMLEX Licensing Examination^a and Year Taken During Osteopathic Medical Education

Content Emphasis	Level 1 Second Year	Level 2-CE Third Year	Level 2-PE Fourth Year	Level 3 PGY-1
Basic and Clinical Science Knowledge	x			
Case-Based Knowledge and Decision Making		x		
Communication and Osteopathic Skill Performance			x	
Case Analysis, Diagnostic Choices, and Patient Management				x

CE, cognitive evaluation; PE, performance evaluation; PGY, postgraduate year

TABLE 3.4

Osteopathic versus Allopathic Education

Category	Osteopathic	Allopathic
Premedical Education	University Degree or equivalent education	University Degree or equivalent education
Medical School Duration	4 y	4 y
Degree	D.O.	M.D.
Residency	AOA or ACGME Approved (3–5 y)	ACGME Approved (3–5 y)
Licensing Exam	COMLEX	USMLE
Board Certification	AOA and/or ACGME	ACGME

COPT AND OPTI

Postdoctoral education is the prerogative of the individual specialties. Each osteopathic specialty has a board that defines the requirements of training for that specialty. These must be within the guidelines and oversight of the basic standards of the COPT. These basic standards are enforced through program inspections, self-study, and reviews by the PTRC. Every osteopathic residency must be a member of an osteopathic postgraduate training consortium known as an OPTI (Osteopathic Postgraduate Training Institution). These OPTIs provide a source of expertise and cooperative education by incorporating member hospitals, COMs, and residencies into a collective entity to design, implement, and assess the delivery of quality osteopathic postdoctoral education and experiences to member programs and its residents. Cooperative activities require the incorporation of osteopathic principles, OMT, faculty development, didactic education, program assessment, peer review, and resident support services between programs and with COMs. The AOA promotes attainment of six basic core competencies in all its residencies, including application of osteopathic philosophy and principles in practice and appropriate utilization of OMT (Table 3.5).

Graduates of osteopathic schools may choose to seek postgraduate training in a number of venues and disciplines. Graduates are selected for ACGME programs, military programs and COPT-approved programs. The COPT will give osteopathic recognition to those ACGME programs that meet COPT standards on an individual basis. Although there is no official designation recognizing approval by both the COPT and the ACGME, these are often referred to as “dual approved.” Approximately 38% of the 3,462 members of the 2008 osteopathic medical student graduating class chose COPT-approved osteopathic programs with 82% achieving their first-choice placement (8). Another 13% of osteopathic graduates were accepted into AOA positions after failing to match in a program (post match “scramble”); thus, a total of 51% of the 2008 graduating class matched in AOA internship or first-year residency positions (8). The remainder matched in ACGME or military programs. Those who do select nonosteopathic programs may request approval from the COPT but must meet stringent programmatic guidelines to gain approval.

RESIDENCY SEARCH AND SELECTION

The search for a residency necessitates the careful consideration of a career track. Osteopathic students are encouraged not to track too early to a specialty area. Many students find their initial expectation for specialty to change often during the medical school time. It is not uncommon to become enamored of each specialty as one proceeds through the clerkship years. Thus, the best option for most students is to seek preparation as a generalist. The best specialists are first and foremost well-prepared generalists. Both core clerkships and elective clerkships allow students to explore various fields of practice and potential sites for later residencies.

Students typically obsess over grades as they prepare to seek residency training. While course grades and standardized

AOA CORE Competencies

1. Osteopathic Philosophy and Principles (OPP) and Osteopathic Manipulative Medicine (OMM)^a
2. Medical knowledge and OPP/OMM
3. Patient Care and OPP/OMM
4. Interpersonal and Communication Skills and OPP/OMM
5. Professionalism and OPP/OMM
6. Practice-based Learning and Improvement and OPP/OMM
7. Systems Based Practice and OPP/OMM

^aThe NBOME has integrated the Osteopathic philosophy and principles competency into all of the other six core competencies in its national board examinations.

Source: AOA Accreditation Document for Osteopathic Postdoctoral Institutions and the Basic Document for Postdoctoral Training Programs.

test scores like the NBOME are important, studies show other characteristics are equally, if not more important (9). These divide into three categories: performance on service (clerkship), personal characteristics, and the COM academic record. Academic performance is important and students should strive for excellence, but residency directors are more likely to select candidates they have encountered on service in their hospital during clerkship time. If the student has not been on service in that hospital, then the same service at a similar hospital known to the residency director becomes important. This allows residency directors to assess the character, work ethic, professional responsibility, and reliability of the applicant. These characteristics are important to residencies due to the necessity of interdependency and teamwork. Secondly, directors tend to seek evidence of intellectual curiosity and leadership. This can be demonstrated by the service record of the student during medical school and by a record of scholarship in research or publication. The “student performance letter” a.k.a. “the dean’s letter” and the other letters of recommendation are viewed as less informative to most residency directors.

Students interview at a number of residency programs during clerkship time and select programs to apply to based upon a number of personal and professional factors and their feeling as to the likelihood of acceptance. Once a student selects the programs, it is necessary to complete the ERAS (Electronic Residency Application Service) forms online via the internet. This also involves submitting various supporting documents, letters of recommendation, and transcripts. There are specific deadlines for these and students are well advised to work with their individual schools to begin this process well in advance. Similar to selecting a COM, students should consider the quality of the program as well as personal quality of life issues in selecting a residency. Physicians are likely to practice near their site of final training, where they grew up or where their significant other grew up.

Residents are chosen by a computer match process. The military programs, osteopathic programs, and allopathic programs all use a similar process. Programs list their preferred candidates in order. The applicants list their programs in order of preference. The computer then selects candidates by matching these preferences through an algorithm established by the oversight committees for the respective programs. The military programs are the first to match and those candidates are removed from the pool. The osteopathic and allopathic matches occur separately. Once a student matches with a program, the match is considered ethically made and both sides are expected to adhere to the results. Prematch deals are considered unethical and are frowned upon. Once the match is confirmed, contracts are signed and registered with the AOA for osteopathic programs. Should a student not “match” there is a period following that seeks to connect the unmatched student and program. Many excellent programs have unmatched positions. This is especially true in primary care. Allopathic programs may try to fill those unmatched spots with foreign graduates.

When a residency is completed, a physician may choose to enter a subspecialty. This may be a fellowship or “plus one” program depending on the nature of the program and the oversight organization or board. It may not be necessary to complete the entire residency to qualify for a fellowship, but a substantial part must be completed. Thus, an osteopathic physician may complete a portion of general surgery residency and apply for a fellowship in urologic surgery or complete an internal medicine residency and apply for a cardiology fellowship. Likewise, a resident might

complete a family medicine residency and choose to do a plus 1 year in osteopathic manipulative medicine. The specifics of these options vary from specialty to specialty and are the prerogative of the specialty. Details are available from the various specialty organizations.

BOARDS

Generically, the term “boards” refers to the examinations that are taken to demonstrate the acquisition of a basic competency. “National boards” refer to the NBOME- or the USMLE-generated examinations given during osteopathic medical school and the first part of postgraduate training. As a physician progresses through training and into practice, additional boards may be required. At the conclusion of residency or fellowship, a physician is termed board eligible. This means that the physician has met the requirements of preparatory training and experience to take the examination that may include written exams, practical exams, and record reviews at the discretion of the specialty. Once the examination is successfully completed, the physician is now considered “boarded” or certified in the discipline. The specialty may impose other criteria in addition to the examination. Specialty board certification is usually time limited and the applicant must meet certain continuing study and reexamination standards as the specialty may specify.

LICENSURE

In the United States, licensure is the prerogative of the licensing boards of the state or jurisdiction in which one chooses to practice. Licensing requirements are stipulated by the state and, at a minimum, include requirements for graduation from an accredited school, a specified length of postgraduate training and the passage of a recognized board exam. States vary on the amount of postgraduate training required from 1 to 3 years. All states recognize the NBOME COMLEX-USA examination. States may impose additional requirements such as attestations as to character, criminal background checks, review of the physicians data bank, and letters of reference. These requirements may change over time and contact with the various state licensing boards is recommended. States may have a single licensing board or have separate osteopathic and allopathic boards. Licensure allows the practitioner to practice generally within the state but does not specify the scope of practice, nor guarantee acceptance by a hospital or inclusion in an insurance carrier’s panel of providers. These privileges are discussed later.

Once granted, licensure is for a specific period of time and must be periodically renewed with evidence of continued education and capacity to practice as specified by individual states. States have the option to reciprocate licensure with other states if the requirements are deemed equivalent. This varies from state to state and should not be assumed. Typically, the military requires licensure in at least one state in order to practice in a military facility. An individual may hold licensure in more than one state.

Osteopathic physicians may be eligible for licensure in other countries. There are an expanding number of countries accepting the osteopathic physicians trained under the AOA guidelines. In some cases, there are not any laws or regulations pertaining to osteopathic physicians because no individual has ever applied. The AOA or particular jurisdiction should be contacted for specific requirements.

CREDENTIALS AND PRIVILEGING

The sum total of a physician's educational history, degrees, awards, residency completion, licensure, and boards constitutes the credentials of a physician. These credentials provide documentation of the achievements of the physician. In many ways, they serve as surrogate evidence of competency or the ability to practice. Various organizations use these credentials along with other information to determine acceptance of the individual physician into the organization and to determine the extent or scope of activities the physician will be allowed within the organization. This right to practice a certain scope of activities is termed privileging—the physician is given the privilege of practicing the activity.

Privileging is the prerogative of a specific organization. Different hospitals and insurance carriers may grant different privileges to the same physician based on their own needs and assessment of the credentials. For example, a physician may have the privilege of doing endoscopies at one hospital in town but not another. Physicians, and particularly residents, should maintain a log of their activities to demonstrate familiarity and currency with diagnostic entities and medical procedures. This will serve to bolster their credentials for privileges when requesting the right to do procedures or attend to patients with certain types of illnesses.

CONTINUING MEDICAL EDUCATION

Continuing medical education (CME) allows a physician to update and refresh an information base that is increasingly challenged with advancing knowledge, techniques, and skills. The ability to interpret and utilize new information is a critical skill for physicians. Licensing boards, specialty societies, and privileging organizations expect physicians to keep current. As such they specify the amount and type of continuing education expected. This may vary from state to state and organization to organization. The nature, content, and amount required are the prerogative of the individual state or member organization. Members of the AOA are afforded a tracking service to maintain a record of CME attendance.

The AOA Council on Continuing Medical Education recognizes continuing education in four categories:

1. Category 1A includes formal osteopathically sponsored and delivered educational programs and osteopathic medical school teaching
2. Category 1B includes osteopathic scholarly production and osteopathic student precepting
3. Category 2A includes formal nonosteopathic continuing education programs
4. Category 2B includes self-study readings and presentation at society meetings

The members of the AOA are expected to accomplish 120 hours of CME in each 3-year cycle of which at least 30 hours are expected in category 1A. Physicians who are certified are expected to maintain 150 total hours including 50 hours of Category 1A credit per 3-year cycle in their primary specialty. Individual states may require specific content hours such as medical liability hours or HIV hours to maintain licensure. Each specialty may impose additional expectations for CME as well (10).

PROFESSIONAL ORGANIZATIONS

Osteopathic physicians enjoy a special place in their communities. Being a physician is both a privilege and an obligation. It is a privilege due to the esteem and trust placed in physicians. It is an obligation due to the responsibility to meet standards of care in an ethical manner and in the best interest of the patient.

Osteopathic physicians are expected to contribute to the advancement, visibility, and credibility of the profession. They can do this as community leaders and as participants in various professional organizations. This includes, but is not limited to, the AOA, the state osteopathic society, and the applicable specialty organization. Just being a member is not enough. True membership includes contributing knowledge, time, energy, and financial resources to promote osteopathic education, political

TABLE 3.6

The Osteopathic Oath

I do hereby affirm my loyalty to the profession I am about to enter. I will be mindful always of my great responsibility to preserve the health and the life of my patients, to retain their confidence and respect both as a physician and a friend who will guard their secrets with scrupulous honor and fidelity, to perform faithfully my professional duties, to employ only those recognized methods of treatment consistent with good judgment and with my skill and ability, keeping in mind always nature's laws and the body's inherent capacity for recovery.

I will be ever vigilant in aiding in the general welfare of the community, sustaining its laws and institutions, not engaging in those practices which will in any way bring shame or discredit upon myself or my profession. I will give no drugs for deadly purpose to any person though it be asked of me.

I will endeavor to work in accord with my colleagues in a spirit of progressive co-operation, and never by word or by act cast imputations upon them or the rightful practices.

I will look with respect and esteem upon all who have taught me my art. To my college I will be loyal and strive always for its best interests and for the interests of the students who will come after me. I will be ever alert to further the application of basic biologic truths to the healing arts and to develop the principles of osteopathy which were first enunciated by Andrew Taylor Still.

advocacy, and membership services. This is clear in the osteopathic oath (Table 3.6) all graduates recite at graduation and in the Osteopathic Pledge (Table 3.7) that practicing physicians recite to renew their commitment to the profession in mind, body, and spirit.

TABLE 3.7

Osteopathic Pledge of Commitment

I pledge to:

Provide compassionate, quality care to my patients;

Partner with them to promote health;

Display integrity and professionalism throughout my career;

Advance the philosophy, practice, and science of osteopathic medicine;

Continue lifelong learning;

Support my profession with loyalty in action, word, and deed; and

Live each day as an example of what an osteopathic physician should be.

International Osteopathic Medicine and Osteopathy

JANE E. CARREIRO AND CHRISTIAN FOSSUM (NORWAY)

KEY CONCEPTS

- Internationally, the practice and training of osteopathic medicine evolved differently influenced by the particular political and socioeconomic conditions within different countries.
- The principles of osteopathy and the practice of osteopathic manipulative techniques are employed by limited-license practitioners and fully licensed medical physicians throughout the world.
- American-trained osteopathic physicians practice *osteopathic medicine* and use osteopathic manipulative *treatment* as a component of *comprehensive patient care*.
- The international osteopathic community has adopted the term “osteopath” to describe osteopathic clinicians with limited medical training and practice, and “osteopathic physician” to describe osteopathic clinicians with full medical training and practice.

INTRODUCTION

Osteopathic medicine was established in America in the last decade of the 19th century. Before the beginning of the 20th century, American osteopathic physicians traveled abroad and began disseminating and practicing osteopathy worldwide. American-trained osteopathic physicians have unlimited practice rights throughout the United States and in several countries around the world. However, not all countries offer full unlimited practice rights to osteopathic physicians. In addition, many countries have osteopathic colleges for students who do not want to become, or cannot become, physicians or surgeons, but are content with having a limited osteopathic manual therapy scope of practice. Thus, there are many foreign-trained osteopaths who practice abroad as well as in the United States; most have licenses to practice some form of manual therapy, but many do not have a formal license to practice osteopathy or osteopathic medicine.

Although Dr. A. T. Still intended his principles of osteopathy to be an extension of traditional medical training and practice, he was met with significant resistance from the medical establishment in the United States. Nevertheless, in a relatively short period of time, the principles and practice he discovered had spread throughout the world, taking on different faces in different countries.

Currently, the principles of osteopathy and the practice of osteopathic manipulative techniques are employed by limited-license osteopaths as well as by fully licensed osteopathic physicians throughout the world (World Osteopathic Health Organization, 2004). In some countries, including the United States of America, licensed MDs have studied and use osteopathic philosophy, principles, and osteopathic manipulative treatment as well. The evolution of the training and scope of practice of osteopathic practitioners has been influenced by the specific cultural, economic, and political factors in individual countries. These varied influences have resulted in the emergence of two recognized models of osteopathic training and practice: osteopathic physicians and osteopaths.

An osteopathic physician is defined as a person with full, unlimited medical practice rights who has achieved the nationally recognized academic and professional standards within his or her country to diagnose and provide treatment based upon the principles of osteopathic philosophy. An osteopath is defined as a person

with limited practice rights who has achieved the nationally recognized academic and professional standards within her or his country to independently practice diagnosis and treatment based upon the principles of osteopathic philosophy.

Individual countries establish the national academic and professional standards for osteopathic practitioners within their countries (Educational Council on Osteopathic Principles, Personal Communication, 2002, 2003; World Osteopathic Health Organization, 2004). Within the last 5 years, two organizations have been formed to help establish standardization within the international osteopathic community. These organizations, the International Osteopathic Alliance (OIA) and the World Osteopathic Health Organization (WOHO), are working together to promote the training and practice rights of osteopathic physicians and osteopaths.

The common denominator existing between the osteopathic professions in different countries is the practice of osteopathic philosophy and principles through the utilization of osteopathic manipulation. Although osteopathic physicians and osteopaths share a core curriculum and core competencies defined by the World Health Organization's *Guidelines for the Training and Practice of Osteopathy*, there are still significant differences in education, clinical competency, and scope of practice between the two recognized groups.

In the United States, osteopathic medicine is established and legally recognized as the purview of osteopathic physicians. The United Kingdom legally recognizes both osteopathic physicians and osteopaths but refers to them both as “osteopaths.” Australia and New Zealand have legislation governing the practice of osteopathy by limited-license osteopaths; however, licensed physicians may practice osteopathic techniques without additional qualification.

In addition, there are many other countries in which osteopathy and osteopathic medicine are not recognized as legal, independent professions, or they fall under the scope of practice of another profession. Depending upon the country, American-trained DOs may need to meet licensing requirements of both medical and osteopathic bodies. This chapter presents an overview of the development of the international osteopathic profession from a chronological standpoint.

EARLY OSTEOPATHIC EDUCATION AND ITS IMPACT ON GLOBALIZATION

The student body at the ASO in its first decade of existence also had international representation from countries such as the Canada, the British Isles (United Kingdom, Scotland, and Ireland), Australia, New Zealand, and the Indian Territories. Several of these international students would later become instrumental in bringing osteopathy to countries outside of the United States. They were educated in a curriculum entrenched with Still's founding philosophy and a manipulative-focused practice, and this is what they brought with them when establishing the profession in countries outside of the United States. They identified with the term "Osteopath" and their designated degree was the DO which stood for "Diplomate in Osteopathy." This tradition continues in numerous countries with many osteopaths (see previous definition) believing themselves to be closer to Still's original idea of a diplomat.

OSTEOPATHIC MEDICINE AND MANUAL MEDICINE IN THE INTERNATIONAL MEDICAL ARENA

The philosophy of osteopathy was a relatively innovative perspective on health care when Dr. Still introduced it in the 19th century. While the whole-body/mind-body paradigms cast a different light on healthcare in the new millennium, the philosophy of osteopathy and the structure-function models which it employs, remain uniquely health centered rather than disease centered. So while osteopathic philosophy continues to retain its unique position, the manipulative techniques used in osteopathic practice fall under the larger discipline of manual medicine.

The application of hands-on techniques to the body for the treatment of disease and promotion of health is ancient. After World War II (WWII), manual medicine in its modern form was in common practice in many countries. The Fédération Internationale de Médecine Manuelle was founded in 1958 as a federation of national societies of physicians who practice Manual/Musculoskeletal Medicine (FIMM, Personal Communication, 2008). Membership in FIMM was, and is, based on national affiliation, with each country having a single national professional organization holding membership. North America had a single organization NAAMM, the North American Academy of Manual Medicine holding membership. Only MDs were allowed membership in NAAMM and attendance at their meetings. In 1977, NAAMM changed its by-laws to allow DOs into the organization. They also wanted access to osteopathic educators.

That year, the annual meeting of the NAAMM was held in Williamsburg, VA. Paul Kimberly, D.O., and Philip Greenman, D.O., were invited to the meeting as attendees. At the instigation of John Mennell, M.D., one of the power leaders of NAAMM, Drs. Kimberly and Greenman were invited to a luncheon meeting with the Board of Directors of NAAMM to discuss osteopathic physicians providing manual medicine courses to the NAAMM membership. Mennell felt that the best place to hold such educational opportunities for the NAAMM members would be at Michigan State University, as it was the only university with both an MD and a DO medical school and could handle the political fallout of such an arrangement (P.E. Greenman, *personal communication*, 2008). Because NAAMM was the organization that was part of FIMM, DO membership in NAAMM automatically carried membership in FIMM. Paul Kimberly was the first DO to gain membership in NAAMM, and Greenman was the second. Subsequently, three DOs served as presidents of NAAMM:

Robert C. Ward, D.O.; Allen W. Jacobs, D.O.; Ph.D., and Philip E. Greenman, D.O. Arguably, these leaders helped change the relationship between MDs and DOs practicing any of the disciplines related to musculoskeletal medicine. In the early 1990s, NAAMM merged with the American Academy of Orthopedic Medicine, the organization that was to continue as the North American representative member of FIMM.

In 1998, The FIMM Congress was held in Australia. Michael Kuchera, D.O., then Professor at the Kirksville College of Osteopathic Medicine, was instrumental in accomplishing two major things for the American Osteopathic community (P.E. Greenman, *personal communication*, 2008). Following the merger of NAAMM and AAOM in the early 1990s, AAOM represented both the United States and Canada. At this Congress, Kuchera was able to negotiate a new arrangement whereby the AAOM represented the United States of America, and the American Academy of Osteopathy (AAO) would represent Canada. Therefore, any member of the AAO automatically became a member of FIMM. Subsequently, this arrangement was used by an American-trained DO to argue parity with MDs and gain practice rights in New Zealand. In the mid-1990s, the AAOM folded leaving the AAO as FIMM's sole North American member.

Individual physician members can join the International Academy for Manual/Musculoskeletal Medicine (IAMMM), which was established in 2008. IAMMM's mission is to enhance and develop scientific approaches that focus on musculoskeletal-related problems and to encourage collaboration between scientists and teachers, based on individual membership, thereby creating a scientific platform independent of National Society interest and representation.

CANADA

Shortly after the opening of the American School of Osteopathy, Osteopathic Medicine quickly spread to Canada with the appearance of the first Canadian DO in 1899. The Ontario Osteopathic Association was chartered in 1901, the Western Canada Osteopathic Association in 1923, and the Canadian Osteopathic Association in 1926. In 1925, 200 American-trained DOs were in practice in Ontario. At the present time, 21 American-trained DOs are registered with the Canadian Osteopathic Association, although not all of those are in full time practice.

In Canada, as in the United States, medical licensure is governed by the State or Province. Each province is free to establish its own standards for the registration of physicians, and for recognizing the equivalency of foreign-issued diplomas. As a result, Canadian-trained MDs do not enjoy full reciprocity of practice rights between provinces. The same is true for American-trained MDs or DOs.

There are three national medical organizations of importance to Osteopathic physicians in Canada: the Medical Council of Canada (MCC), the College of Family Physicians of Canada (CFPC), and the Royal College of Physicians and Surgeons of Canada (RCPS). The MCC is primarily responsible for establishing and maintaining a certification process that in theory, should allow interprovincial reciprocity of accredited physicians. All Canadian medical school graduates complete the two-part MCC qualifying examination. In this regard, it has a role similar to the USMLE or COMLEX process. American-trained DOs have had access to the MCC examinations since 1991. MCC certification is a requirement for licensure in many, but not all, provinces. Some provinces require that all foreign-trained physicians, including American-trained MDs, take these examinations.

The CFPC is responsible for accrediting family medicine residencies in Canada and for certifying graduates of Canadian

family medicine residency programs through an examination process. Two American-trained DOs have completed family medicine residencies in Canada and achieved CFPC certification (CCFP), most recently in 1989. Unfortunately, in 1990, the College rescinded the ability of American-trained DOs to take their examinations, which effectively made them ineligible to apply for residency programs. Recent contact with this organization suggests that beginning in 2009, American-trained DOs will again have access to these examinations.

The RCPSC has the same role for all other specialists that the CFPC has for family physicians. The RCPSC has been intransigent in opening their examination process to foreign-trained physicians, including American MDs. Several provinces have made Royal College certification a requirement for provincial registration for specialists. This has led to a significant barrier in the ability of the provinces to recruit foreign specialists, and many provinces are now enacting regulations to “bypass” the RCPSC certification requirements.

In Canada, the equivalent of the U.S. State Medical Board is the provincial College of Physicians and Surgeons (CPS), which is responsible for physician registration and discipline. The standards for physician registration are established by the provincial ministry of health with significant influence from the respective provincial CPS. Box 4-1 provides an overview of Canadian provincial status.

Not surprisingly, given the needs of a growing and aging population, the demands of new technologies, and the changing practice profiles of new graduates, there is now a serious shortage of physicians across the country. This has led to new opportunities for progress for the Canadian Osteopathic Association, in partnership with the Council on International Osteopathic Medical Education and Affairs of the American Osteopathic Association.

Another condition existing in Canada which differs from the United States of America is the presence of osteopaths who are not trained as physicians. With respect to this, educational and legislative issues remain regarding practice rights and licensure.

UNITED KINGDOM

A key figure in the globalization was John Martin Littlejohn (1865–1947). He was educated at Glasgow University, Scotland, in divinity, law, oriental languages, and political history (Collins, 2005). In 1892, Littlejohn decided to immigrate to the United States for health-related reasons. He enrolled at Columbia University in New York where he studied political theory, political economy, and finance, resulting in the publication of his Ph.D. thesis (Collins, 2005; Littlejohn, 1895). In 1894, he accepted the position as President of the Amity College in Iowa Springs, IA, an educational establishment granting degrees in Arts, Science, Philosophy, and Letters. In 1897 while at College Springs, Littlejohn began traveling to Kirksville, MO, to receive treatment from Still for his throat condition. Impressed with the results, he decided to take up the study of osteopathy (Hall, 1952a). While still a student he was appointed Professor of Physiology, Psychology, and Dietetics, and eventually in 1898 he was appointed as Dean of Faculty of the ASO (Booth, 1924; Collins, 2005; Hall, 1952a). Within a year of his appointments, he had written and published three textbooks on the subject of physiology and inaugurated two osteopathic journals. After graduating from the ASO in 1900, Littlejohn left for Chicago where he and his brother established the American College of Osteopathic Medicine and Surgery, a name chosen because its founders believed that osteopathy was a system of medicine and should be so recognized (Littlejohn, 1924). This may have been the first time the term “osteopathic medicine” was officially used.

Overview of Canadian Provincial Status

British Columbia

There are two pathways for DO registration in British Columbia. The first recognizes the COMLEX examinations and two years of AOA-certified postgraduate training. The DO has a limited license and is restricted from performing surgery and obstetrics. This pathway is primarily intended for the DO that wishes to establish an OMT focused practice. The second pathway requires completion of the MCC examinations and at least one year of postgraduate training in that province. The DO will then receive an unrestricted license.

Alberta

The DO candidate is required to complete the MCC examinations. AOA-certified residencies are recognized. There has been informal interest expressed in considering the COMLEX as an alternative to the MCC examinations.

Saskatchewan

A board exists separate from the provincial College for the registration of DOs, although it has not been active for many years. DOs are registered by the board to practice “osteopathy,” although that is not clearly defined. Interest has been expressed by the Ministry of Health in updating regulations.

Manitoba

As of 2002, American-trained DOs are eligible for registration in Manitoba.

Ontario

In 1926, the “Drugless Practitioners Act” was proclaimed as a “temporary” measure for the registration of American-trained DOs. As the title suggests, the scope of practice was severely limited. Under these conditions, osteopathic practice in Ontario has dwindled severely, in spite of many years of political lobbying on behalf of Ontario DOs and their patients. Action in Ontario has been the focus of activity by the Canadian and American Osteopathic Associations for the past several years and the results are beginning to be seen. In theory, American-trained DOs have been recognized as eligible for registration in Ontario by the Ontario government since the passage of the Medicine Act (Bill 55) in 1991. However, those sections that relate to osteopathic physicians were not “proclaimed” into law, on the objection of the CPS at that time. Nevertheless in the mid-1990s, two American-trained DOs were granted unlimited licensure by exception. In November 2002, the Ministry of Health announced that a new “Fast Track Assessment Program” would be initiated for the registration of qualifying foreign-trained physicians, including American-trained MDs and DOs. As of this writing, the regulations under which this will operate are still unclear.

Quebec

American-trained DOs have been eligible for registration in Quebec for approximately 30 years. The candidate also must pass a French language proficiency examination and complete one year of postgraduate training in the province, although this can be at the fellowship level. MCC certification and Royal College certification are not necessary. Unfortunately, the title protection that exists for MDs does not exist for DOs with the result that the title use is not restricted in that province.

(continued)

New Brunswick:

DOs are eligible for full registration in New Brunswick. There is a pathway that extends reciprocity to a DO with Maine licensure.

Nova Scotia

As of 2002, full registration for American-trained DOs is similar to that extended to American-trained MDs.

Prince Edward Island

At the moment, PEI is the only Canadian province without a current or anticipated registration pathway for American-trained Osteopathic physicians.

Newfoundland

As of 2002, the College has committed itself to seeing that the government establishes a registration pathway for American-trained DOs, although it is anticipated that this may take a couple of years.

Territories (Yukon, Northwest, Nunavut)

In most instances, the Territories will grant registration to any physician that qualifies for licensure in any other province.

Canadian Armed Services

American-trained DOs are eligible for service with the Canadian Armed Services, including scholarship opportunities, although to date this has never happened.

There are several conditions in Canada that have influenced the ability of American-trained DOs to gain licensure. The first has to do with manpower. In the early 1990s, Canada's health ministers were faced with a situation of spiraling health care costs, and a seemingly inexhaustible source of physicians. It was felt that one of the primary drivers of medical costs was an excess of physician manpower. Measures were taken to impede the ability of foreign-trained physicians to acquire licensure in most provinces and Canadian medical school enrollment was reduced by 15% on average. In this environment, it was very difficult for the Canadian Osteopathic Association to make headway in promoting full-practice rights for American-trained DOs in those provinces in which it did not already exist.

Osteopathy as a subject was introduced in the United Kingdom through a series of talks given by Littlejohn in 1898, 1899, and 1900 to the Society of Science, Letters, and Arts in London (Hall, 1952a). William Smith, M.D., D.O., a member of the first graduating class of the ASO and its first anatomy teacher, returned to the British Isles in 1901 to practice osteopathy, and in 1902 he was followed by several other early ASO graduates: L. Lillard Walker, Franz Joseph Horn, and Jay Dunham. By 1910, there were so many U.S.-trained osteopaths in Great Britain that the British Osteopathic Society was formed, which in 1911 became the British Osteopathic Association (Beal, 1950; Collins, 2005).

As early as 1903, Littlejohn held talks with Walker and Horn about establishing a school of osteopathy in Great Britain. These plans did not materialize until Littlejohn returned to the United Kingdom for good in 1913. The British School of Osteopathy (BSO) was incorporated in London in 1917 as a nonprofit organization to train osteopaths, although neither the degree nor the profession was recognized by legislation. Its 4-year curriculum, excluding pharmacology and surgery, was completed in 1921 (McKone, 2001). Access to hospitals, dissection laboratories,

and other aspects of physician training were denied. In the early 1920s, the BSO's faculty consisted purely of graduates from U.S. osteopathic schools under the Deanship of John Martin Littlejohn (Hall, 1952b). As graduates were produced from the BSO, this situation gradually changed, and by the early 1930s a large proportion of the faculty was U.K. trained (Littlejohn, 1931). In 1946, the London College of Osteopathy was opened to provide a postgraduate osteopathic training program to medical doctors. This 18-month program provided medical doctors with core training in osteopathic principles, practices, and techniques. Graduates of the London College became members of the British Institute of Manual Medicine and with the formation of FIMM in 1958, MDs trained at the London College of Osteopathy were granted membership. For 20 years, they remained the only osteopathic physicians in FIMM (P.E. Greenman, *personal communication*, 2008).

In 1936, a voluntary registry was established for the osteopathic profession and the designation MRO (Member of the Registry of Osteopaths) could be secured by individuals meeting the required qualifications. The osteopathic profession made several unsuccessful attempts to secure regulation and legislation between the arrival of Littlejohn and the arrival of the 1990s. Finally, the Osteopaths Act was finally passed by the House of Lords in 1993 granting Statutory Self-regulation to the profession and control of the titles "Osteopath" and "Osteopathic Physician." The entire profession underwent revalidation to ensure that minimal criteria for practice were met. The General Council and Register of Osteopaths were abolished and the General Osteopathic Council (GOsC) was established to oversee educational standards, professional development, and patient safety issues. The GOsC is the regulating body for all individuals practicing osteopathy or osteopathic medicine in the United Kingdom. Registration with the GOsC is now required for the legal practice of osteopathy in the United Kingdom; this includes medical doctors practicing osteopathic medicine. Additionally, osteopathic schools in the United Kingdom need to have a recognized qualification status from the GOsC in order to provide their graduates entry to its register. In early 2008, there were almost 4,000 registered osteopaths in the United Kingdom. American-trained DOs wishing to practice as full-scope osteopathic physicians would need to meet licensing criteria for both the GOsC and the General Medical Council. Those wishing to practice as limited-license osteopaths would need to be accepted by the GOsC only.

AUSTRALIA

Osteopathy spread to Australia and New Zealand via two mechanisms. In the later 1890s and early 1900s, osteopaths who had trained in the United States carried their training "down under," creating an osteopathic profession. After the first and second world wars, manual medicine was introduced to the established medical profession and became a medical discipline under the international umbrella of FIMM. This created parallel pathways for the development of osteopathy in Australia and New Zealand.

Between 1909 and 1913, several early graduates from the American School of Osteopathy returned to Australia to practice osteopathy (Hawkins and O'Neill, 1990). The growth of the osteopathic profession was slow, and as in the United Kingdom, unwelcomed by the medical community. These émigrés founded a professional association in the state of Victoria modeled after the American Osteopathic Association. Although U.K.-trained osteopaths soon arrived in the country, only American-trained DOs were allowed membership in the Australian Osteopathic Association

(AusOA) until the late 1920s. In the early 1930s, a medical doctor who had graduated from the BSO emigrated to Australia and was allowed entry into the AusOA group. Other BSO graduates used this acknowledgement of the BSO training as a successful argument for inclusion in the association. By the 1940s, several private colleges provided osteopathic training, but because of the unregulated nature of the profession, the quality of these courses was variable (Cameron, 1998; Hawkins and O'Neill, 1990). In 1974, the Australian Federal Government Health Minister commissioned an inquiry into chiropractic, osteopathy, homeopathy, and naturopathy, which resulted in a report published in 1977. This report influenced the development of osteopathy in Australia, officially limiting osteopathy's scope of practice to manipulative therapy and primarily the management of musculoskeletal conditions (Cameron, 1998).

During the 1980s, programs in osteopathy as a limited manual therapy practice and osteopathic medicine for physicians developed on parallel pathways. Philip Greenman, D.O., a Professor at Michigan State University, was invited to Australia in 1986 to present a paper to the annual meeting of the Australian Association of Physical and Rehabilitative Medicine. At the suggestion of Vladimir Janda, M.D., the Department of Physiotherapy at the University of Brisbane invited Dr. Greenman to present a 5-day course on Muscle Energy technique to their senior practitioners and faculty. In 1992, Greenman was invited by the Australian Society of Rehabilitation, MDs that did musculoskeletal medicine with heavy emphasis on manipulation, to provide two courses, one on muscle energy and the other on HVLA. He was also invited by the AusOA to provide the same two courses to the osteopathic community. Interestingly, these courses were held separately, although the table trainers for all four courses were from the faculty of one of the osteopathic colleges.

In 1986, the first federally funded course in osteopathy commenced at the Phillip Institute of Technology in Melbourne, Victoria (which later merged with the Royal Melbourne Institute of Technology). This course provided training for manual medicine practitioners, not physicians. As of 1995, the course awarded double degrees to its graduates; graduates from any of the Australian colleges are awarded a Bachelor of Science (Clinical Science) and a Master of Health Science (Osteopathy) (Cameron, 1998). Until the first part of the 21st century, a joint board of chiropractors and osteopaths in each territory awarded licenses. Today, each territory has an osteopathic board to oversee licensing issues for osteopaths. The Australian Osteopathic Association (AOA or AusOA) was founded as a professional society to promote osteopathy, and in 1991 it became the federal body representing osteopaths in Australia. American-trained DOs wishing to have limited practice rights would need to meet the criteria of the osteopathic licensing board in that territory. Those wishing to practice full-scope osteopathic medicine need to meet the criteria of both the Medical and the Osteopathic boards.

NEW ZEALAND

Until the mid-1990s, most osteopaths practicing in New Zealand (N.Z.) received their training in Australia or the United Kingdom. A voluntary registry existed and there was no legislation regarding training or practice. In the late 1990s, the first full-time accredited training program was created at UNITEC in Auckland. David Patriquin, D.O., who was on faculty at Ohio University College of Osteopathic Medicine, became the program's inaugural principal. In 2003, the Health Practitioners Competence Assurance Act was passed establishing the Osteopathic Council of New Zealand to

regulate the training and practice of osteopathy in N.Z. (The legal status of osteopathy and its educational structure in New Zealand is similar to that in Australia.)

As in Australia, there was some attempt to advance the American model of osteopathic medicine in N.Z. in the 1980s. Philip Greenman, D.O., was invited by Barrie Tait, M.D., Department of Rheumatology at the University of Dunedin, New Zealand, to be a Visiting Professor for 6 months. The purpose was to assist Dr. Tait in the preparation of an 18-month diploma course in Musculoskeletal Medicine for the Family Medicine Practitioners in the New Zealand system (P.E. Greenman, *personal communication*, 2008). This required that Dr. Greenman obtain a medical qualification from N.Z. in order to participate in patient care both in the ambulatory and the hospital environment. He was the first American DO in the Medical Registry of New Zealand. His qualification was based upon his Professorship at Michigan State University and having a license to practice medicine and surgery from the state of New York. Since that time, other American DOs have gained registry in N.Z. With the inception of the Osteopathic Council, it is unclear whether American-trained DOs wishing to practice full-scope osteopathic medicine need to meet the criteria of both the Medical Registry and the Osteopathic Council. Dr. Greenman helped develop a 6-month diploma course for physicians, which continues to this day. It was also the model adopted by two universities in Australia (P.E. Greenman, *Personal Communication*, 2008).

CONTINENTAL EUROPE

Initially, osteopathy came to continental Europe after WWII when practitioners trained in America and England immigrated to the continent. Random conferences and courses featuring visiting osteopathic practitioners were held separately for physicians and therapists. Beginning in 1957, faculty from various COMs and the Sutherland Cranial Teaching Foundation were invited to present at conferences and hold courses throughout Europe. The courses were often segregated between physiotherapists and physicians. Over time, this became the norm, rather than the exception, and by the late 1980s, there were many schools of osteopathy scattered throughout Western Europe catering to either physiotherapists or physicians. A rare few of these schools established quality assurance for the examination process by relying upon teachers from other schools to evaluate their students; however, most schools implemented their own curriculums and evaluation processes without objective checks or standardization. As the international osteopathic profession began to come together in the early 1990s, there was a strong movement within both communities to establish a core curriculum and objective, standardized assessment tools.

In most of post-World War II Europe, the practice of manual medicine was incorporated into standard medical training and many countries had national manual medicine societies. Over the following decades, these societies were given the role of standardizing curriculum and practice, becoming the credentialing bodies in their countries. By the 1990s, manual medicine training tended to be a secondary specialty of medical training in Western Europe, rather than primary, with family practitioners and orthopedic surgeons making up the bulk of the providers. Beginning in the early 1970s, physicians practicing in the Netherlands, Sweden, Czechoslovakia, and much of Eastern Europe were exposed to the Gaymann-Lewit technique. Fritz Gaymann and Karel Lewit developed this manual medicine approach that was based upon Fred Mitchell's muscle energy system that Gaymann learned during a prolonged visit

to the United States (P.E. Greenman, *personal communication*, 2008). Later physicians were exposed to the osteopathic approach through their involvement with FIMM. In 1979, faculty members from Michigan State University, Kirksville, Chicago, and Texas were invited to the Canary Islands to present a basic course on osteopathic manipulative techniques to the leadership of the German Manual Medicine Society (DGMM). Under the German medical training structure, the DGMM is the equivalent of a specialty college that grants board certification. In August of that year, MSUCOM offered the first basic course in osteopathic technique to MDs. During the 1980s and 1990s, faculty from the various COMs were recruited to develop and deliver basic courses in osteopathic techniques in Germany, Switzerland, France, Belgium, and the Netherlands. By the mid-1990s, many of the manual medicine societies in these countries had affiliate organizations of M.D.-trained osteopathic physicians with shared prerequisites, curriculum, and standards for examination. Nevertheless, osteopathic medicine was not recognized as a profession but as a manual medicine subspecialty available to trained physicians.

In 1998, the European Union Health Administration included osteopathy in a resolution accepting alternative and complementary medicines, although specifics of education and practice were not incorporated. Initiatives have been taken by the European Union, the Forum for Osteopathic Regulation in Europe, the European Registry of Osteopathic Physicians, the World Health Organization, the WHO, and the Osteopathic International Alliance to promote the regulation of practice and training based on minimum competencies. Although over the years individual American-trained DOs have obtained licensure to practice medicine in European countries, full reciprocity with the United States does not exist for American DOs or MDs. Application for licensure is made on an individual basis.

The following is an overview of osteopathy in Europe by country.

FRANCE

In 1951, the French School of Osteopathy (Ecole Francaise d'Osteopathie) was opened in Paris as a postgraduate training course for physical therapists and medical doctors. The faculty mainly consisted of individuals from the United Kingdom, and because osteopathy was illegal in France, the school was forced to move to the United Kingdom in 1965 (T. Dummer, *personal communication*, 1999). It was initially hosted by the British College of Naturopathy and Osteopathy, but remained a French-speaking part-time course for health professionals. In 1968, the school relocated to Maidstone, England, and in 1971 became the Ecole Europeenne d'Osteopathie. Until 1974, the school functioned solely as a French-speaking part-time course. That same year, it opened its full-time English-speaking 4-year program and became the European School of Osteopathy (Collins, 2005; T. Dummer, *personal communication*, 1999). The school continued its French-speaking part-time course until 1987. The postgraduate part-time course of the Ecole Francaise d'Osteopathie became a model of osteopathic training for nonmedical health care professionals in France in the 1980s and 1990s. During this time, many schools opened throughout France and with them several voluntary registries. The registries tended to be associated with a school or area, and each had its own criteria and standards for training and practice. In 2002, the practice of osteopathy by nonphysicians was recognized in France, and as of 2008 standards for competency rules governing curriculum and scope of practice had been developed (Ducaux, 2008).

Robert Maigne was a French MD who studied at the London School of Osteopathy while Myron Beal, D.O., FAAO was on faculty. Maigne was active in FIMM and brought an osteopathic perspective to that group. In 1975 Myron Magen, D.O., the dean of MSUCOM met with Maigne and other FIMM representatives to negotiate attendance of American DOs at their meetings. In 1977, Robert Ward and Philip Greenman were the first American-trained DOs to attend a FIMM meeting. This was done by special invitation. At that meeting, Greenman and Ward established relationships with Karel Lewit (Czech), Vladimir Janda (Czech), and Heinz-Deiter Neumann (German), leaders in the manual medicine world, which provided the foundation for future collaborations. French physicians were able to obtain osteopathic training through periodic lecture, workshops, and presentations. Several groups were established to provide osteopathic training opportunities for their members after completion of a FIMM-recognized certificate in manual medicine. In France in 1998, the Diploma of Manual Medicine and Osteopathy was developed for medical doctors. Reportedly 13 of the medical universities in France may grant this diploma (Baecher, 1999).

BELGIUM

In 1998, the Belgian Parliament brought forth a bill, which was passed in 1999, to recognize the practice of osteopathy. Standards for training nonphysician osteopaths were also developed. The practice of osteopathic medicine was not specifically covered in the bill, although MD physicians trained in manual medicine may use osteopathic techniques as part of their scope of practice. There is no specific provision for American-trained DOs to obtain full practice rights in Belgium however (AAO International Affairs Committee, 2000).

GERMANY

German law allows medical doctors to practice osteopathic medicine as part of their scope of practice. Medical doctors are trained as osteopathic physicians through programs that share core competencies with the U.S. osteopathic schools and are recognized by the German Manual Medicine Association, the OIA, and the World Osteopathic Health Organization. Graduates of these programs are affiliated with one of the osteopathic medical associations such as the Deutsch German Society for Osteopathic Medicine and the Deutsch American Association of Osteopathy. The European Register for Osteopathic Physicians was created in 2003, and currently osteopathic physician groups in France, Germany, and Switzerland share a common standard for training and examination. At the time of this writing, American-trained DOs have been able to obtain license to practice medicine in Germany.

In Germany, both part-time and full-time training programs are available for physiotherapists and other nonmedical professionals. Some of these are affiliated with universities and offer the equivalent of bachelor or master degrees. There are also several voluntary registries and societies for practicing osteopaths. Non-physician osteopaths may practice osteopathy under the rules governing *heilpraktika* (traditional healers), although osteopathy as a profession is not legislated.

SWITZERLAND

As in Germany, the practice of osteopathic medicine falls within the scope of practice of Swiss manual medicine physicians.

The Swiss Society of Osteopathic Physicians was formed in 2003. It adapted the same curriculum for osteopathic medicine as is used by the German medical groups. Physiotherapists in Switzerland can enter full-time and part-time programs to train as osteopaths. Several cantons have recognized the practice of osteopathy by non-physicians, but specifics of training and scope of practice have not yet been finalized. In 2007, the various registries for the osteopathic medical profession came together to try to create a single cohesive group that could legislate more effectively (Rudolf, 2008).

RUSSIA

Manual medicine is a component of medical training in Russia. Osteopathic philosophy and practice was brought to Russia via U.S.- and U.K.-trained osteopaths and osteopathic physicians such as Viola Frymann. Currently, the practice of osteopathic medicine falls under the purview medical doctors in Russia, although there is no specific legislation. There are schools in St. Petersburg, Moscow, and Vladivostok. The programs are designed for fully trained physicians and generally last 2 to 3 years. U.S.-trained DOs can apply for licensure with a sponsor such as a hospital, business, or school.

JAPAN

Osteopathic philosophy, principles, and techniques were introduced to Japan in the early 1900s. There is at least one Japanese book preserved from 1910, written by Yamada, which describes natural methods of healing, with a focus on manual therapy that includes mention of osteopathy. The study of osteopathy in Japan was promoted by post-World War II lay healers and bonesetters, as well as by oriental medical doctors and acupuncturists. In the 1970s and 1980s, small groups of Japanese traveled to England and America to attend introductory seminars in osteopathy, and osteopaths from England and osteopathic physicians from America were invited to Japan to give short seminars introducing osteopathy to a variety of professionals as well as the lay public.

In 1986, Viola Frymann, D.O., F.A.A.O., and President Philip Pumerantz, Ph.D., representing the College of Osteopathic Medicine of the Pacific in Pomona, CA, presented a 3-day seminar in Tokyo, which was the beginning of the development of formal training programs. Shortly thereafter, representing the Kirksville College of Osteopathic Medicine in Missouri, President Fred Tinning, Ph.D., and Michael Kuchera, D.O., F.A.A.O., visited Tokyo and presented seminars and appealed to the Japanese government to allow osteopathic medicine to become a regulated and accepted practice. John Jones, D.O., also visited the Japanese government with the same plea a few years later, but, also, to no avail.

In the mid-1990s, the first college of osteopathy, the Japan College of Osteopathy, was established. It consists of a three-year curriculum and graduates are granted the Diplomate in Osteopathy degree. Since there is no Japanese osteopathic licensing board or regulating body, its graduates practice osteopathic manual therapy under the auspices of another professional license, such as bonesetter or oriental medical doctor.

There are many supportive osteopathic associations in Japan. From 1996 to 1998, through the AAO, Michael Seffinger, D.O., facilitated the collaboration among three of the larger societies. Along with consultation from Dr. Frymann and members of the AAO International Affairs Committee, he encouraged the formation of the Japan Osteopathic Federation (JOF). The JOF

was incorporated in 1998. It immediately implemented a formal training program and certification mechanism in order to establish a self-regulating body for the practice of osteopathy in Japan. Applicants that meet the criteria for certification are given the status of Member of the Registry of Osteopathy—Japan (MRO-J) designation, which entitles them to participate in JOF-sponsored seminars and courses. Members are licensed professionals who have taken a prescribed number of hours of a variety of osteopathic manipulation courses, and passed standardized written, oral, and practical examinations. There are over 400 members of the JOF and over 150 certified (MRO-J) Japanese osteopaths.

The osteopathic profession in Japan is growing slowly but steadily. Although most of the proponents and leaders have been licensed professionals from other disciplines, this past decade has witnessed an increase in foreign-trained DOs emerging as leaders, developers, and organizers of the profession. In 2008, for instance, a Japanese native and graduate of Still University, Kirksville College of Osteopathic Medicine in America, opened a second college of the osteopathic medical profession, Atlas College of Osteopathy, near Tokyo. Several Japanese have graduated from the British osteopathic schools and are back in Japan helping to teach and develop the profession. Additionally, several Japanese MD, led by long-time proponents of the osteopathic medical profession, and an orthopedic surgeon in Tokyo who learned the osteopathic medical profession through decades of seminars both in Japan and abroad, practice osteopathic manual therapy in various parts of the country.

Introduction: The Body in Osteopathic Medicine— the Five Models of Osteopathic Treatment

FRANK H. WILLARD AND JOHN A. JEROME

The Basic Science section of the third edition of the Foundations for Osteopathic Medicine has two major changes from the first two editions. First, to form the background for this edition of the Foundations, we have adopted the five models of patient diagnosis, treatment, and management frequently used by osteopathic clinicians.

The five models are:

1. Biomechanical model
2. Respiratory-Circulatory model
3. Neurological model
4. Metabolic-Energy model
5. Behavioral model

These five models are commonly used in physical evaluation, diagnosis, treatment, and patient management. A detailed explanation of the five models and their application in osteopathic medicine can be found in Chapter 1 of this edition of the Foundations. To best provide an understanding of the five models, all but three of the chapters in the Basic Science and Behavioral Science sections from the second edition have been completely rewritten or replaced by new material. In addition, the Basic Science chapters and the Behavioral Science chapters have been consolidated into one section, a move that reflects the editor's strong belief that the integration of body and mind lies at the heart of osteopathic medicine.

ORGANIZATION OF MATERIAL IN THE BASIC SCIENCE SECTION

Chapter 06: The Concepts of Anatomy

The Basic Science section begins with a chapter on anatomy since this discipline, of all sciences, is most fundamental to osteopathic medicine. This chapter represents a consolidation of the two anatomy chapters from the previous editions of the Foundations text. The authors (L. Towns and W. Falls) have articulated four concepts that underpin the study of anatomy. A sound knowledge of anatomy is paramount to understanding the application of the five models in osteopathic medicine.

Chapter 07: The Fascial System of the Body

This chapter specifically focuses on the fascias of the body, which play an important role in palpatory diagnosis and osteopathic manipulative treatment. The fascias are also particularly significant within the concepts of the biomechanical and respiratory/circulatory models. Yet while fascia is typically referred to in textbooks of anatomy and manual medicine, it is very rarely defined. To add insult to injury, anatomy texts often decompose fascia sheets into small isolated regions with various eponyms. In attempt to answer these needs, the authors (F.H. Willard, C. Fossum, and P.R. Standley) offer a pragmatic definition of fascia that can easily be applied to any tissue in the body in an effort to determine whether it should be termed fascia or not. Chapter 7 also attempts to consolidate all fascias into four primary fascial layers in the human body; the

composition of each layer based on its distribution and function. This approach emphasizes the unity of fascia in the body. Finally, the chapter surveys some of the major cell types present in fascia and reviews their functions, including the very interesting myofibocyte.

Chapter 08: Biomechanics of the Musuloskeletal System

The chapter on biomechanics by M. Wells has been included in its entirety from the second edition of the Foundations text. The chapter succinctly applies the rules of biomechanics to the muscles, bones, and joints of the musculoskeletal system in a way that is most helpful in understanding the biomechanical model in osteopathic medicine.

Chapter 09: Somatic Dysfunction, Spinal Facilitation, and Viscerosomatic Integration

Central to the concept of osteopathic medicine is somatic dysfunction and its influence on the spinal cord, termed spinal facilitation. Somatic dysfunction plays a key role in the biomechanical and neurologic models and strongly influences the respiratory/circulatory, metabolic-energy, and behavioral models. Working from their previous chapters that appeared in the first and second editions of Foundations, the authors (M. Patterson and Robert D. Wurster) have updated and expanded the concept of somatic dysfunction and its influences on both the somatic and the visceral systems of the body.

Chapter 10: Autonomic Nervous System

The link between the somatic and the visceral systems of the body is very strong and has a major impact on the all of the five treatment models. This link lies at the heart of many referred pain patterns as well as the referral of dysfunction patterns between the musculoskeletal and the visceral systems; between visceral organs in the various body cavities; and between various musculoskeletal tissues. Understanding this link requires practical knowledge of the anatomy of the autonomic nervous system; the bridge between the somatic and visceral tissues. The chapter on the Autonomic Nervous System present in the previous two editions of this text provides a map for translating clinical findings into diagnostics using the integration of the somatic and visceral nervous system. For that reason, the chapter has been retained in the third edition of Foundations; however, the author (F.H. Willard) has significantly revised the figures to allow correlations with *Grant's Atlas of Human Anatomy* (A.M. Agur and A.F. Dalley. *Grant's Atlas of Anatomy*. Philadelphia, PA: Lippincott Williams & Wilkins, 2009).

Chapter 11: Physiological Rhythms/Oscillations

The human body has many intrinsic oscillating rhythms, some of which well-trained osteopathic physicians can detect through palpation. In Chapter 11, the authors (T. Glonek, N. Sergueef, and K. Nelson) examine the myriad of oscillating rhythms known to

exist in a human. These rhythms are central to the respiratory/circulatory model in osteopathic medicine. The authors also describe their work using the noninvasive instrumentation of human subjects to record multiple oscillating rhythms as well as study the possible modification of specific rhythms using osteopathic techniques of manipulative medicine.

Chapter 12: Anatomy and Physiology of the Lymphatic System

A major component of the respiratory/circulatory model is the movement of low-pressure fluids through the tissues of the body. A key component of low-pressure fluid dynamics is the lymphatic system. A new chapter summarizing current knowledge of lymphatic system anatomy and physiology has been added to this edition of the Foundations. The authors (H. Ettlenger and F. Willard) begin by describing the movement of lymphatic fluid into the terminal lymphatic vessels. This is followed by a discussion of the anatomy of the lymphatic vascular system and the physiology of movement of lymph. The significance of osteopathic manipulative treatment and its potential effects on the lymphatic system forms the final portions of this chapter.

Chapter 13: Mechanics of Respiration

The respiratory/circulatory model relies on the mechanical movement of the body walls to perfuse the lungs with air and to assist in moving fluid in and out of tissue. Over the past 10 to 15 years, research has greatly altered the understanding of the biomechanics of the respiratory muscles. To address these issues, Chapter 13, “The Mechanics of Respiration” was added to this section in this third edition of Foundations. In this chapter, the author (F. Willard) presents a review of the major groups of primary respiratory muscles and their influence on the fibroelastic cylinder that represents the thoracoabdominal wall. The chapter ends with a discussion of the thoracoabdominal diaphragm and its role in both respiration and movement of lymphatic fluid from the abdominal cavity.

Chapter 14: Touch

Nothing is as important to the skilled osteopathic physician as the concept of touch. The joining of two individuals through physical contact facilitates diagnosis, treatment, and trust; it is central to each of the five models. With this in mind, a chapter devoted to the physical and emotional aspects of touch has been added to this third edition of Foundations. In this chapter, the authors (F. Willard, J. Jerome, and M. Elkiss) examine the significance of touch for the osteopathic physician and the patient. The physical process of touch from the peripheral receptor to the representation of touch information on the cerebral cortex is reviewed. A distributed network of information processing is described that can function to integrate somesthetic stimuli with primary senses such as visual or auditory to develop an emerging image representing the touch, the touched object or the significance of the touch. Further interactions of this network with areas of prefrontal cortex allow the formation of a palpatory or tactile memory. All of palpatory diagnosis is predicated on previously formed tactile memories; acquiring these memories is a process critical to the development of skills in the osteopathic physician-in-training. The chapter concludes by demonstrating how this distributed cortical network integrates emotional components of our brain to place a meaningful balance on the experience of touch and how this can be very impactful on

the physician-patient relationship thereby significantly influencing the outcome of treatment protocols.

Chapter 15: Nociception and Pain: The Essence of Pain Lies Mainly in the Brain

Pain can impact all aspects of the five models in osteopathic medicine. Pain can influence muscle tone and alter mechanical function. It can sensitize areas of the nervous system creating enhanced painful states. Pain can influence breathing and alter heart rate, changing circulatory mechanics. Pain can induce the secretion of stress response hormones vastly impacting systemic metabolism. Finally, pain influences psychological states and behavior; the concept of “self and other” changes in extreme states of pain. Our knowledge of acute and chronic pain and their etiologies is changing rapidly; thus, this edition of the Foundations has a completely rewritten chapter on pain mechanisms. The authors (F. Willard and J. Jerome) begin with the origin of nociception in peripheral tissue and follow the process through the spinal cord and brainstem to the forebrain and the emergence of the feelings of pain. This chapter should provide an important background for the osteopathic physician to understand the origin of pain in their patient as well as their patient’s response to the presence of this pain.

Chapter 16: Chronic Pain Management

A pain pattern, once it has become chronic, can be very difficult to manage. As the knowledge of chronic pain etiologies grows, treatment possibilities expand. For this reason, the Chronic Pain Management chapter has been completely rewritten from the previous editions. The authors (M. Elkiss and J. Jerome) build the chapter on the basic science of pain perception and neuronal sensitization described in Chapter 15. An emphasis is placed on the integrated response of the neuromusculoskeletal, endocrine, and immune systems to states of chronic pain. The close relationship between the development chronic pain and that of depression is considered. Finally, the role of osteopathic assessment of chronic pain is described as a dynamic process using multifaceted approaches centered on the behavioral model and having a strong focus on the place of the patient in their life cycle.

Chapter 17: Psychoneuroimmunology—Basic Mechanisms

In the past 20 years, the understanding of the relationship between physical and psychosocial stressors and specific disease states has expanded rapidly. It is now apparent that a patient’s general health—somatic, visceral, and psychosocial—can suffer significantly in response to chronic or uncontrolled activation of a complex stress response system—a situation termed allostasis to separate it from the normal homeostatic functions of the body. The first edition of Foundations reviewed the hypothalamic-pituitary-adrenal axis and the neuroendocrine immune basis of stress-related disease, while the second edition extended this concept of allostasis into the clinical realm. In the third edition, the author, J. Jerome expands on earlier versions with new information to emphasize the strong relationship between inescapable stressors and the progressive deterioration of homeostasis, which manifests as worsening of various musculoskeletal, visceral, and psychiatric diseases. In essence, dysregulation in the behavioral model can have significant impact on all four of the other models especially the metabolic model; therefore, a particular emphasis is placed in this

chapter on the behavioral and psychiatric manifestations of stress and their impact on the general health of the patient.

Chapter 18: Psychoneuroimmunology—Stress Management

Stress management involved a multifaceted approach to the patient physical and psychological status. In this chapter, the authors (J. Jerome and G. Osborn) build on the basic material outlined in Chapter 18 to develop a distinctly osteopathic approach to stress management, taking into consideration somatic dysfunctions as well as psychological stressors. The chapter uses the behavioral model to develop insights into the treatment and management of depression, anxiety, alcohol abuse, and insomnia from an osteopathic prospective.

Chapter 19: Life Stages—Basic Mechanisms

Understanding the impact of disease across the life cycle of a human involves knowledge of the composition of human life stages and their changing profiles from preterm to geriatric stages. In essence, this process represents the penultimate application of the five models of osteopathic medicine. Each stage in life is impacted by genetic and environmental factors; as the life stages change, the

susceptibility to disease changes. For this reason, the final chapter in the basic science section is a survey of the life stages in human development, dealing with growth from birth to death. The authors (J. Megan, A. Ley, D. Wagenaar, and S. Scheinthal) meticulously examine the prenatal, infant, school-aged, adolescent, adult, and geriatric stages of life. At each stage in the life cycle, the unique vulnerabilities inherent in the associated physiological changes in each of the first four models are tied to the changes occurring in behavioral model. Viewed through this continuum of life, a better appreciation of human health and disease can be developed.

SUMMARY

The material in the basic science section of the third edition of the *Foundations for Osteopathic Medicine* has been chosen to provide a background understanding of the five models used in diagnosis, treatment, and management by osteopathic physicians. The journey begins with anatomy, fascia, biomechanics, respiration, lymphatics, and oscillating rhythms from which it progresses through such neurological items as somatic dysfunction, viscerosomatic integration, touch, nociception, and acute and chronic pain to end with a strong emphasis on the behavioral model. Knowledge of this material will best provide the future students of osteopathic medicine with the foundations of their profession.

The Concepts of Anatomy

LEX TOWNS, ALLEN W. JACOBS AND WILLIAM M. FALLS (SECOND EDITION)

KEY CONCEPTS

- Early developmental events are reflected in the organization of the adult body.
- Common cellular anatomy imposes anatomical constraints on body structure and function.
- Movement is a defining feature of the living state.
- Body unity is imposed by those structures that interconnect distant parts of the body.

INTRODUCTION

Understanding anatomy is fundamental to the rational practice of medicine. To assess health and disease, physicians must have a detailed knowledge of the structures of the body. A physician's comprehensive anatomical knowledge may be restricted to the particular body area or functional system that he or she uses in a specialized practice. However, effective physicians, even those in specialized practices, need and use a working knowledge of the reciprocal, interactive nature of the body's structure and function. Osteopathic physicians need sufficient knowledge of body structure and function to understand how focal destructive causes may not only lead to localized effects but may also contribute to more subtle, widespread, or distant degenerative, morbid events. The reward for mastering anatomy is to develop the ability to practice medicine—especially osteopathic medicine—in a more intelligent, predictable, and effective manner.

This chapter does not attempt to thoroughly review anatomy. Numerous excellent books and programs are available on human anatomy, and the effective methods of teaching anatomy vary from school to school. The purpose of this chapter is to provide the beginning student with some conceptual bases to guide the study of anatomy and thereby to help maximize the positive impact of anatomical knowledge on the eventual osteopathic medical practice.

Learning the seemingly enormous amount of anatomical detail can be daunting—the oft-repeated “drinking from a fire house” metaphor comes to mind—but there are some simplifying ideas that, if clearly understood, will make the task of comprehending anatomy both easier and more durable. Here, we introduce *four concepts* that we intend to assist in the mental organization of the anatomy of the body: *first*, early developmental events are reflected in the organization of the adult body; *second*, common cellular anatomy imposes anatomical constraints on body structure and function; *third*, movement is a defining feature of the living state; and *fourth*, body unity is imposed by those structures which interconnect distant parts of the body.

We will generally focus on the musculoskeletal system in this overview. However, the principles to be described apply throughout the study of anatomy, and we will point out some instances of more universal application.

NEUROMUSCULOSKELETAL DEVELOPMENT

Understanding the developmental history of the body is the first topic that truly assists the learning of gross anatomy. Principles

of gross anatomy—general rules of where structures are and how they relate to other structures—are predicated on the way the body develops. Thus, understanding general developmental events will greatly enhance the comprehension and retention of the anatomy of the mature form.

At about four weeks of gestation, the embryo is a flat disc composed of three cell layers. The outer layer, ectoderm, will form principally skin and most of the nervous system. The middle layer, mesoderm, will form mainly muscles and bones, and the inner layer, endoderm, will form most of the internal organs. All organs and tissues of the body will develop by differentiation and growth of these three cell layers.

As development continues, the cells of the middle layer—called mesenchyme at this early stage—begin to form into a series of bilaterally symmetric clusters of cells; each cluster is called a somite. The formation of pairs of somites begins in the cervical region and proceeds caudally until about 38 separate pairs of somites are formed. The mature organization of the musculoskeletal system is a direct reflection of the embryologic development of segmental somites.

Each somite differentiates into two parts: a sclerotome and a dermomyotome (Fig. 6.1). The sclerotome will form the bones and cartilages of the axial skeleton (vertebrae and ribs), and two things form from the dermomyotome: the “dermo” part becomes the dermis of the skin and the myotome will form the axial muscles (muscles of the trunk).

As somites form in the middle layer of embryonic cells, related developmental events are taking place in the overlying ectoderm. The ectoderm becomes grooved in the midline, and the edges of the groove then move together until a tube is formed. The tube—now called the neural tube—is the embryonic precursor of the spinal cord. Ectodermal tissue adjacent to the neural tube is called the neural crest and is the precursor of elements of the peripheral nervous system.

As each somite of the trunk forms, there is a simultaneous segmentation of the adjacent part of the neural tube. Sensory and motor nerves of a specific part of the developing spinal cord will be segmentally related to an adjacent developing somite. Thus, a close correspondence is maintained between the developing segments of the body wall and the central nervous system (CNS) (Figs. 6.2 and 6.3). While the close coherence between the spinal cord and the truncal musculoskeletal system is maintained by these developmental events, anticipating topics of visceral-somatic relationships to be discussed below, it is useful to point out that there is also a relationship between the developing thoracic and abdominopelvic organs and the spinal cord. As a result, the nervous

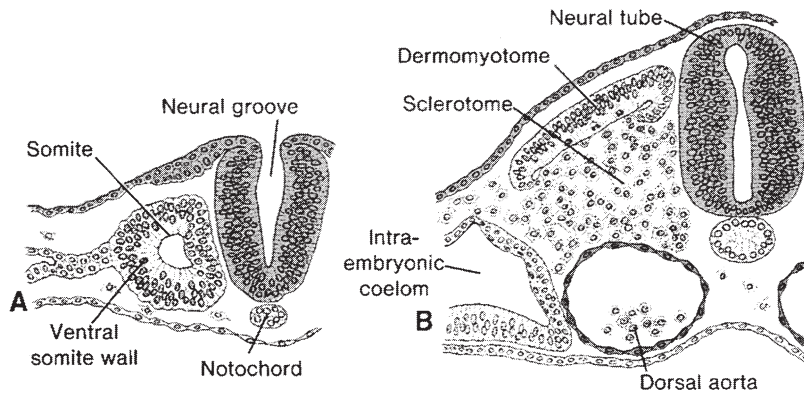

Figure 6-1 A and B. Transverse sections showing differentiation of a somite in relation to development of neural tube.

system provides the link between the somatic tissue of the trunk (i.e., bones and muscles) and the viscera (i.e., heart or gastrointestinal system). This segmental relationship between the body wall and internal organs is hypothesized to be the underlying mechanism for referred pain—perceiving pain on the body wall (i.e., chest pain) when the tissue damage is in an internal organ (i.e., cardiac ischemia).

Development of the Trunk

Segmentation—the result of embryonic somitic and neural development—is most obvious in the adult through levels of the thorax and abdomen. Each thoracic myotome will further divide into an epimere and hypomere. The mesenchymal cells in the epimere become the deep back muscles in the adult, while the mesenchymal cells in the hypomere become the muscles of the anterolateral wall of the thorax and abdomen (Fig. 6.3).

A typical transverse section through the thoracic region demonstrates the basic segmental organization (Figs. 6.3 and 6.4). Throughout the thoracic region, each segmental level is organized symmetrically about a central axis composed of the vertebra and spinal cord. Emanating from the spinal cord at each segmental level will be a pair of spinal nerves that distribute principally to the skin, bones, and muscles derived from that segment's dermatomyotome.

The typical spinal nerve is formed by the union of the ventral (motor) and dorsal (sensory) roots just lateral to the spinal cord. Within a short distance, each spinal nerve divides to form a

posterior primary ramus and an anterior primary ramus (Fig. 6.4). Each ramus contains both sensory and motor nerve fibers. The posterior primary rami of thoracic and lumbar spinal nerves are distributed to the deep (“true”) back muscles, the joints which the muscles functionally move and the skin over these muscles. The anterior primary ramus in the thoracic and lumbar regions innervates the muscles of the body wall (i.e., intercostal and abdominal muscles) and the skin of the thorax and abdomen. The pattern of thoracic and abdominal nerve distribution is clinically demonstrated as the dermatomes—restricted areas of the skin served by individual spinal nerves (Fig. 6.5).

As will be typical throughout the body, there is also a segmentation of blood supply to the thoracic and abdominal wall that is similar to segmentation of muscles and nerves. For example, in the thoracic region, the aorta gives rise to right and left posterior intercostal arteries, which supply the thoracic and abdominal walls segmentally (Fig. 6.4). This area of supply includes the skin, superficial and deep fascia, intercostal and abdominal musculature, ribs, vertebrae, and paravertebral musculature. This parallel segmentation of nerves and vessels is readily seen on the inferior surface of each rib where a neurovascular bundle, which includes the intercostal nerve, artery, and vein (as well as segmental intercostal lymphatics) is located (Fig. 6.4). These structures supply and drain the muscle, connective tissue, and skin within and over the thorax and abdomen.

The segmental pattern of neurovascular distribution in the thorax and abdomen is an example of developmental segmentation that

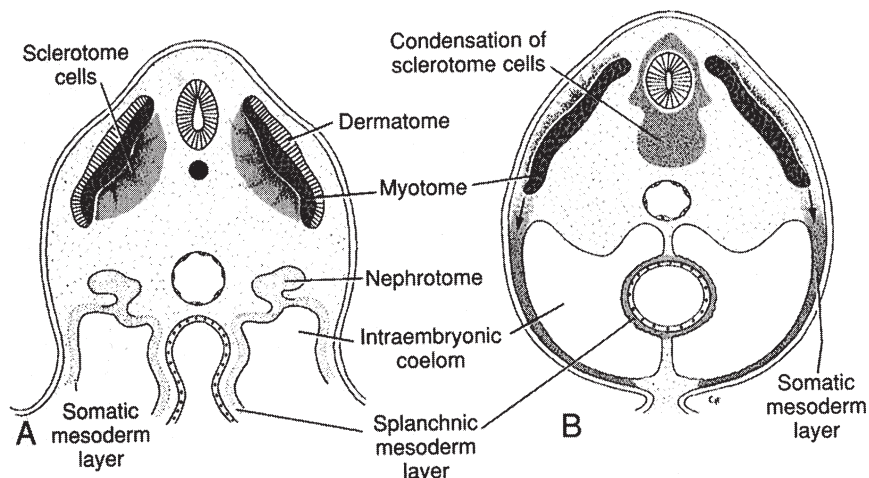

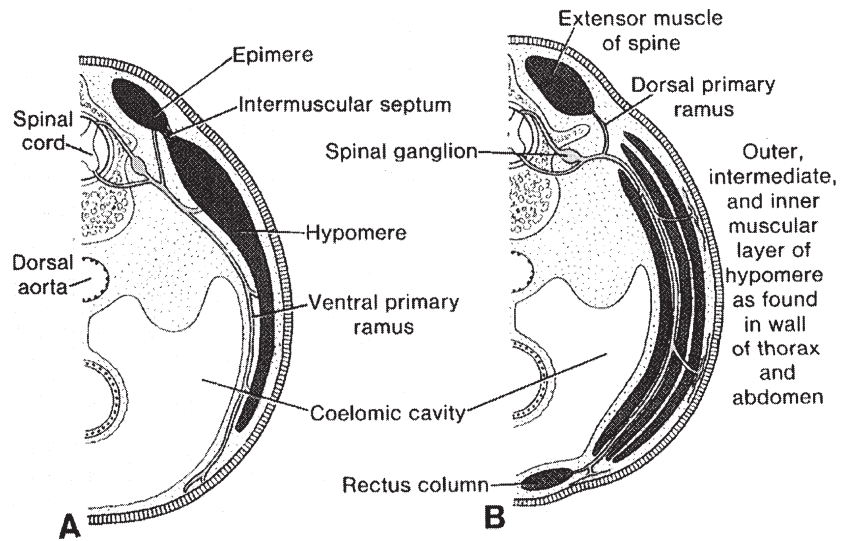

Figure 6-2 A and B. Transverse sections showing migration of cells from sclerotome and myotome during development.

Figure 6-3 A and B. Transverse sections showing segmental nerve from developing spinal cord and innervating developing musculature of thorax and abdomen.

the body maintains in the adult. However, this segmental pattern is modified in the limbs by differential growth and development.

Development of the Upper and Lower Limbs

Segmentation and the results of early embryonic segmentation are not as readily apparent in the adult limbs. Nevertheless, keeping the original segmentation in mind will help you understand the overall anatomy of the limbs. The anatomy of the upper and lower limbs is comparable. The limbs are divided into four major parts. The upper limb is divided into the shoulder (shoulder girdle), arm, forearm, and hand; while the lower limb consists of the pelvic girdle, thigh, leg, and foot.

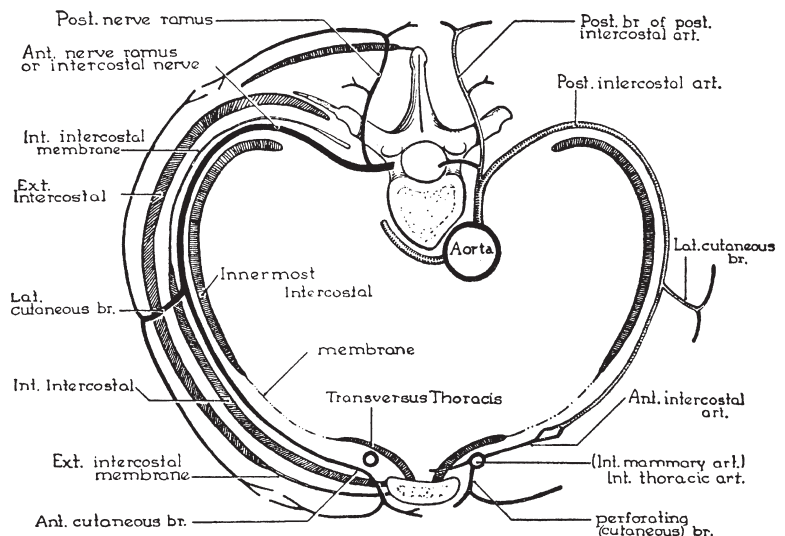

The upper and lower limbs develop from localized enlargements of mesenchyme—limb buds; the limb buds of the upper limb develop from lower cervical and upper thoracic segments (C5-C8 and T1), while the lower limb buds develop from lower lumbar and upper sacral segments (L2-L5 and S1 and S2). The hypomere of the mesenchyme at each of these levels will form bone, connective tissue, and muscle of the limb. As the limb bud expands, anterior primary rami of spinal nerves grow into the developing limb, thus maintaining a segmental correspondence between the developing

limb and the spinal cord (Fig. 6.6). However, through differential limb growth and development (e.g., mesenchymal cells from different segments combining to form a single muscle in the adult), the initial segmental representation of the embryo is modified in the adult.

The bones of the upper and lower limbs arise *in situ* in the developing limb buds. They begin as mesenchyme that condenses and differentiates into hyaline cartilage models of the future bones. These cartilaginous models eventually ossify through a complex process of endochondral ossification. Limb musculature is also derived from mesenchyme but, unlike that which form the bones, muscle mesenchyme is derived from somites adjacent to the developing neural tube and migrates into the limb bud from the hypomere where it condenses adjacent to the developing bones (Fig. 6.6). As the limb elongates, the muscular tissue splits into flexor (anterior) and extensor (posterior) components. Initially, the muscles of the limbs are segmental in character, but in time, they fuse, migrate, and are composed of muscle tissue from several segments. Upper limb buds are opposite neural tube (spinal cord) segments C5-C8 and T1 while lower limb buds lie opposite segments L2-L5 and S1 and S2.

As the limbs grow, posterior and anterior branches derived from anterior primary rami of spinal nerves penetrate into the

Figure 6-4 Transverse section illustrating contents of a segmental level through the thorax.

Figure 6-5 Dermatomal maps of body.

developing muscles (Fig. 6.6). Posterior branches enter extensor musculature while anterior branches enter flexor musculature. With continued development, the posterior and anterior branches from each anterior primary ramus unite to form large posterior and anterior nerves. This union of the original segmental posterior and

Figure 6-6 Transverse section showing that muscles (as well as bone and connective tissues) of developing limbs maintain segmental innervation from developing spinal cord.

anterior branches from each anterior primary ramus is the basis for the formation of the brachial and lumbosacral plexuses (Fig. 6.7A, C, D & E) and comes about with the fusion of segmental muscles. The large posterior and anterior nerves are represented in the adult upper limb as the radial nerve supplying extensor musculature, while the median and ulnar nerves innervate flexor musculature (Fig. 6.7A & C). In the adult lower limb, the large posterior and anterior nerves are represented as the femoral and common fibular nerves supplying extensor musculature and the tibial nerve supplying flexor musculature (Fig. 6.7D & E). Contact between nerves and differentiating muscle cells is a prerequisite for complete functional muscle differentiation. The segmental spinal nerves also provide sensory innervation of the limb dermatomes. The original segmental dermatomal pattern is modified with growth of the limbs, but an orderly sequence is present in the adult (Fig. 6.8).

While the development of the upper and lower limbs is similar, there one major difference: the limbs rotate in opposite directions. The upper limb rotates 90 degrees laterally so that the elbow points posteriorly, the extensor musculature lies on lateral and posterior surfaces while the flexor musculature lies on anterior and medial surfaces, and the thumb lies laterally on the anterior facing palm. The lower limb rotates 90 degrees medially so that the knee points anteriorly, the extensor muscles are on the anterior surface while the flexor muscles are on the posterior surface, and the big toe is medial.

These rotations, thus, determine the functions that the limbs will perform in the adult. In the limbs, deep fascia and intermuscular septa connecting with bone separate or compartmentalize groups of muscles (more on this below). The muscles in each compartment share similar functions, developmental histories, nerve and arterial supply as well as venous and lymphatic drainage.

MUSCULOSKELETAL MICROSCOPIC ANATOMY

As discussed above, understanding segmental developmental events provides an organizational framework by which to comprehend and utilize knowledge of the mature musculoskeletal system. Similarly, a basic understanding of the tissues of the musculoskeletal system provides a conceptual framework through which to understand the mechanisms of health and disease as manifest in body movements. The cellular and extracellular components of the musculoskeletal system are generally classified into two groups: connective tissue and muscle.

Connective Tissue

The connective tissues of the body are derived from mesenchyme. These developing tissues (connective tissue, bone, and cartilage) contain cells (fibroblasts, osteoblasts, and chondroblasts), which produce a matrix of ground substance and fibers that surround the cells. Each type of connective tissue has a unique arrangement of

cell types within a specific matrix of ground substance and fibers. By changing these three elements (cells, ground substance, and fibers), the variable composition and consistency of each type of connective tissue in the musculoskeletal system is produced. Thus, all connective tissue can be classified on the basis of the arrangement of these three elements.

Loose connective tissue forms an open meshwork of cells (fibrocytes; fibroblasts) and fibers (collagen, elastic, reticular), with a large amount of fat cells and ground substance in between. Loose connective tissue also surrounds neurovascular bundles and fills the spaces between individual muscles and fascial planes (Fig. 6.9).

Dense fibrous connective tissue is composed predominantly of collagen fiber bundles and is classified as regular or irregular on the basis of the arrangement of the closely packed collagen. Collagen fibers in dense regular connective tissue show a regular arrangement and run in the same direction. Dense regular connective tissue forms the substance of periosteum, tendons, and ligaments. Irregular connective tissue (e.g., periosteum and deep fascia) is composed of collagen fibers that lack such a consistent pattern (Fig. 6.10).

Cartilage and Bone

Cartilage and bone are highly specialized connective tissues in which the ground substance of the matrix is predominant over the cellular and fibrous elements, and thus, cartilage and bone can have a texture that is considerably different from that of dense connective tissue.

The chondroblast is responsible for producing the ground substance and fibers of the three types of cartilage: hyaline (articular; found in synovial joints), elastic (found in the external ear, auditory tube, larynx, and epiglottis), and fibrous (found in intervertebral disks). These three cartilage types vary in histological makeup on the basis of their ground substance and predominant fiber type (collagen or elastin) and are avascular (Figs. 6.11–6.13).

The osteocytes of bone are maintained in a rigid matrix, which is calcified and reinforced by connective tissue fibers, which are produced by the osteoblasts. The structural unit of bone, the osteon (Haversian system), is formed by concentric lamellae of bone surrounding a microscopic neurovascular bundle in the Haversian canal. The osteocytes are located within microscopic spaces (lacunae) between the concentric bone matrix lamellae and extend processes into the matrix (Fig. 6.14).

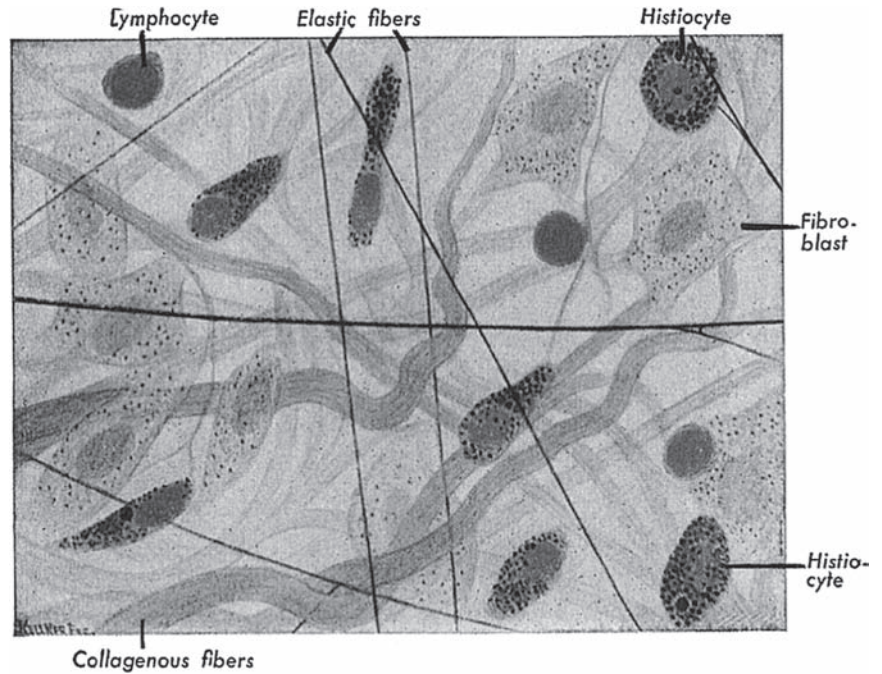

Skeletal Muscle

As described above, skeletal muscle tissue is derived from mesenchyme and is highly modified for the specific function of contraction. The individual skeletal muscle cells (fibers) are arranged in a regular systematic manner to facilitate contraction when stimulated by a nerve impulse. The microscopic appearance of skeletal muscle presents a classic banding pattern, which represents the internal organization of the protein contractile elements in each muscle fiber (Fig. 6.15). The highly differentiated cytoarchitecture of muscle tissue relates closely to the inability of the muscle tissue to heal following injury.

Response to Injury

The inherent capacity of the musculoskeletal system to heal and repair following injury is a direct reflection of the histological organization of connective tissue. At the macroscopic level, the connective tissue invests the neurovascular bundles, which supply specific parts of the body. At the microscopic level, the capillary beds are

Figure 6-9 Cellular elements of loose connective tissue.

located within the open meshwork of loose connective tissue and nourish the cellular elements of the tissue. These cells in turn produce the ground substance and fibers of the connective tissue. Following injury, a complex biochemical reaction results in stimulating the inherent capacity of healing and repair. In general, the more

differentiated any tissue is (i.e., the less it resembles the embryonic tissue from which it was derived), the less capable that tissue is of cell division and, therefore, the less able the tissue is to heal via mitotic addition of new cells following injury. Because of its highly differentiated nature, skeletal muscle and cartilage often repair as a scar mainly composed of irregular dense connective tissue. Bone represents a major exception to this rule. Since bone is actively remodeling in the living state, it will rapidly form a scar following injury and then gradually remodel the scar into the normal architecture of the adult bone. A corollary of this principle on differentiation can be seen in cancerous tissue. Generally, differentiated cells have to dedifferentiate in order to become a malignancy. The more undifferentiated a cell becomes, the more potential it has to divide; thus, some of the most dangerous malignancies are anaplastic lesions in which cells appear to return to a primitive, embryonic-looking state.

Figure 6-10 Cellular elements of dense, regular fibrous connective tissue. Dark fibroblast nuclei lie between bundles of regularly arranged collagen fibers.

FUNCTION OF THE MUSCULOSKELETAL SYSTEM

Understanding the function of the musculoskeletal system remains at the heart of osteopathic medical practice and, so, constitutes a significant portion of most anatomy courses. The musculoskeletal system is approximately 75% of the body mass; this vast system gives stability in health, provides clues to dysfunction and disease, and offers a mode of treatment to support the patient who is diseased or stressed. Osteopathic physicians must understand well the function of the individual components of the musculoskeletal system. This function is seen from two fundamental, complementary perspectives: What action or function does a muscle (joint, bone, ligament, etc.) produce? And, which muscle (joint, bone, ligament, etc.) produces a specific action or function?

Understanding the rule of function in the musculoskeletal system leads inevitably to a series of questions predicated on more complex structural and functional interrelationships: How might dysfunction of the muscle (or other musculoskeletal component) affect total body efficiency and health? How might dysfunction of some visceral element degrade the structural or functional integrity of the musculoskeletal system? And, how are these dysfunctions

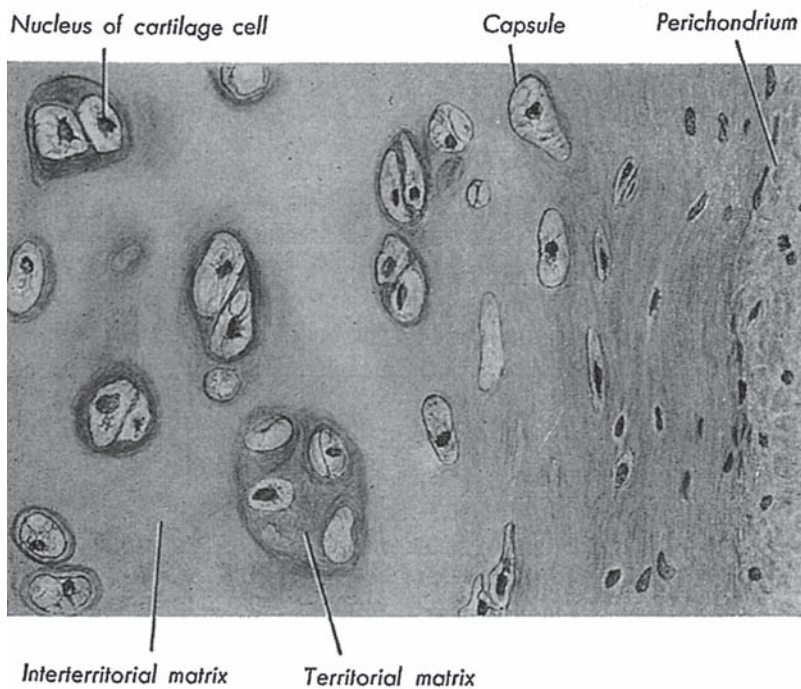

Figure 6-11 Cellular elements of hyaline (articular) cartilage.

segmentally related to other tissues and organ system? These questions form the core of rational osteopathic medical practice.

Muscle Function

A muscle normally contracts because it is stimulated by a motor nerve. A single motor nerve fiber innervates more than one skeletal

muscle fiber. The nerve fiber and all the muscle fibers it innervates are called the motor unit (Fig. 6.16). In general, small muscles that react quickly (e.g., extraocular muscles) have ten or fewer muscle fibers innervated by a single nerve fiber. In contrast, large muscles that do not require fine CNS control (e.g., deep back muscles) may have up to one thousand muscle fibers in a motor unit. When a muscle is resting, some motor units are always discharging. It may

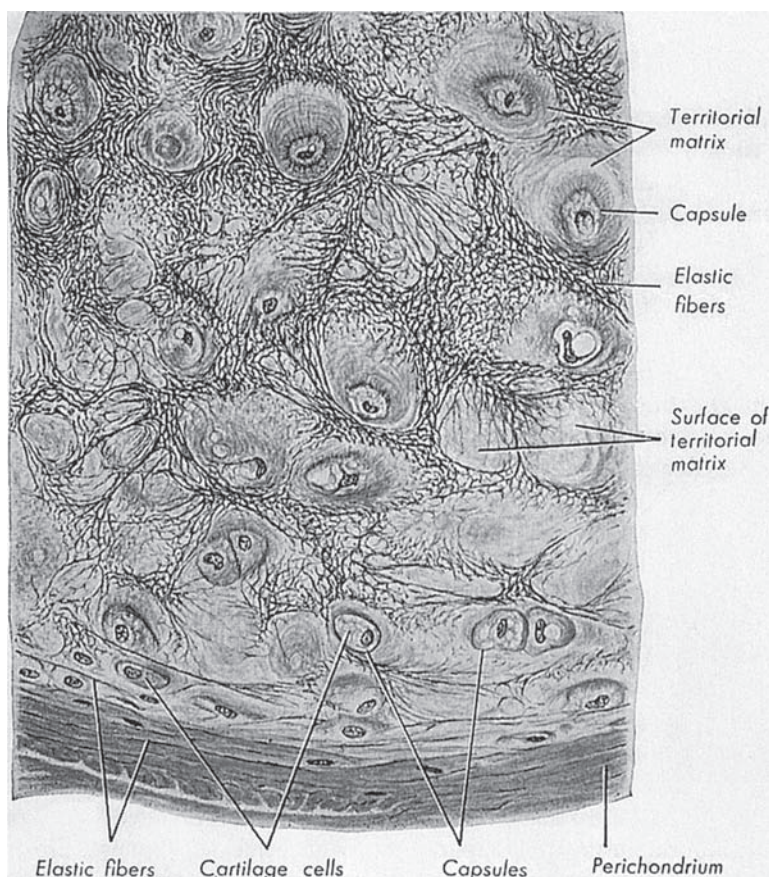

Figure 6-12 Cellular elements of elastic cartilage.

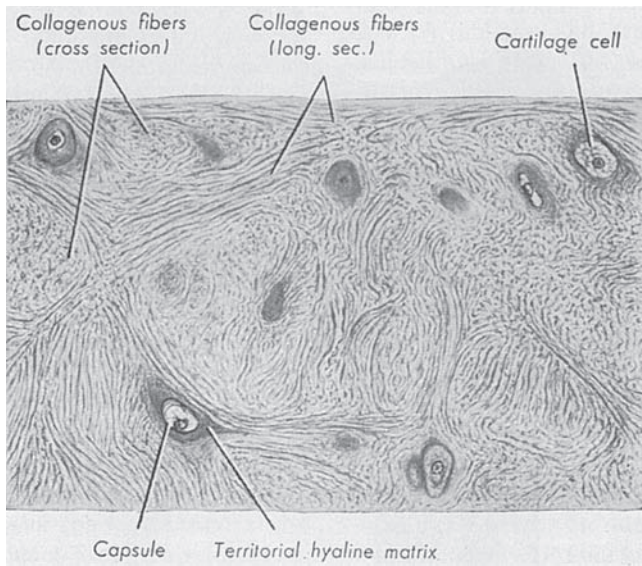

Figure 6-13 Cellular elements of fibrocartilage.

not be the same motor units at each instance in time. This type of motor activity (muscle tone) is the background for muscular contraction in the performance of a purposeful movement.

When most muscles contract, their fibers act through tendons on moveable bones to get the desired action (Fig. 6.17). Movements result in the activation of motor units in some muscles and the simultaneous relaxation of motor units in other muscles. Movement that comes about from muscle contraction causes the muscles to change in length. When this occurs, tension created within the muscle remains constant and the contraction is called isotonic. If movement does not occur as a result of muscle contraction and

muscle length stays constant with elevated tension generated within the muscles, the contraction is called isometric (e.g., posterior compartment muscles of the leg in standing). Isotonic contractions may be concentric (shortening of the muscle) or eccentric (lengthening of the muscle).

Most movements require the combined action of several muscles. The term prime mover is used for those muscles that act directly to bring about the desired movement. Every muscle, which acts on a joint, is paired with another muscle that has the opposite action on the same joint. These muscles are antagonists of each other (e.g., muscles that flex the elbow and muscles that extend the elbow are antagonists of each other). During any movement around a joint, both agonist and antagonists are contracting—the agonist contracts more forcefully to produce movement, but the antagonist maintains some tonus that does not significantly block the action of the agonist, but helps to stabilize the movement. There are times when prime movers and antagonists contract together and are called fixators. This occurs to stabilize a joint or hold a part of the body in an appropriate position. Muscles, which contract at the same time to produce a movement are called synergists. These can be either muscles that aid the agonist in the performance of the desired action or antagonist muscles that contract at the same time as an agonist and thereby prevent unwanted movement that would be counterproductive to the desired action. Individual muscles should not always be considered as units with a single function, and different parts of the same muscle may have different, even antagonistic, actions (e.g., the trapezius).

The function of most skeletal muscles is to produce movement of bones relative to each other. For example, contraction of the arm muscles will cause flexion or extension of the elbow. While emphasis to this point has focused on muscles and bones, we now turn our attention to the site where bones articulate with each other—the joints.

Figure 6-14 Transverse section showing cellular elements of compact bone.

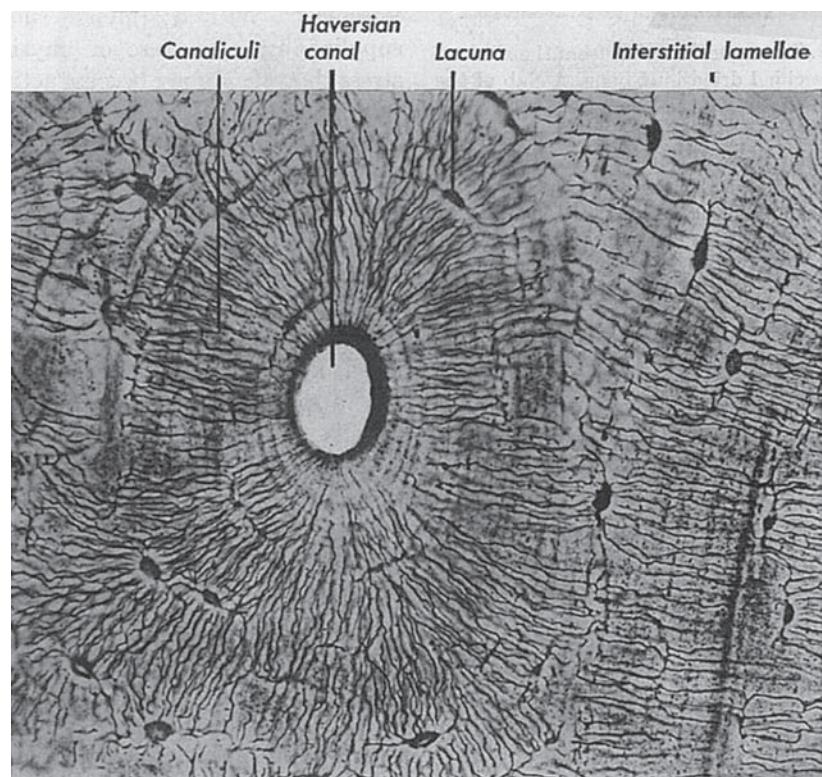

Figure 6-15 Longitudinal section of skeletal muscle showing classic banding pattern found in individual fibers.

Synovial and Nonsynovial Joints

All synovial joints of the body are freely movable and similar in structure. The “typical” synovial joint is exemplified in Figure 6.18. The articular surfaces of the two bones, which form the joint, are covered by hyaline (articular) cartilage, which is specifically modified for the function of articular motion. The two articular surfaces are separated by a monolayer of synovial fluid in the joint cavity. The joint capsule is composed of two layers. The unique inner layer of the joint capsule is the synovial membrane, which lines the fibrous outer layer. This membrane secretes the synovial fluid, which

Figure 6-16 A motor unit.

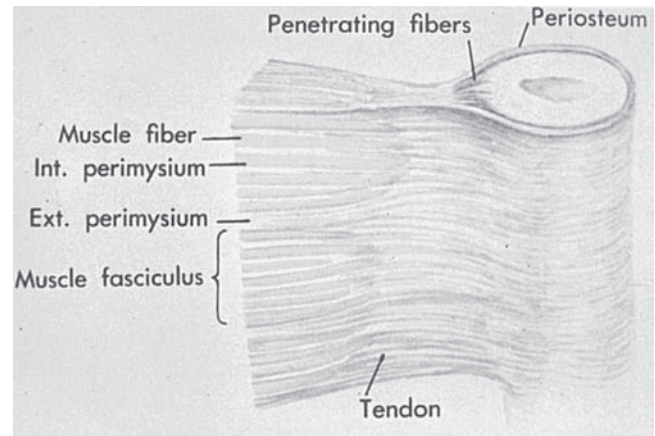

Figure 6-17 Diagrammatic representation of how muscle attaches to bone.

lubricates the internal joint surfaces and the articular hyaline cartilage. The uniqueness of this membrane is that it is derived from mesenchyme. However, microscopically and functionally, this tissue is similar to epithelial tissue, which is an ectodermal derivative.

Each synovial joint is stabilized by specific ligaments. Ligaments may be classified as capsular or accessory. A capsular ligament is a part of the fibrous outer layer of the joint capsule while accessory ligaments are either located within the joint cavity (intracapsular) or outside the joint capsule, separated from the fibrous outer layer (extracapsular). All ligaments are histologically composed of dense regular fibrous connective tissue and have microscopic, structural, and functional continuity with the periosteum of adjacent bone. Some joints (temporomandibular joint or knee joint, for example) are even more specialized as they have the unique feature of either a disk or a meniscus (incomplete disk) within the joint cavity (Fig. 6.19). The fibrocartilaginous disk provides for additional support and stability as it separates the two hyaline cartilage articular surfaces.

Synovial joints are commonly classified according to the shape of the articular surfaces and/or the movements, which are permitted. None of the articular surfaces are truly flat. Biomechanically, these joint surfaces permit motion, which is described as spin, roll, or slide (Fig. 6.20). Spin represents rotation about the longitudinal axis of a bone. Roll is the result of decreasing and increasing the angle between the two bones at an articulation. Slide is the result of a translatory motion of one bone gliding/sliding on the other at the joint. Specific details regarding the classification system and individual synovial joints can be found in any anatomy textbook.

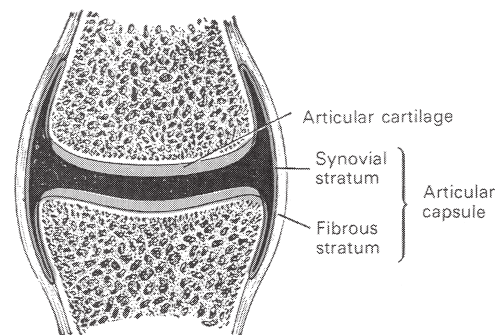

Figure 6-18 Typical synovial joint.

Figure 6-19 Synovial joint with an articular disc.

Nonsynovial joints are subdivided into fibrous and cartilaginous types. These joints where the articulating bones are directly connected by either fibrous tissue or cartilage have no free surface for movement, but provide for strength and stability between adjacent bones. The fibrous joints include the sutures of the skull (Fig. 6.21), teeth in the mandible and maxilla, and the distal tibio-fibular joint. The fibrocartilaginous intervertebral disks between adjacent vertebral bodies and the pubic symphysis (Fig. 6.22) are examples of cartilaginous joints.

The sutures of the skull provide a classic example of the inter-relationship between structure and function. Each suture (joint) between adjacent cranial bones uniquely provides support and mobility. Unlike the freely moveable synovial joints, the sutures are highly restricted to slight gliding motion. However, motion loss/restriction is the clinically significant factor in describing somatic dysfunction of the joint.

Cranial bone motion is also influenced by the tension of the cranial dura mater, which covers the brain and forms the internal lining of the skull. Cranial dura mater consists of two layers: periosteal and meningeal. The periosteal layer is the periosteal lining of the cranium and there is histological continuity of this layer with the fibrous tissue (sutural ligament) at each cranial suture. The meningeal layer of cranial dura mater has continuity with the spinal dura mater (thecal sac) at the foramen magnum of the occipital bone (Fig. 6.23). The direct effect of these connective tissues on cranial bone motion has been described by Sutherland as the reciprocal tension membrane.

In summary, synovial and nonsynovial joints exemplify the osteopathic concept of the inter-relationship between structure and function. Synovial joints, which are freely moveable, allow for the body to have mobility and greater range of motion. The

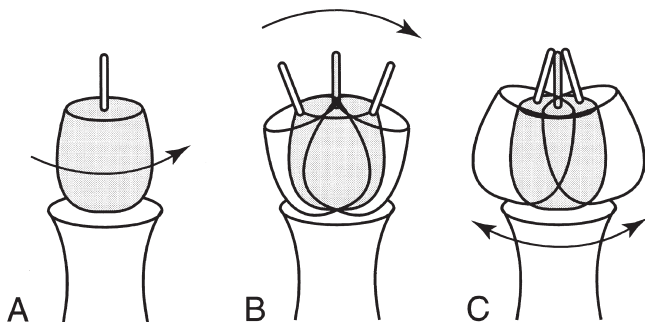

Figure 6-20 Motion at a synovial joint. **A.** Spin. **B.** Roll. **C.** Slide.

Figure 6-21 A suture is an example of a fibrous joint.

nonsynovial joints (fibrous and cartilaginous) provide strength and stability within a limited range of motion.

Joint Play

The voluntary movement of synovial joints is accommodated by joint play as described by Mennell. Joint play is defined as a small but precise amount of movement (<1/8”), which is independent of the action of voluntary muscle function. The normal, easy, voluntary range of active motion at a synovial joint is dependent upon the integrity of joint play. Joint play is only present in the living synovial joint. The movement of joint play can only be demonstrated by passive examination. Each synovial joint has one or more joint play movements. Joint dysfunction is defined as the loss of joint play and therefore a limitation of the voluntary range of motion at a synovial joint. Joint dysfunction is a component of somatic dysfunction (acute or chronic), which is diagnosed in the evaluation of the neuromusculoskeletal system. The restoration of joint play appears to be the basis for the success of synovial joint mobilization using direct or indirect action treatment techniques in osteopathic manipulation.

BODY UNITY

Although to this point we have emphasized the segmental and cellular nature of the human body, in reality, the body is one unified structure. The various regional anatomical and cellular components of the neuromusculoskeletal system—derived embryologically from somites and associated neural precursors—are bound together and unified into a functional whole by arteries, veins, lymphatics, nerves, circulating factors, and fascia.

It has not been customary in modern medicine to point out that the human is a complex, unified organism made up of many overlapping, interconnected systems. Recently, conventional medicine has attempted to reassemble its various specialties and subspecialties, each focused on a body region or functional system, into a holistic understanding of health and disease. Nevertheless, the structure of medicine retains much of its compartmentalization; it is difficult for even the most thoughtful physician, particularly those in a demanding specialty practice, to step back routinely and holistically assess a patient.

A physician’s understanding of body unity and the propensity to view the patient holistically is heightened by remembering a basic unifying principle: although the body is made up of many structurally and functionally discrete elements, the elements

Figure 6-22 A symphysis is an example of a cartilaginous joint.

Figure 6-23 Area of foramen magnum. Cranial dura mater lines the internal surface of cranium, is continuous with fibrous tissue of sutures, and is continuous with spinal dura mater of foramen magnum.

are linked together by a number of connectors. As such, these connectors make up a significant portion of the study of medicine in general and the study of anatomy in particular.

The “connectors” are easily listed; they are connective tissue, the nervous system, the endocrine system, and the vascular and lymphatic systems. The circulatory system serves distant body parts and, among other things, provides a means of communication. The nervous system, although it is traditionally divided into component parts—central, peripheral, autonomic, and enteric—is one continuous, functional entity. The nervous system constantly receives external and internal stimuli filters, sorts and integrates those stimuli, and then produces the coordinated contraction of muscles and/or secretion of glands in response to those stimuli. The nervous system can even impel muscular contraction and/or glandular secretion independent of external stimulation. The endocrine and immune systems, interconnected to each other and to the nervous systems, also bring tissues distant from each other under unified, coordinated control. Indeed, contemporary analyses

suggest that, as the endocrine, immune and nervous systems all use a common set of messengers (e.g., norepinephrine, neuropeptide Y, cholecystokinin, and many others), that they be considered one overlapping system by which body unity is established and maintained.

Connective Tissue

As described above, connective tissue is one important component of the musculoskeletal system. Connective tissue serves both to isolate individual elements of the body and to unify adjacent and distant structures. Connective tissue begins at the molecular level and extends to the gross, macroscopic level.

Connective tissue binds organ to organ, muscle to bone, and bone to bone and literally is the fundamental connector that allows structural and functional systems to be physically grouped into a unified package. Without connective tissue, the body is a dissociated mass of dying cells. It is the connective tissue, most of it a

proteinaceous extracellular matrix, that enforces form and thereby permits function. Connective tissue plays a critical role in body health and disease, but ironically it is so pervasive it is easily overlooked in the study of anatomy, in the maintenance of health, and in the diagnosis and treatment of disease.

Individual skeletal muscle fibers are surrounded by a delicate network of fine connective tissue. At each end of the muscle, this connective tissue forms a tendon composed of dense regular fibrous connective tissue. The tendon is attached to bone through a microscopic interlacing of its connective tissue with the periosteal connective tissue covering of the bone (Fig. 6.17). Each muscle has two parts: a predominant connective tissue at its ends, which attach to bones and a predominance of muscle tissue in its functional contractile belly. The change to connective tissue at its ends provides the muscle a firm attachment to bone.

The musculotendinous junction represents the point at which there is a significant change in the histological composition of skeletal muscle from predominantly muscle fibers to predominantly collagen fibers. Muscle contraction exerts force on the musculotendinous junction and then the tendon, which moves a bone at a joint. The connective tissue of the joint and joint capsule is then connected to and continuous with the connective tissue that surrounds the muscle and anchors the muscle to bone.

Fascia

Fascia is as rather generalized term for sheets or layers of connective tissue that envelop specific structures and segregate one structure, organ, or area from another. For example, throughout the body, there is a subcutaneous layer of loose connective tissue called the superficial fascia (Figs. 6.9 and 6.24). It contains collagen fibers that connect the skin to underlying structures as well as variable amounts of fat. Superficial fascia serves to increase skin mobility, acts as a thermal insulator, and stores energy for metabolic use.

As will be seen in Chapter 7 on the Fascial System, enveloping deep fascia will be defined as irregular dense connective tissue. Deep fascia is the dense connective tissue envelope (also composed primarily of collagen fibers) that both connects and separates individual muscles of the limbs and trunk. Individual muscles are surrounded by a deep fascia. This deep fascia of individual muscles is continuous with the deep fascia that connects muscle to bone and with the deep fascia that ensheaths and separates groups of muscles of similar location and function (e.g., anterior thigh muscles). The deep fasciae passing between muscle groups in the limbs are

Figure 6-24 Diagrammatic representation of a transverse section through the arm, illustrating the organization of superficial and deep fascia. Deep fascia divides the arm into compartments by way of intermuscular septa.

called intermuscular septa. The deep fasciae of muscle groups and intermuscular septa are, in turn, continuous with a tightly adhering deep fascia that completely encircles all of the muscles of the limb, and, as will be mentioned again below, the deep fascia encasing different regions of the body represents a mass of tissue that is everywhere continuous (Figs. 6.25–6.27).

At a basic anatomical level, these fasciae define the individual muscles and muscle groups. For example, each of the muscles in the anterior compartment of the leg has its own investing fascia. The entire group is bounded laterally by a wall of fascia, the anterior crural septum, medially by fascia that is continuous with the periosteum of the tibia, and anteriorly by the encasing deep fascia of the leg. As is typical, the blood and nervous supply to these muscles, as well as venous and lymphatic return, is principally contained within this fascial compartment. These fasciae collectively define the anterior compartment. More importantly, they enhance the extensor functions of the muscles, while simultaneously providing protection, support, and separation from other muscle groups. The fasciae define the normal, healthy limit of the group; they tend to constrain destructive states and prevent the spread of bleeding, infection, tumor growth, etc. into adjacent compartments.

Fascial compartments also separate muscles of the trunk. The muscles of the anterior abdominal wall, for example, are easily divided into planes and groups by tough enveloping fascia. The external oblique, internal oblique, transversus abdominis, and rectus abdominis are delineable as a group and from one another not only by their attachments and orientations but also by the tight-fitting sheets of fascia that enclose them. Planes of fascia are also found in the subcutaneous space, external to the deep fascia that bounds

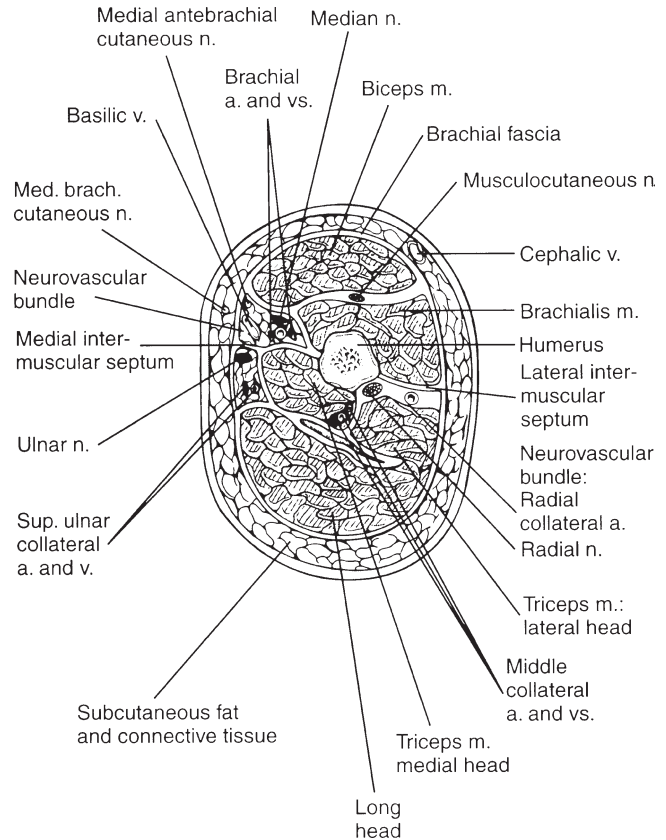

Figure 6-25 Transverse section through the arm. Neurovascular bundles are found between skeletal muscles in anterior and posterior compartments.

Figure 6-26 Transverse section through the back, illustrating the organization of deep fascia. The deep fascia serves to divide the back into compartments for muscles of similar function.

the surfaces of the muscles. Understanding the placement of these fasciae is important in a variety of medical and surgical settings.

Peripheral nerves, blood, and lymph vessels lie in loose connective tissue fascia between muscles. This fascia serves to bind together these nerves and vessels and collectively the components form the neurovascular bundle (Fig. 6.25).

While fascia tends to separate and isolate groups of muscle of similar location and function, many of the layers of fascia, whether subcutaneous or investing, merge together and/or have common points of attachment. The fascia that separate and ensheath the external and internal abdominal obliques merge posteriorly with the thick, connective tissue thoracolumbar fascia; they are

Figure 6-27 Transverse section through the neck, illustrating the organization of the deep fascia. The deep fascia divides the neck into muscular, visceral, and neurovascular compartments.

continuous upward, encasing and separating the erector spinae, the deep muscles of the back. Anteriorly, the fasciae of the abdominal muscles merge, split, and are reflected to contribute to the inguinal anatomy and abdominal aponeurosis. These fasciae are continuous with connective tissue sheets that flow over the crest of the pelvis and become the fascia lata of the thigh. The fascia of the thigh is continuous, in turn, with the crural fascia of the leg. As a consequence of the widespread continuity of fascia, distortion or damage to fascia in one area can have effects in a distant, seemingly unrelated area.

The subcutaneous fasciae are also continuous from one body region to another. The deep layer of superficial fascia of the abdomen (Scarpa fascia) defines a space that is more or less continuous from the flank onto the abdominal wall. It continues inferiorly into the perineum, where it is the superficial perineal space (bounded by Colles and dartos fascia, continuations of Scarpa fascia). Fluid or infection in the abdominal subcutaneous space can, thus, spread to the lumbar area or into the perineum.

The importance of the two-faceted aspect of fascia, that it at once not only separates and segregates but is also continuous structure to

structure and area to area, should not be overlooked. This pervasive connector (along with muscle and bone) helps to regionalize the body and also connects region to region. Such a dualism is apparent in many physical manifestations of both health and disease.

Arteries

Two structural entities, arteries and nerves, are important for the health and maintenance of any organ or area. Arteries supply nutrients, oxygen, and a variety of immune and endocrine regulatory substances to the area of their distribution. Nerves provide ongoing neural control of skeletal and smooth muscle and glandular tissue as well as deliver trophic or regulatory factors to the muscles or organs that they innervate. The rule of supply illustrates a major source for maintenance of health or, conversely, origin of pathology when disrupted.

Few statements are more cogent than A.T. Still's insightful dictum, "The rule of the artery is supreme." An adequate blood supply during varying physiological conditions is a prerequisite for health of an organ or region. Conversely, compromise to the blood supply often leads to diminished functional capacity, cascading, in turn, toward disease. The osteopathic physician must work to ensure continued blood supply in the healthy state and, when treating injury or disease, should attempt to enhance arterial supply to affected regions. One important condition of compromise is bleeding due to trauma or disease. The physician must have sufficient understanding of anatomy to be able to halt hemorrhage quickly and subsequently restore adequate blood flow to ischemic areas. But the physician must also be able to recognize the clinical signs of ischemia due to blockage of arterial supply and work to relieve the blockage.

To optimize strategies that continue arterial supply (and vigor) in the healthy state, and to use appropriate therapeutic interventions in disease or injury to restore adequate blood supply, a physician must have an accurate knowledge of the arterial supply to an area. Consistent with rule 1 above, it is not sufficient simply to know the name of the artery that provides supply; rather, the passage of the arterial supply must be placed in the context of surrounding muscles, bones, organs, lymphatics, fascia, etc.

One of the goals of an osteopathic approach to medical treatment is, first, to recognize which piece of surrounding tissue might be compressing an artery and, having visualized the mechanical impediment to blood flow, adopt appropriate therapies to relieve the compression and thereby restore normal flow. Similarly, the osteopathic physician works to recognize in the healthy individual those areas or organs that might be at risk for reduced blood flow caused by lifestyle, activities, posture, obesity, etc. and adopt a treatment plan to maintain health in zones at risk.

Nerves

As do arteries, nerves also supply vital components to every portion of the body. First, nerves supply control; they are a major component of the body's homeostatic mechanisms. Nerve cell bodies in the CNS send nerve fibers to control contraction of smooth (involuntary) muscles and skeletal (voluntary) muscles and to control secretion of glands. Nerves also provide sensory input; they convey either exteroceptive input concerning physical forces that impinge on the body or interoceptive feedback about the status of the internal milieu. Nerve fibers also supply chemical materials from the CNS to the periphery and vice versa. Through the mechanism of axoplasmic transport, trophic (growth promoting) chemicals are manufactured in the neuron cell body and carried to target muscles

or organs where, after release into the synaptic space, they are taken into the target tissue and there promote healthy function. These substances can be small molecules (e.g., amino acids), well-known neurotransmitters (acetylcholine or serotonin), and more complex molecules also associated with other physiologic functions (substance-P, calcitonin gene-related polypeptide, somatostatin, glucagon, and vasoactive intestinal peptide are examples). Passing in the opposite direction, chemicals from the muscle or organ can cross the synapse, be taken up into the axon terminal, and be transported retrogradely to the neuron cell bodies where the chemicals can then alter basic neuronal function. Thus, a bidirectional communication is established fostering the exchange of information between the nervous system and the somatic and visceral tissues of the body.

As described above, individual peripheral nerves have specific segmental relationship to the CNS and, thence, to the entire body. The segmental origin of nerves is pertinent to three general targets of innervation: skin, muscles, and internal organs. The dermatomal (skin) innervation pattern is relatively straightforward. Pain or sensory loss over some specific dermatomal zone leads the physician to inferences about the integrity of restricted areas of the CNS or nerves near their origin. Innervation of the skin of the limbs becomes a bit more complicated because the sensory nerves from specific spinal cord segments are drawn together into specific cutaneous nerves that contain sensory fibers from more than one segment. A specific peripheral nerve (e.g., the medial cutaneous nerve of the forearm) will contain fibers from two or more segments (in this case C8 and T1), although those fibers will distribute at their termination in the skin in a dermatomal pattern. Here, the notion is that the examining physician must have sufficient understanding of anatomy to be able to differentiate sensory disturbances that arise in a particular peripheral nerve (peripheral neuropathy) as opposed to an entire segmental level as occurs in a radiculopathy.

The innervation pattern of muscles is particularly pertinent to osteopathic medicine because changes in the tone, texture, or function of a muscle may be related to the segmental source of nerve supply to that muscle. The innervation of muscles of the trunk is relatively simple and follows a pattern similar to that of the dermatomes. Nerve fibers to the muscles of the limbs, on the other hand, arise from the spinal cord and are woven through complex networks (the brachial plexus and lumbosacral plexus) that combine fibers from several spinal cord segments into motor nerves that typically serve functional groups of muscles. A physician must understand innervation of limb muscles well enough to reconstruct those nerve fibers from their termination, through the plexus to their spinal cord origin. As with the sensory nerves, the goal for the physician is to be able to differentiate motor losses due to compromise of a distal, peripheral nerve versus losses associated with lesion of one or more spinal cord segments or associated spinal nerves.

The internal viscera receive abundant autonomic nerve supply, and the sensory innervation to the internal viscera that signals functional status, distention, and pain typically accompanies the autonomic innervation to the target organ. The pattern by which this autonomic and sensory nerve supply arises from the spinal cord or brainstem and passes to target tissue is presented in Chapter 10, The Autonomic Nervous System. The key point to be made, however, is that because of developmental and maturational events, an organ in the adult may come to be relatively distant from its embryonic, segmental origin having pulled its nerve supply with it, however. Thus, changes in that organ will be sensed by nerve fibers that report to the part of the developed neural tube (i.e., the spinal cord or brainstem) that was adjacent to its embryonic, segmental origin. As a result, changes in a particular visceral organ may appear as pain to the body surface some distance from the

organ. And, the painful or altered input from an organ can alter the somatic and autonomic outflow from that part of the spinal cord, too. For example, aberrant sensory feedback from a diseased organ can produce changes in muscle tonus or sympathetic function at a seemingly unrelated site. Conversely, painful sensory input from localized musculoskeletal misalignment may produce alteration in autonomic outflow from the related segmental zone of the spinal cord and may disturb function in an internal organ some distance away from that segment. In a very general way, internal organs map to the body surface and vice versa. The osteopathic physician must understand both the general segmental origin and the anatomical pathway by which autonomic nerve fibers and the accompanying sensory nerve fibers pass to the various internal organs and must be alert to the implications of pain and musculoskeletal changes as diagnostic clues and treatment options.

Nerves supply important functional and trophic control to all parts of the body. An important aspect of osteopathic medical practice is to recognize and treat conditions that alter nerve supply to a region or organ. The success of palpation and treatments in recognizing and relieving compression or irritation to nerves and the effectiveness of maintenance of nerve traffic by healthy lifestyles depend directly on how well the physician understands the route that nerves take from their origin to their destination.

Veins and Lymphatics

While the arterial supply is the only means by which fluid and blood cellular components are taken to an area, two pathways remove fluids and blood cells from a region. The venous network collects the deoxygenated blood from the capillary bed; the lymphatic channels drain the relatively cell-free extracellular fluid that accumulates outside the vascular system. Compromise to either of these return channels leads to edema in the affected area: more fluid goes in than comes out.

To alleviate edema, the osteopathic physician may choose to use protocols to enhance venous and/or lymphatic return. The strategy selected depends, of course, on the medical condition of the patient as well as on a thorough knowledge of the anatomy of the venous and lymphatic systems. As with the arterial system, the knowledge of anatomy places venous and lymphatic channels into the context of surrounding organs, muscles, bones, fascia, etc., usually by appreciating those structures on the basis of subtle palpable or surface landmarks.

Peripheral venous channels tend to be somewhat variable, with considerable anastomoses. For general medical application, it is acceptable to understand the overall pattern of peripheral venous drainage and concentrate one's effort on the larger, more predictable central veins. Understanding the anastomoses of peripheral venous channels is useful in the treatment of the venous system. For example, venous anastomoses offer therapeutic strategies for the physician as alternate routes of venous drainage are established. Understanding the routes of venous anastomoses is vital also to correctly diagnosing pathology as significant venous blood flow through some anastomoses is unusual and may indicate a pathological condition. Most venous blood from the gastrointestinal system, for example, is drained through the portal venous system to the liver. But most of the blood from the lower half of the body wall and lower limbs drains into the inferior vena cava. There are some small, usually insignificant anastomoses between these two major venous channels. However, in disease states when large amounts of blood are shunted from the portal system to the caval system, these anastomotic vessels become enlarged. Internal anal hemorrhoids or esophageal varices are engorgements of these anastomotic vessels

and indicate shunting of blood from the portal venous system to the vena caval system and may, thus, indicate blockage of venous drainage to the liver—so-called portal hypertension—that results when the liver is diseased.

The rule of venous drainage is to know by which veins an area is typically drained of blood, by what routes blood drains if the typical route is blocked, and where the veins lie relative to the surrounding structures. This knowledge can assist in designing a plan for restoration of normal function in a patient suffering with edematous conditions.

Arteries bring blood into tissue, in capillary beds a filtrate of plasma, ions, and proteins are extruded into the extracellular spaces. Although veins will absorb some of this fluid, much protein is retained in the tissues. Removal of the protein is the job of the lymphatic system as will be discussed in Chapter 12 on the Lymphatic System.

Lymphatic channels are typically even more variable than veins in their gross morphology; knowing general patterns and spatial relations of lymph drainage is usually sufficient. Although they are less well defined anatomically, they are important to understand. As with venous return, selecting osteopathic approaches to treatment of edema assumes a working knowledge of the location of lymph channels and how to augment lymphatic flow. Lymph collects into blind-ended endothelial tubes in the periphery. These channels throughout the body merge into ever-larger channels, are filtered at predictable intervals by lymph nodes, and finally converge on (usually) two large lymphatic ducts in the root of the neck. These two lymphatic ducts then empty into the venous system near the heart.

As the lymphatic system has no centrally located, intrinsic pump as that seen in the circulatory system, fluid is moved from peripheral to central regions by osmotic pressure, skeletal muscular contractions, external pressure, pressure differences between the thorax and the abdomen, as well as by contraction of smooth muscle surrounding the lymphatic collecting vessels. There are various techniques to increase lymphatic return. When using techniques of muscle contraction or applying local pressure or lymphatic pump mechanisms, one needs prerequisite knowledge of the anatomy of lymphatic flow.

In addition to returning extracellular fluid to the general circulation, the lymphatic system and the lymph nodes are often indicators of disease. The lymphoid system houses important cells of the immune system. As a result of infection, lymphocytes proliferate and are sequestered in lymph nodes, where they attack pathogens (bacteria, viruses, etc.) in the lymph. Because of this important immune function, lymph nodes draining an infected area are often swollen and palpable.

Cancer in an organ will often metastasize to adjacent lymph nodes and will also cause node enlargement. It is crucial, therefore, that the examining physician understand the potential significance of enlarged lymph nodes. For example, breast cancer may metastasize to the lymph nodes on the lateral thoracic wall or in the axilla that drain lymph from the breast. Or, illustrating a less obvious anatomical relationship, an enlarged node above the clavicle in the root of the neck may indicate disease of the stomach. When enlarged lymph nodes are detected, the examining physician can use knowledge of the anatomical pattern by which lymph drains to infer the source of a disease process.

SUMMARY

The body, so often represented as a group of discrete regions or functional systems, is in reality an integrated whole. The integration

of the body region to region and system to system is accomplished by a series of connectors. Some of these connectors, the endocrine and immune systems, are more commonly included in the context of physiology, biochemistry, or immunology. The nervous system, the vascular system, and the lymphatics are also important connectors, the structural components of which are part of anatomical disciplines. Finally, the visible connective tissues of the body, and particularly the fascia, are great physical connectors that bind organs or muscles into larger groups.

Coherent medical practice requires attention to the connected nature of the unified human organism. Typically, one disturbing force (a localized injury, lesion, or infection) causes a cascade of altered structural and functional changes in other areas or systems. Similarly, the treatment of localized disease or injury must be not only localized but must also attempt to bring the whole organism into healthy equilibrium. Planned treatments must account for not only the effect of the treatment protocol on the target site or organ

system, but also the so-called side effect alterations brought about in distant, relatively healthy systems by the treatment.

Observe the obvious examples of body unity. Take time to appreciate the connected nature of the body. For didactic reasons, the body is traditionally disassembled into component parts or regions such as bones, muscles, vessels, nerves, thorax, gastrointestinal system, or upper limb. Yet it is important to be able mentally to reconstruct the intact specimen. The fundamental idea of holistic medicine is predicated on this.

The Fascial System of the Body

FRANK H. WILLARD, CHRISTIAN FOSSUM, AND PAUL R. STANDLEY

KEY CONCEPTS

- Fascial is a unitary body system with a function that can be described as supportive, protective and healing in nature.
- Fascia is composed of irregular connective tissue that can have varying densities.
- Four fundamental layers of fascia can be described: a layer of pannicular fascia covering the body, a denser layer of investing fascia surrounding the musculoskeletal system of the axial and appendicular body, a complex series of meningeal fascial layers surrounding the central nervous system and a fatty layer of visceral fascial surrounding the body cavities and organ systems.
- Fascia has a dynamic aspect imparted by its cellular components especially the fibroblast and the myofibroblast

INTRODUCTION

Definition

Fascia is the connective tissue that unites all aspects of the body. While by definition it functions as packing tissue and organ system cushioning (Clemente, 1985; Standring, 2008), its cellular composition suggests that it is also critical for metabolic activity and immune surveillance (Cormack, 1987; see Chapter 6). Unfortunately, there is much confusion in the literature concerning the components of fascial, its architecture, and the distribution of fascia within the body (see discussion in Fasel et al., 2007). At the time of this writing, there did not appear to be any publication in which fascia is treated as a definable organ system in the body. This poses a problem when trying to decide which tissues actually belong to fascia and which are really part of another organ system such as a tendon, ligament, or joint capsule. Early writings described fascia in a broad sense as being everywhere interconnected and serving a packing function (Anderson and Makins, 1890); however, more recent studies, performed to solve surgical issues, have taken a more fractionated approach (e.g., Garcia-Armengol et al., 2008). *Gray's Anatomy* describes fascia as the “dissectable, fibrous connective tissue of the body, other than the specifically organized structures tendons, aponeuroses, and ligaments, are called fasciae” (Gray, 1948). This definition of fascia was introduced under C.M. Goss as editor of the American version of *Gray's Anatomy* in 1948, and it was maintained by Clemente in the most recent edition (Clemente, 1985). This definition is relatively clear in its exclusion of tendons, ligaments, and aponeurosis from the term *fascia*; it also goes on to describe the investing nature of most fascia providing a packing substance around muscles, tendon, ligaments, and aponeuroses as well as visceral organs. A similar definition of fascia is offered in the English version of *Gray's Anatomy* (Standring, 2008), where fascia is also described as having collagenous fibers that are generally interwoven as opposed to the parallel array of fibers seen in tendons, ligaments, and aponeuroses. In this chapter, we will offer a slightly expanded definition of fascia as a system (a) complete with blood supply, fluid drainage, and innervations and thus the largest organ system in the body, (b) composed of irregularly arranged fibrous elements of varying density, and (c) involved in tissue protection and healing of surrounding systems. As consistent with the definition in *Gray's Anatomy*, tendons, ligaments, and aponeuroses are excluded from the term *fascia* based on

their histological composition. We will then examine the cells and extracellular substance that constitute fascia. We will conclude with a discussion of the dynamics of fascia and its role in tissue repair.

Previous Studies of Fascia

In recent times, there has been a strong resurgence of interest in both basic and applied science research in fascia. Traditionally, the view has been that the fascias are inconsequential residues that are less important than the tissues with which they are associated (Benjamin, 2009). The term *fascia*, derived from Latin for *band* or *bandage*, emerged in its anatomical and medical usage in the 16th and 18th centuries. The sometimes vague and inconsistent descriptions of fascia in anatomy and across languages resulted in the publication of two anatomy texts in the 1930s solely devoted to the anatomy of the fascial planes (Gallaudet, 1931; Singer, 1935). Subsequently, based on developmental approaches involving studies of the sequential development of visceral changes as observed in closely graded series of human embryos, fetuses, newborn infants, and adults, a detailed investigation of the adult fascia was done (Hayes, 1950). It highlighted the process of development and organ migration producing different types of fascia in a predictable and confirmable pattern, referring to it as *migration fascia*. It also described the fascia resulting from fusion of the primitive mesenteries as *fusion fascia* and the *parietal fascia* as intrinsic to the structures in the wall of the developing abdominopelvic cavity (Hayes, 1950). This was probably one of the first attempts at linking embryological development and growth to the anatomy of the adult fascia. Innervation of the deep fascia in both human and animals in the form of nerve terminations consisting of free endings and simple small encapsulated endings was described around the same time (Stilwell, 1956), and it was proposed that they may have a kinesthetic function as well as contributing to pain transmission. Based on such observations and experimentations, it became more obvious that the fascia, rather than being an inert structure, with a passive function, is a very active tissue playing an important role in the economy of the body, and in health and disease (Snyder, 1956). Despite the advancement in the anatomical knowledge of the fascia, some confusion still remains on the proper terminology. Efforts has been made in recent years to standardize anatomical terminology with the introduction and constant revision of the *Nomina*

Figure 7-1 Photomicrographs of dense, regular connective tissue as seen in (A) a tendon (B) a ligament.

Anatomica, but despite this, adequate descriptions of fascial structures from an anatomical point of view are still lacking (Ercoli et al., 2005; Skandalakis et al., 2006).

Overview of Fascia

Tendons, ligaments, and joint capsules are generally composed of dense connective tissue with regularly arranged fibrous elements designed to meet specific functional requirements such as to resist pull, shear, or compressive stress in a given direction (Fig. 7.1). These elements typically have definable anatomical borders where tendons, ligaments, or joint capsules attach to surrounding structures. Conversely, by its very nature, fascia lacks this specificity in design; it packs the spaces around organ systems and interconnects between systems seemingly without providing specific functions (Fig. 7.2). This lack of specificity is best suited by an irregular arrangement of fibrous elements capable of resisting pull or stretch in multiple different directions. The irregular construction of fascial tissue also facilitates its continuity from one region of the body to another without forming the precise borders seen with such structures as tendons and ligaments of joint capsules. Thus, perimysium (fascia) is anatomically continuous with peritenidium, which is anatomically continuous with periosteum on bone. All of these structures lack the well-defined border such as exists at a myotendinous border or an enthesis where muscle joins tendon and tendon joins bone, respectively.

The lack of precise borders seen in the fascial tissue allows it to form long planes spanning multiple organ systems or compartments surrounding one or more muscles. When entering

Figure 7-2 Forms of connective tissue typically found in fascia. **A.** This is a loose connective (areolar) tissue spread demonstrating a fairly random arrangement of collagenous and elastic fibers. (Taken from the University of New England, Histology Site.) **B.** This is a cross-section taken through mesentery demonstrating a thin layer of dense, irregular collagenous fibers underlying the mesothelium with a central core of adipose tissue surrounding several vessels and lymph nodes. Note the thickened tunica adventitia of the vessels. (Taken from the University of Michigan Histology Site.) **C.** This is a magnified view of the mesentery border showing the thin layer of dense irregular collagenous fibers underlying the single cell layer of mesothelium.

fascial compartments, neurovascular bundles—which themselves are surrounded by irregular dense connective tissue fascial wrappings—course along or through fascial planes that would otherwise represent obstacles if composed of highly organized regularly arranged fibrous elements such as seen in a aponeurosis, tendon, ligament, or joint capsule. Lymphatic flow, which would be quickly interrupted if forced through tissue with precise boundaries, can flow easily through lymphatic vessels distributed in the irregular tissue of the fascial plane.

As with any other organ system, fascia has an innervation (see the section “Innervation of the Fascia”). As vessels course through fascial planes, they are typically accompanied by small-caliber nerve fibers. Some of these fibers contain catecholamines

and belong to the autonomic nervous system (Bevan et al., 1980; Burnstock, 1980), whereas others are somatic nerve fibers (Stilwell, 1956), many of which contain neuropeptides (Walsh and McWilliams, 2006) and belong to sensory systems (also see Chapter 15 on Nociception). Endings from these fibers have a basal release of catecholamine and neuropeptide into the vessel wall and surrounding tissue. These compounds exert control over the vasculature and determine, in part, the texture of the tissue and the trafficking of white blood cells through the tissue.

Finally, like any other organ system of the body, fascia has definitive functions and capabilities. Most organ systems, including both musculoskeletal organs and visceral organs, are surrounded by a fascial capsule from which septae arise and penetrate into the organ often subdividing it into functionally distinct regions; this imparts fascia with a packing function as well as providing access routes for metabolic channels. In essence, fascia is acting as the skeleton for the specific organ system. As the body moves, so do its organs; to avoid friction and injury healthy fascia layers distort easily, tolerating stretch in multiple planes, and thereby providing a distensible cushion that allows organs to glide by each other while protecting more delicate fluid channels. Supplying each organ will be one or more neurovascular bundles and numerous lymphatic drainage routes; each of these communicates with the organ through its fascial layers. Thus, fascia is providing a movable conduit through which the neurovascular lifeline for the metabolic activity of the organ system passes.

Generally, all layers of fascia are themselves supplied with a well-organized blood supply and fluid drainage routes through venous and lymphatic channels (see Chapter 12 on Lymphatic System). Given the irregular arrangement of the fibrous nature of fascia, it is quick to initiate repair following injury and often will rapidly form a scar or callous. Thus, it plays an important role in wound healing and tissue repair. Although long thought to be relatively motionless—one prominent textbook of histology defines fascia as “non-contractile connective tissue”—recent evidence is beginning to demonstrate a slow contractile nature to fascial tissue. This contractile nature appears to be closely related the tissue repair process and will be discussed at the end of this chapter.

Architecture of Fascia

General Approach

Several attempts at describing the fascias of the body have been published (Benjamin, 2009; Gallaudet, 1931; Singer, 1935). Numerous discrepancies exist concerning which layers are considered fascia and how many subdivisions exist for each layer. Unfortunately, the lack of a clear definition of fascia has prevented any resolution of such arguments (Fasel et al., 2007; Skandalakis et al., 2006; Wendell-Smith, 1997). In this chapter, using irregular connective tissue as a histological definition, we will describe a system of four primary layers that cover the axial portion of the body. Modification of this fundamental plan will allow accommodation of the limbs.

The four primary layers in the torso are arranged as a series of concentric tubes. Starting with the outermost layer of fascia, it is best termed the *panniculus* or *panniculus adiposus*: a term used by Singer (Singer, 1935) in his treatise on fascia and strongly urged for general usage by Last (Last, 1978) in his textbook. This is an overall layer of fascia that covers the entire body and is exposed by removing the epidermis and dermis. Although the pannicular layer can be subdivided into several additional layers regionally in the body, for the sake of this chapter it will be considered as a primary layer. Deep to the pannicular layer is the *axial fascia* of the torso.

This layer gives rise to the investing fascia or epimysium of the axial muscles of the body and is continuous with the appendicular (investing) fascia in the extremity. As with the pannicular layer, the axial layer is subdivided; however, again in this chapter it will be treated as a primary layer. Internal to the axial fascia are two additional layers: the first surrounds the neural structures and is termed *meningeal fascia* and the second surrounds all body cavities and is best termed *visceral fascia*. In considering the limbs, the pannicular layer extends outward covering the entire surface of the limb. Under the pannicular layer, a fascial layer of similar composition to the axial fascia is present surrounding the muscles of the extremity and can be termed *appendicular fascia*, it lies deep to the pannicular fascia and invests the appendicular muscles. Regional names often relate the fascia to a specific muscle such as deltoid fascia. Internal to the appendicular fascia is the intramuscular septum housing the neurovascular bundles; this septal layer is thought to be derived from developmentally the axial fascia at the base of the limb.

FOUR PRIMARY LAYERS OF FASCIA

Pannicular Fascia

The outermost layer is the pannicular fascia (reviewed in Clemente, 1985). This superficial layer is derived from the somatic mesenchyme and surrounds the entire body with the exception of its orifices such as the orbits, nasal passages, and the oral and aboral openings. It is composed of both loose and dense irregular connective tissue with a highly variable fat content (Fig. 7.3). While the outermost portion of this layer is typically invaded by adipose tissue, the inner portion is membranous in nature and generally very adherent to the outer portion except over the abdomen where the two can be easily separated by blunt dissection. The thickness of the pannicular layer is highly variable in the human population. In the region of the head and neck, humans have several thin muscles embedded in the pannicular fascia; these are the platysma (Fig. 7.4) and associated facial muscles innervated by the facial nerve. Pannicular fascia covers both the axial and appendicular body.

Figure 7-3 The pannicular layer of fascia. This is an anterior view of the thorax and abdomen of a male and a female cadaver. The body on the left is that of a 54-year-old male and on the right a 54-year-old female. Both specimens have had the dermis removed to reveal the pannicular layer of fascia. (Used with permission from the Willard/Carreiro Collection.)

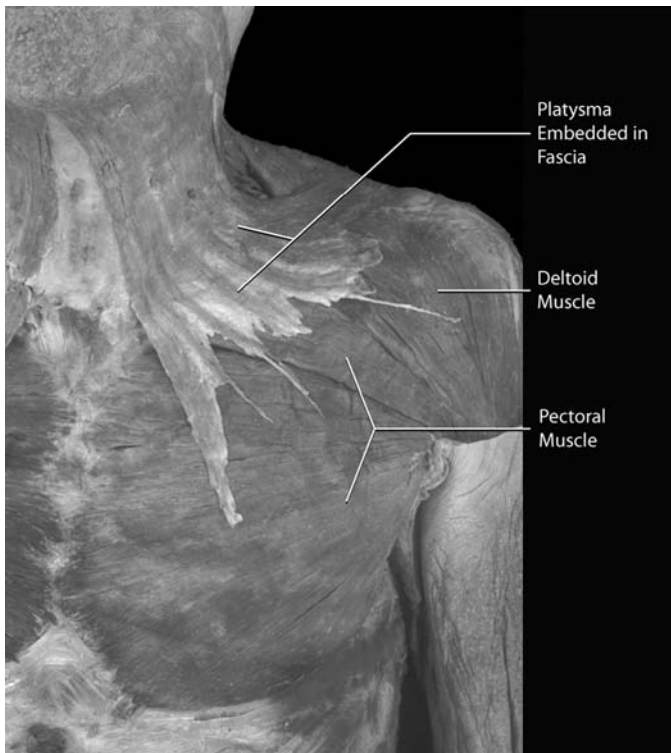

Figure 7-4 This is an anterior view of the upper thorax and neck illustrating the platysma, a pannicular muscle, embedded in the pannicular fascia and separated from the underlying muscles. The deltoid and pectoral muscles are extremity muscles and are normally embedded in fascia derived from the extremity. The investing fascia of the extremity has been cleaned off of the deltoid and pectoral muscles. (Used with permission from the Willard/Carreiro Collection.)

A complex relationship exists where the extremities meet the axial portion of the body. The muscles of the upper extremity form a hood that extends medially from the humerus and scapula, coursing deep to the pannicular fascia to reach their attachments on or near the midline. Each muscle is surrounded by appendicular fascia (also termed *deep investing fascia of the muscle*). The appendicular muscles and their associated fascia pass between the pannicular layer and the axial fascia layers until they can make an attachment. Therefore, these large wing-shaped muscles, such as the trapezius, latissimus dorsi, rhomboideus, and pectoralis muscles, have to reach to the spinous process on the posterior midline or the sternum or ribs anteriorly for their attachment to the torso.

Axial and Appendicular Fascia

Internal to the pannicular layer is the axial or investing fascia (*deep fascia* as described in Clemente, 1985); it is also derived from somatic mesenchyme and is fused to the panniculus peripherally and extends deep into the body surrounding the hypaxial and epaxial muscles (see the chapter on Anatomy). This layer forms the epimysium of skeletal muscle, the periosteum of bone, and the peritendon of the tendons. The axial layer can be depicted as two tubes of fascia separated centrally by the vertebral column (notochord in the embryo; Fig. 7.5): the anterior tube surrounds the hypaxial muscles and attaches to the vertebral column at the transverse process. The hypaxial muscles include the longus and scalene muscles in the cervical region, the intercostals muscles in the thoracic region and the oblique and rectus muscles in the abdominal

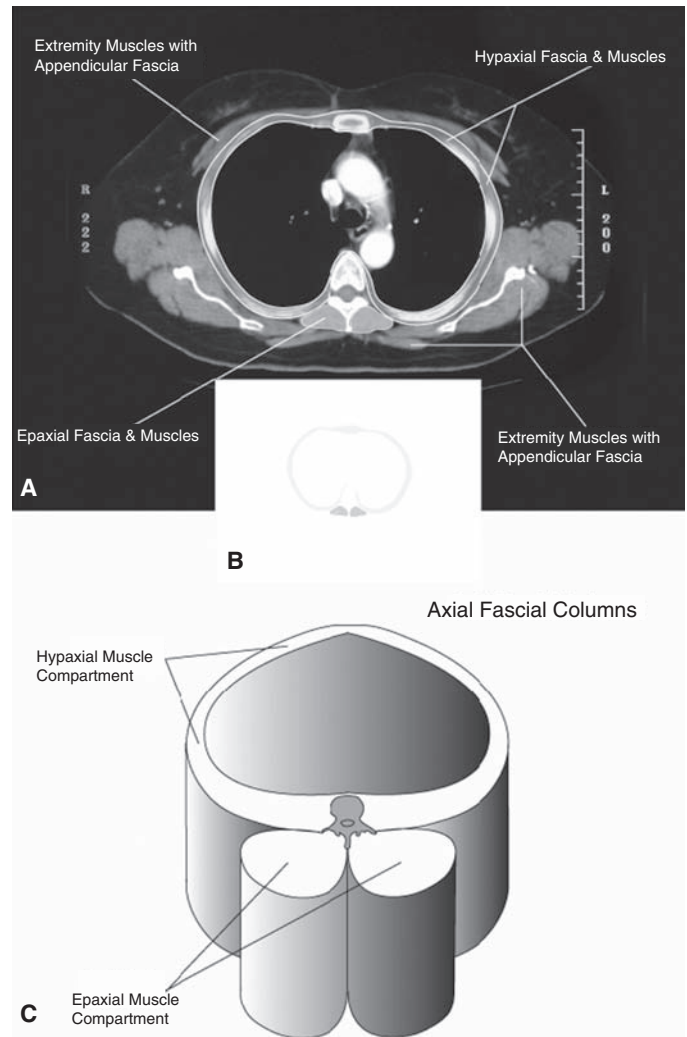

Figure 7-5 This is an axial plane spiral CT taken through a male thorax. The white outline surrounding the axial muscles—hypaxial and epaxial—marks the course of the axial fascia. (Used with permission from the Willard/Carreiro Collection.)

region. The posterior tube of axial fascia surrounds the epaxial muscles and is attached to the transverse processes. At each level, the vertebral spinous process divides the epaxial fascial tube into two “half-tubes” (Fig. 7.5). The paraspinal muscles of the back are contained in the smaller “half-tube” of the epaxial fascia.

Axial fascia extends into the extremities as the intermuscular septum and the appendicular fascia investing individual muscles (Fig. 7.6). The fascial sheath that surrounds the neurovascular bundles such as the brachial plexus and lumbosacral plexus extends outward to form the intermuscular septum in which branches of the neurovascular bundle will course as they progress distally in the extremity.

The arrangement of fascias within the body wall is made very complex by the attachment of the limbs. The muscles of the upper extremity, such as the pectoralis, trapezius, serratus anterior, and latissimus dorsi muscles, form long wing-like expansions that wrap over the torso to attach to the midline of the body or to structures that ultimately attach to the midline such as the thoracolumbar fascia (Fig. 7.7). These extremity muscles pass internal to the panniculus of fascia and external to the axial fascia as they embrace the axial body wall. Each muscle is surrounded by a layer of investing or appendicular fascia. The arrangement of these fascia sheets is visualized in the two dissections illustrated in Figures 7.8–7.12. In Figure 7.8, the

Figure 7-6 The fascia surrounding the neurovascular bundle in the axial portion of the body extends outward into the extremity. (Taken from L. H. Mathers, R. A. Chase, J. Dolph, E. F. Glasgow, and J. A. Gosling. *Clinical Anatomy Principles*, St Louis: Mosby, 1996.)

epidermis and dermis have been removed to expose the underlying pannicular fascia. An elongated rectangular window (outline) was opened into the pannicular fascia to expose the investing fascia (appendicular fascia) of the pectoral muscles. In Figure 7.9 the window was enlarged and divided into two portions, the medial portion still has appendicular fascia covering the muscle, but in the lateral portion the investing appendicular fascia has been removed to expose the pectoralis muscle. With the inferolateral border of the pectoral muscle elevated (Fig. 7.10), the investing (appendicular) fascia separates it from the serratus anterior can be visualized. To expose the

Figure 7-7 Wing-like arrangement of the trapezius and latissimus dorsi. (Used with permission from the Willard/Carreiro Collection.)

axial investing fascia of the intercostals muscles, the pectoral major and serratus anterior muscles and their investing appendicular fascia must be removed (Fig. 7.11). In this figure, the pectoralis major and serratus anterior muscles have been removed to expose the intercostals muscles and their thin layer of investing axial fascia (note that the pectoralis minor muscle is still attached). Finally, Figure 7.12 shows the exposed intercostals muscles by carefully dissecting away all axial fascia.

Meningeal Fascia

The third fascial layer is meningeal fascia, which surrounds the nervous system (Fig. 7.13). This layer, including the dura and the underlying leptomeninges, derives from the primitive meninx that surrounds the embryonic nervous system. Specifically the spinal meninges is most likely derived from the somatic mesoderm, while the brainstem meninges arises from cephalic mesoderm and the telecephalic meninges from the neural crest (Catala, 1998). Meningeal fascia terminates with the development of the epineurium that surrounds the peripheral nerve.

Visceral Fascia

The fourth fascial layer is visceral fascia and is by far the most complex of the four main layers of fascia. Embryologically, this layer of fascia is derived from the splanchnic tissue and thus surrounds the body cavities—pleural, pericardial, and peritoneal. The visceral layer follows the visceral pleura and peritoneum and provides the conduit for neurovascular bundles entering the visceral organs as well as a drainage route out of the organ. On the midline of the body, the visceral fascia forms a thickened mediastinum that extends from the cranial base into the pelvic cavity (Fig. 7.12).

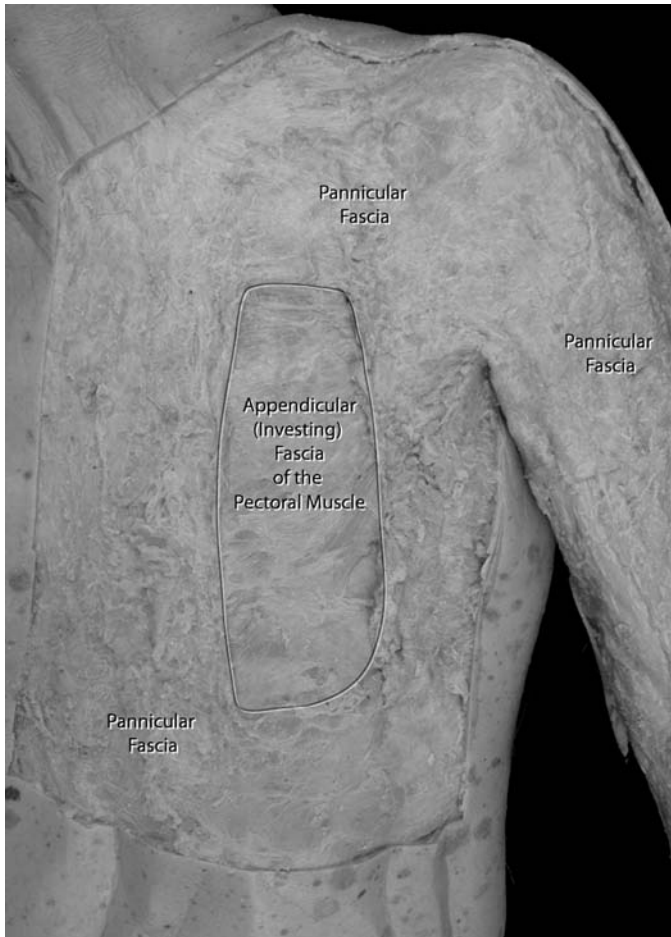

Figure 7-8 This is a photograph of a male with the epidermis and dermis removed to expose the pannicular fascia on the chest wall. A vertical window has been cut in the pannicular fascia to expose the underlying appendicular fascia. (Used with permission from the Willard/Carreiro Collection.)

Figure 7-9 The fascia of the anterior chest wall. A window has been cut in the pannicular fascia on the left side of the window the appendicular fascia investing the pectoralis major is seen. On the right side of the window this fascia has been removed to demonstrate the muscle. (Used with permission from the Willard/Carreiro Collection.)

In the cranial region, visceral fascia surrounds the pharynx and its attachment to the cranial base. Superiorly, visceral fascia includes the pharyngobasalar and pharyngobuccal fascia and, as such, fuses to the cranial base surrounding the attachments of the superior constrictor muscles (Last, 1978). Cervical visceral fascia extends inferiorly into the neck surrounding the nasopharynx, oropharynx, and remaining cervical viscera. Thus, at the cranial base, cervical fascia has a flared opening surrounding the nasal passageways and the mouth (Fig. 7.14, Sections 22 and 46)

In the neck, visceral fascia incorporates such regional fascias as pretracheal, retropharyngeal, and alar (carotid sheath) fascias as well as the fascia surrounding the thyroid cartilage and thyroid gland (Fig. 7.14, Section 66 and 86). Thus, visceral fascia can be conceived of as a continuous vertical sleeve lying internal to the hyoid muscles, anterior to the longus muscles and extending into the thorax (Fig. 7.15).

Upon entering the thorax, the visceral fascia is forced to accommodate the two pleural cavities; this it does by flattening on to the thoracic wall where it is termed *endothoracic fascia*. Centrally, visceral fascia expands in bulk and forms the packing substance of the mediastinum (Fig. 7.-15). In the mediastinum, visceral fascia surrounds the great vessels of the heart and thickens to become the fibrous pericardium anteriorly. Posteriorly, the visceral fascia forms a loose matrix surrounding the aorta, esophagus, trachea, primary

bronchi, and the thoracic duct. This matrix is very loose to allow distension of the esophagus upon swallowing. No significant condensations of fascia are present in this region. Finally, visceral fascia surrounds the bronchi as they pass through the root of the lung; this fascia becomes continuous with the stroma of the airways.

Visceral fascia also accompanies the esophagus into the abdominal cavity. Here, the visceral layer spreads outward to surround the peritoneum where it is termed *endoabdominal fascia* posteriorly and *transversalis fascia* anteriorly. The endoabdominal fascia thickens significantly along the posterior midline and forms a column analogous to the mediastinum of the thorax (Fig. 7.16). As in the thorax, the abdominal mediastinum contains the major vascular and neural channels. Extensions of the abdominal mediastinal fascia pass into the mesogastrium, mesentery and mesocolon to reach the visceral organs of the abdomen. It is along this pathway that the blood supply, innervation, and lymphatic channels reach the peritoneal organs. This situation is remarkably similar to that seen with the mediastinum of the thorax, the root of the lung, and the lung tissue. The endoabdominal (visceral) fascia is especially thick surrounding the kidneys where it forms a perirenal fat pad termed *Gerota's fascia* (Fig. 7.17).

In the pelvic basin, the endoabdominal fascia becomes continuous with the endopelvic fascia, which then surrounds the inferior region of the peritoneum. The inferior border of the endopelvic

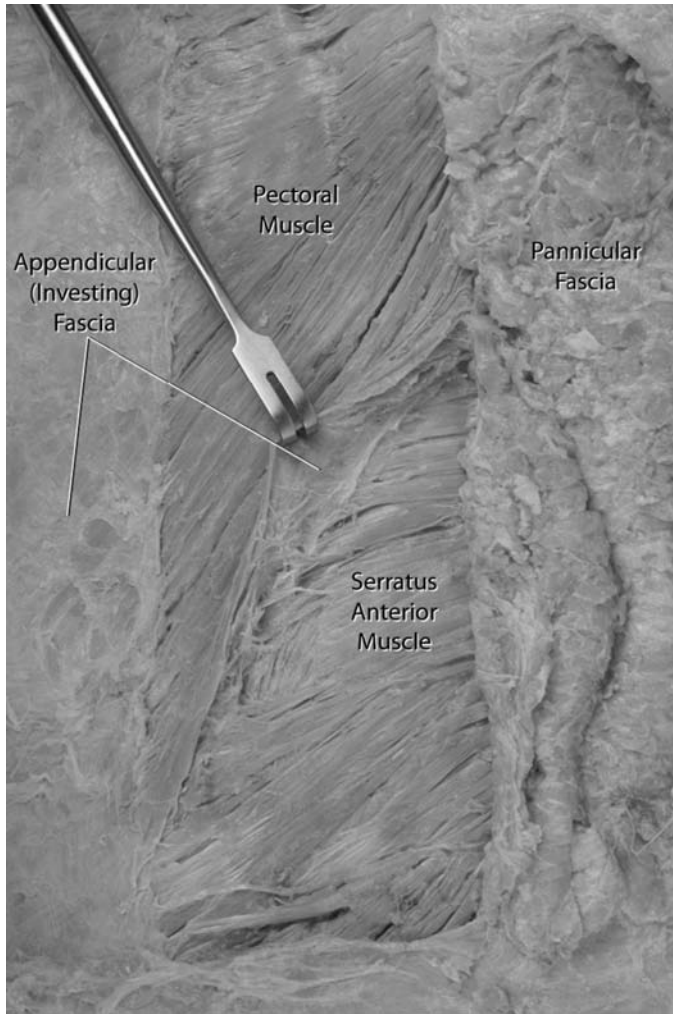

Figure 7-10 The fascia of the anterior chest wall. A window has been cut in the pannicular fascia as described in figure 7-9. fascia is the pelvic diaphragm composed of the levator ani and coccygeus muscles. Inferior to the pelvic diaphragm is the ischioanal (ischoanal) fossa; it is packed with pannicular fascia (Fig. 7.18). The anterior and inferior border of the endopelvic fascia fills the retropubic space surrounding the base of the urinary bladder. As in the thorax and abdomen, the endopelvic fascia thickens on the midline where it again forms a mediastinum surrounding the rectum, reproductive organs, and urinary bladder. Similar to the mediastinum in the thorax and abdomen, the endopelvic fascia serves as a conduit through which the major organ systems in the pelvic basin receive their blood supply and innervations as well as their lymphatic drainage. In the female, extensions of the pelvic mediastinal component of the visceral fascia form the core of the broad ligament and condensations of this visceral fascia form the transverse cervical ligament of the uterus.

In summary, visceral fascia can be traced from the cranial base into the pelvic cavity. It forms the packing surrounding the body cavities where it is compressed against the somatic body wall. It also forms the packing around visceral organs, many of which it reaches by passing along the suspensory ligaments such as the mesenteries. This fascia also functions as a conduit for the neurovascular

Figure 7-11 The pectoralis major muscle has been removed exposing the underlying axial fascia that surrounds the sternum, ribs, and intercostal muscles. The pectoralis minor is still in place on this female specimen. (Used with permission from the Willard/Carreiro Collection.)

and lymphatic bundles as they radiate outward from the thoracic, abdominal, and pelvic mediastinum to reach the specific organs.

Visceral Ligaments

A note here is necessary concerning the used of the word *ligament* when referring to structures found in the body cavity. Visceral ligaments are in no sense of the word similar to the ligaments seen in somatic body parts. Ligaments in the somatic portion of the body are structures that join bone to bone and are composed of dense, regular connective tissue, which itself is surrounded by a thin periligamentum of investing fascia, typically part of the axial or appendicular fascia. The word *ligament* used for structures found in body cavities such as pulmonary ligaments, Trietz ligament, transverse cervical ligament or broad ligament refers to a loose condensation of visceral fascia (irregular connective tissue of varying density) in some cases surrounded by a thin serous membrane. Visceral ligaments generally cannot bear as much strain as somatic ligaments nor are they as clearly defined on dissection. Unlike ligaments in somatic tissue, visceral ligaments typically function to carry blood supply and innervations to an organ system or to loosely anchor an organ in the body cavity. Visceral

Figure 7-12 The axial fascia has been removed to expose the sternum, ribs, and intercostal muscles. (Used with permission from the Willard/Carreiro Collection.)

ligaments also need to be distinguished from fibrotic adhesions that typically develop secondary to irritation and inflammation.

Adhesions

Fibrotic adhesions derive from areas of chronic inflammation (Wynn, 2008). Activated immune cells release cytokines that stimulate fibrocytes to generate additional collagen during the repair process (some of the mechanisms involved in this process will be described in a later section of this chapter). The collagen laid down is irregular in arrangement and is thus similar to fascia in its construction. When excessive, these bands of increased collagen can form adhesions that can reach pathological proportions. Adhesions can occur in any region of the body either visceral or somatic. In the abdomen and pelvis, adhesions can envelope the tubular bowel and be strong enough to obstruct movement within its lumen or interfere with reproductive organ functions. Similarly, adhesions forming in and around synovial sheaths in the carpal tunnel can interfere with movement of the digital flexor tendons.

Innervation of the Fascia

It has been proposed that the fascia plays an important role in musculoskeletal biomechanics, peripheral motor coordination, proprioception, regulation of posture and as a potential pain generator (Langevin, 2008; Langevin and Sherman, 2007; Stecco et al., 2007). Central to these roles is the innervation and the cellular-mediated contractility of the fascia. Reports suggest that the fascia is richly innervated, and abundant free and encapsulated nerve endings have been described at a number of anatomical sites (Benjamin, 2009). These include the thoracolumbar fascia, the

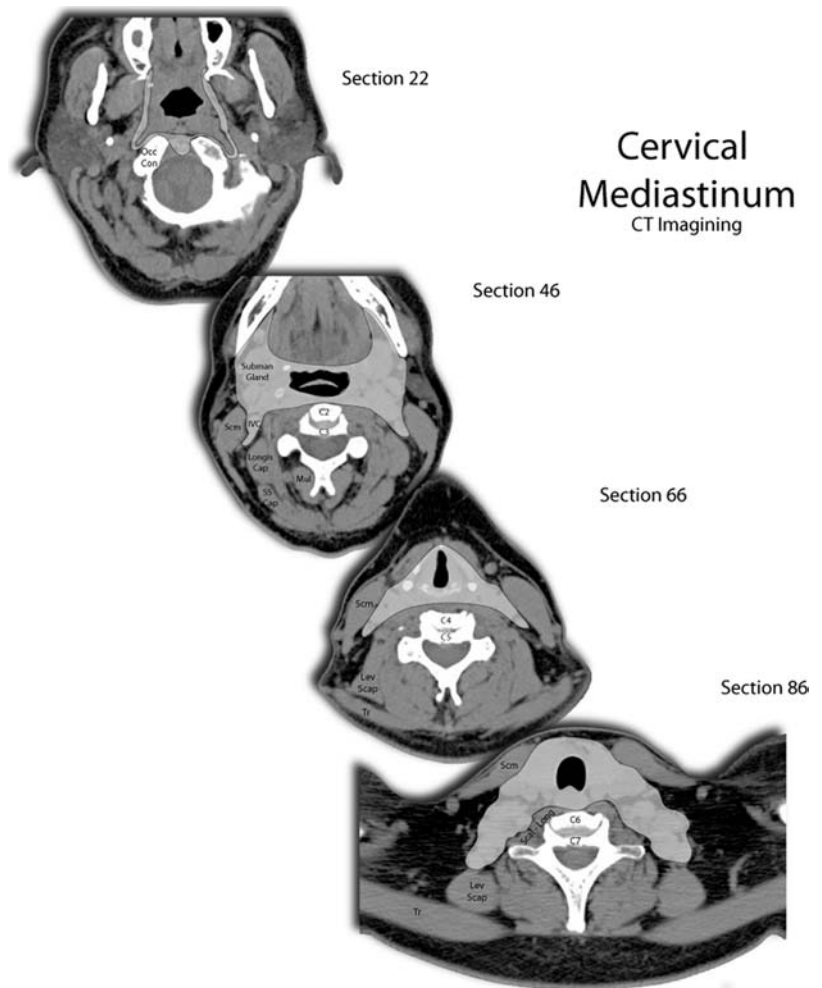

Figure 7-13 The paraspinal muscles have been removed and a total laminectomy performed to expose the spinal dural sac. In addition, the occipital bone was removed to demonstrate the cranial dura. (Used with permission from the Willard/Carreiro Collection.)

bicipital aponeuroses, and the crural fascia (Palmieri et al., 1986; Sanchis-Alfonso and Rosello-Sastre, 2000; Staubesand and Li, 1996; Stecco et al., 2006, 2007; Stilwell, 1957; Tanaka and Ito, 1977; Yahia et al., 1992). These nerve endings are particularly numerous around vessels, but are also distributed homogeneously throughout the fibrous components of the fascia (Stecco et al., 2008). Besides the identified Ruffini, Pacini, and Golgi-Mazzoni corpuscles and their possible proprioceptive role (Schleip, 2003a; Stecco et al., 2007; Yahia et al., 1992), some of the nerve fibers associated with the fascia are adrenergic and likely to be involved in controlling local blood flow (Benjamin, 2009). This is supported by reports that when intrafascial nerve fibers were subjected to morphological evaluation, they exhibited characteristics typical of autonomic nerve fibers (Stecco et al., 2008).

As for the proposed proprioceptive role, the fascia should be considered in close association with its related muscles. When

Figure 7-14 Cervical Visceral Fascia. These images are a series of four cervical CT sections from one individual with the visceral fascia indicated by shading. This fascia begins as a flared opening (section 22 and 46) attached to the cranial base and consolidates into a continuous column of irregular connective tissue as it descends through the neck (sections 66 and 86).

muscles contract, their tension is transmitted to the fascia causing traction of it, possibly activating nerve terminals embedded in the fascia (Stecco et al., 2007, 2008). The degree of innervation may also change in patients with chronic pain, as described in thoracolumbar fascia in patients with back pain (Bednar et al., 1995). Following excessive stimulation, or when the mechanoreceptors are stretched beyond their physiological limit, they

have the ability of becoming nociceptors (Stecco et al., 2007). It has also been suggested that manual loading of fascia as in various manual medicine modalities may cause changes through activation of these receptors (Lundon, 2007; Schleip, 2003a,b). Despite the recent advances in knowledge concerning the innervation of the fascia, our understanding of it is still very incomplete (Benjamin, 2009).

COMPONENTS OF FASCIA

Fascia is composed connective tissue with varying densities of irregularly arranged collagenous fiber. As such, the components of fascia are the items typically found in irregular connective tissue.

Cellular Elements

Fibroblasts

Fascia supports connective, biochemical, and biophysical associations between itself and underlying muscles, bones, and organs. Fibroblasts are the principal cell type of fascia; they synthesize and secrete cytokines (e.g., interleukins [ILs], interferons, growth factors, etc.) as well as connective tissue extracellular matrix proteins (ECMPs) such as collagen, fibronectin, and others (Fig. 7.19). Fibroblasts also secrete and maintain connective tissue ground substance containing glycosaminoglycans, proteoglycans, hyaluronic acid, and glycoproteins. This ground substance provides the medium through which exchange of molecules between

Figure 7-16 This is a series of four axial plane CT scans taken through the thorax, abdomen and pelvis of a patient. The visceral fascia has been outlined and faintly shaded in each image.

blood, lymph, and tissue cells takes place thereby making fibroblast secretions deliverable both locally and systemically.

The shape of the fibroblast is dependent on the environment with which it is located; elongate or fusiform cell shapes are seen when the cell is at rest such as occurs in mature connective tissue

where the cell is typically entangled in thick bundle of collagen fibers. The stellate cell shape is seen when fibroblasts are grown in tissue culture or are present in either immature or healing tissue or in a fibrotic tissue (Rhee and Grinnell, 2007). Fibroblast shape is also sensitive to the tension in the tissue; in the quiescent state, cells have spindle shapes with long dendritic process; however, when mechanically stressed, these cells round up becoming stellate in shape (Grinnell et al., 2003; Langevin et al., 2005).

Some fibroblasts are of mesenchymal origin, similar to osteocytes and chondrocytes; however, other fibroblasts, particularly those found in the connective tissue layers of visceral organs such as lung, liver, and kidney, arise from a process of transformation

from epithelial cells (Neilson, 2006). This metamorphosis occurs through a process termed *Epithelial-Mesenchymal Transition*, which allows the polarized cells located in a sheet of epithelium to transition into highly motile cells inside the connective tissue matrix (Yang and Weinberg, 2008). The formation of fibroblasts from epithelial cells is currently thought to be a significant event in normal developmental processes as well as play a critical role in such pathological processes as tissue repair, fibrosis, and oncogenesis (Thiery et al., 2009). Regardless of their origin, fibroblasts are charged with maintenance of homeostasis in the matrix of the connective tissue through the production and remodeling of both fibers and the extracellular matrix (Laurent et al., 2007). Part of this task also involves monitoring and maintaining the appropriate degree of tension in the connective tissues (Grinnell et al., 2003; Tomasek et al., 2002) and the chemical quality of the tissue. Thus

fibroblasts are capable of both mechanoreception (responsive to tension) and chemoreception (responsive to growth factors).

Fibroblasts exist in the extracellular matrix of the fascia. A primary role of the fascia and its ECMPs is to endow cells and tissues with their specific mechanical and physiochemical properties. As such, the extracellular matrix represents a three-dimensional scaffolding that supports cellular adhesion and tissue-specific functions. Since imposed mechanical loads physically affect the fascia, it plays important simultaneous roles of force sensor as well as a transmitter of force input generated by muscle contractions and by external forces including osteopathic manipulative techniques (OMTs). Fibroblasts can detect the change in tension and generate an adaptive response, which can involve contraction and the secretion of large quantities of collagen. Thus, fascia itself may also be capable of smooth muscle-like contractions, thereby influencing underlying musculoskeletal dynamics and displaying the existence of true (i.e., skeletal muscle-independent) fascial tone (Hinze et al., 2004; Schleip et al., 2005). Osteopathic Manipulative Techniques are hypothesized to mediate corrections of such fascial hypertonicity and/or abnormal tissue collagen crosslinking (Gupta et al., 1998) which may occur postinjury or during prolonged immobilization. Therefore, due to their location within the trafficking ground substance, their ability to secrete ECMPs and mediators of pain and inflammation, and the ability to generate and transduce force input, fibroblasts have been thought to be uniquely poised to be targets of soft tissue injuries, myofascial release, and other Osteopathic Manipulative Techniques (Eagan et al., 2007; Meltzer and Standley, 2007).

Along with changing tension, fibroblasts also respond to growth factors and inflammatory substances secreted into the matrix from epithelial cells, mast cells, macrophages, and lymphocytes. Numerous cell types found in connective tissue, such as macrophages, mast cell, epithelial cells, and fibroblasts, produce transforming growth factor-beta (TGF- β) (Laurent et al., 2007). Similar to physical stress, activation of fibroblasts by TGF- β or inflammatory compounds leads to the expression of as many as 150 genes (Laurent et al., 2007). An end result of this process is the production of collagen and differentiation of the fibroblast into a myofibroblast with focal cellular adhesions to the matrix and a contractile ability (see the section "Myofibroblasts").

Fibroblasts form a distinct network in connective tissue. The long thin processes of the cell make contact with those of other fibroblasts creating a three-dimensional network within the tissue. Control of the formation of dendritic processes and their coupling with other fibroblast processes appears to lie with the balance of growth factors in the tissue. These factors, such as platelet-derived growth factor and lysophosphotidic acid, act on the fibroblast through a family of small g-proteins involving Rho and Rac (Grinnell et al., 2003). The gap junction protein, connexin 43, has been detected at points where fibroblast process make contact, yet, to date, gap junctions, as seen with electron microscopy, have not been visualized at these points of contact between fibroblast processes. However, the presence of the connexin protein on these processes raises the interesting possibility that the fibroblasts have an interconnected communications network throughout connective tissue that functions through the membrane-bound connexin proteins. The concept of an interconnected cellular network among fibroblasts would not be out of context since similar networks are seen between mature osteocytes (mesenchymal-derived cells) located in bone as well as between fibroblasts located around bundles of collagen fibers in tendons. In both bone and tendon, these cellular networks function to detect mechanical stress and orchestrate an adaptive response by the tissue (Banes et al., 1995).

Myofibroblasts

Myofibroblasts are differentiated fibroblasts that share many cellular and biochemical similarities with smooth muscle cells. These cells can arise from fibroblasts in connective tissue (Fig. 7.21); however, they also can be derived from epithelial cells or endothelial cells through a transformation process. In addition, a circulating fibroblast like-bone marrow stem cell capable of forming myofibroblasts has been described (Wynn, 2008) and in liver, stellate cells along the margins of the sinusoids transform into myofibroblasts.

Histochemically, myofibroblasts express a number of specific markers used to differentiate them from undifferentiated fibroblasts. These include alpha smooth muscle actin (α SMA), cadherin II (Ehrlich et al., 2006), and paladin 4lg (Ronty et al., 2006). In some tissues, myofibroblasts play longstanding resident roles of support and immunology. For example, myofibroblasts normally function to maintain and regulate shape of crypts and villi in the alimentary tract but can also act as stem cells and as atypical antigen-presenting cells. They lend structural support to tissues and perform paracrine/endocrine functions. In most other tissues, myofibroblasts exist in the short term to facilitate wound healing. After injury, myofibroblasts resemble many aspects of a smooth muscle cell and, when activated, migrate to sites of damaged tissues and synthesize cytokines and ECMPs to facilitate healing (Hinz, 2007). Signals for fibroblast to myofibroblast differentiation include biomechanical strain and a variety of cytokines, most notably TGF- β (Fig. 7.20). In response to mechanical strain, fibroblasts acquire contractile stress fibers (Werner and Grose, 2003) composed of cytoplasmic actins. At this stage, a unique phenotype, the protomyofibroblast, appears to exist. These cells begin the process connecting to ECMPs via stress fibers and to other cells via N-cadherin-type adherens junctions (Hinz et al., 2004). Normally, at the conclusion of tissue repair, the reconstructed ECMPs (produced by matured myofibroblasts) take over the mechanical load, leading to the lack of further need for resident myofibroblasts (Tomasek et al., 2002). Increased interstitial fluid flow increases fibroblast to myofibroblast differentiation, collagen production, and alignment and fibroblast proliferation. These observations lead to the speculation that enhanced lymphatic drainage may play a role in fibrogenesis and fascial repair by promoting interstitial fluid flow (Hinz et al., 2004). Expression of α SMA allows for significant contractile ability (Hinz et al., 2001). This process appears to be irreversible and be regulated at the level of Rho/Rho kinase-mediated inhibition

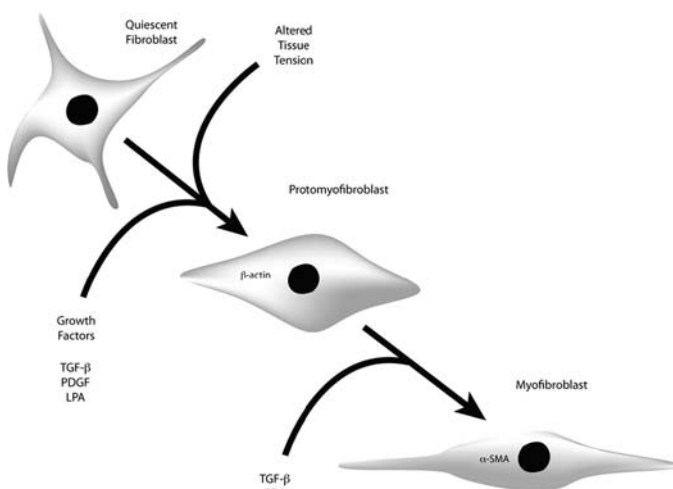

Figure 7-20 The stages in the transformation of a fibroblast into a myofibroblast.

of myosin light chain phosphatase (Tomasek et al., 2006). If this occurs throughout the fascia, then the hypothesis that fascia is capable of contraction may have its origin in the recruitment and/or differentiation of fibroblasts to myofibroblasts (Schleip et al., 2005). Since myofibroblasts express gap junctions, cell: cell communication is facilitated and potential syncytial behavior, such as coordinated contraction of large sheets of myofibroblasts (Gabbiani et al., 1971) lends further support that fascia has the capacity for myofascial-mediated contraction that is propagated and reinforced cell to cell.

Macrophages

Several types of cells typically found in connective tissue appear to have the ability to activate fibroblasts, enhance fibrosis, and most likely increase the transformation of these cells into myofibroblasts. The first of these cell types is the fixed macrophage or histiocyte (Fig. 7.14); these cells represent the major link between the fascia system and the immune system. Macrophages are derived from circulating monocytes that have migrated into the tissue. Once in the tissue, monocytes differentiate into one of three main lineages: tissue macrophages (histiocytes such as is seen in fascia, Kupffer cells in the liver, and microglia in the central nervous system), myeloid dendritic cells such as is found in the skin and gut lining, or osteoclasts in bone. Cellular debris or proinflammatory cytokines in the surrounding extracellular matrix activate tissue macrophages. Activation increases macrophage phagocytic capabilities and their secretory activity, producing additional cytokines. Taken together, macrophages and monocytes are the largest producer of tumor necrosis factor- α (TNF- α) (Papadakis and Targan, 2000). In addition, activated macrophages express more class II MHC molecules and are more potent antigen-presenting cells than resting macrophages. Migration of additional macrophages into injured tissue is further enhanced by proinflammatory substances. Importantly, activated tissue macrophages release TGF- β 1, which promotes the proliferation and differentiation of collagen-producing cells such as fibroblasts and myofibroblasts (Kisseleva and Brenner, 2008). These processes predispose to increased fibrosis and scar or adhesion formation.

Mast Cells

Scattered throughout connective tissue and typically associated with neurovascular bundles are histamine-containing mast cells. The precursors of these histamine-containing cells are generated by hematopoietic stem cells in bone marrow. Contrary to histamine-containing basophils, the precursors of the mast cells enter the circulation in an immature form and do not complete their maturation until they enter the peripheral tissue. Mast cells are heterogeneous with at least two populations identifiable by staining, one group contains trypase and favors visceral organs in their distribution and the other group contains multiple protease enzymes and is more often found in connective tissue such as dermis. Commonly associated with the response to parasite invasion, mast cells are known to have other functions in connective tissue as well. These granule-laden cells are capable of phagocytosis and the production of proinflammatory cytokines. Mast cells express Fc ϵ RI, a receptor that binds the Fc portion of the IgE antibody. When IgE binds to the cell, a degranulation process is initiated resulting in the release of a host of biologically active agents such as histamine, heparin, chondroitin sulfates, neutral proteases (trypase), acid hydrolases, capthepsin G, and carboxypeptidase (Galli, 1993). The location of the mast cell in connective tissue facilitates the delivery of its active agents to fibroblasts. Connective tissue mast cells have been identified as carrying prefabricated stores of TNF- α , a potent proinflammatory

compound that stimulates fibroblasts and results in fibrosis (Galli, 1993). Mast cells have been reported in increased numbers in tissue undergoing fibrosis (Metcalfe et al., 1997), but their role in tissue healing is not yet clarified. Thus, along with macrophages, mast cells appear to be capable of activating fibroblasts and enhancing the fibrosis occurring in and about an inflammatory event.

Extracellular Matrix Components

Connective tissue is composed of two major extracellular components: the first is a fibrous component responsible for the toughness of connective tissue and the second is the gel-like ground substance into which the cells and fibers are embedded. The most prevalent of the fibers present in connective tissue are those constructed of collagen molecules.

Collagen Fibers

Collagen is an insoluble fibrous protein, each fibrous molecule of which is made up of three pro- α -chains of amino acids woven together in a triple helix. The collagen molecules are woven together in a periodic manner as illustrated in Figure 7.21. Variations in the types of amino acids utilized in the α -chains create at least 27 described variants of collagen (Kavitha and Thampan, 2008). Differing collagen types are found in diverse tissue reflecting their various functions (Table 7.1). Major forms in the human body are types I, II, and III.

Although individual collagen molecules are synthesized intracellularly, the fibrils are assembled in the extracellular medium surrounding the cell. Collagen is produced by fibroblasts and myofibroblasts as well as by some forms of epithelial cells (Tabata et al., 2008). Activated monocyte also act as a potential source of collagen. Common factors that can enhance the production of collagen include acetaldehyde, a breakdown product of alcohol, radiation, ascorbic acid and, glucose (type III collagen only). Growth factors such as TGF- β and PDGF increase collagen synthesis, while TNF- α (originally named *cachexin*) suppresses collagen

synthesis. Minerals such as calcium and hormones such as estrogen enhance collagen synthesis, while parathyroid hormone decreases collagen synthesis (Kavitha and Thampan, 2008).

Elastic Fibers

Similar to collagen, elastin is a water-insoluble protein molecule, derived from tropoelastin. This precursor protein is synthesized in the cell and assembled into fibrils in the extracellular matrix. However, unlike collagen, tropoelastin is an amorphous substance and an additional molecule, a microfibril, has to be produced and secreted in order for elastic fibers to form. The microfibril acts as scaffolding into which the tropoelastin molecules are placed.

Elastic fibers are distensible and will rebound when released from a stressor; thus, as the percentage of elastin increases, the connective tissue becomes more resilient. Examples include the ligamentum flavum in the spine and the elastic layers present in the larger arteries.

Laminin and Fibronectin

To maintain healthy and responsive connective tissue, there must be a mechanism for linking its cellular components to the surrounding environment. This involves several glycoprotein molecules of which laminin and fibronectin are key representative examples. These molecules function, in part, to link the cytoskeleton of the cell to the fibrous skeleton—collagenous and elastic—of the surrounding connective tissue. Laminin and fibronectin are secreted from fibrocytes and bind with integrins (adhesion molecules) located on the membranes of cells as well as to matrix components such as collagen, fibrin, and heparin sulfate proteoglycons. In this manner, the cell attaches to the surrounding extracellular matrix and the resulting complex determines cell shape and facilitates cell migration through the matrix as well as enhancing the cells' responsiveness to stressors within the matrix.

Integrins initiate cell signaling processes leading to changes in cell function (Schwartz and DeSimone, 2008). Thus, integrins, by transmitting force across the cell membrane, represent a major

Figure 7-21 A diagram summarizing the formation and periodic nature of collagen fibrils. (Taken from Cormack DH. *Ham's Histology*. Philadelphia, PA: J.B. Lippincott Co., 1897.)

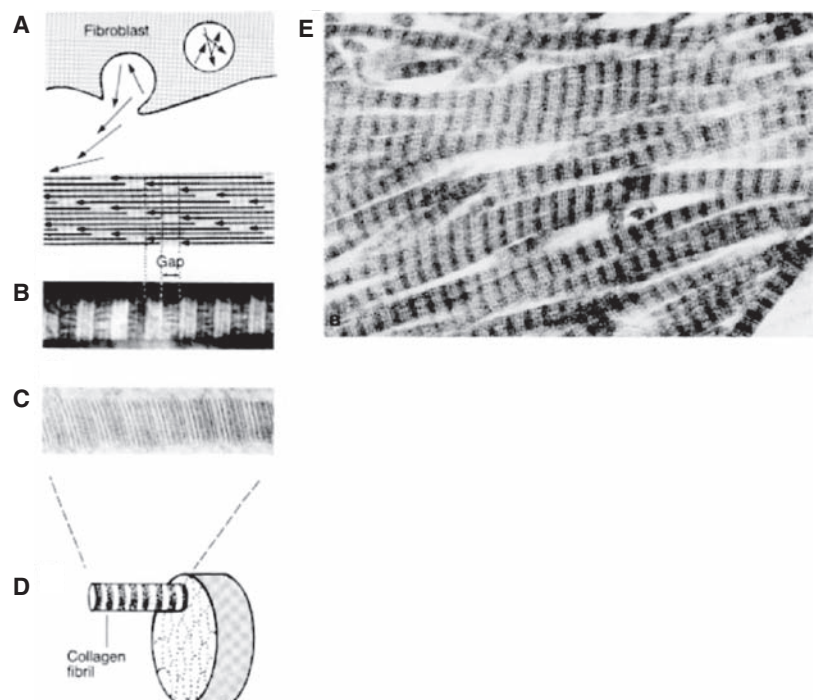

TABLE 7.1

Summary of collagen types along with their structure and function

Classes of Collagen	Collagen Type	Tissue Distribution	Ultrastructure	Site of Synthesis	Function
Fibril-forming collagens	I	Dermis, bone, tendon, teeth, fascia, sciera, organ capsules, fibrous cartilage	Densely packed thick fibrils with marked variation in diameter	Fibroblast, osteoblast, odontoblast	Resistance to tension
	II	Hyaline and elastic cartilage, intervertebral disc, vitreous	No fibers, very thin fibrils embedded in ground substance	Chondroblast	Resistance to tension
	III	Bone, skin, smooth muscle, arteries, uterus, kidney, lung, tendon, periosteum, endoneurium	Loosely packed thin fibrils with more uniform diameter	Fibroblast, smooth muscle cells, Schwann cells, hepatocytes, mesenchymal cells	Structural maintenance in expansile organs, wound healing, mediate attachments of tendon, ligament, and periosteum to bone cortex
	V	Skin, bone, tendon, synovial, membrane, liver, vascular tissue, placenta, teeth	Form quarter staggered fibrils	Fibroblasts, osteoblasts	Control of fiber diameter
	XI	Cartilaginous tissue	Form quarter staggered fibrils	Chondrocytes	Control of fiber diameter
Fibril-associated collagens	IX	Uniform throughout cartilage matrix, vitreous humor	Covalently crosslinked to type II collagen fibrils	Chondrocytes	Contributor of mechanical stability and resistance to swelling of type II collagen framework
	XII	Ligament, tendon, perichondrium, periosteum, periodontal ligament, reticular dermis	Covalently crosslinked to type I collagen fibrils	Fibroblast, myoblast	Control of fiber diameter and interaction of proteoglycans
	XIV	Codistributed with type I	Covalently crosslinked to collagen fibrils	Fibroblast, myoblast, osteoblasts, endoneural and perineural cells	Control of fiber diameter and interaction or proteoglycans
	XVI	Skin and cartilage		Fibroblasts, keratinocytes	Maintenance, organization, and interaction of fibrillar structures in the ECM
Network forming collagens	IV	Basement membranes		Fibroblasts	Separates tissue compartments, surrounds many cell types (e.g., Smooth muscle cells and nerve cells), plays a role in regulation of cell growth, migration, and differentiation.

(continued)

TABLE 7.1 (Continued)

Filamentous collagens	VI	Ubiquitous in connective tissue, concentrated in particular and adjacent to basement membranes of myofibers, blood vessels and intramuscular nerves	Fibroblasts, macrophages	Cell attachment, differentiation, suppression of apoptosis and as an anchoring meshwork for ECM structures
Short-chain collagens	VIII	Cornea and vascular tissue	Smooth muscle cells	Stimulates smooth muscle cell migration, invasion and binding in vascular tissue
	X	Hyaline cartilage	Chondrocytes	Possibly endochondral ossification and indirectly hematopoiesis
	XIII	Blood vessel wall, glomeruli of kidney, myotendinous junction	Fibroblasts, osteoblasts	
Long-chain collagens	VII	Skin basement membrane	Keratinocytes, fibroblasts	Secures basement membrane to adjacent connective tissue matrix

Sources: Liu et al., 1995; Culav et al., 1999; Hou et al., 2000; Kassner et al., 2004; Eble et al., 2006; Zou et al., 2008; Schnorr et al., 2008.

link between external mechanical force applied to the extracellular matrix and the cell and the initiation of movement and metabolic changes within the cell (Katsumi et al., 2004). This process has been termed *mechanotransduction* and is a feature of fibroblasts, chondrocytes, and osteoblasts. Importantly, stress and strain placed on the connective tissue can be transferred, through its fibrous component, to the cell membrane and cell cytoplasm. The time frame on this response is relatively rapid; changes in integrin composition can be noted in stressed cells within tens of seconds to tens of minutes after the onset of the stressor.

Mechanotransduction, leading to intracellular signal transduction, plays numerous roles in normal development, the maintenance of health and the ontogeny of disease, particularly in the aging process (Silver et al., 2003; Wu et al., 2009). Aging can impair the ability of skeletal muscle to respond to altered load and tension; the pathophysiological causes of these changes appear to involve intracellular signaling transduction pathways sensitive to mechanotransduction at the cell surface. Similarly, synovial joints respond best to cyclic stimulation; this quality is mediated by mechanotransduction and diminished in the aging joint. Additional age-related changes in mechanotransduction in the cardiovascular and respiratory systems underlie the onset of the loss of compliance in the heart as well as endothelial cell and smooth muscle dysfunction in the vasculature. Age-related loss in control of smooth muscle cell contraction, leading to airway hypersensitivity and hyper-reactivity, is possibly related to a decreased sensitivity to tension in the airway walls, a result of the slow loss of mechanotransduction in the airway smooth muscle. Finally, age-related loss of contact between fibroblasts process and collagen fibers in the dermis results

in diminishing mechanotransduction and is thought to be related to decreasing resilience of skin with age (Wu et al., 2009).

Growth Factors Associated with Fibrosis

Transforming Growth Factor- β

Extensive cell-to-cell communication is necessary in all tissues in order to maintain normal homeostatic activities and to respond appropriately to any allostatic challenge. Cytokines represent a group of soluble mediators intimately involved in regulating cell function in health and disease. The TGF family is a major group of cytokines regulating the growth and differentiation of cells as well as cellular response to stress and injury including programmed cell death. TGF- β , one of several members of the TGF family, is a protein secreted in an inactive form, which is subsequently activated through proteolysis. Numerous cell types produce TGF- β ; however, a very significant reserve of TGF- β in tissue comes from blood platelets. The receptors for TGF- β are members of a kinase family and initiate signal transduction pathways in the receiving cell (Massagué, 1996). TGF- β plays a significant role in the normal development and maturation of tissues and in tissue healing subsequent to injury as well as in tissue remodeling leading to fibrosis and oncogenesis (August and Suthanthiran, 2006; Border and Noble, 1994; Kitisin et al., 2007; Sporn et al., 1986).

The function of TGF- β is dependent on the specific tissue in which it is located and the surrounding extracellular milieu. Thus, activated TGF- β can either inhibit or stimulate cell proliferation based on environmental factors; however, in most situations, it appears to repress cell division and enhance differentiation

(Massague, 1990). It is also chemoattractive to immune cells and enhances the deposition of extracellular matrix by activating fibroblasts (reviewed in Border and Noble, 1994). Interestingly, TGF- β is also capable of autoinduction of its own production from connective tissue cells such as macrophages. In inflamed tissue, TGF- β can inhibit the production of TNF- α and IL-1 and suppress free radical production by macrophages, giving it an anti-inflammatory role.

TGF- β is extensively involved in wound repair and overproduction of TGF- β is a key feature in tissue fibrosis (Barrientos et al., 2008). Acute injury presents with a transient increase in TGF- β ; however, chronic reinjury results in overproduction of TGF- β and subsequent tissue fibrosis. Elevated levels of TGF- β are seen in disease states and during chemotherapy and are thought to be responsible for the resulting tissue fibrosis in the liver and lung (Kisseleva and Brenner, 2008).

TISSUE DYNAMICS: FIBROSIS AND TISSUE REPAIR

Fibrosis involves the proliferation extracellular matrix material replacing or overgrowing the parachymal tissue resulting the scarring and hardening of the organ. Typically, it develops from a chronic inflammatory state and can occur in such organs as kidney, liver, and lung as well as in muscle and tendon (Wynn, 2008). In acute tissue injury, transient expression of TGF- β leads to the development of myofibroblasts and the synthesis of collagen, both processes beneficial to normal wound repair. However, persistent irritation of the tissue sustains the production of growth factors as TGF- β leading to the persistence of myofibroblasts and the excessive secretion of collagen, processes fostering the buildup of fibrotic scars.

That myofibroblasts normally disappear from newly repaired sites support its role in wound repair, and this process is one of spontaneous and widespread myofibroblasts apoptosis—also termed *programmed cell death* (Carlson et al., 2003). Therefore, proapoptotic molecules such as nitric oxide (NO) signal the end of the reparative stage, and their premature presence could lead to incomplete repair by premature loss of load-bearing myofibroblasts and the ECMP they secrete. In cases where normal apoptosis does not occur, fibroblasts as well as myofibroblasts proliferate leading to fibrosis. The increased secretion of ECMPs by these cells, while affording tissue repair, also potentiates tensile strength and may ultimately restrict the very structures it aims to repair and protect. In fact, fascial restrictions, palpable by clinicians, are the very sites targeted by several osteopathic manipulative techniques (Osteopathic Manipulative Techniques) including direct and indirect myofascial release techniques. Proliferative fasciitis is associated with activated pericytes (fibroblast-like cells found lying along blood vessels), which appear to act as additional sources of fibroblasts and/or myofibroblasts. Presence of additional myofibroblasts, in turn, would perpetuate enhanced fascial tension and exacerbate inflammatory cytokine production. In addition to ECMPs, myofibroblasts also express and secrete numerous cytokines including the interleukins and others. Given that fascia has been shown to support blood cell flow through channels (fascial extensions of inferiorly based fasciocutaneous flaps exhibit erythrocyte flow in vascular channels of the deep fascia; Bhattacharya et al., 2005), it is theorized that fascia-derived cytokines have the ability to be delivered systemically by hematogenous movement. PGE₂ and PGEFr- α have been identified in association with nodular myofibroblasts in the fascia of patients with Dupuytren disease. Therefore, molecules such as these with vasoactive capacity may also play key roles in the recruitment and/or differentiation of myofibroblasts as well as

distribution of myofibroblast-derived cytokines to distant tissues such as brain, lung, heart, or kidney. If true, this could be a mechanism by which Osteopathic Manipulative Techniques targeting fascia in specific anatomical locations could effect change at distant sites (Eagan et al., 2007; Meltzer and Standley, 2007).

Clinically, anti-inflammatory cytokines may play cardinal roles in Osteopathic Manipulative Techniques efficacy as they reduce edema, increase range of motion (ROM), and decrease analgesic requirements (Andoh et al., 2005; Glover and Rennei, 2003; Meltzer and Standley, 2007; Nemet et al., 2002). Relevant to this notion, equibiaxial strain of tendon fibroblasts (3.5% beyond L₀) for 2 hours resulted in increased ATP release and inhibition IL-1 β expression (Tsuzaki et al., 2003). Since IL-1 β is proinflammatory, such fibroblast strain may set in motion a cascade of events to attenuate proinflammatory as well as stimulate anti-inflammatory signaling pathways. Other reports have shown that biophysical perturbation (in the form of shear stress) decreased expression of a number of inflammatory biomarkers (e.g., IL-1 α , IL-14, IL-15, IL-16, and the IL-13 receptor) in endothelial cells (Chen et al., 2001), a process that may be attributed to upregulation of the transcription factors NF- κ B and AP-1 (Resnick and Gimbrone, 1995).

Fascial Response to Stress

The mechanisms by which the fascia generates and responds to biomechanical strain are not clearly elucidated and are likely multifaceted. Mechanosignaling could result from normal movements, injury, Osteopathic Manipulative Techniques, or other stimuli and appears to rely on ion channel gating, integrins, focal adhesions, or by α SMA itself (Goffin et al., 2006). Mechanical deformation of cell shape stretches cells in one or more axes. Types of stretch range from pressure that can be positive (e.g., increased blood vessel flow) or negative (e.g., hypertonic extracellular fluid [ECF]-induced cell shrinking), flow over a cell surface (e.g., shear forces such as seen in vascular endothelial cells), cell elongation (e.g., as seen in muscle cells and various fibroblasts), and bending (e.g., as seen in normal bone cells (Brown, 2000). Fibroblasts and myofibroblasts respond in multiple ways to a wide variety of biophysical perturbations. While integrins and their receptors appear to be critical for some aspects of “outside-in signaling” as reported for ligamentous fibroblasts (Hannafin et al., 2006; Khalsa et al., 2004), strain is sensed at the cellular level by integrin-independent alterations in membrane ion conductances (Yang et al., 2004). Mechanogated ion channels have been reported, and a subset that conducts calcium and that is blocked by the lanthanide gadolinium (Gd) has been termed *stretch-activated calcium channels* (SACCs; see Gupta et al., 1998). Potential roles for calcium in strain-regulated fibroblast function have been reported. For example, palmar fascia responded to mechanical stress by significantly increasing tissue intracellular free calcium concentration (Gupta et al., 1998). In other studies, gingival fibroblasts were stretched in vitro to 1% or 2.8% beyond resting length. While the 1% group showed no intracellular free calcium changes, the 2.8% group displayed a significant increase in free calcium followed by calcium oscillations with a frequency of 2,000/s. These oscillations appear to involve extracellular calcium flux through SACCs in a process that required intact actin scaffolding (Arora et al., 1994).

A Role for Actin in Mechanotransduction

Disruption of polymerized actin, whose expression is greatly elevated upon fibroblast differentiation into myofibroblasts, inhibited strain-induced intracellular Ca²⁺ release as reported in several

studies (Arora et al., 1994; Mohanty and Li, 2002; Wang et al., 2005). These data highlight the potential importance of the actin cytoskeleton in cosensing biophysical strain and perhaps themselves being responsible for changes in SACC conductance observed with strain. The precise role of actin in mediating these responses is unclear, but likely involves the ability of mechanically activated Src (a nonreceptor tyrosine kinase; Wang et al., 2005). Specifically, when actin (by cytochalasin D) or microtubules (by the antineoplastic agent nocodazole) were disrupted, force-induced changes in endothelial cell Src activation were blocked. The directional Src activation observed (i.e., pointing in the opposite direction to the applied stretching of the cell) may aid in the release of cell tension, thus serving as a feedback mechanism for cells to adapt to mechanical perturbations. That others have shown SACC activation to be dependent upon an intact actin cytoskeleton (Arora et al., 1994; Ko et al., 2001; Mohanty and Li, 2002) suggests that injuries and Osteopathic Manipulative Techniques strain could be mechanotransduced cellularly by actin/SACC association.

Direction of the Strain

In addition to strain frequency, magnitude and duration of recent *in vitro* data suggest that strain direction differentially regulates fibroblast growth, ion conductances, and gene expression. For example, human dermal fibroblasts strained multiaxially caused cellular alignment in a manner perpendicular to the strain vector. However, uniaxial shear stress did not affect cells in this regard (Neidlinger-Wilke et al., 2001). Cultured fibroblasts also responded to uniaxial strain with increased thymidine incorporation (signifying DNA replication) and collagen incorporation of labeled proline. Importantly, both these measures *decreased* significantly in fibroblasts strained biaxially (Berry et al., 2003). Fibroblasts depolarized (by increasing nonspecific inward cation current) when compressed, but hyperpolarized when stretched uniaxially between two patch pipettes (Kamkin et al., 2003). Others reported that smooth muscle responded to hyposmotic ECF-induced cell stretch (yielding multiaxial strain) with increased inward calcium current within one minute. This response was not however repeatable if cells were stretched uniaxially between two electrodes (Xu et al., 2000). When C2C12 myotubes were strained multiaxially, ribosomal S6 kinase phosphorylation increased significantly, a response found to be actin dependent since cytochalasin D blocked it. Interestingly, this study also reported that myotubes stretched multiaxially responded with increased p70 signaling, and this was Gd (and therefore SACC) insensitive. Conversely, uniaxial strain of these cells increased protein kinase B expression, a response that was Gd sensitive (Hornberger et al., 2005). Taken together, these data strongly suggest that fascial fibroblasts and myofibroblasts are capable of discerning among various strain directions and responding accordingly with differential stretch-activated calcium channel signaling. Data from these studies suggest mechanisms by which uni- and multiaxial fascia-directed Osteopathic Manipulative Techniques might yield distinct clinical outcomes.

Cyclic stretch of aortic tissue cultures increased mitogen-activated protein kinase (MAPK) phosphorylation. This process led to extracellular signal-regulated kinase-1 and kinase-2 transfer to the nucleus where they phosphorylated transcription factors including NF- κ B and AP-1 (Lehoux et al., 2000). Since these factors are responsible for IL-6 and IL-8 expression (Andoh et al., 2005), they may be involved in strain regulation of fibroblast IL and other cytokine secretion. These data further suggest a mechanism (i.e., MAPK) by which strain stimulates fibroblast proliferation (Berry et al., 2003; Standley et al., 1999, 2001). Fibroblast

proliferation, while often thought of as contributing to tissue congestion, edema, and other proinflammatory processes, could also serve as a mechanism by which myofascial release (MFR) and other manual medicine techniques (MMT) result in long-term positive treatment outcomes. This would be accomplished by further (and potentially sustained) enhancement of cytokine pools from actively proliferating fascial fibroblasts and correction of dysfunctional ECMP crosslinking as has been postulated by others (Gupta et al., 1998). Alternatively, long-term efficacy could result from MFR-induced release of apoptotic cytokines (e.g., NO; see Dodd et al., 2006) causing selective fibroblast death from injury sites and removal of fibrotic materials responsible for pain and attenuated ROM. It has been reported that fibroblasts themselves respond to various strain types by increasing secretion of several ILs, while decreasing secretion of others (Eagan et al., 2007; Meltzer and Standley, 2007). In fact, *in vitro* modeling of repetitive motion strains increases while addition of modeled counterstrain decreases inflammatory IL secretion. Whether this process involves fibroblast to myofibroblast differentiation has not been reported. Clinically, activation of anti-inflammatory cytokines (and/or attenuation of proinflammatory ones) could account for increased ROM of injured tissues and joints, decreased edema, and decreased need for analgesics in manners dependent upon fibroblast growth responses.

SUMMARY

Fascia is defined as irregular connective tissue that plays a role in surrounding and protecting the organ systems of the body.

Four distinct layers of fascia were presented: pannicular, axial (appendicular), meningeal, and visceral.

The components of fascia were presented with particular emphasis place on the myofibroblasts.

The dynamic aspect of fascia was discussed.

KEY CONCEPTS

- Biomechanics describes the relationship between structure and function.
- Motion and forces in three-dimensional space can be divided into components with a magnitude of action in each dimension.
- Stress, strain, and force moments are terms used to describe how forces act on objects and how objects respond to those forces.
- The biomaterial properties of tissues such as bone, cartilage, muscles, tendons, and ligaments, are based on a hierarchy of biomechanical properties from the molecular, cellular, tissue, and gross anatomic levels.
- Tissues are constantly remodeling in response to the stresses placed upon them.
- Excessive stresses or inadequate responses to them (loss of homeostasis) result in injury or disease in tissues.
- The basic biomaterial properties and remodeling capacity (adaptability) of tissues change with age, generally to render them more vulnerable to stresses and injury.
- The gross biomechanical properties of the skeleton are defined by bony structure and the attachment of muscles and tendons that produce forces across joints.
- The primary motions at the surfaces of articulations are gliding (translation), rotation, rolling, compression, and distraction.
- Basic properties of joint kinetics can be described by measuring the forces produced by muscles and the length of moment arms acting across joints.
- The elastic properties of muscles, tendons, and ligaments allow them to store energy in some phases of movements for release during others.
- Normal movement in the spinal column is a composite of smaller motions of individual vertebrae. Restrictions of movement in one area can result in a compensatory increased mobility in others.
- The orientation of intervertebral joint facets in the spine, in association with the direction of spinal muscle contraction, produces a motion coupling of vertebral movement. These coupling relationships differ over areas of the spine.
- It is necessary to consider the biomechanical relationships of the body as a whole when attempting to define the consequences of injury or altered function of a body segment.

BIOMECHANICS DESCRIBES THE RELATIONSHIP BETWEEN STRUCTURE AND FUNCTION

The inter-relationship of structure and function in the body is one of the basic principles of the osteopathic medical profession. The science of biomechanics is dedicated to describing this relationship more generally in biologic systems. This can apply to the organism as a whole (as with kinesiology) or even on a subcellular level (as with microtubular transport mechanisms). The approach to the mechanics of biologic systems is similar to the mechanics of inanimate objects and consists largely of how they respond to forces applied to them. When struck with a hammer, an object may shatter or absorb the force and be accelerated into movement. The response will depend upon a variety of factors including the material comprising the object, the object's shape, internal structure, where and how the force is applied, and so forth. The response of the human body to either externally or internally applied forces can be described similarly, as it must obey the same basic laws of physics. However, the human body and other biologic systems have extremely intricate structural arrangements of highly variable materials down to the molecular level. This can make the accurate

biomechanical modeling of even simple movements very challenging. Additionally, the body also has the essential biologic ability to adapt and structurally remodel itself according to the stresses placed upon it. Some of these adaptations, as in the mechanical properties of tissues, can occur relatively rapidly. This "moving target" property can add an additional layer of difficulty for accurate description.

The capacity of the body to adapt appropriately to environmental stress will make the difference between health and disease. The goal of the osteopathic physician is to assist the body in regaining a balance with the stressors of the patient's environment, usually at multiple levels of consideration. From a biomechanical standpoint, this may involve the correction of somatic dysfunctions or to break cycles of inappropriate responses that have produced them. In doing so, the primary biomechanical considerations for the osteopathic physician must include broad characteristics encompassing both biomaterial characteristics of tissues and the primary mechanical operation of the body as a unit. As opposed to other medical disciplines, this must include a literal "feel" for the characteristics of tissues in addition to figurative "feel" for the understanding of body mechanics derived from a knowledge of anatomy. The primary goal of this chapter is to assist the reader in obtaining this latter knowledge. For this reason, an emphasis

will be placed on basic biomaterial and biomechanical concepts rather than mathematical modeling of properties. As with other chapters in this volume, this chapter is intended to be a summary of biomechanical concepts that are of particular relevance to those who study osteopathic medicine. More comprehensive discussions may be readily obtained from texts on particular topics. It will be assumed that the reader has a basic working knowledge of gross anatomy and the concepts relating anatomy to function.

Motion and Forces Can Be Described as Components With a Magnitude in Each Dimension of Three-Dimensional Space

The strategy for describing the mechanics of biologic materials begins with the same terms and methods employed to describe inanimate objects. The process of interest is broken down into components that can be measured and characterized. These components and their properties are then incorporated into models (often mathematical) that can be used to describe the system and predict its reaction to defined stresses. The terminology used is common to areas of mechanical sciences and can be categorized into terms related to:

1. Dimensions and movement in three-dimensional space
2. The nature of applied forces
3. Properties of biomaterials

Objects and Movements in Three-Dimensional Space Can Be Described as Components in Each of the Three Dimensions

An object can be described by the magnitude of its size in each of its dimensions (length, width, height; Fig. 8.1). Similarly, simple movement (translation) of an object in three-dimensional space can be described as three different components (*vectors*) of movement

Figure 8-1 **A.** An object in three-dimensional space (axes) can be described by the length vectors (height [h], width [w], depth [d]). **B.** The motion of an object can be described as three separate primary vectors of velocity. The actual movement of the object is represented by the resultant vector (r). **C.** A force (F) that is applied to an object may also be represented by separate force vectors in each dimension directed into the object. The object may be moved in a direction (v) by the force. **D.** If one component of the accelerating force is resisted, the object will move in a new direction (Q), determined by the magnitude of the remaining vector components.

(up/down, back and forth, in and out relative to the page) that can occur simultaneously. Vectors will have a magnitude and direction similar to describing the dimensions of an object, except that the magnitude of movement is expressed as velocity (meters per second). Vector components are shown on an axis system (Fig. 8.1) that is used to model three-dimensional space. By describing the vectors of movement in each of these three dimensions, the motion of the object can be characterized. The actual path of the object is referred to as the *resultant velocity vector*. Biomechanical analysis uses similar vector systems to describe most parameters in space, such as velocity, acceleration, and pressure.

Beyond simple models, the properties of each component of a resultant vector can become increasingly complex. For example, an object of irregular shape will require more than a simple length measurement in each dimension to describe it. Similarly, an object moving in space may also rotate about an axis. Because of this, even relatively simple movements of body segments may require sophisticated mathematical modeling to describe the movement.

Applied Forces Can Also Be Expressed as Three-Dimensional Vectors

Applied *forces*, such as a manipulative thrust, are essentially *pressure* (force per unit area) applied to an object. By definition, forces act to accelerate an object of a given mass. Accordingly, an object at rest must have a force applied to it in order to achieve movement through acceleration. An object moving at a constant velocity will require no forces to sustain movement, unless other forces (e.g., friction) are acting to resist the movement. The object's resistance to change of velocity (*inertia*) is also described as the force required to accelerate it from rest (zero velocity) or to decelerate it from movement.

The magnitude of forces and associated force vectors is used to describe external pressures applied to the body and internal forces like those generated in muscles to achieve limb movement. Force magnitudes are expressed as the mass of the object times the acceleration ($F = ma$). The metric unit of force is a newton (N) or 1 kg accelerated to a velocity of 1 m/s each second ($\text{kg} \times \text{m/s}^2$). Like velocity, forces are characterized as a combination of vector components of a certain magnitude in each of the three axes defining space (Fig. 8.1). The *resultant force* is the sum of the individual force vectors. The manner in which the object might be moved or mobilized by the force will depend upon which of the vector components are resisted and which are not (Fig. 8.1). Similarly, a resultant force vector arising from a manipulative thrust would be characterized by describing force components not only directly into the body, but also in lateral directions (rostral, caudal, medial, or lateral) as well as rotational components. Mobilization of body segments by the force will depend upon which components of the thrust meet with direct resistance and obviously how the body is positioned. In biomechanics, it is important to characterize the different components that a force may have in order to understand the ensuing reaction of the material or body structures.

Moments Are Forces that Act at a Distance and/or Produce Rotation of an Object

Forces that act to produce rotation of an object about an axis, or in two-dimensional models, a center point (Fig. 8.2), are called *force moments* (also *moment* or *torque*). The magnitude of a force moment is the product of the force applied and the distance of application from the center of rotation (force \times distance). The latter distance is referred to as the *moment arm*. This is essentially a process of using a lever to produce rotation about an axis. Because of this relationship, it is important to note that moments of the same magnitude may

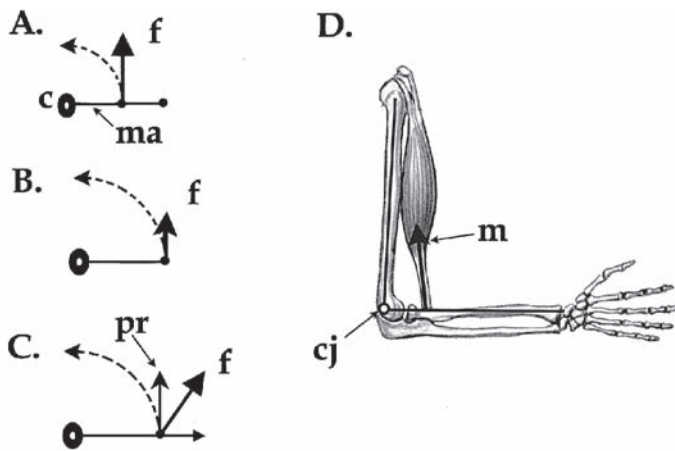

Figure 8-2 Force moments on an object such as a door. **A.** A force (f) applied at a distance (moment arm, ma) in the middle of the door can produce rotation (dotted arrow) around a center or axis (c) located at the hinge. The moment is the force applied times the distance (d) from the center ($f \times d$). A smaller force acting on a longer moment arm at the doorknob (**B.**) will produce the same moment ($f \times d$). **C.** If the force is applied in a direction other than directly against the moment arm, only part (pr) of the force will be used to produce the rotation. **D.** In the body, force moments are generated by muscle contraction forces (m) that produce rotation of a mobile body segment about a center in the joint (cj).

be produced by increasing the force applied while proportionately reducing the moment arm or vice versa (Fig. 8.2). A common example of the properties of force moments can be obtained from pushing open a door (Fig. 8.2). Pushing the door open at the handle usually is relatively easy (low force), because of the long distance (moment arm) between the handle and the center of rotation at the hinge. Note, however, that opening the door at the handle requires a relatively large distance of movement (large displacement). Attempting to push the door open at a point near the hinge (short moment arm) is much more difficult (greater force), but requires less displacement to open the door. Note also that the direction or angle at which the push is applied to the door will determine how much of the force applied is actually used to push the door open (2). This rotation component of the applied force is at a right angle to the surface of the door (directly into the door) at any instant. The remaining force component will be in a direction along the surface of the door. For the same opening force to be maintained, the direction of the applied force must change constantly to move in a circle with the door.

The strategy of changing the force or the length of the moment arm and the direction at which forces are applied is often employed in body mechanics and in manipulation techniques, depending upon the need for more or less force at the cost of greater or lesser displacement.

Moments are used in the biomechanical modeling of body motion because most movements are composites of rotational movements of individual body segments around joints. Force moments are generated from the contraction of muscles attached between two body segments causing the movement of the more mobile segment around a center of rotation (Fig. 8.2). The center of rotation is usually near the articulation surface in the less mobile segment. The moment arm of the contracting force is related to the distance of the muscle insertion on the mobile segment from the center of rotation. In simple biomechanical models of body movement, this

center of rotation in the joint is usually shown as immobile. In actual movements, both segments may be mobile and motions within the joint may also occur to change the center of rotation.

Stresses Are Forces Applied to Objects in Various Orientations

The characteristics of forces applied to an object are described as *stresses* (Fig. 8.3). The magnitude of basic stresses is described as force applied over a defined unit of object surface area or pressure. This may be described as pounds per square inch (psi) or in the metric form, pascals (N per square m). Particular types of stresses are identified to describe their relationship to the object acted upon (Fig. 8.3). For convenience, stresses are usually described for an object that is immobilized or constrained, such that the object must resist the stress and not undergo acceleration or movement other than deformation (see “Strain Is Deformation Produced by Stress,” later in the chapter). *Tension* is a force applied perpendicularly outward from the surface of an object (pull), such that the object would be elongated or stretched. *Compression* stress is a force applied perpendicularly inward (push) to the surface of an object, such that the object would be shortened or compressed. *Shear stresses* are forces applied parallel to the surface of an object. *Torsion stresses* are rotation-like forces, which, on a constrained object, act to twist it about a neutral axis (i.e., an axis that would not be translated or moved by the force). *Bending* is also technically a rotation-like force (or coupled coactive forces) that acts to fold or bend an appropriately constrained object along a neutral axis. The sum of all stresses on an object is termed *load*.

BEHAVIOR OF MATERIALS SUBJECTED TO FORCES

The Behavior of an Object or Material May Be Isotropic or Anisotropic

While stresses may originate from external forces applied to an object’s surfaces, they are also transmitted from the area of contact through the entire substance comprising the object. The primary

Figure 8-3 **A.** Stresses are forces acting from various orientations relative to the object. Stresses are named according to their action upon the object. **B.** Tensile stresses act to stretch an object. **C.** Compressive stresses compact the object. **D.** Shear stresses act parallel to the surface of an object. **E.** Bending stress acts to fold an object about an axis. **F.** Torsion stresses twist an object about an axis.

factors affecting the transmission of forces through an object are its shape and material composition including infrastructure. The characteristics of the material composition of the object will determine if the object can be accelerated or rotated by a stress of sufficient magnitude or physically broken by it. The shape of an object may dramatically affect the manner in which it responds to similar stresses exerted in different places on the object. An object, such as a sphere of homogenous composition, will respond in the same way to a particular type and magnitude of stress applied to any point on its surface. This type of object is referred to as *isotropic* in relation to stresses. Objects having a nonuniform surface shape (such as an irregular cube) or heterogeneous composition will respond to the same stress differently depending upon the point of application. These objects or materials are referred to as *anisotropic*. Most biologic structures fall into this category.

As with surface characteristics, the internal structure or composition of an object will also determine its response characteristics to stresses. The object's composition and molecular infrastructure determine how a force applied to a particular location is transmitted to the remainder of the object's mass. In objects that have an anisotropic internal composition, such as biologic materials, localized internal stresses are often the primary determinant of the toleration of the material for stresses of a particular magnitude and orientation of a stress. As discussed subsequently, bone, muscle, tendons, and ligaments have a linear cellular/molecular structure that causes the response to loads to differ dramatically depending upon the orientation of the applied stress.

Strain Is Deformation Produced by Stress

As muscles contract, they apply primary localized tensile stresses to bone to accelerate the mobile segment(s) and to stabilize the immobile segment(s). Under this condition, the applied stresses produce a change in the shape of the bone or object (*deformation*). The magnitude of deformation produced by stress is referred to as *strain*. The actual deformation of an object will depend upon the same factors defining stress distribution (internal composition and infrastructure) and is characterized as a sum of different strain vectors. These vectors are usually named for the type of stress producing them (e.g., tensile strain, compressive strain, etc.). Many different strain vectors may be produced within an object by a particular type of stress. A simple example is a bending stress that produces tensile strain on the side of the object opposite the neutral axis and compressive strain in the direction of bending (Fig. 8.4). A similar condition exists with strain on a spinal disc with bending between segments.

The Elastic Modulus Shows the Relationship Between Stress and Strain

While it can generally be assumed that increases in stress on an object will produce an increase in strain, the relationship is not direct, particularly for biologic materials. The relationship between the amount of a particular stress applied to an object and the resulting deformation or strain is shown by a stress/strain curve (Fig. 8.5). In this instance, a material is subjected to a defined stress such as tension. In this model, the strain may be quantified as the change in length of the object (as with a tendon or ligament). A similar result could be obtained by the displacement of the center of a bending load (as with a bone). Stress/strain relationships for most materials have a linear region (elastic behavior) in which increasing stress produces a corresponding amount of deformation (Fig. 8.5). Reducing the stress or unloading of the object will allow it to return

Figure 8-4 A. Bending strain produces tensile stress (*t*) on one side of an object and compressive stress (*c*) on the other. B. This same principle applies directly to biologic materials, such as spinal discs.

to its former shape without a permanent change in shape. In this elastic area of the stress/strain curve, the slope of the line (stress/strain) is termed the *elastic modulus*. The elastic modulus is also a quantitative description of *stiffness*, a term commonly associated with the amount of force necessary to bend an object.

When an applied stress is greater than that defined by the elastic area (Fig. 8.5), a permanent deformation of the material or plasticity will result. The plastic behavior area of the curve ends with the material *failure* or breaking of the object. Materials may also be described as *brittle* or *ductile* depending upon the amount of deformation they can undergo before failure. *Brittle* objects such as glass will undergo little deformation before they break (fail), and the pieces after breaking retain their shape such that pieces will fit together to produce a puzzlelike reproduction of the object with little deformation. *Ductile* materials such as a copper wire will have a permanently altered shape beyond their elastic region and after failure. Many factors other than basic structure of a material may significantly affect the stress/strain relationship. The most common of these are temperature and the rate at which a stress is applied.

Viscoelasticity Is the Combination of Elastic and Viscous Properties of Materials in Response to Stress

The rate at which a stress is applied can be a particularly important determinant in the response of materials that exhibit a combination of both elastic and viscous behavior in response to an applied stress. Viscous behavior can be described as resistance to flow, such as that observed with cold syrup. Viscosity in biologic materials arises largely, but not completely, from the resistance of their water content to flow into and out of the material with applied stress. For example, spaces between molecules of collagen in ligaments contain a large amount of water with salts and other small relatively mobile molecules. Tensile stress (stretching) of the ligament will decrease the available space between collagen molecules, forcing the fluid between them out of the ligament. This process is similar to stretching a wet sponge (Fig. 8.6). If the structure is stretched rapidly, there is an increasing resistance to fluid movement out of (and into) these spaces, since this requires time. The time required for fluids to move out of intermolecular spaces acts to slow the rate of deformation of an elastic material. This alters the elastic and plastic regions of the stress/strain curve. In combination with

Figure 8-5 A stress/strain curve (right) of an object undergoing increasing tensile stress (left). The change in length can be used as a measure of strain. The curve has an area of elastic behavior, in which a release of stress will allow the object to return to its original shape. In this area, the stress/strain relationship can be expressed as elastic modulus. With increasing stress, the material has permanent deformation or plastic behavior, followed by material failure.

the elastic properties of the material, this behavior is described as *viscoelasticity*. This property is usually modeled as a spring acting in parallel to a resistance provided by a fluid compartment (Fig. 8.6).

Besides the flow of small molecules from intermolecular spaces, frictional resistance due to molecular movement and ionic interactions between molecules also contributes to the viscosity

Figure 8-6 Left. Viscoelastic behavior occurs when a material containing a mobile fluid phase is stretched (or compressed) from a resting length ($L1$) to force fluid out of an elastic matrix similar to a sponge to a greater length ($L2$). This can be modeled schematically (bottom) as a spring in parallel with a fluid containing resistance compartment with porous baffles. Right. Time-dependent viscoelastic behavior of a material under tensile stress. Creep (top) is a measure of deformation (strain) over time with stress (stretch force) held constant. Stress/relaxation (bottom) is a measure of stress over time with strain held constant. (Portions of this figure have been adapted from Carlstedt CA, Nordin M. *Biomechanics of tendons and ligaments*. In: Nordin M, Frankel VH, eds. *Basic Biomechanics of the Musculoskeletal System*. 2nd Ed. Philadelphia, PA: Lea & Febiger, 1989:59–74, with permission.)

in a material. These molecular interactions, along with the elastic properties of the material, are important in the return of water and other small molecules back into the matrix, again much as a sponge reabsorbs fluid after being squeezed. This recovery process is important if the biomaterial properties of the tissue are to be maintained under repeated loading. Additionally, since viscoelastic behavior involves the movement of small molecules and the interaction between molecules, temperature can significantly affect this property.

Viscoelastic properties can produce significant alteration of material behavior when the rate of loading is too fast for the fluid exchange to occur. Under these conditions, a material may exhibit a higher elastic modulus (i.e., appear stiffer or more brittle) under high loading rates, as compared to the same load applied over a longer period of time. If a viscoelastic material is stretched rapidly and the load is sustained after the initial loading period, there will be a rapid initial deformation of the material followed by a slower deformation as the remaining fluid in the matrix reaches a new equilibrium at a slower rate (Fig. 8.6). Two types of measurements are used to describe this property. First, if the material is subjected to an initial load, such as tensile stress (Fig. 8.6), which is then maintained, the material will stretch to an initial length and then more slowly increase in length as the more resistant fluid in the matrix effuses. The slower phase after the initial stretch is called *creep*.

Another measurement looks at the load necessary to maintain a constant deformation or, in the case of Figure 8.6, the length of the material. As the matrix reaches equilibrium, the load necessary to maintain the length will decrease. This property is referred to as *stress/relaxation*.

Because of their high water and solute content, bone, muscle, ligament, tendon, and other biologic materials have viscoelastic properties that are important for their function. Due to the differences in the cellular structure and the matrix between cells in these materials, the actual viscoelastic properties of these tissues differ markedly.

Fatigue is the Failure of a Material as a Result of Repeated Stress

Fatigue is a multifaceted term that is used to describe material failure after repeated application of stresses that, if applied individually, would not produce failure. In nonbiologic materials such as metals, a significant part of fatigue failure can result from the accumulated breakdown of crystalline structure as the result of repeated stress, such as breaking a steel or copper wire by repeated bending. In biologic systems, the process of fatigue failure becomes more complicated, because of the ability to repair and adapt materials to repeated stress. For example, bone under repeated stress may undergo microfractures in its structure (see the following section). Depending upon the frequency of the stress and the ability of the bone to repair these microfractures, the bone may suffer a fatigue fracture or adapt to the stress by increasing its mass.

PROPERTIES OF BIOLOGIC MATERIALS: BONE

Bone Is an Anisotropic Material Comprising Osteons

Mechanical models describing nonbiologic materials are difficult to apply to biologic systems directly, due in part to their complicated structure. The response of biologic materials to stresses is determined by structural properties layered down to the subcellular level. Still, the material properties of bone structure as a whole are clearly traceable from tissue structure (1). Bone consists of connective tissue cells organized and embedded in a highly mineralized extracellular matrix. Although lower than other tissues, this matrix also contains significant amounts of water and other small molecules, giving bone viscoelastic material properties. The basic unit of organization is the osteon or haversian system. These systems consist of concentric rings of bone cells or osteocytes around a central cavity (the haversian canal) through which the blood vessels and nerves supplying the bone travel (Fig. 8.7). The osteons are arranged in a dense, regular pattern around the shaft of long bones to form cortical or compact bone. The border between osteons is the *cement line*. The cement line is structurally weaker than the substance of the circularly oriented osteons and can often be identified microscopically as the site of failure of bone tissue under high stresses (2). Osteocyte lacunae may also be a site of structural weakness (3). Beneath the cortical layer of compact bone is a central core of more porous bone (termed cancellous, trabecular, or spongy bone), with lacunae comprising the marrow space. While the structure of cancellous bone may initially appear as a random mesh of thin bone, it can be readily shown that areas of organization do exist and contribute to the structural stability of the bone as a whole by distributing stresses internally in the bone structure (4) (Fig. 8.7).

Bones Are Structured to Resist the Primary Functional Stresses Placed Upon Them

As might be expected, the highly organized cellular and gross structure of bone causes it to behave in an anisotropic manner to applied stresses. The outward structure and infrastructure of bones are organized to resist the major stresses to which they are subjected under normal physiologic conditions. For the structure of a long bone such as the tibia, the compressive loading lengthwise will require much higher stress before failure compared to a stress of similar magnitude applied perpendicularly to the long axis. In this manner, from the subcellular to gross structure, bone represents one of the most obvious examples of the structure-to-function relationship. This anisotropic behavior also defines the manner in

Figure 8-7 Histologic and structural properties of bone. **A.** Compact bone structure is organized into cylinder-shaped osteons with haversian canals (*H*) that are separated by a cement line (*outline*). **B.** In long bones, osteons are oriented longitudinally along the axis of the bone and surrounded by circumferentially oriented lamellar bone (*L*). Both surround a marrow space that contains marrow and cancellous bone. **C.** The organization cancellous bone is not random in structures such as the femur, where the trabeculae (*black*) help to distribute stresses through the internal structure of the bone.

which bones will undergo material failure when excessive stresses are placed upon them.

Different Stress Vectors Produce Varying Types of Bone Failure (Fracture)

The material failure (fracture) of bone can be observed clinically for all major categories of stresses, with the mechanism of material failure varying with type of loading (1). Also, the viscoelastic behavior of bone gives it sensitivity to loading rate. At rapid loading rates, bone appears stiffer as the movement of fluid and molecular friction increasingly resists deformation. This causes bone to store more energy before failure. When bone does fail at high loading rates, its more brittle behavior makes it more likely to fragment, much like shattering glass (comminuted fracture) (5). Accordingly, fractures can also be categorized into different types according to the energy absorbed with the resulting failure, low energy, high energy, and very high energy. Higher-energy fractures (automobile accidents, gunshot wounds) are typically accompanied by bone fragmentation and soft soft-tissue damage, as the energy stored under rapid loading is dissipated with biomaterial failure.

Under physiologic conditions, bones will experience a combination of stress vectors at the same time and failures may result from the combination rather than a particular stress type. However, fractures do begin in the stress component direction most prone to failure according to the material properties of the bone. This allows the description of some types of fracture resulting from particular stress categories. Muscles pulling on bone typically generate tensile stress fractures. The tensile fracture of the calcaneus adjacent to the Achilles tendon insertion is a frequent example (Fig. 8.8). Compression fractures are most commonly found in the vertebral column, which is subject to high compressive load and a weakening of the bones with age. Shear forces act parallel to bone surfaces, typically at articulations, where bones are in contact. Shear fractures can

Figure 8-8 Examples of fracture types resulting from a material failure due to a primary stress component. **A.** Tensile fracture of the calcaneus. **B.** Spiral fracture from torsional stress of the tibia. **C.** Bending stress fracture. **D.** Example of how muscle contraction forces can act to counter bending stress. Bending stress produces tensile forces on one side of the tibia and compressive stress on the other (see fig 8.4). Muscle contraction can act to counter the tensile component by producing a compressive moment. (Portions of this figure have been adapted from Gollnick PD, Matoba H. The muscle fiber composition of skeletal muscle as a predictor of athletic success. An overview. *Am J Sports Med.* 1984;12:212–217, with permission.)

occur under conditions of compression loading of a joint, coupled with a shear or a lateral force across the articulation with a failure of the joint bony plateau. Bending and torsional loading produce multiple types of material stresses on bone depending upon the direction of the loading. As described earlier, bending of an object produces tensile stress on one side of an object and compression on the other (Fig. 8.4). Bone is weaker in tension than compression, so bone material failure begins upon the tensile stress side (Fig. 8.8). Immature bone, which is less calcified and more ductile, may be more sensitive to compression and fractures may occur on the compressive side first. Torsional loading (Fig. 8.8), or usually twisting around the long axis of bones, produces shear stresses around the neutral axis while compression and tension loading are diagonal to the axis. The resulting failure (spiral fracture) is initially due to shear stress followed by tensile stress failure along a diagonal axis. As should be expected, if there are weaknesses in the bone structure, such as during rehabilitation after injury, failure will occur at the weakest point or at the site of bony defect with bending loads.

The biomaterial failure of bone under stresses is greatly influenced by the attachment and contraction of muscles. Muscle activity can decrease or counter stresses produced on bone by altering the direction of the resultant stress vectors to those to which bone may be more tolerant. Figure 8.8 shows how muscle activity may alter a bending or tensile stress to produce compression stress. As bone is very resistant to compressive stress (such as weight on the long axis of the tibia), this redistribution of stress can be important to avoiding stress fracture. Consequently, the physiologic tiring of muscle during strenuous exercise can contribute significantly to fractures because the protective mechanism is lost.

While sudden, large stresses are usually associated with bone fracture, failure of the material itself can result from repetitive loading over a period of time. This fatigue-type fracture of bone involves an accumulation of smaller failures within the bone microstructure and is dependent upon the magnitude, frequency, and rate of loading. Even low-level repetitive loads may produce fatigue microfractures in bone (6). In living bone, these microfractures will be repaired by cellular reactions to the injury. If the fatigue process

outpaces the repair, failure will eventually occur as a repetitive stress fracture. A common example of this is the fatigue fracture of metatarsal bones in long-distance runners (7).

Bone Remodels Its Structure in Response to Stress and Depends upon Stresses to Maintain Its Material Properties

In the presence of stresses, bone can alter size, shape, and structure to withstand stresses placed upon it. The unusual corollary to this property is that bone must be subjected to stress in order to maintain its biomaterial properties. The underlying principle of this process in bone has been expressed as Wolff law, which states that bone is increased where needed and resorbed where not needed (8). The resorption of bone under conditions of reduced usage or immobilization (9) is of particular concern clinically, since mechanical stress on bone is reduced during casting or in more limited conditions, such as weightlessness in space travel (10). Immobilization results in the resorption of periosteal and subperiosteal bone (11) and a decrease in bone strength and stiffness (12). Conversely, the hypertrophy (13,14) and increase in density of bone (15) may be observed in normal bones in response to strenuous exercise. Both hypertrophy and resorption of bone may be observed around implant screws and plates used to surgically stabilize bone defects or to attach prosthetic joints (16).

Bone properties also are altered with aging, with a progressive loss of bone density and size (17,18). This is independent of the condition of osteoporosis. The result is a decrease in bone strength and stiffness and altered stress/strain properties, including an increase in brittleness and a reduction in energy storage capacity. These properties make bones more susceptible to material failure under high stress conditions with increasing age.

ARTICULAR CARTILAGE

The Surfaces of Contact Between Bones in Synovial Joints Is Hyaline Cartilage

There are three identified primary types of cartilage in the human body: hyaline cartilage, fibrocartilage, and elastic cartilage. Hyaline cartilage covers the surface of the articulations of almost all diarthrodial joints and will be the focus of our description of basic biomaterial properties of cartilage. Cartilage has some similarity to bone in that it consists of cells (chondrocytes) surrounded by an extensive extracellular matrix that they secrete. However, cartilage is avascular; lacking blood vessels, lymph channels, or nerves within its matrix; and the matrix secreted is not calcified as in bone. The extracellular matrix of cartilage consists primarily of collagen (type II), proteoglycans, and 60% to 87% water with inorganic salts and other minor matrix proteins and lipids (19,20). The collagen and proteoglycans form the major structural elements of cartilage, and these interact extensively on a molecular level with the smaller molecules, including water. The interaction of these elements with each other within cartilage and their interaction with the water in the matrix determine the primary biomaterial properties of cartilage.

The major collagen and proteoglycan structural element on the cartilage of articular surfaces is not randomly organized and can be divided into histologic zones that differ in cellular organization from the surface to the underlying subchondral bone (20) (Fig. 8.9). The orientation of collagen fibril bundles within the matrix differs between the layers (Fig. 8.9) with a tangential orientation at the surface, random organization in the middle zone, and radial

Figure 8-9 **A.** Schematic of the orientation (*arrows*) of collagen fibrils (*drawn lines*) in articular cartilage. The orientation varies from the articular surface to the bone interface. **B.** Representation of cartilage surface separated by a thin layer of lubricating fluid (*L*) that prevents direct surface contact. **C.** With a compressive force on the surface (*cf*), additional fluid is exuded and the matrix is compressed. Lateral movement produces tensile (*t*) and shear (*s*) stress on the cartilage surface and matrix components.

orientation near the subchondral bone surface. This orientation provides the basic structural framework for the cartilage and resistance to the loads placed upon it. Depending upon the particular joint function, the primary stresses may be compression, which, as the joint moves, contributes to shear and tensile stresses on the cartilage surfaces (Fig. 8.9).

Cartilage Has Significant Viscoelastic Properties That Are Essential to Its Function

The collagen and proteoglycan structural elements of cartilage have spaces between them filled with water, salts, and other small molecules, forming a matrix with viscoelastic properties as previously described. Further, the structural elements contain molecules such as hyaluronic acid and have ionically charged groups throughout their structure. This property allows them to strongly bind water and inorganic salt within the cartilaginous matrix. The cartilage matrix has properties of flexibility from a pliable, porous collagen superstructure containing small molecules that can be forced out, but with some molecular and ionic interaction based resistance to the efflux. The properties of this matrix allow a viscoelastic behavior in which the cartilage allows rapid, but declining deformation (cushioning) in response to compressive loads followed by creep or stress/relaxation (21) (Fig. 8.7). The slower deformation will continue until equilibrium is reached between the load and the forces resisting it within the matrix. The differing mechanical properties of the layers of articular cartilage interact dynamically to reach equilibrium in response to a sustained compressive force (22).

On a tissue level more closely related to normal function, the viscoelastic response of cartilage can be explained by a compressive stress that produces a rapid efflux of fluid forced out of the extracellular matrix directly beneath it and in areas immediately adjacent to it (Fig. 8.9). The resistance to this efflux of fluid is dependent upon the effective porosity or space available in the cartilage matrix for fluid to move. Other resistance to matrix deformation includes the internal friction generated by movement

between long polymer molecules such as collagen and attached proteoglycans and the ionic binding of these chains to the water and other small molecules. The time required for the fluid phase to reach a full equilibrium between cartilage layers under the applied load may require hours (21). However, because of the elasticity of the collagenous structural elements and ionic interactions with the small molecules of the matrix, this fluid exchange is reversible and supplies a pumping action of nutrients into and waste products out of cartilage in addition to normal diffusion. This action is particularly important because of the avascular nature of cartilage.

Articular Cartilage Has Several Properties That Act to Prevent Wear Damage

Under physiologic conditions, cartilage surfaces of joints contact each other under a variety of loading conditions while showing little wear. This occurs in spite of the fact that joint surfaces are not perfectly smooth. The prevention of wear is due in part to a system of lubrication of synovial articular surfaces provided by synovial fluid and the properties of the cartilage itself. Fluids lubricate surfaces by preventing their direct contact (Fig. 8.9). The first level of lubrication of joint surfaces is the absorption of lubricin, a glycoprotein in synovial fluid that is absorbed onto articular surfaces. This provides a thin boundary of lubricant on the joint surface. The synovial fluid itself also provides a thin film of fluid between the joint surfaces that can be redistributed under loading conditions. Further, during loading, the fluid extruded as a result of the compressive deformation of the cartilage will provide a fluid layer to separate the opposed surfaces (23).

Under normal conditions, the fluid-lubricating properties of the joint will prevent the direct contact of uneven sections or asperities of joint surfaces to contact each other. If contact does occur, wear of the joint surfaces or interfacial wear (mechanical removal of material from a solid surface) may occur. This may consist of abrasion of the joint surface because of contact of uneven elements of the surface or small fragments of joint surfaces may adhere to each other and be dislodged. The efficient lubricating properties of normal joint usually preclude interfacial wear, but it may occur in damaged or degenerated joints (22).

Cartilage Wear May Result from Several Different Mechanisms, Including Intrinsic Changes with Aging

While cartilage can be damaged as a result of traumatic injury as in shearing stress applied to the meniscal cartilage of the knee, the mechanisms of abnormal wear are not as clear. Hypotheses of the mechanism of cartilage wear include the disruption of the structural molecules of the cartilage matrix through repeated stress (24,25) and the alteration of the matrix content under the same conditions. As with bone, rapid loading of a viscoelastic matrix increases the stiffness of cartilage, and the loss of the fluid component of the matrix will also increase stiffness. This loss of fluid may include soluble proteoglycans from the cartilage surface that are important in the maintenance of its properties. Under conditions of rapidly repeated high-impact loading, the fluid forced from the matrix that would normally provide a cushioning effect cannot be reabsorbed in time to cushion subsequent impacts. This may also produce plastic deformation of cartilage surfaces that does not sufficiently recover for smooth surface contact upon subsequent loading. The increased stiffness and deformation of the matrix increases the likelihood of mechanical wear in addition to rendering the subchondral bone surface more vulnerable to damage.

Cartilage wear may also be complicated by the limited capacity of cartilage to repair or regenerate. This property gives it a limited capacity to adapt to stress. In conjunction with repeated stresses and minor injuries, a cycle of damage, wear, and insufficient recovery may occur, leading to joint degeneration and/or osteoarthritis. The inability of cartilage to recover during repeated high stress loads may be one source of macroscopic structural defects observed in cartilage (26) and responsible for the high incidence of specific joint degeneration and the development of osteoarthritis in persons with certain occupations (football players and dancers).

The intrinsic composition and properties of cartilage also change with age (27). The matrix composition changes and permeability increases, decreasing cartilage stiffness and rendering it less resistant to rapid loading. Along with the accumulation of injuries from which the tissue cannot recover, these age-related changes may contribute to the increased incidence of joint degeneration with age.

LIGAMENTS AND TENDONS

Ligaments and Tendons Are Dense, Regular Connective Tissue with a High Resistance to Tensile Loading

Ligaments and tendons, along with joint capsules, surround the articulations of the skeletal system. Their functions are, in the case of ligaments and joint capsules, to structurally connect, stabilize, and guide the bones forming the articulation (28). They may also act as a sensor for joint position and strain for the joint. Tendons connect muscle to bone and transmit forces from muscle to bone to produce motion. Both tendons and ligaments are classified as dense, regular connective tissues. They have sparse cellular elements and abundant extracellular matrix in a highly organized array. The extracellular matrix is rich in collagen and water with a small amount of elastin, again producing a viscoelastic behavior under stress. The collagen molecules are linked together in lengthwise overlapping arrays to microfibrils, which are in turn combined in similar overlapping arrays to form fibrils, then fibers, and bundles of fibers to form the macroscopic tendon (Fig. 8.10). This successive parallel linkage down to the molecular level makes ligaments and tendons capable of handling high tensile loads. The arrangement of fibrils

Figure 8-10 **Left.** Schematic view of the structural organization of tendon. Microfibrils are the smallest component consisting of collagen molecules. Microfibrils are organized into fibrils that are grouped into fibers. Fibers are grouped into fascicles that comprise the tendon. **Right.** Idealized version of a stress/strain curve for tendon under tensile stress. The toe region is a nonlinear behavior attributed to the “slack” between collagen molecules. The elastic region has a linear relationship between stress and strain. In the plastic region, permanent deformation occurs, eventually resulting in failure.

in ligament tissue is less parallel than tendon and accounts for its higher resistance to tensile loading in orientations other than along the tissue axis. The collagen molecules are also linked to each other by crosslinks. While there are some important biomechanical differences between ligaments and tendons, most of their properties are basically similar and will be described together here.

The Primary Biomaterial Characteristics of Ligaments and Tendons Are Described by Elastic Modulus and Viscoelastic Properties

The primary stress response characteristics of ligaments and tendons are described by their modulus of elasticity properties. Under tensile loading (stretch), ligaments and tendons exhibit a modulus of elasticity that is variable with load (Fig. 8.10). Under low loading, there is a relatively large increase in length in response to the load applied (low elastic modulus). This is attributed to lengthening as the result of macromolecular “slack” within the collagen fiber structure that offers less resistance to an imposed load. As the slack is taken up, fibers slide relative to each other and fluid is extruded from the matrix. The elastic modulus then increases (stiffness increases) gradually with increasing load and shows a linear response up to the point where failure begins. The behavior of tendons and ligaments is similar except for ligament tissue such as the ligamentum flavum of the spinal column, where a high elastic content produces a different pattern of the elastic modulus.

The extracellular matrix of tendons and ligaments between the collagen fibrils has proteoglycans, a high water content, and other small ionically charged molecules that can interact with structural elements. This matrix is comparatively more porous than cartilage or bone, and is structured to resist tensile rather than compressive stresses. The viscoelastic properties become evident at high loading rates, where the tissue will demonstrate increased stiffness and offer increased resistance to tensile stress (stretch). As with cartilage, repeated tensile loading in cycles can result in a slow increase in elastic stiffness due to plastic deformation (29,30). This plastic deformation is presumably due to molecular deformation in the fibrous structural elements of the tendon or ligament, and also to the inability of fluid and small charged molecules to reequilibrate within the molecular structure.

Ligaments and tendons also demonstrate the viscoelastic properties of stress or load relaxation and creep. To characterize these properties, the tissue is placed under a tensile load (stretch) within the linear region of the elastic modulus and maintained at a constant length (stress relaxation) or a constant load (creep). Ligament and tendon tissue adjusts its molecular structure and fluid distribution to the load primarily within the first 6 to 8 hours, but will continue over a period of months. The creep phenomenon is used clinically as plaster casts or braces are employed to place a constant load to correct a soft-tissue deformity, such as some spinal curvatures (31).

Material Failure of Ligaments and Tendons Is Preceded by Microfailure of the Molecular Structural Elements

Overall failure of the ligament or tendon is usually sudden and preceded by the microfailure of the attachments between collagen fibers within the tissue and loss of the ability of the tendon or ligament to recover its length. With tendon and ligament, it is also important to distinguish eventual failure due to a sustained load (creep failure) from sustained cyclic loading and unloading

(fatigue failure). Both are important biomaterial properties for tendon and ligament. As with bone, a smaller degree of microfailure may occur within the range of physiologic loading, suggesting that repeated stress may lead to declining strength or fatigue over time (32). There may be a range of damage depending upon the total deformation and extent of partial failure. Inflammation resulting from such damage is associated with tendonitis (32).

Failure of both tendons and ligaments may also occur at the bone interface. The site of failure may depend upon the loading rate (33). Tendons, with their attached muscles, typically have a higher tensile strength than muscle, and rupture of muscle is more common than tendon. The instability of the joint that may result from tendon, or especially ligament, damage can contribute to and be complicated by damage to the joint capsule. This damage and associated abnormal loading patterns may contribute to osteoarthritis (31).

Ligaments and Tendons Can Adapt to Stresses

Like other tissue, ligament and tendon structurally remodel in response to the stresses placed upon them within the limits of damage (32). They become stronger and stiffer with increased stress and weaker and less stiff with a reduction in stress (34). Physical training can increase the strength of tendons and ligaments along with the ligament-bone interface (35,36). Immobilization (such as from casting) can decrease the strength and stiffness of ligaments. While reconditioning can occur, it can require a considerable length of time (34,37).

The Properties and Structure of Ligaments and Tendons Change with Age

During maturation, the number and quality of crosslinks increases in the collagen of ligaments and tendons and fibril diameter increases as well (38), producing increased tensile strength. The mechanical properties of collagen reach a maximum with maturation and begin to decrease with age (39). The collagen content of ligaments and tendons decreases as well. This loss of collagen results in a decrease in strength, stiffness, and the amount of deformation required to produce to failure (40). However, the overall biomechanical properties of tendon remain reasonably constant with age (41). The amount of time required for tissue repair and reconditioning (discussed previously) will also increase. Other physiologic factors, such as pregnancy, can also affect the biomechanical properties of ligaments and tendons (31,40).

SKELETAL MUSCLE

Skeletal Muscle Provides the Forces for Body Movement

Since a more complete description of muscle is given elsewhere in this volume, only those elements essential to understanding the biomechanical aspects of muscle tissue will be given here. Of the three types of muscle tissue, skeletal muscle is the most abundant tissue in the body, accounting for 40% of body weight (42). The forces necessary to provide movement to the body are provided by the contraction of skeletal muscles acting across joints. These contractions may produce dynamic work or participate in static maintenance of posture. While subcellular units known as *sarcomeres* are the source of muscle contraction, the basic contractile unit of skeletal muscle as a tissue is the *muscle fiber*. The fiber may range in size from 10 to 100 μm in diameter and between 1 and 30 cm in length (43).

The metabolic and contractile properties of muscle fibers may differ according to the physiologic demands placed upon them as described subsequently.

Both Contractile Elements and Connective Tissue Contribute to the Biomechanical Properties of Muscle

Muscle may be histologically and mechanically described as bundles of contractile elements in a series of connective tissue sheaths (Fig. 8.11). The basic unit of the contractile/connective tissue relationship is an individual muscle fiber surrounded by a connective tissue sheath, the *endomysium*. This basic unit of skeletal muscle is then organized into fascicles or groups of fibers by a thicker connective tissue sheath, the *perimysium*. Finally, groups of muscle fascicles are organized into the entire muscle itself and covered by the epimysium, which surrounds the entire structure. The epimysium and loose connective tissue form the fascial planes between muscles. The connective tissue sheaths are continuous with each other and the muscle tendon and/or attachments to bone. Both connective tissue and the contractile elements contribute to the biomechanical properties of muscle. The contractile elements provide active energy expending forces with some elastic and viscoelastic properties, while the connective tissue contributes passive elastic and viscoelastic influences on the pattern of force transduction to the skeleton.

The Basic Relationship Between Nerve and Muscle Is Defined by the Motor Unit

Muscle fibers contract in response to acetylcholine released by motor nerves. An individual motor neuron, with the muscle fibers contacted by it, forms a motor unit. The size of motor units may vary dramatically between muscles and within the muscle itself. The motor neuron generates an action potential lasting 1 to 2 ms that produces a contraction of all of the muscle fibers in a motor unit in an "on-off" fashion. The response of the motor unit

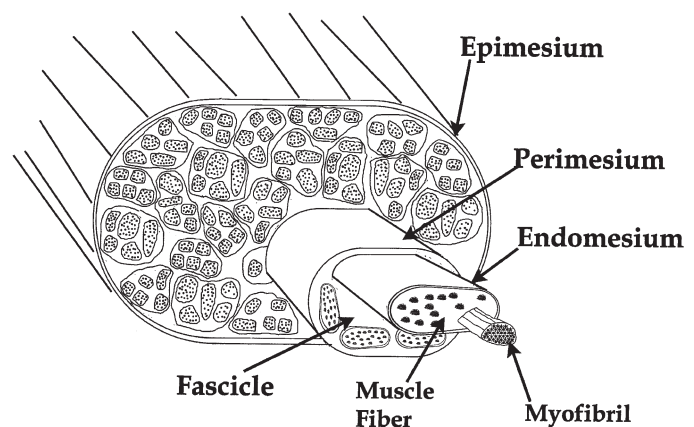

Figure 8-11 Schematic of the structural organization of a muscle. The basic subcellular unit of the muscle is the myofibril. Collections of myofibrils are present in muscle cells (muscle fibers). Muscle fibers are organized into fascicles and groups of fascicles make up the muscle. The connective tissue coverings of the muscle include the endomysium that surrounds muscle fibers, the perimysium surrounding muscle fascicles, and the epimysium surrounding the entire muscle.

to a single action potential is termed a *twitch*, the basic unit of recordable muscle activity. The time required for a motor unit to fully contract and then return to resting length is variable (from 10 to 100 ms) according to fiber type, but in all cases much longer than a nerve action potential. If additional nerve stimulation occurs before the contraction phase of the twitch has ended, contraction can be maintained and increased in a process called *summation*. The limit of summation, such that contraction is maintained and does not increase with a greater frequency of stimulation, is called *tetanic contraction* or *tetany*. The force of contraction of the muscle as a whole may be further regulated by increasing or decreasing the number of motor units used to produce the contraction, a process termed *recruitment*. In this way, the nervous system may control the force of muscle contraction by the size and number of motor units employed to produce the contraction and the frequency of activation of motor units.

Types of Muscle Contraction Are Defined by the Movements Occurring During Contraction

Dynamic muscle contractions in the processes of producing movement can be classified as *concentric* and *eccentric*. Concentric contractions produce movement in the direction of muscle contraction (Fig. 8.12), while eccentric contractions act to decelerate or resist movement, as in slowly placing an object down rather than letting it fall. Muscles also produce contractions without substantial movement, as in static posture against gravity. This type of contraction is termed *isometric*, as no change in muscle length occurs during contraction. Another term, *isotonic* contraction, refers to muscle contraction with a change in length under constant tension.

The Mechanical Properties of Contractile Elements and Their Connective Tissue in Muscle Is Described as a Musculotendinous Unit

The force production characteristics of a muscle as a whole are a combination of the material properties of its contractile

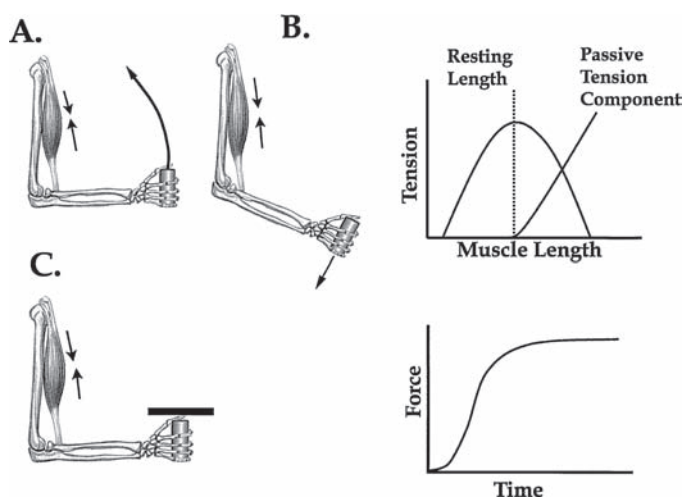

Figure 8-12 Left. Types of muscle contraction. **A.** Concentric. **B.** Eccentric. **C.** Isometric. Right. Top—Muscle tension relationship to muscle length. The greatest active tension is near the muscle-resting length. The passive tension component from stretch of connective tissue increases beyond the resting length. Bottom—Force-time relationship of muscle contraction. The time lag in reaching maximum force is related to the elasticity of tissue components.

components, the connective tissue that surrounds them (and the whole muscle), and the tendon of its insertion. From a mechanical viewpoint, this combination is a *musculotendinous unit* (44). The contractile elements add a rapid tensile load on the connective tissue elements, which in turn respond according to their elastic and viscoelastic properties as described earlier. As with ligaments and tendons alone, this will mean that there is rapid component to stretch, produced in this case by contraction, followed by a slower change in length as the connective tissue elements reach equilibrium with the contracting force (Fig. 8.12).

The connective tissues surrounding the muscle and its tendon have elastic properties that can store energy with stretch like a rubber band. In the process of muscle contraction, the tendon and connective tissue are stretched. The energy is released by moving a body segment or by stretching the contractile elements as the muscle relaxes. The elasticity also helps to keep the muscle prepared for contraction by reducing slackening of contractile elements, preventing passive overstretch of muscle fibers, thereby reducing the danger of injury. This energy storage also occurs as muscles are stretched under load. The muscle contractile elements may also have some elasticlike properties of energy storage (45,46).

The sum of the interaction of the contractile elements and elastic elements of muscle contraction can be demonstrated in the force-time curve of muscle contraction (Fig. 8.12). While the tension or force of contraction of the muscle fibers may reach maximum within a relatively short time, a much longer time is required for this tension to be transferred through the elastic components. Because of this time lag, the active contraction process must be long enough in time for the full transfer of tension to occur.

Many Factors, Such as Length, Load, and Temperature, May Affect the Force Produced by Muscle Contraction

The force of muscle contraction can be affected by various mechanical factors, including length-tension relationships, load-velocity, and force-time properties (43). Other significant factors may include temperature, muscle fatigue, and prestretching. The length-tension property of a muscle as a whole (Fig. 8.12) involves both the active contractile elements and the passive connective tissue elements (47). The maximum force or tension produced by contractile elements, such as the muscle fiber, is obtained at near its resting length. Contraction at lengths beyond or smaller than the resting length results in reduced tension production by the muscle fiber. This is a result of intrinsic properties of muscle fiber sarcomeres. For the muscle as a whole, reducing or increasing the muscle length from its resting position will reduce the tension produced by contractile elements. However, increasing muscle length will also produce a passive tension as a result of stretching the connective tissue elements, although the contractile force is reduced. The passive component of stretch, which is readily detectable by passively stretching a relaxed limb, will eventually become the dominant source of resistance or tension as muscle length increases, effectively protecting the muscle from overstretch. (Fig. 8.12).

Applied Loads Affect the Velocity of Muscle Contraction

The relationship of the load applied to a muscle and the velocity with which it contracts defines the load-velocity property of muscle contraction. The shortening of muscles contracting concentrically is most rapid with no external load and progressively slows with increasing external loads (48). The shortening velocity

will reach zero as the load reaches the maximum contraction force of the muscle (isometric contraction) and then reverse to a lengthening velocity with eccentric contraction. As might be expected, eccentric contraction lengthening velocity increases with increasing external load.

A Rise in Temperature Can Increase the Efficiency of Muscle Contraction

In the process of contraction, muscle efficiency is usually no more than 20% to 25% in the translation of chemical energy into useful work, with the majority of the energy being dissipated as heat (42). Even so, the heat dissipation can have positive effects on muscle contraction properties by increasing temperature. As would be attained through a warm-up procedure, temperature increases usually arise from increased blood flow and the production of heat by the muscle itself from metabolic reactions and friction generated by the sliding of molecules past each other in the contractile and elastic elements. Within physiologic ranges, increases in temperature will increase the conduction velocity across the muscle fiber membrane (sarcolemma) (48), increasing the rate of contraction and increasing the rate at which the muscle can be stimulated. This can mean an increase in the production of muscle force. A rise in temperature can also increase enzymatic activity related to muscle metabolism and increase the efficiency of muscle contraction. The viscoelastic properties of the musculotendinous unit are also affected by rises in temperature, generally increasing the elasticity of the collagen, decreasing stiffness, and enhancing the extensibility of the unit. While these basic biomechanical properties of muscle tissue change with temperature to enhance the contractile properties of the musculotendinous unit, the effects from stretching or “warming up” prior to activity are much more complex and not completely understood (49,50). The physiologic aspects of stretch (or release) involve highly significant neural components and reflexes beyond the biomechanical properties of the tissues alone.

Muscle Fatigue Properties Are Affected by the Muscle Fiber Type(s) Comprising the Muscle

Fatigue of muscle with prolonged contraction activity results from the depletion of the nutrients and oxygen required to produce adenosine triphosphate (ATP) as an energy supply from either aerobic or anaerobic glycolysis. The result is a decrease in force production by the muscle eventually to total cessation (42). The rate at which a muscle will reach fatigue can vary according to the types of muscle fibers it contains. Muscle fiber types are distinguished by the rate at which ATP can be made available to the sarcomeres for contraction and the metabolic pathways through which ATP is generated. The rate of availability of ATP directly affects the rate of contraction or twitch time of a muscle fiber. Accordingly, muscle fiber types can be classified as slow or fast twitch. Two primary metabolic pathways involved to generate ATP (oxidative or glycolytic) further divide these two basic types of contractile behavior. Using these properties, three primary muscle fiber types are distinguished including type I or slow-twitch oxidative fibers, type IIA, fast-twitch oxidative-glycolytic fibers, and type IIB, fast-twitch glycolytic fibers. These different fiber types have varying degrees of contraction time, resistance to fatigue, and a dependence on aerobic or anaerobic metabolism. As their names suggest, type I fibers have slower contraction rates, and, with a metabolism directed toward aerobic pathways, are resistant to fatigue. They are relatively small in diameter and produce a relatively low amount of tension per fiber.

These properties make this fiber type well suited for prolonged low-intensity work (51). Type IIA fibers are fast contracting and rich in aerobic and anaerobic (glycolytic) enzymes with a moderate resistance to fatigue. They appear to be intermediate between type I and type IIB in their capacity for contractile force and resistance to fatigue. Type IIB fibers are fast contracting, rely primarily on glycolytic pathways, and may fatigue rapidly. However, they have a large fiber diameter and can produce relatively large amounts of tension.

Muscles May Have Some Ability to Change Their Fiber Type According to Demand

Most muscles are of mixed fiber types with the proportion of fiber types determined by the nerve innervating the muscle (52,53). The overall distribution of muscle fiber types in the muscles of the body appears to have a strong genetic component (42,51,54). The fiber type can be changed with nerve stimulation (55), suggesting that patterns of activity may alter fiber metabolism. Some changes in fiber types may also occur with physical training, but much of this change is a result of increases in the cross-sectional area of the fiber type corresponding to the activity rather than an actual change in fiber type (54,56). The extent to which actual alterations in the type of muscle fiber occur as a result of activity demand therefore remains unclear.

Muscle Adapts to Physiologic Demands

Although the extent of fiber type change under physiologic conditions is unclear, muscle will clearly remodel according to the stresses placed upon it. Muscle atrophies with disuse and hypertrophies with increased use. Studies of muscle atrophy in both animal and clinical studies suggest that early dynamic motion after debilitating injury may be important in the minimization of atrophy, particularly of type I muscle fibers (57,58). Electric stimulation may also prevent some of this fiber loss (56). Hypertrophy of muscle with physical training is generally the result of increases in the cross-sectional area of all muscle fibers (58,59).

MUSCULOSKELETAL BIOMECHANICS

Primary Biomechanical Musculoskeletal Models Consist of Segments Moved by Muscles Across Joints

Biomechanical aspects of the skeleton involve contributions from all of the biomechanical aspects of the tissues described in the process of producing movement. As a simplistic model, it is easiest to consider the body as a series of segments (bones) containing muscles that are attached across the segments. Joints form the junctions between segments or bones and transfer the forces generated by muscles or from external sources between the segments. In the following simple models of movement, joints will be regarded as simple pivot points, moving in one plane (coplanar). The more complex considerations of joint movement and shape of articulation will be addressed in subsequent sections.

Force Moments Are Used to Describe Models of Musculoskeletal Movement

Using the simple model used for the descriptions of moments earlier in the chapter, a joint, such as the elbow (Fig. 8.13), becomes a rotation system with the flexor system and the extensors using the

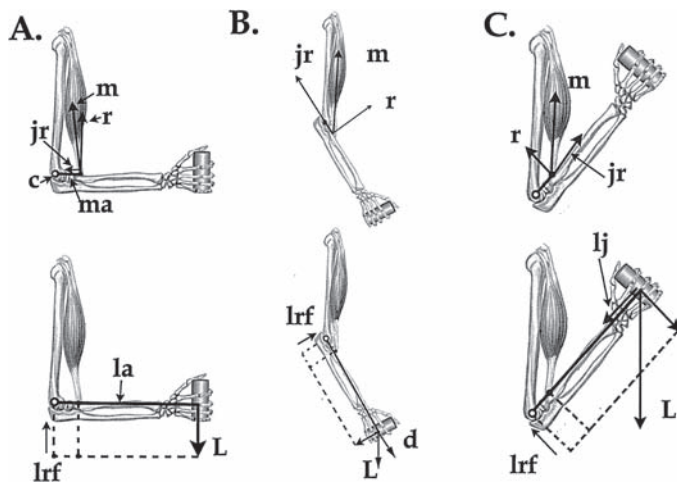

Figure 8-13 Schematic of basic joint moments and their variation with movement. Sections on top represent muscle contraction moments. Figures on the bottom show moments generated by the load. **A.** Right angle resistance to a load (L). **Top.** Moments about the joint center (c) include the moment arm of the muscle (ma) that is moved by a resisting component (r) of the muscle contraction force (m), this is resisted by the load (**bottom**) acting on a load moment arm (la). Joint reaction forces include the portion of the muscle force directed into the joint (jr) and a moment generated from the load into the joint with a center of rotation about the muscle insertion (lrf , dotted lines displaced). **B.** At extension, the angle of muscle pull directs more of the muscle force into the joint (**top**) and a portion of the load force (L) moment pulls out on the joint as a distracting force (d). **C.** In a flexed position, the muscle moment (**top**) is divided into the resisting component (r) and a joint reaction distracting force away from the joint (jr). A portion of the load force (**bottom**) now is directed into the joint (lj).

joint as a center of rotation to move the distal limb and any load on the limb. In mathematical modeling of joint function, the description of such movements is a system of balanced moments produced by the load on the limb and muscle contraction forces. Characterizing movement in this way becomes particularly important as other aspects of joint function (noncoplanar movement, movement within the joint) and more mechanically complicated joint types are modeled.

As a distal segment moves relative to a more proximal segment, the distal segment will rotate about the instant center of the joint or center of rotation (c , Fig. 8.13). The effective distance from the center of the joint's rotation to where the force is acting (muscle insertion) is the *moment arm* (ma) for the muscle. The product of the force applied from the muscle and the moment arm (force \times distance) is the *moment* (or torque) used to resist a load on the distal limb. For concentric contraction to occur, this moment of resistance must exceed the moment produced by the load (distance to the load from $c \times$ weight). In a more complete model, the weight of the limb must also be considered. Note also that if the load moment is resisted by the pull of the muscle, there is also a center of rotation created at the point of muscle insertion about which the load exerts a moment into the joint (lrf , Fig. 8.13). Together with the portion of the muscle contraction force directed into the joint (discussed subsequently), this becomes part of the *joint reaction force* that applies a stress to the joint during movement.

Muscle Moments Necessary to Resist a Load Vary with Joint Position

As can be seen from Figure 8.13, although the length moment arm does not change, the proportion of muscle contraction force (vector) that is applied to resist the load will vary as the limb is flexed. With the joint fully extended, most of the muscle contraction force vector is directed into the joint. This muscle component force also contributes to the joint reaction force and may be particularly important in the stabilization of load-bearing joints, such as the knee. The relative size of the joint reaction and load-resistive forces can be expressed by simple trigonometric functions in mathematical models, but it is sufficient here to be aware of how these forces change with joint position. In this model, the portion of the muscle contraction vector used to resist the load increases as the angle of tendon is closer to a right angle (Fig. 8.13A, orthogonal) to the forearm. Beyond this point, a portion of the load vector becomes directed into the joint (Fig. 8.13C) reducing the effective load on the muscle, but placing stress on the joint and more proximal segments. In the flexed position, the angle of pull by the muscle directs a portion of the muscle contraction force against this load into the joint.

Muscle Moments Are Also Transferred Across Joints by Tendons

Muscle forces are also conveyed to distal segments across joints by tendons. In joints associated with the knee, hands, and feet, tendons cross the joint(s) to produce a "pulley" effect (Fig. 8.14). In this arrangement, as in the knee, the distance between the center of rotation of the joint and the tendon defines the moment arm for the contracting muscle.

The wheel and axle mechanism (60) is an instructive related model used to achieve rotary movements (Fig. 8.14). In this case, muscle contraction forces are applied to the opposite sides of a segment to produce rotation about an axis. The length moment arm in this case is the distance to the center of rotation. This mechanism is used widely throughout the body to achieve rotation of limbs and the body, as in rotation of the head, torso, or shoulder. As with simple flexors and extensors, muscles producing rotational

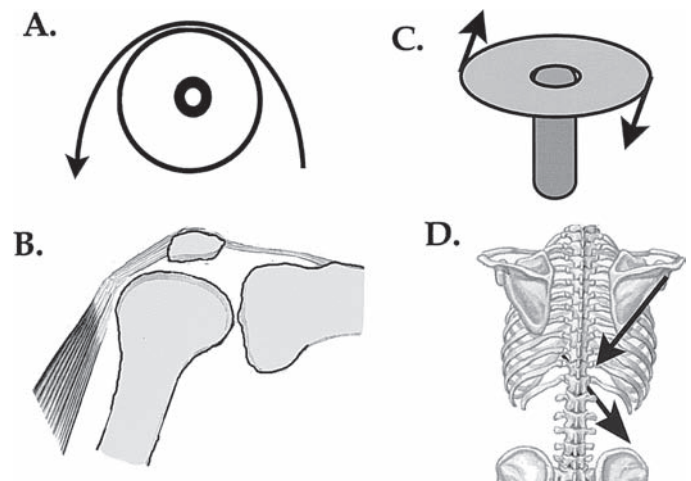

Figure 8-14 Strategies of muscles and tendons pulling across joints. **A.** A pulleylike mechanism in which the direction of pull is changed. **B.** A similar mechanism is used in knee extension. **C.** A wheel and axle mechanism in which coactive forces act to rotate an axle, such as the shoulders (**D**) relative to the spine.

components work in pairs and significant clinical problems may arise from imbalances in function of the pair.

Muscle Moments Generally Have a Low Mechanical Advantage

As suggested in the examples that have been given, the lever arrangement of muscle insertions and joints in limbs is such that a comparatively small distance of muscle contraction can produce a large displacement of the load at the expense of needing large muscle contraction forces. This is described as having a low mechanical advantage. The relative mechanical advantage is a function of the position of the muscle origin and insertion on the two bony segments relative to the joint. Because both the moment arm (distance, d) and the contraction force (f) equally contribute to the moment ($f \times d$) producing the movement or resistance, small differences in the moment arm can produce significant changes in the amount of muscle contraction required. As origins and insertions of muscles and segment lengths vary markedly between individuals, the ability to produce different types of movement using the same muscle contraction force will also differ.

While muscles must create large forces to produce movements at a low mechanical advantage, distally applied loads, such as to the hand acting through the elbow, have a comparatively large moment arm (Fig. 8.13) and require less force to produce large moments about the joint. This will be true of manipulative forces placed distally for purposes of applying passive stretch to muscles and joints. It is a useful principle, but must be approached with caution, since large, potentially damaging force moments can be generated.

Joint Structure Defines How Movements Can Occur Between Body Segments

Beyond movement models that regard joints as simple pivot points for the transfer muscle forces between body segments, the next level of modeling must consider the structure of these intersegmental contacts. In fact, the directions of movement that can occur between body segments are largely defined by the structure of the joints between them. Joints are classified according to the type of tissue they contain and their structure. On a tissue level, joints are classified into three primary types: fibrous, cartilaginous, and synovial. Fibrous joints are located in areas such as the articulations of the skull, while cartilaginous joints include the discs between vertebrae, and synovial joints are located in articulations of the limbs. The vast majority of body motion occurs across synovial and cartilaginous joints. The primary cartilaginous articulations will be described subsequently, with considerations of the spinal column. The remaining synovial joints have been divided into several categories according to the primary types of movements that occur across them. Anatomically, the major types are gliding, hinge, pivot, condyloid, saddle, and ball and socket (61). Other than the joints described later in this chapter, more detailed descriptions of these joint structures and their limitations on range of motion can be found in general anatomic texts.

Range of Motion Describes the Extent of Body Segment Movement Across Joints

Movements are usually described as occurring in one of the primary body planes (frontal, sagittal, or transverse). The extent of joint motion in a plane defines its *range of motion* in that plane, usually in degrees. Although all synovial joints may have some minor range of motion in all three planes, most joints in the

extremities have a primary degree of freedom in one plane, such as in the knees, elbows, or fingers. Shoulder and hip joints are an exception, as they have significant ranges of motion in all three planes. Joints may also have a significant rotational component, usually expressed as range of motion of the distal rotated element, as in pronation and supination of the hand. In general, there is a trade-off between intrinsic structural stability of joints and range of motion, depending upon the physiologic demands placed upon the joint.

Joint Surfaces Have Several Different Types of Relative Movement

As body segments are moved through their range of motion, surfaces within the joint will also move relative to each other. This movement may contribute to various aspects of the motion produced. The relative motion of joint surfaces may include gliding, rolling, rotation, compression, or distraction (Fig. 8.15), or a combination of these movements. Gliding (also referred to as translation or sliding) represents a movement of one surface relative to another without a rotational component. In rolling, one surface of the articulation rolls over the other, like a ball rolling over a surface. Rotation (spinning) consists of one joint surface spinning on the surface of the other without a translational component. Compression represents force pushing the joint surfaces together, while distraction tends to pull the surfaces apart.

Movements between articular surfaces in a joint can occur in consistent combinations (coupled) such that one type of motion is always accompanied by another. This motion coupling can occur for movements within the same articulation (see the upcoming example given under “The Knee”) or in another joint that is part of an articulation complex (see the example given with “The Elbow” later in the chapter) (62). A disruption of one part of a coupled motion will affect the other and can produce dysfunction of the joint or joint complex. An example of this is a coupling of the elbow complex where there is a coupling of the intra-articular

Figure 8-15 Intra-articular movement of joint surfaces relative to each other. In gliding (also referred to as “sliding” or “translation”), surfaces move without rotation. In rolling, one surface rotates and translates over the other at a distance equal to the arc of the rotating surface. In spinning, one surface rotates on the other without translation. Compression and distraction are opposing vertical forces on the joint.

motions of humeroulnar and humeroradial joints during flexion/extension movements (see “The Elbow”). Coupling of articular surface motions within the joint also depends upon which segment of the joint is mobile (62). An example of this difference is the articular surface movement of the knee during weight bearing versus swing phase (see “The Knee”). Significant alterations in the relative movements of joint surfaces can produce problems in joints, including abnormal wear and dislocation.

The Instant Center Defines the Center of Rotation of a Body Segment at Any Given Time

In order to study movement within a joint during functional movement, both the motion of the surfaces relative to each other and the shape of the articulating surfaces must be considered. As one segment moves in a joint such as the knee, the center of rotation located within the joint at any instant will have zero velocity. Because the femoral condyles and tibial plane are not spheric surfaces and translational movement can occur within the joint, the center of rotation of the leg will change as the leg is extended. To determine properties such as the length of the moment arm under these circumstances, the center of rotation must be redefined as *instant center of rotation* joint at any given time (63). The instant center can be defined clinically from sequential roentgenograms or other pictures of movement using the intersection of lines from defined points from the joint segments. This technique can be important for identifying abnormal joint movement. It should be noted, however, that displacement of the instant center can occur in all three dimensions simultaneously. Roentgenograms or other planar depictions of joint motion can be misleading. From a functional point of view, changes in the location of the instant center will change the relative magnitude of the contraction-force vectors of the muscle tendon acting across a joint. This can result in weakness or abnormal stresses within the joint.

SOME PROPERTIES OF SPECIFIC JOINT ARTICULATIONS

The previous discussions in this chapter have focused on the biomechanical properties of tissues and models of forces acting to create movements or stresses on body segments. We will now consider how these properties apply to some of the primary articulation systems in the body. The biomechanical aspects to be considered are not intended to be comprehensive.

THE KNEE

The knee joins two of the body’s longest moment arms (the thigh and leg) in a joint consisting of two primary articulations, the tibiofemoral joint and the patellofemoral joint (Fig. 8.16). Because of its location and weight-bearing properties, the knee sustains relatively high load forces and is particularly susceptible to injury. Stability of the knee is obtained from the internal and external ligaments, joint capsule, and muscles acting across the joint. The cartilage menisci act to distribute the compressive stresses between the condyles of the femur and the tibial plateau.

The Knee Has One Primary Range of Motion in the Sagittal Plane

Although the knee joint itself has some range of motion in all three planes of motion, its primary range of motion is in the

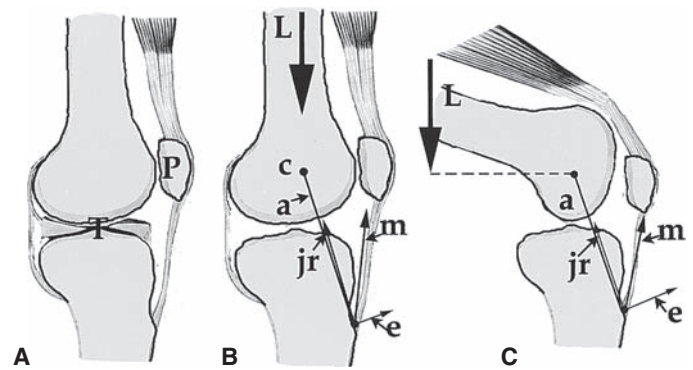

Figure 8-16 **A.** The knee joint consists of the tibiofemoral (*t*) and patellofemoral joints (*p*). **B.** Moments produced by the load (*L*) of body weight require little muscle activity with the knee extended, but are maintained by a muscle contraction force through the patellar tendon (*m*), which produces moments through a moment arm (*a*) to the instant center of rotation of the joint (*c*). The moment is divided by the angle of muscle pull into a joint reaction force (*jr*) and an extending component (*e*). **C.** With the knee flexed, the body weight produces a moment through the joint (*c*) that must be resisted by the extending component (*e*). In this instance, the patella increases the distance of the tendon from the femur to provide a more advantageous angle for the muscle contraction force on the tibia. This increases the proportion of the extension moment. Note that the position of the center of rotation (*c*) has changed slightly.

sagittal plane where a range from full extension to full flexion is approximately 140 degrees (63). Motion in the transverse plane (internal and external rotation) and frontal planes (abduction and adduction) is dependent upon the positioning of the tibia relative to the femur. In the transverse and frontal planes, full extension of the knee precludes almost all motion due to an interlocking of the femoral and tibial condyles, while range of motion increases as the knee is flexed. Maximal internal and external rotation is possible with the knee flexed at approximately 90 degrees ranging from a neutral position to 45 degrees of external rotation and 30 degrees of internal rotation. In the frontal plane, passive adduction and abduction is obtained at approximately 30 degrees of flexion, but it is only a few degrees in either direction (63).

Primary Muscle Forces Through the Knee Are Conducted Through the Hamstrings and the Patellar Tendon

The primary muscle forces through the joint occur through the quadriceps tendon and hamstrings. The hamstrings use the knee joint as a primary lever in flexing, while the quadriceps use the patellar tendon system as a pulley with the center of rotation within the femoral condyles (Fig. 8.16). As with other hinge-type joints, in a basic biomechanical model, muscle contraction forces are divided primarily into a joint reaction force directed into the joint and a force moment that acts to move the mobile segment. In extension of the knee, the moment that acts to straighten the knee pulls on the leg through the patella and tendon. This will act to rotate the tibial plateau relative to the condyles of the femur. Presuming a constant muscle force, this component of moment decreases or mechanical advantage decreases in proportion to the joint reaction force as extension proceeds (Fig. 8.16). This decrease is to some extent compensated by the movement of the patella and the shape of the femoral condyles as described subsequently. With flexing

a straightened knee, the opposite is true; the proportion of the flexor moment increases relative to the joint reaction force as the movement proceeds.

The Knee Must Withstand Very High Joint Reaction Stress Forces

In a load- or weight-bearing model of the knee, the leg is considered stable, and muscle contraction forces and joint structure are used to resist gravity. The force exerted through the knee from the weight of the body is termed the *ground reaction force* (body mass \times the acceleration of gravity). Note that both the ground reaction force and muscle contraction forces contribute to produce the *joint reaction force* or total force directed into the joint as described previously. These combined forces, along with the impact of landing from activities such as jumping, can produce very high compressive and other stress forces on the knee joint surfaces.

If the knee is fully extended, most of the ground reaction force is directed through the bone structure of the femur and tibia (a moment arm through the joint of almost zero), and minimal or no muscle contraction force is required to resist the ground reaction force. This changes as the knee is bent, and at 90 degrees of flexion, extensor muscle reaction forces must resist the ground reaction force consisting of the body weight acting at a distance of almost the entire length of the femur. At this angle, the extensor muscles have a relatively small moment arm. Accordingly, a very high muscle contraction force in excess of body weight must be exerted to resist a moment of this magnitude. The knee joint has several mechanisms to help compensate for the rather low mechanical advantage of muscle contraction forces in this situation.

The Application of Muscle Contraction Forces to Movement Across the Knee Is Affected by the Structural Properties of the Joints

Beyond the basic segment model, there are basic structural properties of the knee that change the mechanical advantage muscles across the joint. These primary structural properties include the patellofemoral joint and the shape and movement of the femoral condyles. The patella and tendon act to increase the moment arm for the quadriceps by increasing the effective distance of the tendon from the center of rotation of the joint, thereby increasing the component of the muscle contraction force vector acting to straighten the joint (Fig. 8.16). This adds mechanical advantage to the extensor muscle contraction forces in a partially flexed knee. The gliding (sliding) motion of the patella between the medial and the lateral femoral facets also alters the moment arm over the range of motion of the knee. Additionally, the patella acts to distribute this force over the surface of the femoral condyles.

The primary properties of the femoral condyles that affect the mechanics of movement include the noncircular shape of the condyles and their movement on the tibial plateau (Fig. 8.16). The shape of the femoral condyles is such that the center of rotation of the joint changes through the knee's range of motion, giving a greater moment arm to extensor forces as the knee is flexed. This can be important in resisting the high forces such as body weight with a partially flexed knee. In addition to a noncircular shape, the femoral condyles also have differences in their effective diameters with the medial being larger. This produces a coupling of flexion and extension with a rotational component to the knee (called the screw-home mechanism), such that flexion is accompanied by an internal rotation component and extension is accompanied

by external rotation of the femoral condyles relative to the tibial plateau (64). This provides additional stability to the joint in certain circumstances.

The Intra-articular Movements of the Knee Depend Upon Which Surface Is Moving and Load Bearing

The femoral condyles also glide (slide, translate) on the tibial plateau as the knee is moved (described previously). These structural properties of the femoral condyles can act to change the center of rotation as the joint progresses through its range of motion and alters the effective moment arm length through which the muscle contraction forces are acting. The relative movements of the joint surfaces in the knee give an example of how motion coupling can depend upon the load status of the joint and which joint surface is mobile (62). In walking, as the leg swings forward (swing phase), the femoral condyles and tibial plateau are not under the compressive load of the body. The movement is a gliding motion of the tibial plateau coupled with a rolling of the tibia on the femoral condyles in the same direction. When the leg is placed on the ground with the knee partially flexed and then extended as the body is moved forward (see "Normal Locomotion (Gait) Employs the Entire Body for Efficiency of Movement" later in the chapter), the tibial plateau is stable relative to the femoral condyles. The motion of the joint surfaces now consists of a gliding and rolling of the femoral condyles on the tibia in opposite directions. This is an example of how compressive forces and segment stabilization change articular surface motion. This can have important implications in surface damage and dysfunction.

Knee Joint Structure and the Movement of Joint Surfaces Promote Efficiency of Movement

Through their structure and interaction during movement, the patellofemoral joint and femoral condyles contribute to the efficient use of muscle contraction forces for movement and joint stability by changing the moment arm (mechanical advantage) of the contracting muscles in the process of extending or flexing the knee. This has important consequences for movement through the knee and load bearing. The effective use of these structural properties is dependent upon internal joint movement and the joint stability provided by soft tissues. For this reason, soft-tissue injury or changes producing either a lack of or excess of internal "play" in the knee joint can contribute to serious problems with joint function.

THE HIP

The Hip Is a Load-Bearing Ball-and-Socket Joint with Ranges of Motion in All Three Planes

The relatively rigid ball-and-socket arrangement of the hip joint between the head of the femur and the acetabulum provides greater intrinsic stability compared to joints such as the knee. In addition to stability, the ball-and-socket structure of the hip allows greater range of motion in all three planes of body movement. Motion in the sagittal plane is greatest with approximately 140 degrees of flexion and 15 degrees of extension from a neutral position. The range of abduction is approximately 30 degrees and adduction 25 degrees. External rotation from a flexed position is approximately 90 degrees and internal rotation approximately 70 degrees. Rotation decreases with extension due to soft-tissue restrictions (65).

The Angular Alignment of the Articular Components Is Important for Normal Hip Function

The angular structure of the joint relative to the pelvis, femoral shaft, and knee joint can vary significantly between individuals and have a great influence on the biomechanics of the lower limb. In the relationship of the joint surface to the pelvis, the location of the acetabulum places the plane of its opening angled 40 degrees posterior to a sagittal plane and 60 degrees lateral to a transverse plane (Fig. 8.17). Both the femoral head and the acetabulum have roughly spheric surfaces of contact. The relationship of the femoral head through its neck with the femoral shaft is important in the biomechanics of hip function and load-bearing stress on the neck. It is an important determinant of the effective moment arms of the muscles producing movement across the joint. The angle of inclination of the neck to the shaft (Fig. 8.17) is approximately 125 degrees, but may vary between 90 and 135 degrees. This angle offsets the femoral shaft from the pelvis laterally. The angle in a transverse plane between lines drawn through the femoral head and greater trochanter and between the medial and the lateral condyles (angle of anteversion) determines the normal relationship of the primary plane of movement of the knee to the hip. It is normally about 12 degrees but can vary widely (65). An angle of greater than 12 degrees tends to produce internal compensatory rotation of the leg during gait, while an angle of less than 12 degrees produces an external rotation. These compensations are made to maintain the stability of the hip. They are common in children and usually outgrown (65).

Models of Hip Function Balance Ground Reaction, Joint, and Muscle Contraction Forces

Biomechanical models of the hip can be used to illustrate some of the important aspects of the structure-function relationship of the joint. Stability of the hip joint is maintained through the alignment of the body over the joint (Fig. 8.18), the joint capsule, and capsular ligaments and muscle contraction to counteract remaining ground force moments. The relative magnitude of forces applied into and across the hip joint can be considered through a model of a single leg stance with the body center of mass (or gravity) balanced (i.e., located on an axis of alignment) over one hip joint (Fig. 8.18). In this balanced condition, little or no muscle contraction forces are necessary to maintain equilibrium, as in the knee. The joint reaction force or force directed into the joint will equal the ground reaction force produced by the weight of the body above the hip. In an unbalanced state, the body center of

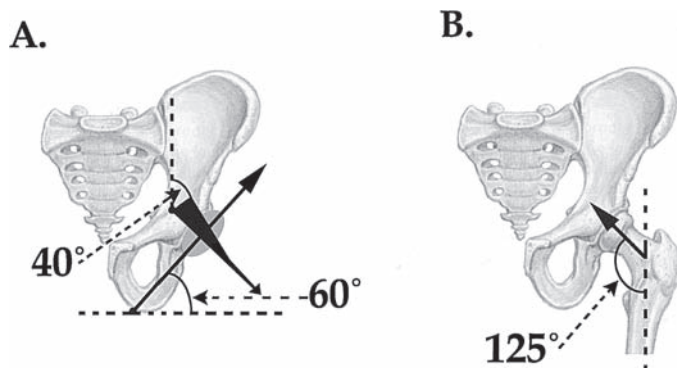

Figure 8-17 A. Angle of the opening of the acetabulum. The opening is oriented 60 degrees lateral to a transverse plane and 40 degrees posterior to a sagittal plane. B. The angle between the femoral neck and the shaft is approximately 125 degrees.

Figure 8-18 A simple coplanar model of a single leg stance moment in balance. A. In the balanced state, the body weight (b) is balanced over the foot (not shown), which would be at the intersection of the *dotted lines*. In this balance, the body weight (b) acts as a force applied on a moment arm (d) through the center of rotation in the femoral head to produce a body moment ($b \times d$). This is balanced by the rotational component (r) of the muscle contraction force (m) acting over a moment arm through the femur (h) to produce a muscle contraction moment ($r \times h$). For balance to be maintained ($b \times d = r \times h$). B. The balanced condition can be disturbed by a shift of the body and a slight change of the angle of pull by the muscle (m). To restore balance, the moment (r) must be increased or altered so that the moments can be rebalanced.

mass is no longer directly over the bony structure and produces an unbalanced moment about the center of rotation of the hip joint. To restore equilibrium, the force of the contracting abductor muscles must generate an equal force moment across the hip in the direction opposite of the moment generated by the body weight. By measuring the length of the moment arms for muscle contraction in the body and knowing the body weight, the approximate resisting moment of muscle contraction can be calculated along with the joint reaction component produced.

Note that in this model, the angle of the femoral neck will affect the relative lengths of the moment arms (or the angle of pull) by muscles. This will directly influence the muscle contraction forces required to resist the body weight moment and the proportion of the contraction force directed into the joint. This is why an abnormal angle of the femoral neck can adversely affect hip function and the stresses on the joint.

Hip Joint Function Requires High Muscle Contraction Forces and the Ability to Withstand High Joint Reaction Forces

As with the knee, it can be seen that hip stability under load-bearing conditions can require high muscle contraction forces because of a relatively short moment arm through which the muscle forces are applied. As a combination of ground reaction force and the portion of the muscle contraction forces directed into the joint, the joint reaction forces are also high relative to the body weight. Calculations suggest that under these conditions, the muscle contraction force is approximately twice the body weight and the joint reaction force almost three times the body weight (66,67). Joint reaction forces are important in consideration of stresses on the

hip joint itself in replacement or repair. Strategies to minimize the joint reaction force can also be important in subjects with arthritic pain in the hip joint. As suggested by the model given earlier, a reduction in joint reaction forces may be achieved by altering the angle of the hip by increasing the muscle moment arms. This can also be accomplished by using a support device, such as a cane on the opposite side, to reduce the opposing body weight moment.

THE ELBOW

The Elbow Is a Complex of Three Joints with Two Primary Ranges of Motion

The upper limb analogue of the knee is the elbow, which has adapted for increased mobility of the upper limb and a reduced load-bearing requirement. In achieving this, the joint has become a complex of three articulations, including the humeroulnar, the humeroradial, and the proximal radioulnar joints (Fig. 8.19). The joint complex allows two primary ranges of motion: flexion-extension and pronation-supination. Flexion and extension occur across the humeroulnar and humeroradial joints, which act as a hinged joint. The normal range of motion in flexion-extension is approximately 140 degrees, with limits established by the angular characteristics of the bony components (68). The axis of motion passes through the middle of the trochlea and is principally a gliding motion (69) up to the last 5 to 10 degrees of flexion, where rolling occurs. Pronation and supination occur at the humeroradial and proximal radioulnar joints. The reported normal range of motion varies between studies (68) with the American Academy of Orthopaedic Surgeons (70) reporting an average of 70 degrees of pronation and 85 degrees of supination. The range of motion required for typical daily activities of both flexion-extension and pronation-supination can be performed between a much more limited range (71).

Much of the elbow joint's stability during normal use is supplied by the shape of the articulating surfaces. Of the three articulations, the humeroulnar articulation supplies the primary anterior-posterior stability, although the radiohumeral articulation can contribute to stability from posterior dislocation at flexion of 90 degrees or more. Beyond the bony stability of the joint, the ligaments and joint capsules around the elbow provide remaining stability and the interosseous membrane binds the radial and ulnar shafts together.

Figure 8-19 **A.** The elbow joint complex consists of the humeroulnar (*hu*), humeroradial (*hr*), and proximal radioulnar joints. **B.** The primary flexor (*F*) and extensor (*E*) moments across the joint.

Basic Functions of the Elbow Can Be Described by Simple Joint Moments

The basic biomechanics of the elbow can be described largely as a system of simple levers or joint moments as suggested earlier in the section on basic mechanics of joint systems (Figs. 8.13 and 8.19). Muscle forces act at a low mechanical advantage to achieve a large movement. Due to disadvantageous vector angles through some of their range, relatively high muscle contraction forces are required. These muscle contraction forces typically generate large joint reaction force components that act through the bony elements to stabilize the elbow. These joint reaction forces may exceed body weight even during normal activities.

The Elbow Complex Provides an Example of Dysfunctions from the Coupling of Intra-articular Motion

As a joint complex, the elbow provides a reasonably simple example of coupling relationships of intra-articular joint motions that, when disrupted, can produce dysfunction. During flexion-extension movements, the humeroulnar joint has a primary gliding motion that is accompanied by a movement of the head of the radius on the capitulum of the humerus. This produces a smaller proximal and distal gliding of the proximal radius in the radial notch of the ulna (62). The extent of this latter movement is greatest when the joint is half-flexed. Although this motion is not a primary component of the segmental motion, its disruption can produce pain and dysfunction in the joint during movement. It is therefore important to understand the coupled movements of the complex as well as the individual articulations. More complicated examples can occur in more extensive joint chains such as in the spine and feet.

THE SHOULDER

The Shoulder Is a Complex of Four Joints with Different Properties

The shoulder consists of a complex of four articulations: the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic articulations (Fig. 8.20). Of these, the scapulothoracic articulation is not a true articulation, but an indirect attachment of the scapula to the thoracic wall indirectly through muscles. The shoulder complex acts in concert with contributions from each joint to produce movement through greater than a hemisphere of range. The glenohumeral joint is a basic ball-and-socket joint, but has much less intrinsic stability than its lower limb analogue at the hip. The reduced stability is reflected by the structure of the articulating surfaces of the joint. The area of the glenoid fossa that contacts the humerus is only one third to one fourth the size of the joint surface of the humeral head (72).

This allows a more circular range of motion relative to the scapula, but at the cost of intrinsic structural stability of the joint. Although some vertical structural support may be derived from the overlying acromion process and attached clavicle, the glenohumeral joint is reliant, to a great degree, on soft-tissue structures (ligaments, tendons, joint capsules, and muscles) for stability (73). During function, the glenohumeral joint primarily rotates, but rolling and translation may also take place. This translation may increase substantially with soft-tissue injury or dislocation.

The scapula attaches to the thoracic skeleton through a chain of two articulations, the acromioclavicular and sternoclavicular joints. The acromioclavicular joint between the clavicle and the proximal

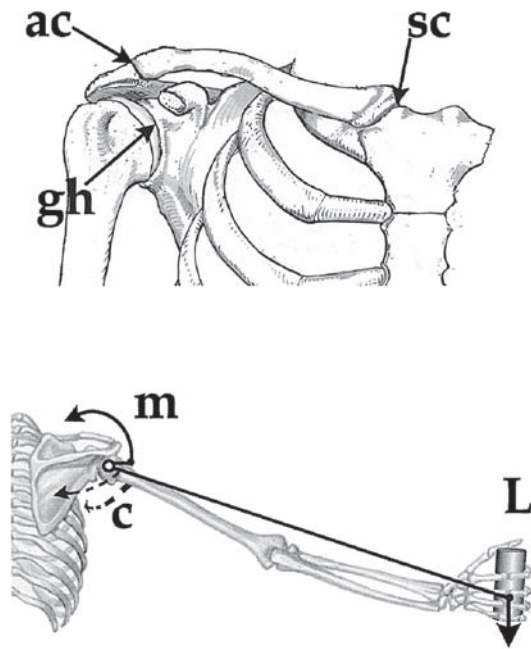

Figure 8-20 **Top.** Front view of the shoulder complex consisting of the glenohumeral (*gh*) acromioclavicular (*ac*), and sternoclavicular (*sc*) articulations. The scapulothoracic junction is not a true articulation, but describes the relationship of the scapula and thorax as can be seen in the lower figure. **Bottom.** An example of the differences in the moment arms of shoulder muscles (*m*) and a load (*L*) in a lift with the shoulder abducted and arm extended. Co-contracting muscles (*c*, dotted arrows) are important to stabilize the shoulder complex during such tasks.

acromion of the scapula has a meniscus of cartilage, a thick fibrous capsule, and supporting ligaments that stabilize the joint and allows the scapula motion in three planes (74). These planes include a vertical axis (protraction and retraction) and transverse axes in the frontal and sagittal planes. The proximal end of the clavicle (sternoclavicular joint) is stabilized by a fibrocartilage, meniscus-containing, articulation capsule and ligaments to the sternum and 1st rib. The joint allows protraction and retraction, elevation and depression, and rotation of the clavicle relative to the sternum.

The concept of a scapulothoracic articulation involves a description of the movement of the scapula relative to the thorax as limited by its muscular attachments and the clavicular chain. This structural arrangement allows a wide range of motion of the scapula including protraction retraction, elevation, depression, and rotation. Movement of the scapula involves the translocation of the entire glenohumeral joint, contributing substantially to the range of motion of the arm. A simple example is the contribution of scapular motion to the elevation of the arm. In this circumstance the scapula rotates to elevate the shoulder and the glenohumeral joint as the arm is raised.

Shoulder Range of Motion Is Usually Described for the Entire Joint Complex Rather than Individual Joints

With the complex interaction of the individual articulations, the range of motion of the shoulder is usually described for the complex as a whole. From a resting position at the side, the range of motion in the shoulder complex is typically described in the context

of range of elevation of the shoulder or movement of the humerus away from the thorax in any of the three primary planes. Forward flexion and abduction are approximately 180 degrees, and in the plane of the scapula may exceed 180 degrees. Backward elevation or extension is approximately 60 degrees. Other motions including bringing the humerus in adduction beyond the midline limit of the body in an upward direction is approximately 75 degrees (70). Horizontal flexion in a transverse plane at 90 degrees of abduction is approximately 135 degrees, with horizontal extension of 45 degrees. Rotation about the long axis of the humerus varies with the degree of arm elevation, but in general, both internal and external rotation can be approximately 90 degrees, with a total range of 180 degrees (74).

The Glenohumeral Joint Depends upon Muscle Stabilizing Forces to Resist Distal Loads

Because of the relative lack of structural stability of the glenohumeral joint, soft-tissue connections through the joint must play a greater role in its stability. In addition to the joint capsule and ligamentous connections, muscle contraction forces that essentially hold the joint together become more important in resisting the loads placed on the distal upper limb. The use of force-coupling arrangements in the muscles of the rotator cuff is particularly important in this process. In force coupling, muscles of the rotator cuff act in concert to produce offsetting moments (a net joint reaction force) to stabilize the joint (Fig. 8.20) as elevation is produced. The actual calculations of joint reaction forces under these circumstances are difficult due to the large numbers of muscles involved in arrangements that will vary according to the plane of motion. Estimates of these forces suggest magnitudes near body weight (75). It is also important to note that the low mechanical advantage of muscles in the shoulder compared to the moment arm of a load in the hand of an extended arm requires very high contraction forces (Fig. 8.20). The low mechanical advantage of shoulder muscles under loading and the dependency of the joint on soft tissues for stability make the shoulder particularly vulnerable to injury.

THE SPINE

The spine as a whole represents an extremely complicated system of articulations and bony segments that act to protect the spinal cord while providing a basic support axis for the upper body. The structure and motion of spinal segments differs substantially over the spinal column. Due to this complexity and variation, only some basic principles of spinal biomechanics can be covered here.

Spinal Motion Segments Consist of Two Vertebrae and Associated Soft Tissues

The functional unit of the spine or motion segment consists of two vertebrae and their associated soft tissues (Fig. 8.21). The segment is functionally and physically divided into anterior and posterior segments. The anterior portion consists of the vertebral body, the disc between them, and the longitudinal ligaments (Fig. 8.21). The posterior segment consists of the vertebral arches, the articulations between the facets, the transverse and spinous processes, and the ligaments binding them together. Besides containing the spinal cord and associated structures, the architecture of the posterior segment acts to guide and limit the motion that can occur between the vertebrae of the segment. The anterior segment of the unit is the primary load-bearing section, with the vertebral bodies and the

Figure 8-21 Left. A basic motion segment of the lumbar spine divided into anterior (A) and posterior (P) portions. The anterior portion contains the vertebral bodies, the spinal disc, and the anterior longitudinal (1) and posterior longitudinal (2) ligaments (right). The posterior portion contains the vertebral canal, the bony segments associated with it, and associated ligaments including the ligamentum flavum (3), the interspinous ligament (4), and the supraspinous ligament (5). Other soft-tissue structures (e.g., capsular ligaments, etc.) are not shown.

intervening disc increasing in size in the lower segments to sustain greater loading stress. Load bearing in the posterior segment can be significant when the spine is hyperextended (76) and during forward bending coupled with rotation (77).

The Bony Structure of the Spine Is Supported by an Intricate Arrangement of Soft Tissues

The soft-tissue support for the spinal column consists of the ligaments, joint capsules, and muscles that connect to the transverse and spinous processes of the vertebrae as part of the posterior motion segments. The primary ligaments include the anterior and posterior longitudinal ligaments, the ligamentum flavum, the supraspinous and interspinous ligaments (Fig. 8.21), and the intertransverse ligaments, all of which provide intrinsic support for the spinal column. The capsular ligaments for the facet articulations also contribute to stability and limitation of motion. The ligaments have a high collagen content except for the ligamentum flavum, which has a high elastin content. The ligaments add stability and store energy during movement of the spinal column. For example, flexion primarily stretches the interspinous ligaments, capsular ligaments, and the ligamentum flavum. These store energy like an elastic band and can be used for subsequent recovery to a neutral position. Other ligaments similarly participate in lateral bending and rotation.

Intervertebral Discs Are Structured to Cushion and Distribute Stresses between Vertebrae

The intervertebral discs sustain and distribute primarily compressive loading of the vertebrae and restrict excessive motion. The disc consists of a tough outer covering of fibrocartilage, the annulus fibrosus, bounded above and below by a plate of hyaline cartilage adjacent to the vertebrae. The collagen fibers of the annulus fibrosus are arranged in concentric layers and differing orientations to the vertical axis of ± 30 degrees in a cross-hatched arrangement. This covering encloses a gelatinous inner core, the nucleus pulposus, that acts to distribute and redirect stresses and store energy, similar to a partially inflated ball. The nucleus pulposus contains a water-binding glycosaminoglycan gel (80% to 88% water) (78) that becomes progressively less hydrated with age (79). This change can reduce the elasticity, ability to store energy, and stress loading distribution properties of the disc and make it less capable of resisting loads.

In the unloaded condition, longitudinal ligaments and the ligamenta flava exert pressure on the disc to create a prestress condition (80). Compressive stress on the disc through the vertebral bodies creates a circumferential tensile stress that is resisted by the annular fibers of the annulus fibrosus. During motions such as flexion bending, the vertebrae rotate forward, creating compression stress and some strain (bulging) on the anterior disc and tensile stress on the posterior portion of the disc (Fig. 8.4). Rotation produces torsional stress on the disc, which is also redistributed through its structure. These strain patterns allow vertebral movement under load, and redistribution of forces across the vertebral-disc interface, to minimize localized extremes in stress.

The Bony Structure of the Posterior Segment Is a Primary Determinant of Intervertebral Ranges of Motion

Aside from their connection through the vertebral bodies and the intervening disc, the vertebrae interact structurally through the facets of intervertebral joints in the posterior portion of the motion segment. Under most circumstances, vertebral movement is restricted by the orientation of these facets relative to the vertebral column and each other (Fig. 8.22). Exceptions include particular regions of the spinal column, where articulations with structures such as the skull, ribs, or sacrum may add additional constraints on vertebral movement. The orientation of intervertebral facets changes throughout the spinal column (81) and the actual angle of the facets may vary significantly between individuals. The orientation of intervertebral facets also acts to produce additional directional components (motion coupling, as described in the next section) in vertebral motion during basic movement, such as flexion, extension, rotation, and lateral flexion.

The primary variation in facet orientation can be defined in the transverse and frontal planes. A positive angle deviation from the transverse plane indicates that the facets are oriented above

Figure 8-22 The orientation of intervertebral joint facets in the frontal and transverse planes relative to the spinal column. In the cervical vertebrae (A, B), the surfaces of the facets on either side are parallel to each and to a frontal plane (A), but inclined at 45 degrees above a transverse plane through a vertebra as viewed from the side (B). In the lumbar spine (C, D), the surfaces of the facets are oriented at 45 degrees to the frontal plane (C) and 90 degrees above a transverse plane as shown from the side (D). The facet orientations restrict the mobility of intervertebral movement and define the motion-coupling characteristics.

a horizontal (transverse) plane through the body (Fig. 8.22). Positive deviation in the frontal plane effectively describes the orientation of the facet surfaces on each side of the vertebra relative to each other, although the angle is defined relative to a frontal plane (Fig. 8.22). The atlas and axis have facets that are almost parallel to the transverse plane, with the remaining facets of the cervical vertebrae oriented at a 45-degree angle to the transverse plane and parallel to the frontal plane (Fig. 8.22). The alignment of the C3–C7 vertebrae allows flexion, extension, lateral flexion, and rotation (82). This can be compared to the facets of thoracic vertebrae that are oriented 60 degrees from the transverse plane and 20 degrees from the frontal plane. This allows lateral bending, rotation, and some flexion and extension. The lumbar vertebrae have facets oriented 90 degrees to the transverse plane and 45 degrees to the frontal plane. This allows almost no rotation, but flexion, extension, and lateral bending. The lumbosacral joints do allow more rotation (83), with facets oriented more obliquely to the transverse plane.

The Motion of the Spine Is a Composite of Small Movements in Individual Vertebrae and Coupling Between Vertebrae

The kinematic and kinetic considerations of spinal movements are particularly complicated, since overall movements are a composite of comparatively small movements of each vertebral segment. Each vertebra has some degree of rotation or translation in each of its transverse, sagittal, and longitudinal axes (or 6 degrees of freedom in movement). This movement is largely limited by the intervertebral joint facet orientations. These orientations vary markedly over the spinal column (81). Flexion-extension movements are greatest in the cervical, lower thoracic, and lumbar spine; rotation is greatest in the cervical and upper thoracic spine; and lateral bending is greatest in the cervical spine and more evenly distributed over remaining vertebrae.

It should be noted here that the convention in osteopathic medicine is to describe rotation of a vertebra as the direction in which the anterior part of the vertebral body or anterior segment rotates. In some biomechanical texts, rotation of the vertebra is described as the direction in which the posterior segment or spinous process rotates. Even though these conventions describe the same rotary motion, they are on opposite sides of the center of rotation and therefore the inverse of each other. This difference can become particularly confusing in relation to descriptions of motion coupling between vertebrae over the spine (discussed subsequently). The osteopathic convention will be used here, unless specific reference is made to the spinous process. Another caveat of the descriptions of vertebral movements given is that active, muscle contraction-based movement characteristics may or may not be similar to movements produced by external forces (e.g., manipulations). This should be taken into account in comparisons of these characteristics as described in the chapters on manipulation.

Physiologically normal movements of the spinal column in any of the primary directions (flexion-extension, lateral bending, rotation) produce additional motion vectors in the vertebrae as a consequence of the orientation of the intervertebral facets and other articulations (Fig. 8.23). This coupling may include motions of lateral bending (flexion), rotation, and translation in several axes simultaneously, although only major coupling relationships are typically noted as clinically significant. The coupling can differ markedly over the spine and only a limited description will be given here. In the thoracic region, rotation is coupled with lateral flexion. This is greatest in the upper thoracic region, with the vertebrae rotating toward the same side as the lateral flexion (81). In the lumbar

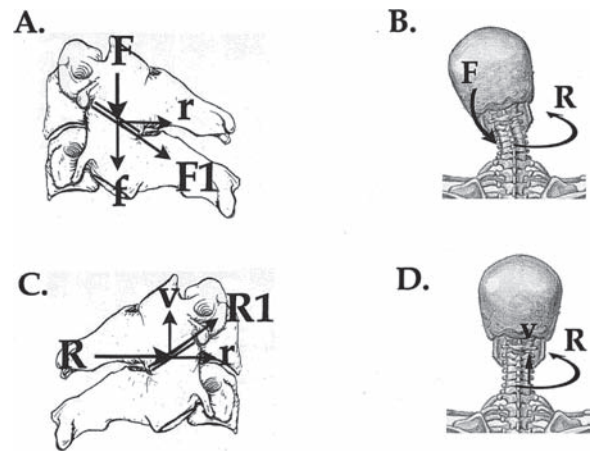

Figure 8-23 Motion coupling as influenced by the orientation of intervertebral facets in cervical vertebrae. **A.** A lateral flexing force (F) on the side of the vertebrae acting to move the upper vertebrae relative to the bottom will be redirected by the facets in a new direction ($F1$). The divided moment will have a remaining flexing component (f) and a rotational component (r) that will add (couple) rotation (R) of the vertebrae to the flexing movement (**B**). **C.** A rotational force (R) on one vertebra is redirected by the facets to glide in a new direction ($R1$). $R1$ has both a vertical (v) and a remaining rotational component (r) (vectors). The vertical component will cause the side of the vertebra to lift upward and produces lateral flexion on the opposite side (**D**). However, in isolated rotation movements, this flexing moment is restricted to produce vertical translation (telescoping) of the cervical spine, particularly at the C1–C2 joint.

spine, rotation is also coupled with lateral flexion, but the vertebrae rotate in a direction opposite the lateral flexion. Additional motion coupling in the cervical spine is described subsequently.

Overall Range of Motion of the Spine Varies Widely Between Individuals

The composite nature of spinal movements along with individual structural and soft-tissue differences help to explain a great variation in the range of motion in individuals. There are also significant variations in spinal range of motion with age and sex (84). This makes the listing of normal values without specification of these factors of little clinical significance. Difficulties in defining normal ranges of motion also derive from a large capacity of the spine to produce compensatory changes in movement to achieve a similar net movement. In this strategy, a limitation of movement that exists in the structural aspects of one area of the spinal column can be alleviated by a compensatory greater mobility in other areas (85). For example, the movement of the spinal column is also accompanied by motion in the pelvis. In body flexion, the initial 50 to 60 degrees of motion occurs in the lumbar spine with little contribution from the thoracic vertebra due to the orientation of the facets and the rib cage. Additional flexion is accomplished by the tilting of the pelvis.

Restriction of movement in the lumbar spine can be replaced, to some extent, by greater and earlier tilting of the pelvis. The movement of the pelvis also contributes to lateral bending and rotation of the trunk, and may be used similarly to compensate for restrictions.

As in other multiple-articulation chains, movements of the spine are accomplished through complex interactions of agonist and antagonist muscle groups. Movement aspects are accomplished

through the cooperative actions of antagonistic trunk and spinal muscles, some contracting to produce the movement, others cocontracting to provide stabilization.

Some Kinetic Considerations of Spinal Loading

Loading characteristics of the spine are similarly complex compared to movement. The loading of the spine includes body weight, muscle contraction, ligamentous prestressing, and externally applied loads. The natural kyphosis and lordosis of the spine add to the elastic resistance to load of the discs, again by redistributing compressive stress into bending stresses that can be resisted by muscle contraction (Fig. 8.24). The primary load-bearing region of the spinal column is in the lumbar spine. During normal standing, the center of gravity of the trunk passes near the center of the body of the fourth lumbar vertebra (86). This distribution and the static load on the spine can be altered appreciably by the angle of the pelvis. Tilting the pelvic angle (sacral angle) forward from its normal 30 degrees to the transverse plane accentuates the lumbar lordosis. Tilting backward from the normal angle flattens the lumbar lordosis. Both movements affect the lever arm of the body weight on the spine and require compensatory muscle activity to resist. This also creates greater loads on the lumbar spine during sitting versus relaxed standing (87). Reorientation of the spine from its normal curvature also produces stresses on the discs by changing the alignment of the vertebrae.

The Orientation of the Spine During Lifting Can Influence the Distribution of Stress on the Lumbar Spine

Lifting an object places added stress on the spine by creating an added load at a distance from the center of support in the spine (Fig. 8.24). The stress on the lumbar vertebrae by the load is primarily a function of the distance of the load from the vertebrae (moment arm or lever arm) and the weight of the load. Bending the body forward adds distance from the body, whether or not

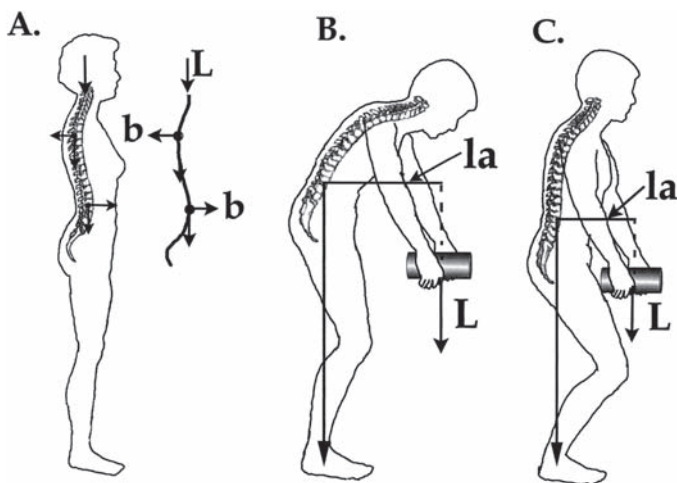

Figure 8-24 A. The normal curvatures of the spine *in situ* and in a model (right) will split vertical compression components into bending forces (*b*) that can be counteracted with muscle contraction. B. Force moments on the back are larger if an object is further from the vertebrae being compressed. The force moment is a product of the load (*L*) and the load arm (*la*). This compressive force alone is not dependent upon the bending of the knees (C), but bending of the knees can help to shorten the load arm.

the knees are bent (82). Contraction of back muscles and to some degree, intra-abdominal pressure must counterbalance the forward-bending forces. In consideration of posture in lifting, the lumbar spine has less resistance to bending compared to direct compressive forces (88) and lateral flexion or flexion combined with axial rotation (87) increases pressure on lumbar discs. This further suggests that a vertical lifting position of the spine is preferred to reduce pressures on lumbar discs.

The Cervical Spine Has Some Unique Structural Properties and Biomechanical Properties

The cervical spine and its articulation with the skull have some special biomechanical and structural properties that require special consideration. It has five of seven vertebrae that are described as more or less typical, except for the presence of the transverse foramen for the vertebral artery in C3-C6. The grooving of the transverse process for the exit of the cervical nerves lends to further structural weakness. Both the presence of the vertebral artery and the comparative structural weakness of the transverse process suggest reason for caution with high-velocity manipulations of this region. This is particularly true for older adults in whom both soft tissue and bone biomechanical properties add weakness to this region. Other structural differences in the C3-C6 vertebrae include more prominent uncinat processes and thinner intervertebral discs. Because of this, uncinat processes may also play a role in guiding and limiting cervical motion (89).

The Atlas and Axis Have Additional Structural Properties That Define Their Range of Movement

The atypical vertebrae (C1 and C2) have unique bony structures that limit their mobility. The atlas (C1) has no true vertebral body or disc, but an anterior arch with an articulating surface for the dens of the axis (C2). The atlas articulates with the skull in two superior facets that have a semicircular shape. This limits the motion of the skull relative to the atlas to almost no rotation. The inferior facets of the atlas articulate with C2 almost parallel to the transverse plane. The axis, with its superior protrusion, the dens, provides an axis of rotation for C1. Posterior translation of the dens within the vertebral foramen is prevented by ligamentous support from the cruciform ligament. It also contains two superior, convex-shaped facets for articulation, with two slightly convex-shaped articulations (62) of the atlas that affect motion coupling in rotation.

These structural properties help to make the cervical region the most mobile region of the spine. The range of motion at the atlanto-occipital articulation is approximately 10 to 15 degrees of flexion extension and 8 degrees of lateral bending (81,89). Axial rotation is largely precluded by the structure of the articulation and is transferred to the C1-C2 articulation. The C1-C2 interface is the most mobile segment of the spine with about 47 degrees of axial rotation, or almost 50% of the axial rotation capability of the entire cervical spine (90). Flexion-extension is limited to 10 degrees, and little or no lateral bending occurs. Throughout the cervical spine, the combined range of motion is approximately 145 degrees of flexion-extension, 180 degrees of axial rotation, and 90 degrees of lateral flexion (89).

Motion Coupling of the Cervical Spine Includes Transverse and Vertical Translation and Rotation

Motion coupling of the cervical spine also has some important characteristics in addition to those mentioned earlier due to its

unique anatomy. Flexion-extension is coupled with transverse translation, particularly at the C1-C2 interface (89,91). As discussed previously, lateral flexion (side bending) tends to rotate the spinous process away (vertebral body toward) from the direction of bending (Fig. 8.23) (81). Isolated rotation produces a vertical translation, or telescoping, of the cervical spine due to the orientation of the facets and restriction of flexor moments (Fig. 8.23).

Increased Mobility of the Cervical Spine Is Accompanied by Reduced Stability

The high range of motion in the cervical spine is accompanied by a lower intrinsic stability, but reduced load compared to the lumbar spine. This makes the cervical spine and associated soft-tissue support particularly vulnerable to excessive dynamic loading, with flexion-extension injuries the most common. As in other areas of the spine, restriction of movement in the cervical spine usually results in an increased compensatory mobility of other areas to achieve a functional range of motion. As a result, restriction of motion at one level, due to injury or a brace, may produce increased motion (and increased stress) at other levels (83,92). This consideration can be important in the determination of symptom-cause relationships in the diagnosis of spinal dysfunction.

BIOMECHANICAL CONSIDERATIONS OF THE BODY AS A UNIT

Normal Locomotion (Gait) Employs the Entire Body for Efficiency of Movement

Motions of the body incorporate the individual biomechanical properties of soft and hard tissues and kinematic aspects of the individual articulations into complicated movement processes. A particularly good example of this integration can be found in normal ambulation or gait (Fig. 8.25). Gait may be described as a controlled falling with propulsion. In this process, the center of mass of the body is subjected to relatively small vertical displacements. The actual energy expended is distributed over many muscle

Figure 8-25 Basic gait patterns using computer-generated (Peak Performance Technologies, Inc., Englewood, CO) stick figures of an individual in normal gait. The gait cycle arbitrarily begins with the contact of one heel with the floor (A). The force of the body weight and motion on the heel (arrow) is decelerated by the anterior muscle group of the leg (m , arrow) through the ankle. B. Body weight is transferred to the supporting leg, which supports the body with slight knee flexion. C. The moving leg is swung forward and the supporting leg is slightly extended (arrow) to raise the body center of mass to its high point (dotted line). D. The body is propelled forward by plantar flexion of the supporting leg to be “caught” with the heel strike of the moving leg and the cycle begins for the opposite side.

groups beyond the legs and by subtle, but significant movements. In normal gait, one leg is moved forward while the weight of the body is supported by the opposing leg (swing phase) (Fig. 8.25). In the swing phase of the leg, the foot goes from plantar flexion to dorsal flexion. The knee is flexed and then extended, the hip moves from extension to flexion, and the pelvis rotates and changes its tilt as muscles of the lower spine and trunk are used to generate power.

Swinging the opposing arm will assist in compensating balance and rotation moments through the trunk. The body is propelled forward and its center of mass moved slightly upward and then forward and down to be “caught” by the heel strike of the extended leg. As the heel hits a surface, the foot rocks down and is decelerated by the anterior muscle groups of the leg. The knee, which initially is almost completely extended, begins to flex and becomes progressively loaded as the body weight is transferred from the opposing leg. The opposing hip and pelvis are then rotated forward to begin the process for the opposite side. Small adjustments, such as increasing the tilt of the trunk and head in the direction of progression, bring the center of mass of the body forward and assist in increasing the rate of movement.

This basic process, grossly simplified here, can reflect one of the most frequently encountered examples of the ability of the body to adapt to injury or degenerative processes. Compensatory gait patterns can vary widely according to the underlying cause, but always have an underlying biomechanical rationale, even though these adaptations may themselves produce problems. In a typical example, an injury to the knee or foot on one side may produce a compensatory shift of the body center of mass over the opposing limb. This will produce pain, stress injuries, or palpable dysfunctions in the opposite knee, back, hip, or even neck, if body posture has been significantly affected. Some aspects of these compensatory adjustments may survive the healing of the original injury, particularly if the recuperative process has been lengthy. This emphasizes the importance of the subject’s history and careful observation and knowledge of mechanical body function in the diagnosis and treatment of somatic dysfunctions.

Somatic Dysfunction, Spinal Facilitation, and Viscerosomatic Integration

MICHAEL M. PATTERSON AND ROBERT D. WURSTER

KEY CONCEPTS

- The osteopathic lesion (somatic dysfunction) was conceived as one of the primary factors influencing body economy and the root of many diseases.
- Louisa Burns and her colleagues performed many studies on the effects of somatic dysfunction on visceral function, thus showing many somatovisceral influences well before they were generally recognized by the scientific and medical communities.
- Reflexes have an afferent arm bringing impulses to the central nervous system (CNS), a central arm within the CNS and an efferent arm taking impulses to peripheral structures.
- While usually thought of as simple hardwired pathways, reflexes are actually complex interconnections influenced by many factors such as ascending messages, descending influences from higher centers, and general CNS excitability.
- Somatovisceral and viscerosomatic reflexes are one of the main integrating mechanisms of body function, closely tying somatic and visceral organs together to achieve integrated function.
- In general, sympathetic control from the brain is often localized to specific visceral organs, suggesting that the brain, through the sympathetic nervous system, can selectively influence specific organ function.
- Manipulative treatment of somatic structures can influence sympathetic function and hence visceral function through the somatovisceral reflex networks.
- Sensitization is a process that occurs in spinal gray matter neurons (interneurons) and results in an increased excitability of the involved neurons, thus increasing the gain of the input pathway.
- Long-term sensitization is a longer-lasting form of excitability increase in the reflex pathways that can last for hours and often occurs with the same stimuli as sensitization.
- Presumably permanent changes of reflex excitability can occur in reflex pathways with inhibitory cell death and new synapse formation.
- Neurons exhibit a continuous flow of intra-axonal substances both away from and toward the cell body. This flow has been shown to include transport of proteins across the synapse from nerve cell to nerve cell and from nerve cell to end organ.

The human body is a machine run by the unseen force called life, and that it may be run harmoniously it is necessary that there be liberty of blood, nerves, and arteries from the generating point to destination (1).

INTRODUCTION

This chapter presents the neurophysiological basis for viscerosomatic and somatovisceral interactions so vital to both function and to the diagnostic and treatment modalities of manual medicine. In addition, the research work of Denslow and Korr on spinal excitability is outlined. This work laid the foundation for the osteopathic profession's modern views of the osteopathic lesion, now known as the somatic dysfunction. The basis of spinal cord excitability changes that underlie chronic and neuropathic pain syndromes is also discussed as it relates to somatic dysfunction. However, the neurophysiology of pain is considered in Chapter 16. Implications for somatic dysfunction of trophic nerve functions are presented, and possible implications of Osteopathic Manipulative Treatment (OMT) for trophic function presented.

The foundations of the osteopathic profession, laid by its founder, Andrew Taylor Still, M.D., D.O., recognize that the state of health

is a continuum from complete breakdown to perfect function. One of Still's basic beliefs about function was that the body was a totally integrated unit, its structures working together harmoniously to produce a state of health. Lacking that harmonious function, the body produced conditions promoting loss of health, or disease. Implicit in these assumptions is the idea that the various parts of the body are functionally interconnected, allowing for necessary adaptations when demands on the body change. This view necessitates that the supply and maintenance organs, mainly the visceral structures, are functionally connected with the primary energy consumer of the body, the musculoskeletal system. This interrelationship has long been neglected in medical practice. The communicating systems of the body, including the immune, endocrine, and neural systems, provide this interconnectedness. When a problem develops in the integrating systems of the body, function cannot help but be compromised, and the stage is set for a lowered state of health, and eventually disease, to occur.

The field of neurophysiology is important to the physician. A thorough knowledge of anatomy and the structural relationships within the body is vital. The physician must also know how these structures function and relate to each other. He or she needs a basis for providing the patient with a rational course of treatment, especially manipulative treatment. The physician must be aware of what palpatory diagnosis is telling him or her about the underlying

state of the body, and therefore of the person. Many excellent neurophysiology texts are available that outline the basics of the field.

This chapter does not attempt to give an overview of the entire field or all the areas of special interest to the osteopathic physician. It focuses on the integration of somatic and visceral function through the reflex pathways and relates these interactions to their specific neural basis. Functional alterations in reflex pathways that can disrupt integration are reviewed, along with the nonimpulse-based or trophic function of the nervous system, and how this provides a means of two-way communication within the body not dependent on the better-understood neural impulse-based communication. These aspects of the integrative activity of the nervous system are important in the osteopathic clinical experience and the role of manipulative treatment in health care. As Still recognized before the turn of the century, proper function necessitates the free interaction and integration of all body systems. Rational treatment of functional problems likewise requires an understanding of how these interactions occur and what can alter their function.

NEUROPHYSIOLOGY IN THE OSTEOPATHIC PROFESSION

The search for mechanisms underlying the efficacy of osteopathic methods began with the founding of the osteopathic profession. Although Still did not pursue what we would call organized research, he certainly was a fine researcher. He constantly questioned his observations and searched for better ways to find health and ameliorate disease. His early students at the American School of Osteopathy soon began to actively investigate the basis for the treatments they were developing. Their observations resulted in the formulation of the concept of the osteopathic lesion (now known as the somatic dysfunction). The osteopathic lesion was a set of palpatory cues and signs that indicated a functional disturbance in the body that predisposed it to disease. The early pioneers of the profession believed that somatic dysfunctions were primary causes of clinical breakdowns that resulted in the many manifestations of disease, either by themselves or by allowing, through reduced function, microorganisms to overwhelm the body defenses. When viewed in this perspective, the statement by Still that “all diseases are mere effects, the cause being a partial or complete failure of the nerves to properly conduct the fluids of life” (1) is more meaningful.

Still believed that various types of diseases were not entities unto themselves but were the result of the body's efforts to regain optimal function in the face of adverse influences, which is a view that is becoming more strongly supported by the current idea of the “illness response” (2,3) this being the initial quick immune response to pathogenic invasion, which can, ironically be triggered by psychological stressors. Thus, the events that led to the disruption of the body's normal function became the primary events to treat in the osteopathic physician's efforts to remove the influences resulting in clinical illness. The osteopathic lesion was viewed as one of the primary factors influencing body function and was amenable to physical manipulations. In addition, Still and his students realized that the body was of necessity an integrated unit; the visceral systems were tightly connected to the somatic systems. They felt strongly that visceral disturbances would cause manifestations in the somatic structures and that somatic disturbances would cause visceral dysfunctions. This reciprocal relationship became very important in the profession's thinking, clinical practice, and research endeavors.

Early research efforts in the profession largely aimed at providing evidence for the somatic problems identified as the osteopathic lesion and the effects of these dysfunctions on various aspects

of function (4). In their efforts to find objective measures of the osteopathic lesion, researchers at the American School of Osteopathy used skiagraphy, an early form of x-ray, to look at bony placement and circulatory function as early as 1898. Another early research thrust was the effects of somatic disturbances on visceral function. Louisa Burns began research in this area early in the 1900s with studies on dogs that showed that stimulation of the lower dorsal region increased muscle contraction in the stomach and intestines but that steady pressure for a time tended to inhibit such contractions (4). Burns eventually became head of the A.T. Still Research Institute in Chicago and produced a body of research suggesting that strains produced in the vertebral column would, over time, have definite and reproducible effects on visceral function and morphology. Aided later by Wilber Cole, effects of somatic strains on neural endplate function controlling visceral organs were found and documented by neural stains. In addition, Cole (5) was able to well delineate the pathways for the effects of somatic influences on visceral function. The early research efforts of the osteopathic profession by Burns, Cole, and others were attempts to describe the effects of somatic disturbances on visceral function and the effects of manipulative treatment on immune and general function, among other things. They established a firm interest in the profession on the interrelationships between somatic and visceral function.

Beginning in the late 1930s, a new era of research in osteopathic medicine began. In an effort to enhance the profession's reputation, J.S. Denslow began a program of research at the Kirksville College of Osteopathy and Surgery that was to span 40 years and add much to the understanding of the methods of manipulative treatment. With his colleagues, Denslow (6) used the then cutting-edge technology of electromyographic (EMG) recording to obtain objective evidence of specific alterations in somatic function that correlated almost exactly to palpatory findings. Joined by Irvin M. Korr (7) in 1945, Denslow used the EMG technology to show that one of the underlying causes of palpatory findings was, indeed, altered muscle excitability. Korr then interpreted these findings in terms of neural function and the concept of the facilitated segment was developed as an underpinning of the osteopathic lesion. The research of the Kirksville group (see discussion later in this chapter) firmly placed the interactions between somatic and visceral structures in the forefront of the underpinnings of osteopathic clinical practice and philosophy. It became obvious that the interactions between visceral and somatic structures were important in health maintenance and disease processes. These interactions also provided an explanatory framework for the impact of manipulative treatment as not only influencing somatic function but also having a real and often vital effect on visceral function. Thus, this chapter will focus on the interactions between visceral and somatic structures and how they are organized. In addition, the alterations in spinal cord function that can occur with somatic input and its influence on visceral function will be discussed. Understanding these interactions and alterations, beginning with the organization of the basic reflex arc, is important in understanding the value of osteopathic treatment techniques and the neural basis of health.

THE REFLEX

In 1905, Charles Sherrington (8) published *The Integrative Action of the Nervous System*. This classic text represented current knowledge about the fundamental aspects of how the nervous system handled and integrated information. Over the ensuing years, considerably more has been learned about the function of the nervous system and how it integrates the many functions of the body. A great deal is known about how the basic structural unit of the nervous system,

the neuron, interacts with other cells through synaptic structures and the release of neurotransmitters and neuromodulators. The billions of neurons and glial cells that make up the nervous system are organized into functional groups, often with widely differing structural and functional characteristics. Many of the neurons are involved in networks that respond to stimuli impinging on or even originating in the body, which results in commands to muscles and glands that produce activity or secretions. These networks, the reflexes, have been more fully analyzed in recent years. What were previously considered to be almost autonomous units of function are actually complex and interactive aspects of an organizational whole. The reflex has been found to be anything but a static unit of input/output relationships, but rather it is an active and ever-changing mosaic. The characteristics of reflex function are modulated by messages from other areas of the nervous system and by activity of the endocrine and immune systems. In fact, reflexes must not be viewed as separate entities but as parts of various programs that control motor and secretory actions. Thus, an individual reflex may serve differing functions depending on which control program is operating (9). However, for purposes of analysis, reflexes have usually been isolated for study, a practice that has erroneously led many students to view reflexes as simple and unchanging entities.

Structure

The common concept of the reflex is basically one of a relationship between an input stimulus to the body and an output action to either a muscle or a secretory organ. Sherrington (8) viewed the reflex as an input/output relationship between information coming into the body and a response to that information. He viewed a reflex as always inherited and innately given. The concept of a reflex includes an afferent or incoming limb from a sensory receptor, which is a central component in the spinal cord or brain. It also includes an output (efferent) limb that is usually a motor component to either somatic (musculoskeletal) or visceral structures terminating in synaptic connections that may either activate or inhibit activity in these structures (Fig. 9.1).

The usual concept of the reflex suggests that the reflex limbs are fairly well defined and limited primarily to one input and one output channel, with little interaction with other reflex networks (Figs. 9.2 and 9.3). Almost all reflex networks can be influenced by a wide variety of other excitatory and inhibitory signals, including those coming from higher or lower levels of the central nervous system (CNS). The picture of a reflex as a simple message pathway from the patellar tendon that causes the quadriceps femoris muscle to contract, resulting in a knee jerk, is a vast oversimplification of the interactions that occur when a stimulus causes a response. The tendon tap reflex, exemplified by the patellar tap/knee jerk reflex activation, is, however, a prime example of the simplest reflex structure.

The tendon tap, or myotatic reflex, is a monosynaptic reflex. It is the only monosynaptic reflex present in the human. The stimulus of a tap to a tendon stretches the muscle attached to the tendon, which in turn stretches the muscle spindle organs in the muscle. Neural signals, or action potentials, are sent from the spindle organs to the spinal cord on the incoming, or afferent, limb of the reflex. In this case, the signals travel through the spinal cord on the axons from the spindles directly to the motoneurons that innervate the muscle that was stretched. They make synaptic contact with the motoneurons causing them to generate action potentials that travel over the efferent, or outgoing, limb of the reflex network back to the muscle, which causes it to contract.

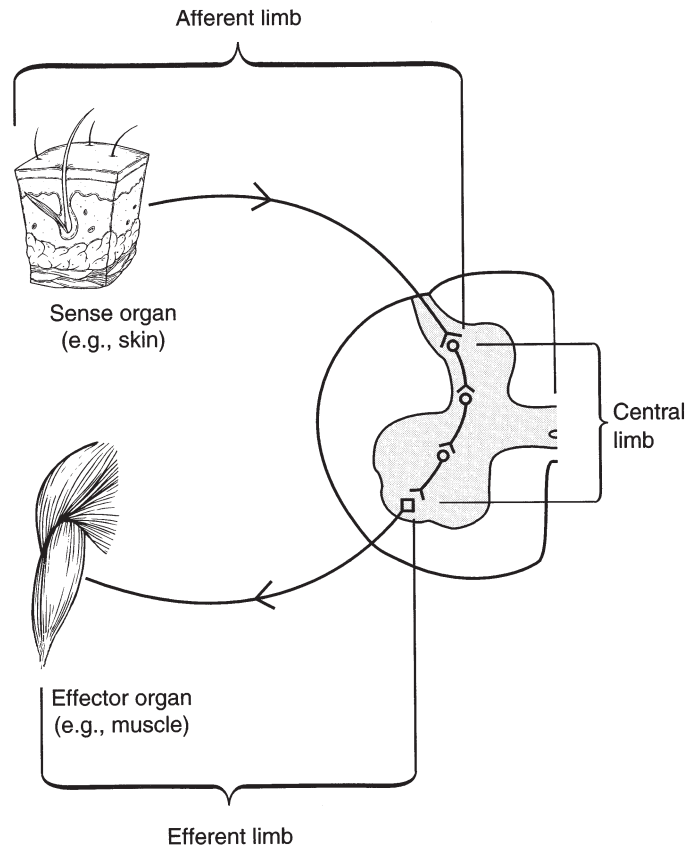

Figure 9-1 Schematic of reflex as it is usually envisioned, with afferent, central, and efferent limbs.

It would be a simple picture if this was all that happened. However, the incoming axons send off branches that go to other neurons in the spinal cord that, in turn, send axons to the motoneurons of the antagonist of the stretched muscle. These axons provide signals that inhibit the motoneurons innervating the antagonist

Figure 9-2 A common, mistaken concept of how a reflex is constructed. Afferent limb simply connects with central limb, which activates efferent limb. **Left**, monosynaptic reflex; **right**, polysynaptic reflex. Actual complexity is better represented in Figure 7.3.

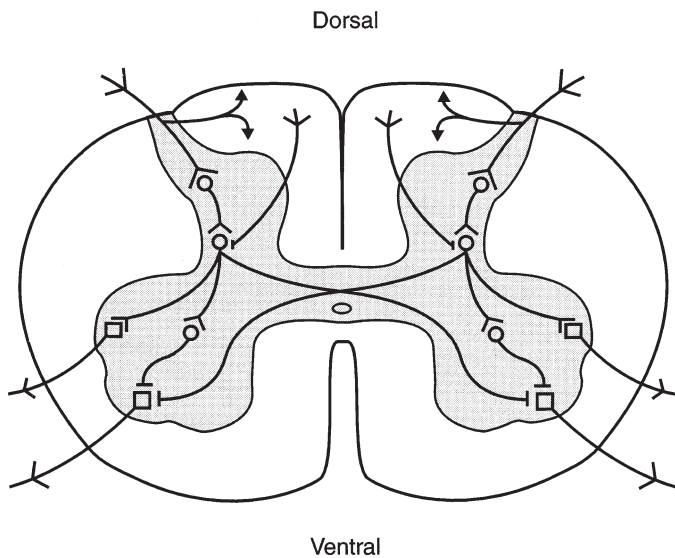

Figure 9-3 Schematic of neural interactions at the spinal level, indicating the complexity of even simple reflexes. Input to the spinal cord sends collaterals up and down the cord and is acted on by ascending and descending influences, as well as input from the opposite side of the cord. Input courses through several synapses and interneurons before acting (in thoracolumbar cord) on both somatic and sympathetic motoneurons. In cervical and sacral cord areas, parasympathetic pathways are involved.

muscle. When the stretched muscle contracts, the antagonist muscle is inhibited to allow a smooth movement to occur. In addition, other branches of the incoming axons go up the spinal cord to other spinal areas (e.g., to the arms if the patellar reflex was stimulated), to the brainstem, as well as down the spinal cord to lower spinal centers. What appeared to be a simple reflex network has become a complex set of pathways within the spinal cord and brainstem. In addition, pathways from both above and below the level of the input axons can directly influence the basic excitability of the motoneurons involved and, hence, alter the reflex activity observed when the tendon is tapped. Indeed, when elicited clinically, the tendon tap reflex is used as a porthole into the nervous system to see how it is functioning, and the clinician is not usually interested in that reflex per se. In fact, the main purpose of using the tendon tap reflex clinically is to test the excitability of the motoneurons, as a function of both local and distant influences.

SOMATOSOMATIC

Although the tendon tap reflex is used a great deal clinically, the most familiar of the spinal reflexes are the defensive reflexes, such as the withdrawal movements of a limb to a noxious stimulus. These somatosomatic reflexes occur when some stimulus is applied to a somatic structure. This initiates a volley of neural activity (often nociceptive) through the afferent limb of the reflex to the spinal cord. The afferent input activity flows through synapses into the interneurons of the spinal cord central gray, and finally into the ventral horn motoneurons. These motoneurons then cause somatic muscle contraction. The reflexes have at least one interneuron between the sensory input in the dorsal horn of the cord and the motoneurons of the ventral horn (Fig. 9.3). They are named from the origin of the information and the locus of action, both somatic.

Many somatosomatic reflexes have been documented and studied. The simple somatosomatic reflexes are exemplified by defensive

withdrawal actions such as when accidentally touching a hot object and the arm jerks back. Very complex activities, such as the righting reflexes that occur, for example, when a cat is dropped upside down and lands on its feet are also found, but even these reflexes do not occur in isolation; as with the myotatic reflexes, they are accompanied by a spread of activity throughout the nervous system.

VISCEROVISCERAL

A second type of reflex is the viscerovisceral reflex, in which sensory input from a visceral structure causes activity in a visceral organ. These reflexes are involved, for example, in distention of the gut that results in increased contraction of the gut muscle. Viscerovisceral reflexes involve afferent activity flowing from the receptors into the spinal cord through interneurons to produce efferent or outflow activity within the sympathetic and/or parasympathetic motoneurons.

REFLEX INTERACTIONS

We might expect to find that afferent input from somatic structures has some influence on visceral organs and that input from visceral structures has some effect on somatic organs. Somatovisceral and viscerosomatic reflexes have been known for many years but, until recently, have received little attention from the research and medical community. However, these types of reflex interactions are very important for the practice and understanding of osteopathic palpatory diagnosis and treatment and for the integration of body function.

A familiar example of a viscerosomatic reflex is pain and muscle tightness in the left shoulder with onset of a myocardial infarction (MI). The nociceptive input from the compromised myocardium (a visceral structure) is exciting not only the pathways that are interpreted as shoulder pain (a somatic structure) but is also causing the motoneurons supplying the shoulder muscles to become active. In a classic study, Eble (10) showed several such reflexes by stimulating visceral structures and recording somatic muscle activity. He demonstrated that stimulation of various visceral structures produced somatic muscle activity.

Conversely, activity in a somatic structure can alter visceral function. In a number of studies over the last several years, Sato (11) clearly demonstrated the effect of somatic stimulation on various visceral functions, ranging from heart rate to adrenal output. These studies have also shown that some of these reflex interactions occur directly in the spinal cord. With others, the afferent activity from the somatic stimulation travels up the spinal cord to the brainstem, resulting in a cascade of activity from the brainstem back down to the spinal autonomic motoneurons.

In both viscerosomatic and somatovisceral reflex networks, activity resulting from the stimulation of a structure can have either an excitatory or an inhibitory influence on the motoneurons involved. For example, stimulation of the belly skin usually results in inhibition of gut activity (a somatovisceral reflex) but increases heart rate.

In daily life, the body's somatic system is active. The skeletal muscles are the machines that carry out activities. The visceral organs are the means by which the energy demands and maintenance of the muscles are met and by which waste is disposed of. Without a continuous and highly integrated communication between these two systems, the body could not continue to achieve a balance among:

Its energy needs and supply

The amount of blood necessary to carry nutrients and waste and fulfill the demands of the muscles and bones

Supply and demand in general

The neural connections represented by these reflex systems are one of the primary ways this integration is carried out.

For the osteopathic physician, the viscerosomatic and somato-visceral reflexes are of extreme importance. When using palpatory diagnosis to detect subtle problems in function, whether it be tissue texture changes, motion characteristics, or temperature variations of the body, the physician is sensing clues from the musculoskeletal system, skin, muscles, and fascias. These clues reflect not only aspects of these tissues but also functional characteristics of the underlying visceral organs and tissues through the viscerosomatic reflex networks. When the physician uses manipulative treatment to correct somatic dysfunctions, underlying visceral function is affected through the somatovisceral reflex networks. Thus, for both palpation and treatment, an understanding of reflex function is necessary.

NEURAL BASIS FOR REFLEX INTERACTIONS

Evidence is accumulating about the neural basis of viscerosomatic and somatovisceral interactions. When a stimulus is applied, afferent input from either visceral or somatic structures flows into the spinal cord along the dorsal roots and enters the upper areas of the spinal gray matter. The spinal gray matter is commonly divided into ten layers, first documented on cytoarchitectural evidence by Rexed (12) (Fig. 9.4). Large-diameter, cutaneous afferent input that signals nonnociceptive stimuli enters the spinal gray of the dorsal horn and terminates primarily in layers III and IV. Nociceptive afferents from both somatic and visceral structures enter the cord and send branches rostrally and caudally in Lissauer's tract that runs along the apex of the dorsal horn. Branches of this nociceptive input then terminate in layers I, II, V, VII, and X. Layers I and V display an especially tremendous overlap of the input from somatic and visceral nociceptors (13).

It now appears that in most areas of the spinal cord, practically every interneuron that receives input from a visceral nociceptor also receives input from a somatic source. It also appears that almost 80% of interneurons that receive input from somatic structures also receive visceral input. Presently, there is no evidence for any ascending pathway that transmits only visceral sensory signals from the spinal cord to the brain. This raises the question of how an individual can distinguish visceral from somatic pain or sensation at all. In many cases, visceral pain is felt as a diffuse and poorly localized sensation and is referred to somatic structures. The overlap of somatic and visceral input explains the referral of visceral pain to somatic structures, which is designated as referred pain.

Impulses arriving from visceral structures and converging onto interneurons also receiving somatic afferents activate ascending pathways to the brain that result in the perception of pain in the somatic structure. In addition, more somatic than visceral input occurs because the viscera are much more sparsely innervated with sensory receptors. This suggests that visceral input has much more diffuse functional effects than the corresponding somatic afferents do. For example, it appears that many of the somatic C fibers terminate primarily in focal areas of layer II of the cord. Visceral C fibers extend for several segments and give off collaterals at regular intervals. Only about 10% of the inflow into the thoracolumbar spinal cord comes from visceral structures (14). This sparse innervation but wide distribution of visceral afferents may be the basis for the diffuse nature of most visceral pain. The evidence indicates that the widespread effects of visceral input are due more to functional (spread of activity through networks) than anatomic (many collateral branches) divergence (15). Figure 9.5 shows the afferent

Figure 9-4 Rexed layers. Laminae at the L7 segment of a cat spinal cord. From Rexed B. The cytoarchitectonic organization of the spinal cord in the cat. *J Comp Neurol* 1952;96:415-495, with permission.

terminations of somatic and visceral afferent fibers in the various levels of the spinal cord.

The overlap of input onto common interneurons within the gray matter of the spinal cord is also the basis for the activation of somatic muscle activity seen with visceral disturbances. The excitatory drive provided onto common interneurons by visceral input activates not only sympathetic outflow back to visceral structures but also motoneurons (both alpha and gamma) that innervate skeletal musculature. The result is a tonic activation of skeletal muscles in the referral area of visceral input. This is the viscerosomatic reflex manifestation, or splinting, that is seen, for example, in appendicitis.

These relationships also underlie the reverse phenomenon, that of the somatovisceral reflex, in which somatic input alters sympathetic and parasympathetic outflow. The data on the convergence of somatic and visceral input are beginning to explain the interrelations between visceral and somatic structures, especially when nociceptive input is activated.

There are descending influences on the activity of both somatic and visceral reflex pathways. In many of the reflex loops driven by both visceral and somatic input, there is a strong effect of descending pathways on the long-lasting excitability of the reflex outflow. These descending influences can maintain the excitability of the reflex for extended periods. They may account for some of the long-term increases in sensitivity, muscle contractions, and hyperexcitable sympathetic output seen especially with visceral disturbances. Likewise, the long-lasting descending influences can be inhibitory, resulting in lowered somatic or autonomic outflow. For example, the effects of rib-raising techniques (a somatic stimulation) on

Figure 9-5 Terminal patterns of primary afferent collaterals in the transverse plane of spinal cord. **Left**, primary afferent terminations of axons not associated with nociception. A, C-low-threshold mechanoreceptor; B, innocuous cooling receptor; C, A hair afferent; D, G-1 and G-2 hair receptors; E, slowly adapting type I and II afferents; F, primary and secondary muscle spindle afferents; G, Golgi tendon organ. The arrow indicates that the parent axon bifurcates and ascends and descends the spinal cord for 17 segments giving off collaterals along this course. **Right**, nociceptor afferents from both somatic and visceral structures. Both visceral and somatic A and C fiber nociceptor afferents terminate in Rexed lamina I, II, V, and to some extent in VII and X. Laminae are indicated on the right and outlined by dotted lines. From Light AR. *The Initial Processing of Pain and Its Descending Control: Spinal and Trigeminal Systems*. Basel, Switzerland: Karger, 1992:88, with permission.

sympathetic outflow seem to be primarily inhibitory through the descending brain influences, resulting in decreased vasoconstriction and better fluid flow in the thoracic area (16).

Although much of our information on the activation of sympathetic afferents by skeletal input has come from nociceptive input, there is evidence that sympathetic output can also be strongly driven independent of nociception by muscle proprioceptors. For example, Kaufman (17) has shown large effects on sympathetic outflow driven by alteration of proprioceptive input from muscles. Pickar and his colleagues have also found evidence for somatosympathetic reflex interactions from the low back (18). Thus, the evidence for activation and control of sympathetic activity by somatic input strongly suggests a basis for musculoskeletal activity in the regulation of body function through somatovisceral reflexes. Likewise, recent research by Jou and Foreman (19)

has shown that cardiac efferents can have dramatic influences on muscle activity, supporting the role of viscerosomatic reflex connections as underlying the effectiveness of palpatory diagnosis in visceral disease states.

However, the direct interactions through the spinal cord of visceral and somatic inputs are not the only important means of interactions. Goehler and her colleagues have delineated a strong vagal to brain input that is primary in signaling pathogenic disturbances in the gut (20–22). The vagus is a very potent signaler for the very short latency first immune response to impending infections. The total response to vagal signals involves autonomic, somatic, and psychological responses that prepare the body to fight the infection. Called the bottom-up response, it prepares the whole system for defense. Interestingly, the same response can occur from the “top down” being triggered by psychological stress (21). The complexity of visceral, somatic, and psychological interactions is truly remarkable and only beginning to be understood.

CARDIAC CONTROL

We will now consider a model of viscerosomatic and somatovisceral interactions shown in cardiac control. Neural input from somatic structures may affect neural activity to both somatic and visceral structures. A good example of the interaction between somatic afferents and autonomic outflow is the control of the heart. As with most visceral structures, the heart receives its autonomic innervation from both sympathetic and parasympathetic nerves.

SYMPATHETIC INNERVATION OF THE HEART

Excitation of the cardiac sympathetic nerves (Fig. 9.6) causes the following effects:

- Increased heart rate
- Increased atrial and ventricular contractility
- Decreased conduction time from the atrium to the ventricle

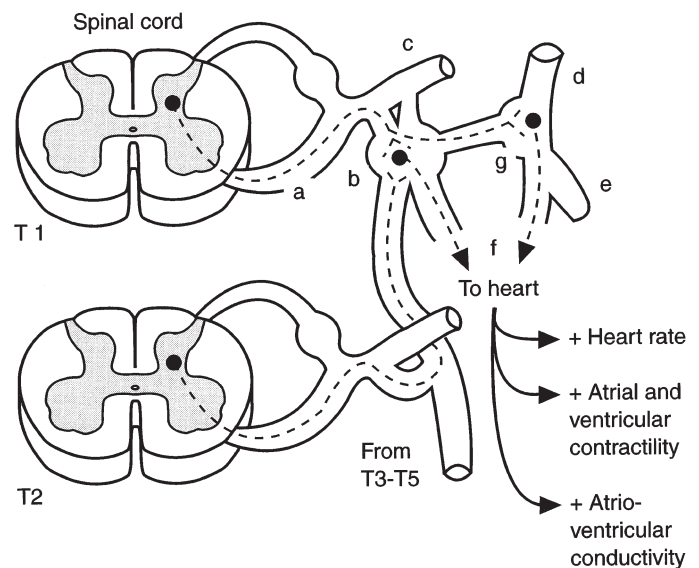

Figure 9-6 Sympathetic innervation of heart. A, ventral root; B, stellate ganglion; C, spinal nerve; D, vagosympathetic trunk; E, vagus nerve; F, cardiac nerves; G, middle cervical ganglion.

The heart's spinal innervation is associated with spinal cord levels from T1 to about T5, with T2 probably contributing the most (Fig. 9.7).

The preganglionic fibers leave the spinal cord via the ventral roots and course a short distance in the spinal nerves (Fig. 9.6). The preganglionic fibers then exit the spinal nerves to enter the adjoining sympathetic chain ganglia. Most preganglionic sympathetic fibers controlling the heart course through the stellate ganglion to the middle cervical ganglion. There, they excite ganglion cells that send their axons, the postganglionic fibers, via the cardiac nerves, to innervate:

- Pacemaker cells
- Myocardium
- Conductile system
- Coronary arteries

The first paravertebral ganglion associated with the heart is the stellate ganglion, where some preganglionic axons excite ganglion cells whose axons also run directly to the heart (23).

Segmental-like innervation to different portions of the heart does not seem to occur (24). In other words, a particular spinal

level (e.g., T4), sends its sympathetic influences to most areas of the heart, not to one area. One should be cautious in relating problems in one portion of the heart to problems associated with one spinal level. However, different spinal segmental levels innervate different organs, for example, heart versus lungs. Some degree of segmental-like innervation does occur.

Understanding the spinal cord levels that control the heart is helpful in understanding responses of spinal cord-injured patients (Fig. 9.7) (25,26). With spinal cord lesions above T1, the brain has no control of the heart via the spinal cord and sympathetic nerves, but it can still activate the parasympathetic pathways. However, marked cardiac alterations may occur via reflexes mediated by sensory input that enters the spinal cord below the C8 level. For example, input from the urinary bladder may cause markedly increased sympathetic activity to the heart. Patients with spinal lesions below T1 have some brain control of the heart via descending spinal pathways. Patients with lesions below T5 rarely show any spinal reflexes influencing the heart from the spinal afferents entering the cord below the lesion level. Specific levels of the spinal cord innervate specific visceral organs.

Sympathetic motoneurons located in both sides of the spinal cord and their corresponding sympathetic nerves innervate the heart. There are some quantitative differences in the regions of the heart that are innervated (24). For example, stimulation of sympathetic preganglionic nerves from both sides of the spinal cord causes increases in heart rate. The right side has a greater influence on heart rate and the sinoatrial node function. Both sides innervate the atrioventricular node, both ventricles, and atria. However, sympathetic output from the left spinal cord has a greater effect on cardiac output and myocardial contractility (24,26). Visceral organs receive asymmetrical autonomic control from the left and right sides of the spinal cord.

Several different descending spinal pathways can affect autonomic outflow from the spinal cord. Many of these pathways are located in the lateral funiculus of the spinal cord. Both anatomic (27) and physiologic (28) evidence suggests that the descending spinal pathways are organized according to a viscerotropic pattern. Localized lesions of the spinal cord, or portions of the descending spinal pathways, may result in loss of brain control of one particular visceral organ, which also suggests that the brain has the potential to separately control different visceral organs (Fig. 9.8).

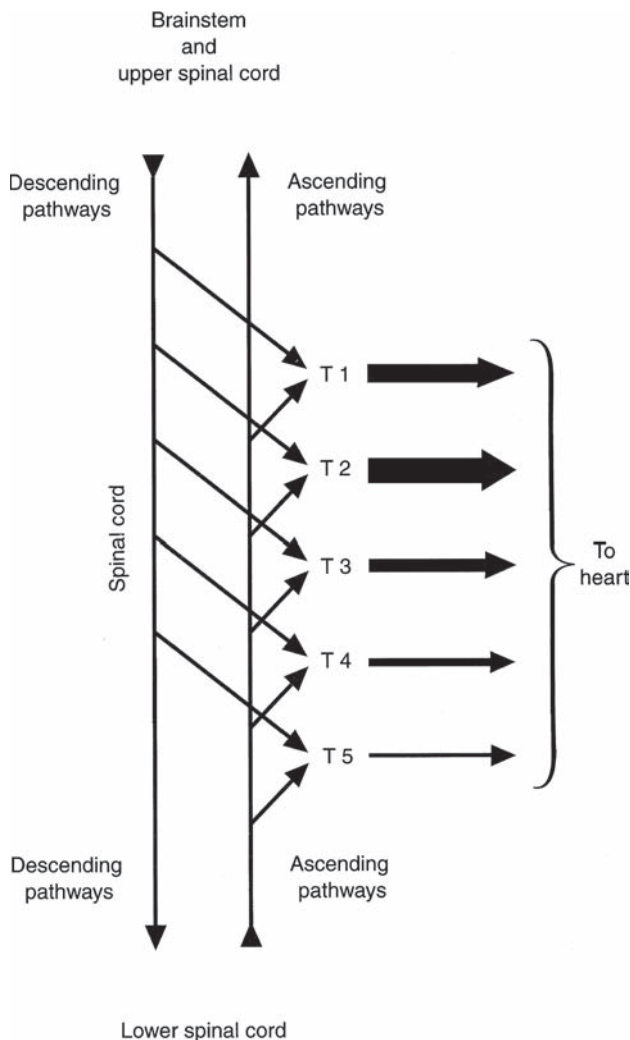

Figure 9-7 Spinal sympathetic innervation of the heart and related ascending and descending pathways. The heart receives spinal cord control via T1-T5 spinal cord levels with T2 making the largest functional contribution. Lesions above T1 and below T5 block brain control of cardiac sympathetic activity and reflex responses to ascending afferent activation, respectively.

PARASYMPATHETIC INNERVATION OF THE HEART

Parasympathetic innervation of the heart is via the vagus nerve that causes the following (Fig. 9.9):

- Decreased heart rate
- Slowed atrioventricular conduction

Figure 9-8 Viscerotropic organization of the descending spinal pathways controlling autonomic outflow.

Decreased atrial contraction
 Limited decrease of ventricular contractility

The cardiac vagal fibers travel in the cervical vagus nerve (vago-sympathetic trunk) into the thorax where they separate from the vagus nerve to form the cardiac nerves. These cardiac vagal nerves have their cell bodies in the medulla, that is, the nucleus ambiguus and the dorsomotor nucleus (29–33).

These two medullary regions may subserve different cardiac functions. For example, the nucleus ambiguus may mediate heart rate while the dorsomotor nucleus regulates ventricular contractility (31). Not only are there regions of the brainstem controlling

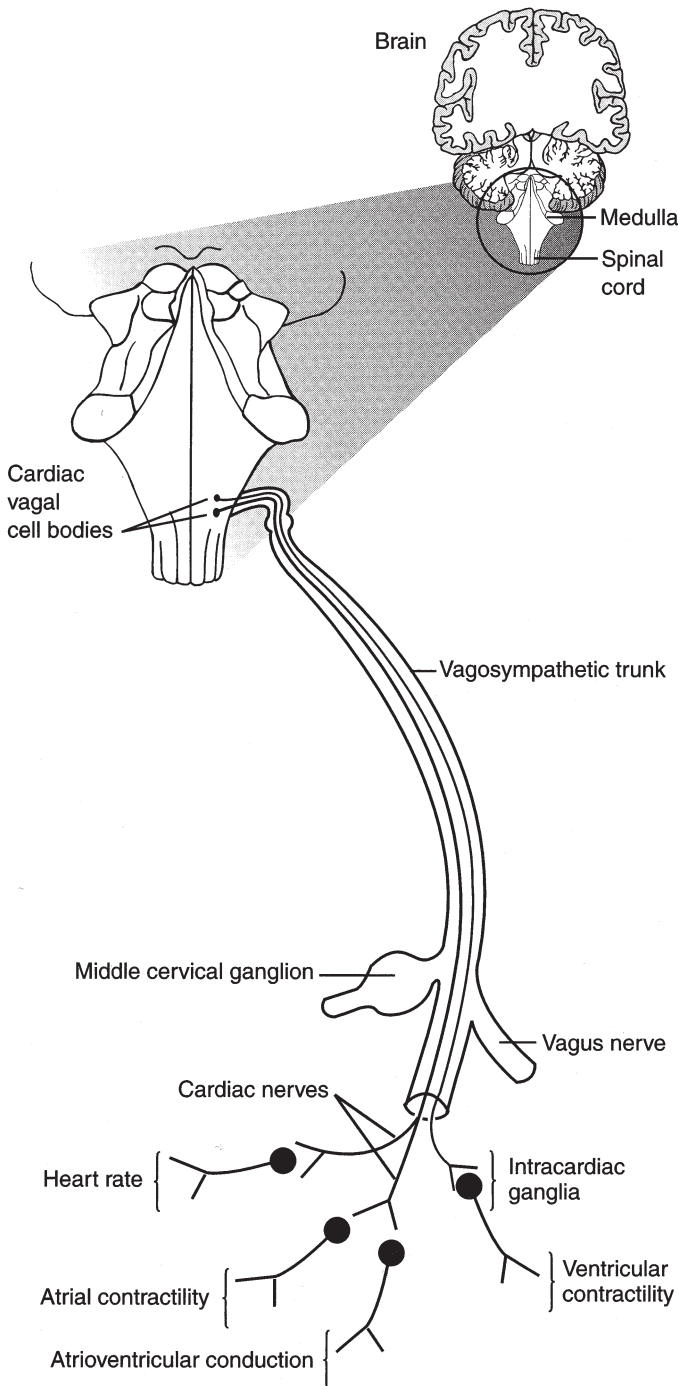

Figure 9-9 Parasympathetic innervation of the heart.

cardiac function that seem to be distinct from those controlling gastrointestinal function and other visceral organs, but different brainstem regions may also control separate cardiac functions.

VISCERAL FUNCTION CONTROL

Cardiovascular function can be reflexively controlled by somatic afferents via the somatosympathetic reflexes. These reflexes may be mediated at the spinal cord level or via suprasegmental connections. The spinal somatosympathetic reflexes demonstrate dependency on segmental organization. These sympathetic reflex responses at one segmental level are larger if the somatic afferent activity enters at the same spinal level than if it enters at adjoining levels (34,35). These reflexes also demonstrate laterality, because they are larger for ipsilateral reflexes than for contralateral reflexes (Fig. 9.10).

Visceral afferents can also influence somatic reflexes, and muscle tone may be altered by visceral input. Many of these reflex possibilities are very important for osteopathic palpatory diagnosis and treatment because they provide mechanisms for the use of muscle tone as an indicator of visceral disturbances. The work by Eble (36) showed activation of skeletal muscles with stimulation of visceral structures, and Schoen and Finn (37) reported EMG activity in shoulder muscles of the cat following experimental MI. The cardiac viscerosomatic reflex has an influence on somatic musculature (19).

Not only can there be activity from somatic or visceral structures that influences the opposite structures, but another type of activity, independent of the brain or spinal cord, may also occur. Recently, neural activity has been recorded from *in vitro* sympathetic ganglion cells and intracardiac ganglion cells, demonstrating considerable action potential activity even when the neuronal connections to the CNS are severed (29,31–33). These observations suggest that the autonomic ganglia may function as little brains within peripheral ganglia and the heart. These ganglia may have the neural circuitry to act almost independently and have the ability to integrate intrinsic cardiocardiac reflexes as well as information from the CNS. However, the functional roles of these peripheral nervous system interactions are presently unknown (Fig. 9.11).

The possibility of little brains within the autonomic ganglia presents many more possibilities. If visceral afferents have reflexes

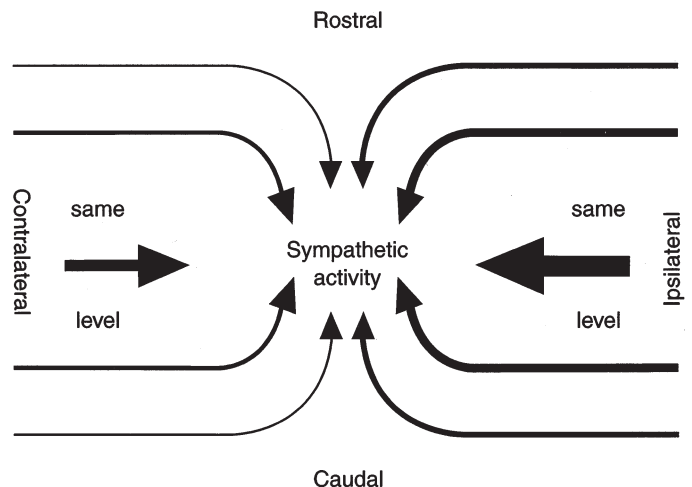

Figure 9-10 Laterality of cardiac sympathetic control and segmental organization of spinal sympathetic reflexes.

Figure 9-11 Afferent reflex control of autonomic effectors may be mediated via reflexes within peripheral autonomic ganglia as well as via CNS connections.

within the autonomic ganglia, somatic afferents could also have reflex connections within them. Some somatic afferent fibers pass through the autonomic ganglia. It is possible that somatic afferents influence sympathetic activity not only to the somatic structure but also to visceral structures such as the heart. Activation of somatic afferents might cause reflex alteration of cardiac function via direct ganglionic reflexes as well as via the CNS-mediated reflexes. Likewise, visceral afferents might activate sympathetic ganglion cells with axons supplying somatic structures (38–41). The therapeutic implications of reflexes within autonomic ganglia may be important.

INTERACTIONS OF SOMATIC AFFERENTS AND BARORECEPTOR CONTROL OF AUTONOMIC ACTIVITY

Blood pressure and cardiac function are reflexively controlled through alteration of autonomic activity mediated by arterial blood pressure afferent receptors called baroreceptors. Increased arterial blood pressure excites baroreceptor activity, which is carried to the brainstem via the glossopharyngeal and vagus nerves. In the brainstem, the baroreceptor afferent activity eventually leads to excitation of the medullary cardiac vagal cell bodies. It also leads to inhibition of the sympathetic activity to the cardiovascular system via descending brainstem/spinal pathways (42). Baroreceptor reflexes involving the cardiac vagus nerves have parallel inhibitory effects on the sinoatrial node (slowing heart rate) and atrioventricular node (slowing atrioventricular conduction) (43).

Although these baroreceptor reflexes have powerful influences on cardiovascular function, they also interact with other spinal reflexes, especially from small, high-threshold, afferent fibers. With activation of these spinal afferents, reflex changes in sympathetic activity (somasympathetic reflexes) occur at the spinal cord level and through suprasegmental reflexes involving ascending and then descending pathways to and from the brainstem (44,45).

Baroreceptor reflexes inhibit both spinal and supraspinally mediated somatosympathetic reflexes (46). Presumably, other visceral afferents that also mediate sympathetic reflexes are also inhibited by these powerful baroreceptor reflexes.

Somatic afferent activity can modulate baroreceptor reflex vagal control of the heart. Baroreceptor activation excites the cardiac vagus nerve activity. However, somatic afferent stimulation attenuates or blocks the baroreceptor influence of vagal cardiac

Figure 9-12 Wind-up or sensitization. When a stimulus is repeated at a rate of once every second or two, response to stimulus may continue to grow for 20 seconds or more. Finally, a stable response level is reached that can continue at an increased level as long as the stimulus is continued.

nerves. Somatic afferents and baroreceptors compete for control of autonomic activity. The ascending and descending pathways for these reflexes have been localized in the dorsal portion of the lateral funiculus of the spinal cord (47–49).

Summation Characteristics of Somatovisceral Reflexes

Somatovisceral reflexes demonstrate temporal and spatial summation as indicated by the wind-up phenomenon and the effect of input from different parts of the body. These somatovisceral reflexes do not reach their maximal activity immediately (50). Rather, when stimulated at a slow repetition rate, these reflexes exhibit wind-up. With each repetition of the stimulation up to about 20 times, the autonomic response increases in size (Fig. 9.12).

The wind-up, or as it has also been termed, sensitization phenomenon suggests that maximal effectiveness of therapeutic procedures involving somatic afferent influences on autonomic control may require frequent repetitions of the procedure to allow the response to build to its maximum. Furthermore, afferent input from different portions of the body can summate to activate autonomic responses (51). Accordingly, one would expect that a subliminal or noneffective stimulus to one part of the body might actually have an effect if combined with stimulation to another area (Fig. 9.13).

The reflex system is truly a complex integrating network. Perhaps most important for the osteopathic physician is the fact that somatic input can and does influence visceral function, just as input from the viscera causes changes in output to the somatic structures. This can often be felt as altered tissue tensions or changes in motion characteristics of joints. Maps have been published listing somatic areas that become abnormal to palpation with various visceral disturbances (52).

A corollary of this is that manipulation of the somatic structures can alter the function of visceral structures through the same pathways. The reflexes are not simple systems with only local influences, but interconnected networks that receive input from many sources and process that information for distribution to both local and distant areas of the body.

ALTERATION OF INTEGRATIVE FUNCTION

Input from each area of the body and from descending brain areas interacts on a highly overlapping and integrated neural network in the spinal interneurons. Afferent input from any source influences both visceral and somatic structures. For normal functioning of organs, muscles, fluid motion, and other body activities, these complex and interacting networks within the nervous system must act in concert. Should one area of the neural network respond either more or less than normal, the finely tuned balance necessary for normal and optimal physiologic function will be disturbed. Not only must the control mechanisms from the brain be normal for proper reflex function, but the networks of neurons that make

Figure 9-13 Summation of autonomic responses. Input from two different locations adds together to produce a larger autonomic response than either input produces when it occurs alone.

up the reflexes must also be acting normally. Unfortunately, these networks themselves can be altered, resulting in a loss of proper function.

Although Sherrington postulated that reflexes are innately given, evidence is accumulating that the function of reflex networks can be influenced by many factors. They are subject to both short-term and long-term changes that can have consequences for the health of the individual.

In the early and mid-1940s, Denslow et al. (53–55) were among the first to show the results of changes in the integrative function of reflex networks in humans. They performed a series of studies on normal, young adult volunteers to determine whether the reflex excitabilities at various spinal levels of the body were stable and comparable. They measured how much stimulation it took to evoke muscle activity (EMG) in the paraspinal muscles of the back at several levels of the thoracic spine.

They found that, on the average, reflex excitability to pressure on the spinous processes was highest in the upper thoracic area and lowest in the midlumbar area. Although decreased excitability from the upper thoracic to the lower lumbar areas was seen overall in the subjects studied, practically all individuals studied had areas that were very highly excitable, responding to small amounts of pressure on the spinous process at that spinal level. In normal areas, in contrast, even a fairly heavy pressure in the spinous processes did not produce any muscle activity in the associated muscles. The highly excitable areas were characterized by not only the increased muscle activity to pressure on the spinous process but also often by pain and tenderness in the area. The areas of increased sensitivity to stimulation were not uniform from individual to individual and were long lasting (some cases remaining almost the same for years). In most cases, the individual did not realize that any change was present.

These long-lasting, low-threshold areas to afferent input could be activated not only by stimulating tissues at the same level of the spinal cord but also by stimulating other areas of the back or even by providing a psychological stress to the individual. With remote input, such as pressure on a spinous process four vertebrae away from the level of the low-threshold area, the muscles at the level of the input remained silent while those at the level of the low threshold became active. The same pattern occurred with psychological stressors. The normal areas remained silent, but the low-threshold areas showed muscle activity.

In later studies, Denslow and co-workers (56,57) found that not only was muscle activity affected but so were the activities of visceral organs through altered sympathetic output. Here, again, the interrelatedness of the somatic and visceral portions of the body was shown.

Although many otherwise normal subjects had low-threshold or high-excitability areas, it became evident from subject-to-subject variability, and from further data showing that the excitability

increases often accompanied injury and disease, that the excitability changes were not a normal state. They represented areas of neural function that were operating out of synchrony with other areas of the neural system, causing the organs served by those neural supplies also to be out of synchrony with the total body function.

Korr (7) suggested that these low-threshold spinal reflexes represented pathways that were being held in a hyperexcited state, perhaps by continued bombardment of input. He termed these areas the facilitated segment (although “segment” is a misnomer), as the areas rarely follow dermatomal boundaries. He pointed out that they acted to magnify input to the area from any source and to cause a magnified outflow to the organs innervated by that level of the spinal cord. Thermographic studies were also conducted (56,57). Not only did the skeletal muscles respond in an exaggerated fashion in the low-threshold areas but the sympathetic outflow also increased. Such areas of abnormally increased excitability or decreased threshold within the otherwise normal areas of the spinal cord must act to decrease the overall integration of body function. No matter the source of input to a facilitated spinal area, the neural outflow would be exaggerated relative to the same response at other spinal levels. Such a situation lasting over time can have only undesirable consequences for total body function.

Beginning and Maintenance of Reflex Facilitation

The finding that facilitated or low-threshold areas could continue for long periods of time and the fact that these areas were not the same between individuals suggested that some process could occur that would establish these chronically hyperactive areas. Initial speculation suggested that the hyperexcitability was maintained by tonic afferent input. Most input from either somatic or visceral structures, however, decreases dramatically with activities such as sleep or other forms of relaxation. Why should the hyperexcitability continue even with the loss of afferent activity? What is the nature of the neural processing within the reflex pathways to afferent stimuli that might explain the appearance of regions of hyperexcitability? More recent studies have provided some answers that have a bearing on how changes in reflex excitability can at times be an adaptive process and at times a detrimental one.

ALTERATION OF REFLEX EXCITABILITY

The concept of the reflex as a simple, unchanging, static input/output relationship is oversimplified. Although he characterized reflex function as innately given, even Sherrington recognized that reflex excitability could be momentarily altered by influences such as signals from higher brain structures or by rapid and repeated use, which, he noted, caused reflex fatigue. The notion that reflexes are fundamentally unchanging, static input/output relationships is still widespread despite the fact that it is now clear that the excitability of spinal reflex pathways can be altered by many influences. These changes can range from short-lasting, fleeting changes to very long-lasting ones that may even become permanent. These long-lasting alterations may well be the basis for the changes shown by Denslow in his studies of human motoneuron excitability and for the facilitated state hypothesized by Korr. These threats to functional integration of the body may be related to the effects of nociceptive stimuli at the periphery.

ALTERATION OF NOCICEPTIVE INPUT

Inflammation from strong stimulation of the skin or other peripheral somatic or visceral structures produces a set of changes in the

sensory receptors of the organ that dramatically alters the amount of neural activity sent to the spinal cord (58). Most tissues are innervated by various sensory receptors, such as:

- Touch
- Temperature
- Stretch
- Nociceptors

The nociceptors are composed primarily of naked (unmyelinated) nerve endings that respond to potentially tissue-damaging stimuli. In the hollow visceral organs, they respond to stretch or dilation of the organ, for example. These receptors send impulses through thin myelinated (group III or A) or unmyelinated (group IV or C) fibers into the spinal gray matter, where they synapse primarily in Rexed layers I and V. When activity occurs in these pathways, the resulting sensation is usually discomfort or pain, although the input may be blocked (by other neural activity) from reaching the areas of the brainstem where they are appreciated as pain. However, even though a nociceptive input to the spinal cord does not reach the conscious level, it may affect the dynamics of the spinal pathways (59).

Once a stimulus sufficiently strong to activate nociceptive input begins, impulses travel into the spinal cord via the dorsal roots. At the branches of the peripheral neurons, the afferent impulses invade the afferent branches and are conveyed back out to the nerve terminals where they cause release of various peptides into the surrounding tissues. The sites of peptide release may be some distance from the original stimulus. The result of this release is the start of a cascade of events that leads to involvement of the sympathetic postganglionic nerve terminals and to the release of serum from the surrounding capillaries. Prostaglandins released from the sympathetic nerve terminals continue the serum release that leads to local inflammation.

This process begins the healing process, although it may be sufficiently severe that the healing process is retarded (60). The inflammation also produces dramatic changes in the characteristics of the local nociceptors in the area. Schmidt (58) demonstrated in the cat knee joint that the number of nociceptors responding to a stretch stimulation may be between 3,000 and 4,000 after inflammation. In contrast, even severe stretch of the normal joint may cause only 400 nociceptors to fire. Also, the receptive fields of the active nociceptors enlarge dramatically in the inflamed area, and the threshold to activation significantly decreases. The result of an inflammatory process (or a strong stimulus that produces tissue damage) will be to lower nociceptor thresholds and dramatically increase input to the spinal cord. Peripheral events can lead to dramatic changes in the amount of stimuli caused by changes in the peripheral receptors.

What happens to spinal reflex networks when stimulus input changes? In the normal reflex pathway, repeated activation of the pathway by a weak afferent input results in a temporary decrease in the output of the network. Sherrington described this short-term decrease in reflex pathway excitability as reflex fatigue. This process, now termed habituation, has been studied extensively and is a characteristic of polysynaptic reflex pathways in the spinal cord and brainstem.

Habituation is characterized by a decrease in output from a neural pathway that has repeated stimulus input of a mild to moderate intensity. A stimulus may initially produce a response of a certain magnitude, but if the stimulus is repeated several times, the response decreases. If the stimulus is then terminated, the response returns to its initial level in a matter of seconds to minutes (61). The process of habituation is a ubiquitous phenomenon, occurring in almost all animals and in all mammalian reflex pathways except the monosynaptic myotatic reflex. It is a necessary part of the neural integration, because it allows nonessential stimuli to be muted in their effects on the nervous system.

The opposite of habituation is an increase in reflex excitability. Earlier, we described the phenomenon of wind-up, in which a stimulus repeated several times causes an increased number of neural firings. Wind-up has also been called sensitization in earlier studies (Fig. 9.12). In this process, a repetitive stimulus can cause an increase in output rather than a decrease. A stimulus causing habituation can cause sensitization simply by increasing its intensity. This causes more nociceptors to become active, or the same nociceptors to produce more impulses. Like habituation, sensitization can occur within a matter of seconds, and it can also dissipate in a matter of seconds when the stimulus is terminated (61).

Both habituation and sensitization have been extensively studied at the cellular level. In the mammal, both occur within the spinal central gray matter in the interneuron pathways. They are probably subserved by two different sets of interneurons, which then synapse on the motoneurons of both the sympathetic and the somatic systems. Both sensitization and habituation are apparently presynaptic processes that either inhibit (habituation) or enhance (sensitization) the release of neurotransmitter with each activation of the presynaptic terminal (62). They are independent of descending influences from higher nervous centers. Both processes can be demonstrated in humans with spinal cord transections.

Habituation and sensitization are different processes but occur at the synaptic level and can occur over a few seconds of sensory input. Although the process of sensitization may not be a unitary one (because there may be more than one form of sensitization), when the initiating stimulus is terminated, both processes do appear to dissipate in a fairly short time.

Habituation allows the organism to damp the response to nonthreatening stimuli, while sensitization allows the individual to respond more forcefully to a stimulus that is stronger and thus threatens tissue damage. These two processes are valuable in maintaining the organism in its everyday existence. Under normal conditions, the opposing processes of habituation and sensitization function to maintain a balance between overreaction and underreaction to normal stimuli. When the inflammation process occurs, whether it is a minimal or a maximal inflammation, the balances of habituation and sensitization are disrupted. The normal damping effects of habituation are shifted toward the sensitization process. This is caused by the larger and more extreme responses of the peripheral receptors to what would usually be a nonthreatening stimulus. The result is a larger-than-normal motor output to both the visceral and the somatic structures innervated by the affected reflex pathways and, thus, to an overresponse to stimuli. The process disrupts the normal integration of physiologic function.

Once the process of sensitization has begun, often over a few seconds of strong input, a secondary process begins to occur. Sensitization dissipates a few seconds or minutes after the stimulus is gone. A longer-lasting process, termed long-term sensitization, begins to develop in the reflex pathways once sensitization has been in place for several minutes. This process precludes the excitability of the neural pathways from returning to normal for some time, often hours.

The effects of this process can often be seen in laboratory experiments when bursts of stimulation are given followed by an occasional stimulus pulse to test the responsiveness of the reflex system. After initial sensitization and the rapid decrease of reflex excitability after stimulus termination, the response being tracked does not return to its prestimulation baseline but remains a small but significant amount above the base level. This hyperexcitability does not decay for varying amounts of time depending on the time and strength of the stimulus. Unlike sensitization, long-term sensitization is thought to be a postsynaptic event, possibly involving

the elaboration of proteins in the postsynaptic neuron that remain active for some time after the initiating event.

Recently, Mantyh et al. (63) have shown dramatic changes in the substance P receptors and even structural reorganization of the dendrites of spinal interneurons after nociceptive input. These changes could be the basis for long-term sensitization. Long-term sensitization involves a different mechanism than the short-term process does and can have effects that far outlast the originating stimulus.

Once a stimulus has acted on a reflex network for a longer time, the results can be even more dramatic. For many years, a process known as spinal fixation has been known but not fully recognized. First shown in anesthetized animals, spinal fixation was manifest as remaining active leg flexion after 3 to 4 hours of limb flexion secondary to a cerebella lesion. The lesion produced disrupted outflow from the postural centers in the cerebellum, resulting in sustained flexion of a leg. When the spinal cord was sectioned immediately after the lesion, the limb dropped to the usual flaccid paralysis of the animal. However, if the spinal cord was allowed to remain intact for 3 to 4 hours after the lesion and then transected, the limb remained flexed to some extent. The explanation was that the strong outflow from the injured cerebellum caused a hyperexcitability to develop in the target interneurons of the cord that remained active after spinal transection and resulted in continued motor activity.

In the mid-1960s, research showed that the minimal time necessary for the fixation of this excitability was approximately 45 minutes. Animals receiving the spinal transection within 35 minutes showed no remaining flexion, but those having 45 minutes between lesion and transection showed remaining flexion (64). This effect has now been shown to occur not only as a result of a cerebella lesion but also with stimulation of the skin of the hind limb, and it has also been shown to occur in either intact or animals with spinal transection (65–67). The change in the spinal reflexes produced by the cerebella lesion was caused not by pain or nociceptive input but by changes in outflow from the postural centers.

This, along with more recent research, shows that changes in the reflex functions can occur with both nociceptive and nonnociceptive input, although nociceptive input produces the changes more quickly than nonnociceptive input does. Reflex excitability changes can be influenced by many factors, including:

- Stress prior to stimulation
- Length and severity of stimulation
- Whether the spinal cord is intact or sectioned

The changes have been traced for 3 days to 3 weeks after only 45 minutes of fairly intense nociceptive stimulation and may last even longer. With intense stimulus input, the effect is seen after as little as 20 minutes of stimulation (68). Obviously, strong input, especially nociceptive in nature, can have rapid and long-lasting effects on the excitability of reflex circuits. Although the locus of the changes seen in fixation is not yet known, it seems likely that the alterations observed are processes akin to long-term sensitization but which last a much longer time. It appears that the fixation process is also dependent on the elaboration of proteins in the postsynaptic cells and that it would affect the responsiveness of those cells not only to the original input but also to all input to the cell.

Another line of evidence of long-lasting increases in reflex excitability comes from studies of peripheral inflammation that show that there are peripheral effects of inflammation on afferent input and receptive fields. Continued afferent input from peripheral inflammation produces dramatic changes in the responsiveness

of spinal interneurons. Interneurons on which afferent fibers from affected nociceptors synapse begin to respond much more easily to input from a variety of sources, such as touch, pressure, and even the movement of distant muscles. These dramatic changes in excitability also last for long periods (days and weeks) and develop during the initial inflammatory episode (69,70).

Knowing something about the mechanisms of the changes may allow us to restore more normal function. Dubner, Ruda, and Gold (71,72) summarized a series of intracellular changes that are linked to the excitability alterations seen with the inflammation process. The cells activated by nociceptive input from inflamed peripheral structures begin to show enhanced activation of specific parts of the postsynaptic cell membrane called *N*-methyl *D*-aspartate receptors. When these receptors become more active, the excitability of the cell is increased. If cellular activation continues even longer, changes in the activity of genes within the neuron are seen. A class of genes called intermediate-early genes, *c-fos*, and *c-jun*, become more active, causing increased dynorphin release within the cell. Dynorphin is a substance that causes increased cell excitation. With more of it being produced, the cell is then held in a hyperexcitable state. Wolpaw (73) provided strong evidence that excitability increases and decreases can be produced not only by nociceptive input to the spinal circuits, but also by nonnociceptive input. In Wolpaw's studies, both increased and decreased spinal reflex excitability were produced by long-term input that was nonnociceptive. Thus, it is beginning to appear that spinal circuits can be altered rapidly by nociceptive input, and more slowly by nonnociceptive input.

Other studies have begun to show that a fourth type of spinal circuit excitability alteration can occur. With heightened excitability over several days, a process begins to occur in the interneuron cell body that finally destroys the cell. Although both inhibitory and excitatory interneurons should theoretically be affected by this process, it appears that inhibitory interneurons are affected primarily (74). Thus, after the long-term excitability increases of the fixation type are established, continued activation of the pathways may result in the loss of inhibitory interneurons. This is certainly an almost permanent event. However, it is apparently not the end of the story. In some cases where inhibitory interneurons have been lost, there may be new excitatory synapses actually formed to replace the lost inhibitory synapses (75). These two additional processes would further shift the balance of excitation in the spinal cord toward enhanced excitability, perhaps permanently.

We have outlined four steps that have been shown to occur in the spinal cord reflex circuitry to alter the excitability of those pathways:

- Sensitization
- Long-term sensitization
- Fixation
- Loss of inhibitory interneurons/new excitatory synapse formation

These four overlapping and progressive stages in spinal excitability alterations are underlain by different neural processes, ranging from simple synaptic transmission alterations to complex changes in the genetic function of the cell. With increased understanding of the underlying processes involved, it may be possible to find ways to stop or even reverse them and, hence, re-establish normal excitability in an affected region. In addition, the restoration of normal input to an affected spinal area would have an ameliorative effect on the function. However, at present, little is known about how to reverse the effects of these excitability alterations.

These four steps are a progression from short-term to long-term and even permanent alterations of spinal excitability. It seems almost certain that these steps underlie the changes recorded by Denslow et al. (53) and interpreted by Korr (7) as the facilitated segment. They saw these alterations as having widespread and often grave consequences for the patient. Although they had no way to understand the basis of the facilitated segment at that time, they rightly viewed these alterations in function as a real threat to the health and function of the patient. An area of spinal reflex pathways that are either temporarily or permanently in a state of increased excitability would respond to all input in an exaggerated way, with the result that the organs or tissues innervated by those areas of the spinal cord would receive exaggerated neural drive. Thus, the affected tissues, somatic or visceral, would be driven to respond in a fashion that was not in harmony with the rest of the body. Over time, this increased drive on the tissues would be expected to take a toll on the functional ability of the tissues and could result in premature breakdown or loss of normal function.

It is also evident that areas of increased spinal excitability would respond to central commands in an inappropriate way. This could be the reason why some people respond to stress with heart palpitations while others respond with gastric distress. The abnormally excitable area of the cord would be the one to respond with abnormal drive onto the innervated tissues, resulting in clinical manifestations not seen in other tissues. Thus, a clinical problem may be the result of a long-standing facilitated area of the spinal cord.

In addition to spinal circuit changes, it is now becoming apparent that nociceptive input may cause changes in the brainstem and even in the cortical areas that could account for many of the usual symptoms seen with chronic pain. Indeed, there is evidence that in the prefrontal cortex, cortical neurons analogous to the spinal inhibitory interneurons may be destroyed with some types of pain input (76). The probable result of these changes in the brainstem and even cortex that may be analogous to those seen in the spinal cord will be to alter the ability of the system to respond to environmental stress, and may predispose to disease, altered immune function, and depressive states.

Thus, the spinal excitability alterations first seen by Denslow and Korr seem to be underlain by a series of progressively longer-lasting spinal circuit alterations that result in altered outflow to central brain areas and to both somatic and visceral tissues innervated by that area. As noted above, the restoration of normal input to the area from somatic and visceral tissues would almost surely help normalize the function of the affected areas in all but extreme cases. The restoration of normal tissue function by manipulative procedures would be expected to help restore normal function in the spinal circuits. Thus, given an altered reflex network, that area can no longer respond in concert with other networks, producing diminished functional integration, and beginning the loss of health associated with disease.

NONIMPULSE-BASED INTEGRATION

Neurons not only convey impulses throughout the body to integrate function, but there is also a steady stream of material flowing from the neural cell body out the axon and dendrites (anterograde flow) as well as a flow of materials from the periphery of the nerve back to the cell body (retrograde flow). These flows are called axoplasmic flow. Anterograde flow transports materials from where they are manufactured in the cell body down a complex microtubular structure within the axon. Materials to supply rebuilding of

the axon walls, to resupply the transmitter substances, and so forth are carried on this system. The most common clinical effects of the loss of this transport system can be seen when neural contact is withdrawn from an end organ, such as when a muscle is denervated by cutting its motor nerve (a relatively common occurrence). Not only does the muscle cease to contract, but unless the nerve regrows again to contact the muscle, the muscle fibers eventually lose their ability to contract. They change their structure to that of noncontractile connective tissue. Likewise, if an end organ is damaged, its nerve supply often retracts and the synapses are lost. The end organ supplies something to the nerve that allows the synapses to remain viable.

A great deal of study has been done on the uptake of substances supplied by the end organ to nerve terminals. A family of substances known as nerve growth factor (NGF) is essential to continued nerve contact with an end organ and for continued viability of contacts between nerves higher up the chain. If the end organ does not supply NGF, the synaptic contact is lost.

This factor is also essential in development, allowing appropriate nerves to reach and establish contact with the appropriate end organs. Loss of appropriate NGF causes deterioration of the nerve and its contacts. NGF is elaborated in the end organ and taken up by the presynaptic membranes, where it is transported up the axon to the cell body (retrograde transport). There, it regulates the function of the nerve and the nerve's ability to maintain synaptic contacts. Many other substances can be taken up and transported to the cell body, but not all of them are helpful to nerve function. The tetanus toxin, tetanospasmin, is made in peripheral structures after infection by the *Clostridium tetani* bacterium. The toxin is taken up by nerve terminals and transported to the CNS, where it affects neural function, causing the clinical signs of tetanus.

Many common nerve-tracing techniques rely on the ability of the neuron to take up substances and transport them from the periphery of the nerve to the cell body. For example, horseradish peroxidase is used as a nerve tracer by injecting it into the area of nerve terminals, where it is taken into the cell and transported up the axon, eventually filling the cell body and even dendrites. A fixative can then be used to turn the horseradish peroxidase a dark brown-black, providing an easily visualized portrait of the cell. Many other dyes and materials are commonly used in this way to visualize nerve cells.

Although much is known about the NGF family and some other substances and about the actual transport mechanisms within the axon, less is known about the delivery of substances to end organs through transport from cell body to axon (anterograde flow), such as what is delivered to keep a muscle functional. In 1967, Korr et al. (77) published the results of a study that showed that amino acids placed on the cell bodies of the hypoglossal nucleus on the floor of the fourth ventricle were incorporated into the cell body and transported down the axon to the tongue muscle, where they were delivered into the muscle fibers. Later work showed that not only was the material transported but it was also transported at several different rates of flow. That study and others since have shown that flow rates within an axon vary from as slow as 0.5 mm/d to as fast as 400 mm/d. The observed rates are (78):

- Slow (0.52 mm/d)
- Medium (25 mm/d)
- Fast (up to 400 mm/d)
- Very fast (up to 2,000 mm/d)

While his work on transsynaptic flow of proteins was at first not taken seriously, in 1971, Grafstein (79), previously one of Korr's most vocal critics, published data supporting protein transport

across synapses in the optic system. There is currently much data supporting both anterograde and retrograde transport of materials across synapses throughout the nervous system (80–83).

Although much of the anterogradely transported materials are related to support of the neuron and synaptic functions (such as supply of neurotransmitter components), materials delivered by the nerve to its end organ are necessary for either its function or continued existence (84).

Thus, the nervous system is not only the network for rapid communications within the body, but it also serves as a vast network for a far slower two-way communication between the central nervous structures and every part of the body. Disruption of this slow transport of materials has consequences for continued function that may not be immediately evident but that range from subtle to disastrous. Complete withdrawal of NGF or of the materials delivered by the nerve to its end organ may result in loss of function. Disturbance of the flow of materials in either direction results in less than optimal function of the organs involved (85).

Many questions remain about the two-way communication of axoplasmic flow. What substances are being delivered? How necessary are they? What do the materials transported from the periphery to the nerve cell bodies do to the function of the cell or of the entire CNS? Are there crucial times for delivery of nerve factors to end organs for proper development? However these questions are answered, it is important to recognize the vast integrating nature of the nonimpulse-based transport systems of the nervous system and the importance of proper function of this system.

Many things have been shown to affect the material flow within the nerve cells. Even small pressure on axons can impede proper axoplasmic flow. A sustained increased number of impulses carried by the neuron (as in those originating in facilitated areas of the cord) may decrease flow rates. Improper supplies of nutrients and oxygen to the cell body or axon alter the flow. The occurrence of the tissue tensions and fluid flow disturbances often associated with somatic dysfunctions can be factors in altering axoplasmic flows. The somatic dysfunctions treated with the use of manipulation would be expected to have a positive effect on the flow of materials in axons of the area and, hence, to improve body function and integration.

CONCLUSION

In the normal, integrative function of the nervous system, a great number of influences obviously act on any neural pathway. Afferent input activates reflex outflow. Descending activities from higher nervous centers modulate excitability of interneurons. Ascending influences from lower spinal areas increase or decrease activity. Psychological effects are played out on all levels of the neuraxis. The nerves deliver the materials necessary for normal function to their end organs, while the end organs send the substances necessary for continued synaptic viability to the nerves.

These influences come together to determine the moment-to-moment excitability of any area of the CNS and to determine overall outflow to both somatic and visceral structures. If all of these influences are working in harmony, optimally integrated function can be expected from the various organs. If, however, one area is in a hyperexcitable state, the output from that area of the system will not be in harmony with the output of the other areas. In that case, the optimal function is disrupted and the individual becomes increasingly prone to loss of function and disease.

The long-term alterations in spinal reflex excitability (now well demonstrated by various studies) seem almost certain to underlie the alterations demonstrated by Denslow and his colleagues.

These breaks in the normal integration of the nervous system were shown to affect both visceral and somatic structures. The interaction between visceral and somatic input in the spinal cord provides the basis for that common effect. The changes shown in response to nociceptive input can easily account for the long-lasting nature of the facilitation identified in those studies. The facilitation was hypothesized by Korr to be the basis for the somatic dysfunctions long recognized by the osteopathic profession.

Because the neurons involved in the altered excitability are interneurons (the neurons on which a variety of different pathways synapse), the data also support the effects of excitability changes on both somatic and autonomic outflow. The inputs from both visceral and somatic structures end on common interneurons. When the excitability of those interneurons is altered, the outflow to all structures innervated by motoneurons to which those interneurons connect is affected.

The reflex networks of the nervous system are not at all static, genetically determined entities. They are a vast network of highly interconnected pathways that are continually changing to meet local needs and to maintain integration of function. These processes allow the delicate moment-to-moment integration that characterizes optimal functional capacity. The integration, however, can be turned against the very system it serves. When abnormal or very strong input occurs, the result can be a long-term disruption of the normal excitatory/inhibitory balances and a shift to excessive excitability (or in some cases, to excessive inhibition). The result, in either case, is the loss of functional integration and a decrease in functional capacity of the individual.

There are many factors that influence the total function of the individual, including their:

- Accumulated effects of life
- Habits
- Living environment
- Food
- Psychological and spiritual makeup and state

The role of the state of the nervous system is but one of the factors influencing the total health of the person. Because it affects all organs and structures with which it communicates, an area of central excitation or facilitation delivers the effects of all other stressors on the individual to the end organs. In essence, it is the final common factor in communicating with the end organ. Most of the other stressors in life are difficult to change, and the osteopathic physician has little impact on or control over them. However, the physician can directly affect the course of the facilitation and its effects by recognizing that it occurs and by using modalities, especially manipulative treatment, that alter it.

Rational therapy dictates the normalization of afferent input as quickly as possible. In chronic situations, use methods to reduce the abnormal input to allow the body to restore normal balances of excitation and inhibition as fully as possible. In this way, the goal of total osteopathic treatment, to optimize each individual's function and to restore the individual's dynamic functional balance of optimal health, can be brought closer to reality.

Autonomic Nervous System

FRANK H. WILLARD

KEY CONCEPTS

- The two components of the peripheral nervous system are somatic and autonomic.
- The somatic component provides innervation of the skeletal muscle; while the influence of autonomic portion, representing the predominant component, is seen on almost all other tissues in body.
- Organization of the autonomic nervous system is similar to the somatic nervous system, including the following roles: receiving afferent fibers, processing information in central circuits, and forming output to connective tissue cells, smooth muscle cells, secretory cells, and immune cells.
- The distinctive feature of the autonomic nervous system is the two-step output pathway involving centrally located preganglionic neurons and peripherally located ganglionic neurons.
- There are two anatomically, biochemically, and functionally distinct divisions of the peripheral autonomic nervous system: sympathetic and parasympathetic, with dual effects on many organ systems.
- Innervation of the visceral organs occurs through the great autonomic plexus that extends from the base of neck through the thorax, diaphragm, and abdomen and terminates in the pelvis.
- The great autonomic plexus is supplied with parasympathetic fibers from the vagus and pelvic splanchnic nerves and sympathetic fibers from the thoracic, lumbar, and sacral splanchnic nerves.
- The central origin and importance of sympathetic and parasympathetic innervation for organ systems in the head, neck, thorax, abdomen, and pelvis.
- The origin and importance of sympathetic innervation for the peripheral vasculature.
- The primary afferent innervation of organ systems is instrumental in controlling the output of the autonomic nervous system.
- Neuropeptide markers in afferent nerve fibers and small-caliber, primary afferent fibers involved with detection of nociceptive stimuli.

Our daily existence depends on the coordinated activities of our internal organ systems. A major factor in orchestrating the diverse functions of these internal structures is the autonomic nervous system. Through an extensive network of connections, the autonomic nervous system helps maintain the normal rhythm of activity in the visceral organs, adjusting their output to accommodate any external challenge. The limbic structures of the brain control the autonomic nervous system through the hypothalamus. The hypothalamus itself is closely integrated into a complex network involving the endocrine and immune systems. This conglomerate of interlocking systems, with its pervasive influence on our physiology and psychology, is called the neuroendocrine-immune network.

The terminology used to describe the part of the nervous system usually not under voluntary control varies widely. Since the 18th century, different terms have been used by researchers in different countries. None of these terms refers to the exact same group of structures or functions. Examples include:

- Vegitive nervensystem
- Grand symapathique
- Ganglionic nervous system
- Visceral nervous system

The two most commonly used terms are vegetative and autonomic nervous system. For a thorough discussion of the history of terminology concerning this system, see Clarke and Jacyna (1). The present chapter uses the term autonomic nervous system to refer to all components of the nervous system using preganglionic and ganglionic neurons as an efferent pathway. This definition excludes

only the neuromuscular junctions between the ventral horn of the spinal cord (and a few cranial nuclei) and the skeletal muscle.

The clinical importance of understanding the circuits of the autonomic nervous system cannot be overstated. Almost all communication between neurons in these circuits occurs via synaptic transmission. This process depends on the production, distribution, and recognition of specific neurochemicals. Most pharmaceutical agents, either as a desired first action or as an undesired side effect, affect these metabolic and stereologic events. Knowledge of nervous system structure, function, and chemistry is a necessity for the educated use of these substances and the intelligent approach to the maintenance of health.

The autonomic nervous system is sensitive to events occurring in somatic tissue such as cutaneous and musculoskeletal systems. The autonomic and somatic nervous systems are interlocked through numerous somatovisceral and viscerosomatic reflexes. Visceral symptoms may be the primary manifestations of somatic dysfunction and vice versa. This chapter examines the organization of the autonomic nervous system and its afferent component and emphasizes the pattern of innervation reaching the major organs of the thoracoabdominopelvic viscera and the segmental representation of these organs in the spinal cord.

ORGANIZATION OF THE AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system has components in both the central and the peripheral nervous systems (PNS) (Fig. 10.1).

The major autonomic components of the central nervous system (CNS) include:

- Limbic forebrain
- Hypothalamus
- Several brainstem nuclei
- Intermediolateral cell column of the spinal cord

The autonomic components of the PNS include numerous ganglia (collections of neuron cell bodies located outside of the CNS) and a network of fibers distributed to all tissues of the body with the exception of the hyaline cartilages, the centers of the intervertebral disks, and the parenchymal tissues of the CNS. This review focuses on the peripheral distribution of the autonomic nervous system.

Peripheral Nervous Systems

The axons from neurons located in the CNS enter the periphery through spinal and cranial nerves. The peripheral portion of the nervous system can be divided into two fundamental parts based on the target structures of efferent fibers. Axons derived from the somatic component of the PNS innervate skeletal muscle. Axons derived from the autonomic component of the PNS enter the periphery and form complex interwoven plexuses containing clusters of cell bodies called ganglia. Neurons in these ganglia innervate all other targets, including:

- Smooth muscle
- Cardiac muscle
- Glands
- Connective tissue
- Cells in the immune system

This fundamental division in the PNS also reflects differential methods in cellular communication. The mechanism of transmission in the neuromuscular junction of the somatic system involves ionotropic principles (2). This mechanism uses the ion-gated channels to quickly depolarize the cell membrane, a process referred

to as fast transmission. Conversely, chemical signaling in the autonomic PNS uses metabotropic principles and volume transmission (3), the diffusion of transmitter substance away from axonal vesicles, as well as fast synaptic transmission. The metabotropic methods of signaling usually involve a neuromodulator that binds to a membrane receptor, activating second-messenger pathways within the target cell. These methods are also called slow transmission and often lead to altered gene expression. To further understand the distinction between somatic and visceral PNSs, compare the typical neural circuitry present in reflex arcs.

SOMATIC REFLEX ARC

Input and output for the peripheral somatic nervous system occur through spinal and cranial nerves. Figure 10.2 diagrams a typical spinal nerve, illustrating the basic circuitry of the somatic reflex arc. In its simplest form, the reflex arc contains a primary afferent neuron in a ganglion and a centrally located motor neuron connected by a synaptic junction. Because only one synapse separates the input from the output, this circuit is called a monosynaptic reflex. The cell body of the primary sensory neuron is located in the dorsal root ganglia or in the peripheral ganglia of a cranial nerve. The peripheral process of the sensory neuron is directed outward along a spinal or cranial nerve to reach its target in the peripheral tissue. This process either acts as a receptor end organ itself or is attached to one located in skin, muscle, or connective tissue. Each sensory neuron also has a central process (axon) that extends into the dorsal horn of the spinal cord or into the brainstem.

Two fundamental types of primary afferent neurons are present in sensory ganglia. One class of sensory neuron features a large cell body with a myelinated process; this kind of cell forms the A-afferent or large-caliber fiber system and is involved in proprioception or discriminative mechanoreception (4). Conversely, other sensory neurons have small cell bodies, with lightly myelinated or unmyelinated processes. These cells form the B-afferent or small-caliber fiber system and are involved in crude touch and nociception (4) (see Chapters 7 and 8 for additional discussion of this concept).

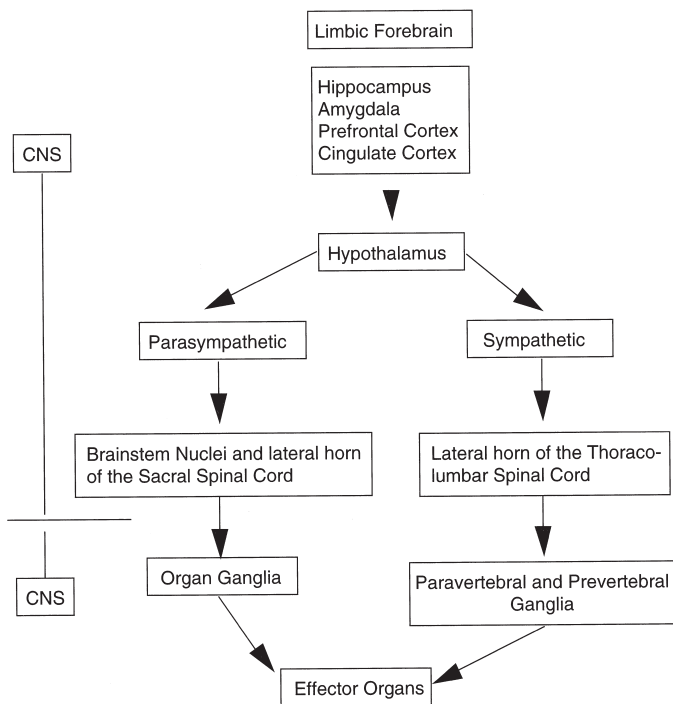

Figure 10-1 General organization of the autonomic nervous system.

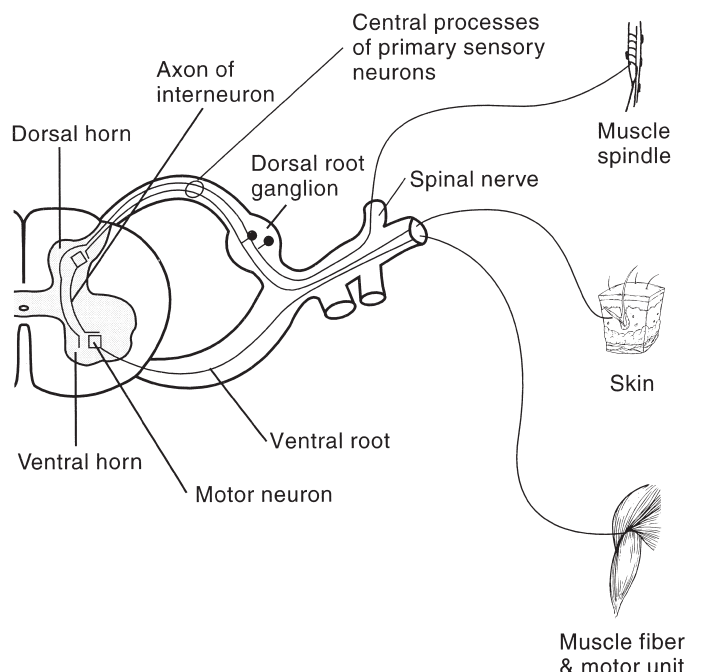

Figure 10-2 Components of somatic reflex arc.

The second component of the monosynaptic reflex arc, the motor neuron, has a cell body in the ventral horn of the spinal cord or a brainstem nucleus. Motor neuron axons leave the CNS in the ventral root of a spinal nerve or in a cranial nerve, eventually innervating its effector organ, skeletal muscle, through a neuromuscular synaptic junction. These monosynaptic reflex connections occur between the largest sensory neurons (the A-afferent system) and ventral horn motor neurons innervating skeletal muscle.

All other somatic reflexes involve the presence of interneurons situated between the central processes of the sensory neuron and the motoneurons; several synaptic connections must be traversed to complete the arc. Such circuits are called disynaptic or polysynaptic reflex arcs. The polysynaptic reflexes involve input from both A-afferent and B-afferent systems. Although the addition of interneurons into the circuit slows the conduction of information through these reflex arcs, it greatly facilitates the construction of more complex circuits and, consequently, more complicated behavior patterns in response to sensory information.

AUTONOMIC REFLEX ARC

Input and output for the peripheral autonomic nervous system occur via spinal, cranial, and splanchnic (visceral) nerves. Figure 10.3

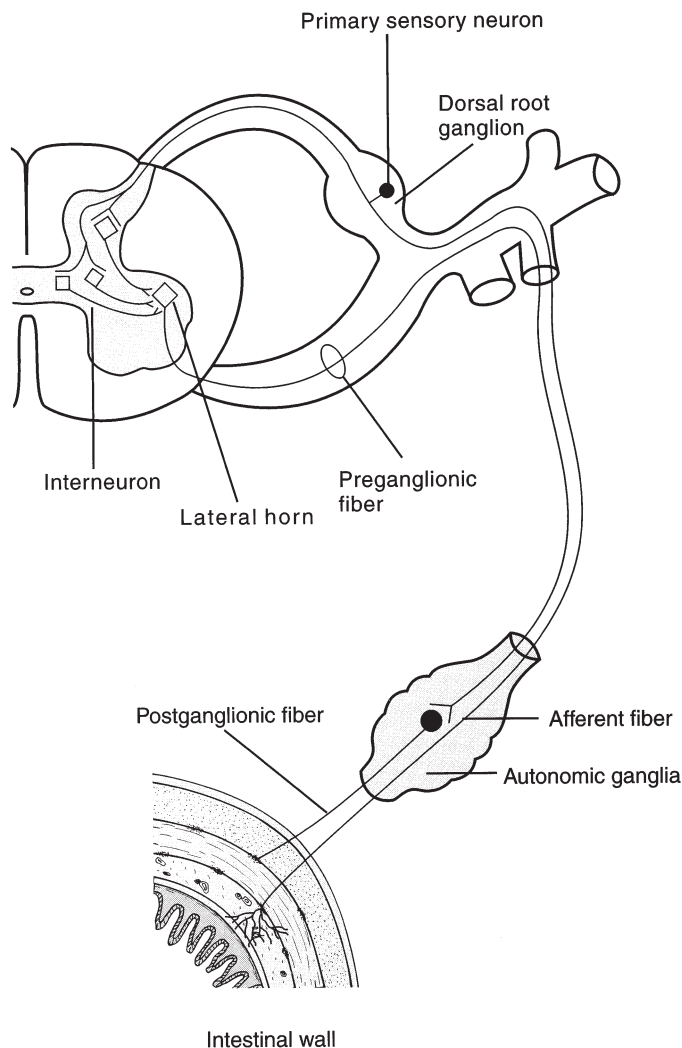

Figure 10-3 Components of visceral reflex arc.

is a diagram of a typical spinal nerve and its connections with a splanchnic nerve. The afferent neuron has a peripheral process ending in a visceral organ or a blood vessel, a cell body located in the dorsal root ganglia, and a central process that terminates in the dorsal horn of spinal cord. This central process terminates on interneurons that, in turn, innervate the effector (motor or pseudomotor) neurons in the gray matter of the spinal cord or brainstem. The effector or preganglionic neurons are found in the lateral horn of the spinal cord or in specific brainstem nuclei; their myelinated preganglionic axons terminate on ganglionic neurons located outside the CNS. These peripheral neurons are found either in encapsulated ganglia in the fascia of the body wall or in ganglia embedded in the fascia surrounding a specific organ. Unmyelinated, postganglionic axons travel from peripheral ganglia to cellular targets in visceral organs. The presence of two sequential neurons in the output pathway is a critical feature distinguishing the autonomic from somatic PNSs. The sensory neurons of these two systems are otherwise very similar in morphology and function.

Ganglionic neurons of the autonomic system are found primarily in three locations (Fig. 10.4):

1. The paravertebral ganglia or sympathetic trunk lying along the side of the spinal cord.
2. The prevertebral ganglia or collateral ganglia scattered in several clusters associated with the large vessels of the abdominal cavity.
3. In isolated ganglia or hypogastric ganglia embedded in the adventitial tissue of specific visceral organs of the pelvis.

These ganglia contain a variety of chemically differentiated neurons producing numerous neuroregulators. The ratio between pre- and postganglionic neurons has been reported to range from 1:2 to 1:196 for sympathetic ganglia and 1:1 to 1:6,000 for parasympathetic ganglia (5). This arrangement of a few central neurons influencing effector organs through a large battery of chemically distinct, postganglionic neurons is divergent in nature. As such, it allows for a limited number of input channels to initiate numerous, complex motor and secretomotor responses.

Many of the peripheral ganglia, especially in the gastrointestinal system, also contain sensory neurons that do not communicate with the CNS; instead, their axons terminate on ganglionic efferent cells (6). Local reflex arcs are established that do not communicate with the CNS. In this respect, the visceral autonomic ganglia act as small brains; in fact, these ganglia can maintain some visceral organ functions even when all communication with the CNS is severed. In such cases, even though the organ responds to changing internal stimuli, it is not able to respond to changes in external stimuli. Autonomic ganglia are capable of managing their specific organ systems in isolation, but rely on input from the CNS for signals concerning the conditions in the external environment.

DIVISIONS OF THE AUTONOMIC NERVOUS SYSTEM

The peripheral autonomic nervous system can be separated into two major divisions based on structure, chemistry, and function: sympathetic and parasympathetic. In general, each organ receives innervation from both divisions, one acting to enhance or accelerate the activity of the organ and the other division acting as an inhibitor or decelerator. The major exception to this rule is the innervation of the peripheral vasculature, hair follicles, and sweat glands of the trunk and extremities. These latter structures are serviced solely by the sympathetic system. However, in this situation,

cholinergic fibers arising in the sympathetic ganglia are involved in at least hair follicle and sweat gland innervation, if not the peripheral vasculature (7). These fibers have been termed the sympathetic cholinergic system. The distribution of the sympathetic nervous system is illustrated in Figure 10.4 and that of the parasympathetic nervous system in Figure 10.5.

A morphologic distinction between sympathetic and parasympathetic systems is seen in the arrangement of their ganglia. In

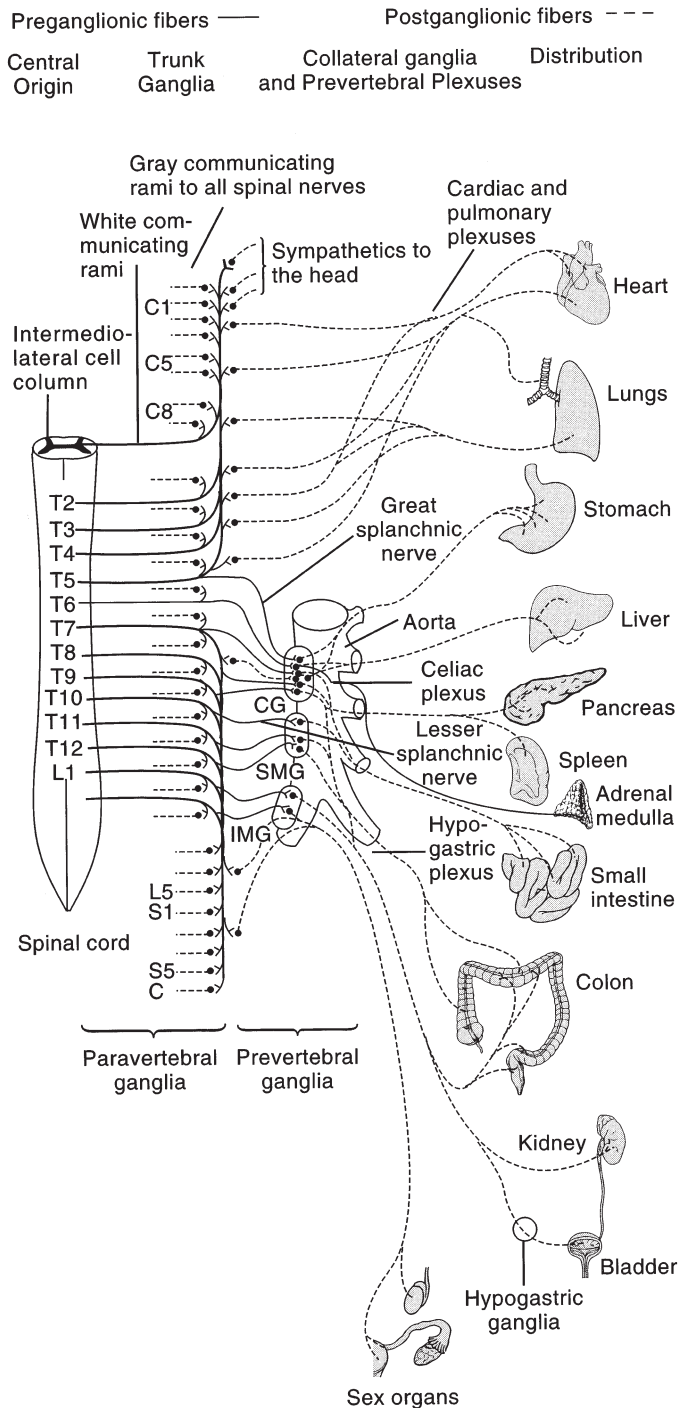

Figure 10-4 Sympathetic division of peripheral autonomic system. CG, celiac ganglion; SMG, superior mesenteric ganglion; IMG, inferior mesenteric ganglion. (From Chusid JG. *Correlative Neuroanatomy and Functional Neurology*. Los Altos, CA: Lange Medical Publishers, 1985, with permission.)

general, the ganglionic neurons of the sympathetic nervous system are located in the paravertebral and prevertebral ganglia with the exception of scattered ganglia found in the hypogastric plexus of the pelvis. Those of the parasympathetic nervous system are found in ganglia located on either cranial nerves or organ walls. The preganglionic axons of the sympathetic system tend to be short, reaching only to the paravertebral and prevertebral ganglia, and the postganglionic axons, which reach to the visceral organs, are longer. The situation is reversed in the parasympathetic system where the preganglionic axons tend to be long (extending all the way to the ganglia in the organ wall) and the postganglionic axons

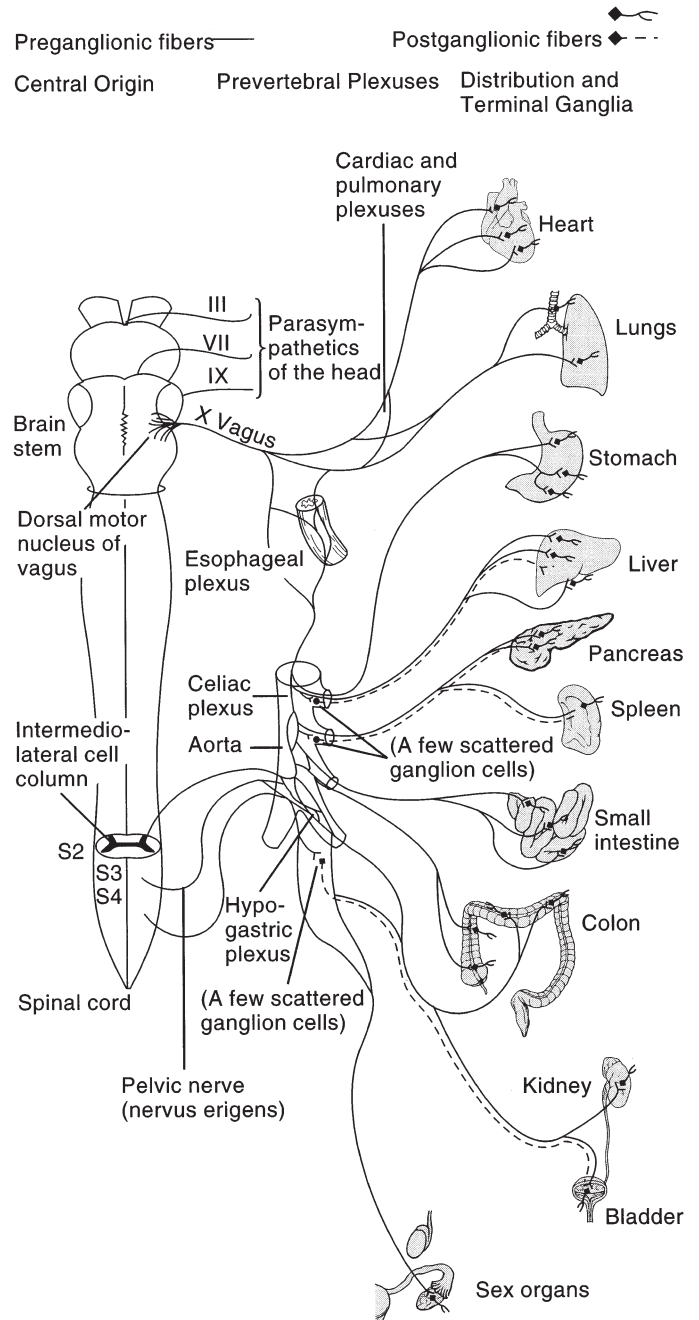

Figure 10-5 Parasympathetic division of peripheral autonomic system. (From Chusid JG. *Correlative Neuroanatomy and Functional Neurology*. Los Altos, CA: Lange Medical Publishers, 1985, with permission.)

tend to be short (confined to a distribution along the organ wall) (Fig. 10.6).

This distinction between the major divisions of the autonomic nervous system is further reflected in their chemistry. The sympathetic system arises from cholinergic preganglionic neurons located in the lateral horn of the thoracic and lumbar spinal cord; it is also called the thoracolumbar system. In general, the postganglionic neurons of the sympathetic system are adrenergic and secrete norepinephrine. However, there are important exceptions. For example, some cholinergic ganglionic neurons contribute to the innervation of the hair follicles and sweat glands as well as possibly innervating the vasculature in skeletal muscle (7). The parasympathetic system arises from cholinergic preganglionic neurons located in either cranial nerve nuclei of the brainstem or the lateral horn of the sacral spinal cord, and it is therefore called the craniosacral system. The postganglionic neurons of the parasympathetic system secrete acetylcholine and a wide variety of other neuron modulators such as the neuropeptides. Given that these two divisions of the autonomic nervous system can be differentiated on the basis of their anatomy and chemistry, it is not surprising that they have differing influences on their target organs.

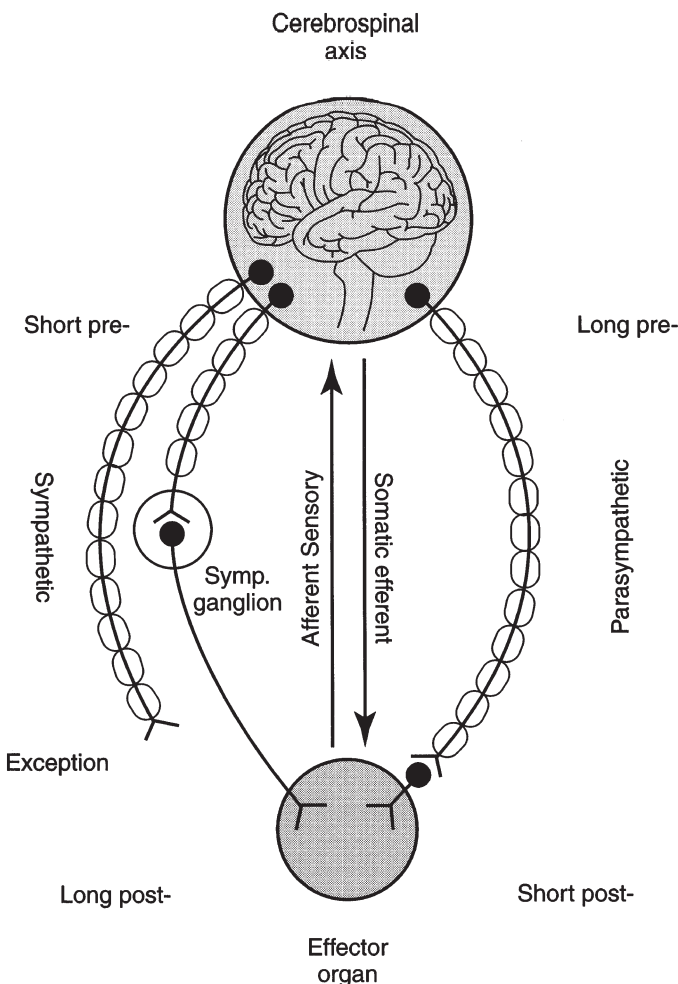

Figure 10-6 Major anatomical differences between sympathetic and parasympathetic divisions of autonomic system. (From Harati Y. Anatomy of the spinal and peripheral autonomic nervous system. In: Low PA, ed. *Clinical Autonomic Disorders*. Boston, MA: Little, Brown and Company, 1993, with permission.)

Sympathetic Autonomic Nervous System

The sympathetic autonomic nervous system has two major components: vascular and visceral. The vascular component is associated with the spinal nerves and innervates:

- Fascia
- Smooth muscle of vasculature
- Smooth muscle of hair follicles
- Secretory cells in the sweat glands of the skin

The visceral component innervates:

- Smooth muscle
- Cardiac muscle
- Nodal tissue
- Glandular organs of the thoracic, abdominal, pelvic, and perineal viscera

Also, portions of the sympathetic visceral system provide an innervation to the neurons of the parasympathetic ganglia in the walls of the visceral organs.

The ganglionic neurons of the sympathetic nervous system are located in two types of ganglia: paravertebral and prevertebral (Fig. 10.4). The paravertebral ganglia form two long chains called the sympathetic trunks, which are located on either side of the vertebral column (Fig. 10.7). Each sympathetic trunk extends from the upper cervical vertebrae along the heads of the ribs in the thorax, on the sides of the lumbar vertebral bodies in the abdomen, and along the ventromedial aspect of the sacroiliac joint in the pelvis. Inferiorly, the two trunks terminate by uniting to form the ganglion impar, a small neural structure on the ventral aspect of the coccygeal vertebrae. The three major prevertebral ganglia are found in clusters, embedded in the abdominal plexuses that surround the anterior branches of the aorta. Additional small clusters of prevertebral ganglia are found scattered in the autonomic plexus of the pelvic basin.

The detailed organization of the sympathetic system is illustrated in Figure 10.4. The following features are critical:

1. All preganglionic cell bodies are located in the lateral horn of spinal cord segments primarily between T1 and L2; however, they can extend as high as C7 and as low as L3. Their axons leave the spinal cord through ventral roots T1-L2 and course along the corresponding spinal nerves to reach white communicating rami (Fig. 10.8). The white rami carry the myelinated, preganglionic fibers from the spinal nerve directly into the paravertebral ganglia. They also carry sensory processes from the vasculature and viscera back to the spinal nerve.
2. The paravertebral ganglia are present on both sides of the spinal cord in the following distribution (8):
 - Three cervical segments (superior, middle, and stellate)
 - Ten to twelve thoracic segments
 - Four lumbar segments
 - At least four or five sacral segments

Often, the upper thoracic and lower cervical ganglia are fused to form the stellate ganglion. Only the ganglia between T1 and L2 receive white rami, because preganglionic fibers arise from only these segments.

3. Neurons in paravertebral ganglia located either above T1 or below L2 receive their innervation from preganglionic fibers arising in spinal segments T1-L2. These preganglionic axons enter the sympathetic trunk at their segmental level of origin and ascend or descend through the trunk to reach ganglia positioned above or below T1-L2.

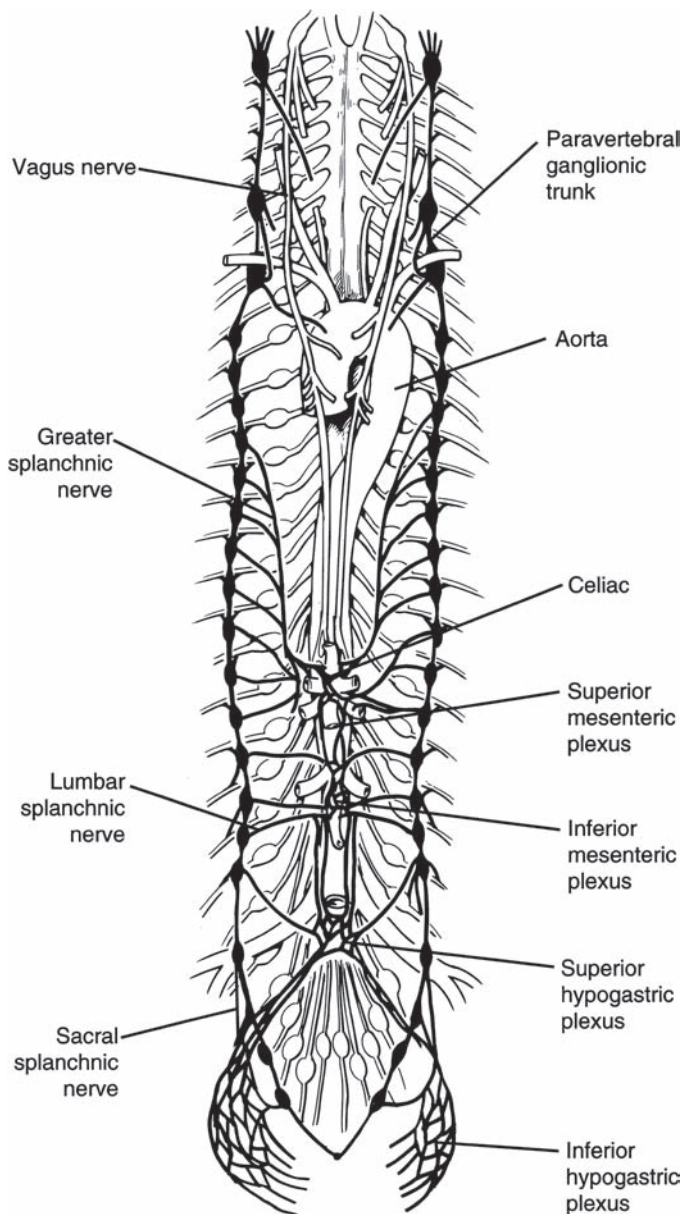

Figure 10-7 Paravertebral ganglia (sympathetic trunk) lying along median axis of body. (From Rohen JW, Yokochi C. *Color Atlas of Anatomy*. New York, NY: Igaku-Shoin Medical Publishers, 1983, with permission.)

4. Ganglionic neurons destined to innervate blood vessels, smooth muscles, and glands of the skin are found in all the paravertebral ganglia. Their postganglionic axons gain access to spinal nerves by passing over gray rami (Fig. 10.8). All paravertebral ganglia give rise to gray rami; each spinal nerve receives at least one gray ramus. The postganglionic axons follow the spinal nerves distally before shifting to assume a position in the fascia along the wall of a blood vessel.
5. Ganglionic neurons with axons innervating thoracic, abdominal, and pelvic viscera are found in the three cervical ganglia, the upper five thoracic paravertebral ganglia, and the prevertebral ganglia. These are the celiac and the superior and inferior mesenteric ganglia, as well as small scattered ganglia in the pelvic plexus. These prevertebral ganglia receive their preganglionic axons through thoracic, lumbar, and sacral splanchnic nerves.

The term splanchnic refers to the viscera; splanchnic nerves are simply visceral nerves. Thoracic, lumbar, and sacral splanchnic nerves carry sympathetic fibers and pelvic splanchnic nerves carry parasympathetic fibers.

The sympathetic ganglia receive information from the CNS through the axons of the preganglionic neurons. A preganglionic axon of the sympathetic system has a number of options after passing through a white ramus between T1 and L2 to enter a paravertebral ganglion:

1. It can innervate a ganglionic neuron in the paravertebral ganglion at its spinal cord level of entry.
2. It can pass either up or down in the sympathetic trunk to innervate ganglionic neurons located at levels not serviced by white rami.
3. It can proceed through the paravertebral ganglia without forming synaptic contacts, join a thoracic, lumbar, or sacral splanchnic nerve, and subsequently innervate neurons in one of the retroperitoneal prevertebral ganglia.

These options are diagrammed in Figure 10.8, which illustrates a typical thoracic spinal segment and its accompanying spinal nerve and paravertebral ganglia. The significance of these innervation patterns is further considered as the innervation of specific organs is examined.

Parasympathetic Autonomic Nervous System

The parasympathetic autonomic nervous system, unlike its sympathetic counterpart, innervates only visceral organs and blood vessels in the:

Head and neck
Thorax
Abdomen
Pelvis

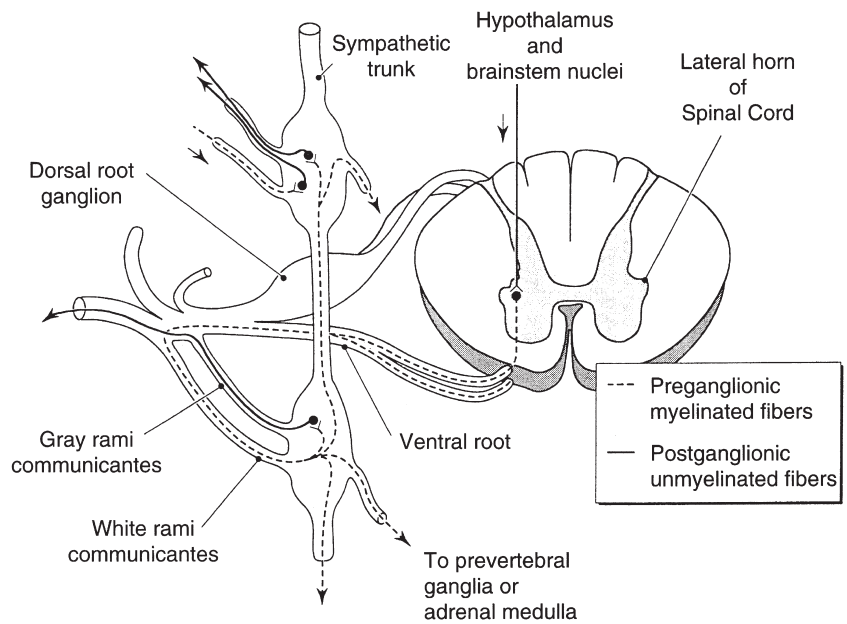

The parasympathetic nervous system lacks a division innervating the peripheral vasculature of the extremities and trunk. It is divided into two portions: cranial and sacral. These are based on the location of its preganglionic neurons (Figs. 10.5 and 10.9). The cranial portion consists of several brainstem nuclei and their preganglionic nerves. Cranial nerves III, VII, and IX give rise to parasympathetic preganglionic fibers that innervate ganglia located in the:

Orbit (ciliary ganglion)
Sphenopalatine fossa (sphenopalatine ganglion)
Inferior temporal fossa (otic ganglion)
Floor of the mouth (submandibular and sublingual ganglia)

Cranial nerve X, the vagus nerve, innervates ganglia in the organs of the cervical, thoracic, and superior portions of the abdominal viscera.

The vagus nerve is a significant source of parasympathetic innervation to the thoracic and upper abdominal viscera. It enters the thoracic cavity along the upper portion of the mediastinal wall and passes posterior to the root of the lung to gain a position on the walls of the esophagus. Vagal branches are given off to the cardiac and pulmonary plexuses and to the esophageal plexus. Through the upper portion of the vagus, the nucleus ambiguus of the medulla contributes innervation to the pharynx, larynx, and skeletal muscle portion of the upper esophagus. Preganglionic vagal fibers from the dorsal motor nucleus of the medulla terminate in ganglia on the walls of each organ beginning in the upper esophagus and extending to the splenic flexure of the colon. From these ganglia,

Figure 10-8 Neuronal circuitry present in typical peripheral thoracic spinal segment. (From Harati Y. Anatomy of the spinal and peripheral autonomic nervous system. In: Low PA, ed. *Clinical Autonomic Disorders*. Boston, MA: Little, Brown and Company, 1993, with permission.)

postganglionic fibers arise and course in and around the smooth muscle layers and glands of the organ. The left and right trunks of the vagus rotate around the esophagus (due to the fetal rotation of the gut), forming the anterior and posterior trunks of the vagus, respectively. At the distal end of the esophagus, these two trunks slip through the esophageal hiatus of the diaphragm riding in the fatty adventitial fascia of the esophageal walls. Although the identity of the vagus nerve is lost as its axons join the celiac plexus, its preganglionic fibers continue in the celiac and superior mesenteric plexus eventually reaching the full extent of these two corresponding neurovascular territories. The vagal preganglionic axons reach only as far inferiorly as the splenic flexure of the colon.

The lower portion of the gastrointestinal tract located distal to the splenic flexure, as well as the pelvic viscera, receives their parasympathetic innervation from the pelvic splanchnic nerves. These latter nerves form the sacral component of the parasympathetic nervous system. The preganglionic neurons are located in the lateral horn of spinal cord segments S2-S4. Their axons exit the spinal cord by traveling in the sacral nerve roots. As these roots pass through the endopelvic fascia, small pelvic splanchnic nerves branch off. These branches quickly join the inferior hypogastric plexus (pelvic plexus), which is also located in the endopelvic fascia. Through this plexus, the preganglionic axons can reach the visceral organs of the pelvic basin such as the urinary bladder, the internal reproductive organs, and the rectum. By ascending along the hypogastric plexus, these axons also enter the inferior mesenteric plexus of the abdomen. From the inferior mesenteric plexus, these preganglionic axons follow the vascular branches of the inferior mesenteric artery to service structures such as the descending and sigmoid colon. The preganglionic axons of the vagus and of the pelvic splanchnic nerves terminate in ganglia located in the walls of the abdominopelvic viscera. Short, postganglionic axons invade the organ to terminate in layers of smooth muscle and in surrounding glands. The pattern of parasympathetic innervation of the visceral organs continues in an uninterrupted manner through the abdominopelvic cavity even though the source of this innervation shifts from cranial origins to sacral origins at the splenic flexure of the large bowel.

The autonomic nervous system provides input to the:

- Vasculature and fascias throughout the body
- Visceral organs of the head and neck
- Visceral organs of the thoracoabdominopelvic cavity
- Spleen
- Thymus
- Bone marrow
- Lymph nodes

The remainder of the chapter focuses on the innervation of the vasculature, fascia, and major organs.

Primary Afferent Fibers

The autonomic nervous system is not strictly an efferent system (9). All nerves containing autonomic efferent axons also carry primary afferent fibers. The principal targets of these primary afferent fibers are the:

- Dorsal horn of the spinal cord from approximately T1-L2 and S2-4
- Solitary nucleus of the vagal complex in the medulla

Although the majority of primary afferent fibers in autonomic nerves are of the small-caliber variety (B-afferent system), a few larger, myelinated fibers are also present (A-afferent system). In general, the input over visceral afferent fibers to the medullary brainstem involves the non-noxious regulation of organ function. Conversely, many of the primary afferent fibers targeting the spinal cord have the characteristics of nociceptive fibers. They produce neuropeptides such as substance-P and calcitonin gene-related polypeptide and respond to nociceptive stimuli. In addition, some are capable of eliciting a neurogenic inflammatory response in the surrounding tissue (10,11). Nociceptive input from these fibers to the spinal cord can facilitate spinal segments. This initiates vasomotor changes and alters the output to somatic musculature (viscerosomatic reflexes) and refers pain to the somatic structures (12,13). (The relationship of the visceral afferent fibers to viscerosomatic reflexes is reviewed elsewhere in this text.)

REGIONAL DISTRIBUTION OF THE AUTONOMIC NERVOUS SYSTEM

Trunk and Limbs

Peripheral Vasculature

The vascular tree is divided into four different types of vessels based on their distinctive functions (14):

1. Conduit vessels comprise the arterial system prior to arterioles.
2. Resistance vessels represent arterioles.
3. Exchange vessels are capillaries.
4. Capacitance vessels consist of veins.

Most aspects of the vascular tree receive an innervation that controls the resistance of these vessels to blood flow (7,14,15). Different types of axons in these vascular nerves can be identified by their neurochemistry. Sensory fibers, coursing in the vascular nerves, typically contain neuropeptides such as substance-P and calcitonin gene-related polypeptide. Efferent axons in the peripheral autonomic nerves can be (14):

Adrenergic
Cholinergic
Histaminergic
Purinergetic

In general, the adrenergic fibers function as constrictors, contracting smooth muscle in the tunica media and increasing the resistance in the peripheral vasculature. These norepinephrine-containing fibers arise from the paravertebral ganglia of the sympathetic nervous system and innervate all vasculature of the body. Cholinergic fibers are much fewer in number in most tissue and are vasodilating in nature. These nerves are of mixed origin, and most often arise from the parasympathetic ganglia innervating the vasculature in the head and neck and the visceral organs of the thorax, abdomen, and pelvis. Cholinergic vasodilator fibers, innervating blood vessels in the extremities, arise in the sympathetic trunk of some mammals; however, the importance of this system in humans is not known (16). Purinergetic and histaminergic axons also mediate relaxation of vascular wall smooth muscle, but their origin and role in vasodilation are not clear (14).

The sympathetic innervation of blood vessels in muscle and skin is accomplished by preganglionic neurons located in the lateral horn of spinal segments T2 through L2-L3. Their axons leave the spinal cord in the ventral roots and pass through white rami to innervate neurons located in the paravertebral ganglia (Fig. 10.8). Vasomotor neurons present in the paravertebral ganglia give rise to axons that leave the ganglia over the gray rami to rejoin the spinal nerves. In this way, they reach the somatic peripheral tissue where they innervate blood vessels, sweat glands, and hair follicles. A topographic map of the vasculature in the body is contained within paravertebral ganglia such that (17,18):

1. The vasomotor fibers to the head and neck come from spinal segments T1-T4. Their axons travel superiorly in the sympathetic trunk to reach the cervical ganglia. Postganglionic axons follow the carotid vascular tree to reach the head and neck. Segments T1-T2 provide innervation for the brain and meninges; T2-T4 provides innervation to the vasculature of the face and neck.
2. The vasomotor fibers to the upper extremity come from spinal segments T5-T7. Their axons course superiorly in the sympathetic trunk to reach the upper thoracic and lower cervical ganglia. Postganglionic axons join the spinal nerves of the brachial plexus to reach the vasculature of the upper extremity.

3. The vasomotor fibers to the lower extremity come from spinal segments T10 through L2-L3. Their axons descend in the sympathetic trunk to reach the lower lumbar and sacral ganglia. Postganglionic axons join the spinal nerves of the lumbosacral plexus to reach the vasculature of the lower extremity.

Sympathetic fibers course along the outer border of the tunica media of the artery and secrete their neuroregulators into the extracellular fluids surrounding the vascular smooth muscle. Most sympathetic fibers release norepinephrine from small swellings along the terminal distribution of the axon. This neuromodulator interacts with its specific receptors on the vascular smooth muscle cell membranes. Both α - and β -adrenergic receptors are present on these plasma membranes (19). Activation of α -adrenoceptors leads to contraction of the smooth muscle cells and vasoconstriction, while activation of the β -adrenoceptors mediates relaxation of the muscle cell, resulting in vasodilatation. In general, the α -adrenoceptors predominate on the smooth muscle of resistance vessels; therefore, adrenergic stimulation yields vasoconstriction in skeletal muscle.

Additional control of skeletal muscle resistance arteries is accomplished through numerous endothelium-derived substances such as the vasodilator nitric oxide or the vasoconstrictors prostacyclin, endothelin, and angiotensin (20). The tone in the vessel wall is the product of a complex interaction of these vasoactive substances (21). Neurally mediated, active vasodilation of cutaneous capillary bed is well established in the literature (16). Sympathetic cholinergic fibers do not appear to innervate the cutaneous vascular tree; instead, a nonadrenergic, noncholinergic vasodilatory mechanism exists for these vessels (22). Neurally mediated, active vasodilation of skeletal muscle vascular beds appears to be doubtful and has recently been questioned (16).

Along with the efferent innervation of the vascular tree, afferent or sensory fibers also course in the walls of the blood vessels. Little is known of the sensory feedback to the spinal cord provided by these fibers. The nomenclature of these afferent fibers is confusing because it is not clear whether they are somatic or visceral afferent fibers. Jinkins et al. (23) have termed the vascular afferent fibers found in somatic tissue somatosympathetic fibers because they course through somatic tissue but are related to the autonomic nervous system. However, because these afferent fibers are generally small caliber and contain an array of neuropeptides such as substance-P, much of the information they carry is most likely related to nociceptive stimuli. The normal, baseline release of neuropeptides such as substance-P from these fibers may play an important role in maintaining vascular tone (24). Thus, the small-caliber, primary afferent fibers appear to have additional homeostatic functions in the peripheral tissue beyond that of nociception.

When irritated, some of these small-caliber, sensory axons can secrete quantities of substance-P (a proinflammatory, vasodilatory neuropeptide) into the surrounding tissue. This release of an inflammatory agent from a peripheral nerve terminal is involved in initiating the processes of neurogenic inflammation and edema (25). Neurogenic inflammation is a critical component in inflammatory joint disease, which suggests an important role for the small-caliber, primary afferent fibers in these diseases (26).

An interaction between sensory axons and sympathetic neurons appears to occur in the peripheral tissues. Sympathetic adrenergic terminals often end in close association with the peripheral processes of sensory neurons. Secretion of norepinephrine can increase the levels of prostaglandins E_2 and I_2 in the tissue (27). Prostaglandins are irritating to many small-caliber, primary afferent fibers. Sufficient sympathetic discharge therefore can result in a nociceptive input to the spinal cord. In addition, evidence strongly suggests

that small-caliber, primary afferent fibers can become sensitized to sympathetic nervous system activity (27). This interaction between sympathetic efferent axons and primary afferent neurons is a possible mechanism for sympathetically dependent hyperalgesia such as that present in reflex sympathetic dystrophy (28).

Sweat Glands and Connective Tissue

Along with innervating the vasculature, the peripheral autonomic fibers also provide an innervation to sweat glands and fascia. Sweat glands receive an exclusively cholinergic innervation from the sympathetic trunk ganglia; these fibers are termed the sympathetic cholinergic system (15). The cholinergic fibers stimulate secretory activity in the gland.

Small-caliber, neuropeptide-containing, primary afferent fibers innervate all forms of connective tissue. These fibers often course in close association with adrenergic sympathetic axons and blood vessels. A close relationship between these fibers and the connective tissue components of the fascia is seen in such tissue as the:

- Cranial dura (29,30)
- Gastrointestinal tract (31)
- Synovium of diarthrodial joints (32)

In several locations, such as joints, these fibers have been demonstrated to play a role in modulating the cellular components (mast cells) of the connective tissue and to contribute to the maintenance of tissue integrity (32,33). Finally, the interaction of these two fiber types appears to play an important role in the maintenance of normal vascular tone in connective tissue (24).

Head and Neck

The autonomic innervation of the head and neck arises from two general sources: sympathetic and parasympathetic. The sympathetic innervation originates in the intermediolateral nucleus of the upper thoracic segments (T1-T4) of the spinal cord, and their ganglionic neurons are located in the cervical sympathetic ganglia of the neck. Postganglionic fibers from the superior cervical ganglion enter the head following the course of the carotid and vertebral arteries and the jugular vein. The parasympathetic innervation originates from several nuclei in the brainstem, and the ganglionic neurons are located in these ganglia (Fig. 10.9):

- Ciliary sphenopalatine
- Otic
- Geniculate

Recently, additional parasympathetic ganglia located on the walls of the internal carotid artery have been described (34–36). The autonomic innervation of the cranial viscera, the function of these nerves, and the neurology of their dysfunction are amply described elsewhere (17,37–40).

The third cranial nerve contains parasympathetic axons that arise in the Edinger-Westphal nucleus of the midbrain and innervate the ciliary ganglion of the eye (Fig. 10.9). These axons are responsible for constricting the pupil through the pupillary sphincter muscles and contracting the ciliary body to thicken the lens in the accommodation reflex. The facial (VII) cranial nerve carries parasympathetic preganglionic axons from the superior salivatory and lacrimal nuclei in the pontine region of the brainstem. These secretomotor and vasomotor axons course along the superficial petrosal nerve to reach the sphenopalatine ganglion. Postganglionic axons follow branches of the trigeminal nerve to reach the lacrimal gland and mucosal glands of the nasal and oral cavities. Preganglionic axons from the superior salivatory nucleus also follow

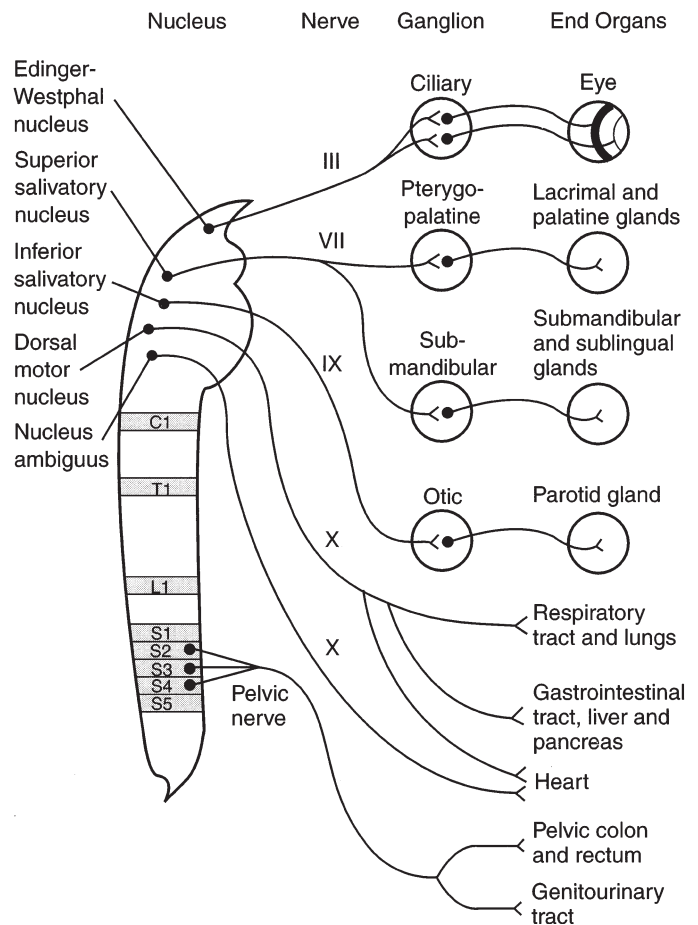

Figure 10-9 Summary of parasympathetic nervous system emphasizing distribution of cranial nerves III, VII, IX, and X. (From Barron KD, Chokroverty S. *Anatomy of the autonomic nervous system: brain and brainstem*. In: Low PA, ed. *Clinical Autonomic Disorders*. Boston, MA: Little, Brown and Company, 1993, with permission.)

the chorda tympani, a branch of the facial nerve, to reach the submandibular and sublingual ganglia. Postganglionic axons from these ganglia supply the salivary glands on the floor of the mouth. The glossopharyngeal nerve carries secretomotor and vasomotor axons from the inferior salivatory nucleus located at the pontomedullary border to the otic ganglion. These latter axons pass over the lesser petrosal nerve. Postganglionic axons from the otic ganglion extend to the parotid gland over branches of the third division of the trigeminal nerve.

Cranial nerve X, the vagus, is the largest of the parasympathetic nerves. It supplies preganglionic parasympathetic innervation of the viscera in the thorax and abdomen to the level of the splenic flexure in the transverse colon. Efferent vagal axons arise in the dorsal motor nucleus and nucleus ambiguus of the medulla. The vagus is largely a sensory nerve; afferent fibers outnumber efferent fibers in the mammalian vagus by more than 10:1 (41). These sensory fibers include the afferent innervation of the thoracoabdominal viscera and the general sensory innervation of the:

- Pharynx
- Larynx
- Skin of the ear
- External auditory meatus
- External surface of the tympanic membrane

The cell bodies for these afferent fibers are located in the two nuclei of the vagus: the superior (jugular) ganglion and the inferior ganglion. Their central brainstem targets include the nucleus solitarius, nucleus ambiguus, and spinal trigeminal nucleus.

An area of much recent interest is the autonomic innervation of the vascular and dural systems in the head. Preganglionic sympathetic input to the cranial vasculature and dura arises in the upper thoracic spinal segments. Those controlling the vasculature of the brain and meninges are located in segments T1-2, and those involved with the vasculature of the face and neck are located in T2-T4 (17). Ganglionic neurons are located in the superior cervical sympathetic ganglion and in small ganglia embedded in the fibers of the internal carotid nerve (18). Their axons course along the carotid arteries; those going to the cerebral vessels and dura form the well-developed internal carotid nerve. Within the dura, the adrenergic fibers diverge away from the vasculature to form a dense plexus within the connective tissue substrate of the dura itself (30). The extensive autonomic innervation may play a role in regulating the metabolic activity of the dural tissue. The sympathetic innervation of the dura and associated vasculature is of interest due to its proposed role in the cause of migraine headache (42).

Parasympathetic axons innervating the cerebral vasculature arise in these ganglia: sphenopalatine, otic, and internal carotid (36,43-45). Axons from the ganglia contain acetylcholine and neuropeptides such as vasoactive intestinal polypeptide and neuropeptide-Y, among others (35,46). The axons form a delicate plexus wrapped around cerebral arteries as they travel through the subarachnoid space. Primary afferent fibers containing neuropeptides such as substance-P and calcitonin gene-related polypeptide are also present in the plexus surrounding the cerebral vessels. These fibers arise in the ophthalmic and maxillary divisions of the trigeminal ganglion (47) and constitute the "trigeminovascular system" (48). Similar primary afferent fibers containing substance-P and calcitonin gene-related polypeptide have been described in the dura mater (30). Some of these fibers form free endings and are postulated to have trophic relationships with the connective tissue cells in the dura such as the fibroblast and mast cells. Release of these proinflammatory peptides has been indicated in the pathogenesis of certain inflammatory headaches such as the migraine and cluster varieties (49,50).

Thorax

A large autonomic plexus of fibers extends from the superior mediastinum inferiorly through the posterior mediastinum and continues into the abdominopelvic cavity, using the esophageal hiatus of the diaphragm as a conduit (Fig. 10.10). In total, this complex arrangement of fibers is best termed the thoracic plexus, although it has several regionally named components. The thoracic plexus is derived from the vagus nerve and its branches and from splanchnic branches from the paravertebral ganglia. The thoracic plexus is located near the midline and divided approximately into two parts: superior and inferior. Superiorly, this complex arrangement of fibers contains the interwoven cardiac and pulmonary plexuses that are distributed around the great vessels of the heart and the large airways. Inferiorly, it contains the esophageal plexus wrapped around the esophagus as it courses through the posterior mediastinum. Figure 10.11 is a schematic diagram illustrating the thoracic plexus. Branches from this autonomic plexus in the thorax supply the following with afferent and efferent nerves:

- Heart
- Trachea

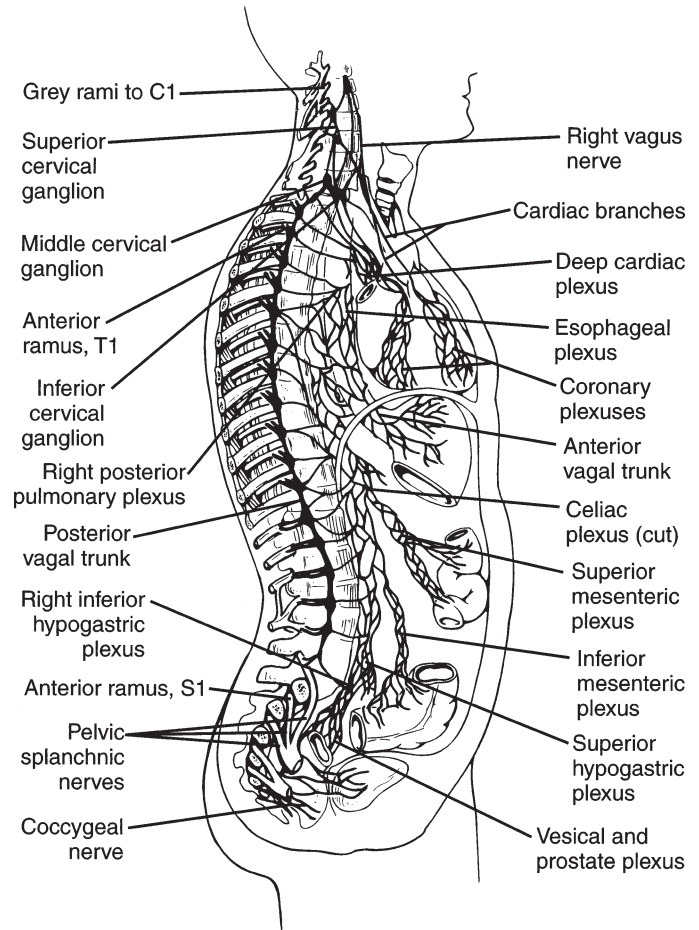

Figure 10-10 Great autonomic plexus extending from the lower cervical region through the thorax and abdomen to reach the pelvis. (From Bannister LH, Bery MM, Collins P, et al., eds. *Gray's Anatomy*. New York, NY: Churchill Livingstone, 1995, with permission.)

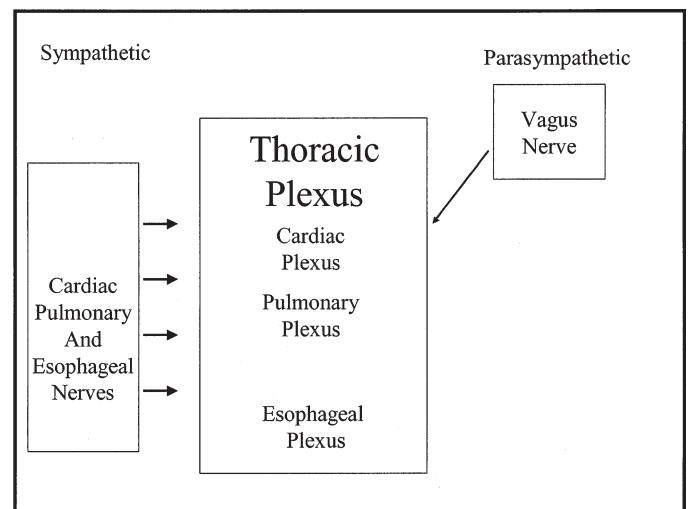

Figure 10-11 A schematic diagram illustrating the thoracic plexus and its associated systems. The thoracic, cardiac, pulmonary, and esophageal nerves are a source of sympathetic postganglionic fibers into the plexus. The vagus nerve is a source of parasympathetic preganglionic fibers to the plexus. Organ ganglia for the parasympathetic system will be found within the parts of the thoracic plexus.

- Bronchi
- Lungs
- Esophagus
- Thoracic duct

Sympathetic innervation of the thoracic viscera arises in spinal cord segments T1 through T5 or T6. Axons from these preganglionic neurons synapse with ganglionic neurons in the superior, middle, and inferior cervical ganglia as well as in the sympathetic trunk ganglia T1 to T5-T6. Sympathetic postganglionic axons from these paravertebral ganglia join the thoracic plexus via a series of small, delicate cardiac, pulmonary, and esophageal nerves. Within the thoracic plexus, sympathetic cardiac and pulmonary nerves descend through the superior mediastinum joining with similarly named parasympathetic branches from the vagus and recurrent laryngeal nerves. They form the complex cardiopulmonary plexus of fibers surrounding the great vessels of the heart (Fig. 10.12) and the vasculature and airway structures of the lungs (Fig. 10.13). The individual superior, middle, and inferior cardiac nerves of the sympathetic trunk and vagus are extremely inconsistent in actual form (51). The esophageal sympathetic nerves arise from the thoracic paravertebral ganglia and course diagonally downward across the thoracic vertebral bodies to reach the adventitial fascia surrounding the esophagus in the posterior mediastinum. Here, they join with the main trunks of the vagus nerve (parasympathetic) to form the esophageal plexus.

The mixing of parasympathetic and sympathetic axons begins in the most superior aspect of the thoracic autonomic plexus as it

extends upward into the cervical region. Scattered communicating branches unite the vagus and recurrent laryngeal nerves with the sympathetic trunk. Therefore, even at the most superior aspect of the plexus, there are no pure sympathetic or parasympathetic nerves. Also, all fibers in the plexus contain a mixture of afferent and efferent axons, so the plexus cannot be considered a purely efferent structure either.

Cardiovascular Plexus

The cardiac plexus represents a region of the thoracic plexus closely related to the innervation of the heart. The cardiac plexus consists of a mixture of sympathetic and parasympathetic fibers (as well as afferent fibers) woven around the great vessels of the heart (Fig. 10.12). Sympathetic input to the cardiac plexus arises from preganglionic neurons located in the nucleus intermediolateralis of the lateral horn of the spinal cord extending from segments T1 to T5. This column of spinal cord neurons contains a topographic map of the heart. The ventricular innervation is represented in the higher thoracic segments, but the atrial representation is found in the lower segments (52). This inverted cardiac map results from the embryologic origin of the heart; the ventricular system forms superior to the atrial system (53). The preganglionic axons of the spinal cord neurons enter the sympathetic trunk by passing over white rami in the upper thoracic segments. Once in the trunk, most of these fibers ascend to reach their ganglionic neurons located primarily in the two to three cervical ganglia. Variable numbers of cervical and thoracic sympathetic cardiac nerves leave the cervical and upper thoracic ganglia, course through the fascia of the mediastinum, and join the cardiac branches of the vagus to form the cardiac plexus. This plexus is primarily located on the walls of the pulmonary arterial tree (54).

The parasympathetic input to the cardiac plexus arises from preganglionic neurons in the dorsal motor nucleus of the vagus and the nucleus ambiguus of the medulla (55,56). These preganglionic axons leave the vagus nerve over its variable (one to three) cardiac branches beginning in the neck and extending into the superior mediastinum. The axons target a parasympathetic ganglion embedded in the cardiac plexuses, termed Wristberg ganglion. Short cholinergic axons from these ganglia reach the sinoatrial (SA) and atrioventricular (AV) nodes and course in the myocardium of the ventricles. The parasympathetic innervation of the ventricular wall is much less dense than that of the sympathetic fibers (57).

From the cardiac plexus, sympathetic adrenergic and parasympathetic cholinergic, postganglionic axons form a rich network of fibers distributed along the coronary vasculature, coursing throughout the myocardium of the atria and ventricles, and reaching the SA and AV nodes (57). The innervation of the intrinsic nodal system of the heart is bilaterally asymmetric; the right side of the plexus favors the SA node but the left side of the plexus tends to target the AV node. Thus, stimulation of the sympathetic fibers on the left side accelerates cardiac output but is arrhythmogenic because it is directed to the AV node (58). A similar reaction is obtained by cooling the right sympathetic fibers, indicating that cardiac activity is influenced by the balance of activity between the two sympathetic inputs (58). Stimulation of the parasympathetic vagal fibers tends to stabilize heart rate. It appears that the balance of tonic neural activity occurring in the vagus and sympathetic systems influences, in part, heart rate and volume output.

Cardiac afferent nerves are an important consideration in understanding reflex control of the heart, patterns of referred cardiac

pain, and patterns of cardiac-facilitated segments. Small-caliber, primary afferent fibers are distributed throughout the (59–61):

- Myocardium
- Coronary vasculature
- Roots of its great vessel
- Parietal pericardium

There are at least two different pathways for these cardiac sensory fibers. Those coursing with the sympathetic nerves have their cell bodies located in dorsal root ganglia extending from C6 to T7, and their central processes terminate in the dorsal horn of the spinal cord (62,63). Sensory axons coursing with the parasympathetic nerves have cell bodies located in the nodose ganglion of the vagus nerve and central processes that terminate in the solitary nucleus of the medulla. In addition to the autonomic nerves supplying an afferent innervation of the pericardium, afferent fibers reach this structure over the phrenic nerve as well. These phrenic afferent fibers enter the spinal cord over segments C3–C5.

Along with the dual origin of sensory nerves, there is a differential distribution of these two sensory pathways in the cardiovascular system. The afferent fibers of the vagus nerve terminate in the (61):

- Ascending aorta
- Aortic arch
- Pulmonary trunk

- Arterial walls
- Atrial walls
- Atrioventricular valve
- Ventricular walls

The afferent fibers from the sympathetic nerves reach the (60):

- Atrial walls
- Pulmonary arteries
- Atrioventricular and aortic valves
- Parietal peritoneum

Afferent fibers from both systems reach the coronary arteries. Those from the vagus extend to a more distal level of the vasculature closer to the apex of the heart than do afferent fibers associated with the sympathetic nervous system. Both A δ - and C-afferent fibers are present in the heart (64). Many of these fibers contain neuropeptides such as substance-P or calcitonin gene-related polypeptide that are typical of small-caliber, primary afferent fibers. At least one population of these cardiac C-fibers has the physiologic properties of nociceptive axons.

In general, the afferent fibers coursing with the sympathetic nerves are involved with cardiac nociception, and those following the parasympathetic nerves are mainly involved in reflexogenic regulation of heart functions through their brainstem connection (62). Section of the sympathetic nerves to the heart can relieve cardiac pain in the chest, arms, and neck (65). These cardiac afferent fibers

enter the spinal cord over a range of segments from C6 to T7, but the influence of these nerves can extend at least two segments below T7 (66). The signs of segmental facilitation due to cardiac disease can present in the vicinity of the cervicothoracic junction and extend downward through at least T9 (67). Importantly, the nociceptive afferent fibers reaching the dorsal horn of the spinal cord influence neurons with concomitant somatic receptive fields. This viscerosomatic convergence of nociceptive information provides an explanation for the referral of pain from cardiac structures to the body wall and extremity (68).

Respiratory Plexus

The airways of the respiratory system receive their innervation through the large pulmonary plexus that surrounds the pulmonary artery and extends onto the posterior surface of the trachea and bronchi (Fig. 10.13). Sympathetic preganglionic neurons that contribute to this plexus are located in the lateral horn of spinal segments T2-T7, and their ganglionic neurons are located in the cervical and first four thoracic ganglia. Postganglionic axons from these ganglia course through cardiac and esophageal nerves from the sympathetic trunk to reach the pulmonary plexus. These adrenergic axons primarily target the glandular tissue surrounding the bronchi and bronchioles; little direct adrenergic innervation of the bronchial musculature has been noted. β -adrenergic receptors are present on the glandular cells and on bronchial smooth muscle cells. Stimulation of the β -adrenergic, sympathetic nervous system leads to bronchial dilation and the release of a more viscous secretion (69).

The vagus nerve is the source of parasympathetic innervation for the respiratory airways. After entering the thorax, the vagus shifts posteriorly in the mediastinum to pass behind the root of the lung. Anterior and posterior pulmonary branches are given off that contribute to the pulmonary plexus. Parasympathetic ganglia located in the walls of the airways receive preganglionic fibers from these vagal branches. Postganglionic parasympathetic fibers course in the arteriobronchial tree to terminate around bronchial smooth musculature, mucosal glands, and blood vessels. Stimulation of these cholinergic fibers causes (69):

- Bronchoconstriction
- Hypersecretion of a serous secretion
- Vasodilation

The pulmonary plexus and ganglia contain intrinsic neurons, i.e., cells whose processes remain in the peripheral tissue and do not innervate the CNS. Such cells are called interneurons. Some of these cells produce a variety of neuropeptides, among which is vasoactive intestinal polypeptide, a potent bronchodilator (70). In addition, several neuropeptides corelease with norepinephrine from sympathetic terminals and with acetylcholine from parasympathetic terminals. These ubiquitous neuropeptides have recently gained considerable interest due to their role in controlling the diameter of the bronchial lumen and the initiation of bronchial wall inflammation (71).

Small-caliber, primary afferent fibers are also present in the pulmonary plexus. These fibers provide sensory information to the brainstem via the vagus and to the spinal cord via the sympathetic trunk. This information is involved in reflex arcs related to:

- Sneezing
- Coughing
- Bronchospasms
- Pulmonary congestion

Many of these fibers, and particularly the smallest of them, contain neuropeptides such as substance-P and calcitonin gene-related polypeptide, among others. Irritation of these sensory fibers results in the release of proinflammatory substances, leading to neurogenic edema and inflammation in the lung. Substance-P, released from these sensory axons into the pulmonary parenchyma, is a potent bronchoconstrictor, vasodilator, and secretagogue (72).

Activation of these primary afferent nociceptors can also facilitate segments in the spinal cord extending from the cervical region into the low thoracic cord (67). The extended range of activation most likely relates to the wide distribution of the central processes of these primary afferent fibers. Changes in spinal cord activity are seen in response to pulmonary afferent stimulation. Electrical stimulation of inflamed tracheobronchial mucosa produces a decrease in electrical skin resistance in the T2-5 dermatomes followed by cutaneous hyperalgesia hours later (65). Unlike the heart, pain from the lungs and bronchial tree is carried in the vagal fibers as well as in the spinal afferent fibers. Lung tumors can refer pain to the skin around the ear (73), which is a region of the head innervated by small cutaneous branches of the vagus nerve. Electrical stimulation of the laryngeal and tracheal mucosa refers pain to the neck, and similar irritation of the bronchial tree refers pain to the anterior chest wall. Section of the vagus nerve below the recurrent laryngeal branch ameliorates the pain (74), suggesting that the nerve is the conduit for this referred pain.

The costal parietal pleura receive an afferent innervation derived from the intercostal nerves of the thorax. The mediastinal pleura are innervated by sensory fibers from the phrenic nerve, and diaphragmatic pleura is innervated by twigs from the intercostal nerves (65). The parietal plural membrane is sensitive to noxious stimuli. The visceral pleura in the lungs receive sympathetic and sensory fibers from the autonomic plexuses surrounding the bronchi, but is insensitive to pain (65).

Esophageal Plexus

The esophagus extends from an upper sphincter region located at the inferior border of the pharynx to a lower sphincter region located at the border of the stomach. Along its route, the body of the esophagus is lodged in the loose connective tissues of the superior and posterior mediastinum.

The upper esophageal sphincter is mainly derived from the cricopharyngeus and thyropharyngeus muscles (together they compose the inferior pharyngeal constrictor), which receive their innervation from the pharyngeal plexus composed of the superior laryngeal and pharyngeal branches of the vagus nerve (75). The body of the esophagus is surrounded by a plexus of autonomic nerves derived from the inferior laryngeal branch of the vagus and esophageal branches of the sympathetic trunk (76). The superior portion of the esophagus is a mixture of skeletal and smooth muscle, although the lower portion is composed of smooth muscle only. The preganglionic parasympathetic innervation to the superior portion of the esophagus (skeletal muscle portion) is derived from the nucleus ambiguus. The smooth muscle of the esophagus is derived primarily from the dorsal motor nucleus of the vagus nerve (77). The left and right vagal trunks approach the esophagus at the root of the lung and form an elaborate plexus, which follows this structure through the esophageal hiatus in the diaphragm. The postganglionic parasympathetic neurons are contained in two intrinsic ganglia in the walls of the esophagus: Auerbach's, or the myenteric plexus; and Meissner's, or the submucosal plexus. Sympathetic preganglionic neurons are located in

the intermediolateral nucleus of spinal cord segments ranging from T2 to T8 (78):

Cervical esophageal portion T2-T4
 Thoracic esophageal portion T3-T6
 Abdominal portion T5-T8

The preganglionic axons synapse in the cervical and upper thoracic sympathetic ganglia. Small esophageal branches, derived from the cervical to fourth and fifth thoracic ganglia and carrying postganglionic sympathetic fibers, join the vagal plexus along the walls of the esophagus (78).

At rest, the cricopharyngeus and thyropharyngeus muscles maintain a tonic contraction driven by the vagal fibers from the nucleus ambiguus (75). During swallowing, the tonic vagal drive is inhibited and the upper esophageal sphincter relaxes. Peristalsis in the upper portion (skeletal muscle portion) of the esophagus is driven by the nucleus ambiguus of the vagus nerve (75), although that in the body and lower portion of the esophagus is driven by the dorsal motor nucleus of the vagus. The relaxation of the lower esophageal sphincter is accomplished by the nitrergic neurons in Aurbach's plexus driven by the dorsal motor nucleus of the vagus nerve (79).

Afferent fibers from the esophageal walls follow the vagus nerve back to the solitary nucleus of the medulla. They also follow the sympathetic fibers back to the dorsal horn of the upper segment of the spinal cord (80). Vagal afferent fibers ending in the solitary nucleus of the medulla contribute to a viscerovisceral reflex arc by synapsing on premotor neurons of the nucleus ambiguus and preganglionic neurons of the dorsal motor nucleus of the vagus nerve (75). The premotor neurons subsequently innervate the motor neurons of the nucleus ambiguus. The premotor neurons form the central pattern generator for organized movements of the esophagus such as swallowing (79). The spinal afferent fibers from the esophagus contribute to the referral of pain. These afferent fibers innervate spinal segments that also receive afferent information from the:

Heart
 Pulmonary tree
 Chest
 Upper back and torso

Esophageal pain can refer substernally (heartburn) or posteriorly through the back into the area of the scapula (81). Referred pain from the esophagus has numerous patterns, the more common of which are gripping, pressing, boring, or stabbing (82).

Aortic Plexus

The thoracic aorta has an intimate relationship with both divisions of the autonomic nervous system. Sympathetic input and sensory fibers reach the superior thoracic aorta through cardiac and pulmonary nerves as well as by following direct branches from the sympathetic trunk. The inferior thoracic aorta receives branches of the thoracic splanchnic nerves. The preganglionic sympathetic axons arise in the upper five thoracic spinal segments and the postganglionic fibers arise from the upper five thoracic paravertebral ganglia. Once on the wall of the aorta, these fibers form an adrenergic plexus in the adventitial tissue. Afferent fibers from this large, elastic artery follow the sympathetic nerves back to the upper five thoracic spinal segments (65). This observation accounts for the referral of pain from the thoracic aorta to the thoracic spinal segments, resulting in their subsequent facilitation. Vagal cardiac nerves traverse the walls of the aorta as they descend toward their targets. Small twigs from these branches provide afferent as well as parasympathetic efferent innervation (Fig. 10.14).

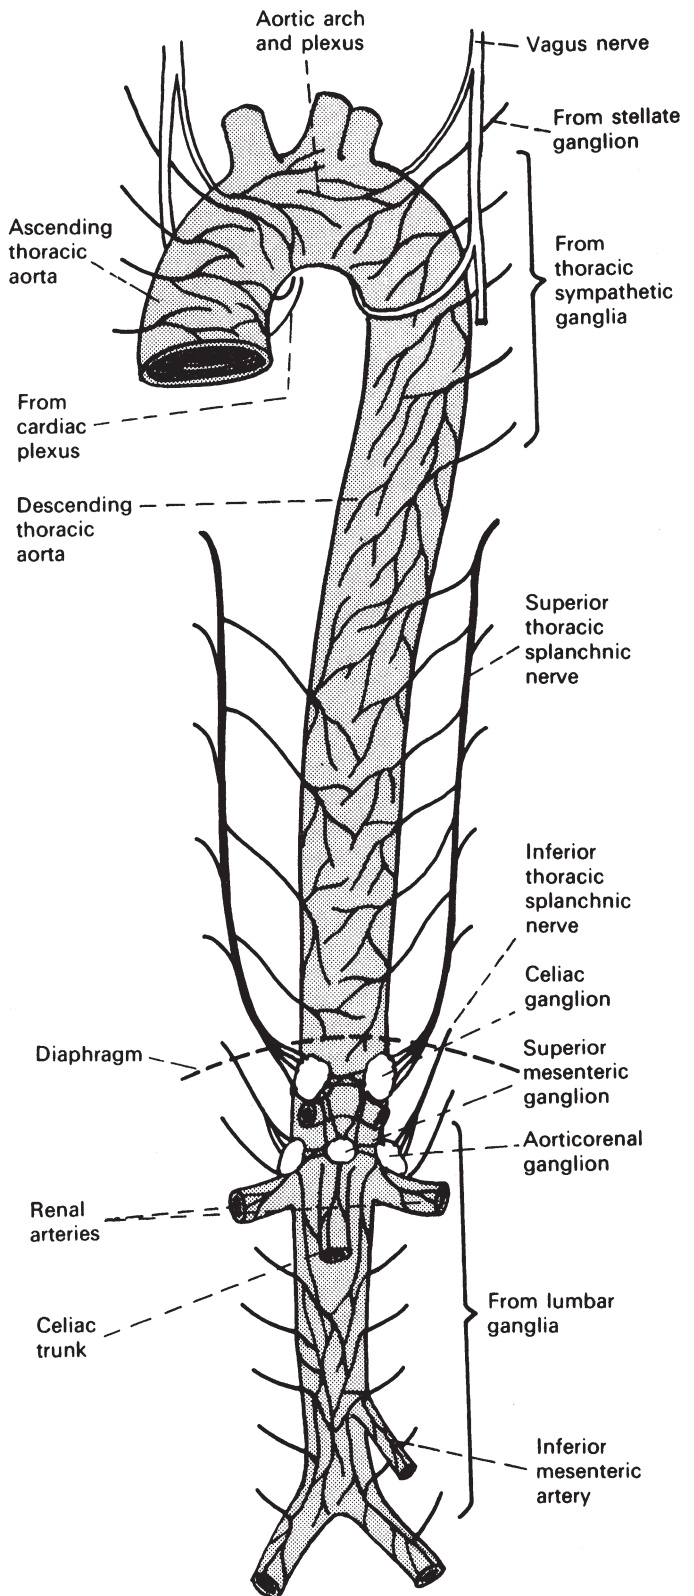

Figure 10-14 Innervation of thoracic and abdominal aorta. (From Bonica JJ. General considerations of pain in the chest. In: Bonica JJ, ed. *The Management of Pain*. Philadelphia, PA: Lea & Febiger, 1990:979, with permission.)

Thoracic Duct Innervation

The thoracic duct, located in the posterior mediastinum near the esophagus, receives an innervation similar to the vascular innervation elsewhere in the trunk. Its muscular walls receive cholinergic innervation from the vagus nerve and sympathetic adrenergic innervation from branches of the intercostal nerves in a segmental pattern. The eleventh thoracic ganglion and the left splanchnic nerve innervate the cisterna chyli, which is the origin of the thoracic duct (83). Norepinephrine and epinephrine act to increase the flow of lymph through the thoracic duct (84). The effect of these adrenergic compounds on lymph vessels appears to be mediated through α -receptors on the smooth muscle cells of the lymph vessel wall (85).

Abdominopelvic Region

The thoracic plexus passes through the diaphragm to continue inferiorly in the abdominopelvic cavity as the abdominopelvic plexus. This plexus is a massive network of fibers lying along the midline

astride the aorta and extending from the abdominal diaphragm to the pelvic diaphragm.

At the level of the abdominal diaphragm, the plexus has two major components: parasympathetic and sympathetic. The two vagal trunks and their associated branches, representing the parasympathetic component, enter the abdomen riding on the walls of the esophagus. The sympathetic component (or thoracic splanchnic nerves) passes directly through the crura of the diaphragm or under the medial arcuate ligament to enter the abdomen. Once in the abdominal cavity, the vagal trunks and thoracic splanchnic nerves unite around the aortic prevertebral ganglia. The resultant abdominopelvic plexus of fibers follows the abdominal aorta to the pelvic brim and bifurcates slightly above the sacral promontory, and the resulting two divisions of the plexus descend into the pelvic basin (Fig. 10.15). Throughout the abdomen, the plexus contains both sympathetic and parasympathetic axons and also has numerous afferent fibers. Toward the inferior end of the abdominopelvic plexus, additional sympathetic contributions arise in the lumbar and sacral splanchnic nerves, although additional parasympathetic

Figure 10-15 The great abdominopelvic plexus. This diagram illustrates the position of the prevertebral and paravertebral sympathetic ganglia in the abdominopelvic plexus. The plexus lies in the visceral fascia surrounding the abdominal aorta. (Figure taken from A. M. Agur and A. F. Dalley. *Grant's Atlas of Anatomy*. Philadelphia, PA: Lippincott Williams & Wilkins, 2009.)

contributions come from the pelvic splanchnic nerves in the pelvic basin.

Like the thoracic plexus, the abdominopelvic plexus can be divided into several geographical regions. Along the abdominal aorta, the major prevertebral ganglia mark out differing territories:

- Celiac
- Superior mesenteric
- Inferior mesenteric

The superior hypogastric plexus lies between the inferior mesenteric plexus and the sacral promontory. Below the sacral promontory, the plexus splits to pass laterally around the pelvic organs. This region is called the inferior hypogastric plexus or, simply, the pelvic plexus. Frequently, the fibers of the superior hypogastric plexus unite into a few large cords in the region directly over the sacral promontory and just prior to bifurcation into the two inferior hypogastric plexuses. These cords are often referred to in the surgical literature as the presacral nerve (86). Although the abdominal autonomic nervous system has regional names, in reality the components blend together to form one great abdominopelvic plexus. The abdominal portion of this great plexus supplies efferent and afferent nerves to the organs of the abdominal cavity including the gastrointestinal organs, spleen, and kidneys. The pelvic portion of this plexus supplies the rectum, urinary organs, and reproductive organs. In addition to the organs, the abdominopelvic plexus also innervates the vasculature of the abdominopelvic cavity.

Gastrointestinal Tract

The gastrointestinal system receives a complex pattern of extrinsic innervation involving splanchnic nerves derived from the thoracolumbar and sacral portions of the spinal cord and the terminal portion of the vagus and pelvic splanchnic nerves (Figs. 10.4 and 10.5). These nerves form a complex network of fibers lying along the abdominal aorta and extending from the thoracoabdominal diaphragm to the pelvic diaphragm (Fig. 10.15). This elaborate plexus, like its visceral blood supply, can be divided into three zones based on embryologic partitions of the gastrointestinal system:

- Celiac (foregut)
- Superior mesenteric (midgut)
- Inferior mesenteric (hindgut)

A complex network of intrinsic fibers and neurons called the enteric nervous system is found within the walls of the gut. The enteric or intrinsic neural system controls the activity of gut smooth muscle and glands. In turn, it is modulated by the extrinsic fibers from the CNS via the sympathetic and parasympathetic nerves. Numerous sensory feedback loops exist in the gastrointestinal system. Afferent fibers within the luminal surface and gut wall form short feedback loops within the enteric nervous system. Longer feedback loops connect the gut to the prevertebral ganglia, and still longer loops connect the gut with the spinal cord and brainstem (6,13,87–90). Figure 10.16 is a schematic diagram of the abdominopelvic plexus demonstrating its input from sympathetic and parasympathetic sources.

The gastrointestinal tract has a special pattern of sympathetic innervation that differs significantly from that of the thoracic viscera. Preganglionic fibers arise in the lateral horn of spinal segments T9–L2, but they do not terminate in the paravertebral ganglia. Instead, they pass through a series of thoracic, lumbar, and sacral splanchnic nerves (branches off of the sympathetic trunk) to reach the prevertebral sympathetic ganglia on the anterior wall of the abdominal aorta (Fig. 10.15).

The major prevertebral ganglia are distributed around the three abdominal arteries:

- Celiac
- Superior mesenteric
- Inferior mesenteric

Anatomical authorities subdivide the celiac ganglia into numerous parts based on its location about the celiac artery and aorta; however, from a practical perspective, it is simpler to consider it as one anatomical unit. Also, the celiac and superior mesenteric ganglia are often fused together into an inseparable mass surrounding the trunks of their two arteries. An older term for this arrangement is the solar plexus. Additional clusters of sympathetic ganglia neurons are found scattered in the hypogastric plexus as it enters the pelvic basin.

Neurons in each prevertebral ganglion give rise to postganglionic fibers that innervate abdominal and pelvic viscera. These axons travel to their target organs by hitchhiking on abdominal and pelvic arteries. Each prevertebral ganglion innervates a different region of the viscera.

Celiac Ganglia

The celiac ganglionic mass surrounds the celiac trunk. It is often fused to the superior mesenteric ganglia to form one large, complex mass. When carefully dissected, the precise shape of the ganglion complex is very irregular and defies meaningful classification (51). The celiac ganglia receive afferent fibers from the thoracic splanchnic nerves (T5–T9). In turn, it supplies postganglionic sympathetic axons to the vascular territory of the celiac artery including the (Figs. 10.17 and 10.18):

- Distal esophagus
- Stomach

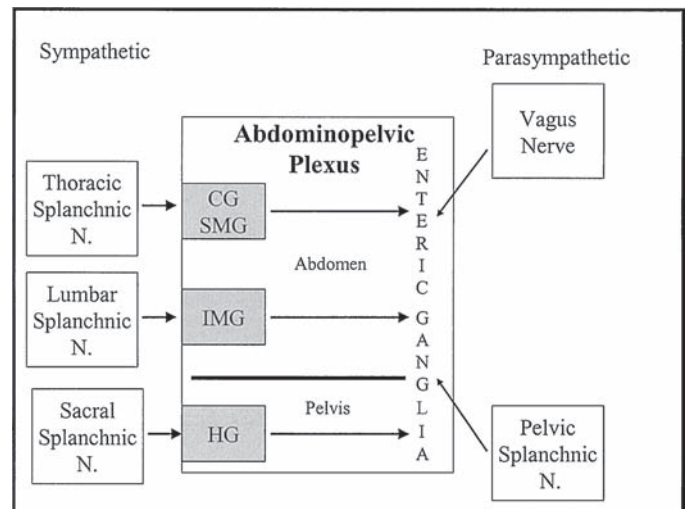

Figure 10-16 A schematic diagram of the abdominopelvic plexus illustrating its ganglia and sources of input. Thoracic, lumbar, and sacral splanchnic nerves for the sympathetic trunk carry sympathetic preganglionic fibers to the paravertebral ganglia located in the plexus. Postganglionic axons from the paravertebral ganglia target the intrinsic enteric ganglia of the organ walls. Parasympathetic fibers arise in the vagus nerve superiorly and the pelvic splanchnic nerves inferiorly. These fibers also target the intrinsic enteric ganglia located on the organ walls. CG, celiac ganglion; SMG, superior mesenteric ganglion; IMG, inferior mesenteric ganglion; HG, Hypogastric ganglion.

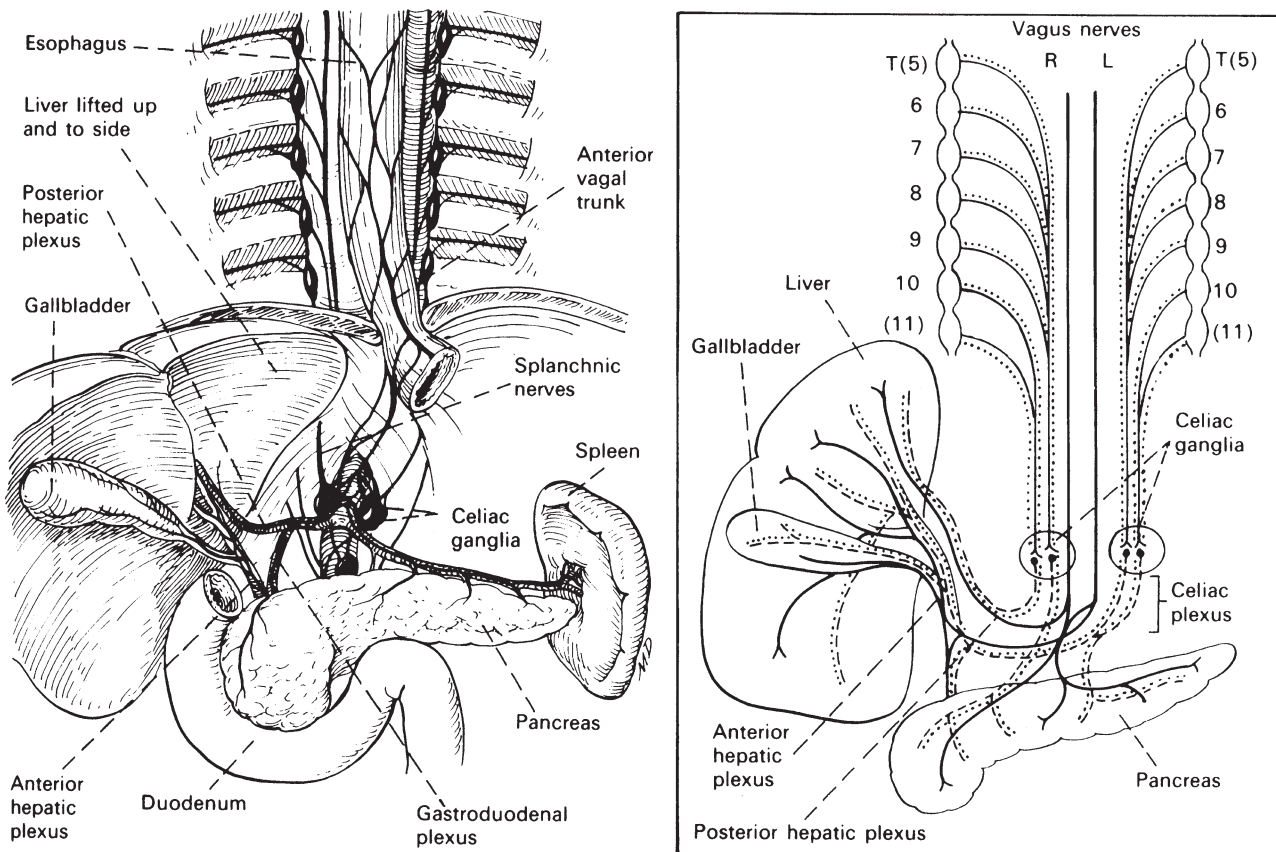

Figure 10-17 Connections of celiac ganglion and innervation of stomach. (From Kimmey MB, Silverstein FE. Diseases of the gastrointestinal tract. In: Bonica JJ, ed. *The Management of Pain*. Philadelphia, PA: Lea & Febiger, 1990:1189, with permission.)

- Proximal duodenum
- Liver
- Gall bladder
- Spleen
- Portions of the pancreas

Superior Mesenteric Ganglia

This ganglion is found wrapped around the superior mesenteric artery. As mentioned above, it is often fused with the celiac ganglia. The superior mesenteric ganglia also receive preganglionic axons from the thoracic splanchnic nerves. Its distribution of postganglionic axons reaches the territory supplied by the superior mesenteric artery (Fig. 10.19):

- Distal duodenum
- Portions of the pancreas
- Jejunum
- Ileum
- Ascending colon
- Proximal two thirds of the transverse colon

Inferior Mesenteric Ganglia

The most ventral of the three prevertebral ganglia, the inferior mesenteric ganglia, surrounds the abdominal artery of the same name. It receives axons from the three lumbar splanchnic nerves

and supplies postganglionic axons to the vascular territory of the inferior mesenteric vessels, namely the (Fig. 10.18):

- Distal third of the transverse colon
- Descending colon
- Sigmoid colon
- Rectum

Postganglionic fibers from the prevertebral ganglia follow their specific blood supplies through the mesenteric ligaments to reach the specific organs. The termination of these noradrenergic fibers is primarily on the neurons in the enteric ganglia (91). Sympathetic fibers also terminate in the muscular coat of blood vessels, and an abundance of these fibers reaches the sphincter musculature of the enteric wall. Only scattered sympathetic fibers are present in the muscularis externa and submucosa of the gastrointestinal tract (92). There are almost no adrenergic cell bodies in the enteric plexus; therefore, most enteric adrenergic fibers are of external origin. In general, stimulation of the sympathetic fibers inhibits the activity of cholinergic neurons of the parasympathetic system and slows peristalsis and motility.

The parasympathetic innervation of the organs located below the thoracoabdominal diaphragm has a dual origin, which also segregates along vascular and embryologic divisions. The organs of the foregut and midgut, serviced by the celiac and superior mesenteric arteries, receive parasympathetic preganglionic fibers from the vagus nerve (Figs. 10.17–10.19). The vagus nerve follows the esophagus through the diaphragm to enter the abdominal cavity on

Figure 10-18 Connections of celiac ganglia and the innervation of the liver and biliary tree. (From Mulholland MW, Debas HT. Diseases of the liver, biliary system, and pancreas. In: Bonica JJ, ed. *The Management of Pain*. Philadelphia, PA: Lea & Febiger, 1990:1215, with permission.)

the walls of the stomach. The esophageal hiatus of the diaphragm is the last place the vagus can be identified as a distinct nerve. Vagal axons, however, continue into the abdominal cavity, joining those of the sympathetic system in the celiac and superior mesenteric ganglia and forming mixed nerves, which pass along celiac and superior mesenteric blood vessels eventually to reach the abdominal viscera. Vagal fibers are plentiful in the walls of the stomach and small bowel, and a few reach as far distally in the enteric plexus as the splenic flexure of the large colon. The preganglionic vagal axons terminate on neurons in enteric ganglia. Short postganglionic fibers from these neurons innervate the glands and course within the layers of smooth muscle of the alimentary canal. Cholinergic stimulation increases glandular secretions and peristaltic activity.

The organs of hindgut origin (transverse colon to anus) receive parasympathetic preganglionic innervation from the pelvic splanchnic nerves (Fig. 10.20). These nerves arise in the lateral horn of the S2-S3 spinal cord segments and exit the spinal canal with the sacral nerve roots. As the roots pass along the pelvic wall on their way to the greater sciatic foramen, the delicate pelvic splanchnic nerves are given off. These thin nerves course through the endopelvic fascia to reach the inferior hypogastric plexus surrounding the walls of the rectum. Once in the hypogastric plexus, these parasympathetic preganglionic fibers can ascend to the origin of the inferior mesenteric artery. By hitchhiking along the branches of this artery, they reach upward to the splenic flexure of the large colon. Not all parasympathetic axons from the pelvis follow this route to reach the inferior abdominal organs. Some preganglionic

fibers in the inferior hypogastric plexus gain access to the enteric plexus in the wall of the rectum and ascend along the colon to reach more proximal levels of the hindgut. The preganglionic axons of the pelvic splanchnic nerves eventually terminate on the neurons of the enteric nervous system. Stimulation of the parasympathetic fibers increases gut peristalsis and mobility.

The enteric ganglia and plexus within the walls of the gut form a highly complex and elaborate network, often referred to as the third division of the autonomic nervous system. It exerts a major influence over all activities in the gut (6,93). The enteric nervous system is estimated to possess as many neurons as are found in the entire spinal cord (94). The enteric system is divided into two layers: The external layer is the myenteric plexus (Auerbach's) controlling the muscularis externa, and the internal layer is the submucosal (Meissner's) controlling the glandular and immune components of the submucosal layers. A full understanding of these structures requires a knowledge of the gastrointestinal histology and is beyond the scope of this review (95,96).

Numerous neurotransmitters and neuromodulators are found within enteric neurons, for example:

- Acetylcholine
- Serotonin
- Purines
- Gamma-amino butyric acid
- Histamine
- There are also many peptides such as Substance-P

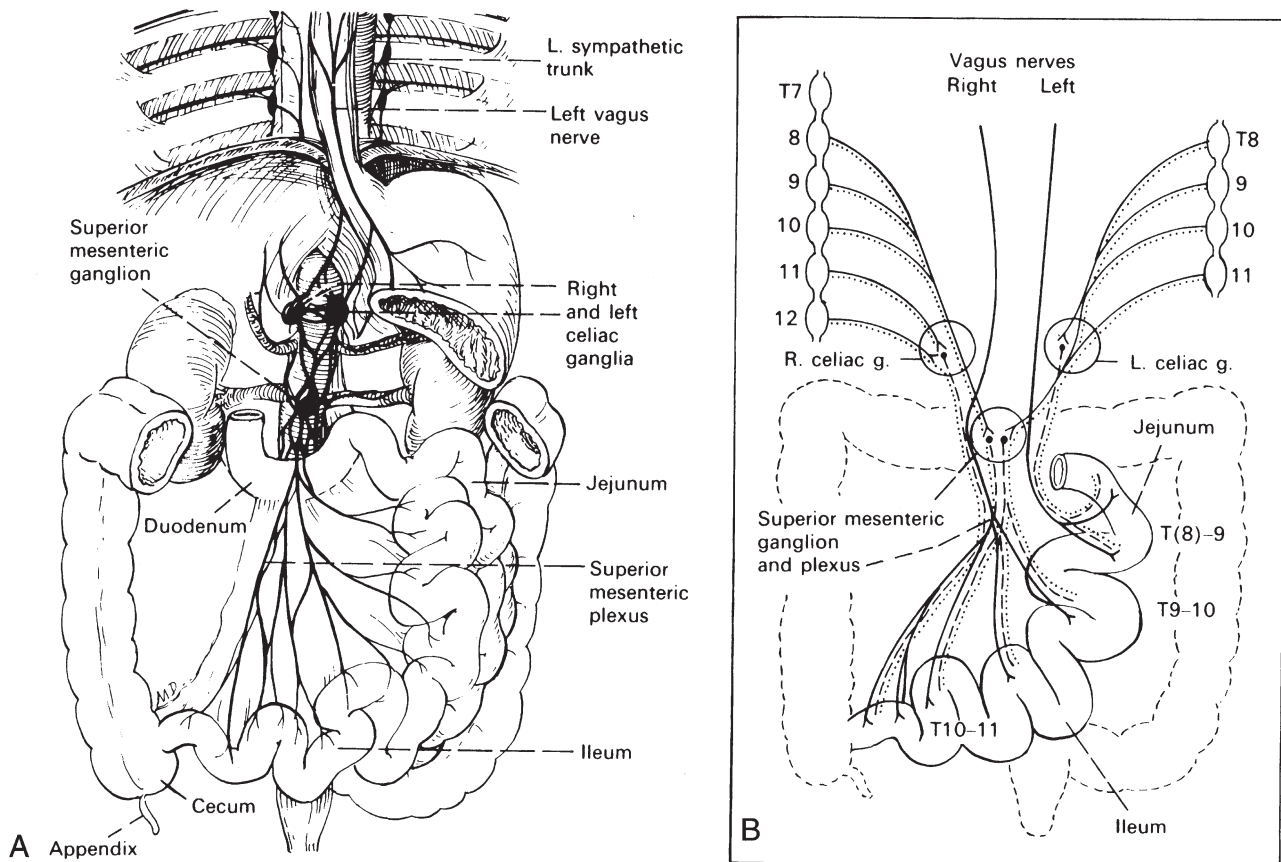

Figure 10-19 Connections of superior mesenteric ganglion and the innervation of the small bowel. (From Kimmey MB, Silverstein FE. Diseases of the gastrointestinal tract. In: Bonica JJ, ed. *The Management of Pain*. Philadelphia, PA: Lea & Febiger, 1990:1198, with permission.)

Somatostatin
 Vasoactive intestinal polypeptide
 Enkephalins

Recently, nitric oxide has been described as a significant noncholinergic, nonadrenergic mechanism of neurotransmission in the enteric nervous system as well as elsewhere (97,98). Nitric oxide is synthesized from the amino acid arginine by neurons in the myenteric plexus and is a potent smooth muscle relaxing factor. For this reason, it is postulated to be important in dilation of the alimentary canal.

Three levels of sensory information processing are necessary for the proper regulation of gastrointestinal tract function (6,87). The first level features afferent neurons that form a short loop interconnecting the gut mucosa, submucosa, or muscle to the enteric ganglia only. These neurons are responsible for local reflexes along the gut wall. The second level of sensory information processing involved is arranged in a longer loop involving afferent neurons from the mucosa that project to the prevertebral ganglia along the aorta. These sensory neurons participate in intra-abdominal reflex arcs coordinating various regions of the gastrointestinal system. Neither of these two sensory levels can reach consciousness; thus, we are generally unaware of the reflex control activity occurring in the gut wall. Finally, the third level of sensory feedback loops involves afferent neurons that project from the gut wall to the brainstem via the vagus nerve or to the spinal cord via the thoracic, lumbar, and pelvic splanchnic nerves. These visceral afferent neurons assist the CNS in integrating the activity of the alimentary canal with that

of external environmental conditions. Information in this third sensory level can, on occasion, reach consciousness.

There are significant differences in distribution, morphology, and neurochemistry between the visceral afferent fibers associated with sympathetic nerves and those coursing with the parasympathetic nerves. There are very few large, encapsulated nerve endings in the gut wall, most of which are related to axons from the parasympathetic vagus nerve. However, the majority of afferent terminals in the gut are small-caliber, naked nerve endings (87). In the vagus nerve, mechanoreceptive, chemoreceptive, and polymodal fibers have been described with their receptive fields in the mucosa and submucosa of the gut wall. At least in the stomach, very few of these vagal fibers contain calcitonin gene-related polypeptide, a neuropeptide typically related in nociceptive afferent fibers of the somatic tissue. However, some nociceptive information is carried in the vagus nerve because pain from a hiatal hernia can be referred to the face (99) via the vagus nerve. Little is known of nociceptive function in vagal fibers below the level of the diaphragm. The visceral afferent fibers that follow the sympathetic nerves to the spinal cord are mechanoreceptive and chemoreceptive, and they tend to be distributed to the mesenteries and peritoneal ligaments of the gut and along its vascular system. In contrast to the vagal fibers, those projecting to the spinal cord are mostly of small caliber and are rich in calcitonin gene-related polypeptide, suggesting that they have a role in nociception. Their endings are commonly distributed within the mesentery and supporting ligaments of the abdominal organs (88). These nerve endings are frequently present

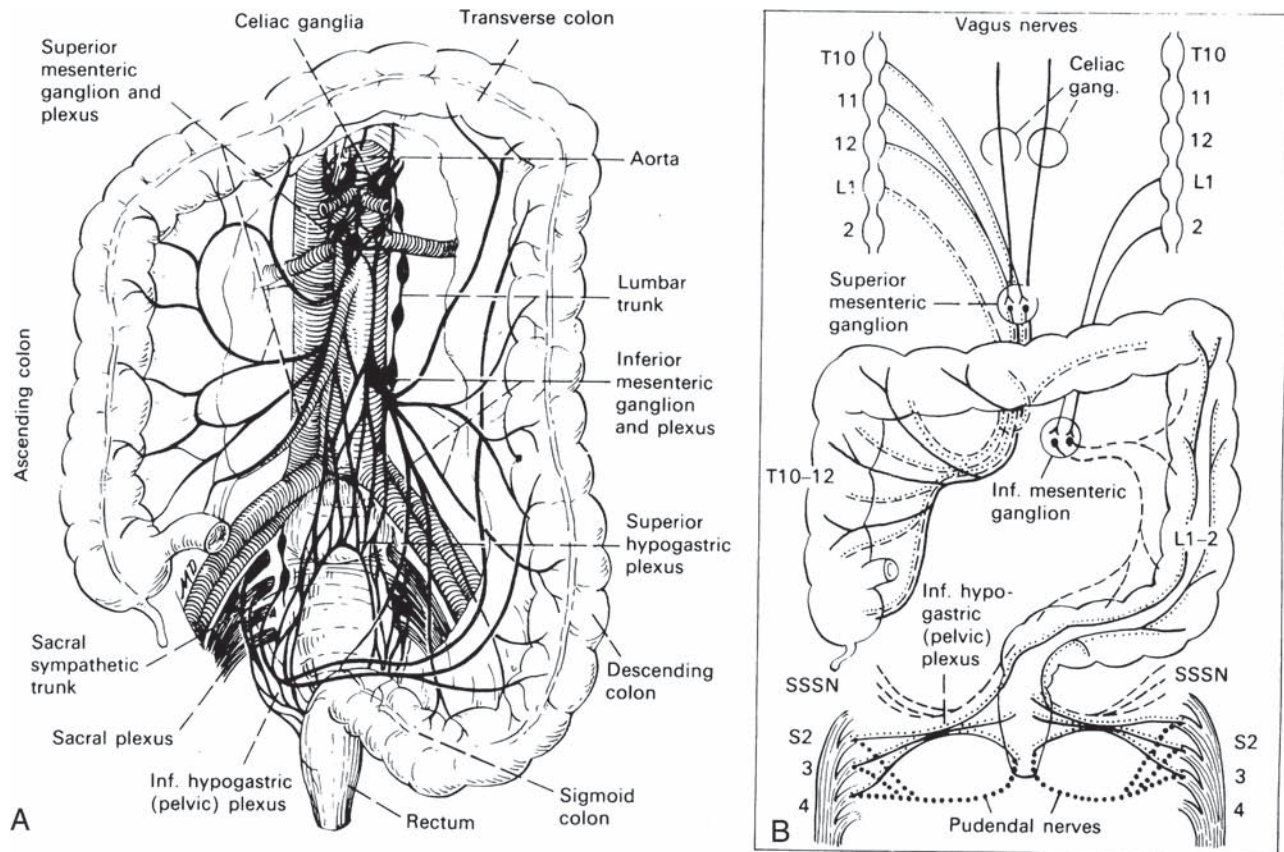

Figure 10-20 Connections of inferior mesenteric ganglion and the innervation of the large bowel and rectum. SSSN, sacral sympathetic splanchnic nerve. (From Kimmey MB, Silverstein FE. *Diseases of the gastrointestinal tract*. In: Bonica JJ, ed. *The Management of Pain*. Philadelphia, PA: Lea & Febiger, 1990:1199, with permission.)

near the branch points for the vasculature in the peritoneal lining. Few small-caliber nerve endings are present within the visceral organs themselves. (See additional comments concerning vagal activity in Chapter 8.)

Physiologic (68) and clinical studies support the general separation of regulatory information into the vagal system and nociceptive information into the spinal cord. Stimulating the greater thoracic splanchnic nerve at surgery elicits severe pain; however, blockade of the splanchnic nerve relieves pain (100). In addition, applying local anesthetic to the greater thoracic splanchnic nerve after abdominal surgery prevents the endocrine metabolic responses such as increased plasma cortisol and urinary adrenaline levels that are usually present in the early stages of recovery (101). The projection of the viscera afferent fibers through the sympathetic system creates a nociceptive map of the abdominopelvic organs on the dorsal horn of the spinal cord. This map has been demonstrated in humans by sectioning the white rami communicans during the surgical treatment of visceral pain [White and Sweet, as cited in Jänig and Morrison (88)]. A summary of the organotopic map of the human viscera is presented in Table 10.1. The position of a specific organ in the visceral afferent organotopic map of the spinal cord coincides approximately with the origin of the sympathetic efferent system to that specific organ. The nociceptive input to the spinal cord over these visceral afferent fibers is not precisely mapped; instead, input from any one organ overlaps considerably with that from surrounding organs (88).

Hepatobiliary Tree and Pancreas

The vasculature and parenchyma of the liver and pancreas, as well as their associated ducts, receive innervation from both divisions of the autonomic nervous system (Fig. 10.18). In addition, these organs have an abundant supply of visceral afferent fibers that course in the vagus and thoracic splanchnic nerves. Preganglionic sympathetic innervation to these organs arises in thoracic segments at approximately T6 to T9-T11 and approaches the abdomen through the thoracic splanchnic nerves. Sympathetic ganglionic neurons are located in the celiac ganglia. Their postganglionic axons reach the liver and pancreas by hitchhiking on the hepatic and pancreatic branches of the celiac trunk. Preganglionic parasympathetic axons, derived from the vagus nerve, pass through the fascia of the celiac region and follow the vasculature to the target organs. Little is known concerning the effects of autonomic nerve stimulation on liver function. However, in general, sympathetic activation drives the liver toward increasing the output of glucose (102).

A significant percentage of the axons in the vagus and thoracic splanchnic nerves traveling to the liver and pancreas are sensory in nature. Approximately 90 of the vagal axons and 50 of the splanchnic axons to the liver are visceral afferent fibers (103). These two afferent systems perform different functions (13). Those afferent axons traveling with the vagus nerve respond to such stimuli as plasma glucose concentration, portal venous blood osmotic pressure, and temperature changes. The visceral afferent fibers associated with the splanchnic nerves are high-threshold

TABLE 10.1

Visceral Organs and Their Approximate Spinal Cord Level for the Origin of Their Preganglionic Neurons^a

Heart	T1-5	
Stomach	T5-9	
Liver and gall bladder	T6-9	
Pancreas	T5-11	
Small intestine	T9-11

Prostate	L1-2	

^aThese levels create a viscerotopic map in the lateral horns of the spinal cord.

mechanoreceptors and chemoreceptors located in the walls of the biliary system, among other places, and are responsive to stretch and bradykinin concentration. The evidence available to date suggests that all pain sensation from the liver and biliary tree is transmitted via the splanchnic nerves and not the vagus nerve.

Kidney and Urinary Tract

Kidney

Although the kidney is primarily controlled by endocrine mechanisms, it does receive significant innervation from the sympathetic adrenergic system that regulates, in part, the retention of sodium (Table 10.1) (104–107). Alterations in the neural activity in sympathetic fibers are involved in the generation of certain forms of hypertension (108). Very little vagal parasympathetic (cholinergic) input to the kidney has been reported. This organ does, however, receive neuropeptide-containing, primary afferent fibers that course along with the adrenergic fibers (Fig. 10.21).

The kidney receives most of its innervation from the thoracolumbar spinal cord. Preganglionic sympathetic neurons regulating the kidney are located in the lateral horn of the spinal cord extending approximately from segments T11 to L1. Their axons enter the abdominopelvic plexus over the lower thoracic and first lumbar splanchnic nerves (Table 10.1). The postganglionic sympathetic adrenergic fibers are derived from laterally positioned ganglia (sometimes called aorticorenal ganglia) in the celiac and superior mesenteric plexuses and course into the hilus of the kidney along the renal vasculature.

The adrenergic axons of the mammalian kidney terminate on the (109):

- Afferent and efferent glomerular arterioles
- Proximal and distal renal tubules
- Ascending limb of Henle loop
- Juxtaglomerular apparatus

All portions of the cortical tubular nephron are under neural influence. The relative density of adrenergic fibers is greatest around the ascending limb of the loop of Henle, followed in decreasing

relative density by the distal convoluted tubule and the proximal convoluted tubule (110,111). α -adrenoceptors have been located on the proximal convoluted tubule (112) as well as on the smooth muscle of the vasculature. Sympathetic innervation of the kidney is involved in the normal regulation of sodium retention, both by increasing the transport of sodium across the tubule walls and by directly increasing the release of renin from the juxtaglomerular apparatus (113,114). Studies have shown that there is increased activity in the renal sympathetic nervous system in essential hypertension in humans (108).

A dual sensory innervation of the kidney exists: afferent fibers follow the thoracic splanchnic nerves back to the spinal cord and the vagus nerve back to the brainstem. Within the kidney, peripheral endings of both mechanoreceptors and chemoreceptors are found in close association with ureteric blood vessels (arteries and veins) and in the walls of the pelvis of the ureter (115). Their cell bodies are in the dorsal root ganglia located mainly in segments at the thoracolumbar junction (T10-L3), and their central processes terminate in the dorsal horn of the spinal cord. These afferent axons are classified as A and C-fibers. Vagal afferent fibers, both mechanoreceptors and chemoreceptors, play a role in renorenal reflexes. The mechanoreceptors are also involved in modulating cardiovascular reflexes, thus regulating blood pressure (115). Pain is the only detectable sensory perception that can be elicited from the kidney (13). This modality is carried in the visceral afferent fibers of the thoracic splanchnic nerves to reach the spinal cord and the spinothalamic tracts. In a study of the sympathetic renal afferent fibers in the primate, all spinothalamic tract cells excited by renal afferent fibers were also excited by somatic afferent fibers, indicating a powerful somatovisceral convergence on these cells (116). This convergence has been suggested as a mechanism to explain the referral of pain from the kidney out to somatic structures such as the flank of the body. In addition, this relationship may explain the changes in the tone of muscle innervated by the segments T10-L1 that accompany renal infection or inflammation.

Ureter

The ureter is the conduit for urine from the kidney to the bladder. Its primary function of the ureter is the unidirectional flow of urine from the kidney to the urinary bladder. Although it is richly invested with nerves (117), peristalsis in the ureter is primarily myogenic in nature, driven by specialized pacemaker cells (118). The course of the ureter is retroperitoneal, lying along the posterior abdominal body wall and embedded in the transversalis fascia. The walls of the ureter consist of interlacing bundles of smooth muscle fibers woven into a theca muscularis. Individual smooth muscle cells interconnect via numerous gap junctions, making the muscularis a functional syncytium (119). Modified smooth muscle cells within the muscular layer serve as pacemakers, initiating peristaltic contractions (120). A plexus of efferent and afferent nerve fibers that are capable of regulating the pacemaker cells is wrapped around the muscularis (119).

The ureter receives its innervation in a segmental fashion. The upper portion is innervated by the lower thoracic and upper lumbar segments (T10-L1) and by the vagus nerve. The lower portion of the ureter is innervated by the upper lumbar segments (L1-L2) and the pelvic splanchnic nerves (Table 10.1). The sympathetic innervation reaches the upper ureter through the lesser thoracic and lumbar splanchnic nerves. Ganglionic neurons are located in the celiac and associated renal and gonadal (testicular or ovarian) ganglia. The lower ureter receives its sympathetic innervation from lumbar and sacral splanchnic nerves that contribute to ganglia located in the superior and inferior hypogastric plexus (121).

Figure 10-21 Innervation of the kidney. (From Ansell JS, Gee WF. Diseases of the kidney. In: Bonica JJ, ed. *The Management of Pain*. Philadelphia, PA: Lea & Febiger, 1990:1233, with permission.)

Fibers containing tyrosine hydroxylase and neuropeptide-Y, markers for sympathetic axons, are in the outer muscle layers and the surrounding adventitia of the human ureter (122–124). Activation of α -adrenergic receptors increases ureter peristalsis and elevates luminal pressures; whereas activation of β -adrenergic receptors decreases ureter peristaltic frequency and lowers intra-ureter pressures (125). The actual role of the noradrenergic system in human ureter peristalsis has been questioned, and it appears that control over the surrounding vascular system is the dominant theme for the ureteric nerves (118).

Parasympathetic innervation for the upper portion of the ureter arises in the vagus nerve and reaches the ureter through the celiac and superior mesenteric plexus. The lower portion receives its cholinergic innervation from spinal segments S2–S4. These pelvic splanchnic nerves communicate with the ureter via the inferior hypogastric plexus. Acetylcholine-containing neurons are present in the mural ganglia of the ureter, and fibers containing acetylcholine are present in the mammalian ureter. These fibers are of greatest density as the ureter enters the vesical wall. Stimulation of the ureter wall with acetylcholine results in an increased contractile activity and an increased basal tone of the mural smooth muscle (125,126). Acetylcholine also relaxes the ureter resistance arteries using a mechanism involving endothelium-derived nitric oxide (125).

Afferent fibers to the ureter are derived from dorsal root ganglia ranging from L2–L3 to S1–S2 (in guinea pigs) (127). Two classes of mechanoreceptors have been described in the ureter walls (128). One class has low thresholds and is responsive to peristaltic-type contractions of the ureteric smooth muscle. The other class of mechanoreceptor has higher thresholds of activation and is most

likely related to nociception. Many of these primary afferent fibers contain neuropeptides such as substance-P and calcitonin gene-related polypeptide, thereby suggesting that they are involved in nociceptive activities.

Pain, presumably from these nociceptors, is the only sensory perception obtainable from the human ureter (13). In the thoracolumbar dorsal horn of the spinal cord, input from the ureter converges with somatic input from thoracolumbar spinal segments. Pain from distention of the ureter is often referred to the somatic body wall over a range of body segments. From the upper ureter, pain refers to the area from the anterior superior spine of the ileum anteriorly to the border of the rectus abdominis muscle (T11–T12). From the middle ureter, pain refers to the area from the inguinal ligament anteriorly to the rectus abdominis muscle (T12–L1). From the lower ureter, pain refers to the suprapubic area (L1) and below into the scrotum or labia (L2) (121). This descending segmental pattern of primary afferent fibers from the ureter is responsible for the descending movement of facilitated segments as any obstructing material moves through the ureteric lumen.

Urinary Bladder

The muscular components of the urinary bladder can be divided into two anatomical and functional parts: the body (or detrusor urinae muscle) and the base (or the trigone muscle). The detrusor urinae muscle is the larger of the two parts and is active during expulsion of urine from the bladder. The trigone muscle surrounds the openings of the ureter in the base and the opening of the urethra in the neck of the bladder. It acts as an internal sphincter and, when

contracted, helps to prevent the flow of urine from the bladder. The detrusor and the trigone tend to oppose each other in activity. Both detrusor and trigone muscles comprise multiple layers of smooth muscle fibers and receive an efferent innervation from the large autonomic pelvic plexus. A third muscle related to bladder function is located inferior to the trigone in the layers of the perineum. It is the deep transverse perineal muscle; the portion of this muscle that surrounds the urethra is called the sphincter urethra. Unlike the detrusor and trigone, this component of the perineal diaphragm is composed of skeletal muscle and innervated by branches of the pudendal nerve, a somatic nerve (S2-S4).

The autonomic innervation of the urinary bladder is accomplished through the hypogastric plexus that is embedded in endopelvic fascia (Fig. 10.22). Parasympathetic preganglionic (cholinergic) fibers from the intermediolateral nucleus of spinal segments S2-S4 enter the hypogastric plexus via the pelvic splanchnic nerves. These axons continue anteriorly into the vesicle plexus to terminate on ganglionic neurons located in the walls of the bladder. Their postganglionic (cholinergic and purinergic) axons supply motor innervation to all portions of the bladder wall. Stimulation of the parasympathetic system, which occurs during voiding, is excitatory to the detrusor muscle and inhibitory to the trigone muscle (129).

Sympathetic preganglionic fibers arise in the intermediolateral nucleus of spinal segments T11-L2 (Fig. 10.22). They leave the sympathetic trunk coursing on lumbar and sacral splanchnic nerves to enter the inferior hypogastric plexus, eventually targeting prevertebral ganglia (130). Sympathetic postganglionic (adrenergic)

axons pass anteriorly through the inferior hypogastric plexus and ultimately contribute to the vesicle plexus in the bladder adventitia. Their major target is the smooth muscle cells of the trigone muscle with a much smaller contribution to the smooth muscle of the detrusor urinae. Sympathetic tone facilitates contraction of the trigone muscles and relaxation of the detrusor urinae muscle, which is necessary to allow expansion of the bladder while it is filling (130).

The vesicle plexus contains many ganglionic neurons traditionally associated with the parasympathetic system. However, it is now clear that these neurons also receive input from adrenergic axons in the sympathetic system. Thus, the sympathetic system can influence the activity of the parasympathetic system by modulating the activity of the ganglion cells. The ganglion cells innervating the trigone muscle have α -adrenoceptors on their membranes and respond to sympathetic stimulation with contraction. Conversely, ganglion cells innervating the detrusor muscle have β -adrenoceptors on their membranes and respond to sympathetic stimulation with relaxation. It is through this differential distribution of adrenoceptors that the sympathetic nervous system is capable of increasing the tone in the trigone while simultaneously relaxing the detrusor urinae (130).

The sphincter urethrae muscle, or external urethral sphincter, at the base of the bladder, is skeletal muscle; it receives its innervation from the perineal branches of the pudendal nerve (Fig. 10.22). This is a somatic nerve containing axons from motoneurons located in the ventral horn of the spinal cord (S2-S4).

Figure 10-22 The hypogastric plexus and the innervation of the male pelvic basin. **A.** This figure demonstrates the distribution of autonomic nerves to the pelvic and perineal organs. (Figure taken from A. M. Agur and A. F. Dalley. *Grant's Atlas of Anatomy*. Philadelphia, PA: Lippincott Williams & Wilkins, 2009.) **B.** This figure illustrates the origin of pelvic and perineal nerves in the male. (Figure taken from W. F. Gee and J. S. Ansell. *Pelvic and perineal pain of urologic origin*. In: J. J. Bonica, ed. *The Management of Pain*. Philadelphia, PA: Lea & Febiger, 1990:1368–1394.)

The release of urine from the bladder requires an integrated viscerosomatic reflex involving:

1. Excitation of the parasympathetic system to activate the detrusor urinae muscle.
2. Inhibition of the sympathetic system to relax the trigone and internal sphincter muscles.
3. Subsequent inhibition of the pudendal nerve to relax the external sphincter muscles.

Vesicle afferent fibers arise from mechanoreceptor endings in the connective tissue and epithelium of the vesicle mucosa and travel over the lumbar and pelvic splanchnic nerves as well as pudendal nerves to reach the cord at the L1-L2 and S2-S4 levels. Cell bodies for these nerves are present in the associated dorsal root ganglia. Many of these fibers contain neuropeptides such as those represented in the small-caliber, primary afferent fibers system (130). The afferent fibers reach only to the dorsal horn of the spinal cord near their segmental level of entry; however, a small number of these fibers enter the spinal cord and follow the ascending tracts rostrally to terminate in the lower regions of the medulla.

Sensory information from distension of the bladder initiates the reflexes involved in voiding. Initial filling of the bladder

triggers low-level afferent volleys that increase the tone in the trigone muscle and external sphincter muscles and inhibit the tone in the detrusor urinae muscle, allowing the bladder to serve as a reservoir for urine. After a certain level of filling is reached, a higher intensity of afferent volleys from the bladder wall reverses these reflexes such that the detrusor urinae muscle tone is enhanced and the tone of the trigone and external sphincter is inhibited. This reversal of reflexes prepares the bladder for voiding. The last step, relaxation of the external sphincter, requires cooperation of the suprasedgmental control of the bladder musculature, allowing volitional control of voiding (130).

Reproductive Tract

The pelvic and perineal organs of the male and female reproductive systems receive both sympathetic and parasympathetic innervation through the complex abdominopelvic plexus (Fig. 10.23). This innervation targets the glandular cells and smooth muscle of the vasculature as well as the mural smooth muscle present in the tubular portions of these organs. The origin of this innervation varies according to the embryonic origin of the specific organs. The testis and the ovary, which arise in the gonadal ridge of the posterior abdominal wall, receive their afferent and efferent supply

Figure 10-23 The origin and distribution of the hypogastric plexus in the female pelvic basin. (Figure taken from A. M. Agur and A. F. Dalley. *Grant's Atlas of Anatomy*. Philadelphia, PA: Lippincott Williams & Wilkins, 2009.)

from the abdominal portions of the abdominopelvic plexus. The remaining pelvic organs of reproduction are innervated from the pelvic portion of the plexus. Afferent fibers are present in each of these organs, and their input to the spinal cord is a key feature in the presentation of pelvic pain.

Testis and Ovary

Gonadal tissue receives sympathetic innervation from preganglionic neurons located in spinal segments T10 and T11. These preganglionic axons target neurons in the celiac and superior mesenteric ganglia. The gonadal (spermatic or ovarian) plexus of fibers arises from these ganglia and follows the course of the gonadal arteries. Additional sympathetic postganglionic axons join the gonadal plexus from the superior hypogastric plexus in the lower abdomen. In females, the gonadal (ovarian) plexus innervates the ovary and extends on to reach the uterine tubes. In males, the gonadal (spermatic) plexus joins the spermatic cord with the vas deferens and proceeds through the inguinal canal to reach the scrotum. Adrenergic fibers in the testis are present around blood vessels and interstitial cells of the seminiferous tubules and in the tubules of the epididymis (125). Stimulation of the sympathetic nervous system initiates strong peristaltic waves in the vas deferens, which is responsible for the propulsion of sperm. Parasympathetic innervation of the gonadal tissue is less dense than that of the sympathetic fibers. Cholinergic fibers arise from the vesical plexus and join the gonadal plexus as it passes through the pelvis. These fibers primarily target the vas deferens and the seminal vesicles.

Afferent fibers from the testis, epididymis, and vas deferens extend through the gonadal plexus to reach the thoracolumbar spinal cord. Fibers arising in the testis target segment T10, those from the epididymis enter the spinal cord at T11 and T12, although those from the vas deferens enter at T10-L1 (131). Afferent fibers from the ovary also ascend in the gonadal plexus to enter the spinal cord at the T10 level. The return of afferent axons from the gonadal tissue to the lower thoracic level of the spinal cord is responsible for the referral of pain to the thoracolumbar junction and the facilitation of segments in this area consequent to irritation of the gonadal tissue.

Uterus, Uterine Tube, Cervix, and Vagina

The distal portion of the abdominopelvic plexus bifurcates as it descends over the sacral promontory to enter the pelvic basin. The pelvic portion of this complex neural structure is called the inferior hypogastric or pelvic plexus. This network of ganglia and fibers sweeps laterally along the pelvic walls to surround the midline organs of the female pelvis. As this plexus crosses over the transverse cervical ligament, its fibrous network thickens to form the elaborate plexus of Frankenhuser (a regional subset of the inferior hypogastric plexus). From here, autonomic axons accompany the uterine vessels medially along the transverse cervical ligament to gain access to the uterus, cervix, and vagina. The remainder of the inferior hypogastric plexus extends anteriorly to surround the bladder (this collection of fibers is often referred to as the vesical plexus).

Sympathetic preganglionic neurons capable of influencing the uterus and cervix are located in the T10-L2 spinal segments (Fig. 10.23). Their axons target neurons in the celiac ganglia and other prevertebral ganglia. Postganglionic fibers from these ganglia descend into the pelvic basin coursing in the superior and inferior hypogastric plexus to eventually reach the uterus. For the most part, these adrenergic fibers end on the vasculature of the

uterus. Some axons terminate in the smooth muscle of the myometrium, particularly in the longitudinal layer (132) and among the glands of the endometrium. The parasympathetic input to the uterus and cervix arises in the intermediolateral nucleus of spinal segments S2-4. These axons target ganglia located in the plexus of Frankenhuser; whereas postganglionic (cholinergic) axons extend from this plexus into the uterus following the uterine artery. Most of the cholinergic input to the uterus is confined to the vascular supply with a small amount reaching the glands of the endometrium and a few fibers in the circular muscle layer of the myometrium (132). Beyond regulation of the vasculature, the function of this elaborate autonomic innervation of the uterus is not well known. Evidence suggests that stimulation of the adrenergic and cholinergic inputs can enhance the contraction of mammalian uterine myometrium (133). The number and size of adrenergic nerves appears to increase in the uterus during pregnancy (134), further suggesting a role for these fibers in the uterine contractions of labor and delivery.

The uterus, cervix, and vagina receive a complex afferent innervation that influences the referral of pain during parturition (135). Experimental studies in cats demonstrate that afferent fibers from the uterus and cervix enter the spinal cord over a range of levels (T12-S3) (136). The majority of fibers from the fallopian tubes have cell bodies in the dorsal root ganglia of the lumbar segments, whereas the majority of fibers from the cervix have cell bodies in the dorsal root ganglia of the sacral segments. Clinical studies suggest that the afferent fibers from the human uterus project to even higher levels of the spinal cord (T10) (135) and that the majority of pain fibers from the uterus enter the thoracolumbar spinal cord (137,138). Nociceptive fibers from the uterus pass upward through the superior hypogastric plexus and lumbar splanchnic nerves to enter the spinal cord over the white rami of the lower thoracic and lumbar segments. For this reason, the white ramus at L1 can be particularly large. The pathways handling sensory information from the female reproductive tract are split. Input from above the cervix ascends through the superior hypogastric plexus to the thoracolumbar junction, although afferent fibers from the cervix and below descend into the sacral spinal cord (68). This arrangement of primary afferent fibers is responsible, in part, for the presentation of low-back pain late in pregnancy as well as accompanying facilitation of spinal segments around the thoracolumbar junction.

Erectile Tissue of the Penis and Clitoris

The sympathetic innervation of the vasculature and erectile tissue in the penis and clitoris has its origin in the intermediolateral cell column of spinal cord segments T11-L2 (Fig. 10.23). At least two routes exist through which these fibers reach the penis. One route involves preganglionic axons that arise in the thoracolumbar spinal cord and synapse in the associated paravertebral ganglia. From these ganglia, adrenergic postganglionic fibers join the hypogastric plexus to pass into the pelvic basin, eventually entering the penis at its root on the perineal diaphragm. The second route comprises sympathetic preganglionic axons from thoracolumbar segments that pass by the paravertebral ganglia to terminate in pelvic ganglia located deep in the pelvic plexus. Postganglionic adrenergic axons from these ganglia reach the root of the penis or clitoris by following the associated perineal vasculature.

Parasympathetic innervation of the vasculature and erectile tissue arises in the sacral (S2-S4) spinal cord. Postganglionic axons from neurons in the scattered ganglia of the pelvic plexus join the sympathetic axons entering the penis or clitoris over its root. Non-adrenergic, noncholinergic axons, presumably from cells located in

the pelvic ganglia, also innervate the erectile tissue. Somatic motor innervation of the clitoris and penis arises in Onuf's nucleus of the ventral horn of spinal cord segments S2–S4. Their axons travel the course of the pudendal to the perineum where they innervate the following structures, all of which are composed of skeletal muscle:

- Bulbocavernosus muscles
- Ischiocavernosus muscles
- Superficial and deep perineal muscles
- External urethral sphincters
- Anal sphincters

The sex act requires coordinated viscerosomatic reflexes involving the organs and musculature of the pelvic and perineal region (130). Initially, somatic and/or emotional stimuli activate parasympathetic outflow from the sacral cord to the vasculature of the erectile tissue. The cholinergic fibers activate the release of nitric oxide from endothelial cells, which relaxes the vessel walls and results in increased perfusion of the tissue. Once the erectile tissue is engorged, additional stimuli initiate a sympathetic barrage from the thoracolumbar junction of the cord. This output results in contraction of smooth muscle in the vas deferens in the male and in the walls of the vagina in the female. Coordinated reflex activation of the perineal nerve subsequently results in contraction of the bulbospongiosus, ischiocavernosus, and transverse perineal muscles. The rhythmic contraction of these muscles assists in forcing the ejaculate along the urethra in the male and constricts the vestibule of the vagina in the female. Integration of these three efferent pathways (parasympathetic, sympathetic, and somatic) occurs in the circuitry of the sacral spinal cord segments and is necessary for successful completion of the sex act.

CONCLUSION

The autonomic nervous system is a major factor orchestrating the diverse functions of internal structures. Through an extensive network of connections, the autonomic nervous system helps maintain the normal rhythm of activity in the visceral organs as well as adjust their output to accommodate any external challenge. This conglomerate of interlocking systems, with its pervasive influence on our physiology and psychology, is called the neuroendocrine-immune network. This network is described in more detail in Chapter 8 and in Chapter 9 of the previous edition of this book (139).

Physiological Rhythms/Oscillations

Complementary, Alternative, and Integrative Considerations of Biorhythms

THOMAS GLONEK, NICETTE SERGUEEF, AND KENNETH E. NELSON

KEY CONCEPTS

- An oscillation is any periodic vibration relative to an equilibrium position.
- Osteopathic Manipulative Technique (OMT) uses the laws of mechanical physics to generate effective therapeutic intervention.

“Vibration is an accepted fact in science. Solid bodies are composed of atoms which are vibrating at almost infinite velocities. One substance differs from another mainly in the modulus of vibratility, the different planes of substance representing the planes of gradually increasing vibratility. The higher vibratility governs and molds the lower, just as the sun centralizes the solar system. The most refined vibrations that mean life and light with all their accompaniments to the planets in the solar system. In man this vibratile characteristic also predominates, for within his organism he combines the higher and lower grades of vibratility in connection with mind, brain, bone, muscle, blood. So long as these combined vibratilities are in harmony the organism enjoys life and health” (1).

BIOLOGICAL CYCLES

Human physiology is dynamic. It is important to understand this point and keep it in mind when considering physiological phenomena. Everything in living things is changing with time—but not necessarily at the same rate. Keeping everything coordinated is paramount. Moreover, geology/physics impinges upon life processes; the more fit organisms are those that exploit the cycles of the solar system, from the oscillations of planets in their orbits to the vibrations of phospholipids in the cellular membrane.

Holistically, the totality of human physiology may be considered in the context of waves upon waves upon waves, wherein each rhythm or vibrational frequency, although independent, influences and is influenced by those frequencies above and below it. The authors have been working (Fig. 11.1) at physiological frequencies in the range of 0.002 to 0.500 Hz (Hertz, cycles/s), but the total picture is far grander than this.

Cellular Rhythms

A single-celled organism is completely surrounded by its external environment. As such, cellular physiology occurs in the context of that environment. Nutrients are withdrawn from the environment and waste materials are deposited into that same environment. These activities support cellular respiration: The cell exists autonomously. In the single-cell organism, the cell is either subject to the external movements of its environment or it must itself move within the environment in search of nutrients and to keep from being overwhelmed by its own waste products. This relationship between the cell and the environment becomes more complicated in the progression from single cell to multicellular organisms.

Multicellular organisms of higher phyla up to the level of Coelenterata (sponges) are organized in such a way that all of the

constituent cells remain in direct contact with the external environment. Organisms of greater complexity contain individual cells that are, of necessity, not in direct contact with the external environment. This creates a new environment that is external to the cell but internal to the organism, thereby necessitating the need to regulate this resultant internal extracellular environment.

Cellular biochemistry demonstrates intrinsic rhythmic activity that creates a need to coordinate with the extracellular environment. The cell is absorbing nutrients and excreting waste products in harmony with its intrinsic biological rhythms. These rhythms dictate the need for similar rhythmicity of nutrient supply and waste transport in the extracellular environment. This can be accomplished by modulating the environment to provide for the needs of the cell or by modifying cellular activity to adjust to the provisions of the extracellular environment.

A component of this extracellular environment is other cells, cells that are nearby and carry out identical functions, and cells that are more distant but that act as integrated components of an organ. Such cells interact through processes of signal entrainment and signal modulation so that they perform as a regulated unit. For some organs, these regulated units exist as specific tissues having well-defined histology, for example the suprachiasmatic nucleus (SCN) in the brain, the atrioventricular node of the heart, the pancreatic ganglia (2). For other organs and systems, for example, smooth muscle, specific tissues have yet to be identified, yet physiological measurements indicate that they exist. Further, these internally regulated units communicate with other units within complex multiorgan systems and also with external signals from the environment; eating, for example, or activities such as singing and Tai Chi Chuan, all known collectively as *zeitgebers*. Because of this mutual dependency between the cell and the organism and its interaction with the environment, complex physiological rhythms and signaling have developed.

External Time Setters, *Zeitgebers*

Zeitgeber: Literally, “time-giver” [*zeit* “time” + *geber* “giver,” coined by Jürgen Aschoff (3)]. A time cue capable of entraining circadian (and other) rhythms (3,4), it establishes the phase of an oscillating wave and can be used as a synchronizer for systems of waves.

When crowds of pedestrians started using London’s Millennium (foot) Bridge, it began to sway from side to side. The pedestrians fell into step with the bridge’s oscillations, which amplified them (5). The effect of pedestrian walking, a periodic mechanical cycle, was to entrain the bridge, which then began to entrain additional pedestrians. Later (6) it was determined that amplification of the swing was the result of the way people balance themselves while walking. The

bridge had to be closed until it was strengthened with oscillation-damping reinforcements. This is an example of group entrainment of humans through an external mechanical motion. Humans are entrained by the bridge, which synchronizes the ambulatory rhythmic motion of the pedestrians, which in turn amplifies the oscillation of the bridge. [The bridge was modeled mathematically as a weakly damped and driven harmonic oscillator (5).] This is analogous to the amplification of the Traube-Hering wave in humans with incitant Osteopathic Manipulative Technique (OMT) (7,8) and the entrainment of this wave's frequency by baroreceptor outflow (9).

Everything must be synchronized in order that exchanges of energy take place. One must push the swing at exactly the right time to impart additional amplitude for the request "push me higher." The phenomenon is called resonance. This also is the principle behind incitant Osteopathic Manipulative Technique (OMT). This is why Osteopathic Manipulative Technique (OMT) works, because we are using the laws of mechanical physics to generate an effective therapeutic intervention. Cranial Osteopathic Manipulative Technique (OMT) is an exogenous zeitgeber.

Oscillations

An oscillation is any periodic vibration relative to an equilibrium position. As such, oscillations are characterized by:

Frequency: The number of complete oscillations occurring in a given unit of time.

Period: The time required for a complete oscillation or vibration.

Amplitude: The maximum displacement of a wave crest from its equilibrium position.

Period and frequency define the cycle, and amplitude defines the strength (the power).

Oscillating phenomena can regulate mechanical, chemical, physical, and physiological systems having interacting parts. They do so by continually sampling the system to determine the magnitude of an intervention that must be applied in order to maintain the system at equilibrium.

In the steady state, the position of equilibrium is subject to drift unless a corrective force (electrical, chemical, mechanical) is applied to oppose the drift. An oscillation is a dynamic phenomenon that is the result of forces acting upon the system and that provides a way to regulate the system by constantly returning it to the point of equilibrium. It is advantageous for a system to oscillate, because the oscillation provides a stable regulator, a reference point, if you will. Because of uncertainties in the universe, such as the motions of molecules caused by heat, chemical and physical systems lacking a reference will tend to drift and eventually become unstable. Oscillation is a mechanism for maintaining a system at its normative level of activity.

The body consists of multiple systems, each with their own equilibrium. Oscillation allows communication because waves can influence each other through the processes of entrainment, modulation, and phase coherence.

There are three components necessary for a system to oscillate. They are resonance, gain, and positive feedback, and all must be present. Resonance in this context is the ability of something to store energy at a certain frequency. Gain feeds energy into the oscillation at the resonant frequency to make up for inevitable losses. Positive feedback keeps the energy properly timed to reinforce the oscillation. If any one of them is missing or irregularly spread out (called dispersion), oscillation will not occur.

When visualized geometrically, oscillations in two dimensions appear as sinusoidal plots in three dimensions: Envision a train of footballs end to end. Physiological oscillations are usually

combinations of sine waves, resulting in complicated looking waveforms (Fig. 11.5).

Rhythms

In rhythms, energy is provided regularly, but is delivered as a series of sharply focused impulses rather than as a smooth sinusoidal change. Usually the amplitudes of these rhythmic "spikes" are fairly uniform; think of the percussion section of an orchestra, or consider a train of neuronal impulses. (One way of looking at impulse trains is to consider them "digital" signals.) For digital signals, timing is everything because the energy is sharply focused. Further, we tend to think of rhythms in terms of slow periodic processes, such as the spinning of the Earth, even though the waveform may be quite sinusoidal, as in "circadian rhythms."

Chronobiology, Chronopharmacology, Chronotherapeutics

Most biological activities fluctuate throughout the day and contribute to a better adaptation to the organism's daily activity; they also are coordinated. During the last 30 years, chronobiology has aimed at studying these biological rhythms, explaining the operant biological mechanisms and (recently) identifying their methods of communication, their crosstalk. Moreover, the description of specific biological rhythm disorders and rhythm problems at the cellular and even the molecular level has prompted the emerging fields of chronopharmacology and chronotherapeutics.

It is all about timing. Where on the clock face are the hands pointing? Is the observed signal leading or trailing? Only when the timing is precisely matched will resonance occur and transfer of information take place.

In 1902, Littlejohn had this to say regarding biological oscillations: "The vital cycle depends upon vibration. Waves of vibration pass along the tissues, especially from the nerves and the brain to and along the muscle tissues. There is no function of the body that does not have peristaltic or rhythmic vibrations. . . . the power of osteopathic treatment occurs from its effect upon physiologic oscillations" (1).

Physiological Oscillations

The periodic physiological phenomena that exist in nature have been quantified, and there is a developing consensus that these rhythms are synchronized (10) from the level of the cell to that of swarms, and from periods of only millisecond duration (11) to rhythms spanning millennia (12). As preposterous as this may sound, it is, nevertheless, logically consistent with the evolution of the genome from its seminal progenitor, LUCA [last universal common ancestor (13)], and its requirement, like all machines, for a master time setter. Moreover, an evolutionary advantage will be imparted to those chromosomes that can time the activities of their organism to exploit the Earth's periods, hence the spur for development of a zeitgeber (3,4,14,15). At this moment, technology is providing the raw data, the objective measurements. From these, then, just as we gaze at a star and from its wiggles deduce the structure of a distant solar system (16), so in analogous fashion we can discern precisely how biological rhythms influence each other and how these rhythms synchronize biological systems (10).

Regarding the existence of a master oscillator intrinsic to all living systems, an important caveat to consider is that while there may be a specific discrete physical structure housing this oscillator, such a structure is not absolutely necessary. It is entirely possible that the mutual synchrony of an organism's oscillations may serve as the

organismal reference clock [see “Jenna’s clocks” (17)]. This is the concept of metastability in rhythm generation (18,19). The oscillation of electrically coupled pacemaker neurons has been, in fact, computationally modeled and compared successfully with tissue preparations (20).

Still, the idea of running a machine without a reference is uncomfortable. At this writing, the best candidate for a reference timer is the circadian clock residing in the SCN in man (21), yet this oscillator seems inappropriate as a reference, for example, for discerning (22) musical pitch. How do our brains tell us that the various instruments of the orchestra are in tune (23), when the fundamental frequency may be completely absent from the sound that reaches our ears (24)? And why are people all over the world comfortable with the pitch of A set to 440 Hz (25)? [Mozart’s tuning fork oscillated at 421.6 Hz; however, Handel’s oscillated at 422.5 Hz (26).] Moreover, there are pitch-sensitive neurons in marmoset monkeys that appear similar in pitch perception to humans (27). Could it be that all of life possesses a fundamental reference frequency without which it could not exist?

The circadian clock is referenced to the rotation of the Earth (the circadian *zeitgeber*), specifically the perception of light (28). The Earth is a good reference. It is stable by virtue of its size and its nearly perfectly circular orbit about the Sun. Successful life forms exploit the circadian cycle to gain evolutionary advantages over less well-adapted organisms.

An alternative reference is the oscillation of the cellular plasma membrane. The membrane is a good reference because all living things contain the same phospholipid components in their bilayer membranes. Further, the membrane oscillates at the high-frequency end of the biological rhythmic spectrum, a good position for a reference oscillator.

As mentioned above, a reference oscillator could result from the mutual synchronization of all oscillators in a living system. And there is another consideration; there apparently is a hierarchy (29) among oscillators in organisms having complex multiorgan systems (30–32). The SCN can entrain the peripheral clocks of the heart, kidney, liver, and pancreas, but, apparently, these peripheral clocks cannot entrain the SCN. “Thus, there may be tissue-specific differences in the molecular composition of the circadian clock, and clock components that have subtle effects on central clock function may play a more prominent role in the regulation of peripheral clocks and vice versa.” (29). For a humanistic discourse concerning “who sets the clock and who keeps the time,” see Ref. 33.

THE BIOLOGICAL RHYTHMIC SPECTRUM

The frequencies of biological rhythms can be considered in analogy to the electromagnetic spectrum of physics and chemistry, in that there exist frequency ranges where phenomena (and their measurement) occupy essentially nonoverlapping frequency bands that the research community has given convenient descriptive names (see Ref. 34, Table 1.1, p. 2). For example, the electromagnetic spectrum has been partitioned into bands for x-rays, visible light, infrared, and microwaves, among others. Between these bands discrete physical phenomena are fairly rare. These *gaps*, thus, provide convenient dividing points. Considering the biosphere and human physiology, one can devise analogous groupings.

(When a concept is in its infancy, investigators will describe their observations in terms familiar to themselves and usually in the language of their analytical methods. Thus, the electromagnetic spectrum has radio waves and gamma rays, which are studied by very different technologies. Considering periodic phenomena in the realm of biology, these phenomena also are described through a variety of terms that reflect the frames of reference and the

analytical procedures of the individual investigators. This will lead to confusion when the same signal is referred to by different names, particularly when these names refer to different physiological functions. The problem is avoided when a specific signal is referred to by its frequency. A signal’s frequency is its unequivocal name that does not depend upon the prejudices of investigators. Nomenclature problems are exacerbated, however, when the precision of measurement inadequately resolves adjacent signals. For this reason, there is often ambiguity as to the precise frequency of specific phenomena.)

The frequency range from annual through tenths of a second can be discussed in terms of frequency bands that more or less describe physiologic functions in mammals. Beginning with the low-frequency end, these may be described as follows: Annual/seasonal rhythms, for example, seasonal affective disorder (SAD); menstrual cycle; circadian rhythm, for example, sleep disorders; ultradian rhythms, for example, endocrine and digestive cycles; vasomotor phenomena, for example Traube-Hering waves; cardiac cycles, for example, RR variability, and finally, oscillations of the cellular membrane.

Biological rhythms, however, can be as long as millennia and as short as milliseconds. On the long end, signals are usually manifest as trains of spikes or pulses analogous to drum beat rhythms. On the short end, signals may appear as sinusoidal waves, such as Traube-Hering waves or electroencephalographic (EEG) waves, or as trains of spikes, such as nerve impulse trains or the electrocardiogram (ECG). Regardless of form, their common characteristic is that they are periodic phenomena that can be transformed into a spectrum of frequencies through the mathematical procedure of a Fourier transformation (FT) (Fig. 11.1). The FT converts the time-domain waveform, such as an EEG, into an X-Y frequency plot that displays the component signals of a wave along with their frequencies (how fast), their amplitudes (how strong), and their dispersion (how regular). Random oscillations, called noise, and incoherent signals simply produce another spectrum of noise that usually contains little to no useful periodic information.

Clinically, the physician will encounter conditions affecting periodic phenomena having frequencies from annual to fractions of a second. At the beginning of the 21st century, and particularly in the realm of medical science, these are the frequencies that have undergone the most intensive scrutiny.

Biological Rhythm Definitions

A number of terms describing frequency bands within the biological spectrum (defined below) have entered the biological rhythm/oscillation lexicon. Some terms are in common use and well understood as to precise meaning, for example, circadian. Individual research groups working in specific areas favor others, and there is overlap in meaning among investigators.

Geologic time: Pleistocene and Holocene to decades, periodic phenomena.

Annual, biannual, seasonal

Circatrigentan: About every 30 days (once a month).

Infradian (infradian < circadian): Relating to biological variations or rhythms occurring in cycles less frequent than every 24 hours (35).

Circadian: Relating to biological variations or rhythms with a cycle of about 24 hours (35). Circadian time (CT): A standardized 24-hour notation of the phase in a circadian cycle that represents an estimation of the organism’s subjective time. CT 0 indicates the beginning of a subjective day, and CT 12 is the beginning of a subjective night. For example, for a nocturnal rodent, the beginning of a subjective night

(i.e., CT 12) begins with the onset of activity, whereas for a diurnal species, CT 0 would be the beginning of activity. Bourdon suggested that the term circadian should be used only for endogenous rhythms.

Nyctohemeral: Both daily and nightly (35), restricted to rhythms other than endogenous rhythms.

Ultradian (ultradian > circadian.): Relating to biological variations or rhythms occurring in cycles more frequent than every 24 hours (35) but usually not applied to cardiovascular rhythms in the nominal range of 0.003 to 2.0 Hz, although these frequencies are ultradian.

Nanomechanical oscillatory motion: 1 to 10 kHz (11); cellular oscillations up to 10 kHz are possible (36).

Cycles from Millennia to Years

There is now hard evidence from speleothems (isotopic variations and organics present) for the regular waxing and waning of micro-organism populations covering periods of millennia. At least three cycles from 20,000 to 10,000 year BP have been documented (12). Data from oxygen isotope ratios in stalagmites often vary in a cyclic fashion and correlate with marine oxygen isotope cycles and with other records of global climate change (the *zeitgeber*). At longer time scales, small mammal extinctions and turnover cycles, having periods in the range of 1 to 2.5 million years, correlate well with ice sheet expansions and cooling cycles that affect regional precipitation. It is inferred from more than 200 rodent assemblages from Central Spain that long-period astronomical climate forcing is a major determinant of species turnover [van Dam et al., their Fig. 0 (37)]. Imagine (if you can) what *zeitgebers* and what processes exist that are capable of regulating life over such gigantic periods of time?

In Illinois, we experience the periodic cicada (17-year locust) (38). Our population, brood XIII, is one of the more spectacular populations in North America in terms of numbers and the timing of their emergence. One of the authors has personally witnessed the ground beneath an old Forest Preserve District oak explode from a condition of no insects visible to no ground visible in less than 30 minutes, as if someone had fired a starting gun—a swarm, on cue, after 17 years, not unlike the synchronous spawning of corals (39). These phenomena are periodic, most certainly; however, their *zeitgebers* are not yet fully understood nor is their communication with life cycles of higher frequency, although surely such communication must exist.

Annual/Seasonal Cycles

Annual cycles abound. We have all witnessed migrating geese (their *zeitgeber* appears to be temperature) and migrating monarch butterflies. Bears and other animals hibernate or winter, usually with marked biochemical changes, as seen in frogs and toads (40,41), where the chemical signal for wintering may be phosphodiesterases (42) derived from the phospholipids (43). Salmon populations migrate on an annual cycle (individual fish every 3 to 5 years), even when saltwater species have been translocated into fresh water lacking any of the fish's familiar chemical cues (44). Moreover, these Pacific Ocean species, when transplanted into (fresh water) Lake Michigan, migrate and spawn at the same time as their parent Pacific population (mid-September to mid-October). Leaves of deciduous trees fall from the trees. The *zeitgeber* here is the rapidly diminishing daylight at the autumnal equinox.

Higher vertebrates living outside the tropics compare changes in photoperiod (a daylight duration *zeitgeber*) with their circadian

clocks to adapt to seasonal changes in environment and to initiate reproductive activity. At the molecular level, light signals initiate coordinated gene-expression events in the brain, and the resultant increased thyrotrophin (TSH) in the pars tuberalis triggers long-day photoinduced seasonal breeding (45).

From the perspective of medicine, sudden cardiac death increases during winter months in both men and women, and the heart rate-corrected QT (QTc) interval exhibits a circadian variation. The question of a seasonal variation in QTc was answered through a retrospective analysis of 24,370 ECGs (46). It was found that the maximum monthly mean QTc interval for men (413 ± 18 ms; $N = 560$; $P < 0.05$) occurred in October, whereas the maximum for women (417 ± 16 ; $N = 350$; P , N.S.) occurred in March, but the variation for women was not significant. In a similar study of seasonal QT dispersion in 25 healthy subjects, again it was found that the winter dispersion was greatest (66 ± 21 ms) while the spring value was smallest (48 ± 18) (47). Thus, there exists a seasonal signal in heart rate QT interval.

For the human animal, SAD is an affective, or mood, disorder resulting in depressive symptoms in the winter or summer. (The summer condition is referred to as reverse SAD; both conditions mimic dysthymia.) SAD is (at least in part) a circadian rhythm sleep disorder that follows the seasonal darkening at high latitudes that shortens the light component of the circadian rhythm (48,49).

Garai et al. (50) observed seasonality in the occurrence of the first missed menstrual bleeding in perimenopausal women, indicating that human menstrual function is influenced by seasonally varying environmental factors. A similar process, although in the reverse direction, takes place at the start of the reproductive span (51). Seasonal variation in the timing of menarche also has been described, with increased rates during summer and early winter (52). In a historical sample of women born at the end of the 19th century, fecundability, which strongly depends on menstrual function, was higher during late spring and late autumn, and the strength of the variation depended on age.

Monthly Cycles (Circatrigentan Cycles)

The menstrual cycle in humans modulates, or is modulated by, body temperature variability (53). In normally cycling females, the body temperature varies in a predictable manner within the menstrual cycle. This menstrual cycle variation (see Ref. 54, Fig. 1) is well known within clinical medicine, unlike most other sources of temperature variation. It is often factored into temperature interpretations and has been used for fertility planning purposes (53). In the luteal phase of the menstrual cycle, there is a rise in mesor (mean temperature) and a decrease in the amplitude of the circadian temperature rhythm. It is believed, however, that these changes represent corrections over a 4- to 6-day time frame and are not immediate responses to ovulation, thus making them marginally useful for pinpointing ovulation (54). The menstrual cycle variation of a biological rhythm is known as a circamensal rhythm and has a period approximately equal to the length of one menstrual cycle.

Investigators have attributed circamensal rhythms to changes that occur in response to hormone levels during the menstrual cycle. For example, the menstrual cycle is modulated by a diurnal rhythm in free estradiol of four cycles per day (55). In addition, there is a circadian rhythm to serum estradiol during late pregnancy (56). The circadian rhythm of body temperature also persists throughout the menstrual cycle. Thus, the menstrual cycle layers one rhythm on top of another existing rhythm (53). The result is a complex modulation of three waveforms.

In another example of a chemical entity acting as an entraining exogenous zeitgeber, this time between individuals, the existence of human pheromones was first suggested by the demonstration that women living together can develop synchronized menstrual cycles under specific conditions (57). The process (in rats) is mediated by two different pheromones (58). In a human study involving students and staff at The University of Chicago, odorless compounds from the axilla of women in the late follicular phase of their menstrual cycles accelerated the preovulatory surge of luteinizing hormone of recipient women and shortened their menstrual cycles. In a reciprocal action, compounds collected later in the cycle (at ovulation) had the opposite effect (59).

Regarding sleep-wake and rest-activity rhythms, the phase of circadian rest-activity rhythm may be modulated by the menstrual cycle; however, the sleep-wake cycle in normally cyclic healthy women does not appear to be affected (60).

Axoplasmic Flow (10 days)

Axoplasmic flow (macromolecules synthesized in hypoglossal nerve cell bodies and conveyed proximodistally in the axoplasm) oscillates with a period of 10 days (see Ref. 61, Fig. 5). This transport of neuronal protein was assessed using radioautography of incorporated tritiated leucine in the innervated muscle.

Circadian Rhythms (Frequency about 1 day, 24 hours)

The Earth's daily rotation about its axis has imposed potent selective pressures on organisms. The fundamental adaptation to the environmental day-night cycle is an endogenous 24-hour clock that regulates biological processes in the temporal domain. This clock coordinates physiological events around local (geophysical) time, optimizing the economy of biological systems and allowing for a predictive, rather than purely reactive, homeostatic control. Circadian clocks contribute to the regulation of sleep and reproductive rhythms, seasonal behaviors, and celestial navigation (62).

So what are the circadian rhythms? They are the external expression of an internal timing mechanism that measures daily time (63). (For light entrainment, see Ref. 28; for a review of light effects on humans, see Ref. 64.)

Circadian rhythms, such as locomotor activity, body temperature, and endocrine release, are regulated by a master pacemaker located in the SCN (65) that has a period of 24.18 hours (66). (For a perspective, see Ref. 67.) The circadian rhythm, which is regulated by the SCN clock, is reset by the environmental light-dark (LD) cycle (28), and this oscillation is called the light-entrainable oscillation (65). "The SCN imposes its rhythm on to the body via three different routes of communication: (a) The secretion of hormones; (b) The parasympathetic; and (c) The sympathetic. Imposed on these routes of communication are feedback loops" (68). The nature of these feedback loops is incompletely understood. They exist, however, as a myriad of dynamically counterbalancing entities, such that the whole reflects an integrated communications web.

The biological circadian clock was believed to be physically located exclusively in the SCN. However, cloning of the clock genes in the late '90s (for genetic and physical mapping, see Ref. 69) revealed that clock genes are expressed and oscillate with a circadian rhythm in each organ or cell, suggesting that each organ or cell has its own internal clock. These clock systems are called the peripheral clocks in comparison with the central clock in the SCN (70).

Concerning the timing of circadian clocks in tissues, fibroblasts from human skin biopsies were examined in culture following

treatment with lentivirus containing a circadian promoter of the gene *BMALL* (71). This promoter directs the protein luciferase to be expressed. When the fibroblasts are infected with the lentivirus, they emit photons of light according to the circadian rhythm of their intrinsic clock. Surprisingly, the periods of the cultured fibroblasts did not depend on the time the biopsy was taken or on the site of the skin biopsy; it did depend on the individual who provided the biopsy [Brown and Schibler, Fig. 2 (71)]. Biopsies provided by all subjects exhibited a mean circadian period of 24.5 hours, however, which was similar to observations of others.

A number of clock genes, for example, *Per1*, *Per2*, *Clock*, *Bmal1*, *Cry1*, and *Cry2*, are expressed in the SCN of the hypothalamus (72,73). Moreover, these genes are expressed not only in the SCN, but also in other brain areas, as well as in peripheral organs (72,74–76). "The intracellular molecular clockwork of the SCN consists of interacting positive and negative transcriptional/translational-feedback loops" (63). Maemura et al. (70) demonstrated that the *CLOCK/BMAL* heterodimer transcription factor upregulated 29 genes including transcription factors, growth factors, and membrane receptors and that these showed circadian oscillation.

"For orchestrated circadian timing, the collective SCN synchronizes the timing of slave oscillators, each of which is a multioscillatory entity. Synchronized slave oscillators in turn regulate local rhythms in physiology and behavior. A hierarchical multioscillatory system seems to confer precise phase control and stability on the widely distributed physiological systems it regulates" (77).

Rodents, which have been given an SCN lesion during a restricted-feeding schedule, however, are still able to anticipate mealtimes. This food-anticipatory activity appears to be mediated by the circadian oscillator because entrainment of this activity is limited to the circadian range (22 to 31 hours) (30,31). Thus, there are at least two types of biological clock oscillator: a light-entrainable oscillator, which is found in the SCN, and a feeding-entrainable oscillator the location of which was unknown to Damiola et al. in 2000 (32). Restricted feeding is an entraining signal for peripheral tissues (32,76,78), similar to light for the SCN. Peripheral clock entrainment by brain-driven fasting-feeding cycles allows peripheral tissues to anticipate daily fasting and daily feeding, potentially optimizing processes for food ingestion, metabolism, and energy storage and utilization (76). Such peripheral zeitgebers, however, *do not* entrain the SCN.

The circadian rhythm of mice is entrained by the LD cycle when food is plentiful; however, when access to food is restricted to the normal sleep cycle, mice shift many of their circadian rhythms to match food availability. A key transcription factor is *BMAL1*, which can be specifically disrupted (76). Restoration of *BMAL1* within suprachiasmatic nuclei of the hypothalamus restores light-entrainable, but not food-entrainable, circadian rhythms. Restoration of this gene only in the dorsomedial hypothalamic nucleus, however, restores food entrainment but not light entrainment (79).

For opaque mammals, such as humans, light resets (28,80) the time of the central pacemaker in the SCM via ocular mechanisms, and the SCN clock then synchronizes peripheral oscillators via signal modulations, neuronal connections, or chemical signals. The peripheral clocks of semitransparent organisms, however, can be light entrained directly via nonocular mechanisms (81), as can the peripheral organ clocks of vertebrate tissues (82). Results from zebrafish heart and kidney tissue cultures indicate that the circadian system in vertebrates exists as a decentralized collection of peripheral clocks. Each tissue is capable of detecting light and using that signal as the zeitgeber to set the phase of the clocks they

contain (82). Such a capability could impart a survival advantage to semitransparent fish embryos and fry.

Astronauts were examined during protracted space flight (83), where the circadian period (or absence thereof) is artificially established by the shorter orbital period of the space station. Systolic and diastolic blood pressures and heart rate were determined at 24-, 12-, and 8-hour intervals: (a) Systolic blood pressure during sleeping hours showed an unprecedented increase during space flight; (b) The approximately 24-hour circadian rhythms of blood pressure and heart rate shortened during the early stages of space flight, but after 6 months reverted to the established 24-hour flight activity cycle; and (c) Even during space flight, the periodic components of blood pressure and heart rate were preserved.

Regarding the diffusible gas neurotransmitter nitric oxide (NO), there is a circadian oscillation in urinary nitrate and cyclic GMP excretion rates, which are two marker molecules for systemic NO production in healthy humans. NO production is increased in the morning, concomitantly with the morning increase in blood pressure, indicating that NO may buffer blood pressure increase. In hypertension (HT), diurnal variation in these NO markers is absent, suggesting impaired NO formation in HT. The major change in peripheral arterial occlusive disease is an increased nitrate/cyclic GMP ratio, which points to increased oxidative inactivation of NO in this disease (84).

Regarding ocular tissues, there are circadian rhythms in axial elongation and choroidal thickness. Part of the underlying mechanism controlling the rhythm in elongation is the circadian rhythm in scleral proteoglycan synthesis (in isolated tissues) (85). Moreover, in the absence of temporal cues, a 24-hour rhythm in choroidal NO synthesis persists, indicating the presence of a circadian oscillator in the isolated tissue. Peak NO synthesis is coincidental with the peak in choroidal thickness in normal eyes, suggesting that NO might mediate the observed diurnal changes in choroidal thickness (86). [8-Nitro-guanosine 3',5'-cyclic monophosphate is a new NO messenger that contains an NO₂ group on the purine ring system of (cyclic) GMP. This discovery further illuminates the downstream effects of NO that could be relevant to NO-linked biological responses and diseases (87).]

The Circadian Clock

The zeitgeber (3,4) for the circadian clock is light (28), although with man social zeitgebers also are important (88). The physiological circadian oscillator, however, resides within cells, and it can be relatively simple and remarkably regular. For example, three proteins, KaiA, KaiB, and KaiC [kai, Japanese for cycle; KaiC crystal structure at 2.8 Å resolution (89,90)] were identified as important for the daily activity of the cyanobacterium *Synechococcus elongates*. In a reconstituted system where these three proteins were mixed with adenosine 5'-triphosphate in a test tube, they spontaneously generated sustained oscillations in the phosphorylation state of one of the proteins (91,92.) Mutations in the KaiC protein changed the circadian rhythm in a manner identical to the results obtained in vivo. The oscillations arise from the slow, orderly addition and then subtraction of two phosphates from the KaiC protein. Phosphorylation-dephosphorylation is a well-established mechanism for regulating a protein's function. If the protein is part of a network of interacting factors, then its phosphorylation status may relay information that affects some cell behaviors.

Reversible phosphorylation usually occurs on a time scale of seconds or minutes and seems poorly suited for a clock ticking once a day; however, KaiC is phosphorylated at two sites and in a particular order: first on a threonine residue and then on a serine. Subsequently, the threonine and then the serine are dephosphorylated,

and the KaiC protein returns to the unphosphorylated state. The KaiA protein regulates these transitions by promoting auto-phosphorylation and inhibiting autodephosphorylation by KaiC.

It is known that phosphorylation-dephosphorylation by itself does not create an oscillator; however, in this zeitgeber system, the serine-phosphorylated form of KaiC (S-KaiC) binds stoichiometrically to both KaiA and KaiB. The formation of the three-protein complex prevents KaiA from activating KaiC phosphorylation. Thus, when the concentration of S-KaiC is high, KaiA is sequestered by S-KaiC and KaiB, and KaiC dephosphorylation predominates. When S-KaiC is low, KaiA is released and KaiC phosphorylation is activated. The rate that the clock ticks is, thus, regulated by the rate of a chemical reaction, which depends on the concentration of a key reactant—simple but elegant physical chemistry.

Although eukaryotic oscillators do not appear to operate the same way, and none have the three protein KaiA, KaiB, KaiC system, the design principles of the two oscillators are quite similar. Both circuits include double-negative-feedback loops that mitigate function as bistable triggers, and both include slow negative-feedback loops (63,77) for tunability and robustness (93). Robustness and tunability are essential elements of oscillator systems, be they gene circuits or circadian clocks. We now have the ability to generate such oscillators in synthetic biological systems (94–96).

A feature of circadian clocks in both animals and plants is the incorporation of feedback loops. In plants, cyclic adenosine diphosphate ribose modulates the circadian oscillator's feedback loops and drives circadian oscillations of Ca⁺⁺ release (97). In mice, phosphorylation by nutrient-responsive AMP-activated protein kinase enables the clock component cryptochrome to transduce nutrient signals to circadian clocks (98,99).

[Using DNA microarray technology, which is facile and rapid, temporal patterns of gene expression may be determined in whole organisms. Applied to the yeast cell cycle, Holter et al. (100) characterized the patterns of gene expression as consisting of two sinusoidal modes, each with a period of 2 hours, and about 30 minutes out of phase. Plotting the weights of these two functions for each gene monitored provides a graphical representation of the sequence that genes turn on and off. This clock mechanism operates at the level of gene expression; its action can be expected to modulate the activity of all other clock mechanisms by regulating the availability of clock proteins. The authors state, "...the complex 'music of the genes' is orchestrated through a few simple underlying patterns of gene expression change."]

The Redox State and Circadian Rhythms

"The concept that circadian rhythmicity and redox state are necessarily and intimately linked is widely accepted" (101). The relationships among cyclical melatonin production, oxidative stress, and circadian rhythms in a variety of organisms have been discussed at length (102).

The sirtuins, which are a highly conserved family of NAD⁺ enzymatic silencing factors, have been connected to activities that encompass cellular stress resistance, genomic stability, tumorigenesis, and energy metabolism (103). SIRT1 (one family member) directly modifies core components of the circadian clock machinery, thus, for the first time, linking enzymatic genomic regulation with at least one established biorhythm (104,105).

Circadian Rhythms and Mental Health

A link between the circadian oscillation and Seasonal Affective Disorder (SAD) has been established, providing a proof of principle

that circadian rhythms that are out of sync could underlie some mood disorders. Psychiatrists working with small patient groups have shown that correcting abnormal circadian rhythms can treat these disorders and also can benefit patients with neurodegenerative diseases, such as Alzheimer's. "The circadian model is clearly beginning to bear fruit," says David Avery, a psychiatrist at the University of Washington School of Medicine in Seattle. "It is logically getting extended beyond SAD and should lead to better treatments for a number of psychiatric disorders (48)."

Further, and logically, irregularities in higher frequency rhythms that are synchronized with the circadian rhythm, or that originate in the same neurological networks as the circadian rhythm, also may adversely impact mental health, and, conversely, treatment of such rhythmic irregularities may benefit mental well being. For example, humans can be classified as "larks," who are at their best in the morning, and "owls," who are more effective at night. In industrialized societies, it has been suggested that people suffer from "social jet lag" because their innate circadian rhythms or chronotypes are out of phase with their daily schedule (106).

Stem Cells

"Haematopoietic stem cell (HSC) release is regulated by circadian oscillations." (107) The number of HSC progenitors oscillated in synchrony with a steady-state, 12-hour light/12-hour dark cycle, peaking 5 hours after initiation of light (Zeitgeber time, ZT5) and reaching the nadir at ZT17 ($P = 0.005$). The number of HSCs in the circulation (mice) at ZT5 is twofold to threefold that at ZT17. "These results suggested that photic cues, processed in the central nervous system, could influence the trafficking of HSCs in unperturbed steady-state animals." HSC release is triggered by rhythmic expression of *Cxcl12* in the bone marrow.

Ultradian Rhythms (Frequency Restricted Here to Higher Than 1/24 hours but Lower Than 1/minute)

Definition: The Traube-Hering-Mayer (THM) oscillation, respiration, the cardiac rhythm, the pulse, the activity of neurons, the oscillation of the cellular membrane, and the angular velocity of molecular motors all exhibit ultradian rhythms. For the purpose of this work and in deference to current usage in the biomedical literature, we define the ultradian band to be that set of frequencies lying between the circadian band (once per 24 hours) and the low-frequency THM oscillation of hemodynamics (once per minute).

In analogy with the response of luteinizing hormone and follicle-stimulating hormone to pulsatile administration of gonadotropin-releasing hormone, an ultradian pulsatile secretory pattern has been described for all the classic fuel-regulatory hormones, including insulin, glucagon, growth hormone, cortisol, and epinephrine (see Ref. 108, for a review). The dominant signal for cortisol exhibited a period of one cycle per 80 to 90 minutes; a second signal with a power approximately 50% of the dominant signal occurred at a frequency of 240 min/cycle (see Fig. 2 of Ref. 108). Examining normal subjects, Sonnenberg et al. (109) found that the ultradian insulin secretion pulses with a periodicity of 75 to 115 minutes. In the *in vivo* canine pancreas, a nicotine-stimulated insulin release (period 7.6 ± 0.6) was blocked by the post-synaptic nicotinic receptor antagonist α -bungarotoxin, providing evidence that pancreatic ganglia may have a role in the generation of oscillatory hormone release (2). Insulin secretion has a common pacemaker (the hypothalamus) or a mutually entrained pacemaker with the cardiovascular, autonomic, and neuroendocrine systems (110).

The contractile lymphatic elements of the bat *Myotis lucifugus* can generate as high as 6 to 8 mm Hg pulsatile pressure at a rate of nine contractions per minute [0.15 Hz, measured in the wing by light microscopy at 640 \times (111)]. Lymph flow in the thoracic duct (anaesthetized and unanesthetized adult sheep) was determined by ultrasound transit time flow and found to be 5.2 ± 0.8 per minute. The prominent pulsatile signal has no relation to heart or respiratory rates (see Ref. 112, Fig. 2). The human leg generates pulses ranging from 1 to 9 per minute, with an average of 4 per minute. "Each pulse wave lasted for six to eight seconds—in most cases for six seconds" (113).

The nasal cycle [the phenomenon of relative nostril dominance (114)] exhibits a cycle that varies between 2 and 8 hours among subjects, with an average value of about 3 hours (115).

Skin-surface properties revealed, in addition to the circadian rhythm [forehead, forearm, shin (116,117)], ultradian (harmonic) cycles of 12 and 8 hours [face and forearm (117)]. Transepidermal water loss revealed a bimodal circadian rhythm with two peaks located at 08:00 and 16:00 along with the 12 and 8 hour harmonics. The 8-hour cycle also was detected for sebum excretion. The 12- and 8-hour signals were not detected for measurements of skin capacitance, pH, or temperature (117). Although not specifically reported by the authors, an 8-hour harmonic is apparent in the control record from the transmeridian (Chicago/Cologne) diurnal excretion pattern of 17-hydroxycorticosteroids [see Ref. (118), Fig. 1, top chart].

Autonomic Rhythms (Frequency Range 0.66/h to 30/min; 0.0004 to 0.5 Hz)

In 1942, using simultaneous pneumoplethysmographic of the tips of the fingers and toes and the posterosuperior portion of the pinna, Burch et al. (119) were able to differentiate five types of pressure waves (pulse wave, respiratory wave, and α , β , and γ waves) and obtain relative quantification of the contribution of each signal to that of the total waveform. In later work (120), these signals are attributed to the pulse, respiration, the 0.1 Hz oscillation [α , associated with the baroreflex and often referred to as the Mayer wave (121,122)], and a signal at about 0.02 Hz [β , associated with the thermoreflex (9,123)]. The γ wave varied in frequency from 1 to 8 per hour, with a mean value of 40 minutes (119); it has no assigned physiological function. (One half-cycle of this wave can be seen as the baseline slope in Figure 11.7.) Considering the plant Kingdom, the NADH oxidase activity of soybean plasma membranes oscillates with a temperature-compensated period of 24 minutes (124).

The 0.1 Hz oscillation exhibits the same frequency range as the cranial rhythmic impulse (CRI) and exhibits a characteristic sinusoidal waveform (Fig. 11.1) that may be determined through a wide range of instrumental methods: Plethysmography (119), photoelectric plethysmography (123), transcranial bioimpedance (125,126), NADH fluorescence and reflectance spectrophotometry (127,128), functional MRI (129,130), infrared (from acupuncture needles) (131), ultrasound (132,133), cranial bone movement (125,134), pulsatile (2 MHz) echo-encephalography (135), and including the sphygmometry of Louisa Burns (see Ref. 136, last figure, p. 59). Of particular importance among these studies are those involving brain cortical reflectance, where the oscillation was recorded in the absence of blood flow (127,128). Imaging of scattered and reflected light from the surface of neural structures can reveal the functional architecture within large populations of neurons. These techniques exploit, as one of the principal signal sources, reflectance changes produced by local variation in blood volume and oxygen saturation

related to neural activity. It was found that a major source of variability in the captured light signal was a pervasive 0.1 Hz oscillation (137). Our work utilizing flowmetry to assess the signals in this band in the context of cranial osteopathy is presented below under the heading, "Osteopathic Manipulative Medicine and the Traube-Hering-Mayer Waveform."

With respect to the baroreflex in cardiac physiology, two mechanisms are invoked to explain rhythms of arterial pressure and RR interval occurring between 0.003 and 0.05 Hz (β signal, 0.18 to 3/min); the first of these is thermal regulation. This signal can be entrained by very-low-frequency thermal stimulation (such as alternating immersion of the arm in warm and cold water) (138). Based upon such data, Hyndman (138,139) suggested that they reflect thermoregulation, and Eckberg (140) agrees. There are no published data, however, to indicate whether human core temperature fluctuates spontaneously at these frequencies.

In a second proposed mechanism, RR interval rhythms are modulated by the renin-angiotensin-aldosterone system (141). Angiotensin-converting enzyme blockade augmented these RR rhythms in postinfarction patients (142); similar results were obtained using healthy volunteers (143). The incitant cranial manipulative procedure of bilateral temporal bone rocking specifically augments the low-frequency signal at 0.1 Hz (8). During the CV-4 procedure, the 0.1 Hz signal is suppressed until the still point is achieved. Upon release by the physician, this signal rebounds to levels significantly greater than that determined for the pre-treatment control (144). "This response to CV4 as measured by the laser-Doppler flowmeter was mirrored in the changes seen in heart rate variability" [from poster (145)]. Heart rate variability calculated from the ECG and the cardiac component of the flowmetry record demonstrated a correlation of 0.97 ($P < 0.00$, reflecting flowmetry's ability to detect RR interval with accuracy. The "Traube-Hering component of the laser-Doppler-flowmetry wave (0.08 to 0.15 Hz), when compared with the low-frequency component of ECG/heart-rate-variability (0.08 to 0.15 Hz), demonstrated a correlation of 0.712 ($P = 0.00$); this reflects simultaneous changes between the Traube-Hering component of the laser-Doppler-flowmetry wave and heart rate variability" (146). The RR interval also is entrained by the circadian rhythm (147), and is modulated by the liver (63,148) and kidney (63) peripheral clocks, blood pressure (83), and NO synthesis (84). (More under "Entrainment.")

Power spectral analysis of the RR interval in heart rate yields two prominent and well-characterized signals, the low-frequency domain signal (0.08 to 0.12 Hz) and the high-frequency domain signal (0.23 to 0.27 Hz). These signals provide an index of cardiac vagal activity (149). For example, after 15 days bed rest in a 6-degree head-down tilt position ($N = 8$ subjects), the spectral power of both signals was reduced approximately 50% ($P = 0.012$ and 0.017), with essentially no difference in the ratio of low- to high-frequency signals, which is an index indicative of cardiac sympathetic activity ($P = 0.49$) (150). The authors concluded that prolonged head-down-tilt bed rest reduced cardiac vagal activity, while changes in cardiac sympathetic activity were indistinguishable.

In a spectral power analysis involving systolic pressure, RR interval, and capillary blood flow, the prominent signal in this spectral band was found to lie in the region between 0.05 and about 0.2 Hz (3 to 12/min, centered at 0.1 Hz) in subjects having a resting breathing rate of 18/min (0.25 to 0.35 Hz). One hypothesis explains this signal as representing a simple cause-and-effect arterial baroreflex mechanism. A competing hypothesis attributes this signal to a "resonance," with the periodicity dictated by the time constants of norepinephrine release, vascular responses, and dissipation of vascular effects. The *frequency* of this signal does not

appear to entrain with circadian or ultradian rhythms; however, the signal's *amplitude* does follow a circadian oscillation (147). Note that with borderline hypertensive subjects, the 0.1-Hz wave is shifted to lower frequencies (0.084 Hz/d) and displays a marked circadian frequency modulation (0.075 Hz, night). The lowered frequency observed with borderline hypertensive subjects is indicative of an increased risk for developing essential HT (151).

The influence of three types of breathing (spontaneous, frequency controlled [0.25 Hz], and hyperventilation with 100% oxygen) and apnea on RR interval, photoplethysmographic arterial pressure, and muscle sympathetic rhythms was determined (152). Coherence among the detected signals (0.05 to 0.5) varied as functions of both frequency and time. The mode of breathing did not influence these oscillations, and they persisted during apnea. The data document the independence of these rhythms from the respiratory activity and suggest that the close correlations that may exist among arterial pressures, RR intervals, and muscle sympathetic nerve activity at respiratory frequencies result from the influence of respiration on these measures rather than from arterial baroreflex physiology. The results indicated that correlations among autonomic and hemodynamic rhythms vary over time and frequency, and, thus, are facultative rather than fixed. We, however, do not agree with this interpretation but consider signal coherence a regulatory mechanism that if disrupted stimulates network components to create corrective responses.

Feedback loop mechanisms for generating the 0.1-Hz oscillation independent of *zeitgeber* regulation from the cerebral cortex fail to address the work of Dóra and Kovách (127). Their observed slowing of cortical oscillations (observed using fluorometric techniques directly assessing the cortex) by pentobarbital resembled the effects of barbiturates on cortical P_{O_2} and blood flow oscillations described by others (153,154). This suggests an underlying energy-dependent mechanism. The occasional absence of blood volume cycles during *persistent* *cyt aa₃* redox fluctuations (in unanesthetized cats), and the complete postbarbiturate abolition of blood volume oscillations during *continued persistent* cortical *cyt aa₃* oscillations, "strongly suggest that the cyclic increases in cortical oxidative metabolism represent the primary oscillatory process, followed by reflex hemodynamic changes." (128). Our prejudice is that there exists a 0.1-Hz oscillator and that it is located in the brain, perhaps in the SCN. Moreover, it is the amplitude of this signal and its dispersion that may be affected by cranial manipulation, but not its central frequency. Yet, although there is strong evidence for a central oscillator as the generator for the 0.1-Hz oscillation, there also is strong evidence supporting a resonance phenomenon (155,156) in the baroreceptor reflex loop (157). The matter, therefore, must be considered unresolved as of this writing.

Neurons, Impulse Trains (Frequencies up to 30 Hz)

The EEG record may be used to produce a plot of brain electrical activity, which in its simplest form is displayed as a time-domain plot of energy (voltage) as a function of time. The data also may be processed into two-dimensional brain plots or transformed via a FT procedure, into frequency-domain plots analogous to that presented in Figures 11.10 and 11.13. The raw EEG is usually described in terms of frequency bands: delta < 4 Hz; theta, 4 to 8 Hz; alpha, 8 to 12 Hz; beta, 12 to 36 Hz, and gamma >36 Hz. These bands, which represent the summed output of brain electrical activity at the position on the skull of the sensing electrode, can be used to assess the functional state of the brain and to document pathologies.

Employing the above EEG system of bands, Wernitz et al. (158) demonstrated that relative changes of electrocortical activity have a direct correlation with changes in relative nostril dominance (the nasal cycle). In this cycle, the efficiency of breathing alternates predominantly through the right or the left nostril with a periodicity ranging from 25 to greater than 200 minutes. A relatively greater integrated EEG value in one hemisphere correlates ($P < 10^{-6}$) with predominant airflow in the contralateral nostril, establishing an interrelationship between cerebral dominance and peripheral autonomic nervous function.

Crosstalk between EEG bands, manifested as phase entrainment and amplitude modulation, has been documented (159). When low-frequency visual stimuli are presented at an appropriate rate, the low-delta band EEG oscillations of the cortex [~ 1.3 Hz (160)] entrain to the low-frequency stimulus, and the higher cortical frequencies (30 to 70 Hz gamma-band neuronal oscillations that appear integral to visual attention) are modulated in phase with the low-frequency band. A key functional property of these oscillations is the rhythmic shifting of excitability in local neuronal ensembles. It has been demonstrated (159) that when the stimuli are in a rhythmic stream, the delta-band oscillations in the primary visual cortex entrain to the rhythm of the stream, resulting in increased response gain for task-relevant events and decreased reaction times. Through hierarchical crossfrequency coupling, the delta phase also determines momentary power in higher-frequency activity. Consequently, cells become most excitable at the times when the stimulus is expected.

Regarding neuronal network processes, such as perception, attentional selection, and memory, gamma oscillations of the hippocampus split into distinct high- and low-frequency components that differentially couple to inputs from the medial entorhinal cortex, an area that provides information about an animal's current position, and a hippocampal subfield essential for storage of such information. These two types of gamma oscillation occur at different phases of the theta rhythm and mostly on different theta cycles. The results suggest routing of information as a possible function of gamma frequency variations in the brain and provide a mechanism for temporal segregation of information from different sources (161).

Thirteen examples of regular SCN cellular oscillations are shown by van den Pol and Dudek (162) in their treatise on communication within the SCN. Their Figure 3A illustrates a regular period of 100-ms pulses obtained from SCN slices. By contrast, calcium-induced oscillations in these same tissues exhibit a period of about 20 seconds, while glutamate induces calcium waves having a period of about 35 seconds.

Bendor and Wang (27) demonstrate the existence of neurons in the auditory cortex of marmoset monkeys that respond to both pure tones and missing fundamental harmonic complex sounds having the same fundamental pitch, providing a neural correlate for pitch constancy. These pitch-sensitive neurons are located in a low-frequency cortical region near the anterolateral border of the primary auditory cortex, and this finding is consistent with the location of a pitch-sensitive area identified in humans (163).

The Cellular Envelope (Frequency ≥ 1.6 kHz)

Cellular movements are generated at the molecular level by protein molecules that convert chemical energy into mechanical work (36). Prominent examples are the linear (164,165) and rotational motors (166) of eukaryotic cells. The linear motors are specialized to work by interacting with paired filaments of the cytoskeleton. Myosin motors generate motion along actin filaments, while kinesin and

dynein motors move along microtubules (164,165). In certain situations, cells can generate oscillatory motion. The periodic motions of cilia and flagella are examples of such mechanical oscillation. The common structural feature of these cilia and flagella is the axoneme, a well-conserved machine composed of microtubule doublets organized in a cylindrical fashion. The activity of the dynein molecular motors coupled to the microtubules leads to periodic bending deformations and waves. Note that these waves are motions at the molecular level, very small relative to the macroscale of ordinary objects, so their frequencies can be expected to be very high.

The cellular wall of living *Saccharomyces cerevisiae* (baker's yeast), the only organism for which the vibration of the cellular envelope has been measured, oscillates at 1,600 Hz on the high end of its frequency range [range: 0.8 to 1.6 kHz (11)]. This is a fundamental oscillation at the level of a single cell; it is energy dependent and can be blocked by metabolic inhibitors. The magnitude of the forces observed suggests that concerted nanomechanical activity is operative in the cell. The authors believe "The observed motion may be part of a communication pathway or pumping mechanism by which the yeast cell supplements the passive diffusion of nutrients and/or drives transport of chemicals across the cell wall."

The plasma membrane of the animal cell ought to behave similarly, although its fundamental frequency could be considerably greater, since the animal cell is not constrained by a rigid cell wall. The spring constant of the animal membrane is approximately 0.002 N/m, that of the yeast 0.06 N/m, a difference of 30-fold, which conceivably could permit an oscillation as high as 54 kHz for the animal membrane, only 10-fold less than the commercial AM radio band. This cellular oscillation is an excellent candidate for an endogenous zeitgeber at the cellular level. It resides at the high end of the biological spectrum, which is an excellent position for a reference frequency, particularly if cellular membrane oscillations may be entrained, as in "brainwave synchronization," increasing net signal power. But that is another story (167).

The Integument as Antenna (Frequency Gigahertz)

Sweat ducts are capable of picking up 100-GHz radiation, the extremely high-frequency range lying between microwaves and terahertz radiation (168). This antenna behavior arises from the helical shape of the ducts. The ducts, which are filled with an electrolyte, act like coils of wire, that is, an inductance that resonates with radiation across the millimeter and submillimeter wavelength band. This helical antenna array makes skin a kind of biological metamaterial, in which the array's response to electromagnetic radiation is determined by physiological structure rather than composition. The spectral response has been correlated to physiological stress (see Ref. 168, Fig. 5).

ENTRAINMENT

Entrain: To mount a movement. Webster's: the process of carrying along or over (169). And what is carried along? Information is carried along.

Oscillations in Biological Communications

The scientist thinking about observations makes productive use of quiet time. In 1665, the Dutch physicist and inventor of the pendulum clock, Christiaan Huygens, was confined to his room by a minor illness. With nothing to do, he observed two of his clocks that were suspended by a common support and noted that they were locked in perfect synchrony and remained that way. Even if one was

stopped and restarted out of phase with the other, synchrony would be regained shortly. Only if they were relocated to opposite sides of the room could the lockstep of their pendulums be disrupted. Thus was initiated a subbranch of mathematics: Theory of coupled oscillators. The Universe has ample examples of coupled oscillators: The realm of biology is particularly so (10). In the life sciences, in phenomena observed in medicine, oscillators appear to communicate through three basic modes: synchrony, commonly referred to as entrainment; modulation, our familiar AM and FM radio; and timing or phase.

Entrainment

Entrainment (synchrony) is what Huygens observed, oscillators in lockstep. The oscillators in this coupled system have the same frequency and the same phase. (They are each at the same point in their cycle. Imagine a wall full of identical clocks, each with its pendulum making the same angle with its clockwork, the wall, and the floor.) Groups of cells in local tissue clocks tick this way.

Should one cell fall off the pace, small corrective forces bring it back into synchrony at the mean frequency of the aggregate, the center-band output. How well the cellular aggregate does this is reflected in the amplitude and dispersion of the output signal at the mean frequency of the clock.

Amplitude (the power of the signal) is a measure of the strength of each component signal and the number of component signals in the aggregate. Further, it is a measure of signal dispersion, that is, how close is the frequency of each component oscillator to the mean frequency? And, additionally, how close is the phase of each oscillator to the mean phase of the aggregate? (They are at the same frequency, exactly, but have they fallen behind or are they running ahead, i.e., where on the circumference of a circle do they lie, and how close to the resultant vector do they lie?) The closer the component frequencies are matched AND the closer the component oscillator phases are matched, the greater will be the signal power at the center-band frequency and the narrower will be the signal width at half-height. [See the luminescent algae figure of Ref. 10, also digital entrainment with fireflies (170).] Regulation, that is, entrainment, is easy to observe in a power spectrum (120,141): A regulated signal rises well above the background noise, is narrow relative to the other signals in its band, and, at the apex of the signal, exhibits a well-defined frequency. Poorly regulated signals, by contrast, exhibit low signal to noise, are broad, sometimes to the point of being undetectable. Their center-band frequency may be difficult or impossible to locate or may exhibit multiple peaks (fine-structure). Such characteristics indicate loss of control, or decoupling of the coupled oscillators. These traits are exhibited by the respiratory (signal 3) and heart rate (signal 4) frequency peaks in Figure 11.1.

Coupled oscillators may exhibit continuous-wave (analog) properties, such as circadian cycles, digestive cycles, or low-frequency blood pressure (Traube-Hering) waves, or they may be pulsatile (fireflies, crickets chirping, neurons communicating via action potentials). Southeast Asian fireflies actually synchronize after individual flies begin flashing using a random-flash pattern. Subsequently, the male fireflies are entrained by their mutual light emissions to about three times every two seconds (170). Mathematically, continuous systems are easier to deal with than pulsatile systems; however, there now are mathematical tools for dealing with both systems (171).

Tissue Entrainment

A consensus is emerging that every living cell has a clock. This intrinsic clock times cellular events. Further, it can be entrained,

that is, reset, by a signal (physical, chemical, or electrical) external to the cell. Cells organized into tissues may mutually entrain themselves to generate an output signal of amplified power for the purpose of regulating an organ or set of organs. Such cells in the tissues of higher organisms may be entrained by the cellular milieu, which is external to individual component cells but internal to the organism. All cells can be entrained by the ecosystem in which they or their parent organism resides. The ecosystem signal may act directly on individual cells, for example, light through a transparent zebrafish juvenile, or indirectly through a signal transducing system, such as the photoreceptors and neurons of optical tissues in vertebrates. Moreover, bacteria have now been genetically engineered to coordinate their molecular timepieces (172). Cells in tissues also can be entrained by other signal generating tissues. Thus, our thermal regulating system and our blood pressure follow our circadian clock, and the RR interval in heart rate can be entrained by respiration.

Modulations, Mechanisms for Communication

An oscillating (periodic) wave can be varied in order to convey a message. For example, the sound of a trombone (the carrier wave form) may be varied in volume (amplitude), timing (rhythm, beat), and pitch to convey a musical message that is detected by our ears and processed by our brains. Ordinarily (but not necessarily always), a high-frequency sinusoid waveform, usually the highest frequency in any system, is used as a carrier signal. The three (key) signal parameters of amplitude ("volume"), phase ("timing"), and frequency ("pitch") are modified through interaction with a (usually) lower-frequency information signal to obtain the modulated signal. On the receiving side, a demodulator performs an inverse operation on the modulated signal to retrieve the original information. The information can be high or low frequency, coherent or incoherent in phase or not, and analog or digital in format.

In amplitude modulation, the frequency of the carrier waveform does not change but its strength varies with the modulating signal. Arterial pressure is modulated by the RR interval (140). In cranial treatment, manipulation amplifies the 0.1 to 0.2 Hz waveform in bloodflow velocity (8,144,173).

In frequency modulation, the strength of the carrier wave remains constant but the frequency of the carrier wave is changed. An identified 21% change of frequency of the 0.1 to 0.2 Hz waveform in bloodflow velocity (120,174) and heart rate variability (141) are examples of frequency modulation.

Phase modulation, which is modulation of the timing of the onset of a waveform with respect to a second waveform of the same amplitude and frequency, also is of considerable interest. The best example in biology is the phenomenon of jetlag, which involves resetting the phase of the circadian rhythm with respect to the destination's meridian following long-distance jet travel (175,176). The phase shifts of human biological rhythms observed in aircrews operating transoceanic routes are well documented (118,175–178); measurements have been recorded of sleep, fatigue, EEG, EMG, temperature, ECG, urine constituents, catecholamines, as well as outcomes records, including self-ratings, performance evaluations, sleep logs, and the Stanford Sleepiness Scale (179).

In digital modulation, a digital bit stream of either equal length signals or varying length signals modulates an analog carrier wave, and there are a multitude of digital modulation techniques. In a *hypothetical* scenario, nerve axon impulse trains could modulate the kHz signal of the cell membrane. We are not aware of any documented example of digital modulation in biology. The phenomenon, however, is possible, and, further, it would not be restricted to

communication within a single organism, since the kHz frequencies of cell membranes are high enough for effective long-distance communication through empty space. Perhaps outliers like that reported in Michie and West (167) should be reconsidered with new experimentation.

Crosstalk Among Oscillators

Circadian rhythm is entrained externally by the daily LD cycle, a geological zeitgeber (3,4,28,80). Circadian rhythm in turn modulates ultradian rhythms, including the low-frequency rhythms of cardiovascular physiology. Normal cardiac sinus arrhythmia demonstrates circadian modulation as does digestive physiology involving liver, pancreas, and gastrointestinal rhythms. It is of interest to note that cellular level oscillations occur at, and are linked to, low-frequency vascular rhythms (127–129,180,181). Ultradian rhythms with similar frequencies entrain, and thereby amplify, one another. Low-frequency cardiovascular rhythms may be entrained by respiratory rate (122,182–184), including singing and chanting (185,186) and rhythmic postural change (9,187), including Tai Chi Chuan (188).

In vertebrates, the genesis of essential biological rhythms as widely separated in frequency as circadian and cardiac rhythms demand stability, yet the population of multiple local oscillators that generate these rhythms, the cells of an organ, for example, may be dispersed in intrinsic frequencies. This raises the question of how the constituent oscillators interact so that a stable population rhythm emerges. The evidence shows that, even outside the intrinsic frequency range of individual oscillators, a periodic input across a wide frequency range can produce a stable population rhythm. This feature arises from interactions at the single oscillator level, which with their intrinsic frequency spread confers the population with metastability for rhythm genesis (19).

In a study of 10 musically trained and untrained subjects where breathing was correlated to the rhythmic beat of a melodic line, the “data advance(d) the following hypothesis: musical rhythm can be a zeitgeber, with its ability to entrain respiration dependent on the strength of its signal relative to spurious signals from the higher neural centers that introduce noise into the central pattern generator. Tapping reinforces the zeitgeber, increasing its signal-to-noise ratio and thereby promoting entrainment” (185). (Also, see Ref. 189.)

A lower-frequency oscillation (*ca.* 0.02 Hz, 1.2 cpm) detected in arterial blood pressure also has been measured through skin-surface blood flowmetry (120) and photoelectric plethysmography (123). Kitney was able to entrain this signal (plethysmography of the right hand) through a hot-cold stimulus administered to the contralateral (left) hand (see Ref. 123, Fig. 2), thereby changing the signal's frequency and amplitude and also markedly reducing signal dispersion (signal spreading and multiple fine-structure). Entrainment could be accomplished only when the stimulus frequency lay within a short range of 0.02 Hz. In addition to demonstrating thermoentrainment (123), this experiment suggests that the natural signal at 0.02 Hz is linked with temperature regulation mechanisms, an interpretation that is consistent with previous work (190).

A Primary Reference Oscillator

It is known that circadian rhythm is linked closely to activity within the SCN (162,191,192). Visual stimulus, LD sensation, is transmitted from the retina to the SCN of the hypothalamus, to the upper thoracic intermediolateral cell column and from there through the superior cervical ganglion to the pineal (67). The daily LD cycle entrains the somewhat longer inherent circadian rhythm

(28), and at least one input pathway for light-entrainment proceeds through the p42/44-mitogen-activated protein kinase (MAPK) cascade of the SCN. The MAPK signal transduction pathway is a potent regulator of numerous classes of transcription factors and has been shown to play a role in neuronal plasticity (193).

The clock for low-frequency (0.1 to 0.2 Hz) cardiovascular oscillations appears to be located in the nucleus of the tractus solitarius linked to the baroreceptors innervated from the upper thoracic region. Whether these rhythms emanate from their respective zeitgebers or are the result of complex entrainment and modulations from multiple source signals is a subject of significant debate (19,120,127,128,154–157,194). Current thought appears to favor the complex multisource origin in a holistic matrix organized according to a hierarchical model in which neurons of the SCN of the hypothalamus may drive the central circadian clock and all the other somatic cells (195), thus linking everything from circadian (and probably even slower rhythms) to cellular level oscillations at least as high as that demonstrated from the yeast cell wall.

Individual cellular clocks in the SCN, the circadian center, are integrated into a stable and robust pacemaker with a period length of about 24 hours. The clock ticks via synchronization of clock gene transcription across hundreds of neurons (192). How the clock regulates cellular functions is being worked out. It is known that in the mouse, the core mechanism for the master circadian clock consists of interacting positive and negative transcription and translation feedback loops (196). In *Drosophila*, despite the central role for the transcriptional regulator protein dTim, the relevance of another protein, mTim, remained equivocal; however, knockdown of mTim expression in the rat SCN disrupted SCN neuronal activity rhythms and altered levels of known core clock elements (197). Thus, the complete regulator consists of a zeitgeber and transmission proteins that carry the clock's timing signal to other elements in the cell's regulatory machinery. Moreover, the activity of these is further regulated through phosphorylation-dephosphorylation reactions (198) and the reduced or oxidized state of nicotinamide cofactors (199).

Circadian clocks produce output signals in order to impose their rhythms on organism behavior. These signals are controlled by the genetic machinery and have been identified as peptides or proteins. In *Drosophila*, the peptide PDF (for pigment-dispersing factor) was identified because of its resemblance to a peptide called pigment-dispersing hormone, which drives a daily rhythm of color changes in some crustaceans (200). Using mutant mice, Cheng et al. (191) showed that a cysteine-rich protein, prokineticin 2, secreted from the SCN, controls physiological and behavioral processes.

An early review by van den Pol and Dudek (162) provides background for research in the circadian zeitgeber and the means for intercellular communication in the SCN, including calcium spikes in presynaptic dendrites, ephaptic interaction, paracrine communication, glial mediation, and gap junctions; their Figure 3 is particularly valuable for showing the signals for intercellular communication and their relative time scales. For a review of the functional properties of the cellular circadian clocks of nonmammalian vertebrates, see Ref. 201.

As mentioned previously, the crystal structure of the central clock protein, KaiC, at the heart of the cyanobacterium clockwork has been determined as having a number of key residues involved in regulating KaiC phosphorylation status and circadian period (89). (For an overview, see Ref. 90.)

Multiple Oscillators

Entrainment (synchrony) of frequency occurs when two nonlinear oscillatory systems are coupled and operating at close but different

frequencies (9,123,137,138); the coupling causes the two oscillators to lock into a common frequency. The THM oscillation has been entrained utilizing rhythmic alteration of body position (9), exposure to fluctuating temperature (123), and respiratory activity (9,122,182,183). Entrainment of THM has been accomplished using baroreceptors and vasomotor reflexes; the lower limit of the entrainment bandwidth is 0.0841 (SD 0.0030) cycles/s and the upper limit is 0.1176 (SD 0.0013) cycles/s (202). Entrainment of the THM by the respiratory rate specifically occurs over the same frequency range of 5 resp/min (0.083 cycles/s) to 7 resp/min (0.12 cycles/s) (184). Although cranial manipulation involves more complexity of intervention than merely modulating the primary (cellular) respiratory mechanism (PRM)/CRI, the concept of oscillatory entrainment offers an interesting explanation for this one aspect of treatment, as has been proposed by McPartland and Mein (203).

Breathing rate is modulated by musical tempo (204); no other aspect of music appears to be relevant. "Even short exposure to music can induce measurable and reproducible cardiovascular and respiratory effects, leading to a condition of arousal or focused attention that is proportional to the speed of the music and that may be induced or amplified by respiratory entrainment by the music's rhythm and speed" (204). The effect appears to be independent of preference, or repetition, or habituation, and is clearer when the rhythmic structure is simpler.

The gestalt of an orchestral performance, however, goes far beyond the musical demands of the score. "How interval, melody and harmony act on the emotions is central to our understanding of music." Moreover, there are data to suggest that affective and cognitive processing of music might involve different neural pathways (205). (See Ref. 189 for a comprehensive treatise on the subject of musicophilia.)

It really is a very odd business that all of us, to varying degrees, have music in our heads. If Arthur C. Clarke's Overlords were puzzled when they landed on Earth and observed how much energy our species puts into making and listening to music, they would have been stupefied when they realized that, even in the absence of external sources, most of us are incessantly playing music in our heads (189).

In examining daily rhythms in sleep and waking performance, Dijk and Schantz (206) state, "in the absence of externally imposed LD and social cycles, sleep-wake cycles remain consolidated but desynchronize from the 24-hour day (external desynchrony). This loss of entrainment is accompanied by a dramatic change in the internal phase relationship between the sleep-wake cycle and the body temperature rhythm. The sleep-wake cycle shifts approximately 4 to 6 hours later, and most sleep initiations now occur at the body temperature nadir rather than before the temperature nadir. This change in the internal phase relationship suggests that separate oscillators drive the sleep-wake cycle and body temperature rhythm. The phenomenon of spontaneous internal desynchrony, during which the sleep-wake cycle oscillates with a period much longer or shorter than the rhythms of core body temperature, urine volume, and other physiological variables, provides stronger evidence for the existence of multiple oscillators."

Consider this musical relationship between rhythm and temperature. Birdsong has a precise, hierarchically organized structure that provides a look into the central control of motor neuron timing. A direct link between the clock of the premotor nucleus HVC (high vocal center) in zebra finch songbirds and the rhythm components of its song has been demonstrated by manipulating the biophysical dynamics in different regions of the forebrain (207). The clock signal may be slowed by cooling the HVC of the brain.

This cooling then slows the bird's song, thus linking temperature with rhythmic timing. Song tempo, syllable duration, and intervals between motif onsets are lengthened with cold; however, the stereotypical acoustic structure is not cold sensitive.

This idea of multiple oscillators is supported by a study of baroreceptor denervation (decerebrated cats), where sympathetic nerve discharge contains a prominent 10-Hz rhythmic component. The 10-Hz signal is ubiquitous to postganglionic sympathetic nerves with cardiovascular targets (e.g., heart, forelimb vasculature), and the 10-Hz discharges of these nerves are strongly correlated. It is has been proposed "that rather than arising from a single source, the 10-Hz rhythm is generated by a system of coupled brain stem oscillators, each targeting a different end organ." (208) The 10-Hz signal is interpreted as arising from an unrecognized form of phase walk in which the participating oscillators remain strongly coupled (208).

Other systems oscillate in a manner analogous to that of circadian systems but at different frequencies and for different purposes. In the nematode *Caenorhabditis elegans*, for example, proteins regulating the molting cycles of postembryonic development oscillate on a cycle of every 6 hours (209). In mice, cortical gamma oscillations (20 to 80 Hz) are generated by synchronous activity of fast-spiking inhibitory interneurons, with the resulting rhythmic inhibition producing neural ensemble synchrony (210).

Mathematical Models

Mathematical models describing mechanisms for intercellular communication have been developed. Li and Goldbeter (211) formulated a square-wave (pulsatile) model for intercellular communication and have analyzed the response to various types of stimulating systems (stochastic, chaotic), including the optimal periodic signal maximizing target cell responsiveness (34,212). In a hysteresis-based model, global transcription or translation rates have only small effects on the period; however, changes in these rates alter the signal amplitude (213).

Soto-Treviño et al. (20), using a model of the lobster pyloric pacemaker network, addressed the problem of coupling compartments that in isolation are capable of producing very different oscillations. At the neuronal network level, the model was used to explore the range of coupling strengths for which an intrinsically bursting neuron drives a tonic spiking neuron to burst synchronously with it. The model was tested and compared with the performance of isolated preparations of the stomatogastric nervous system of the spiny lobster *Panulirus interruptus*. The examples presented illustrate that neuromodulation can effectively modify neuronal network behavior.

Synthetic Genetic Oscillators

At the level of genes and proteins, positive and negative feedback loops of interacting molecular systems generate sustained oscillations, where it is possible to achieve a widely tunable frequency at near-constant signal amplitude (94). An engineered, synthetic tunable genetic oscillator in *Escherichia coli* has been created (95). The oscillator's modeled-network architecture contains linked positive and negative feedback loops. Oscillations in individual cells were monitored through repeated cycles using the fluorescence from incorporated yemGFP (monomeric yeast-enhanced green fluorescent protein) gene protein. The experiment demonstrated that the key design principle for constructing a robust genetic oscillator is a time delay in the negative feedback loop, which can mechanistically arise from the cascade of cellular processes involved in forming a functional transcription factor.

Apoptosis (Programmed Cell Death)

Apoptosis appears to be a universal feature of animal development, and abnormalities in it have been associated with an array of diseases, including certain cancers and neurodegenerative pathologies. In plants, it is essential for development and survival, including xylogenesis, reproduction, senescence, and pathogenesis (214). Employing two different sequential developmental stages, exponential growth and polynomial death, the process can be modeled by incorporating a parametric approach for exponential growth and a nonparametric approach based on the Legendre function (Legendre polynomial order 3) for polynomial death. The model was validated by a real example in rice (215) and should be universally applicable.

Cardiovascular-Respiratory Control/Congestive Heart Failure in Humans

A model of the cardiovascular-respiratory control system, incorporating constant state equation delays and the use of Legendre polynomials for feedback control, has been formulated (216). The model was used to study the transition from the awake state to stage 4 (NREM) sleep for normal individuals and for individuals suffering from congestive heart problems. The model steady states are consistent with observation both for the normal and the congestive heart state conditions. [Use of Legendre polynomials for feedback loop models (217,218) and for random regression modeling of longitudinal (time-dependent) data (219).]

Reviews

These literature citations refer to reviews focused on biorhythm frequency bands (10,34,36,38,110,138,156,162,169,201,220–223). Published mathematical models used to describe specific systems are given in these citations (20,34,36,80,123,137,138,171,224,225). Osteopathic concepts clearly have a place here, particularly those treatments that incorporate oscillatory mechanisms (7,144,187,194,203).

Other Work Related to Biological Communication through Rhythms

Viewed as valuable by the authors of this chapter is the article on entrainment of the Earth's ice ages through frequency modulation of the Earth's orbital eccentricity (226). The documentation of this phenomenon demonstrates that frequency modulation represents a powerful regulatory mechanism, not only for radio transmissions, but also for the vast periods of geological time and most assuredly for all frequencies lying between these extremes.

The exceptional continuity that occurs among different cells, tissues, and organs when responding coherently to a set of stimuli as a function of self/species survival is appreciable. Coherent response alludes to a central rhythm that resonates throughout the cell and that is capable of synchronizing a diversity of physiological processes into a functional biological unity. It is probable that this rhythm exists for both prokaryotic and eukaryotic cells. Collectively, this resonance for the subphylum Vertebrata is hypothesized to emanate as the craniosacral respiration (227). Experimental data suggest that, at least, the circadian cycling of energy metabolism is mediated by an activator of gene expression (228).

It is this that lies at the basis of all mechanical systems of healing, the setting up of increase or the checking of the vibratile impulses, the correction in the distribution of the normal vibrations sent out from the brain center of control and distributed by co-ordination from the different planes of center activity—Littlejohn (1).

MAGNETORECEPTION

When considering the regulation of organisms through oscillating phenomena, one additional aspect of communication physics needs to be considered: There is a sixth sense, magnetoreception, and this sense also can be expected to give rise to oscillating (magnetic) fields. There are at least two different mechanisms for intracellular magnetic detection (229): (a) The biological compass composed of magnetite crystal chains (230) that are present in many species from microorganisms through vertebrates. (b) The radical-pair mechanism (231), which is based on the cryptochrome protein, an intracellular entity that produces two possible intermediate states depending upon its orientation to the ambient magnetic field. Because cryptochrome is located in the retina, it has been proposed that it feeds information to the brain through the optic nerves. Such a system is analogous to the light-entrainment system of the circadian clock (28).

So, what will studies of magnetoreception reveal? Magnetite crystals are aligned along cellular microtubules, a position where they could efficiently modulate cell membrane oscillations. Thus, from what is known today, a system of biomagneto-communication certainly is physically possible.

OSTEOPATHIC MANIPULATIVE MEDICINE AND THE TRAUBE-HERING-MAYER WAVEFORM

As was pointed out at the beginning of this chapter, Littlejohn observed over one hundred years ago that human physiology is dynamic (1). Everything in life is changing with time, but not necessarily at the same rate. Holistically, human physiology may be considered in the context of waves upon waves upon waves (Fig. 11.1, top, trace a), wherein each independent vibrational frequency influences and is influenced by those frequencies above and below it. Within the broad spectrum of physiologic rhythms, one area is of particular interest to practitioners of osteopathic manipulative medicine, the frequency range from 0.003 to 0.50 Hz (0.18 to 30 cpm). In cardiovascular physiology, this range is subdivided, by spectral peaks, into very-low-frequency (0.003 to 0.05 Hz, 0.18 to 3.0 cpm), low-frequency (0.10 to 0.20 Hz, 6.0 to 12 cpm), and higher-frequency (0.25 to 0.50 Hz, 15 to 30 cpm) components (140). The very-low-frequency peak reflects autonomic (parasympathetic) and renin-angiotensin interaction. The low-frequency spectral peak is predominantly the result of sympathetic, baroreflex, activity. The activity in the higher-frequency area, pulmonary respiration, impacts the cardiovascular system through the interaction of the autonomic (parasympathetic and sympathetic) nervous system (141).

In osteopathic manipulative medicine, the PRM (232) is often monitored by palpating the CRI (233–237). The rate of the CRI, first measured by Woods and Woods in 1961 (238), has since been measured repeatedly, with a reported range of 2 to 14 cpm (0.03 to 0.23 Hz) (125,131,173,226,238–246). This frequency range encompasses the low-frequency peak between 0.10 and 0.20 Hz in cardiovascular physiology.

In the mid-19th century, activity in the 0.10 and 0.20 Hz frequency range was observed in blood pressure, independent of pulmonary respiration (247,248). This low-frequency rhythm has since been identified as Traube-Hering waves (249–251), as Mayer waves (122) or as THM waves (120). To avoid confusion, rather than using eponyms in the discussion that follows, the oscillations will be identified by their frequencies.

Oscillations in the low-frequency range of 0.10 to 0.20 Hz have been identified throughout human physiology: blood pressure

Figure 11-1 Top traces (a) and (b): (a) Waves upon waves upon waves; the time-domain record of a complete blood flow velocity record, demonstrating the heart rate waveform upon the low-frequency baroreflex waveform upon the very-low-frequency waveform. (b) Filtered record showing respiratory, low-, and very-low-frequency components only. **Bottom spectrum:** The FT, frequency-domain spectrum of waveform (a), demonstrating: (1) very-low-frequency signal component, (2) low-frequency signal component, (3) higher-frequency respiration signal, and (4) the heart rate spectral component.

(122,138,247,248), heart rate variability (122,252–254), pulmonary blood flow (250), peripheral blood flow (122,250,252,255,256), muscle sympathetic tone (254), cerebral blood flow and movement of the cerebrospinal fluid (126,148,251,255,257,258), and cerebral cortical cellular activity (128,129,180,181). Because these phenomena occupy the same frequency range as the CRI, it was decided to monitor that particular frequency in a known physiologic phenomenon to provide insight into cranial osteopathy.

Peripheral vascular manifestations of the low-frequency, 0.10 to 0.20 Hz, rhythm are readily measured by laser-Doppler flowmetry and may be recorded simultaneously with cranial osteopathic procedures. In the basic science protocols described below, where the low-frequency, 0.10 to 0.20 Hz, rhythm was monitored, a laser-Doppler perfusion monitor (Transonic Systems, Inc., Ithaca, NY) was employed to determine Doppler velocity of circulating blood that was then digitized for subsequent data reduction (WinDaq data acquisition and playback software).

This method provides time-domain records that may be obtained simultaneously with cranial diagnostic and therapeutic procedures. These records provide striking illustrations of what cranial practitioners have been describing for years. They lend themselves to the identification of the interaction between the practitioner and the subject and for determination of the rate of the CRI. The recorded bloodflow velocity record is the result of a very complex group of physiological processes with multiple contributing frequencies, resulting in waves upon waves upon

waves (Fig. 11.1, top, trace a). Because of this complexity, visually identifying where any given intervention actually has an effect is extremely difficult, if not impossible.

However, because these complex visual records are digital, the data may be converted mathematically through an FT (Fig. 11.1, bottom). This provides frequency-domain spectra that clearly identify the frequencies of individual spectral peaks (location on the x -axis), their power (height of any given spectral peak, y -axis) and dispersion, or irregularity, (width of a spectral peak measured at half-height) that result in the complex waves upon waves upon waves of the visual time-domain records. FT spectra may be filtered—spectral regions selected and then inverse FTs performed—to create time-domain records that focus upon the contribution of any spectral area to the observed time-domain record (Fig. 11.1, top, trace b). Frequency-domain records also may be analyzed comparatively to determine where in the complex waveform an intervention has had effect. This may be done by comparing the relative height of consecutive measurements of the same spectral peak. Or by subtracting one FT spectrum from another, and thereby calculating the changes that have occurred in frequency, power, and dispersion throughout the entire spectrum as a magnitude difference spectrum (Figs. 11.10 and 11.13).

These methods provide opportunities to study cranial osteopathy in the context of quantifiable aspects of human physiology through cutaneous bloodflow velocity. The following protocols were implemented by our group with able assistance, in the first protocol, from Celia M. Lipinski, D.O. and Arina R. Chapman, D.O. These studies, spanning a period from 1998 to the present, represent our attempt to quantify the CRI and demonstrate the effect of cranial manipulation upon the vibrations manifest in human bloodflow velocity.

The Research Protocols

Protocol 1: *Comparing low-frequency bloodflow velocity waves with cranial palpation* (120). First, it was appropriate to establish a correlation between the palpated CRI and the 0.10 to 0.20 Hz oscillation.

Twelve subjects participated in this study. With the laser-Doppler probe affixed to the subject's earlobe, they rested quietly on an Osteopathic Manipulative Technique (OMT) table. A baseline flowmetry record was then obtained. Next, an experienced examiner, blinded to the laser-Doppler record, monitored the CRI. As they palpated, they identified the CRI, saying "f" for flexion/external rotation and "e" for extension/internal rotation. At each verbal indication, an event mark (EM) was entered into the computer by the recording technician.

Figure 11.2 is the compressed laser-Doppler flowmetry time-domain records of two subjects. The palpation of the CRI is indicated by the vertical EMs on the right side of each record.

The flowmetry records for each subject were Fourier transformed and dissected, removing frequencies above 0.50 Hz. Inverse FT was performed on the remaining data, resulting in a time-domain record of frequencies below 0.50 Hz. This demonstrated that the dominant low-frequency wave phenomena apparent in the original flowmetry records represented the low-frequency, 0.10 to 0.20 Hz, wave and not harmonic aberrations from some other frequency (Figs. 11.3 and 11.4).

Of the 12 subjects, 11 provided data suitable for analysis. Six hundred thirteen low-frequency wave peaks (maxima) and troughs (minima) were visually identified. One hundred sixty-six flexion/external rotation events and 162 extension/internal rotation events

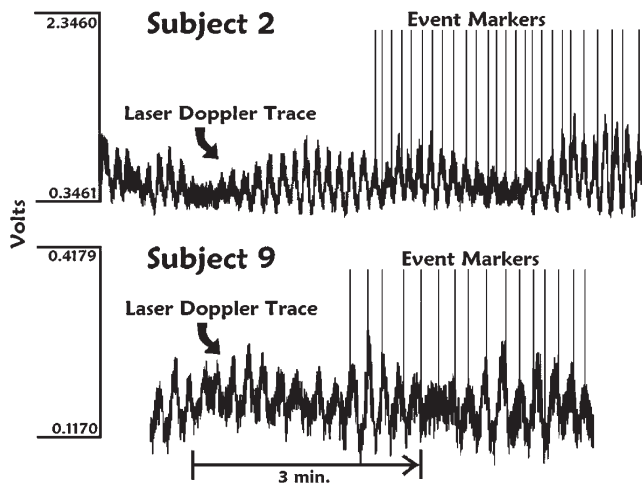

Figure 11-2 Compressed laser-Doppler-flowmeter bloodflow velocity (waveform) and flexion-extension records (vertical EMs) from two subjects.

($n = 328$) were identified. These were associated equally between low-frequency maxima ($n = 164$) and minima ($n = 164$).

There was no correlation between palpation (flexion/external rotation, extension/internal rotation) and the low-frequency wave maximum or minimum in the flowmetry record (Pearson R value, -0.085 ; approximate significance, 0.123). In further analysis, the time of each palpation event was compared with the time recorded for the nearest maximum or minimum in the flowmetry record. The paired t -test, in this case, showed *no statistical difference* between the flowmetry low-frequency 0.10 to 0.20 Hz wave record and the palpated CRI. With 328 data pairs, both groups of time values were highly correlated (correlation, 1.000 ; significance, 0.000).

Figure 11-3 Expanded laser-Doppler-flowmeter relative-blood-velocity record of Subject 2: **Top**—Flowmeter trace, revealing cardiac cycle fine-structure. The double-headed arrow indicates the wavelength of one low-frequency cycle. **Bottom**—Low-frequency waveform component only of the top trace. The bottom waveform was created from the top waveform by filtering (removing) the high-frequency cardiac component, leaving only the very-low-frequency, low-frequency, and respiratory components. Inverse FT of this digitally filtered data generates the bottom trace. Both traces are in register with respect to time, and the event markers indicate the positions of the palpatory findings.

Figure 11-4 Inverse FT time-domain spectra from Subject 2: Top trace, all frequency-domain data used in the inverse computation; bottom spectrum, only the frequency component lying below 0.5 cycles/s (30 cycles/min) used. The bottom spectrum is the trace resulting from very-low-, low-, and respiratory frequency contributions. The insert box shows that portion of the FT frequency-domain spectrum used to compute the inverse very-low-, low-, and respiratory frequency spectrum.

Even though over the length of the recording the low-frequency, 0.10 to 0.20 Hz, waves demonstrated a frequency modulation of up to 20%, the palpation events precisely mirrored the oscillating flowmetry wave.

Discussion of Protocol 1: This study demonstrated that the CRI and the low-frequency, 0.10 to 0.20 Hz, bloodflow velocity waves are concomitant phenomena. The bloodflow velocity waves demonstrated a frequency modulation of up to 20% that was precisely mirrored by the palpation record. This frequency modulation also was reported by Lockwood and Degenhardt in their analysis of Frymann's 1971 data from instrumental measurement of the CRI (174,259).

The flowmetry records and FT of the data contained within them consistently demonstrate contribution from the very-low-frequency (0.003 to 0.05 Hz, 0.18 to 3.0 cpm) and low-frequency (0.10 to 0.20 Hz, 6.0 to 12 cpm) components. These frequencies in bloodflow velocity are remarkably consistent with the "slow tide" (six cycles in 10 minutes) and the "fast tide" (8 to 12 cpm) of the PRM as described by Becker (260) (Fig. 11.5).

Figure 11-5 Waves upon waves, flowmetry record demonstrating the contribution from the very-low-frequency (0.003 to 0.05 Hz, 0.18 to 3.0 cpm) and low-frequency (0.10 to 0.20 Hz, 6.0 to 12 cpm) components. These frequencies in bloodflow velocity are remarkably consistent with the "slow tide" (6 cycles in 10 minutes) and the "fast tide" (8 to 12 cpm) of the PRM as described by Becker (260). Inset shows the low-frequency wave with the heartbeat upon it.

Additionally, it is of interest to note that the palpated CRI in this study was consistently palpated, such that ratio of the CRI to the low-frequency (0.10 to 0.20 Hz) oscillations was 1:2 (Fig. 11.2). This relationship was recognized retrospectively when additional flowmetry records were analyzed to measure the rate of the CRI (see *Protocol 5*) (Fig. 11.13).

Protocol 2: *Affecting low-frequency bloodflow velocity waves by cranial manipulation* (7). When the palpable CRI and low-frequency, 0.10 to 0.20 Hz, bloodflow velocity oscillations were demonstrated to be temporally concomitant, the question then arose: Does cranial manipulation exert an effect upon the low-frequency oscillations?

Twenty-three subjects were randomly divided into control ($n = 13$) and experiment ($n = 10$) groups. The laser-Doppler probe was affixed to the subject's earlobe. Subjects rested quietly on an Osteopathic Manipulative Technique (OMT) table. A baseline flowmetry record was obtained, followed by cranial manipulation (experimental group) or sham intervention (control group). The sham intervention consisted of 5 minutes of cranial palpation using a biparietal modification vault-hold. Subjects in the experimental group received an individually determined cranial treatment, applied until a therapeutic endpoint was achieved (5 to 10 minutes). Immediately following the sham or manipulative intervention, a 5-minute postintervention laser-Doppler recording was acquired. During the entire process the subjects, in both groups, remained on the treatment table; the laser-Doppler recording was continuous and the probe was undisturbed.

FT was performed upon the pre- and postintervention flowmetry records of each subject. Four major component signals from the flowmetry records were analyzed: very-low-frequency signal (0.003 to 0.05 Hz), low-frequency signal (0.10 to 0.20 Hz), higher-frequency, respiratory, signal (0.25 to 0.50 Hz), and the cardiac signal (1.0 to 1.5 Hz). Preintervention and postintervention data were compared for both the control and the experimental groups (Fig. 11.6).

For the control group, the very-low-frequency signal decreased to an almost significant degree ($P = 0.054$) while the low-frequency ($P = 0.805$), higher-frequency ($P = 0.715$) and cardiac ($P = 0.511$) signals showed no statistically significant changes. The experimental group showed a significant decrease of the very-low-frequency signal ($P = 0.001$) and an increase of the low-frequency signal ($P = 0.021$). The higher-frequency ($P = 0.747$) and cardiac ($P = 0.788$) signals showed no significant changes.

The effects of the cranial treatment seen in Figure 11.6, although visually exceptional, are consistent with changes induced in all of the subjects. Figure 11.7, a compressed continuous flowmetry record (~30 minute duration), demonstrates the progressive organization resulting from the increased low-frequency wave activity readily seen from the end of the treatment period through the posttreatment period.

Discussion of Protocol 2: This study demonstrated that cranial manipulation, specifically directed at cranial patterns of individual

Figure 11-6 Laser Doppler blood flow recording of two individuals, before and after cranial manipulation.

Figure 11-7 Continuous flowmetry record of approximately 30-minute duration. Although the record is greatly compressed to afford visualization of it in its entirety, the progressive organization resulting from the increased low-frequency wave activity can be readily seen from the end of the treatment period through the post-treatment period. The bottom tracings are the contributions to the flowmetry record from very-low-, low-, and respiratory frequencies before and after manipulation.

subjects, affected bloodflow velocity oscillations. The amplitude of the very-low-frequency (0.003 to 0.05 Hz) wave decreased and that of the low-frequency (0.10 to 0.20 Hz) wave increased. It is of interest to note here that cranial manipulation has been demonstrated to exert a comparable effect upon similar frequency oscillations (0.08 to 0.20 Hz) in intracranial fluid content as measured by transcranial bioimpedance (258).

Because the low-frequency wave in bloodflow velocity is mediated by sympathetic, baroreflex, activity (141), cranial manipulation can be inferred to affect the autonomic nervous system. Additionally, since the control palpation did not greatly affect bloodflow velocity oscillations, control palpation may be used as a sham treatment in future research.

Protocol 3: *Affecting low-frequency bloodflow velocity waves on demand* (8). Since individually determined cranial manipulation changed bloodflow velocity, it was decided to see if an affect could be obtained on demand, using palpation only, alternating with incitant bitemporal rocking. This alternating palpation and manipulation sequence was continued for a total of 35 minutes (maximum recording time for an uninterrupted laser-Doppler record). To eliminate the possibility that there might be an independent oscillation in bloodflow physiology, two different time sequences were decided on for the protocol. Five- and seven-minute intervals, both divisible into 35, were chosen. The timing of the treatment/nontreatment sequence was established for each subject before the initiation of the protocol.

Fifteen subjects participated. The laser-Doppler probe was placed in the midline on the subject's forehead. It was felt that the previously used ear site was too close to the temporomastoid region (area being manipulated) and could therefore be directly affected by the intervention.

The subjects rested upon the Osteopathic Manipulative Technique (OMT) table with their heads upon the practitioner's hands in position for the manipulative procedure. A baseline bloodflow velocity record was obtained. Following this, incitant bitemporal rocking was performed synchronous with the subject's CRI. The manipulation was stopped and, without changing hand placement, a period of cranial-palpation-only followed. This alternating sequence continued uninterrupted for the maximum laser-Doppler recording time.

Figure 11.8 shows the compressed, 35-minute long, flowmetry records for two subjects treated with cranial manipulation at

Figure 11-8 Compressed laser-Doppler-flowmetry, relative blood velocity waveforms, of two subjects treated by cranial manipulation at designated 5-minute (Subject 1) and 7-minute (Subject 2) intervals. EM indicate points in time when cranial manipulation started and stopped.

5-minute (Subject 1) and 7-minute (Subject 2) intervals. EMs identify where cranial manipulation was started and stopped. Expansion of the first and third nontreatment/treatment pairs of the flowmetry record for Subject 1 (Fig. 11.9) clearly shows the low-frequency (0.10 to 0.20 Hz) wave and the amplifying effect upon it resulting from incitant manipulation.

Using FT, the very-low-frequency, low-frequency, higher-frequency and cardiac rate, signals were identified to determine which changed. Signal intensities as a function of the respective component's frequency are plotted in Figure 11.10 for Subject 1: third nontreatment segment (top), third treatment segment (center).

Figure 11.10 (bottom) exhibits the difference spectrum obtained by subtracting the data in Figure 11.10 (top) from the data in Figure 11.10 (center). It demonstrates that the incitant cranial manipulation increased the very-low-frequency signal and greatly increased the low-frequency signal. Additionally, the heart rate can be seen, from the resultant sinusoidal shape for the cardiac signal, to have increased from approximately 70 to 82 beats per minute.

Discussion of Protocol 3: This study demonstrated that incitant cranial manipulation could, on demand, alter the physiologic parameters of bloodflow velocity. The low-frequency (0.10 to 0.20 Hz) component increased most markedly and the very-low-frequency component (0.003 to 0.05 Hz) increased to some degree. These effects occurred within a few seconds and, in this instance, the flowmetry record returned to near-baseline levels within fractions of a minute after the intervention was stopped. FT analysis, however, revealed that the flowmetry record does not return precisely to baseline following intervention, rather it exhibits a small residual effect with a considerably longer half-life. This persistent residual amplification may, in part, account for the therapeutic effect of some forms of cranial manipulation.

Protocol 4: *Affecting low-frequency bloodflow velocity waves by Compression of the Fourth Ventricle (CV-4)* (144). Because incitant cranial manipulation affected the amplitude of the low-frequency

oscillations, it was decided to study the response to CV-4, a manipulative procedure that, during its application, is intended to dampen the CRI. CV-4 offers the advantage of having a specific starting point and a generally agreed upon physiologic end point, the still point. This endpoint is then reportedly followed by amplification of the CRI. This allowed us to measure the duration of time the CV-4 procedure was applied and any impact it had on bloodflow velocity.

Twenty-eight experienced cranial practitioners performed the CV-4, each with a different subject ($N = 26$; two subjects participated twice). One physician plus one subject at one treatment constituted one statistical case.

The physician sat at the head of an Osteopathic Manipulative Technique (OMT) table. The subject lying supine, with the laser-Doppler probe attached to the midline of their forehead, rested quietly for an equilibration period. A baseline record of 5 to 7 minutes, the Control (C) segment (Fig. 11.11, Control), was then obtained. During the Control segment period, no treatment was administered, but the subject's head rested upon the physician's hands in the appropriate position for palpatory diagnosis and treatment using CV-4. At the end of the Control segment, the physician was instructed to begin implementation of CV-4, and upon the treating physicians' indication that they had started, an EM was entered into the record by the technician (Fig. 11.11).

The Treatment (T) phase lasted until the physician indicated that they had obtained their therapeutic goal. At this point, a second EM was entered into the flowmetry record, indicating the end of the Treatment segment (Fig. 11.11, Treatment). The physicians removed their hands from contact with the subject's head, and the Response (R) to treatment was followed for an additional 5 to 7 minutes (Fig. 11.11, Response). Both treating physicians and subjects were blinded to operations at the computer console.

The duration of Treatment for the CV-4 procedure from the 28 individual records (Table 1) was computed by measuring the

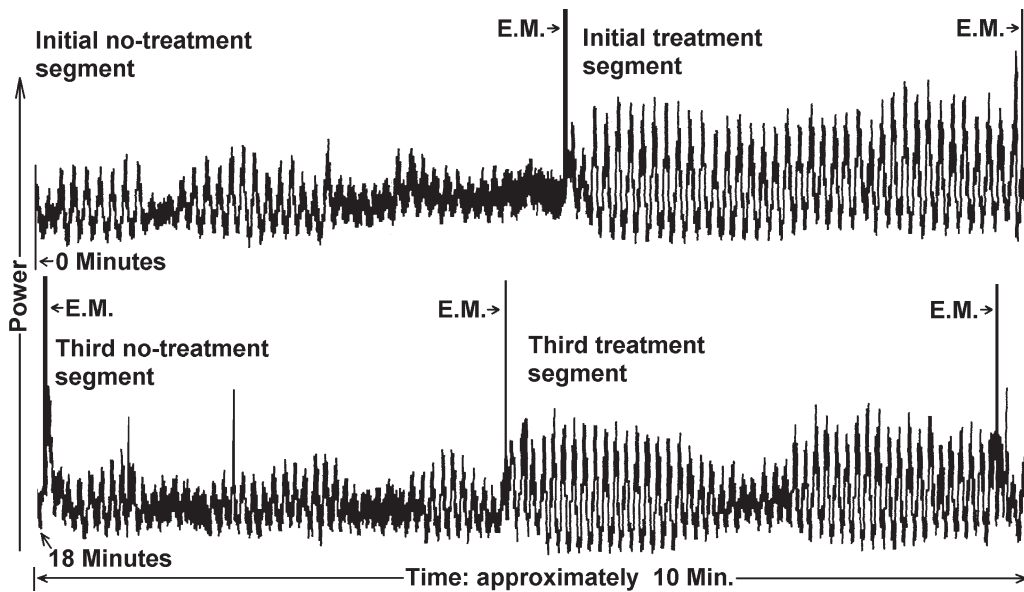

Figure 11-9 Expansion of the laser-Doppler flowmetry record of Subject 1 of Figure 8: The **top record** shows the initial resting segment followed by the first treatment segment; the **bottom record** shows the analogous segment pair beginning at 18 minutes, both records demonstrating that incitant cranial treatment amplifies the power of the low-frequency oscillation.

time elapsed on the flowmetry record between the first EM, when the physician started the procedure, and the EM indicating they had attained their therapeutic goal. The mean duration of Treatment was 4.43 minutes, range 8.65 minutes (minimum 1.42, maximum 10.07), a standard deviation ± 2.22 minutes, and a variance of 4.94. This duration is consistent with a published report of 3 to 7 minutes for CV-4 application (260).

The impact of the CV-4 procedure was then determined. Among the 28 CV-4 records obtained, high-frequency noise in 8 (29%) records made them unsatisfactory for data reductions and statistical analyses. The remaining 20 records, ranging from 15 to 24 minutes duration, were useable. Each of these records contained the three continuously linked segments (total waveform segments = 60) separated by the EMs. These segments (Fig. 11.11), the pretreatment resting period (Control), the CV-4 treatment period (Treatment), and the immediate response period (Response), were identified for intergroup comparisons. Within each segment, a 4- to 6-minute portion of the record was selected. The shortest of these segments, for each subject, was identified and its duration, to the nearest 0.01 second, noted. Portions of the remaining two segments, from that record, each of identical duration as the shortest segment, were extracted for FT.

FT spectra, for each of the segments, were then computed to generate 60 frequency-domain spectra (Fig. 11.12). Point-by-point subtraction, generating Control minus Treatment (C - T), Treatment minus Response (T - R), and Control minus Response (C - R) difference spectra, was then carried out (Fig. 11.13). The resulting difference spectra were plotted and then integrated to obtain spectral signal areas.

From these difference spectra, signal areas were computed from three signals in the low-frequency region. The 0.02 Hz signal represents physiological activity in the range of the very-low-frequency wave; the 0.10 Hz signal represents activity consistent with the low-frequency wave. A new minor signal, at 0.08 Hz, was resolved in flowmetry data but not reported in earlier work. Sufficient data at this point were accumulated verifying the existence of this minor resonance. Additionally, areas were computed from both the low- and the high-frequency halves of the cardiac signal (centered approximately at 1.10 Hz), and minimum and maximum frequency components of the cardiac signal were recorded.

To determine significance among the three groups (C - T, T - R, C - R) for each selected signal-area and frequency value analysis of variance was used. Seven scalar variables were considered: areas of the signals centered at 0.02, 0.08, and 0.10 Hz; areas of the lower-frequency and higher-frequency cardiac bands; and the frequencies at the maximum amplitude (either positive or negative) of both cardiac bands. Also evaluated were pair-wise comparisons between group pairs, using Scheffé, Bonferroni, Tukey, and Least-Significant Difference range tests (respectively, from most conservative).

Significant differences were identified for the minor signal at 0.08 Hz (sig. = 0.041) and the low-frequency signal at 0.10 Hz (sig. = 0.000). There was no significant difference for the very-low-frequency signal at 0.02 Hz or for any of the four cardiac signal variables. Using the Scheffé range test, significant differences were found only for the 0.10-Hz area variable at the alpha.05 level; however, the 0.08-Hz signal did exhibit parallel differences at the .072 level. Therefore, it is believed that both signals are affected together, and in the same sense, by the CV-4. The differences in significance between the two variables most likely reflect the much lower signal-to-noise ratio of the minor 0.08-Hz signal than fundamental differences in the behavior of each signal band with manipulation.

The variable that demonstrates the largest mean difference in response to CV-4 is the low-frequency area of the 0.10-Hz signal, where all three combinations, C - R, C - T, and T - R, are significantly different from each other.

Discussion of Protocol 4: This study demonstrated that the duration of the CV-4 was 4.43 ± 2.22 minutes, consistent with the previously published report of 3 to 7 minutes (260). During its application, bloodflow velocity was affected in a manner consistent with what would be expected from descriptions of the impact of CV-4 upon the CRI (234). As the occipital was held in extension to decrease the amplitude of the CRI, the low-frequency oscillation was damped and essentially eliminated when a still point was obtained (Figs. 11.11 and 11.13). The therapeutic impact of CV-4 is said to be increased amplitude of the CRI, which enhances the fluid motion of the PRM (234); following CV-4, the amplitude of the low-frequency wave in bloodflow velocity increases (Fig. 11.11).

Protocol 5: The Rate of the CRI (245). It is important to establish normative values when studying physiologic phenomena.

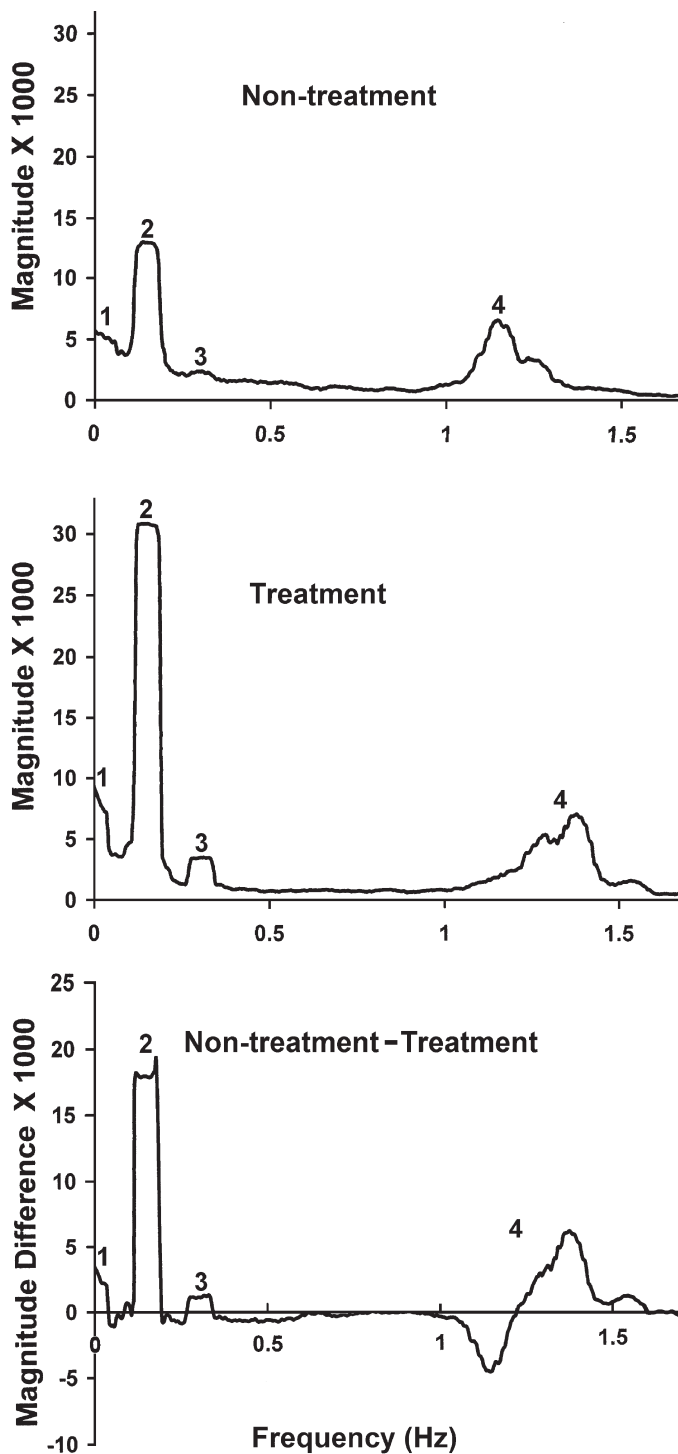

Figure 11-10 FT magnitude spectra: Plotted is component intensity as a function of component frequency for Subject 1: Third non-treatment segment (**Top**) and third treatment segment (**Center**), with the (1) very-low-, (2) low-, (3) respiratory, and (4) cardiac frequencies identified. **Bottom:** Magnitude difference spectrum obtained by subtracting the nontreatment spectrum from the treatment spectrum: In this difference spectrum, the pronounced signal enhancement of the low-frequency, 0.10 Hz oscillation (2) stands out. Also, the heart rate (4) increased from approximately 70 to 82 beats/min during cranial manipulation.

Figure 11-11 Real-time demonstration of the flowmetry record of a CV-4, consisting of a baseline bloodflow velocity record, the Control segment, the Treatment segment, and the posttreatment, Response segment. The EMs were entered into the record by the research technician upon verbal indication by the treating physician at the onset and culmination of treatment. The insets (1, 2, and 3) are representative segments (~2 minutes each) of the flowmetry record for each of the three segments of the procedure. Inset (4) is that portion of the record immediately before and following the still point.

Using laser-Doppler flowmetry in comparison to cranial palpation, we measured the palpated rate of the CRI. We further determined how clinicians palpate the CRI in comparison to the flowmetry record.

The CRI rate was determined from the records of 44 different examiners, each palpating a different subject. The examiners were experienced osteopathic physicians attending various professional meetings. Each palpated a different subject who was recruited randomly from attendees at the same meetings.

The laser-Doppler probe was placed onto one earlobe, and the subject then rested quietly on an Osteopathic Manipulative Technique (OMT) table. Examiners were seated at the head of the table. With a contact position of their preference, the examiners palpated their subject's CRI. As they palpated, they said, "f" indicating the perception of the flexion/external rotation and "e" indicating extension/internal rotation. At each verbal indication, an EM was entered into the computer by the recording technician. Continuous, unbroken records were recorded for each subject. The recording length, nominally of 5- to 15-minute duration, was determined by the examiner.

A portion of each record was selected for computation where the CRI was palpated consistently, without large "palpatory gaps." Calculating from 44 records acquired, the mean rate for the palpated CRI was 4.54 cpm, with a range of 7.26 (minimum 1.25, maximum 8.51). The standard deviation was 2.08, the standard error 0.313, and the variance 4.32.

The vast majority of examiners in this study palpated the CRI such that a flexion event was perceived coincident with one low-frequency oscillation and an extension event perceived coincident with the next low-frequency oscillation. This resulted in a ratio

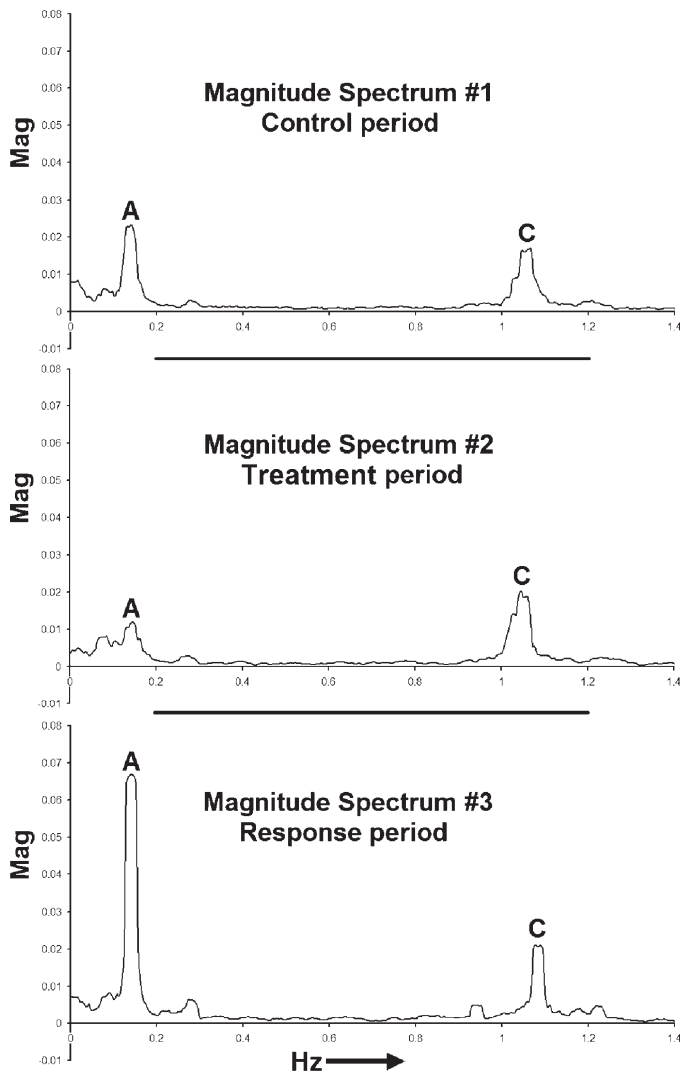

Figure 11-12 FT of each segment, (no. 1) Control, (no. 2) Treatment, and (no. 3) Response, of the CV-4 procedure, with the low-frequency (A) and cardiac (C) components indicated.

of palpated CRI to recorded low-frequency (0.10 to 0.20 Hz) oscillations of 1:2. (Fig. 11.14). It is worthwhile to note that infrequently an examiner palpated the CRI at a 1:1 ratio to the low-frequency oscillation (Fig. 11.15).

During flowmetry recording, irregularities were observed resulting in gaps in both the palpatory and the flowmetry records. In some instances, these gaps were recognized and reported by the examiners as “still points” (Fig. 11.16) (261).

Discussion of Protocol 5: This study provides a normative rate for the CRI and insight into previously unexplained discrepancies in its reported rate. Also, by observing the relationship between the palpated CRI and bloodflow velocity, an explanation may be advanced for the difficulties encountered when sequentially comparing palpated rates for the CRI for the purpose of establishing interrater reliability.

The rate of the CRI, first reported as 10 to 14 cpm (238), has remained the accepted rate in the majority of osteopathic textbooks (233–237). Review of the literature, however, reveals an interesting paradox. Studies using palpation tend to report lower rates for the CRI (240–244) than those obtained by instrumentation (125,131,174,239,258) (Fig. 11.17). This occurs independent of

Figure 11-13 Difference spectra comparing the component parts (Control, Treatment, and Response) of the CV-4 procedure, with the low-frequency (A) and cardiac (C) components indicated: (no. 1) Control minus Treatment, (no. 2) Treatment minus Response, and (no. 3) Control minus Response.

the type of instrumentation, such as plethysmography applied to the upper extremity (236), infrared light reflected from acupuncture needles implanted into the cranial bones of human subjects (131), retrospective analysis of data obtained by Frymann using a pressure transducer placed upon the head (173), and fluctuation of intracranial fluid content using transcranial electrical bioimpedance (125,258) (Fig. 11.17 and companion Table).

The palpated CRI rate in this study (4.54 ± 2.08 cpm, 0.04 to 0.11 Hz) is consistent with the lower rates obtained by palpation and reported by the majority of previous investigators (240–244) (Fig. 11.17 and companion Table 17). The inconsistency between palpation and instrumentation may be explained by the observation that the majority of examiners in the current study palpated such that a flexion event was perceived coincident with

Figure 11-14 Palpation of the CRI compared to the laser-Doppler blood flow velocity record. The top trace shows the low-frequency (LF) oscillation (oscillating trace) and the CRI (palpation of "flexion/extension," vertical EMs) in a 2:1 ratio. Bottom trace: Compressed flowmetry record demonstrating the 2:1 ratio. This is the most frequently encountered LF oscillation to CRI ratio demonstrated by skilled examiners.

one low-frequency oscillation and an extension event perceived coincident with the next low-frequency oscillation (Fig. 11.14). This resulted in a ratio of palpated CRI to recorded low-frequency (0.10 to 0.20 Hz) oscillations of 1:2. If instrumental measurement of the CRI tracks the dominant low-frequency oscillation, then the discrepancy between the palpated and instrumental measurements is explained.

There is, however, the issue of the higher palpated rate (10 to 14 cpm) consistent with the rates obtained by instrumentation, reported by Woods and Woods (238) and identified in osteopathic textbooks (233–237). Infrequently an examiner will palpate the CRI at a 1:1 ratio to the low-frequency oscillation (Fig. 11.15).

The difference between these palpation-to-flowmetry ratios may be explained by the observation from *Protocol 4* of the previously unreported 0.08 Hz (4.5 cpm) frequency wave in bloodflow velocity. The reported rate for the CRI in this study is 2.46 to 6.62 (4.54 ± 2.08) cpm, or 0.04 to 0.11 Hz. The low-frequency wave between 6 and 12 cpm (0.10 to 0.20 Hz) is twice as great. Thus, it may be concluded that the majority of individuals track the 0.04 to 0.11 Hz frequency while some individuals track the greater 0.10 to 0.20 Hz frequency.

It is worth noting here that an additional study (*Protocol 6*), using an entirely different method to measure the CRI rate, fully corroborates the findings of *Protocol 5* (246). This study provides a statistical *N* of 727 subjects, consisting of several smaller groups, from 16 to 86 individuals each, divided according to level of experience, that is, students with 1-year training, students with 2-year training and practitioners with 1 to 25 years of postgraduate experience. Participants palpated CRI rates on each other. Half of each group acted as examiners, while the other half were subjects. The examiners palpated the CRI using the classically described vault hold (233,234). They were not told how long they would be palpating, only to count the number of complete biphasic CRI cycles that they palpated during the acquisition period. The number of cycles each examiner reported was kept private so that no one was aware of the rates other participants reported. Following this, the pairs exchanged positions, and the protocol was repeated. The statistician

Figure 11-15 Bloodflow velocity record and CRI (palpation of "flexion/extension") in a 1:1 ratio.

Figure 11-16 Pause in the palpation record coincidental with a decrease in low-frequency oscillation amplitude. Several examiners have commented on the perception of a "still point" at such times, although they were blinded to the flowmetry record.

then computed the CRI rate in cycles/min for each recorded value by dividing the total number of CRI cycles counted per subject by the time in minutes allowed at each measurement session.

The mean reported CRI rate for the entire study (*N* = 727) was 6.88 ± 4.45 cycles/min. When the groups were subdivided and analyzed according to experience level, it is of interest to note that examiners with the greatest experience level palpated at a rate of 4.78 ± 2.57, a rate that is identical to the rate (4.54 ± 2.08 cpm) reported in *Protocol 5*.

Additional Observations: Variability in the Flowmetry Record: To date with more than one hundred and fifty blood flow velocity recordings obtained, certain additional observations regarding bloodflow velocities in the 0.003 to 0.50 Hz frequency range can be made. The frequencies of the various oscillatory contributions to the bloodflow velocity record are reliably constant in the frequencies that the component signals exhibit. The FT spectral peak of the very-low-frequency component (ranged between 0.003 and 0.05 Hz) is found consistently between 0.01 and 0.04 Hz, and the low-frequency spectral peak (ranged between 0.10 and 0.20 Hz) is found consistently between 0.10 and 0.17 Hz. The respiratory, or higher-frequency, spectral peak (0.25 to 0.50 Hz) is more variable, dependant upon the individual's respiratory rate. Despite this consistency, visibly distinctive variability occurs from record to record depending upon the degree to which the respective components contribute to the overall bloodflow velocity waveform. This results in visually recognizable patterns in the oscillations observed in the blood flow velocity record. Six flowmetry record subsets have been identified (Fig. 11.18) that are observed with reasonable frequency (264).

Three of these subsets exhibit a regular waveform that is easily recognized either in the original record or a record filtered using inverse FT. They differ in the amplitudes of the very-low-frequency and low-frequency signal components. In high-amplitude, strong-regular (sr) and intermediate-regular (ir) records, the regular waveform can be observed in the original record (Fig. 11.18, 1 and 2). In the weak-regular (wr) record, the regular waveform is masked by the high-frequency cardiac signal, which must be removed by filtering in order to observe the lower-frequency regular waveform (Fig. 11.18, 3) (262).

Flowmetry records in certain cases lack any visibly distinct low-frequency waves. CRI palpation of subjects exhibiting such a flowmetry record is often extremely difficult. Weak-irregular (wi) records are characterized by diminished very-low-frequency and low-frequency components (Fig. 11.18, 4). Often a relatively strong respiration signal also is present. Records with greatly diminished or undetectable low-frequency wave components are characterized as "low-baro" (lb) records (Fig. 11.18, 5) Excessive noise is the characteristic of high-noise (hn) records (Fig. 11.18, 6). This noise emanates from the subject. It is not an artifact of experimentation and cannot be removed by moving the probe to a new location (262).

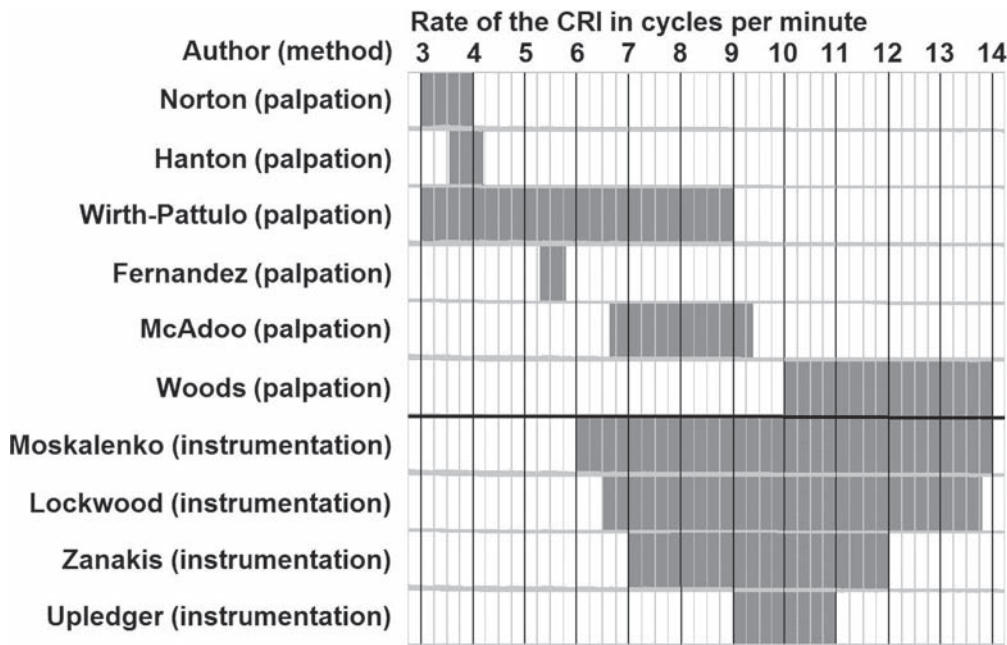

Figure 11-17 A graphic representation of quantified rates for the CRI reported in the literature over the past 45 years. It is of interest to note that (with the exception of Woods, 10 to 14 cpm) when palpation is employed to obtain data, the reported rate tends to be lower (3 to 9 cpm), while if data are obtained by instrumentation, of any type, the reported rate tends to be higher (7 to 14 cpm).

Figure 11-17 Companion Table Caption. Comparison of palpated and instrumental CRI rates.

Interrater Reliability: During flowmetry recording, irregularities were observed resulting in gaps in both the palpatory and the flowmetry records. In some instances, these gaps were recognized and reported by the examiners as “still points” (Fig. 11.16) (261) When calculating the rate of the CRI (144), it was necessary that portions of each record be selected where the CRI was palpated consistently, without large “palpatory gaps.” This was necessary because examiners often had difficulty consistently following the CRI. Additionally, it has now been noted, in two separate publications, that the CRI demonstrates a significant frequency modulation, which causes the rate to vary rhythmically approximately 20% (120,174).

Even if the issue of individual examiners palpating at 1:1 and 1:2 when comparing palpated CRI to the low-frequency oscillation in the flowmetry record is not given consideration, the irregularity of the palpatory records, the presence of still points, and the presence of a frequency modulation of 20% in the rate of the CRI will all contribute to such temporal variability in the sequential palpatory records of two individuals tracking the CRI that sequential interrater reliability becomes virtually impossible to establish. (This addresses the inability to demonstrate interrater reliability between sequential examiners but not between two examiners simultaneously palpating.)

Conclusions from the Above Six Protocols

From the protocols described, the following conclusions can be drawn:

1. Palpation of the CRI tracks identifiable frequencies in blood-flow velocity (*Protocol 1*).
2. The very-low-frequency (0.003 to 0.05 Hz, 0.18 to 3.0 cpm), low-frequency (0.10 to 0.20 Hz, 6.0 to 12 cpm) components of the flowmetry record, respectively, are remarkably consistent with the “slow tide” (six cycles in 10 minutes) and the “fast tide” (8 to 12 cpm) of the PRM as described by Becker (260) (*Protocol 1*).
3. Cranial palpation alone may be employed as sham treatment for research into the clinical impact of cranial manipulation (*Protocol 2*).

4. Cranial manipulation appears to exert effects upon baroreflex physiology (*Protocols 2 to 4*).
5. Cranial manipulation affects the low-frequency, 0.10 to 0.20, Hz signal, and to a lesser extent the very-low-frequency, 0.003 to 0.05 Hz, signal in bloodflow velocity and does so in a manner consistent with the type of manipulative procedure being employed (*Protocols 2 to 4*).
6. A signal of frequency 0.08 Hz (0.04 to 0.11 Hz) has been identified in the flowmetry record that is closely related to the 0.10 to 0.20 Hz signal. Both are demonstrated to be affected by cranial manipulation, in this case CV-4 (*Protocol 4*).
7. Although not everyone appears to be palpating the CRI at the same frequency, everyone tracks the 0.10 to 0.20 Hz signal, with the majority tracking at 0.04 to 0.11 Hz or one CRI cycle to two low-frequency bloodflow velocity waves (*Protocol 5*).
8. The nearly identical palpated rates for the CRI of 4.54 ± 2.08 cpm (*Protocol 5*) and 4.78 ± 2.57 cpm (*Protocol 6*) appear to indicate that the majority of experienced practitioners are tracking the 0.08-Hz (4.5 cpm) minor signal (*Protocol 4*).
9. A new normative range for the CRI of 2 to 7 cpm, as palpated by experienced examiners, has been identified (*Protocols 5 and 6*).

Human physiology abounds with oscillating phenomena in the low-frequency (0.10 to 0.20 Hz) range. Many of these phenomena can be directly or indirectly linked to oscillations in the autonomic nervous system, particularly, but not limited to, the sympathetic nervous system. The CRI, with reported rates ranging from 2 to 14 cpm (0.04 to 0.23 Hz), shares the spectral frequency band with these physiologic phenomena. It is naïve, therefore, to draw the conclusion that these measurable phenomena are the PRM, or even the CRI. They are not. But they are certainly linked to one another and offer points of access through which the elusive aspects of cranial osteopathy may be studied.

The above protocols represent only the beginning of the work that needs to be done. They provide potential explanation for the physiology underlying the PRM. The conclusions offered, although controversial to some, cannot be denied. Although the oldest

Figure 11-18 Observed flowmetry record subgroups: sr (47% of cases), ir (9%), wr (11%), wi (17%), low barrow (lb; 13%), and hn (3%). For each subgroup illustrated, the filtered trace (a), top, shows the oscillation created from only the very-low-, low-, and respiratory frequency components (below 0.5 Hz), and the bottom trace (b) shows the complete data record containing all component frequencies.

protocol involving flowmetry was published a decade ago, these studies have not, as yet, been replicated. It also must be acknowledged that these studies provide no clinical validation of cranial osteopathy. They address only basic science issues and offer no understanding as to how modulation of low-frequency physiological oscillations provides any therapeutic benefit. The door has been opened for further study.

CLOSING REMARKS

This chapter has looked at the entire frequency spectrum of oscillation that affects human beings, from milliseconds to millennia. Oscillation impacts all aspects of human life. The steady state, the position of equilibrium in any system, is subject to drift unless a corrective force is applied to oppose the drift. Oscillation is a process that regulates the drift of a system by constantly returning it to a point of equilibrium. Thus, it is advantageous for systems to

oscillate. Oscillation provides a stable regulator, a reference point. It is a means for maintaining a system at its normative level of activity.

Oscillations are, in fact, energy. They are NOT matter. They are transmitted by matter, and in the process they transmit information. That information is a product of the frequency and power of the oscillation. It is further enhanced by the interaction of the specific oscillatory frequency with that of other oscillations. The strength of an oscillation may be augmented by entrainment with other oscillations of appropriate frequency. The resultant synchrony increases the power of the communicating frequency.

Frequency defines an oscillation's position within any given (frequency-domain) spectrum. It is a function of the rate of the regulated processes. Oscillation is a form of communication. The power of the communicating oscillation can be transferred to other frequencies through appropriate modification, that is, the various modes of modulation. Modulation is the result of communication among interacting frequencies.

The timing or phase of a given oscillation can enhance or negate another oscillation. To the degree that two oscillations are in phase, the power of the resultant oscillation will be augmented (or diminished).

A guitar string, in of itself, makes no sound until energy is provided by plucking the string. The string then oscillates at the frequency that its length, diameter, and tension dictate. This in turn excites the surrounding air that carries the waveform to your ear from where the information from the energy of the waveform is transmitted to your auditory cortex to be interpreted. The complexity of the message may be increased by simultaneously, plucking several strings to form a cord, and by sequentially playing cords to produce a tune. When several variations of that tune are provided by many musical instruments, a symphony results.

This simple example applies to all waveforms in all the ways that the laws physics permit their interaction. Oscillations all carry information and are subject to synchrony, modulation, and phase. They interact with other oscillations with resultant harmony or dissonance. Thus, it has been said, "The order of music is a bastion against chaos" (263). It may be an oversimplification, but health can be seen as harmony among physiological oscillations and disease as dissonance (264). As Littlejohn pointed out (1):

It is this that lies at the basis of all mechanical systems of healing, the setting up of increase or the checking of the vibratile impulses, the correction in the distribution of the normal vibrations sent out from the brain center of control and distributed by co-ordination from the different planes of center activity.

Practitioners of manual therapeutics are aware of the significance placed upon oscillatory rhythms in several aspects of osteopathic theory and practice. Certainly, the low-frequency oscillation of the CRI immediately comes to mind (144). In this paradigm, the incitant procedure of temporal rocking and the intentional dampening of the rhythm with CV-4 are both examples of therapeutic control of a biological oscillation. Fulford's percussion hammer is another such example. This device vibrates in the range of the frequency of middle C on the piano (262 Hz) and is proposed to affect fascial dysfunction (265). (Middle C is the major sixth relative to A at 440 Hz.)

There are, however, many more examples that may not immediately spring to mind. Among the first therapeutic procedures taught to osteopathic students is the soft tissue stretching of the spinal paravertebral musculature. The student is taught to laterally

stretch the paravertebral soft tissues, to gently release them, and then to repeat the process. The aware student quickly realizes that there is a comfortable rate with which this procedure can be applied. One may have had a similar experience when performing rib raising or the pedal fascial lymphatic pump of Dalrymple. As Dr. Littlejohn indicated, the body will respond optimally when therapeutic manual procedures are applied rhythmically and at the proper frequency. Not just in the case of the examples here listed, but for essentially all types of manipulative treatment from cranial and indirect functional to direct articular and even high-velocity low-amplitude procedures. Additionally, the application of vibratory forces may be employed diagnostically, like sonar, that in skilled hands can pinpoint a locus of dysfunctional restriction (266).

When performing an examination of any tissue, after having read this chapter, should clinicians take the time of day into consideration because of the presence of the circadian rhythm? Is the patient hungry and their ultradian rhythms no longer synchronized with their circadian rhythms? Is their heart rate variability damped and no longer responding to their circadian or ultradian signals?

Contemporary medicine considers homeostatic parameters and defines pathology as existing outside of those parameters. As such, therapies are commonly directed at lowering or raising the abnormal average. There may well be a better way! As Dr. Littlejohn indicated, the body will respond optimally when therapeutic procedures are applied rhythmically and at the proper frequency. He proposed that the therapeutic effect of osteopathic treatment is through the use of the physiological frequencies to affect the oscillations that share those frequencies. Thus, it is proposed that osteopathic treatment entrains physiological phenomena replacing dissonance with enhanced power and harmonic resonance (1,194,203).

Anatomy and Physiology of the Lymphatic System

HUGH ETLINGER AND FRANK H. WILLARD

KEY CONCEPTS

- The lymphatic system removes fluid, particulates, and extravasated proteins from the interstitium, maintaining osmotic balance between the extracellular, intracellular, and intravascular fluids
- Inflammation is the generalized response of the body to injury or infection.
- Virtually all vascularized tissues have lymphatic capillaries that provide lymph drainage.

The extracellular fluid provides the environment in which cellular exchange of gases and nutrients takes place. Within these confines, intrinsic homeostatic mechanisms operate to maintain concentration gradients for cellular exchange. The lymphatic system plays an integral role in this process, removing fluid, particulates, and extravasated proteins from the interstitium, to maintain osmotic balance between the extracellular, intracellular, and intravascular fluids (Fig. 12.1). Overall, approximately 10% of intravascular protein and fluid volume “leak” out into the interstitial space each day and must be returned to the circulation via the lymphatics. Acute inflammation disrupts the homeostatic process in the interstitium and dramatically increases the burden on the lymphatic system. This chapter will review the anatomy and physiology of the lymphatic system, including the role it plays during inflammation and healing.

Inflammation is the generalized response of the body to injury or infection. It is a hallmark of most acute illness. Inflammation is perhaps most accurately viewed as part of a process by which the body defends against injury or infection and repairs the injured tissue. This process involves the vascular system, the immune system, and the nervous system, as well as the surrounding connective tissues. A wide variety of chemical mediators, produced locally and systemically, communicate between the cells of these systems, and control the progression of inflammation and healing. Continuous production and removal of these inflammatory mediators is essential for smooth and efficient progression and resolution of inflammation and healing. Delay in the removal of inflammatory mediators and exudates early in the process may result in prolonged inflammation with poor or delayed healing. Delayed removal of mediators later in the process may lead to a prolonged healing process, eventually leading to adhesions and/or fibrosis. The tissue drainage provided by the lymphatics offers an escape route for many of these mediators, as well as the inflammatory exudate, and plays a role in virtually every aspect of the inflammatory process. Understanding the factors influencing lymph formation and removal from tissue is critical to the Osteopathic diagnosis and treatment of any patient with an acute or chronic inflammatory process.

THE LYMPHATIC SYSTEM AND INFLAMMATION

Vasodilatation and increased capillary permeability occur early in the inflammatory process, and together are responsible for the tremendous influx of fluid and plasma protein into the interstitium of the inflamed tissue. This leaves a preponderance of red blood cells in the intravascular space, greatly increasing its viscosity, and potentially creating stasis of venules and capillary beds (Movat and

Wasi, 1985). The lymphatic system, therefore, becomes responsible for virtually all fluid drainage from inflamed tissues. The rate of blood supply, and the delivery of antibodies, centrally produced mediators, medications, and the oxygen and nutrients necessary to fuel cellular activities will be limited, or even determined, by the rate of lymph flow.

Normal venous drainage will be restored when capillary permeability returns to normal and the osmotic gradient between the interstitium and the vascular system permits sufficient fluid return to reduce the viscosity of capillary blood. Capillary permeability is controlled by a variety of endogenous vasoactive mediators, including histamine, bradykinin, and prostaglandin E. Although these mediators can be inactivated locally, there is evidence that lymph drainage also provides a means by which they are removed and/or inactivated. Bradykinin has been shown to be inactivated systemically by plasma (Hurley, 1984). Histaminase, responsible for 30% of histamine breakdown, has been identified in high levels in the thoracic duct (Atkinson, 1994). Prostaglandin E has been identified in the lymph effluent draining from inflamed tissues (Movat and Wasi, 1985). The relative importance of tissue drainage and other mechanisms in the inactivation of these mediators has not been elucidated. The osmotic pressure in the interstitium will change when proteins and other osmotically active particles are removed. Extravasated protein and large particulates cannot return via the venous system, even when capillary permeability is maximally increased (Hurley, 1984), nor is there any evidence that protein is catabolized in the interstitium (Aukland and Reed, 1993). It is therefore evident that the removal of protein from tissue depends heavily on the lymphatic drainage of the tissues.

Inflammation generates both local and central immune responses. Locally, chemotactic mediators draw neutrophils and monocytes to the area. Neutrophils release lysosomal enzymes into the interstitium that can kill bacteria, but can also be destructive to local tissues. They are responsible for much of the tissue damage that accompanies acute and chronic inflammatory processes. The tissue damage created by neutrophilic lysosomes can be similar to that caused by pancreatic enzymes. However, a recent study has suggested that the macrophage in combination with the lymphatic system may serve to blunt the effect of the neutrophil in chronic inflammatory diseases. As the inflammation progresses, the polymorphonuclear leukocytes (also termed PMNs) undergo apoptosis and the remains are ingested by macrophages in a manner that does not release lysosomal enzymes or provoke proinflammatory responses (Lawrence and Gilroy, 2007). If the PMNs are not phagocytized, they eventually undergo secondary necrosis, releasing their damaging lysozymes into the tissue. The ingesting macrophages

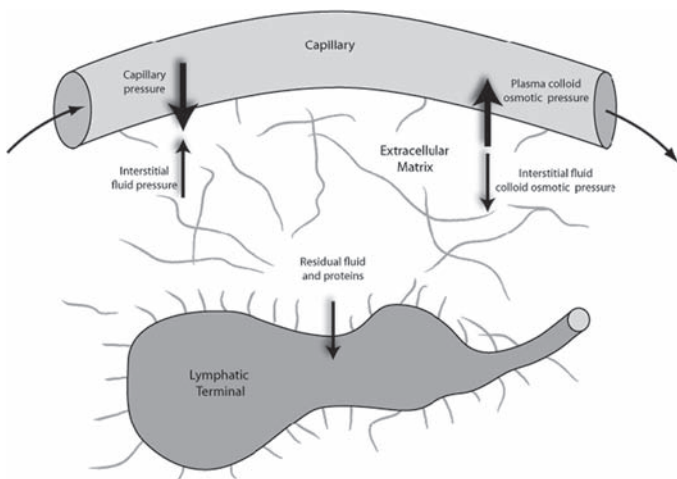

Figure 12-1 Tissue fluid homeostasis and the lymphatic system. Blood is passing from left to right in this capillary (small curved arrows). The high capillary pressure on the left side of the bed forces fluid and small proteins outward into the extracellular matrix (large downward arrow). Toward the right side of the bed, the oncotic pressure from concentrated proteins in the capillary blood draws fluid back into the capillary. Residual fluids and proteins are left in the extracellular matrix; these fluids pass into the terminal lymphatic vessels for reentry into the system circulation through the venous connections in the upper thorax.

must then be either removed from the tissue or themselves undergo apoptosis. Bellingan et al. (1996) have found most macrophages are removed via lymphatic drainage, implicating lymph drainage in another important aspect of resolving the inflammatory process.

Lymph drainage has been shown to dramatically reduce the tissue-damaging effects of pancreatic enzymes with obstruction of the main pancreatic duct in dogs (Witte and Witte, 1984). Neutrophilic lysosomes have been identified in lymph draining from inflamed tissues (Movat and Wasi, 1985). Drainage of these enzymes may be important in limiting their destructive effects on tissues.

Central immune responses involve stimulation of T-cells and B-cells by antigen in lymph nodes and other lymph organs. Delivery of antigen to these lymphoid organs occurs entirely by lymphatic drainage of antigen and antigen-containing macrophages from the site of injury. Weakening of antigenic stimulation has been demonstrated in chronic lymph stasis and lymphedema (Witte and Witte, 1984). Conversely, the B-cell response to immunization in medical students was increased by manipulating the rate of lymph drainage using the lymphatic pump technique (Measel, 1982).

Systemic responses to inflammation occur in the liver and brain. The proinflammatory cytokine interleukin-1 (IL-1) is involved in the stimulation of both of these organs. IL-1 stimulates the production of acute phase reactant proteins from the liver (Movat and Wasi, 1985). It has also been shown to reach circumventricular organs in the ventricular system of the brain, where it produces fever and stimulates the hypothalamic-pituitary axis (Dinarello, 1992). IL-1 is produced by monocytes and macrophages locally during an inflammatory process. Although there are systemic sources of IL-1 production, locally produced IL-1 has been shown to produce fever and stimulate acute phase protein production (Movat and Wasi, 1985). Locally produced IL-1 gains access to the systemic circulation via lymphatic drainage. Both prostaglandins and leukotrienes have been found in lymphatic drainage of inflamed tissues, and there is evidence that lymphatic drainage is involved

in the removal and inactivation of bradykinin and histamine. A variety of inflammatory mediators, including bradykinin, prostaglandins, leukotrienes, IL-1, and histamine, can stimulate primary afferent nociceptors (Levine et al., 1993), potentially resulting in hyperalgesia of the surrounding tissue. As these mediators are dissipated, the rate of depolarization of the primary nociceptors will remit, and inflammatory pain will be reduced.

The repair of injured or infected tissue proceeds as the acute inflammatory process resolves. Fibroblasts, which lay down the matrix of the scar tissue, are stimulated by the inflammatory exudate, as well as several complementary factors and cytokines. As the balance between proinflammatory factors and profibroblast forces shifts, the inflammatory process shifts to the healing phase. By continually clearing the interstitium of exudate, including inflammatory mediators, the lymphatics can allow this shift to occur more rapidly and smoothly. Should proinflammatory mediators remain in the interstitium, acute inflammation will persist, and healing will be delayed. The healing process resolves when the inflammatory exudate is removed, and fibroblast activity decreases. Persistence of the inflammatory exudate in peripheral tissue will lead to excess local scarring and fibrosis. Plasma proteins, when trapped in the interstitium, attract monocytes. Platelets, extravasated into the tissue, release growth factors such as epidermal growth factor, platelet-derived growth factor, and transforming growth factor β (TGF- β). The latter, TGF- β , helps in the conversion of monocytes to macrophages. These latter cells also release numerous growth factors including Fibroblast Growth Factor (FGF) and TGF- β , which attract and stimulate fibroblasts, eventually leading to fibrogenesis, which can contribute to tissue repair in the acute state as well as fibrosis of tissue in the chronic state (Witte and Witte, 1984; also see chapter 7 on the fascial system in this volume). Repeated experimental injection of plasma into soft tissue produced both chronic inflammation and scar formation (Witte and Witte, 1984). The lymphatics are the predominant means by which the inflammatory exudate is removed, and so are intimately involved in the progression and resolution of the healing phase of the inflammatory process.

The process of inflammation and healing is the body's response to injury and infection. The lymphatics play a role in every aspect of this process. In essence, the lymphatic system is responsible for maintaining an interstitial environment conducive to the rapid, unimpaired progression and resolution of this complex process.

There are several categories of disease processes which warrant a focus on the lymphatic system:

1. Chronic inflammatory diseases: These range from smoldering, subclinical infections such as osteomyelitis to autoimmune and collagen vascular diseases such as rheumatoid arthritis. Although most chronic inflammatory diseases are attributed to persistent inflammatory stimuli, there are suggestions that reduced lymph drainage may play a role. Weak antigenic stimulation of regional lymphocytes was found in experimental lymphedema (Witte and Witte, 1984). This finding was implicated in the susceptibility to infection that often complicates lymphedema. Increased lymph drainage from the site of infection should improve immune response and local circulation.

Rheumatoid arthritis is thought to occur as a response to immune complexes. These complexes, and the inflammatory exudate they produce, are removed by lymphatic drainage. The inflammatory exudate is responsible for the pain and tissue destruction associated with this disease. Increased lymph production and drainage from rheumatoid ankles has been demonstrated in humans; in addition, this drainage contained elevated levels of proinflammatory cytokines (Olszewski et al., 2001).

2. **Fibrotic diseases:** Progressive interstitial fibrosis is a characteristic of chronic lymphedema. The pattern and time course of the fibrosis produced by experimental lymphedema is strikingly similar to a variety of diseases, including cirrhosis, interstitial lung diseases such as silicosis, regional ileitis, and even atherosclerosis (Witte and Witte, 1984). Each of these diseases involves repeated inflammatory events with a progressive build-up of protein rich tissue fluid, influx of leukocytes, release of proinflammatory cytokines, and fibroblast stimulation, eventually leading to fibrosis. Postoperative adhesions, common in abdominal surgeries with peritonitis, or other massive inflammatory processes, may result from inadequate drainage of the abdominal exudates. Similarly, surgeries involving lymph node dissections or disruption of lymphatics, such as a modified radical mastectomy, may result in lymphedema from fibrosis and adhesions. OMT to promote lymph drainage early in these diseases may help prevent the development of these long-term problems.

ANATOMY OF THE LYMPHATIC SYSTEM

General Aspects

Virtually all vascularized tissues have lymphatic capillaries that provide lymph drainage, the only exceptions being the central nervous system, bone and bone marrow, the maternal placenta, and the endomyceum surrounding muscle fibers. Cartilage, the lens and cornea of the eye, the epidermis, and the inner portion of the walls of large blood vessels are not vascularized and also have no lymph drainage. The lymph system begins in the interstitial space of tissues with initial lymphatics, also termed terminal lymphatics, or lymph capillaries (Fig. 12.1). These coalesce into collecting channels, which drain into progressively larger prenodal or afferent vessels (Fig. 12.2). All lymph then passes through one or more lymph nodes, which filter and alter the lymph in a variety of ways before draining into larger postnodal or efferent trunks. These trunks ultimately return lymph to the venous system either via the thoracic duct on the left or the right lymphatic duct. Lymph from the lower portion of the body, as well as the left thorax and part of the left lung, the left arm, and the left side of the head and neck return via the thoracic duct. Lymph from the heart, all of the right lung and the right arm, right side of the head and neck and diaphragm drain to the right lymphatic duct (Fig. 12.3).

ANATOMY OF THE LYMPH VESSELS

Initial Lymphatics—Lymphatic capillaries are blind-ended terminals that end in interstitial spaces (Fig. 12.2). They comprise endothelial cells in a single layer, which contain no tight junctions, and are therefore permeable to large particles and proteins. Although their morphology differs in different tissues, there are notable similarities in anatomic microstructure that are critical to the function of these capillaries in lymph formation. Initial lymphatics consist of overlapping endothelial cells lacking tight junctions but contain anchoring filaments. Anchoring filaments are collagenous bundles that attach to the external aspect of the lymphatic endothelium and imbed into the interstitial matrix (Figs. 12.1 and 12.2). Their form and function are described in a series of articles by Leak (Leak, 1976, 1987; Leak and Burke, 1966; Leak and Jamuar, 1983). During situations of edema, anchoring filaments prevent the collapse of the initial lymphatics as interstitial pressure rises. These filaments also cause the lymphatic vessel to change shape and volume in response to tissue movement (Fig. 12.4). The overlapping endothelial cells are theorized to act as a “primary

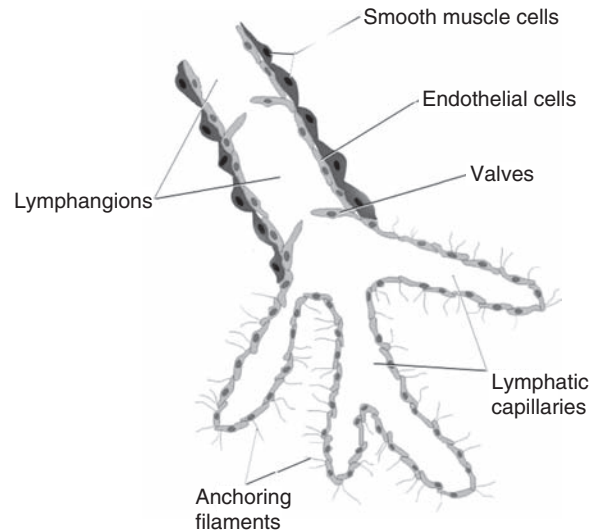

Figure 12-2 The cytoarchitecture of the terminal lymphatics. The terminal lymphatics or lymphatic capillaries are seen as endothelial-lined cul-de-sacs anchored into the surrounding extracellular matrix by small filaments. The endothelial cells overlap creating one-way valves allowing fluid in the ECM to leech into the terminal lymphatic but preventing back drainage. The terminal lymphatics lack smooth muscle walls. The collecting vessels begin at the first valve and have both smooth muscle walls and periodic valves derived from the endothelium. (Modified from L. N. Cueni and M. Detmar. *The lymphatic system in health and disease. Lymphat.Res.Biol.* 6 (3-4):109-122, 2008.)

valve system” that prevents reflux of fluid into the interstitium from the initial lymphatic (Mendoza and Schmid-Schonbein, 2003; Trzewik et al., 2001; Schmid-Schonbein, 2003). A recent study demonstrated the lack of adhesion molecules at the junction of the endothelial cells of the initial lymphatic, a structural feature necessary for this function (Murfee et al., 2007). In addition, the basement membrane of the terminal lymphatic is discontinuous, thereby facilitating the movement of fluid into the vessel (Witte et al., 2006). This arrangement provides for a one-way flow of lymphatic fluids from the extracellular space into the initial lymphatic vessels. It is important to note that these valves do not act as filters; thus, fluid moving into the lumen of the terminal lymphatic vessel has the approximate composition of extracellular fluid. Finally, lymphatic capillaries lack smooth muscle cells in their walls; thus, they are dependent on outside forces to both fill the terminal vessel and then expel lymph into the collecting vessels; this concept will be discussed further in the section on lymph formation. The discontinuous basement membrane, open interendothelial junctions, and the anchoring filaments all help to distinguish the terminal lymphatic from a capillary bed (Witte et al., 2006).

COLLECTING VESSELS

The initial lymphatic ends at the first bicuspid valve, which demarcates the beginning of the collecting vessel (Fig. 12.2). Collecting vessels develop a thin connective tissue layer to support the endothelium, and an increasing amount of smooth muscle, which is arranged in a woven mat surrounding the vessel and concentrated near the valves. The smooth muscle layer progressively thickens in a proximal direction and eventually the vessels develop a three-layer arrangement much like a small vein, with a tunica intima, media, and adventitia. Lymphatic vessels differ from veins in that they have far more valves in the vessels to prevent backflow. Lymphatic

Figure 12-3 The lymphatic system scheme. This diagram illustrates the overall distribution and flow patterns of the lymphatic system. (Taken from Basmajian JV. *Grant's Method of Anatomy*. Baltimore, MD:Williams & Wilkins Company, 1975.)

valves are bicuspid, collagenous, and attach so as to have their narrow end pointed in the direction of the lymph flow, that is toward the larger vessels (Fig. 12.5). They operate at low flow rates and, since the valve flaps are adherent to the vessel wall, are closed by retrograde fluid pressure. The vessel between the valves and the proximal valve constitute the “lymphangion.”

Figure 12-4 The mechanics of the terminal lymphatic vessel. An endothelial cell-lined blood vessel is seen above and a terminal lymphatic below. Fluid, particulates, and protein diffuse out of the vessel and into the extracellular matrix. From the matrix, these items can enter the terminal lymphatic vessel by passing through the small gaps in the endothelial lining. Due to the overlapping nature of these endothelial cells, back flow from the lymphatic into the matrix cannot occur. (Taken from Swartz MA. *The physiology of the lymphatic system*. *Adv Drug Deliv Rev* 50(1-2):3-20, 2001.)

Figure 12-5 The collecting vessel valves. On the left is a longitudinal view of the valve in a collecting vessel. On the right are cross-sections taken through the valve at three separate levels indicated by the horizontal lines. The leaflets of the valve are fused to each other and to the wall of the vessel. As one progresses up the valve, the fusion of the leaflets moves closer to the midline making it impossible for the valve to invert and thus producing one-way flow. (Taken from Swartz MA. *The physiology of the lymphatic system*. *Adv Drug Deliv Rev* 50(1-2):3-20, 2001.)

Lymph is passed through nodes before draining into larger postnodal vessels. The collecting vessels prior to the lymph nodes are termed the afferent (prenodal) vessels, while those draining the node are termed the efferent (postnodal) vessel (Fig. 12.6). Lymph nodes are encapsulated and contain sinusoids that allow the lymph to “percolate” through a large surface area of cells and vessels. This filtration system is the means through which antigens in the lymphatic fluid are trapped and immune responses are generated. Foreign particles are also removed by nodal macrophages via this mechanism. The lymph sinusoids are permeable to fluid and small particles. This provides an area for exchange between the lymphatic and the venous systems. Free water may travel down a hydrostatic gradient from lymphatics to the venous system, effectively concentrating postnodal lymph (Adair et al., 1982). This can improve the overall efficiency of the lymphatic system since removal of protein from the extracellular space is considered the primary function of the lymphatic system (Adair and Guyton, 1985). Increased venous pressure or congestion in the area of the nodes will interfere with this process, thereby increasing the resistance to lymph flow (Adair and Guyton, 1983; Aukland and Reed, 1993). Osteopathic treatment to decongest areas around nodes, such as the popliteal spread or pectoral lift, may help maintain the downward hydrostatic gradient between the lymphatic and the venous systems.

Postnodal or efferent vessels follow fascial planes, progressively moving toward the midline of the body, where they enter the mediastinum in either the abdomen, thorax, or cervical region. Eventually, the postnodal vessels drain into the right lymphatic duct or left thoracic duct. These large lymphatic ducts, such as the thoracic duct, are organized histologically like a medium-sized vein, except for the greater amount of smooth muscle and valves. Spontaneous, peristaltic contractions have been consistently observed in the thoracic duct of various species; the rate of these spontaneous contractions can be modulated by the sympathetic nervous system (Reddy and Staub, 1981).

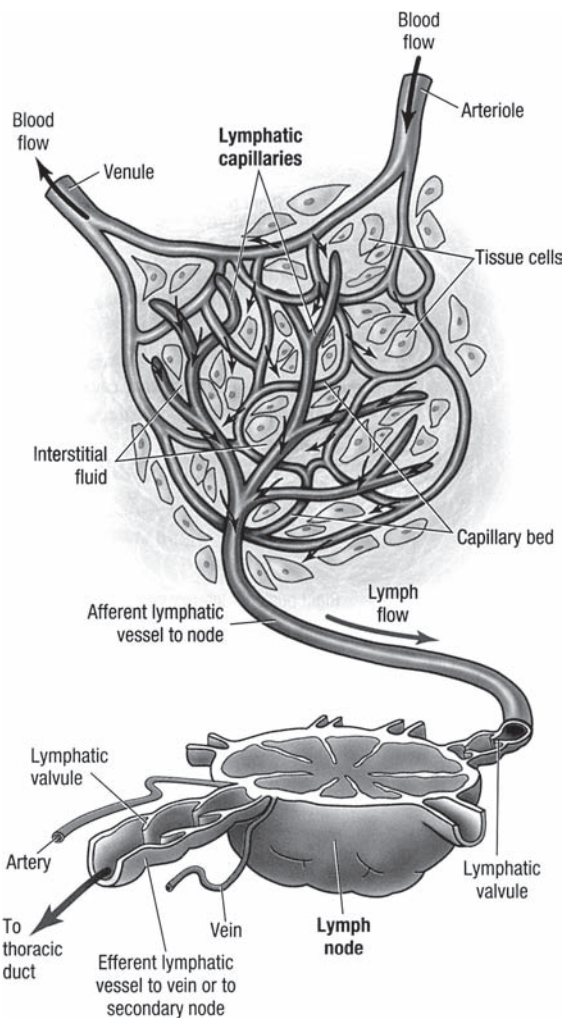

Figure 12-6 The lymphatic system. This figure illustrates the afferent lymphatic collecting vessels arising in the tissue between the arterial and venous system and extending to the lymph nodes. The efferent vessels arise in the capsule of the lymph node and progress toward the thoracic duct. (Taken from Agur AM, Dalley AF. *Grant's Atlas of Anatomy*, Philadelphia, PA: Lippincott Williams & Wilkins, 2009.)

INNERVATION OF LYMPHATIC VESSELS

The smooth muscle in the wall of the lymph vessel contains adrenergic, cholinergic purinergic, and peptidergic nerves (Alessandrini et al., 1981; Witte et al., 2006), although a sympathetic innervation has been more consistently observed (McHale, 1990). Chemical stimulation *in vitro* of the adrenergic receptors causes contraction of the lymphatic smooth muscle (Thornbury et al., 1989); the effect of cholinergic stimulation has been variable (McHale, 1990) and has been questioned by a more recent study (Thornbury et al., 1989). Beta adrenergic receptors have been identified that cause relaxation of lymphatic smooth muscle (Ikomi et al., 1997). Electrical stimulation of sympathetic nerves and/or ganglia also consistently increases the contractility of the smooth muscle, increasing stroke volume of the vessels (Benoit, 1997; McGeown et al., 1987; Thornbury et al., 1993). The innervation, like the presence of smooth muscle, is greatest in the larger vessels. The overall effect of sympathetic stimulation, which appears to be increasing lymph flow, is mediated via the alpha receptors. The role of

beta-receptors and cholinergic innervation has not yet been fully elucidated. Eliminating the effects of the sympathetic nervous system on the lymph vessels does not eliminate the peristaltic contractions but prevents field stimulation from increasing lymph flow (Hollywood and McHale, 1994), indicating the sympathetic nervous system does not initiate the peristaltic contractions, but is capable of modifying the intrinsic rate of contraction. This modification is most likely accomplished by varying the sensitivity of the autoregulatory mechanism in the lymphatic vessels to stretch (Witte et al., 2006). The finding of peptide containing fibers in the innervation of the lymph vessels suggests the possibility of sensory reflex modulation of lymph pumping, as well as an alternate means of modifying the pumping rate, as the lymphatic smooth muscle is responsive to substance P, which was identified in the peptidergic nerves (Hukkanen et al., 1992).

All lymph organs have been demonstrated to receive a sympathetic innervation; however, no consistent findings of parasympathetic innervation have been reported (Nance and Sanders, 2007). Sympathetic stimulation has been shown to modify lymphocyte activity (Felten et al., 1984), as well as cause contraction of the lymph node capsule, resulting in an increase in the output of lymphocytes from nodes (McGeown, 1993; McHale and Thornbury, 1990; Thornbury et al., 1990). It has been theorized that the primary role of the sympathetic innervation of the lymphatic system is to modify the immune response, rather than increase flow through the vessels (McHale, 1992).

REGIONAL LYMPH DRAINAGE

The movement of lymphatic fluids progresses from the peripheral tissues toward the midline of the body and, once on the midline, upward toward the cervicothoracic junction where these fluids are returned to systemic circulation through the jugular or subclavian veins. In general, lymph from the two lower extremities, pelvic basin, abdomen, left thorax, left upper extremity, and left side of the head targets the thoracic duct for return to the venous compartment. Lymphatic vessels draining the right thorax, upper extremity, and right side of the head flow into the right lymphatic duct before entering the venous compartment (Fig. 12.7).

There are slight variations in the structure and of initial lymphatics and collecting channels in various organs and tissues that offer insight into the physiology of lymph formation and propulsion. Some of those differences will be described here as well as the main pathways of drainage of the lymph system.

Peripheral Tissues

There is a superficial and deep drainage of the upper and lower extremities. The superficial drainage follows subcutaneous routes to proximal nodes at the axilla and inguinal areas. Deep drainage follows the neurovascular structures to the same ultimate endpoint and has various nodes at intermediary sites. The upper limb lymph exits the axilla via a somewhat vulnerable route through the thoracic outlet, exiting the limb beneath the pectoralis minor muscle, and entering the thorax through the costoclavicular space (Fig. 12.8). Here, the upper extremity lymph channels join with those from the anterior thoracic wall including the breast tissue in the female. The lower extremity drainage enters the abdomen through the femoral triangle, in close proximity to where the iliopsoas tendon crosses the hip joint (Fig. 12.9). The deep drainage of the foreleg passes into the popliteal space between the two heads of the gastrocnemius and exits the popliteal space between the heads of the hamstrings. The small, pliant lymph vessels are most vulnerable to tissue

Figure 12-7 Regional lymphatic drainage of the thorax. The thoracic duct and right lymphatic duct are shown in green. (Taken from Agur AM, Dalley AF. *Grant's Atlas of Anatomy*, Philadelphia, PA: Lippincott Williams & Wilkins, 2009. Figure 1-73.)

tension as they pass through narrow spaces such as these. When sufficient tension is present, it may limit the lymphatic drainage of the respective extremity. Increasing outflow pressure has been shown to reduce lymph flow in vitro (Eisenhoffer et al., 1993).

The small collecting vessels draining skeletal muscle have been shown to have significantly less smooth muscle. In fact, the smooth muscle wall of the lymphatic vessels does not develop until the

vessel is relatively large in size, suggesting the effectiveness of the skeletal muscle contraction in propulsing the lymph through these small vessels (Schmid-Schonbein, 1990b).

The synovial fluid of large joints is drained via the lymphatic system. Radiolabeled tracer placed into the synovial space of the knee joint of a pig could be followed as it was removed through the lymphatic channels and entered the thoracic duct. The synovial

Figure 12-8 Regional lymphatic drainage of the upper extremity. The lymphatic drainage of the upper extremity is seen entering the axillary region where it merges with that of the anterior chest wall including the breast tissue in the female. (Taken from Agur AM, Dalley AF. *Grant's Atlas of Anatomy*. Philadelphia, PA: Lippincott Williams & Wilkins, 2009. Figure 1-8.)

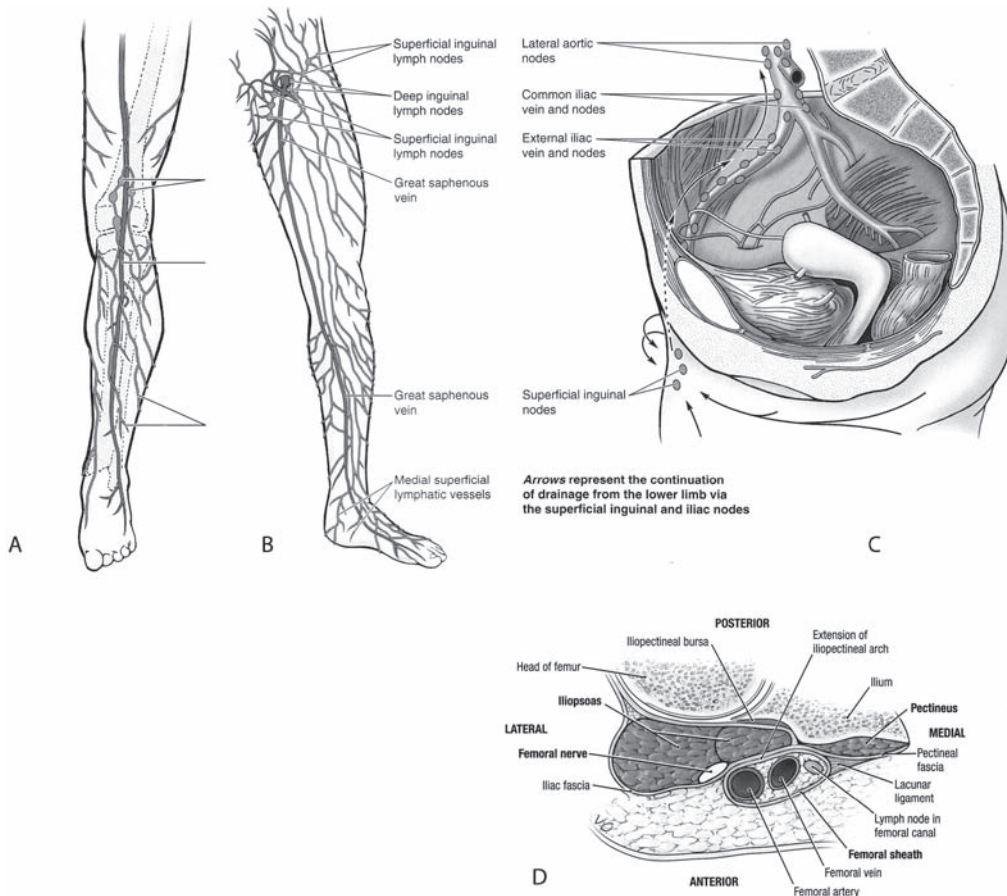

Figure 12-9 Regional lymphatic drainage of the lower extremity. Lymphatic drainage from the lower extremity is directed to the inguinal region, from which it passes along iliac nodes to reach the preaortic and aortic nodes. **A** and **B** are anterior and lateral views of the lymphatic drainage of the lower extremity, respectively. In **C** the drainage of the inguinal nodes in to the iliac nodes is illustrated. Illustration **D** is a cross-section through the femoral triangle illustrating the narrow region through which the lymphatic drainage must pass. This is a lateral. tracer was estimated to have a half-life of approximately 8.3 hours suggesting that synovial clearance via lymphatics is relatively quick from the large joints of the extremities (Jensen et al., 1993).

Head and Neck

The deep cervical vessels and nodes lie in the carotid sheath, and this is the terminal pathway for all drainage of the head and neck (Fig. 12.10). Superficial drainage will usually pass through superficial nodes before passing to deep nodes. Many of these nodes lie along the sternocleidomastoid muscle. Others lie in the sup occipital space, over the parotid gland, and under the mandible. Much of the deep drainage, including that of the ear, sinuses, pharynx, upper larynx, and upper teeth, drain via the upper nodes through the jugulodigastric node, which open into the deep chain in a narrow space between the mastoid process and the angle of the mandible. Drainage through this area may also be affected by local tissue tension.

Thorax

The heart has endocardial, myocardial, and epicardial lymph drainage (Fig. 12.11A). The vessels also have little smooth muscle and depend on myocardial activity for flow. The flow of drainage is from endocardial to myocardial to epicardial. The epicardial channels converge on the posterior aspect of the heart into a single, principal lymphatic trunk that drains to a pretracheal node and the cardiac lymph node. The drainage of the heart enters the right thoracic trunk (Fig. 12.11F). The pericardium drains into the thoracic duct and enters the left subclavian vein.

The lymphatics of the lung drain the pulmonary vasculature and also the bronchial airways (Fig. 12.11B). Lymph channels travel as far as the terminal bronchiole and are thought to be important in the drainage of particulates and fluid from the alveoli. Pulmonary lymph is formed by the expansion of the lungs during respiratory excursions, and drains out of the lungs at the hilum into the tracheobronchial nodes and into the right lymph trunk and thoracic duct (Fig. 12-11E & G).

Figure 12-10 Regional lymphatic drainage from the head and neck. Lymphatic channels in the neuro- and visceral cranium converge on the carotid sheath, from which lymph passes downward to join the right lymphatic duct or the thoracic duct on the left.

Abdomen

There is lymphatic drainage of the gut tube, abdominal viscera, and mesenteries (Fig. 12.12A-D). The lymphatics of the intestines have lacteals for the unique purpose of absorbing fat (chyle) as part of the digestive process, giving abdominal lymph the characteristic milky color and consistency. The collecting lymphatics of the gut tube are similar to that of skeletal muscle, lacking smooth muscle for an unusually long distance, indicating the ability of peristalsis to propel lymph in this area (Schmid-Schonbein, 1990a,b). The lymphatic drainage of the mesenteries follows the vascular structures back through the roots, where they join the iliac and preaortic nodes on route to the cisterna chyli and thoracic duct. The preaortic and aortic nodes are clustered around the three large unpaired arteries on the anterior aspect of the aorta, the celiac, superior mesenteric, and inferior mesenteric arteries (Fig. 12.12A-D).

Peritoneal and Pleural Fluid

Diaphragmatic stomata have been discovered on the inferior, and to a lesser degree the superior surface of the diaphragm that are open to the peritoneal and pleural cavities, respectively (Negrini et al., 1991; Tsilibary and Wissig, 1977; Wang, 1975). These stomata are believed to act as "prelymphatics," connecting to the diaphragmatic lymphatic channels and represent a major pathway for the drainage of peritoneal and pleural fluid. Of radiolabeled tracer absorbed out of the abdomen of a sheep, 42% returned into circulation via the diaphragm and the remainder passed through other routes that include the organ walls and somatic body wall (Abernethy et al., 1991). In another study, Zakaria et al. (1996) found three routes for the removal of radiolabeled tracer from the peritoneum: 55% passed through the diaphragmatic, 30% through visceral lymphatics, and 10% to 15% through parietal lymphatics. Given these data, the diaphragm may be acting like a large sponge, absorbing fluid from the peritoneal and pleural cavities as it relaxes and pumping that fluid into the lymphatic collecting ducts on each contraction.

PHYSIOLOGY AND MECHANICS OF LYMPH FLOW

The movement of lymph is a fairly complex process involving several steps or stages. Fluid must first move from the interstitium into the initial lymphatic. It then travels through a series of progressively larger vessels until it drains into right lymph trunk or the thoracic ducts, which in turn drain into the subclavian veins. Lymph formation involves the movement of fluid across a permeable membrane.

Fluids move in the direction determined by the sum of the hydrostatic and osmotic gradients across the membrane (Fig. 12.1). Capillaries generally have a hydrostatic gradient that moves fluid out at their arterial end and an osmotic gradient that returns fluid to the capillary at the venous end. The search for similar hydrostatic and osmotic gradients across the lymphatic endothelium to account for the formation of lymph has been without success. Sampling of fluid from the initial and small collecting lymphatics has consistently shown a protein concentration identical to interstitial fluid (Benoit

Figure 12-11 (continued)

et al., 1989; Zawieja and Barber, 1987), virtually eliminating the possibility that an osmotic gradient accounts for lymph formation (Aukland and Reed, 1993). Similarly, the discovery of a negative interstitial pressure in most tissues eliminates the possibility of a continuous hydrostatic gradient from the capillary to the initial lymphatic (Aukland and Reed, 1993; Guyton and Barber, 1980). Although a negative pressure has also been found in the initial lymphatic, there appears to be a small uphill gradient between the interstitium and the lymphatics (Aukland and Reed, 1993). Without a net osmotic or hydrostatic gradient to account for the formation

of lymph, one is naturally led to consider mechanical forces. The anatomical design of the initial lymphatic allows it to respond to a variety of forces in its environment. There are two anatomical features of initial lymphatics that are crucial in this regard.

The anchoring filaments that tether the outside of the lymphatic endothelial cells to the collagen of the interstitium cause the lymphatic to change shape and volume in response to tissue movement. Alternating movements create alternating volume changes in the initial lymphatic. These produce intermittent pressure gradients that move fluid into the initial lymphatic. In the lung, for example,

movements of inhalation and exhalation alternately increase and decrease intralymphatic volume. The increased volume during inhalation lowers intralymphatic pressure and produces a gradient for the influx of fluid. During exhalation, the fluid is propelled forward into the collecting vessel. In the intestine, lymphatics lie between layers of muscle where they respond to peristalsis as well as the movement of the diaphragm during breathing. Interestingly, the resting position of the abdominal lymphatics appears to be an

open position, that is, anchoring filaments hold the endothelial cells apart. This position is best suited for response to the compressive forces of peristalsis and the downward movement of the diaphragm (Schmid-Schonbein, 1990a,b). The situation appears reversed in the lungs, which allows the lymphatics to respond to expansion during exhalation. This suggests a structure/function relationship, where the lymphatic structure develops to best utilize the local forces available for lymph formation.

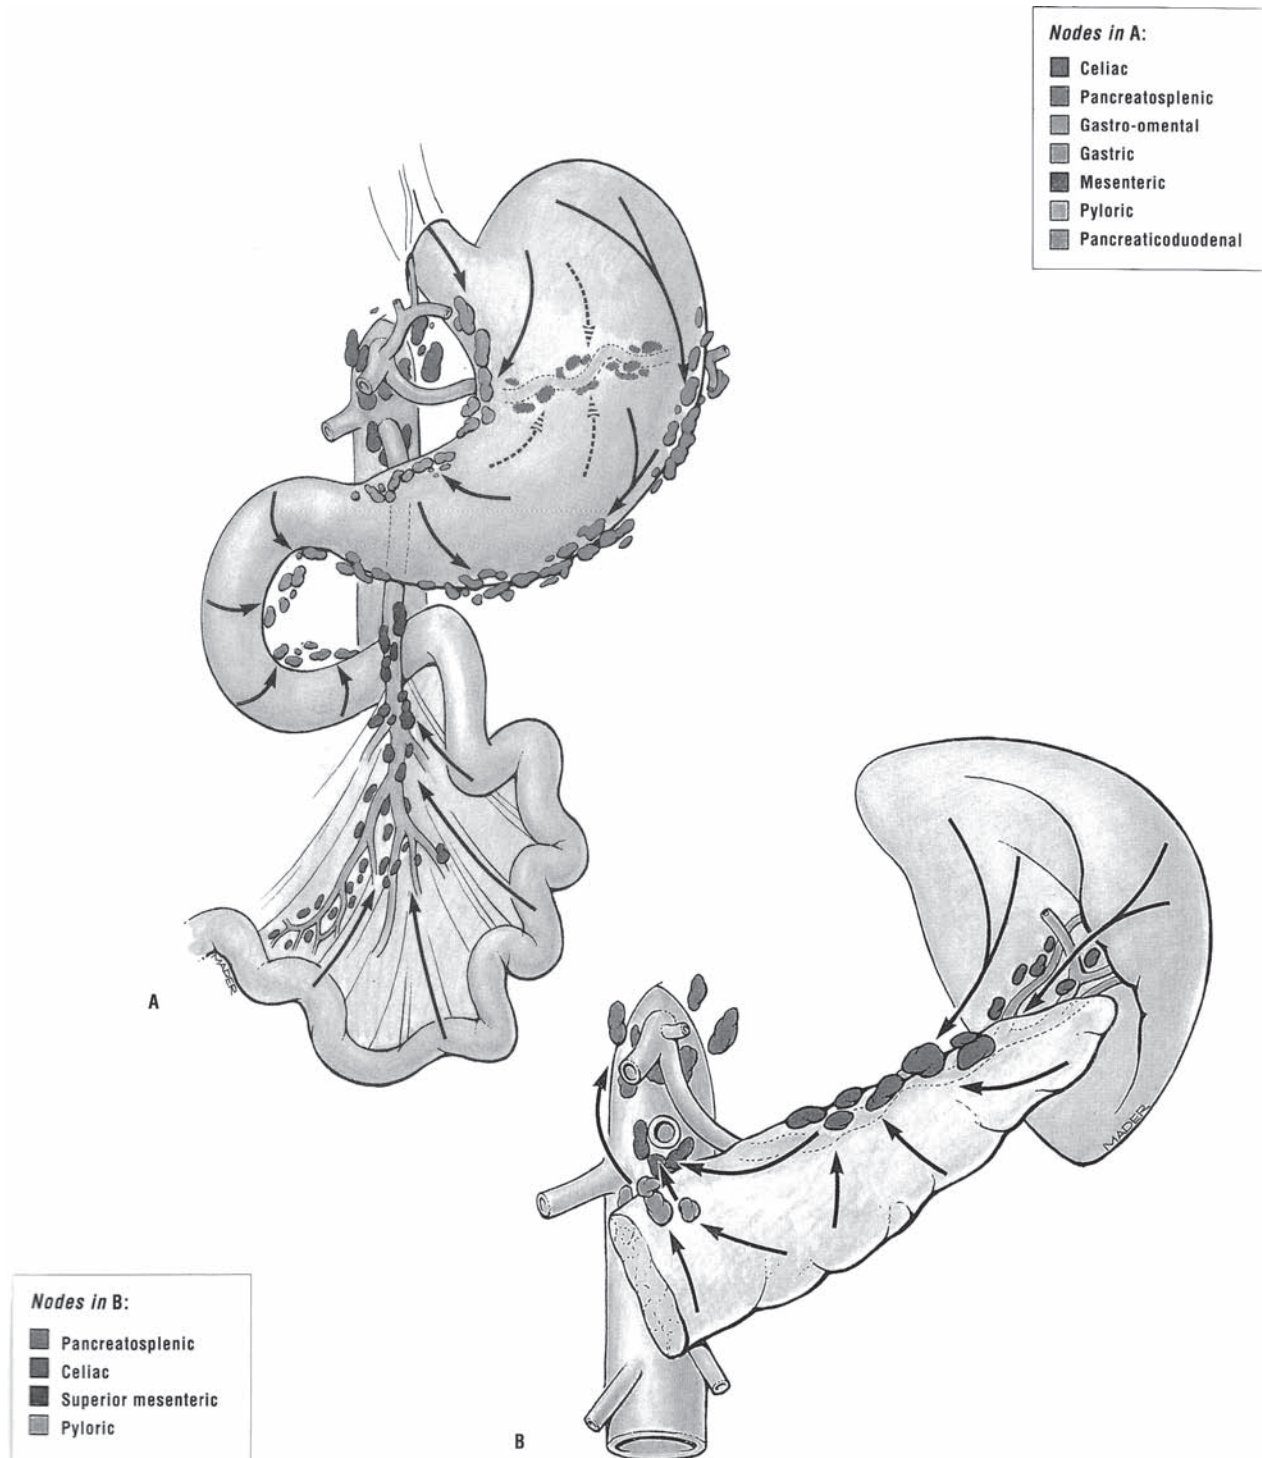

Figure 12-12 Lymphatic drainage of the abdominal organs: **A.** Regional lymphatic drainage of the stomach and proximal small bowel is illustrated. **B.** Regional lymphatic drainage of the spleen and pancreas is illustrated. **C.** the lymphatic drainage routes of the large bowels are illustrated. **D.** the lymphatic drainage routes of the liver and kidneys are illustrated.

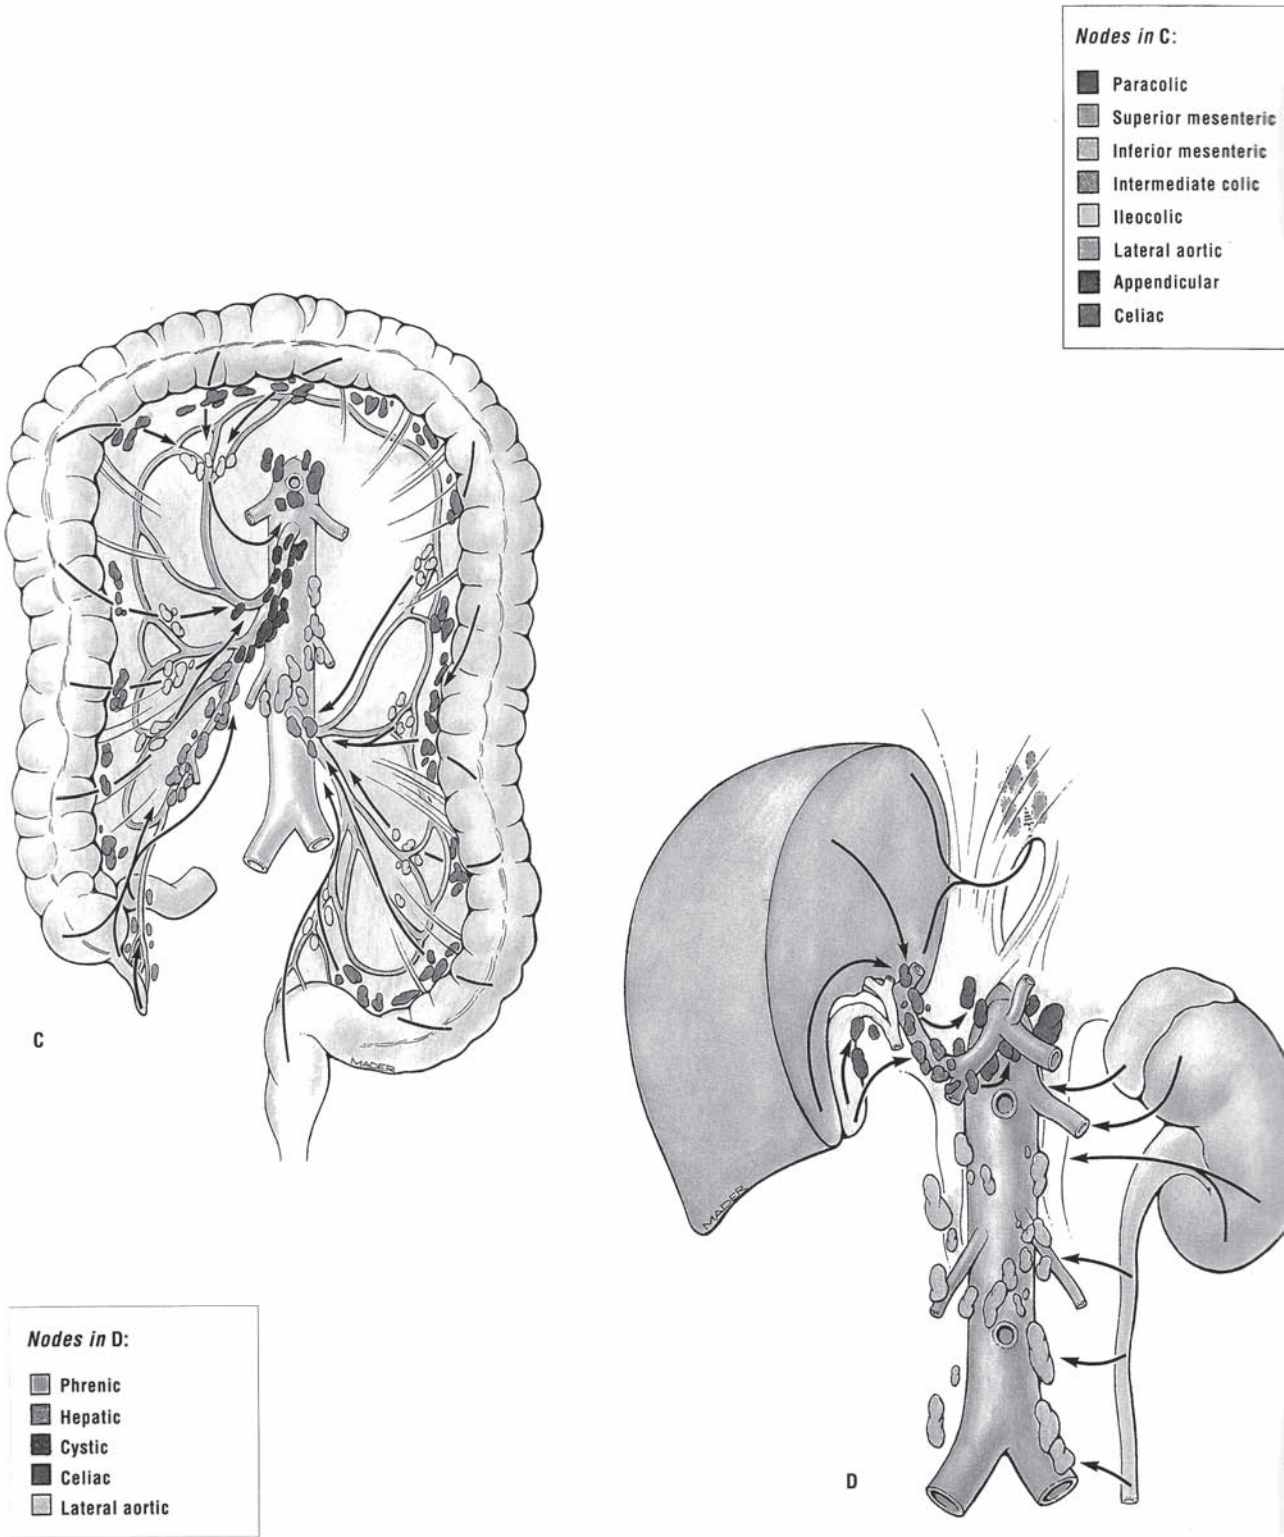

Figure 12-12 (continued)

Lymphatics have been shown to respond to a variety of forces, including skeletal muscle contraction (Mazzoni et al., 1990), passive motion of the extremities (Gnepp and Sloop, 1978; Ikomi and Schmid-Schonbein, 1996; Ikomi et al., 1997), external tissue compression (McGeown et al., 1987), arterial pulse, and arteriolar vasomotion (Intaglietta and Gross, 1982). Lymphatics are oriented

in tissue to maximize their exposure to the various external forces in their environment. Many lymphatics closely follow the arterial system, where they can respond to the pulse and vasomotion. Those in muscle are situated between layers, where they are effectively compressed. Although the forces that form lymph are varied, all involve movements that alternately expand and compress the

initial lymphatics, creating oscillatory, dynamic pressure gradients between the interstitium and the initial lymphatic.

At the terminal lymphatic, passive motions could play an important role in loading the vessel with extracellular fluids (Witte et al., 2006). Alternating passive movements could not effectively form lymph if bidirectional flow across the lymphatic endothelium were possible. This is prevented by the overlapping endothelial cells in the initial lymphatic. These cells form a valve mechanism that allows the movement of fluid into the initial lymphatic, but prevents movement out (Schmid-Schonbein, 2003). Coupled with the anchoring filaments, this allows the lymphatic to utilize alternating tissue motion to create unidirectional movement of fluid from the interstitium into the lymph system. Additionally, this feature also allows the initial lymphatic to respond to fluctuations of fluid in the interstitium. A fluid pulse creates a pressure wave in the interstitial fluid. As the pulse approaches the lymphatic, a gradient is produced that opens the endothelial cells and permits fluid to enter. After the pulse crosses, the cells close preventing backflow out of the lymphatic. Arteriolar vasomotion appears to create a fluctuant displacement of interstitial fluid, which may influence lymph movement (Intaglietta and Gross, 1982). Fluid fluctuation may account for the movement and exchange of fluid within the interstitium. Capillary hydrostatic gradients dissipate quickly and do not account for the movement of fluid within the interstitial spaces (Aukland and Reed, 1993).

After moving into the initial lymphatic, fluid is propelled through the collecting channels. These channels contain bicuspid valves that ensure unidirectional flow of lymph (Schmid-Schonbein, 1990b). An intrinsic myogenic pump has been identified that accounts for significant lymph propulsion. This pump consists of smooth muscle in the wall of the lymph vessel and the valves. Lymphatic smooth muscle exhibits spontaneous contractions that are peristaltic, traveling distal to proximal at a rate of 4 to 5 mm/s (Ohhashi et al., 1980). Evidence suggests that the contraction wave migrates retrogradely along the lymphatic vessels (Macdonald et al., 2008). A pacemaker initiates the spontaneous contractions (Beckett et al., 2007; Benoit, 1991; McHale and Meharg, 1992; Ohhashi et al., 1980; Van Helden, 1993; Van Helden et al., 2006). The pacemakers are situated in the wall of the lymphatic vessel between the endothelial cell layer and the surrounding smooth muscle; they begin just beyond the first valve (McCloskey et al., 2002; Ohhashi et al., 1980). The impulses are then coupled to the smooth muscle along the vessel in order to propagate a wave of contraction, producing a peristaltic action. Hogan proposed a mechanical coupling, based on the finding of stretch receptors in the lymphatic wall distal to the valve that initiated a smooth muscle contraction of the lymphangion (Hogan and Unthank, 1986). The initial pacemaker, located just proximal to the first valve near the initial lymphatic capillary, is also responsive to vessel distention and is stimulated by the distension created by lymph formation. The contraction of this distal segment propulses fluid beyond the valve where stretch receptors continue to stimulate smooth muscle contraction, and the peristaltic wave is propagated. In this model then, lymph propulsion is dependent on filling of the terminal lymphatic, or lymph formation.

More recent studies have demonstrated electrical coupling of smooth muscle cells (Crowe et al., 1997; Zawieja et al., 1993), likely mediated by calcium (Cotton et al., 1997). This, combined with a spontaneously contracting pacemaker, would allow a completely independent, electrically coupled peristaltic wave. Zawieja et al. (1993) found both upstream and downstream propagation of the contractions, supporting the idea of electrical coupling, since a volume-dependent mechanism should only propagate contraction centrally.

Crowe's study suggests that both electrical and mechanical coupling contribute to the propagation and coordination of

the intrinsic lymph pump (Crowe et al., 1997). They found that without a minimum amount of filling, no contractions occurred. They also found that more than half of the specimens studied, the contractions were preceded by a transient dilatation of the vessel, and that the propagation of the wave occurred relatively slowly, consistent with mechanical coupling. A minority of lymph specimens (9/22) demonstrated characteristics of electrical coupling, bidirectional propagation at a more rapid speed. Crowe's group also found that perfusion-induced contractile activity in most lymphangions, regardless of how the contraction was propagated, and that the contraction frequency was dependent on the rate of perfusion. Lymph formation then appears to be capable of initiating propulsion in some cases and significantly modifying it in others. Currently, there continues to be debate as to the relative importance of these two mechanisms in the functioning of the intrinsic lymph pump, but little debate about the relative importance of this pumping mechanism in the propulsion of lymph through the lymph vessel (Ohhashi et al., 2005; Witte et al., 2006). Ohhashi gives evidence of two separate pacemaker mechanisms, one near the valve that responds to filling, and one near the middle of the lymphangion that responds to adrenergic stimulation, which may represent the source of the electrical pacemaker.

Lymph propulsion is also modified by a variety of other factors. Lymphatic smooth muscle responds to both adrenergic and humoral influences. Adrenergic stimulation has been shown to increase contractility and stroke volume of lymphatic smooth muscle (McHale, 1992). Humoral influences are important in lymph propulsion during inflammation. This area of study is in its early stages. An experimentally induced inflammatory process caused an increase in the stroke volume of the lymphatic vessels and an increase in lymph drainage (Benoit and Zawieja, 1992). Endotoxin, on the other hand, has a strong negative effect on lymph pumping and may explain some of the hemodynamic consequences of septic shock (Johnston et al., 1987). *In vitro*, IL-1 and prostaglandin E₁ reduced lymph contractile activity (Hanley et al., 1989), while bradykinin, PGH₂, and NO increased lymph contractility (Johnston and Gordon, 1981; Shirasawa et al., 2000; Yokoyama and Benoit, 1996), as did Substance P (Zawieja, 1996). Neurogenic and humoral influences appear less important in the myogenic pump than volumetric displacements (Aukland and Reed, 1993).

The effect of external forces of lymph propulsion is somewhat controversial. Lymphatic vessels lack anchoring filaments that would allow them to respond to the various forces that form lymph. On the other hand, the anatomical design of a thin-walled vessel with valves is consistent with propulsion from external compression. This is supported by the finding that lymphatics in the intestine and skeletal muscle have an absence of smooth muscle for a much greater distance from their origin than those from other tissues (Schmid-Schonbein, 1990b), presumably because compression from muscle contraction provides the necessary propulsive forces. Most studies on the effect of external forces on lymph flow do not distinguish the effect of these forces on lymph formation and propulsion. A study by McGeown et al. (1987) attempted to distinguish the effects of external compression on lymph formation versus propulsion. They created an inflammatory process on the hoof of a sheep, and then applied compressive forces to the hoof, directly over the area of lymph formation, and compared that to compression over the metatarsal area, where the larger collecting vessels are found. The study demonstrated a fourfold increase in flow when the forces were applied to the hoof, the area of lymph formation, and virtually no change when applied to the metatarsal area, where the collecting vessels were found. Although this study by itself does not exclude the possibility that external forces

contribute to the propulsion of lymph, it provides compelling evidence that external forces are most effective in promoting formation of lymph. A further study demonstrated that the ability of external pressure to increase lymph flow was both rate and amplitude dependent (McGeown et al., 1988). This carries significant clinical implications for osteopathic approaches to lymph drainage, and should be considered in the design of Osteopathic treatment plans to promote lymph drainage, especially those using “lymphatic pump” techniques. Since lymph formation has been shown to initiate and/or strongly increase lymph propulsion, treatment to enhance lymph formation may increase lymph drainage in a number of important ways.

Postnodal lymph continues to move centrally, eventually draining into the right lymphatic duct or left thoracic duct before reentering the venous circulation at the subclavian vein. There have been numerous studies of the forces that move lymph through the thoracic duct (Browse et al., 1971; Browse et al., 1974; Dumont, 1975; Reddy and Staub, 1981; Schad et al., 1978). The smooth muscle in the thoracic duct exhibits spontaneous contractions similar to other lymphatic smooth muscle (Reddy and Staub, 1981). Respiration has been shown to have a consistent effect on the flow and pressures within the thoracic duct (Browse et al., 1971). Although these studies do not exclude the effect of respiration on the formation of lymph in the thorax and abdomen, and its contribution to thoracic duct flow, pressure changes associated with respiration are considered important in central lymph flow (Aukland and Reed, 1993).

Osteopathic treatment has been directed toward improving lymph drainage since the time of A.T. Still. Early writing by Millard focused on removing obstruction to the flow of lymph by treating somatic dysfunction along the course of fluid return (Millard, 1922). Although this concept has not been studied experimentally, it stands to reason that tissue strain in the area of lymph vessels will increase the resistance to lymph flow through those vessels. Earlier descriptions of lymph drainage pathways attempted to identify areas where compression might be likely. Experimentally increasing resistance to lymph flow has reduced lymph flow in distal lymphatics (Aukland and Reed, 1993).

J. Gordon Zinc discussed osteopathic treatment to improve the intrathoracic pressure gradients for their effect on central or terminal lymph drainage (Zinc, 1970, 1973). Treatment to improve thoracic excursion and increase negative intrathoracic pressure may not only increase thoracic duct flow, but it will also help stimulate lymph formation in the thorax and abdomen.

Lymph pump techniques, directed at actually moving lymph, have also been part of the Osteopathic approach to the lymphatics. McGeown's recent studies about the effects of external compression (McGeown et al., 1987, 1988), and the discovery of the intrinsic peristaltic contractions of lymphatic smooth muscle responsible for a considerable proportion of lymph propulsion, suggest that specific treatment to pump lymph should be directed toward lymph formation at the site of inflammation or lymphedema. Stimulation of the myogenic pacemaker by increasing lymph formation may also increase lymph propulsion.

KEY CONCEPTS

- The thoracoabdominal wall is a fibroelastic cylinder controlled by the respiratory muscles; fixation of the upper border of the ribs facilitates inhalation while fixation of the lower border of the ribs enhances exhalation.
- The thoracoabdominal diaphragm is a dome-shaped muscle, its function is greatly facilitated by its vertical component, termed the zone of apposition.
- The abdominal muscles play a role in fixing the lower border of the ribs as well as compressing the abdominal viscera and thereby expanding the zone of apposition to support the actions of the diaphragm.
- Structural changes in some respiratory muscles are seen at the molecular, cellular and gross structural levels in disease states such as COPD, kyphosis, and obesity, these changes decrease motion, ultimately decreasing the ability of the respiratory mechanism to supply adequate pumping activity.
- An emphasis is placed on having sufficient motion in the respiratory musculature to insure adequate ventilation of the tissue; an important role of the Osteopathic physician is to improve the range of motion in the respiratory mechanism.

INTRODUCTION

Definition of Respiratory Mechanics

The thorax is a flexible fibroelastic cylinder that is rhythmically distorted by the action of numerous respiratory muscles that are located both within the thorax and abdomen and extremities (Fig. 13.1). The changing shape of this cylinder creates the alternating inhalation and exhalation events necessary for perfusing the lung with air; these movements constitute the mechanics of breathing. Diseases that alter the shape of the thorax or its compliancy can have a substantial impact on the mechanics of respiration and, consequently, on the health of the individual.

Importance of Respiratory Mechanics in Osteopathic Manipulative Medicine

While alternating thoracoabdominal pressures are critical for the aeration of the pulmonary alveoli, this movement is also an important influence on the redistribution of fluid in the lymphatic system as well as the movement of blood in the venous network associated with the epidural venous plexus of Batson located in the spinal canal (See Chapter 12 on the lymphatic system). These facts emphasize the importance of striving for smooth continuous respiratory movements in the thoracoabdominal wall of the patient regardless of the etiology of their particular disease processes. This chapter will examine the anatomy and function of the muscles involved in respiration and the alteration of these movements in specific diseases involving structural changes in the thoracic wall as well as considering the influence of respiratory activity on the movement of fluids in the low pressure systems of the torso.

MUSCLES OF THE THORACIC CYLINDER

Intercostal, Scalene, and Abdominal Muscles

Anatomy of the Intercostal, Scalene, and Abdominal Muscles

The intercostal muscles form a distensible fibroelastic sheet surrounding the rib cage (Fig. 13.1). The sheet is divided into three

incomplete layers. These layers are arranged in loose helical spirals (Fig. 13.2), each layer having a different pitch to the helix. Together, these layers act to both protect and alter the structural geometry of the thoracic wall and thus the volume of the pleural sacs. This fibromuscular tube is anchored from above by the scalene muscles that attach to the first and second ribs and below by the abdominal muscles that attach to the subcostal margin (Fig. 13.3).

The scalene muscles. Three scalene muscles—anterior, medius, and posterior—extend from the transverse processes of the cervical vertebrae (anterior C3-6, medius C1-7, and posterior C4-6) to reach the first rib and, to a lesser extent, the second rib (reviewed in O’Rahilly, 1986) (Figs. 13.2, 13.3 and 13.4). Occasionally, a scalenus minimus is found descending from the 6th and 7th transverse process to reach the inside of the 1st rib and the fascia of the apical pleural of the thoracic cavity (Sibson fascia). With the neck fixed in position by tonic contraction of the longus and paraspinal muscles, contraction of the scalene muscles elevates the first and second ribs, an important first step in inhalation. Activity in the scalene muscles is obligatory even in quiet respiratory movements (De Troyer and Estenne, 1988).

External intercostal muscle. This thin sheet of muscle arises from the costotransverse ligaments posteriorly at the level of the tubercle of the rib and tapers to become a membrane anteriorly at the level of the costochondrial junction. In the upright position, the orientation of the muscle fibers is close to vertical (Figs. 13.1–13.3, 13.5, and 13.6). Throughout its course in each interspace, the muscle is attached to the lower margin of the rib and costal cartilage above and to the upper margin of the rib and costal cartilage below (O’Rahilly, 1986). The external intercostal muscle is thickest and thinnest best developed in the superior posterior aspect of the thorax, thinnest inferior and medially (De Troyer et al., 2005). The pitch of its helical spiral is from superioposterior to inferioanterior (Fig. 13.2). Based on its geometry, thickness, and data from electromyography (EMG) studies, the external intercostal is a powerful muscle of inhalation in the human with the exception of its most anteromedial border, where the muscle is thinnest. This latter region, located in the anterior portions of spaces 6 to 8, appears to represent a weak muscle of exhalation (De Troyer et al., 2005).

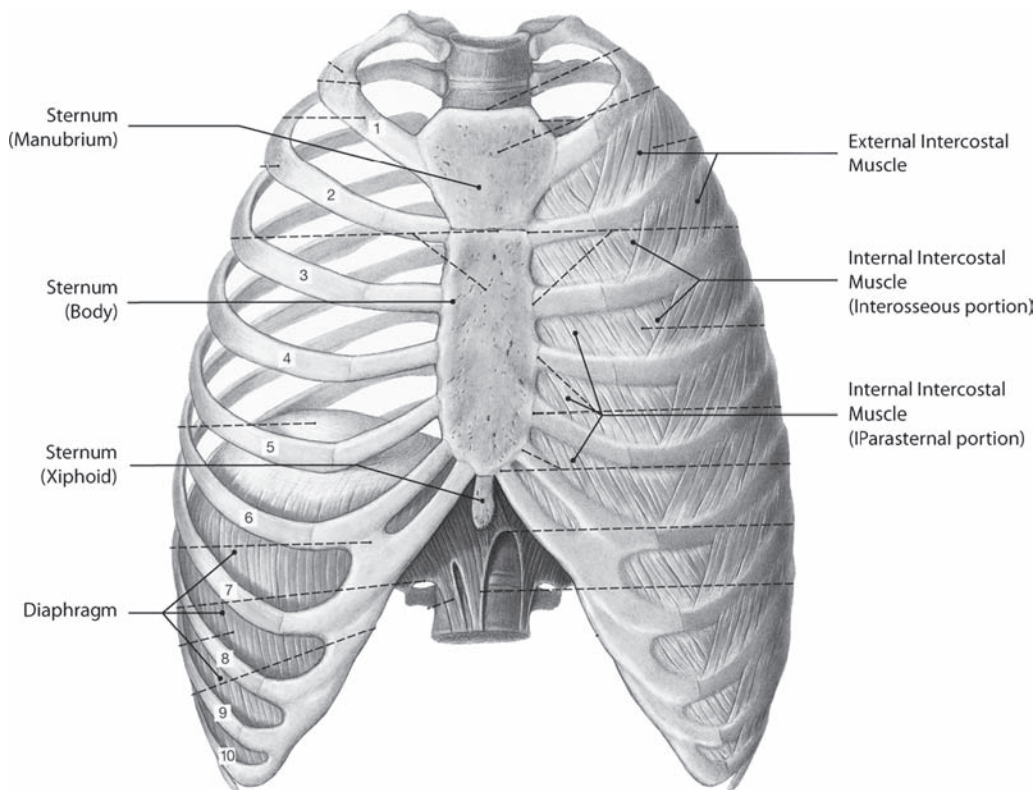

Figure 13-1 This figure illustrates the invasion of muscle fibers by proinflammatory cytokines such as interleukin-6 and tumor necrosis factor- α . Once in the muscle these cytokines can act through at least two routes to enhance muscle wasting. In (A) TNF- α works with interferon- γ to suppress the ability of the nuclear transcription factor MyoD to stimulate production of myosin. Thus, less myosin heavy chain is produced in the myocyte. IL-6 is also capable of enhancing the production of ubiquitin and ubiquitin-ligase, two proteins used in labeling cellular protein for degradation by the proteasome as shown in (B). Thus, cachexia and muscle atrophy develops due to the blockage in myosin production and enhancement of its destruction. (Taken from C. D. Clemente. *Anatomy: A Regional Atlas of the Human Body*. Baltimore: Williams & Wilkins; 1997.)

Internal intercostal muscles. The internal intercostal muscles are found deep to the external intercostals (Fig. 13.1–13.3, 13.5–13.7). These thin muscles arise from the lateral border of the sternum and wrap around the ribs to eventually become a thin

membrane in the posterior intercostal spaces (Fig. 13.1). Like the external intercostal muscles, the internal is attached to the lower margin of the rib and costal cartilage above and to the upper margin of these structures below. The muscle is thickest in the anterior

Figure 13-2 This is a lateral view of the thorax demonstrating the helical spirals established by the external and internal intercostal muscles. The arrow that starts on the left represents the pitch of the spiral of the external intercostal muscle while the arrow beginning on the right represents the same for the internal intercostal muscle. (Taken from the Willard/Carreiro Collection.)

Figure 13-3 This is a lateral view of a male thorax and upper abdomen. The skin and superficial fascia have been removed to reveal the external intercostal and external oblique muscles. (Taken from the Willard/Carrero Collection.)

and superior portions and tapers as it passes posteriorly (O’Rahilly, 1986). The resulting spiral pitch of its muscle fibers is oriented from superioanterior to inferioposterior. The muscle is divided into two functionally distinct components. The parasternal portion exists between the costal cartilages, while the interosseous intercostal muscle exists between the bony ribs (De Troyer and Estenne, 1988). Analysis of geometry, thickness, and EMG data supports the contention that the interosseous portion is strictly involved in

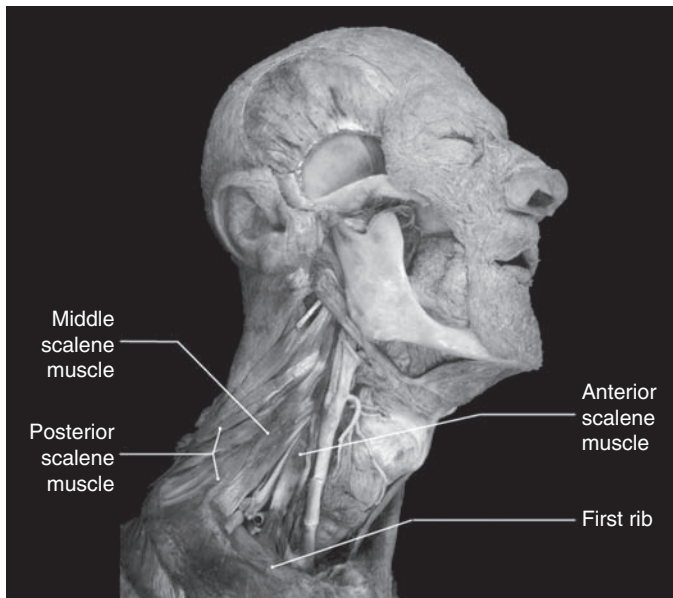

Figure 13-4 This is an oblique view of a male head and neck with the skin, superficial fascia, and upper extremity removed to display the three scalene muscles. A deep dissection was done into the temporal region for other purposes. (Taken from the Willard/Carreiro Collection.)

exhalation while the parasternal portion represents a significant muscle of inhalation (De Troyer et al. 1998, 2005).

Innermost intercostal muscles. The innermost internal intercostal muscles are oriented orthogonal to the ribs (Fig. 13.7). These muscles are very thin and inconsistent in their presence. When present, the internal investing fascia of the innermost internal intercostal muscle is intimately adhered to the endothoracic fascia. Given this muscle’s close geometric relationship with the rib, contraction of the muscle is most likely to assist in moving the ribs closer to each other. Functional analysis of the internal intercostal muscle by EMG analysis is currently lacking. The muscle is related embryologically to the transverses thoracic and transverses abdominus muscles.

Transversus thoracis. The transverses thoracis muscle, also termed sternocostalis or triangularis sternae muscle, arises from the inner surface of the lower sternum, xiphoid process, and lower costal cartilages (Fig. 13.7). It radiates outward to attach to the inner borders of the costal cartilages of ribs 2 through 6 (O’Rahilly, 1986). Only rarely is the muscle symmetric in disposition; often, additional slips of the muscle can be found scattered in the second through fourth interspace as seen in the specimen displayed in Figure 13.7. Developmentally, the muscle appears to be most closely related to the innermost internal intercostal group of muscles and the transverses abdominus muscle. In Figure 13.7, the transverses thoracis muscle is seen blending with the superior border of the transverses abdominus muscle; this is most apparent on the left side of the specimen. The transverses thoracis muscle is active typically on forced exhalation. Quiet, restful breathing in humans does not appear to use the muscle. However, exhalation below functional residual capacity (FRC) such as in speech and forceful exhalation such as in coughing, expectoration, and laughing utilize the power of this muscle (De Troyer et al. 1987, 2005).

Subcostal muscles. The subcostal muscles are present most often in the lower segments of the thorax. These muscles arise from the inner aspect of the rib near its angle and descend two to three ribs below to find an attachment to the upper margin of a rib (O’Rahilly, 1986). The subcostal muscles run in the same plane as the innermost intercostals and appear to be an embryological derivative of that layer. The subcostal muscles are most prominent in the inferior portion of the thorax and with the exception of the 12th rib and remain lateral to the angle to the rib at all levels. The common orientation of these muscles with the internal intercostal suggests a possible function in exhalation.

Levatores costarum. The levatores costarum are a group of small muscles located deep to the paraspinal muscles and attached to the ribs on their posterior aspect. These muscles arise from the transverse process at the level of the costotransverse joint and extend downward diagonally to attach to the rib or ribs below (Fig. 13.8). The short head (brevis) of the muscle attaches one rib below its origin while the long head (longus) attaches two ribs below. Given the position of these muscles on the rib, it is evident that they contribute to elevating the rib on inhalation (De Troyer et al. 2005) but have not received extensive physiological examination to date.

The external oblique muscle. The outermost abdominal muscle arises from the external and lower borders of the lower eight ribs. The attachment of this muscle interdigitates with the slips of the serratus anterior and latissimus dorsi, both extremity muscles, as well as fusing with the external intercostal muscle of the lower eight ribs (Fig. 13.9). The muscle fibers form a broad thin sheet passing anterior and inferior, similar to those of the external intercostals, to reach their attachment to a medially positioned aponeurosis, which extends from the xiphoid process superiorly to the pubic symphysis inferiorly. The inferior border of this aponeurosis

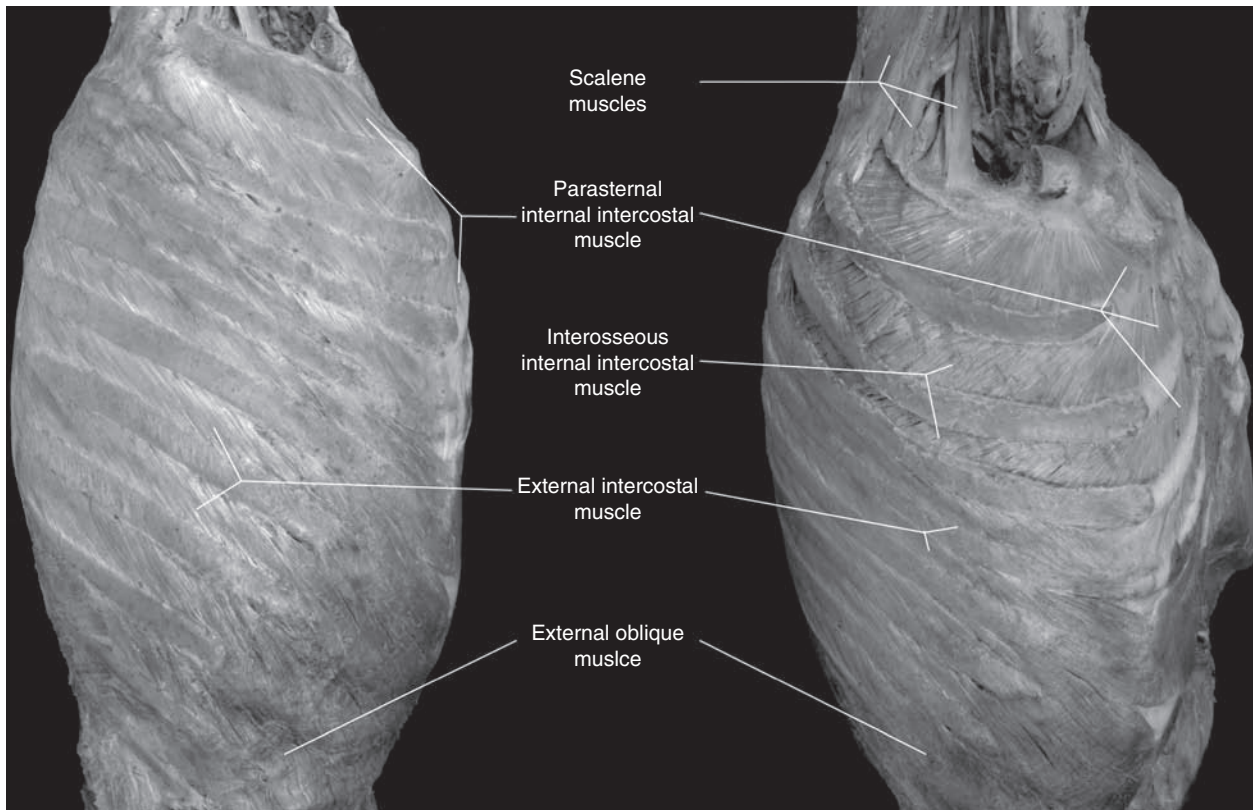

Figure 13-5 These are lateral views of the thorax to illustrate the distribution of the intercostal muscles. In the dissection on the left the external intercostal muscle is exposed. In the dissection of the right, the external intercostal muscle in the first 3 interspaces has been removed to expose the internal intercostal muscle. (Taken from the Willard/Carreiro Collection.)

participates in the formation of the inguinal ligament and its medial border contributes to the rectus sheath (O’Rahilly, 1986). The muscle fibers of the external oblique rarely extend below a line drawn between the umbilicus and the anterior superior iliac

spine, the remainder of the sheet being aponeurosis. Contraction of the external oblique muscle is capable of distorting the human rib cage (Mier et al., 1985). The external oblique is quiet during restful breathing but engaged during forceful exhalation (Epstein, 1994).

Internal oblique muscle. The internal oblique muscle has a radiate shape (Fig. 13.10), emanating from the region of the iliac crest and low back and attaching along a line from the pubic symphysis upward along the rectus sheath and posteriorly along the subcostal margin to reach the thoracolumbar fascia. Specifically, the broad sheet of muscle takes its origin from a curved line involving the upper portion of the inguinal ligament anteriorly, the iliac crest centrally, and the thoracolumbar fascia posteriorly. From this line, the fibers of the muscle radiate inferiorly to reach the conjoint tendon and pubic symphysis; in doing so, they help form the *falx inguinalis* under which the spermatic cord or round ligament will pass. Superiorly this muscle radiates toward the back where fibers attach to the inferior margin of the subcostal cartilage as well as interdigitate with the internal intercostal muscles. The middle fibers of the muscle pass anteriorly around the curve of the abdomen to join a medially positioned aponeurosis, which eventually splits to house the rectus abdominis muscle (O’Rahilly, 1986). Quiet respiration does not appear to engage the internal oblique muscle; however, it will become active on forced exhalation (Epstein, 1994).

Transversus abdominis muscle. Internal to the abdominal oblique lies a third muscle with a predominant horizontal fiber orientation (Fig. 13.11). The transversus abdominis arises from the lateral portion of the inguinal ligament, the iliac crest, the thoracolumbar fascia, and the inferior margin of the lower costal cartilages. On the posterior aspect of the anterior abdominal wall,

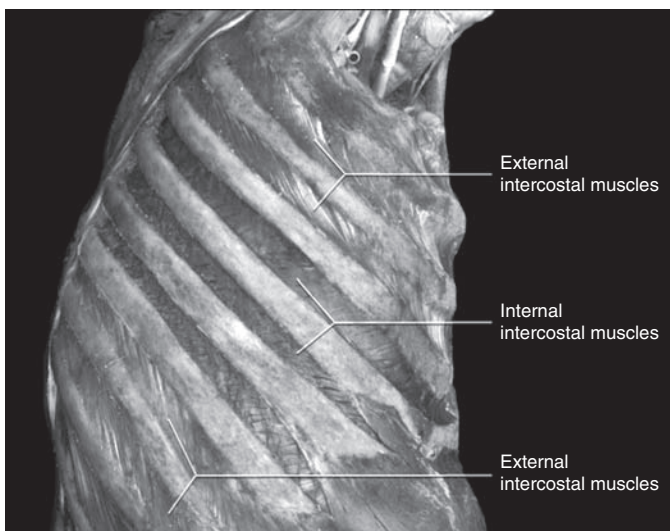

Figure 13-6 A lateral view of the thorax. In this dissection, the skin, superficial fascia and upper extremity were removed. The external intercostal muscle is seen in the first two interspaces. This muscle was removed in the next three interspaces to reveal the internal intercostal muscles. The external intercostal is seen in the remaining interspaces. (Taken from the Willard/Carreiro Collection.)

Figure 13-7 This is a posterior view of the anterior thoracic wall. The anterior wall was removed by sectioning the ribs laterally. The parietal pleura was removed from the right side of the wall but has been retained on the left side. The transversus thoracis muscle is seen radiating away from the inferior portion of the sternum. Note the asymmetry of this muscle. Slips of the innermost intercostal muscle can be seen in the upper interspaces. (Taken from the Willard/Carreiro Collection.)

the transversus abdominis dovetails with slips of the diaphragm along the subcostal margin. Medially, the fibers of this broad, flat muscle attach to an aponeurosis that extends from the xiphoid process superiorly to the conjoint tendon inferiorly (O’Rahilly, 1986). All muscle fibers are horizontally oriented except for the most inferior border where the muscle bands turn downward dramatically to join those of the internal oblique and form the conjoint tendon. The horizontal orientation of the muscle fibers allows this muscle to act as a retinaculum, pulling the rectus sheath toward the posterior body and increasing the intra-abdominal pressure. This mechanical action has the effect of raising the diaphragm in the thoracic cavity (De Troyer and Estenne, 1988). EMG studies have demonstrated that the transversus thoracis is an obligatory muscle of respiration and is active in both exhalation and inhalation, ceasing its activity only as it approaches the portion of maximum inhalation (De Troyer et al., 2005).

Rectus abdominis muscle. The rectus abdominis muscle forms a vertically oriented band of muscles extending from the pubic crest and symphysis to the xiphoid process and medial subcostal margin (Fig. 13.12). The muscle is typically divided into four plates by three tendinous horizontal bands. The rectus abdominis is housed in a dense fibrous connective tissue wrapping termed the rectus sheath. Essentially the sheath is composed of anterior and posterior plates derived from the splitting of the aponeurosis of the internal oblique. This sheath completely surrounds the muscle with the exception of the posterior wall inferior to the umbilicus; here, a defect in the posterior wall of the fibrous sheath transmits the rectus abdominis muscle. Inferior to this line, termed the arcuate line, the posterior wall is composed primarily of the transversalis fascia. Although a major function of the rectus abdominis is flexion of the torso and counterbalancing the paraspinal muscle of the back, the rectus, when used in combination with the other abdominal muscle particularly the transversus abdominis, functions as a corset trussing the abdominal organs in place and pushing them upward to make a fulcrum (see section on the diaphragm) over which the

thoracoabdominal diaphragm is draped (De Troyer and Estenne, 1988).

Combined Function of the Intercostal, Scalene, and Abdominal Muscles

The various intercostal muscles have differing functions in respiratory movements. The external intercostal muscle and the parasternal muscle are key players in inhalation, while the interosseous portion of the internal intercostal muscle is involved in exhalation.

However, electrical stimulation of any isolated intercostal muscle will close the ribs regardless of its location, thus the factors differentiating the action of the external intercostal and parasternal muscle from the remainder of the internal intercostal muscle must reside outside the geometry of these muscles alone. The actions of the intercostal muscles are dependent on the resistance to motion at either end of the thoracic cylinder. This resistance is dependent on the state of contraction of the muscles attached to the cylinder ends. Fixation of the first rib supports inhalation and fixation of the subcostal margin facilitates exhalation. The function of the scalene muscles is to fix the position of the first rib and thus initiate inhalation. A function of the abdominal muscles is to fix the position of the lower ribs thereby initiating exhalation. The contraction of the intercostal muscles is coordinated with the activity of the scalene and abdominal muscles. As the scalene muscles contract, a wave of activity begins in the superior external intercostal and parasternal muscles sweeping sequentially down the thoracic wall from the first interspace. A reverse or ascending wave is seen following contraction of the abdominal muscles and leads to lowering of the ribs and exhalation (De Troyer and Estenne, 1988; De Troyer et al., 2005).

Control over the sequential contraction of the intercostal muscles has been shown to reside in the pattern of connectivity regulating ventral horn interneuron activity. These cells regulate the discharges of the ventral horn motor neurons, which in turn

Figure 13-8 Posterior view of the back with the paraspinal muscles on the left side removed to display the levatores costarum muscles. Levatores costarum longus spans two segments while brevis spans one segment. (Taken from the Willard/Carreiro Collection.)

innervate the intercostal muscles. The spinal cord interneurons are modulated by input coming from both the medullary portion of the brainstem and peripheral input from muscle spindles. However, this combined input is relatively weak compared to that of the central respiratory drive potential present in the ventral horn, thus suggesting that the spinal interneurons of the ventral horn are the dominant force (De Troyer et al., 2005). Therefore, as with the control of individual muscle contractions in such repetitive actions as locomotion, there is a central pattern generator formed by the interneuronal pool in the ventral horn. This group of cells generates repetitive patterns of activity for the motor neurons to deliver to the appropriate skeletal muscles. These patterns can be influenced by both the descending activity from the medullary brainstem and the peripheral activity from the muscle afferent fibers; ultimate control however appears to reside in the spinal cord.

The Pumphead in the Thoracic Cylinder

The Thoracoabdominal Diaphragm

The diaphragm is often described as a dome-shaped structure composed of skeletal muscle and tendinous attachments that

partially close the passage from thorax to abdomen (Fig. 13.13). However, if the diaphragm is removed from the body and spread on the flat surface, it takes on the shape resembling that of a large butterfly with the central tendon as the body and the leaflets resembling head, wings, and tail. Each of the diaphragm's leaflets is named by its attachments. The sternal leaflets (head of the butterfly) are small and attach to the posterior aspect of the xiphoid process; occasionally they are missing. The costal leaflets (wings of the butterfly) are the largest and attach to the lower six ribs where their muscle fibers interdigitate with muscular slips from the transverses abdominis. These two leaflets form the broad sheet of diaphragmatic muscle that courses vertically along the internal margin of the ribs. Finally, the lumbar leaflets (tail of the butterfly) extend from the medial borders of the central tendon inferiorly to form two aponeurotic arches, as well as the cura of the diaphragm.

The medial arcuate ligament of the diaphragm attaches to the body of L1 medially arches over the psoas muscle and the tip of the anterior surface of the L1 transverse process laterally. The lateral arcuate ligament attaches to the anterior aspect of the L1 transverse process medially and reaches over the quadratus lumborum muscle to anchor laterally to the tip of the 12th rib near its midpoint. The

Figure 13-9 Lateral view of the torso illustrating the external oblique muscle and its attachment to the rectus sheath and the inguinal ligament. Note the interdigitation of the external intercostal muscle with the finger-like attachments of the serratus anterior. In addition, the most inferior fibers of the pectoralis major also blend into the superior medial attachment of the external oblique. (Taken from the Willard/Carreiro Collection.)

midline portion of the lumbar leaflets forms the crura of the diaphragm. Both crura arise from the medial most portion of the central tendon and sweep downward, attaching to the anterior longitudinal ligament on the bodies of the upper three lumbar vertebrae. The right crus is larger than the left. The medialmost fibers of each crus unite on the midline to form the median arcuate ligament that surrounds aorta as it passes from thorax to abdomen.

Function of the Diaphragm

The dome shape of the diaphragm is created by a piston of viscera including the liver, stomach, and spleen, which is forced upward into the central tendon by the abdominal musculature (Fig. 13.14), particularly the transverses abdominis. Much of the costal leaflet passes vertically along the wall of the rib cage to reach the subcostal margin and their attachment. This dome-shaped arrangement

Figure 13-10 The internal oblique muscle. This is an anterior view of the abdominal wall. The skin and superficial fascia have been removed. The external oblique muscle was cleaned and a window cut into the muscle to expose the internal oblique. This photograph demonstrates the middle fibers of the internal oblique as they arise from the iliac crest and attach to the rectus sheath. (Taken from the Willard/Carreiro Collection.)

creates what is termed the “zone of apposition” between the diaphragmatic muscle and the thoracic wall (De Troyer and Estenne, 1988). The length of this zone proves crucial to the function of the diaphragm. With the visceral piston placed in the full upright position, contraction of the costal leaflets will pull the subcostal margin upward while attempting to force the visceral piston downward. If the visceral piston is adequately buttressed by the abdominal musculature, the central tendon only descends a short distance, less than two segmental interspaces, and the subcostal margin of the ribs is elevated. Since the lower ribs are attached by movable joints anteriorly and posteriorly, the body of the rib rotates outward and upward (referred to as “bucket-handle” motion). Thus, the abdominal viscera can be considered to function to form a fulcrum over which the diaphragm is bent. The motion occurring across this visceral fulcrum greatly increases the volume of the thorax while minimizing the amount of descent required by the central tendon. It is important to realize that for the diaphragm to maximally lift the ribs during respiration it has to maintain its vertical zone of apposition along the costal wall. Structural changes that alter this arrangement can significantly impair the ventilatory mechanics of the diaphragm.

ACCESSORY MUSCLES OF RESPIRATION

Abdominal Muscles

External and Internal Oblique Muscles

Neither the external nor the internal oblique is active on quiet respiration. However, both muscles will become involved in respiratory movements during forced exhalation (reviewed in Epstein, 1994). These muscles exert a downward pull on the subcostal margin thus sliding the thoracic walls over the diaphragm and visceral organs, in essence seating the piston high in the cylinder. This gliding motion helps to decrease the volume of the pleural cavities in the thorax and thus facilitates exhalation. The gliding motion is also important in re-creating the large zone of apposition preceding the next respiratory cycle.

Limb Girdle Muscles

Seratus Anterior Muscle

The most powerful of the limb muscles capable of influencing the ribs is the seratus anterior. This thin, sheet-like muscle arises from the fleshy attachments to the anterior surface of the first eight or nine ribs (Fig. 13.15). Each band of the muscle wraps around the thorax

Figure 13-11 This is a lateral view of a male abdomen. The skin, superficial fascia and the external and internal oblique muscles have been removed to reveal the transversus abdominis muscle. The rectus sheath has also been removed. The whitish material is the transversalis fascia. Cotton has been placed in the abdominal cavity to expand the transversus abdominis muscle to its full extent. (Taken from the Willard/Carreiro Collection.)

passing between the posterolateral thoracic wall and the scapula to reach the medial border of this bone. The involvement of the serratus anterior with movement of the scapula is well detailed in numerous anatomy books and will not be covered here. If the upper extremity is fixed by grasping an external object, the serratus can assist in raising the ribs. Thus, the serratus anterior can become an accessory muscle of respiration in stressful situations. Use of this muscle to assist in respiration can be observed in cases involving hyperinflation of the chest such as chronic obstructive pulmonary disease (COPD). Here, the patient may grasp the bed rails, fixing the scapula, in an effort to recruit the serratus and assist in respiratory movements.

Oropharyngeal Muscles and Respiratory Movements

Protecting Airway Patency

The upper airway (the larynx and above) is a collapsible tubular structure. Compromise of the airway lumen can occur during inspiration and neonates are especially vulnerable to this event. Several

muscles act in concert to protect the patency of the air; these are the muscles of the tongue such as the genioglossus and those of the hyoid such as the geniohyoid, sternohyoid, sternothyroid, and thyrohyoid (Thach, 1992; reviewed in Lee et al., 2007). Bursts of activity in phase with inspiration have been recorded from these muscles (reviewed in Thach, 1992). In addition, an especially important muscle for opening the airway is the posterior cricoarytenoid muscle since it is the only abductor of the vocal folds. Although little is known concerning the respiratory-related activity of this muscle in humans, work in other species has confirmed an inspiratory rhythm in the muscle. Contraction of all of these upper airway muscles functions to increase airway rigidity and protect the patency of the lumen (Fig. 13.16). The neural pathways underlying the presence of a respiratory rhythm in the upper airway muscles have not been fully worked out. However, this activity may be in part due to pressure changes in the lumen of the airway detected by trigeminal afferent fibers and relayed to the hypoglossal nucleus through the trigeminal complex (Hwang et al., 1984).

RESPIRATORY MUSCLE PATHOLOGY

Airway Diseases

Structural Changes in COPD

COPD currently is the fourth most common cause of death worldwide and has been estimated to rise to the third most common cause by 2020 (Barnes, 2004). It is most often related to smoking although it can be caused by exposure to any noxious gas including poorly ventilated cooking fumes.

Functionally COPD involves the increased resistance to airflow, typically expressed as a reduction in forced ventilation rate with air trapping in the lungs at end-stage exhalation. At a tissue level, COPD involves loss of alveolar architecture and narrowing of the small airways either through thickening of the wall from chronic inflammation or plugging with mucous secretions. Structurally, air trapping in the lungs at full exhalation results in hyperinflation with enlargement of the A-P dimension of the chest as is

typically seen on clinical and radiographic examination of the patient with COPD (Celli, 1995). The hyperinflation is due to either loss of static recoil in the parenchymal tissue or to dynamic hyperinflation, for example, the presence of residual air in the lung at the end point of exhalation (reviewed in Fitting, 2001). In essence, the narrowing of the distal end of airway allows air to be drawn into the alveoli but impedes movement of the air out of the lung. In hyperinflation, the diaphragm is typically lower in the thoracic cavity and shorter in length with a slightly increased radius of curvature.

Structurally the diaphragm in the COPD patient creates a straighter line between the subcostal margins at a lower level in the thorax, thereby significantly reducing the zone of apposition (Cassart et al., 1997) as well as the overall surface area of the muscle (Fig. 13.17). Normally the zone of apposition represents 60% of the muscle's length, but that can be reduced to 40% in COPD. This structural change significantly decreases the efficiency of the diaphragm as a muscle of inhalation (Cassart et al., 1997).

In addition, the reduced length of the muscle alters the length–tension relationship for the muscle fibers; this reduction in length–tension relationship further compromises the diaphragm’s efficiency. In the physically lowered state, contraction of the diaphragm can, in fact, become an expiratory action in nature.

An example of this expiratory conversion of the diaphragm is seen when attempting deep inhalations from the flattened state with a

marked reduction in the zone of apposition. The subcostal margin is drawn inward at the end stage as the flattened diaphragm pulls the ribs inward; this is a paradoxical motion termed Hoover sign (reviewed in De Troyer and Estenne, 1988). However, it appears that not all of the inward motion of the subcostal margin during attempted inhalation can be blamed on the loss of the zone of apposition. Additional inward force is most likely derived from the

large negative intrathoracic pressure against which the diaphragm is pulling in the COPD patient (Laghi and Tobin, 2003).

Biochemical Changes in Respiratory Muscles in COPD

Along with the structural changes seen in the diaphragm of patients with COPD, significant histological and biochemical changes result in adaptations aimed at increasing the efficiency of the muscle.

Figure 13-14 The abdominal viscera (arrow) act as the fulcrum of the diaphragm allowing it to elevate the ribs. (Taken from De Troyer A and Estenne M. Functional anatomy of the respiratory muscles. *Clin Chest Med N Am* 1988;9:175–193.)

A significant change involves the fiber types present in the muscle of the diaphragm. Current estimates of respiratory muscle histological composition in the normal adult human diaphragm indicate that 55% of the fibers are of the slow type (type I fibers), 21% fast oxidative (type IIA fibers), and 24% fast glycolytic (type IIB and 2X fibers). Intercostal muscle histology finds greater than 60% are slow fibers (reviewed in Polla et al., 2004). This relatively high percentage of type I (slow twitch) fibers present normally is thought to represent an adaptation imparting the respiratory muscles a fatigue-resistant quality (Ottenheijm et al., 2008).

Interestingly, the diaphragm muscle of COPD patients demonstrated a further increase in the slow-twitch fibers with a shift to the slow isoforms of the myofibrillar proteins (Levine et al., 1997; reviewed in Polla et al., 2004). Stubbings et al. (2008) have shown a strong negative correlation between the forced expiratory volume in 1 second (FEV_1) and the percentage of type I fibers contained in the diaphragm. Thus, all COPD patients in their study had a higher percentage of type I fibers in the diaphragm and a lower FEV_1 . In addition, there was a positive correlation between the FRC and the percentage of type I fibers in the diaphragm. Thus COPD individuals had a greater percentage of type I fibers and a greater residual of trapped air in the lung than the non-COPD controls.

The shift toward increasing type I fibers in the diaphragm muscle of COPD patients is suggestive of a further adaptive process to help minimize diaphragm muscle fatigue in these patients (Ottenheijm et al., 2008). It was also demonstrated that the amount of ATP consumption was proportional to the rate of the contraction. Since type IIA fibers contract faster than type I, then for a given contraction of equal length, type I fibers consume significantly less ATP than type IIA fibers. From this, it is clear that the shift to type I fibers with reduced consumption of ATP in the COPD patient helps to conserve energy.

The benefits of an increased percentage of type I fibers in the diaphragm may be partially offset by a decreased amount of myosin in each sarcomere. Since the contractile force of a muscle is related to the density of myosin per sarcomere, the muscle fibers of the COPD patient are weaker in nature (Balasubramanian and Varkey, 2006).

These structural changes in fiber type found in the diaphragm were not detectable in other respiratory muscles such as the intercostal muscles, nor have they been documented in other muscles of the body. In fact, evidence suggests that the extremity muscles suffer a reverse effect. Histological observation has demonstrated a shift from type I to type II fibers with a concordant reduction in the diameter of both type I and II fibers that is proportional to the severity of the of the COPD as measured by a reduction in FEV_1 (Gosker et al., 2003). Atrophy, fatty replacement, and fibrosis were enhanced in the extremity muscles of the COPD patients when compared to control subjects. Other metabolic and microstructural changes in extremity muscles of COPD patients have been reviewed recently (Balasubramanian and Varkey, 2006). All of these alterations in muscle anatomy and chemistry contribute to significantly increased weakness in COPD patients, a weakness and muscle mass loss that can be exacerbated by glucocorticoid therapy and reduced motion seen in a sedentary existence.

System Influences

COPD however is much more than a pulmonary system disorder; widespread systemic effects of the disease have been documented in patients with this disease. Systemic proinflammatory cytokines result in cardiovascular effects and generalized muscle wasting secondary to muscle and bone loss (reviewed in Balasubramanian and Varkey, 2006). The weight loss seen in COPD most likely is associated with cachexia secondary to elevated proinflammatory

Figure 13-15 The upper illustration is a lateral view of the serratus anterior in a specimen where the scapula has been freed from the body wall but sectioning the latissimus dorsi, trapezius and rhomboid muscles and cutting the clavicle. The scapula was then abducted as far laterally as possible to stretch the serratus to its full length. The lower illustration is an anterior view of a specimen prepared in a similar manner. The scapula has been fully abducted to expose the serratus anterior muscle. (Taken from the Willard/Carreiro Collection.)

cytokines such as TNF- α in circulation. The weight loss problem is best termed cachexia—selective muscle loss and protein degradation—not malnutrition, which is more generalized (Debigare et al., 2001). In essence, in COPD, the body has entered a negative energy balance state. In addition to the musculoskeletal system, cardiovascular, renal, and nervous system dysfunctions have been documented in COPD (Agusti et al., 2003).

Downward Cascade Associated with COPD

The structural alterations in the diaphragm muscle geometry and fiber type make rapid breathing movements more difficult; thus, a sedentary lifestyle is common with COPD. It is well demonstrated that extremity muscle wasting is also a common feature of COPD associated with both a sedentary lifestyle and the systemic release of rhabdomyolytic proinflammatory cytokines (Gosker

Figure 13-16 This is a schematic view of the muscles supporting the hyoid bone. Simultaneous contraction of these muscle pulls the hyoid anteriorly opening the airway. (Taken from van de Graaff WB, Gottfried SB, Mitra J et al. Respiratory function of hyoid muscles and hyoid arch. *J Appl Physiol* 1984;57(1):197–204.)

et al., 2003). Proinflammatory cytokines also have a stimulatory effect on the activity of osteoclasts, thereby enhancing the loss of bone. Principal areas of bony regression involve the proximal femur and the endplates of the vertebral bodies (reviewed in

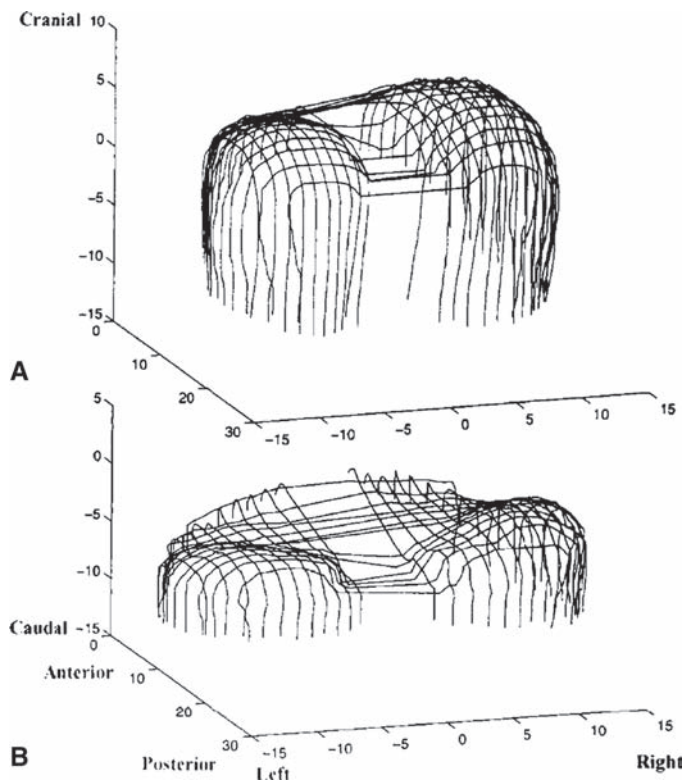

Figure 13-17 This figure illustrates a comparison of the shape of the diaphragm in a normal individual (A) and a patient with COPD (B). Tracings represent three-dimensional reconstructions derived from a spiral CT imaging study. (Illustration taken from Cassart M, Pettiaux N, Gevenois PA, et al. Effect of chronic hyperinflation on diaphragm length and surface area. *Am J Respir Crit Care Med* 1997;156(2 pt 1):504–508.)

Balasubramanian and Varkey, 2006). These changes increase the patient's susceptibility to femoral neck fractures and vertebral body collapse. Chronic hypoxemia, a condition that is ubiquitous in the later stages of COPD, will exacerbate many of the previously noted changes in musculoskeletal system. Diminished protein synthesis secondary to hypoxemia leads to diminished production of myosin in muscle sarcomeres and lower production of oxidative enzymes in mitochondria (reviewed in Balasubramanian and Varkey, 2006).

Thus in COPD, a downward spiral is established; compromised respiratory muscle function leads to reduced motion as well as hypoxia and inflammatory reactions. All of these results culminate in loss of muscle and bone mass with further reduction of motion in the patient. Lack of activity favors the stagnation of proinflammatory substances in the tissue further exacerbating the process. Although movement and exercise cannot restore the damage that has occurred in the lung, it can help arrest the downward spiral and improve the quality of life for the patient. The osteopathic approach to COPD should include consideration of the overall body structure and function in an effort to enhance the patient's ability to increase motion.

Obesity

Structural Changes

Abdominal obesity expands the subcostal margins of the rib cage without necessarily altering the superior margin. With

Figure 13-18 The torso of an obese female illustrating the flared, bell-shaped subcostal border. (Taken from the Willard/Carreiro Collection.)

the expanding subcostal margin, the rib cage takes on a more bell-shaped appearance (Fig. 13.18). When this occurs without raising the apex of the diaphragm, the entire muscle becomes more flattened in shape. In essence, the lateral margins are moving outward and upward getting closer to the level of the apex of the diaphragm and thereby reducing the zone of apposition. Attempted deep excursions of the diaphragm result in lower the apex closer to the level of the subcostal margin and can convert the diaphragm into a muscle of exhalation.

Influence on Systemic Disease

In an effort to maintain consistent minute volume of oxygen to the lung in the face of reduce amplitude of rib motion, the frequency has to rise; thus, a high-frequency, low-amplitude panting results. The hypoxia that associates with reduced respiratory muscle capacity, in a manner similar to that described for COPD, may be a partial cause of the systemic inflammatory response seen in morbidly obese patients.

Kyphosis

Structural Changes

Individuals with decreased bone density can suffer either acute or progressive loss of height in the anterior aspect of the vertebral bodies. In such cases, the vertebral column slumps anteriorly creating a kyphotic posture in the thorax with enhanced lordotic curvature of the cervical spine as compensation. The kyphotic curvature allows the ribs to move downward effectively diminishing, and in many cases completely eliminating, the intercostal spaces. Loss of the intercostal muscles prevents the upward and outward movement of the ribs on inhalation, thereby compromising the depth of the respiratory excursion and the efficacy of respiratory movements. Again a downward spiral of health ensues; compromised respiration yields hypoxia and reduced motion. Restricted movements lead to increased bone loss, furthering kyphosis and loss of thoracic motion.

SUMMARY

The anatomy of mandatory and selected accessory muscles of respiration has been reviewed. The structure of these muscles has been related to their specific functions in the respiratory movements. Dysfunction of these muscles occurs in a number of disorders such as COPD, obesity, and kyphosis. The implications of these structural changes on the respiratory movements have been examined and their resulting systemic effect considered. Each disorder leads to a vicious downward spiral involving motion restriction, hypoxia, inflammation, and further motion restriction. The role of the Osteopathic Physician is to help the patient restore homeostasis by facilitation motion in both the thorax and the extremities in an effort to arrest the vicious cycle.

KEY CONCEPTS

- Our brain derives much of its perception of the world around us through the activity of our receptors in the skin and particularly from the skin over our hands.
- The communication developed through the touch of the physician in the physical and structural exam is the first step in helping the patient retrace his or her steps back to a healthy state of body and mind.
- Touch is a perception that is emergent from neural activity in a complex network that includes the somatic sensory cortex as well as numerous other regions of the cerebrum.

INTRODUCTION**Touch as a Primary Sensation**

The sense of touch plays an important role in our awareness of the world around us. From the moment we awake in the morning, our hands contact the surrounding objects and communicate to us where we are and what we are doing. Throughout the day, touch provides a focal point for orientation and communication between us and the environment as well as between us and others in our lives. Our brain derives much of its perception of the world around us through the activity of our receptors in the skin and particularly from the skin over our hands. We make contact and explore surrounding objects and individuals using the somesthetic sense generated by touch with our hands. Texture, shape, weight, and size as well as friend, foe, harmless, or dangerous can all be determined, in part, through palpation. Our response to touch is filtered by the highly individualistic and personal emotional axes of our brain. Thus, whether the touch evokes kindness and trust or hatred and anger all depends on the context of the environment in which the touch occurs and the background of our daily lives. Finally, touch is a dynamic process, adapting to use or disuse, differing between sexes, changing with age and varying with culture.

Touch as a Primary Mechanism for Communicating with Patients

Touch can be a primary diagnostic tool. The physician touches the patient; the patient, in many ways, touches the physician. The dynamics of this contact between individuals are essential to the establishment of a trusting, respectful relationship (Fig. 14.1). The communication developed through the touch of the physician in the physical and structural exam is the first step in helping the patient retrace his or her steps back to a healthy state of body and mind. What begins as a palpatory examination quickly becomes a tactile conversation. The physician gains greater proprioceptive awareness of the structural impediments underlying physical as well as emotional and behavioral dysfunctions.

Significance of Touch to an Osteopathic Physician

Students begin to develop discriminative palpatory skills by touching other students, gradually transferring these abilities to the examination of patients. Through repeated practice, palpation progresses into deeper layers of the body—skin, fascia, muscle,

bone, joint, and finally viscera—slowly unmasking the health of the tissue to the examiner. Palpation of tissue may tell the skilled physician much more about the state of the patient's health than the patient can put into words. Putting the patient at ease while the physician is diagnostically touching him or her includes an explanation of intention and nature of the touching, its purpose, and what the patient is likely to experience. This dialogue enhances confidence and trust. Skillful touching and communication forges a deep verbal and tactile relationship between the physician and the patient. Gradually, the skilled osteopathic physician develops tactile memories of tissue dysfunctions both within a patient and across multiple patients. With time, palpatory skills may be used to monitor the patient's progress in his or her return to a healthy state. Even with chronic illness where healing and cure are unlikely, there is a reestablished human connection based upon compassionate touch and careful attention to the dialogue. This is the osteopathic path to restored function and self-healing. This chapter explores the biophysical mechanisms involved when the contact between the skin of the examining physician and the skin of the patient is converted into touch in the minds of both individuals.

TOUCH: ANATOMY AND PHYSIOLOGY**Overview**

We do not see with our eyes alone, we do not hear with our ears alone, nor do we touch with our hands alone; instead seeing, hearing, and touch are accomplished when our brain interacts with the information provided by receptor epithelia located in our eyes, ears, and hands. Thus, it is to this neural-based process that we must turn to understand our perception of touch. Touch is a perception that is emergent from neural activity in a complex network that includes the somatic sensory system as well as portions of many cortical regions in the cerebrum. This activity begins with the formation of a stimulus code in the peripheral process of primary afferent neurons distributed in the dermis and epidermis throughout the extremities, body, and head. The characteristic features encoded by these sensory neurons are stimulus quality, intensity, duration, and location on the surface of the body. The primary neurons bring this stimulus code to the dorsal aspect of the spinal cord. While some of this information is delivered to the dorsal horn of the spinal cord, a significant amount ascends the cord to reach the dorsal column nuclei in the caudal medulla. From these nuclei,

Figure 14-1 Touch in osteopathic medicine.

projections ascend through the brainstem to the posterior and ventral thalamus and are relayed on to the postcentral gyrus of the parietal cortex.

The entrance of primary axons into the spinal cord is done in an orderly fashion; thus, their addition to the spinal tracts creates a topographic map of the body—termed a somatotopic map. In essence, these maps, composed of nuclei and fiber tracts, contain information based on the segmentation pattern of the body. This orderly arrangement is preserved in the medulla, thalamus, and postcentral gyrus of the cerebrum. From the postcentral gyrus, the sensorineural code is mapped to several somatic sensory regions in the parietal cortex; these codes are modified and distributed across a large network of neural connection involving parietal, insular, occipital, temporal, and frontal lobes of the cerebral cortex. It is in this cortical network that the somesthetic input becomes integrated with that from our other senses, such as eyes and ears. Our perceptions of touch represent abstractions derived through extraction from the activity of these complex neural networks on the surface of our cerebrum. These perceptions are also colored by interaction with the pervasive emotional systems also present in the human forebrain.

CENTRAL PROCESSING: FROM PHYSICAL STIMULUS TO NEURAL CODE

The Primary Afferent Neurons Have Peripheral Processes in the Skin Deep Tissue and Central Processes in the Spinal Cord

Most of our sensation of touch arises from mechanical energy generated as an object makes contact with our skin. In the dermis underlying the epidermis, there are at least two major groups of primary afferent nerve endings: free endings that can give us a sensation of general contact with an object and encapsulated endings that

Figure 14-2 The sensory endings typically involved in tactile sensation. (Taken from Bear M, Connors BW, Paradiso MA. *Neuroscience: Exploring the Brain*. Philadelphia, PA: Lippincott, Williams & Wilkins, 2001, Figure 12-1.)

purvey discriminative and localizable touch (Fig. 14.2). Free nerve endings are typically associated with unmyelinated or lightly myelinated axons and are discussed in Chapter 15. The peripheral processes of the encapsulated endings are illustrated in Figure 14.2; they include Merkel discs, Meissner corpuscles, pacinian corpuscles, and Ruffini endings typically found in glabrous skin. However, additional specialized receptors are found innervating the bases of follicles in hairy skin. Typically, the encapsulated endings are associated with well-myelinated (Group II) axons. The cell bodies for these fibers are invariably found in the dorsal root ganglia or the trigeminal ganglion. Central processes of these neurons course through the dorsal root to enter the spinal cord through the dorsal root entry zone (Fig. 14.3).

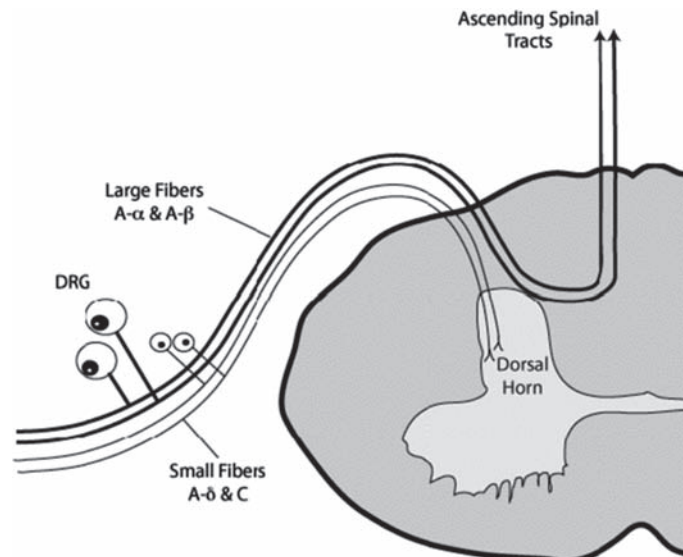

Figure 14-3 The dorsal root entry zone. The fibers of the dorsal root segregate prior to entering the dorsal horn of the spinal cord.

The Primary Afferent Neurons Detect Physical (Mechanical) Stimuli in the Peripheral Tissue, Develop a Sensorineural Code Based on the Stimulus, and Conduct This Information to the Spinal Cord and Brainstem

Primary afferent fibers detect various aspects of mechanical energy in the skin and encode this information into a series of discharge patterns that are conducted to the spinal cord (1). Four general patterns of activity have been cataloged based on the response properties and general position of each sensory neuron in the dermis. Two types of receptors have rapidly adapting endings and quickly change discharge patterns to a static stimulus; these are the Meissner and pacinian corpuscles, both with onion skin–like encapsulations. These rapidly adapting receptors are much better at recording a dynamic or moving stimulus than a static stimulus. The other two receptors, Merkel discs and Ruffini endings, demonstrate slowly adapting discharge patterns, much better designed to detect a static stimulus. Of these four types of receptors, the Meissner corpuscles and Merkel discs are located superficially at the epidermal–dermal junction, while the pacinian corpuscle and Ruffini ending are located in the deeper portion of the dermis. Each of these receptors is capable of encoding a specific characteristic of the physical stimulus presented to the skin; thus, for any given object touching the skin in any specific manner, a unique sensorineural code will be generated. This sensorineural code is conducted into the spinal cord by the central processes of the primary neurons.

The Position of the Sensory Axon in the Dorsal Root Entry Zone Is Related to Its Function

The dorsal root enters the spinal cord through the dorsal root entry zone; this zone is segregated based on fiber size. The small fibers move laterally in the root and enter directly into the dorsal horn. These fibers encode nociceptive stimuli and activate appropriate reflexes (see Chapter 15). Conversely, the large myelinated fibers shift medially, passing over the dorsal horn and gaining entrance to the more medially located dorsal columns of the spinal cord. As fibers add to the dorsal columns, they do so in an orderly manner, thus preserving the topography of the body. The dorsal columns ascend the full length of the spinal cord to reach the inferior aspect of the dorsal column nuclei located at the cervicomedullary junction.

Central Processing of Fine Tactile Information Begins in the Dorsal Column Nuclei

Neurons in the dorsal column nuclei receive the large myelinated, Group II afferent fibers in an orderly, somatotopic fashion. Within the dorsal column nuclei, each ascending axon synapses on a limited number of neurons, thereby maintaining the high fidelity of the information. These synapses are large and secure to ensure transmission of the information to the target neurons. In addition, the neurons of the dorsal column nuclei also receive the synaptic endings of corticonuclear fibers arising in the parietal cortex; thus, central processing of the sensorineural code really begins at this point.

The Chief Sensory Nucleus of the Trigeminal System Is Analogous to the Dorsal Column Nuclei

Primary afferent neurons innervating touch corpuscles in the face have their cell bodies in the trigeminal ganglion. Central projections from these ganglionic neurons reach the chief sensory nucleus in the trigeminal complex, which is located in the pontine portion

of the brainstem (Fig. 14.3). The chief sensory nucleus is similar in function to the dorsal column nuclei; thus, the chief nucleus represents the first relay for discriminative information from the face. Projections from the chief sensory nucleus cross the midline and ascend to the contralateral thalamus.

The Posterior Thalamus Receives the Ascending Sensory Tracts from the Dorsal Column Nuclei and Trigeminal System

Axons from the dorsal column nuclei cross the midline and ascend to the posterior thalamus in a large, well-organized fiber tract termed the medial lemniscus. Above the pons, the medial lemniscus is joined in its course by the ascending trigeminal fibers from the chief sensory nucleus of the trigeminal system. These combined sensory pathways enter the posterior aspect of the thalamus to terminate in the ventroposterior nucleus (Fig. 14.3). Laterally, the ventroposterior thalamic nucleus (VPL) receives axons from the medial lemniscus in an orderly fashion, thus preserving the topographic map of the body (feet laterally positioned and arms more medially located). Medially, the ventroposterior thalamic nucleus (VPM) receives ascending axons from the chief sensory nucleus, representing discriminative sensory information from the face. Thus, the thalamus is the first region in the ascending sensory systems where the body and the face are represented in somatotopic register with each other.

The Thalamocortical Circuitry Functions as a Unit in the Processing of Sensory Information

Neurons in the ventroposterior thalamic nuclei project axons in an orderly fashion onto the postcentral gyrus of the parietal cortex—the primary region of the somatic sensory system. Precisely mapped reciprocal connections from primary somatic sensory cortex to ventroposterior thalamus mean that the thalamocortical circuitry acts as an interlocked functioning unit. The reciprocal connections between the thalamus and the overlying cortex establish a strong oscillating rhythm through which information is transferred to the cerebral cortex.

The Neocortex Is Partitioned into Functional Regions Based on Its Distinct Cytoarchitecture and Connectivity

Human cerebral neocortex is partitioned in several domains principally associated with motor or sensory functions; these domains are surrounded by significantly larger cortical regions, termed association cortex, which are given over to the integration of cortical information between multiple sensory and motor areas (Fig. 14.4). The primary somatic sensory cortex is located along the postcentral gyrus and is directly posterior to the somatic motor cortex located on the precentral gyrus (Figs. 14.5 and 14.6). Although these cortical areas were originally defined by their distinct cytoarchitecture, they have been confirmed and elaborated based on their connections and functions. Three distinct regions are present in the primary somatic sensory cortex—areas 3, 1, and 2—with area 3 further subdivided into 3a and 3b (Fig. 14.6). Although each of these areas is organized into a somatotopic map of the body including the hand, neurons in each of these areas receive a different type of input from the periphery. This map is arranged by body segments proceeding from the trigeminal nerve through the cervical segments located laterally on the convexity of the cortex and eventually extending medially to the sacral segments located on the medial aspect of the

Figure 14-4 The spinal cord and brainstem pathways involved in tactile sensation. (From Campbell WW. *DeJong's The Neurologic Examination*. Philadelphia, PA: Lippincott Williams & Wilkins, 2005, Figure 32.4.)

cortex just above the corpus callosum. There is a disproportional representation of hands and mouth, which is reflective of increased density of sensory receptors; this disproportionate representation translates into increased sensitivity and sensory discrimination for the hand and oral regions of the body (Fig. 14.7).

Primary Somatic Sensory Cortex Receives High-Fidelity Sensory Information

Each region receives input from differing sources: Group I muscle afferent input coming from muscle spindles and Golgi tendon organs targets area 3a; area 3b receives input from Group II slowly adapting cutaneous receptors, while area 1 receives input from rapidly adapting receptors, although this differentiation is not complete. Finally, area 2 neurons are very complex; they receive input from joint receptors, periosteum, and deep fascias but respond more to movement than to individual stimuli (2). Unlike areas 3a, 3b, and 1

Figure 14-5 The location of the somatic sensory cortex on the convexity of the cerebral hemisphere. The primary somatic sensory cortex (areas 3, 1, and 2) is illustrated in blue; posterior to the primary somatic sensory area lies the large posterior parietal association cortex. where digit representation is relatively discrete, digit representation is overlapping in area 2, thus creating a more complex pattern of neural activity (3). Considering the areas posterior to the primary somatic sensory cortex, it is found that precise topography is lacking

and neuronal response properties are very complex; this is in keeping with regions involved in higher cortical functions (3).

Representation of Body Schema on the Primary Somatic Sensory Cortical Surface Is Plastic and Can Be Influenced by the Environment

Often, the impression given by textbook descriptions of sensory maps is that these systems are relatively hardwired from birth; nothing could be further from the truth. Cortical mapping is very dynamic and can expand in response to exercise and contract in response to nonuse (4; reviewed in Refs. 5,6). Witness the expansion of the cortical maps for the digits seen in musicians such as a violinist; a similar expansion undoubtedly occurs in the cortex of a physician when training his or her hands in palpation. A similar expansion was seen in the digital representation of experimental subjects with sight who were taught to read Braille. Conversely, anesthesia, immobilization, or removal of a digit results in a rapid loss of the cortical area representing the missing digit, and the newly available territory is claimed by surrounding digit

representations. Such reallocation of territory occurs on a larger scale when an entire extremity is lost. Abuse of the somatic sensory system can also alter the cortical somatotopic maps. Studies that created chronic repetitive strain injury in primates have demonstrated a loss in precision of the somatic sensory cortical maps, suggesting that proper rehabilitation following such injury may involve reforming and refining these cerebral projection maps (7). These studies suggest that learning any type of manual skill will alter the cortical surface map; thus, as students hone their palpatory skills, their cortical somatic sensory map is most likely responding by allocating increased area for the representation of digits.

CENTRAL PROCESSING: FROM NEURAL CODE TO PERCEPTION

Primary Somatic Sensory Cortex Is Involved in a High-Speed Feedback Pathway for Primary Motor Cortex

The dorsal column–medial lemniscus pathway is a high-speed pathway carrying touch and proprioceptive sensory information to the primary somatic sensory cortex. Intracortical connections map these data onto the primary motor cortex where it can act as a feedback system regulating discrete movements of the hands and feet. Motor cortex can control the actions of individual muscles in the distal extremities through the corticospinal tracts and their connections in the ventral horn of the spinal cord. Using this system, we can regulate the force we apply during palpation of an object (1). The osteopathic physician utilizes this feedback system as he or she learns to adjust the depth of palpation accomplished by his or her fingers.

Integration with Surrounding Areas of Association Cortex Provides the Complexity of the Sensory Experience

The primary somatic sensory cortex has our tactile world mapped in a high-fidelity Cartesian system of intersecting body segments and receptor types as previously described. Yet, we know that we do not feel specific receptor types or specific segmental boundaries; instead, we feel objects, textures, and shades of firmness, often colored by emotions; clearly, this is not happening solely on primary somatic sensory cortex. Rather, data from the Cartesian map on primary somatic sensory cortex are projected outward to surrounding cortical regions termed association cortex; typically, these are located in the posterior parietal cortex, the parietal operculum, and the inferior temporal cortex. The association areas establish complex interconnections with numerous surrounding cortical regions as well as the primary somatic sensory areas. In addition, portions of these association areas also map to other major sensory systems such as the visual system and auditory system; thus, neurons in these areas are often polysensory in nature. What emerges is a complex neuronal network involving high-fidelity data representation in the primary cortex and numerous network activity nodes spread across the posterior association cortex of the brain. The sustainability of activity in these nodes depends on the power contained in the thalamocortical circuitry; each region of the node is mapped to a unique region in the thalamus. Repeated thalamocortical oscillations augment the intracortical connections and contribute to network sustainability. In addition to repetitive thalamic input, dense connections from the prefrontal cortex serve to augment and reinforce the activity on this network. It is currently believed that from the summated activity of this complex neuronal interaction emerge our sensations of feeling, sight, and audition.

Two Major Processing Streams Through the Cerebral Cortex Help Integrate Somatic Sensory Input with Other Sensory Systems to Render Our Complex Feelings of Touch

The dorsal visuospatial stream, or “where pathway,” involves occipital cortex projections to the superior posterior parietal lobule (Fig. 14.8). This stream processes information involved with attention to the stimulus as well as location of the stimulus. Activity in this information stream helps in fitting the stimulus into a three-dimensional map of extrapersonal space. The ventral visuospatial stream or “what pathway” involves occipital cortex projections to the inferior temporal lobe. This stream provides information useful in recognizing, cataloging, and naming a stimulus. The somatic sensory parietal cortex has a dorsally directed projection that appears to participate in the “where pathway” and ventrally directed projections that contribute to the “what pathway” (8). This cortical organization affords us the ability to integrate visual and somesthetic senses into coherent images.

CENTRAL PROCESSING: FROM PERCEPTION TO COGNITION

The Prefrontal Cortex Is Involved in Reenforcing the Network Established in the Posterior Association Cortex Contributing to the Formation of Tactile Memories

Dorsolateral prefrontal cortex is strongly interconnected with the posterior parietal cortex and the inferior temporal cortex. These prefrontal cortex connections function to integrate information between the dorsal and the ventral information streams in the posterior association cortex (9). Through this integration of multiple distributed cortical networks, prefrontal cortex helps to create tactile memories. Thus, the prefrontal cortex uses the same information streams in parietal and temporal cortical areas that initially process tactile information to create our working memory of the experience (10). Tactile memory is used to compare tissue feelings;

Figure 14-8 The information processing streams in the posterior association cortex. A dorsal stream arises from the visual and somatic sensory cortex termed the “where pathway.” A ventral stream arises from the visual and somatic sensory cortex and is termed the “what pathway.” (Used with permission from the Willard/Carreiro Collection, University of New England.)

from this memory, the student develops a sense of normal and abnormal tissue texture.

Representation of Body Schema Is Complex and Occurs in Hierarchical Process of Layers

The thalamic projections to the primary somatic sensory cortex are highly organized by body segment and by receptor type; this represents one level in a hierarchy of body maps. The topography of body representation in this portion of somatic sensory cortex is distorted by sensitivity; areas of skin having the greatest sensitivity have disproportionately larger representation in the primary somatic sensory cortex; yet, this distortion in sensory representation is not perceived by our mind. A second level of representation based on topography is necessary to accurately register stimulus location regardless of innervations density and tissue sensitivity (11). This map must be updated temporally to account for age-related changes in body habits. Such updating occurs slowly; witness the clumsiness seen in pubescent individuals experiencing a “growth spurt” (12). A third level of representation is required to adjust the body map dependent on body posture (6). Finally, an additional level of processing is postulated to involve the mapping of the conscious body image; evidence suggests that this process may be located in the posterior parietal cortex (12).

CENTRAL PROCESSING: FROM PERCEPTION TO EMOTION

Integration with More Distal, Limbic Areas of the Cerebral Cortex Provides the Emotional Context of the Sensory Experience

The somatic sensory pathways discussed so far in this chapter all involve input from well-myelinated systems with elaborate encapsulated sensory endings. An additional nonmyelinated sensory arising from fibers with naked nerve endings also provides input through the thalamus to the cerebral cortex. This latter system targets a portion of the insular cortex in a region that represents an extension of the somatic sensory cortex around the operculum into the lateral fissure. This small fiber input system is postulated to play a significant role in modulating our body’s response to touch through its influence on the autonomic nervous system. This input also appears to influence our emotional state through its projections to the orbital prefrontal cortex and the anterior cingulate gyrus (13). These regions of the brain are associated with what many researchers have termed the limbic system—a loosely defined system that is believed to strongly regulate to our emotions (14). Activity in the orbital prefrontal cortex affects a strong reinforcement system, augmenting our positive or negative impressions of the particular tactile stimuli (15,16). Thus, tactile stimuli, using high-speed myelinated pathways, gain access to a discriminative and cognitive cortical system, allowing analytical evaluation of touch such as one might use in physical diagnosis; however, there is an additional component of the tactile information, which employs slower, less well myelinated systems that percolate through a strong cerebral emotional filter in and that play a large role in our final impression of touch (17).

This emotional aspect of touch gathers all of our past experiences—good or bad—to color our feelings and influence our decisions. To touch another is to be touched back, in essence tactility is bidirectional, intimate and reciprocal. The physician’s and patient’s boundaries are united with the intent to heal. The intangible emotions of physicians as they touch patients, encompassing all of their past experiences, may thus play a large role in the diagnosis that they pronounce and the treatment that they endorse.

Nociception and Pain: The Essence of Pain Lies Mainly in the Brain

FRANK H. WILLARD, JOHN A. JEROME, AND MITCHELL L. ELKISS

KEY CONCEPTS

- Tissue injury activates small primary afferent fibers in a process termed nociception.
- Nociceptive information from these afferent fibers passes through the dorsal horn of the spinal cord to reach the brainstem and thalamus.
- In the brainstem reflexes are initiated that can modify the individual's homeostatic mechanisms in a protective manner.
- From the thalamus, numerous cortical areas are engaged, creating a matrix of activity in the cerebrum contributing to the emergence of our feelings of pain.
- Based on this feeling of pain, protective physiological and psychological reflexes are initiated by the individual.
- Acute injury typically results in acute pain, a process which should resolve as the tissues heal.
- However, each level in the system is capable of sensitizing to the nociceptive activity and thereby enhancing our response both physiologically and psychologically to the noxious event.
- Excessive modification in the neural circuitry involved in processing nociception can lead to activity that out lasts the inciting event, thus entering the realm of chronic pain.
- In chronic pain patterns, protective physiological and psychological reflexes now become pathological, such dysfunction will affect the individual overall health and well being.
- Continued obsession with the pain further facilitates the involved forebrain circuitry creating a progressively worsening downward dysfunctional cycle carrying the individual into despair and depression.
- It is the role of the osteopathic physician to identify the physical (somatic and visceral) as well as behavioral factors contributing to these chronic dysfunctional patterns. It is the philosophy and practice of the osteopathic physician to assist the patient in seeking ameliorative and restorative strategies in the quest to regain health.

INTRODUCTION: THE NOCICEPTIVE SYSTEM AND PAIN

Every organism requires some form of protective system to detect and avoid potential external and internal environmental threats and to craft the behavioral expression of defensive behaviors. An ideal protective system would activate just before tissue damage is done and cease activation when the threat has remitted. In addition to protective reflexes, such a system should also trigger a strong learning experience that sensitizes the organism to future situations and helps foster avoidance behavior. Humans are endowed with just such a system; it is composed of small slowly conducting peripheral nerve fibers that can trigger rapid defensive responses at both spinal cord and brainstem levels as well as slower longer-lasting defensive changes involving neural, endocrine, and immune adaptations orchestrated from complex forebrain circuits. Accompanying these physiological and behavioral adaptations, there can also be a hard-to-define feeling of unpleasantness often simply termed "pain." The activity generated by a dangerous or potentially dangerous stimulus is not pain, it is best termed nociception, a mechanical and neurochemical process that is similar in physiology and intensity regardless of the individual concerned; pain is however the perception placed on this activity by the brain; pain is the learning experience. Thus pain arises, not from the small, primary afferent fibers in the periphery detecting a stimulus, but from the response of complex interacting systems contained in the forebrain, reacting to the barrage of nociceptive peripheral input. Along with the response to noxious stimulus, the "feeling of pain" also involves the integration of many previous situations as well as being set in the context of current emotional status of the individual; for this reason, painful

feelings may vary tremendously in intensity and quality from individual to individual as well as within an individual over time.

In this chapter, we will examine the small-fiber systems in the periphery that respond to potentially damaging stimuli and their initial short-loop reactions in the gray matter of the spinal cord. Next, a treatment of longer loop reflexes generated in the brainstem and forebrain will be developed. This will be followed by considering the integration of nociceptive input into the other defensive systems such as the endocrine response and the immune response to make an elaborate supersystem sculpting the organisms overall physiological and behavioral adaptations. Emphasis will be placed on the role of integrating the emotional circuitry of the brain into the defensive response in an effort to understand normal individual adaptations as well as the pathological responses associate with chronic pain scenarios. As with any physiological system, the central processes can regulate the peripheral systems; therefore, we will explore the descending neuronal and endocrine systems that influence the operation of the input systems both at the peripheral level and in the spinal cord and brainstem.

Finally, as with any complex system, failures can and do occur frequently. Complete loss of the small-fiber system, which can occur in certain familiar disorders, has catastrophic consequences for the individual concerned. Lack of a warning system allows self-mutilation to occur and the eventual demise of the musculoskeletal system (reviewed in Nagasako et al., 2003). From the study of such patients, it is clear that the normal activity of a nociceptive system is necessary for the maintenance of health in the individual. However, other seeds for destruction are contained in the very nature of the power in the system. The nociceptive system is a feed-forward system, explosive in activity and designed to mount a quick, effective, and powerful

protective response. The mechanisms underlying this powerful response require strong inhibition if they are to be adequately controlled; loss of these controls leads to excessive responses, very similar to the development of seizures disorders expressed in the cerebral cortex. This excessive activity in the nociceptive pathways or in the target regions of the forebrain can generate the feelings of pain when no peripheral generator exists. Facilitation of this activity can lead to physical neuronal damage with a resulting deepening and hardening of the aberrant synaptic patterns such that eventually an indelible chronic pain circuit becomes ingrained in the patient. This chapter will discuss some of the mechanisms involved in establishing these chronic pain patterns and their effect on the general health of the individual.

DISTINCTION BETWEEN PAIN AND NOCICEPTION

When we injure ourselves, we activate small primary afferent fibers in that carry action potentials to the spinal cord capable of initiating protective reflexes. This is a mechanical and electrochemical process termed nociception, the activation of sensory fibers by noxious stimuli. However, this event allow does not necessarily result in a sensation of pain. The spinal cord can become facilitated and relay these nociceptive signals to the brainstem where other reflexes concerning the autonomic nervous system and endocrine system may be then be initiated; however, these events still do not necessarily result in a sensation of pain. In fact, all of these events can occur without conscious awareness of the situation. Projections from the spinal cord and trigeminal brainstem nuclei also reach the thalamus and activate thalamocortical circuitry generating a network of activity on the cerebral cortex. Regions of the cortex involved in localization, the autonomic nervous system, emotions and affectation are involved creating a large matrix of activity from which pain is an emergent feeling (Chapman, 2005). Thus the feeling of pain, which is defined as an unpleasant sensation, does not arise from any one region in the cerebrum but instead from a network which itself is colored by our past physical and emotional experiences.

Since nociception and pain are separate but related entities, they can be disassociated from each other. People can experience physical trauma and not feel pain and, conversely, patients can experience much pain but lack any physical evidence of ongoing nociception in peripheral tissue. Many of the patients that you will experience fall into this latter category. This chapter will focus on the mechanisms of nociception first and then consider the experience of pain and its impact on the patient's health.

DISTINCTION BETWEEN ACUTE AND CHRONIC PAIN

Fundamentally, pain can be divided into two major categories: that which is good for you (protective), termed eudynia, and that which is not (maladaptive), termed maldynia. Good pain is commonly designated as acute pain. It is an expected symptom of tissue damage; it is protective in nature and lessens in intensity as the tissue returns to normal. Chronically recurring or unremitting pain is not a normal experience; it is a pathology and as such is an indicator that something has gone seriously wrong with the nociceptive system. Either tissue is very abnormal in its composition (chronic inflammation) and thus a constant nociceptive signal is being generated, or the neural pathways of the spinal nociceptive system and the cerebral cortex have become facilitated and as such have suffered a significant change in organization and are malfunctioning. A combination of both peripheral tissue and central system dysregulation is also possible. Ultimately, this abnormal activity can result in the system overresponding

to noxious stimuli (hyperalgesia) or even nonnoxious stimuli (allodynia) or, in some cases, simply generating spontaneous activity that the brain then interprets as continuous pain. Chronic pain, that is pain which is persisting past a reasonable, acute period of time (2 to 4 months), is often associated with a wide array of biopsychosocial reactions (Gatchel et al., 1996) and is now a pathological state.

Both acute and chronic pain involve facilitation in the spinal dorsal horn or trigeminal system. Spinal facilitation is reasonably well understood and the mechanisms by which this initially protective state converts into a pathology are slowly becoming understood. This transition from acute to chronic pain states represents a breaching the body's inherent capacity to heal its self and has to be understood as such in order to achieve effective treatments in the clinic. A significant manifestation of chronic pain can be the presentation of altered function in the musculoskeletal and visceral systems of the body. Recognizing the signs and symptoms of spinal cord or trigeminal nuclear facilitation and its manifestation as chronic pain becomes critical to the differential diagnosis of its myriad of etiologies. A major feature of this chapter will be consideration of the conversion from an acute pain scenario to that of a chronic pain disease; to begin we will examine the peripheral nervous system and discuss its involvement in nociception and the perception of pain.

THE PERIPHERAL NERVOUS SYSTEM

Compartments of the Peripheral Nervous System

The peripheral nervous system of the body can be divided into three major compartments. The first is the somatic system that innervates the skin, dermis, fascias, and deep tissues such as muscle, bone, tendon, and enthesis as well as joint capsule. The second is the visceral system that provides sensory innervation to the organs of the body located the in the thoracic, abdominal, and pelvic cavities. Finally, a third category consists of vascular afferent fibers that course along the neurovascular bundles and provide innervation to the vascular system both in the somatic and the visceral locations.

Primary Afferent Neurons Innervate Peripheral Tissue

The sensory cells of the peripheral nervous system are termed primary afferent neurons. Their cell bodies are located in a dorsal root ganglion. The central processes of these cells terminate in the spinal cord or brainstem (Fig. 15.1). In general, these primary afferent neurons are divided into four fundamental types of fibers based on the size of their axon and the type of peripheral ending (Table 15.1). The four fiber types of the peripheral nervous system can be grouped into roughly two general categories: large-caliber myelinated fibers with encapsulated endings and small-caliber unmyelinated or lightly myelinated fibers with naked nerve endings. Although this division is not perfect, it is supported by evidence that suggests the cell bodies of the two types differ in size, the development of the two groups occurs on differing timetables, and their immunohistochemistry is differentiated (Precht and Powley, 1990; Fitzgerald, 2005).

The Large-fiber System Is Mainly Involved with Discrimination and Proprioception

The large-fiber sensory system is composed of heavily myelinated, rapidly conducting A-alpha and A-beta fibers. Of these, the A-alpha fibers are the largest and connect to muscle spindle and Golgi tendon organs at their distal endings, while the A-beta fibers are slightly smaller in diameter and are typically attached to cutaneous touch corpuscles or related endings located in deeper tissues such as joint capsules. Table 15.1 compares the properties of these two rapidly

Figure 15-1 The termination of primary afferent fibers in the spinal cord. Large myelinated fibers with large cell bodies in the dorsal root ganglion (DRG) can be seen passing dorsal to the dorsal horn to enter the dorsal columns while small laterally positioned fibers with small cell bodies in the DRG are shown entering the dorsal horn laterally. (Used with permission from the Willard/Carreiro collection.)

conducting fiber systems. Typically, members of the largest fibers are easily activated, being sensitive to low levels of mechanical energy, and have the fastest conduction velocities. The ascending projections of the large-fiber system travel in the dorsal column—medial lemniscus system as well as the spinocerebellar systems to reach the thalamus from which they are relayed on to somatic sensory cortex (Fig. 15.2). This mapping is fairly precise and supports high-fidelity representation of the homunculus on the postcentral gyrus of the cerebral cortex (reviewed in Kandel et al., 2000). Collectively, the large-fiber system gives us the sensory modalities of vibratory sense, discriminative touch, and proprioception. Individual fibers of this system are said to be line labeled in so much as they represent a specific modality; varying the intensity of the stimulus for this fibers does not significantly alter the modality that they represent. Thus, an A-beta fiber associated with a Pacinian corpuscle, when activated, gives the individual a sense of vibration regardless of the intensity of the activation. This consistency in sensory perception contributes to the accuracy and precision of the system. An additional property, prominent in the large-fiber system, is ability of many of its endings to undergo adaptation to repetitive stimuli. In such fibers, repetitive

stimuli initially activate the fiber ending, which then adapts to the stimulus by altering its shape in such a way that it becomes nonresponsive to that particular stimulus. Adaptation of these fibers facilitates the detection of novel stimuli in the environment.

The Large-Fiber System is Active in Pain Control

Although the major target of A-beta fibers is the dorsal column nuclei of the brainstem, many of these fibers, as they enter the spinal cord, give collateral branches that invade the dorsal horn as well. These collateral branches, through an inhibitory mechanism, can modulate the transmission of information in the small-fiber system in the dorsal horn and thereby prevent nociceptive information from ascending in the spinal cord tracks. This mechanism has been termed the gate-control theory of pain modulation and appears to play a significant role in controlling the activity of the small-fiber system. (Melzack and Wall, 1965). Conversely, under situations of intense peripheral stimuli involving inflammation, some members of the large-fiber system have been observed to undergo a phenotypic change such that they can now activate dorsal horn neurons and produce a neuropeptide termed substance-P, a marker for the small-fiber system (Neumann et al., 1996). This alteration in fiber function would have profound effects on the amplification of signal in the dorsal horn and the patient’s perception of pain.

THE SMALL-FIBER SYSTEM

The small-fiber sensory system is composed of A-delta and C-fibers; collectively these fibers have been referred to as primary afferent nociceptors (PANs). The A-delta fibers have a thin myelin sheath; whereas the C-fibers only have a thin wrapping derived from the Schwann cell but no myelin. A common feature of these fiber types is their termination as an exposed or naked axon ending, also termed free nerve ending, embedded in the extracellular matrix of the surrounding tissue. In general, many of these small-caliber fibers have high thresholds of activation, requiring tissue-damaging or potentially tissue-damaging levels of energy before generating action potentials. However, there are some A-delta fibers with thresholds of activation in the same range as the large-fiber systems previously described (Meyer et al., 2006); these low-threshold fibers will not be considered further.

The Small-Fiber System Targets The Dorsal Horn

The central process of the small-caliber fibers terminates in the ipsilateral dorsal horn of the spinal cord (Fig. 15.1) or if the fiber arises

TABLE 15.1

Classification of Fiber Types in the Peripheral Nervous System

Classification	Fiber Size and Velocity	Myelin	Origin	Receptor Organ	Effective Stimulus
Group Ia (A α)	12–20 μ m; 70–120 m/s	Yes	Muscle	Annulospiral	Stretch—low threshold
Group Ib (A α)	2–20 μ m; 70–120 m/s	Yes	Muscle	Golgi tendon organs	Active contraction of muscle organs
Group II (A β)	5–12 μ m; 30–70 m/s	Yes	Muscle	Flower-spray	Stretch—low Threshold
Group III (A δ)	2–5 μ m; 12–30 m/s	Yes	Skin	Touch corpuscles	Mechanical deformation of skin
Group IV (C-fibers)	0.5–1 μ m; 0.5–2 m/s	No	Muscle and skin	Nociception	Mechanical deformation of skin; heat; cold; chemical stimulation
			Muscle and skin	Nociception	Mechanical deformation of the skin; heat; chemical stimulation

in the trigeminal territory of the face, its central process terminates in spinal trigeminal nucleus of the medullary brainstem. Specifically, these small-diameter afferent fibers reach laminae I, II, and V of the dorsal horn as well as the central portion of the gray matter around lamina X. Ascending projections from the dorsal horn neurons cross the midline in the anterior white commissure of the spinal cord and

course upward in the anterolateral tract or system to reach the brainstem and thalamus (Fig. 15.3). Low-level activation of the small-fiber systems (most likely A-delta fibers) gives us the perception of touch without much localizing capability; however, increasing the activity of this system transforms the perception from that of touch to the sensation of pain. Thus, instead of being line labeled such

Figure 15-3 The Anterolateral or spinothalamic system. (From Campbell WW. *DeJong's the Neurologic Examination*. Philadelphia, PA: Lippincott Williams & Wilkins, 2005.)

as the large-fiber system, some members of the small-fiber system appear to change their specificity with the intensity of activation.

The Output of the Small-Fiber System is Protective in Nature

In addition to warning signals (pain sensation), the small-caliber system activates a complex response from the brainstem termed by Hans Selye the general adaptive response (Selye, 1946). This response involves alterations in the autonomic nervous system and the hypothalamic-pituitary-adrenal axis, both reflexes which will contribute to the inherent ability of the body for self-regulation and the reestablishment of health. These concepts will be further discussed toward the end of the chapter.

An additional distinctive property of the small-caliber system is its ability to sensitize to repetitive stimuli. Unlike the large-fiber system, which tends to adapt to a stimulus, many of the components in the small-fiber system—either at the level of the peripheral neuron, spinal cord neurons, or even higher in the CNS—will increase their sensitivity to the stimulus. This enhanced activity secondary to sensitization has significant implications for the small-fiber system in the pathology of chronic pain (Ji et al., 2003).

SUMMARY

Both small- and large-fiber systems can play a role in the human perception of pain. However, typically, the small-caliber system has by far the greatest impact. In normal tissue, only small fibers transmit nociceptive information and only their activity is perceived as pain. In addition, the large-fiber system helps to gate the activity of the small-fiber system and control the amount of nociceptive information gaining access to the spinal cord neurons. However, in injured tissue, the situation changes dramatically. The large-fiber system can now become a key player involved in generating the perception of pain. The next section of this chapter will be focused on the anatomical organization and functional properties of the small fibers and their interaction with the large-fiber system in pathologic situations.

SMALL-FIBER LOCATION

PANs terminate with naked nerve endings in numerous tissues throughout the body. The specific locations in which these fibers terminate are important for understanding the patterns of pain that they develop.

Skin And Fascia

PANs are present in the dermis and underlying fascia throughout the body (Munger and Ide, 1988). Upon entering the dermis, much branching of these fibers occurs before their termination. A variety of molecular receptor types are present on cutaneous afferent fibers (Julius and Basbaum, 2001). The PANs in the deep fascia are mostly associated with blood vessels, while a few in the dermis can have small terminal branches that actually penetrate the epidermis to end embedded between cells of the squamous epithelium; these are termed intraepithelial endings. PANs also reach the specializations of the integument such as the nail beds, tympanic membrane, and cornea.

Muscle

Muscle nerves can be as much as 50% small fibers in composition (Mense and Simons, 2001). Within the muscle, PANs are seen to course in the connective tissue surrounding the vasculature. While PANs do not directly innervate myocytes, they do remain in the

surrounding connective tissue termed the perimycium and are thought to play a major role in regulating the vascular dynamics of the muscle. Many of these small fibers contain neuropeptides such as substance-P and calcitonin gene-related peptide consistent with their role as sensory fibers and neurosecretory fibers. Thresholds for activation muscle PANs are usually somewhat lower than that necessary actually to damage the surrounding muscle tissue. Distribution of the PANs is complex; many of these fibers have more than one receptive field in the peripheral tissue, and often the two fields are not contiguous. Muscle PANs appear to be sensitive to inflammatory substances and to the breakdown products resulting from intense muscle activity. Finally, muscle PANs are well noted for their ability to increase activity in the spinal cord, leading to sensitization of the dorsal horn neurons (Wall and Woolf, 1984).

Tendon

The PANs found in tendons are not very well characterized at this time. Mense describes small fibers in the peritendineum and in the enthesis but not in the body of the tendon (Mense and Simons, 2001). Alpantaki described nerve networks extending the length of the human bicep tendon and especially dense at the enthesis, but not in the tendon-muscle junction (Alpantaki et al., 2005). The small fibers in these neural networks contained several neuropeptides typically associated with sensory fibers such as PANs. Concentration of these fibers at the enthesis could be related to the notably painful presentation of enthesitis.

Blood Vessels

Somatic and visceral blood vessels receive small-caliber sensory fibers as well as a sympathetic innervation. PANs follow the sympathetic nervous system coursing in the tunica adventitia of these blood vessels. These small vascular fibers release vasodilatory neuropeptides and can act as a counter-regulatory force to the vasoconstrictive nature of the sympathetic system. This is especially interesting in light of the fact that the somatic peripheral vasculature does not receive a parasympathetic innervation; thus, the PANs could be providing some, if not most, of the external dilatory signals to the vasculature (Premkumar and Raisinghani, 2006).

Nerves

The connective tissue sheath surrounding nerves contains a PAN innervation (Bove and Light, 1995). Where studied, these fibers contain and release proinflammatory neuropeptides and have high thresholds of activation similar to nociceptors. It is possible that some of the pain arising from chronic injury of a nerve could be arising from the PANs in the connective sheath surrounding the nerve rather than from the discharge of axons contained within the nerve itself.

Joints

Joints typically receive multiple articular nerves. These nerves have been demonstrated to contain as much as 80% small-caliber (C-fiber range) axons; of these small fibers, there is approximately an even split between those of the sympathetic nervous system and PANs (Schai-ble and Grubb, 1993). Fibers of all calibers innervate the joint capsule, ligaments, menisci, and surrounding periosteum; however, only small-caliber, peptide-containing fibers are typically seen in the synovial membranes. Increased density of innervation is a feature in abnormal, osteoarthritic joints and suggests that the PAN system is plastic and dynamic and can respond to injury by proliferating into the damaged tissue along with the blood supply (Fortier and Nixon, 1997).

Viscera

The axons entering viscera are typically small in size, being in the A δ - and C-fiber range (Bielefeldt and Gebhart, 2006). Afferent fibers enter the thoraco-abdomino-pelvic cavity either with the vagus nerve or the splanchnic nerves. These fibers are distributed via suspensory ligaments (mesenteries and mesocolons) to the hollow viscera. Sensory innervation can be found in the suspensory ligament as well as in the muscular wall and mucosa of the organ. Solid organs, such as the liver, are primarily innervated in the region of the fibrous capsule with very little projecting into the organ parenchyma. Many fibers are mechanosensitive, responding only to inflammatory compounds in the tissue. As such, they have been termed silent nociceptors to denote the lack of initial response to mechanical deformation (Cervero and Jänig, 1992), for example, during surgery. Although the total number of visceral afferent fibers is marginal compared to the somatic afferent system, the visceral system compensates for this by heavy branching and ramification of the central terminals in the spinal cord and brainstem (Cervero, 1991).

Meninges

Small-caliber fibers innervate the dura and extracerebral blood vessels surrounding the brain. These small fibers are components of the trigeminovascular system. Their cell bodies are located in the trigeminal ganglion and their peripheral processes follow the cerebrovascular system until it penetrates the brain. Inflammatory irritation of these fibers plays a crucial role in migraine and other vascular head pains (Sanchez del Rio and Moskowitz, 2000).

Annulus Fibrosis

PANs penetrate approximately one third of the way into the disc, reaching most of the annulus fibrosis but do not extend into the nucleus pulposus (Stilwell, 1956; Groen et al., 1990). These fibers are derived from the sinu vertebral nerve (recurrent meningeal) posteriorly and from the prevertebral plexus (somatosympathetic nerves) anteriorly (Jinkins et al., 1989). Many of these fibers contain neuropeptides typical of small-caliber primary afferent fibers and are involved in discogenic pain. In addition, PANs are found in the anterior and posterior longitudinal ligaments and in the facet joint capsules as well as in other ligaments of the vertebral column. This network of small-caliber fibers surrounding the vertebral column is involved in the axial pain syndromes (Willard, 1997).

SUMMARY

PANs have an almost universal distribution in the body; only a few areas have been demonstrated to be devoid of PANs. These regions include such regions as brain parenchyma, articular cartilage, the parenchyma of the liver, and lung and the nucleus pulposus. The density of small-fiber distribution is not uniform throughout the tissue of the body, being greatest in the dermis and more scattered in distribution through the visceral organs. There also appears to be some differential distribution of neuropeptides within various regions of the body. The widespread and plentiful nature of these small-caliber primary afferent fibers is a testament to their important role in the maintenance of our health.

SMALL-FIBER ACTIVATION

Primary afferent nociceptors can respond to mechanical, heat, and chemical irritation. Several different forms of membrane-bound receptor mechanisms and ion channels are present and a variety of events can activate these fibers (Table 15.1). However, not all PANs have the same constellation of receptors. Mechanical distortion of tissue can open ion channels of some PANs and initiate

depolarization of the fiber. Thermal stimuli also open thermal-sensitive ion channels on some PAN fiber membranes. These heat-sensitive channels have been identified and were originally described as vanilloid receptors (V1) or, as more recently termed, “transient receptor potential channels” (TRPV1). However, the chemoreceptors are the more important of the receptor types related to chronic pain seen in the musculoskeletal. Substances released in the environment of the chemoreceptive PANs, during tissue injury or inflammation, activate receptors located on the exposed membrane of these fibers (Fig. 15.4). Many different substances (called alodynogens) can activate or sensitize PANs, either directly through their receptors or indirectly by stimulating the production of other compounds that in turn can activate their receptors; thus, chemoreceptive PANs are responsive to a wide range of modifications in the chemical milieu of the surrounding tissue (Levine et al., 1993). Receptors are of three general types: ion channels, G-protein-coupled receptors, and cytokine-type receptors (Table 15.2).

There is a growing list of alodynogens capable of activating PANs; some of the better known examples are listed in Table 15.3. Most of these substances are present either in a blocked form or sequestered in cells, to be unlocked or released in the face of tissue injury. Histamine is contained in the granules of mast cells, which is situated along neurovascular bundles in fascia. Injury disrupts the mast cell releasing the histamine into the tissue. Similarly, disruption of vascular endothelial cells releases prostaglandins into the surrounding tissue. Finally, bradykinin, a plasma protein produced in the liver, is present in blocked form termed preprobradykinin. Tissue damage activates enzymes similar to the clotting cascade that ultimately results in the release of bradykinin in the surrounding tissue.

Inflammation releases a cascade of chemicals, many of them capable of helping cleanse the tissue and stimulating wound repair in short-term exposure; however, most of these substances are also alodynogens. PANs have receptors for many of these chemicals and can record their release into the tissue by depolarization and action potential formation. Peripheral release of neuropeptide alodynogens from PANs can initiate or exacerbate an inflammatory response (Fig. 15.5). Some of these same substances are also used as neurotransmitters or neuromodulators, released from the central process of the PAN in the dorsal horn. PAN activation serves as a warning and initiates spinal cord and brainstem level reflexes to protect the injured area. In addition, exposure to some of these compounds activates G-protein-signaling cascades capable of sensitizing the PAN. In essence, the PANs are interoceptors, sensitive to the quality of our tissue and can inform the central nervous system of our tissue health.

Figure 15-4 Primary afferent fiber ending. Primary afferent nociceptors are covered with a Schwann cell sheath containing little or no myelin. At the end of the fiber, the sheath terminates to expose the naked end of the axon. The membrane of the axon has receptors that can detect chemicals in the surrounding extracellular fluids. TABLE 15.2

PAN Receptors and Their Activating Substances

PAN Receptor Class	Activating Substances	Examples	Function
Ion-channels	Heat; mechanical force	Transient receptor potential channels (vanilloid receptors); proton-gated channels; sodium channels; potassium channels; calcium channels; serotonin (5-HT ₃) channels	Na ⁺⁺ and Ca ⁺⁺ influx into the axon
G-Proteins	Bradykinin, Prostaglandin; Ednocannabinoids	BK-1, BK-2, DP, EP, FP, IP, TP	Initiate second messenger cascades in the axon
Cytokine receptors	Growth factors and cytokines	Trk-A, Trk-B, Trk-C, NT-4/5, NT-3, IL-1RI, sIL-6R, TNFR1	Modify surrounding ion channel activity

PANS CONTRIBUTE TO A FEED-FORWARD ALLOSTATIC PROCESS INVOLVED IN SOMATIC DYSFUNCTION AND TISSUE REPAIR

When activated, certain PANS can secrete potent, proinflammatory neuropeptides that enhance the release of histamine, prostaglandins, and cytokines. A feed-forward loop is established, with the PANS releasing substances that ultimately provoke additional activity from the same fiber. Importantly, this feedback loop has no established end point or set point. These types of reactions, rapidly fulminating, epitomize a process characterized by the term allostasis (Schulkin, 2003a). In allostatic processes, rapid change in the tissue chemistry is protective and contributes to the long-term survival of the individual. This is contrary to homeostasis, in which inhibitory feedback control establishes boundary parameters that oscillate around a defined set-point. Allostatic processes lack immediate boundaries or set-points; thus, this inflammatory process can potentially run out of control and become a chronic issue. Eventually, the increasing systemic levels of norepinephrine and glucocorticoids, due to long-loop inhibitory feedback systems, should aid in suppressing the inflammatory response. Acute exposure to an allostatic process can be very protective, creating an area of increased sensitivity to mechanical stimulation (allodynia), an increased response to a stimulus which is normally painful (hyperalgesia), and in initiating protective reflexes.

Most likely, the allostatic condition involving the release of alodynogens and the enhancement of the inflammatory soup of chemicals in the tissue environment resulting in sensitization of the

PANS epitomizes the conditions found in somatic dysfunction. The potentiated PANS would generate a condition of hyperalgesia and the surrounding inflammatory cocktail would produce edema or a boggy, ropy texture to the tissues on palpation. Increased sensitivity to touch and tissue texture changes are two of the cardinal manifestations of somatic dysfunction (Denslow, 1975).

NERVE DAMAGE AND THE FEELINGS OF PAIN

Acute damage to a peripheral nerve fiber is usually relatively painless and, when done experimentally, rarely produces more than a few seconds of rapid axonal discharges. Acute damage to the dorsal root ganglion can produce long periods of excitation and rapid firing lasting 5 to 25 minutes; thus, the ganglion is the most sensitive part of the nerve to compressive injury. However, acute compression of a chronically injured, inflamed nerve represents a different situation and will produce several minutes of repetitive firing; it has been suggested that this long-duration rapid firing is the basis for radicular pain (Howe et al., 1977). Injury to a nerve can facilitate sprouting from the peripheral terminal of fibers within the nerve; this can be accompanied by the invasion of sympathetic axons into the dorsal root ganglion with inappropriate synapse formation and abnormal sprouting of axon terminals in the dorsal horn (McLachlan et al., 1993; Amir and Devor, 1996; Ramer and Bisby, 1997). All of these scenarios can contribute to the development of an intense chronic pain condition, termed neuropathic pain, which is pain initiated or caused by a primary lesion of dysfunction in the nervous system (Merskey and Bogduk, 1994).

THE SPINAL CORD AND PAIN

When PANS become active, they transmit a signal to the dorsal horn of the spinal cord via their central process (Fig. 15.5). Various cells, including both neurons and glia in the dorsal horn, are influenced by this sensory information. Interestingly, the response of the dorsal horn cells can outlast the activity of the PAN. The sustainability of this activity pattern among neurons in the dorsal horn represents central sensitization and is believed to be a major component of numerous pain syndromes. The interaction in the spinal cord of the central process of PANS from various regions in the body can substantially alter acute pain patterns (referral and association patterns), as well as states of chronic pain.

PANS TERMINATE IN THE DORSAL HORN OF THE SPINAL CORD

The central process of the PANS enters the spinal cord by coursing in the lateral aspect of the dorsal root entry zone, entering

TABLE 15.3

The Alodynogens and their Receptors

Alodynogen	Receptor	Origin
Bradykinin	BK1 and BK2	Plasma protein from liver
Histamine	H1	Mast cells
Serotonin	5-HT _{2A}	Blood platelets
Prostaglandins	DP, EP, FP, IP, TP	Vascular endothelial cells
ATP	Purine	Local cell rupture
Protons	Vanilloid receptor (VR1)	Local cell rupture

Figure 15-5 Activation of a PAN and the release of proinflammatory compounds into the surrounding tissue. Tissue irritation results in the release of proinflammatory compounds from the distal ends of some primary afferent nociceptors. Interactions with compounds from immune cells, mast cells, and platelets result in an inflammatory soup that sensitizes the PAN leading to the increased release of neurotransmitters and neuromodulators in the dorsal horn of the spinal cord (used with permission from the Willard/Carreiro collection).

the dorsal most aspect of the dorsal horn and extending inward to terminate generally in laminae I, II, and V. Conversely low-threshold, mechanoreceptive fibers tend to terminate deep in laminae III through VI. The organization of the PANs in the dorsal horn is orderly, forming a somatotopic body map extending roughly from medial to lateral across the dorsal horn (Wilson and Kitchener, 1996); however, much overlap in receptor territories exist allowing for referral of activity patterns to associated regions of the somatotopic map.

PANs represent a heterogeneous population of fibers; thus, not all PANs are the same in terms of anatomy and neurochemistry. Beyond the size difference seen between A δ -fibers and C-fibers, the C-fibers divide into two groups: those that contain neuropeptides such as calcitonin gene-related peptide or substance-P and those that do not contain neuropeptides (Hunt and Rossi, 1985; Todd, 2006). The neuropeptide-containing fibers seem to terminate principally in laminae I, while the non-peptide-containing fibers terminate in laminae II. This dichotomy of fiber types and distributions suggests that differing aspects of nociception could be carried by specialized PANs; specifically, the peptidergic PANs terminating in lamina I are thought to be involved in localization, and the nonpeptidergic fibers in lamina II are more associated with the affective nature of the pain (Braz et al., 2005).

DORSAL HORN NEURONS AND PAN CENTRAL SYNAPSES

The three anatomical types of dorsal horn neurons are 1) projection cells, 2) interneurons, and 3) propriospinal cells. Projection cells, the best studied of the three types, send their axons upstream in the ascending tracts to reach brainstem and thalamus. Local circuit interneurons confine their projections to the segment that their cell body is located within, while propriospinal cells represent a combination of the first two types; their axons ramify in the spinal cord, interconnecting the various segments, but do not extend out of the spinal cord. Several different forms of projection cells exist in the spinal cord (Cervero, 2006); each form of these cells receives synaptic endings from the PANs. Projection cells in the superficial layer of the dorsal horn are relatively specific to PAN input and have been termed nociceptor-specific cells. The interaction of PANs with the superficial dorsal horn neurons is complicated and still not well understood (Graham et al., 2007). Projection cells located deep in the dorsal horn typically respond to a wide range of inputs, including A β -fibers, A δ -fibers, and C-fibers, and have therefore been termed wide-dynamic-range (WDR) neurons (Mendell, 1966). Although gentle mechanical stimulation can

activate a WDR neuron; maximal response from these cells can only be obtained from noxious stimuli (Willis, 1979). Evidence does support the concept that our affective perception of pain is related to the activity of the WDR neuron, while our perception of the pain location may be due to the activity of the nociceptor-specific cells (Mayer et al., 1975); however, these concepts remain a controversial area in perceptual neuroscience.

EXAMINATION OF A PAN CENTRAL SYNAPSE

Central Pan Synaptic Terminals Contain At Least Two Types of Neurotransmitters

The central process of the neuropeptide-containing PANs forms terminals on the dendrites of dorsal horn neurons. A closer look at the neurochemistry of these PAN synapses will help in understanding the central sensitization of dorsal horn neurons. Neuropeptide-containing PAN synaptic terminals produce excitatory amino acids, such as glutamate or aspartate, and neuropeptide neurotransmitters, such as substance-P or calcitonin gene-related peptide (Basbaum, 1999). These transmitters are coreleased from the terminal; however, while the amino acid is released during any sufficient depolarization of the ending, neuropeptide release requires more prolonged summation of depolarizations such as would occur during tonic discharges (Millan, 1999).

Excitatory Amino Acid

The most common excitatory amino acid (EAA) in the PAN central terminal is glutamate. Release of glutamate activates the alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors on the postsynaptic surface. AMPA receptors are ion channels that allow sodium to enter the cell when open, as such these channels can cause a rapid depolarization of the postsynaptic process when activated. This type of transmission is relatively quick, involving milliseconds at most, and has thus been termed fast transmission. Most neurons in the dorsal horn express AMPA receptors on their membranes.

Neuropeptide

A specific population of PAN central terminals contain neuropeptides as well as excitatory amino acids. Upon release, these peptides diffuse onto receptors located on the postsynaptic membrane, but not necessarily in the synaptic cleft. Tonic or repeated activation of the PAN is required to cause enough peptide release to activate the peptide receptors. Thus, the time required to obtain adequate volume of peptide release, and the longer diffusion route to a more

distant receptor complex, combine to increase the time required for a response (Millan, 1999). When activated by attachment to the peptide, the peptide-receptor complex internalizes into the postsynaptic neuron through a process of endocytosis (Mantyh et al., 1995). Thus, the peptide is acting on the postsynaptic neuron in a way that is similar to some hormones in that it physically enters the postsynaptic cell to effect changes at the cytosolic and nuclear levels. Once across the cell membrane, the peptide-receptor complex can act as an enzyme and initiate second-messenger cascades leading to the phosphorylation of the AMPA receptor as well as surrounding NMDA receptors. Phosphorylation of EAA receptors allows calcium ions to enter, thereby facilitating the activity of the dorsal horn neuron. This type of transmission requires seconds to minutes and has thus been termed slow transmission. The result of this cascade of events is a potentiation of the responsiveness of dorsal horn cells that contributes to central sensitization that is the response properties of these dorsal horn neurons undergo a leftward shift on the stimulus-response curve. Interestingly, excessive activation of the PANs can lead to the spread of neurons expressing receptors for SP in the dorsal horn (Abbadie et al., 1997); this change would also facilitate the response of the dorsal horn neurons to afferent stimuli.

BEHAVIOR OF NOCICEPTIVE NEURONS IN THE DORSAL HORN

Transient Change in Dorsal Horn Circuitry—Activity-Dependent Plasticity

Neurons in the dorsal horn demonstrate a plasticity in their response properties that is directly related to the afferent activity to which they are exposed (Abbadie et al., 1997). This type of plasticity is characteristic of any biological system that is adaptive in nature. Through these plastic changes, afferent activity involving PANs can result in sensitization of the dorsal horn circuitry. These rapid changes in sensitivity represent a form of allostasis, similar to that already described in the periphery, and can be very protective in the short term. Numerous cellular mechanisms contribute to the plasticity of the dorsal horn system (Ji et al., 2003). Initially, dorsal horn cells show a progressive increase in activity to a train of constant stimuli, an event termed wind-up, which will cease when the stimulus ceases. Prolonged exposure to the stimulus leads to the development of a classic form of central sensitization, where the heightened central neural response outlasts the end of the peripheral stimulus by tens of minutes. High-frequency PAN stimulation of dorsal horn neurons can result in a much longer lasting response termed long-term potentiation (LTP); in fact, the duration of the response exceeds that of most experimental studies. Other events contributing to the sensitization of the dorsal horn neuron include the activation of protein kinase enzymes. Within the postsynaptic neurons, protein kinase activation with subsequent phosphorylation events can lead to the induction of numerous genes; this form of sensitization is referred to as transcription dependent and can be very long lasting in nature. While the large projection neurons are undergoing an excitatory form of sensitization, their surrounding inhibitory neurons can also be changing their activity. Long-term depression can occur in inhibitory interneurons located in the dorsal horn, resulting in reduced inhibition on the projection neurons and thus, more information traveling upstream to the brainstem, thalamus, and cerebral cortex. Finally, two additional events can lead to a permanent form of sensitization: inhibitory cell loss (Scholz et al., 2005) and rearrangement of synaptic connections (Doubell et al., 1997; Abbadie et al., 1997).

Central Sensitization and Secondary Hyperalgesia

Sensitization of dorsal horn neurons can alter their response properties, typically shifting the response versus stimulus intensity curve to the left. An additional prominent feature of sensitization is the expansion of the neuron's receptive field. Expansion of the cell's receptive field outside the area of immediate injury will contribute to the formation of secondary hyperalgesia (Cook et al., 1987; Laird and Cervero, 1989; Hylden et al., 1989; Grubb et al., 1993; Koerber and Mirnics, 1996). That is, noninjured tissue contiguous with the primary site of injury will develop increased sensitivity to mechanical stimuli. In addition to receptive field expansion, some dorsal horn neurons, particularly those driven by skeletal muscle afferent fibers, can develop new and, in some cases, noncontiguous receptive fields (Mense, 1991).

Irritation of the noncontiguous receptor fields results in the sensation of pain in the area of primary and secondary hyperalgesia (Hoheisel et al., 1993; Mense and Simons, 2001). While the expansion of the receptive field contributes to the phenomena of secondary hyperalgesia, the development of new, noncontiguous receptive fields could contribute to the expression of either tender points or trigger points.

Central Sensitization and Glial Cell Activation

The classic notion is that a neuronal synaptic chain extends from periphery to cerebral cortex representing the pathways for processing nociception and generating the sensation of pain. However, recent evidence has forced a revisal of this concept to include other cells, such as glia, that can modify the information processing in the neuronal chain (Watkins et al., 2007). Glial cells form a matrix surrounding all dorsal horn neurons and central neurons in general. Multiple types of glia are present but the ones most associated with immune responses are the astrocytes and microglia. In the dorsal horn (and to date only in this region), these two glial cell types express receptors for substance-P. Interaction with SP can activate these two forms of glia. Activated glial cells release proinflammatory cytokines such as tumor necrosis factor- α and interleukins 1 and 6. Although it is not clear at this time how proinflammatory cytokines work in the dorsal horn, it is certain that they contribute to increasing spinal facilitation and hyperalgesia. Activated glia also increase the production of NO and PGE2 in the dorsal horn; both substances are known to increase spinal facilitation and the resulting hyperalgesia; interestingly, these glial cells also increase the release of SP from the central terminals of the PANs, thus creating another feed-forward loop in the interoceptive system pathways. Neurons in the dorsal horn have been demonstrated to express receptors for proinflammatory cytokines and IL-1 is known to increase the influx of calcium ions through the NMDA receptor, also increasing spinal facilitation. Thus, multiple factors occurring within the dorsal horn are combining to create plastic changes in the dorsal horn neurons. Finally, glial cell-neuron interaction can explain the formation of mirror-image pain, that is, pain that occurs contralateral to injured tissue (Wieseler-Frank et al., 2005). Spinal cord glial cells are interconnected with each other by gap junctions, thereby constructing a large and complex syncytial matrix that extends across the midline in the spinal cord. Blocking the spread of information through these glial gap junctions prevents the development of mirror-image pain in experimental models. From all of this, it is clear that glia cell activity in the dorsal horn can modify the processing of nociceptive information and increase the sensation of pain. While protective in the short term, this response has the potential to fulminate and become part of a chronic problem.

Permanent Change in the Dorsal Horn Circuitry

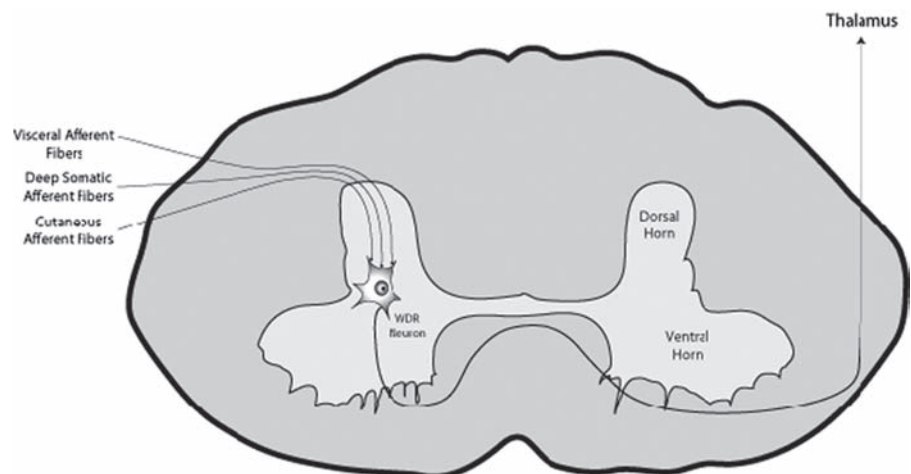

All of the changes in dorsal horn circuitry discussed so far appear to be reversible; however, excessive PAN stimulation or peripheral nerve injury can also result in a permanent alteration in the dorsal horn. The smallest neurons in the dorsal horn, typically GABA-ergic neurons, appear to undergo an apoptotic cell death following excessive activation (Scholz et al., 2005). Loss of these neurons would diminish the inhibition in the spinal cord circuitry thus creating a more easily excited segment, possibly one that displays spontaneous activity. A second method of permanent change in the dorsal horn involves the sprouting of $A\beta$ -afferent fibers following peripheral nerve injury (Neumann and Woolf, 1999). The normal distribution of the $A\beta$ -afferent fibers is focused on the deeper layers of the dorsal horn. In animal models, following nerve injury, the terminals of the $A\beta$ -afferent fibers can be seen in the superficial layers replacing sites occupied typically by PANs. Both of the above alterations in the dorsal horn circuitry would create permanent change and could contribute to chronic pain scenarios.

DORSAL HORN INVOLVEMENT IN MODIFIED PAIN PRESENTATION PATTERNS

Dorsal Horn Alteration in Chronic Pain States

Normal plasticity in the dorsal horn circuitry is necessary to insure adequate warning information and protective reflexes during the healing process. To be protective, these changes have to occur rapidly; they typically involve numerous feed-forward events without an immediate set-point, thus fitting the definition of an allostatic process (Schulkin, 2003a). However, excessive activation of the dorsal horn or inadequate control mechanisms (to be discussed below) can turn the normal plasticity into a pathologic response that leads to the development of a chronic pattern of abnormal neuronal activity, underlying the onset of chronic pain in the patient. Adaptive changes that can become pathologic include the spread of neurons expressing receptors for SP (Abbadie et al., 1997), expansion of dorsal horn neuron receptive fields, the loss of GABA-ergic inhibitory interneurons, and the sprouting of $A\beta$ -fibers into the superficial layer of the dorsal horn. Thus, the chronic pain state can be considered as a failure of normal allostatic mechanisms leading to a pathological condition similar to other chronic stress-related diseases such as depression (Schulkin et al., 1994; McEwen, 2003), type 2 diabetes mellitus (Stumvoll et al., 2003), and cardiovascular disease (McEwen, 1998).

Figure 15-6 The convergence of PANs for cutaneous, deep somatic, and visceral sources on the WDR neurons in the dorsal horn of the spinal cord. Primary afferent fibers from visceral, deep somatic, and cutaneous sources are shown converging on a WDR neuron in the dorsal horn of the spinal cord (used with permission from the Willard/Carreiro collection).

Clinical Expressions of Sensitization

Following the onset of central sensitization, the activity pattern of neurons in the dorsal horn is altered. Expanding receptive fields of dorsal horn neurons create a zone of increased sensitivity that surrounds the initial injury site, which is termed secondary hyperalgesia. Many dorsal horn neurons have projections or at least collateral axons that terminate in the ventral horn. Sensitization of dorsal horn neurons can then alter the activity patterns of the large ventral horn alpha motoneurons (Grigg et al., 1986; He et al., 1988). The ventral horn output can produce muscle spasms and, when prolonged, increased muscle tone and hyperreflexia akin to that seen in spasticity.

Convergence of Visceral and Somatic Input in the Dorsal Horn

Visceral afferent fibers from thoracoabdominal and pelvic organs enter the spinal cord through the dorsal root and terminate in the lateral aspect of the deep dorsal horn (fig. 15.6; also see Chapter 9 on Somatic dysfunction, spinal facilitation and viscerosomatic integration). Visceral PAN input overlaps with much of the somatic PAN input and many cells in the dorsal horn can be driven by both visceral and somatic input (Sato et al., 1983; Sato, 1995). Somatic input can sensitize dorsal horn neurons eliciting specific reflexes. Subsequent visceral input can activate the previously facilitated circuit, eliciting a similar pain pattern and some of the same reflexes. The reverse situation is also often seen clinically, as pointed out by Sir Henry Head many years ago (Head, 1920): that is, visceral input first sensitizes the dorsal horn circuitry and subsequent somatic injury elicits the previous visceral pain pattern and associated reflexes (Henry and Montuschi, 1978).

Influence of Primary Afferent Fibers Along the Spinal Cord

As PANs enter the spinal cord through the dorsal root entry zone, they undergo a trifurcation (Fig. 15.7). One branch enters the dorsal horn at that segment, one branch ascends, and one descends along the dorsal margin of the dorsal horn in a bundle of fibers termed Lissauer's tract (Carpenter and Sutin, 1983). Older diagrams of PAN termination clearly indicated this branching pattern (Ramon y Cajal, 1909), although it has been removed from most modern text for simplification. The division of the PAN is important since it can result in the spreading of information up and down the spinal cord to reach distant segmental levels. How far this information can spread is not clear, cutaneous PANs spread out

Figure 15-7 The trifurcation of primary afferent fibers as they enter the spinal cord. This is a longitudinal view of the spinal cord taken through the upper portion of the dorsal horn. Primary afferent fibers are seen entering the vertically oriented tract of Lissauer from the left. Upon entry into the tract, these fibers trifurcate giving a branch to the dorsal horn at the point of entry, an ascending branch to higher spinal levels, and a descending branch reaching lower spinal levels. (From Ranson SW and Clark SL. *The Anatomy of the Nervous System: Its Development and Function*. Philadelphia, PA: W.B. Saunders Comp., 1959; Figure 141.)

at least two to three segments, while visceral PANs have reported distributions involving greater than five segments (Sugiura et al., 1989); however, even greater distances are possible (Wall and Bennett, 1994).

The three-dimensional distribution of PAN information in the spinal cord allows for the interpretation of otherwise confusing pain patterns. For example, a patient could have an existing area of spinal facilitation in the midthoracic region consequent to an old process such as gall bladder disease. A recent revival of this old pain pattern, despite the prior removal of the gall bladder, could indicate the new onset of another disease process such as myocardial ischemia or gastric ulcer. The visceral PANs from the myocardium or the stomach enter the spinal cord in the upper thoracic region; early in the disease processes their input may be present in lower thoracic segments due to segmental spread of afferent input, but below the threshold of detection by the patient. However, spread of low-grade neural activity in the caudal direction could easily activate the portion of the spinal cord originally sensitized by the remote history of gall bladder disease. The patient perceives the gall-bladder-associated pain pattern, however this time the etiology of the nociception lies in the myocardium and not in the gall bladder. In general, the recent and otherwise unexplained revival of an old pain pattern should be considered the harbinger of new disease until proven otherwise.

The Dorsal Horn and Dorsal Root Reflexes

Normally, one thinks of the dorsal root as a strictly afferent system carrying action potentials from the peripheral tissue into the

spinal cord only; however, it is now known that under appropriate conditions, the dorsal root can act as an efferent pathway from the spinal cord; when this type of antidromic activity occurs in an intact sensory nerve it has been termed a dorsal root reflex (Rees et al., 1994). Centrifugally conducted activity on dorsal rootlets has been known since the late nineteenth century but was not really in detail examined until the middle of the 20th century (Willis, 1999). Dorsal root reflexes can be present in both large myelinated and in small myelinated and unmyelinated fibers (see Willis, 1999 for a discussion of the difficulties in recording DRRs from the smallest fibers); in this review, we will focus on those reflexes present in the small fibers such as PANs. To trigger these reflexes in PANs, the initial input stimulus to the spinal cord has to be in the range required to activate the PANs (C-fiber range). When such an afferent barrage reaches the dorsal horn, a wave of depolarization, termed primary afferent depolarization (PAD), occurs and is spread outward for several segments up and down the spinal cord. Interestingly, dorsal horn depolarization is facilitated by central sensitization of dorsal horn neurons; thus, past experience can influence the magnitude of this depolarization event. When an area of the dorsal horn depolarizes, the central terminals of other primary afferent fibers contained within this area also depolarize. This mechanism is most likely a spin-off event of presynaptic inhibition and is known to involve GABA-a receptors and GABA released by local interneurons as well as being influenced by serotonin receptors (Peng et al., 2001). Significant depolarization of the central terminals of primary afferent fibers can result in the generation of action potentials within these fibers that move antidromically (outward) to invade the peripheral terminals of this PAN. The resulting antidromic output from the dorsal horn can be recorded as a compound action potential, termed dorsal root potential (DRP) on adjacent dorsal rootlets that have been truncated. In the peripheral terminals of these PANs, the antidromic action potentials act similar to those involved in a classic axon reflex, that is they trigger the release of neuropeptides into the peripheral tissue (Fig. 15.8), thus either initiating or exacerbating an inflammatory reaction. Antidromic activity over dorsal roots can occur both ipsilateral and contralateral to the input root (Rees et al., 1996). DRR have been demonstrated to play a significant role in the spread of peripheral inflammation (Lin et al., 1999). Finally, recent studies have revealed that DRRs can be enhanced by stimulation of the periaqueductal gray region of the midbrain (Peng et al., 2001); this finding has significant implications with respect to the generation of diffuse pain patterns and will be reconsidered in the section on descending pain control mechanisms.

Figure 15-8 Comparison of an axon reflex to a dorsal root reflex. **A.** Diagram of an axon reflex. **B.** Diagram of a dorsal root reflex. Note that the dorsal root reflex simply involves the conduction of an action potential to the spinal cord, depolarization of surrounding fibers in the dorsal horn, and the conduction of an action potential out to the periphery on a depolarized sensory fiber. (From Willis WD. Dorsal root potentials and dorsal root reflexes: a double-edged sword. *Exp Brain Res* 1999;124:395–421.)

ASCENDING PATHWAYS FOR PAIN

The Anterolateral System in the Spinal Cord and Brainstem

Information from the neuronal activity in the dorsal horn is projected upstream to the brainstem and thalamus via dorsal horn neurons with long ascending axons (Fig. 15.9). These projection neurons arising mainly in laminae I, IV-V, and VII-VIII in the dorsal horn send their axons contralaterally to reach the anterior and lateral quadrant of the spinal cord (Dostrovsky and Craig, 2006). Most of these neurons represent either nociceptive-specific cells located in lamina I or wide-dynamic-range cells located in the deeper laminae of the dorsal horn. Axons from these neurons leave the dorsal horn to ascend diagonally, crossing the midline of the spinal cord in the anterior white commissure. The tract formed by these axons has been termed the anterolateral tract (ALS); within the ALS axons are arranged such that the cervical fibers are positioned most medially and the sacral fibers are most lateral. Also, anterior-lateral segregation of axons occurs within the tract such that the anterior portion of the ALS contains fibers activated by light touch and the lateral portions of the ALS contain more of the pain and temperature responsive fibers. Finally, based on target site, two basic components of the anterolateral tract can be identified: the spinoreticular and spinothalamic tracts.

Spinoreticular Tracts

The spinoreticular fibers arise from neurons located in the dorsal horn and terminate in nuclei of the medulla, pons, and mid-brain. Specific sites targeted by the spinoreticular fibers include the

Figure 15-9 Anterolateral system of the spinal cord. The entry of spinal nerves is shown on the left with their synapse on a dorsal horn neuron. The spinothalamic axons arise in the dorsal horn, decussate over the midline, and ascend to the brainstem and thalamus in the anterolateral tract, also termed spinothalamic tract. (From Larsell O. *Anatomy of the Nervous System*. New York, NY: Appleton-Century Crofts, Inc., 1942. Figure 205.)

catecholamine cell groups (A1 to A7), subnucleus reticularis dorsalis, the ventrolateral medulla, the parabrachial nucleus, periaqueductal gray, and the anterior pretectal area (Westlund, 2005; Dostrovsky and Craig, 2006). Since these areas are thought to regulate much of the descending brainstem-spinal cord projections, they therefore could play a significant role in the modulation of pain. Of these two tracts in the anterolateral system, the spinoreticular appears to be the most important in regulating the arousal system of the brainstem.

Spinothalamic Tract

Axons from dorsal horn neurons that project to the thalamus form the spinothalamic tract; these axons are also embedded in the ALS system along with those projecting to the brainstem. In fact, many of the brainstem terminals can be collateral branches of the spinothalamic fibers. Spinothalamic axons located in the lateral most portion of the ALS tend to be most responsive to pain and thermal stimuli. At the rostral end of the spinothalamic tract a division occurs; the larger fibers in the tract remain laterally positioned to enter the thalamus, terminating in the vicinity of the ventroposterior and ventromedial nuclei, while the finer fibers in the tract segregate and enter the medial thalamus and terminate in the intralaminar nuclei. This arrangement creates medial and lateral pain systems in the thalamus. Many of the ascending fibers entering the medial thalamus appear to be of brainstem origin rather than spinal cord origin. In general, the lateral pain system is thought to be a phylogenetically newer system involved with localization of the noxious stimulus, while the medial system is an older system more likely involved in arousal and affectation of event.

Thalamic Representation of Pain

Until this point in the chapter, we have been describing a nociceptive system, a system that can generate a signal in response to tissue-damaging or potentially damaging energy. At the level of the thalamus a transition occurs, we are no longer describing a strictly nociceptive system but a system that can precipitate a feeling of pain and its associated emotions such as anxiety and depression. Neural activity below the thalamus can occur without perception resulting in reflexes as well as certain behaviors; however, the thalamus and cerebral cortex function as a unit and it is at the thalamocortical level that perception is initiated. While the spinal cord and brainstem can initiate primitive, withdrawal-type reflexes to nociceptive stimuli, the thalamocortical system is required to initiate more elaborate evasive movements as well as the complicated psychological responses to painful situations.

The thalamus is a major target for ascending information from the spinal cord and brainstem to the cerebral cortex. Two pain systems, medial and lateral, can be identified in the thalamus, separated from each other anatomically and having differing functions (Dostrovsky, 2006; also see Fig. 15.10). Functional imaging has demonstrated that the thalamus is the site where active is most expected in the acute pain state (May, 2007).

Lateral Pain System

The spinothalamic tract (often termed the neospinothalamic tract) innervates laterally and ventrally positioned nuclei of the thalamus including the ventroposterior lateral nucleus, ventromedial nucleus, portions of the posterior nuclear group, and portions of the ventrolateral nucleus (Fig. 15.10). These structures rapidly relay information to somatic sensory and insular cortex and play a role in

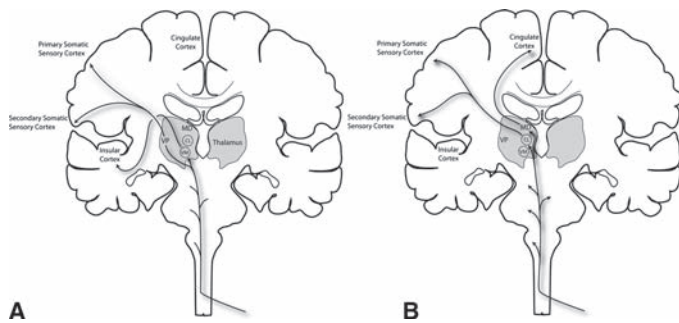

Figure 15-10 The ascending nociceptive systems in the thalamus. **A.** This figure demonstrates the projection of spinothalamic axons to the ventroposterior (ventral caudal) and ventromedial nuclei of the lateral thalamus and their relationship with primary and secondary somatic sensory cortex and in the insular cortex. **B.** Other spinothalamic and spinoreticulothalamic axons terminate in the central lateral and dorsomedial nuclei of the medial thalamus. Their cortical representation involves the cingulate cortex as well as the major somatic sensory areas.

the localizing qualities and intensity of the pain perception. In one published case of a patient with a lesion involving the postcentral gyrus of the cerebral cortex (a significant target of the lateral pain system of the thalamus), the individual lost the ability to accurately localize painful stimuli but retained the ability to experience the affective nature of the pain (Ploner et al., 1999).

Medial Pain System

The medial fibers of the spinothalamic tract (often termed the paleospinothalamic fibers) enter the thalamus medially (Fig. 15-10) to innervate the centromedian nucleus, centrolateral nucleus, dorsomedial nucleus, nucleus submedius, and the intralaminar nuclei (Dostrovsky, 2006). In the hypothalamus, this system innervates the paraventricular nucleus. Included in this ascending system would be projections from lower brainstem areas that have themselves been innervated by the spinoreticular axons. These connections form the medial pain system and primarily relay to the prefrontal cortex and anterior cingulate cortex, areas critical for the transformation of sensation to perception. The medial pain system is slower than its lateral counterpart and is more closely related to the affective and emotional nature of pain (Sewards and Sewards, 2002). Damage, typically from vascular accidents, involving the lateral and posterior thalamus appears to unmask spontaneous activity in the medial system. The unfortunate patient experiences an intense burning pain, usually in a limb, that is refractive to analgesics. This presentation is termed the thalamic pain syndrome or the syndrome of Dejerine-Roussy (Victor and Ropper, 2001).

The Cerebral Cortical Pain Matrix—From Sensation to Perception

Our understanding of the role of the forebrain in pain processing was limited to animal and electrophysiological studies until sophisticated human brain imaging methodologies were refined and complex meta-analysis of study results performed (Apkarian et al., 2005; Tracey and Mantyh, 2007). Appreciation of brain involvement in pain perception was also slowed by the state of physiology at the turn of the century (Head and Holmes, 1911), which questioned the participation of the cortex in human pain perception. In fact, Ronald Melzack in the 1970s at one point even proclaimed

that neuroscientists were “scooping out the brain” and ignoring the fact that a person could have, for example, a pain in their foot and not have a foot as illustrated with phantom limb pain (Melzack, 1991).

Fortunately, there has been a flood of refined scientific data driven by recent technologies such as a positron emission PET scan, functional MRI, single-photon computed tomography (SPECT), magnetoencephalography (MEG), and electroencephalography (EEG) studies that have visualized the brain processing nociception (see Davis, 2005). These studies measure such factors as perfusion, metabolism, glucose, and oxygen utilization. We now have data to explain how a painful experience can occur in the forebrain without a concurrent primary nociceptive input in the peripheral nerve (Derbyshire et al., 2004; Eisenberger and Lieberman, 2004; Singer et al., 2004; Casey, 2004). The shift in mindset that considers pain that is unrelated to or out of proportion with the nociceptive stimulus as being a disease state rather than a symptom has accelerated treatment paradigms. When examining a patient with a chronic pain pattern it is now necessary to consider the whole person and their environment rather than just the presenting signs and symptoms; this is an approach that is quite consistent with the Osteopathic Philosophy.

With the brain now available for direct examination, there has been a virtual revolution in accessing the role of forebrain structures in the formulation of a neural matrix used in the perception of pain (Tracey, 2005a; Tracey, 2005b). These data have emphasized the concept that facilitation, long known to occur in the spinal cord secondary to tissue injury, can also occur in the forebrain profoundly influencing our perception (Apkarian et al., 2005). In addition, it is now clear that both bottom-up and top-down processing occurs in pain perception, with the forebrain structure responding to signals from the spinal cord as well as providing descending modulatory information that can influence many ascending signals, all of which creates the complex sensory experience termed pain.

MRI has been particularly useful in identifying pathways and brain regions involved in encoding various aspects of the pain matrix (Tracey and Mantyh, 2007), thereby linking nociception system to pain perception. The lateral-medial division seen in the thalamus is reflected in the organization of the cerebrum, with the lateral component of the nociceptive pathway involved in pain localization and recording pain intensity, while the medial system encodes an emotional-motivational component. This later system is further tempered by powerful escape and avoidance behaviors (Price, 2000), sculpting the biopsychosocial modulation of pain. Pain is a conscious perception and an emergent property of a complex neuromatrix through which the brain transforms a nociceptive input into a disagreeable perception (Melzack, 1999; May, 2007). Based on functional imaging studies, the areas involved with the pain matrix include the somatic sensory cortex, insula, anterior cingulate cortex, prefrontal cortex, and amygdala (Fig. 15.11).

Cortical level activity does appear to be related to pain perception. Coghill and coworkers found a significant correlation between the intensity of the patient’s feelings of pain and the amount of cortical activity detectable with functional imaging (Coghill et al., 2003). Specifically, the neural activity was present in somatic sensory cortex, anterior cingulate cortex, and prefrontal cortex. A similar correlation was not found in the thalamus suggesting that cortical level processing is closely tied to our perception of pain.

No one portion of the cortex can entirely account for the perception of pain. Conversely, the perception emerges from simultaneous activity and the interaction of numerous cortical areas of this matrix (Chapman, 2005). Each of these areas will be discussed below. The behavioral responses elicited are shaped by previous

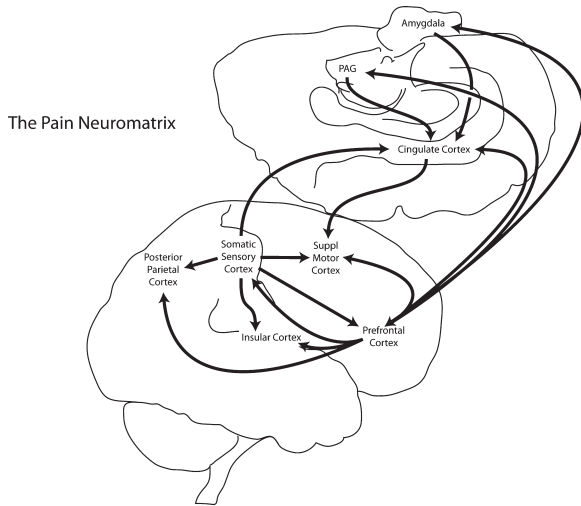

Figure 15-11 The pain Neuromatrix. Numerous regions of the cerebral cortex are interconnected and function to process nociceptive information. From this matrix emerges our complex feelings of pain. (Used with permission from the Willard/Carreiro collection.)

learning, stress levels, attention and arousal, memories, as well as cognitive, emotional, genetic, age-related, gender-related, and sociocultural factors. Pain is inherently unpleasant and associated with real or anticipated tissue damage; its presentation can be masked in a cloud of abnormal body function, chronic pain, and suffering. What has become very clear is that many factors influencing the pain experience are centrally mediated.

Recent studies raise the possibility that patients suffering from chronic pain scenarios may have undergone a significant alteration in the base mechanism of brain function. In 2001, Raichle proposed a Default Mode Network (DMN) as a means of understanding the baseline activity of the cerebrum (Raichle et al., 2001). The DMN represents the resting state of connected activity in representative cortical and subcortical structures. These structures show basal activity when the person is conscious and relaxed. The activity of the DMN is typically greatest at rest and decreases during cognitive processing. Using f-MRI, Blood Oxygen Level Dependent (BOLD) analysis and functional connectivity MRI (fc-MRI), signal fluctuations of various regions of interest and their temporal relationship are being explored.

DMN includes prominently the structures of posterior cingulate cortex (PCC) and ventral anterior cingulate cortex (ACC). In addition, the ventromedial prefrontal cortex (VMPFC) and the left inferior parietal cortex (LIPC) are involved. The ventral ACC is linked to limbic and subcortical structures of orbitofrontal cortex (OFC), nucleus accumbens, hypothalamus, and midbrain. These connections represent an emotional affective link in the brain. The PCC is mainly related to cortical structures suggesting a role in consciousness. These all show a decrease in activity on f-MRI, in healthy subjects, when they are asked to perform a simple task. At the same time, with task performance, attention, and cognition, there is an increase in activity in the ventrolateral prefrontal cortex (VLPFC) and in the dorsolateral prefrontal cortex (DLPFC). The lateral prefrontal regions include the OFC, left DLPFC, bilateral IPC, left inferolateral temporal cortex, and the left parahippocampal gyrus (PHG) (Greicius et al., 2003).

Chialvo has confirmed with f-MRI the DMN activity at rest in healthy subjects reveals an equilibrium that shows a decrease in activity when they are asked to pay attention or perform a task

(Baliki et al., 2008). However, in chronic back pain subjects, the DMN activity does not reduce when the subjects are asked to perform simple tasks (Baliki et al., 2008). Those with pain were able to perform the tasks as well as the healthy subjects, but they used their brains differently. This effect was greatest among the patients who had been in pain for the longest period of time. Though the study group was small, it suggests functional reorganization of the brain, altered patterns of brain activity and a possibly irreversibility of these patterns in patients with chronic pain.

Somatic Sensory Cortex (SCC)

The somatic sensory portion of the cerebral cortex is divided into two major regions—SI and SII (Fig. 15.12). SI is located on the post central gyrus and receives input from the ventroposterior thalamic nuclei, while SII is positioned at the base of the post-central gyrus wrapping over the operculum and reaching into the posterior insula lobe and receives input from the ventroposterior inferior nucleus, a small thalamic nucleus closely related to the VP complex (Friedman and Murray, 1986). SI has a high-fidelity representation of the contralateral body, while SII contains a less well-defined representation of the body bilaterally (Millan, 1999; Casey and Tran, 2006). Although considerable question has existed in the older literature as to how much if any nociception is represented in the somatic sensory cortex, recent function mapping studies have shed much light on this situation (reviewed in Aziz et al., 2000). SI appears to be involved in the localization-discrimination of a painful stimulus. At least one carefully documented case of a parietal stroke involving SI in a human diminished the patient's ability to localize a painful stimulus but left him with a strong unpleasant feel induced by the stimulus (Ploner et al., 1999).

Visceral sensory information is also represented on the surface of the parietal cortex. Visceral afferent fibers from the thoracic and upper lumbar spinal cord ascend in the dorsal columns to reach the ventral and medial thalamic nuclei, from which they are relayed to both SI and SII cortex. Although SI can be activated by some noxious visceral stimuli, SII appears to function as primary cortex for visceral information (Aziz et al., 2000). From SII, connections are established with the anterior cingulate cortex and the insular cortex. Ramping up the delivery of visceral noxious stimuli will result

Figure 15-12 Areas I and II of the somatic sensory cortex. (Used with permission from the Willard/Carreiro collection.)

in the spread of the activation outward from SII into the region of the anterior cingulate and insular areas. Thus, SII has been depicted as a gateway into the paralimbic regions of cortex. The differential processing between visceral and somatic nociceptive stimuli at the cortical level may underlie the difference in feeling that characterizes visceral and somatic pains (Aziz et al., 2000).

Insular Cortex (IC)

Located in the depths of the lateral sulcus, between the frontoparietal cortex above and the temporal cortex below (Fig. 15.13), the insula is a major area in the pain cortical pain matrix (Hofbauer et al., 2001). This region of cortex receives thalamic projections from the ventromedial nucleus and posterior nuclei (Friedman and Murray, 1986), areas that are innervated by the spinothalamic tract (reviewed in Craig, 2002). The insula also receives cortical projections from adjacent somatic sensory areas. In primates, SI and SII project to the rostral and caudal portions of the insula (Friedman and Murray, 1986). The same regions of insular cortex that receive pain-related projections feed this information into the limbic forebrain, including such structures as the hypothalamus, amygdala, anterior cingulate cortex, and medial prefrontal cortex (Augustine, 1996; Jasmin et al., 2004). Finally, the insula also has descending projections to the brainstem through which it exerts control over the autonomic nervous system (Jasmin et al., 2004) as well as apparently regulating the descending pain control systems. The insular cortex activity is anatomically heterogeneous (M.-M. Mesulam and E. J. Mufson. *Insula of the old world monkey. I: architectonics in the insulo-orbito-temporal component of the paralimbic brain.* *J.Comp.Neurol.* 212:1-22, 1982.) and processing in its posterior portion may be more related to sensory aspects of pain. The anterior IC is anatomically more continuous with PFC and as a result it may be more important in emotional, cognitive, and memory-related aspects of pain perception. Recent studies have documented the presence of opioids such as dynorphin and enkephalin in the insular cortex and suggested a role for these opioid systems in the generation of cortically mediated analgesia (Evans et al., 2006)

One possible interpretation of this neurological arrangement is that the insula, working through the autonomic nervous system, helps to orchestrate physiological response to pain, including pain control or enhancement depending on the situation (Craig, 2002). Interestingly, disruption of the deep white matter at the caudal border of the insula can produce an intense central pain, similar

Figure 15-13 The insular cortex. (Used with permission from the Willard/Carreiro collection.)

in quality to thalamic pain; an event termed pseudothalamic pain syndrome (Schmahmann and Leifer, 1992). Conversely, a tumor compressing the posterior aspect of the insula altered tactile perception and the perception of mechanical and thermal pain by raising pain thresholds (Greenspan and Winfield, 1992). Finally, damage to the insula or disconnection of the somatic sensory areas of parietal cortex from the insula has been proposed as the mechanism for the presentation of asymbolia for pain (Geschwind, 1965). In asymbolia, patients can localize the painful stimulus but do not experience the normal emotional or affective nature of the pain. In this state, it is proposed that the link between the somatic sensory system and the limbic system has been interrupted.

Besides interoceptive (somatic and visceral) input, the insula also is the target of olfactory, gustatory, and vestibular information (Shibley and Geinisman, 1984). Recent studies suggest that the anterior insular cortex plays a significant role in forming a short-term memory of an acute pain (Albanese et al., 2007) and possibly integrating the response into a balanced homeostatic mechanism. Thus, the insula could be pooling a wide range of information and passing it on to the limbic system as well as regulating autonomic response patterns (May, 2007).

Anterior Cingulate Cortex (ACC)

A common feature of almost all studies using functional imaging to examine the cerebral processing of pain is the engagement of anterior cingulate cortex. The ACC is traditionally considered part of the limbic system and, as such, is located on the medial aspect of the cerebral hemisphere, wrapped around the genu of the corpus callosum (Fig. 15.14). A major afferent contribution to the anterior cingulate cortex arises in the dorsomedial nucleus of the thalamus and constitutes a significant portion of the medial pain system. Other contributions arise in the intralaminar nuclei of the thalamus and, as such, also involve the medial thalamic pain system.

Activation of ACC has been repeatedly reported in PET studies of somatic or visceral pain and linked to the emotional response to pain (Rosen et al., 1994; Hsieh et al., 1996). Lesions of the ACC do not destroy the ability to perceive acute pain or reduce pain

Figure 15-14 The cingulate cortex and the amygdala. (Used with permission from the Willard/Carreiro collection.)

related behaviors; however, they do blunt the affective nature of the pain (Rainville et al., 1997; Johansen et al., 2001; May, 2007).

The anterior cingulate cortex is also associated with the anticipatory emotional aspects of pain (Sewards and Sewards, 2002; Wager et al., 2004). Anticipation can be a particular problem for patients with chronic pain because such patients are already in varying degrees of distress. Researchers have used imaging techniques to characterize brain activation related to the intensity of expected pain and experienced pain, finding that pain-related brain activation overlapped partially with expectation-related activation in regions including anterior insula and the anterior cingulate cortex (Koyama et al., 2005). The ACC is not only involved in the actual perception of pain but also in imagined pain experience and in the (empathic) observation of another human receiving a painful stimulus (Devinsky et al., 1995). When expected pain decreased, activation in this portion of the cerebral cortex also diminished.

The relationship between activity in the ACC and our anticipation and expectation of pain feelings is very strong. Anticipation and expectation have a powerful influence on our eventual perception of pain. Directing attention away from a painful stimulus is known to reduce the perceived pain intensity and results in decreased activation of ACC subregions responsive to painful stimulation (Petrovic et al., 2000; Frankenstein et al., 2001). The placebo response in pain seems to be mediated, at least in part, by the ACC (Wager et al., 2004; Rainville and Duncan, 2006) as does the response to hypnosis (Faymonville et al., 2003; Derbyshire et al., 2004) and numerous other pain distracting techniques discussed in chapter 16.

Pain can be learned through the conditioned process of operant learning, possibly involving processing in the ACC. In some instances, for example, individuals might receive positive reinforcement for the expressions of pain. In studies of patients with chronic back pain who were given a painful electrical stimulation, those with a “solicitous” spouse present had an exacerbated pain response compared with those in the company of a nonsollicitous spouse. Imaging showed that the brain of patients with a solicitous spouse had increased activity in the ACC (Hampton, 2005).

Anticipation of pain can lead to the development of avoidance pain behaviors (Fordyce, 2009). These behavioral patterns represent powerful reflexive activity initiated in an attempt to minimize or avoid triggering a painful pattern. These behaviors can also be learned and are fairly automatic and not always in the patient’s conscious awareness. The anticipation of pain can cause patients to avoid movement, tense the muscles, or move completely differently—disrupting mechanisms for posture and balance. These biomechanical imbalances may affect dynamic function, increase energy expenditure, alter proprioception, change joint structure, impede neurovascular function, and alter metabolism. Osteopathic manipulative techniques could be employed to not only restore posture and function but to also reduce fear of movement and the experience of anticipatory pain.

Prefrontal Cortex (PC)

It has been known since the early 1990s that pain is represented in multiple areas of the cerebral cortex and that these areas included portions of the prefrontal cortex (Talbot et al., 1991). In humans, the prefrontal cortex is formed by the very prominent rostral pole of the frontal lobe (Fig. 15.15). This region of cortex receives extensive afferent projections from the medial thalamus including the rostral portion of the large dorsomedial nucleus; however, unlike the other regions of the cortical pain matrix, the prefrontal cortex does not receive input from any portion of a thalamic nucleus

Figure 15-15 The prefrontal cortex. The darker red and blue stripes represent the precentral and postcentral gyri, respectively. (Artwork by Rachel Milner; used with permission from the Willard/Carreiro collection.)

known to receive ascending nociceptive information. Instead, the prefrontal cortex is activated in response to nociceptive stimuli via other regions in the cortical pain matrix such as the ACC (Bushnell and Apkarian, 2006; also see Fig. 15.11).

The prefrontal cortex can be divided into two major regions (Parent, 1996). The prefrontal cortex proper, usually termed dorsolateral prefrontal cortex (DLPFC) represents the convex surface of the frontal lobe. The second region is the orbitofrontal prefrontal cortex (OFC) involving the inferior or orbital surface and the medial (mesal) surface of the frontal lobe. In most functional MR imaging studies, the use of the term OFC also includes the anterior region of the cingulate cortex (ACC) as well.

The prefrontal cortex is activated in some but not all studies of brain representation of nociceptive events; in addition, when prefrontal cortex does demonstrate neuronal activity it is not necessarily proportional to the intensity of the painful stimulus (Coghill et al., 1999; reviewed in Bushnell and Apkarian, 2006). The dorsolateral portion of PFC is thought to be involved with executive functions and appears to play a significant role in the attentive and cognitive aspect of pain (Lorenz et al., 2003). The distinction in functional activity between the OFC and ACC is still not clear in the literature; however, it has been suggested that the strong affective-motivational character of pain develops from activity to this region (Treede et al., 1999) and that the ACC specifically is involved in the unpleasantness of some painful stimuli, while the orbitofrontal cortex, with its massive limbic system connections, may process some of the secondary effects of pain such as emotional feelings and suffering.

Although the precise role of the DLPFC in the forebrain pain matrix is not known at this time, there is a strong suggestion that it is intimately involved in regulating our perception of pain. Consistent with this concept is the observation that, in a paradigm using a thermal probe to sensitize skin, increased activity in the DLPFC correlated with suppression of activity in the medial thalamus and midbrain (Lorenz et al., 2003). This phenomenon suggests that given the proper conditions, the DLPFC can initiate a source of descending inhibition on the ascending nociceptive pathways.

A significant problem encountered when attempting to assign specific pain processing functions to anatomically defined regions of the prefrontal cortex relates to the alteration in cortical activity patterns with temporal sequence (acute vs. chronic). In a recent metastudy reviewing published functional imaging studies of acute and chronic pain patients, it was concluded that the thalamic-somatic sensory cortical pathways leading to activation of the insular cortex and ACC are strongly involved in acute pain patients, whereas in chronic pain patients these same pathways appeared somewhat reduced in activity; conversely in these latter patients, the DLPFC area imaged with increased activity (Apkarian et al., 2005). The shift in brain activity between acute and chronic pain states strongly suggests a plasticity exists in the forebrain processing and that the chronic pain state is a pathology representing uncontrolled or dysregulated activity in certain forebrain areas.

The role of the DLPFC in the pathology of long-term pain states is further suggested by the observation that a significant alteration in brain chemistry (Grachev et al., 2000) and an accompanying loss of neural tissue (Apkarian et al., 2004) occur in this region in patients suffering from various forms of chronic pain (Obermann et al., 2009). The loss in gray matter from the DLPFC was related to the duration of the chronic pain scenario, thereby suggesting some type of fulminating process. Since the loss of gray matter volume has been seen in numerous different forms of chronic pain (May, 2008), it therefore does not appear related to the origin of the pain, but rather to its chronicity.

Interestingly, since studies have shown that the DLPFC is not directly involved in recording the intensity, quality, or location of pain, it may play a more general role in our attending, or not attending to pain. This concept would fit well with the generally accepted role of the DLPFC in working memory, controlling our attention to stimuli, and weighting our decision on whether or not to act on neuronal information processed in other regions of cerebral cortex. Recent studies have pointed to the DLPFC as playing a significant role in our attention to painful stimuli (Lorenz et al., 2003). The amount of activity imaged in the midbrain and thalamus—representing ascending information—triggered by a noxious stimulus was inversely proportional to the activity imaged in the DLPFC. In essence, it is suggested that this region of the prefrontal cortex functions to modulate activity in the ascending pathways and therefore the amount of pain that we may feel. Thus, pathological mechanisms occurring in DLPFC could manifest as increased activity in cortical pain matrix even in the absence of noxious peripheral stimuli. In such a situation, a patient could be feeling significant amounts of pain even though there is no obvious peripheral source for the pain.

Like the dorsolateral PFC, the ventrolateral PFC does not receive direct input for regions of thalamus responding to spinothalamic tract activity. Therefore it also relies of activation to nociceptive stimuli via other cortical areas. Functional imaging studies have provided data linking the activity of VLPFC to descending pain modulation systems in the brainstem (reviewed in Wiech et al., 2008). Recent evidence has tied VLPFC to pain modulation consequent to specific religious beliefs. This context-dependent pain modulation specifically involved the right (nondominant) VLPFC and engaged the ventral midbrain suggesting the initiation of activity in the descending pain modulation systems to create increased tolerance to painful stimuli (Wiech et al., 2008).

All of these observations taken together strongly suggest that the PFC plays a major role in determining our attention to a painful stimulus as well as our ability to modulate the intensity of our feelings of pain. The importance of these observations in developing a sound strategy for pain management in chronic pain patients

and of getting the patient to accept the treatment strategy cannot be over stated. Total lack of confidence in the strategy and obsession over the pain state can initiate a downward spiral that results in pain management failure as well as magnification of the perceived pain on the part of the patient.

Amygdala

The amygdala is located on the medial aspect of the temporal lobe, forming a prominent enlargement termed the uncus, which is visible externally (Fig. 15.14). The amygdala receives numerous projections from most associative portions of the cerebral cortex—particularly the orbitofrontal cortex—as well as a set of subcortical projections from the parabrachial region of the pontomesencephalic border of the brainstem termed the spino-parabrachio-amygdaloid pathway (Jasmin et al., 2004). Intensely painful stimuli, acting through the spino-parabrachio-amygdaloid pathway, exert a strong drive on portions of the amygdala (Neugebauer and Li, 2002). This aspect of the medial temporal lobe is well known for its ability to facilitate (a form of central sensitization), and through this process to form memories of fear-provoking stimuli (Schafe and LeDoux, 2004). Efferent fibers from the amygdala provide a strong drive on hypothalamic and brainstem areas involved in control of the sympathetic-adrenal system. In this manner, the amygdala is capable of initiating a strong arousal response to a painful stimulus, or to the threat of a painful stimulus (Gauriau and Bernard, 2002).

Some of the input to the amygdala is subcortical in nature—that is, it passes from the posterior thalamus to the amygdala without cortical processing. This mechanism provides a possible explanation for patients who, having been exposed to a traumatic event at some earlier point in their life, later experience strong emotional arousal over seemingly inconsequential stimuli. This type of presentation would resemble that seen in posttraumatic stress disorder or PTSD. The initial traumatic event or events facilitated areas in the medial temporal lobe. Subsequently, innocuous stimuli that might only tangentially be related to the initial event can now evoke a major protective response from the amygdala. Given its plasticity, it is possible that the amygdala is a junction point between chronic pain states and those of depression and anxiety along (McEwen, 2005) with the concomitant physiological responses (Neugebauer et al., 2004).

Cerebellum and Basal Ganglia

Functional imaging of an individual exposed to various pain states has frequently demonstrated the involvement of the cerebellum and basal ganglia in the central processing nociceptive information (Bingel et al., 2004; Bushnell and Apkarian, 2006). The cerebellum arises mostly from the pontine portion of the brainstem. The cerebellum is often seen to contain neural activity in pain imaging studies of pain states (Saab and Willis, 2003). Nociceptive events have also been demonstrated to alter neuronal activity in the cerebellar vermis and portions of the hemispheres. Descending pathways from the deep cerebellar nuclei reach several brainstem locations that contribute to the control of nociceptive activity. Nociceptive-related cerebellar activity could relate to the coordination of motor programs necessary to control the individual's pain-related movements. The cerebellum is very clearly involved in learning and memory related to the motor system, and recent studies have suggested that the cerebellum can control large areas of the cerebral cortex, extending much beyond pure motor function (Fiez, 1996; Barinaga, 1996). Supporting this contention is the observation that patients suffering cerebellar damage can present with cognitive and behavioral deficits as well as the expected ataxic movements

(Schmahmann and Sherman, 1998; Schmahmann, 2004). Thus, it is possible that the cerebellar activity evoked by pain is involved in cognitive learning processes.

The basal ganglia are located in the deep white matter of the cerebrum and have well-described connections with much of the cerebral cortex (Parent, 1996). This collection of nuclei represents an integral part of a recurrent pathway linking various regions of the cerebral cortex. Like the cerebellum, the basal ganglia function to regulate the output of the cerebral cortex. A fairly consistent finding in most broad-based functional imaging studies is the involvement of the putamen, a portion of the basal ganglia, in the processing of nociceptive information. As a functional unit, the basal ganglia is known to exert inhibitory influences on the thalamocortical circuitry; thus in processing nociceptive input, the basal ganglia may be modulating the amount of activity in the medial thalamocortical circuits that are critical to the perception of pain (reviewed in Chudler and Dong, 1995). In support of this concept are the observations that diseases of the basal ganglia can interfere with pain thresholds and pain sensitivity.

The Pain Matrix

Our current understanding of supraspinal pain mechanisms based on recent neuroimaging studies and meta-analyses shows a nociceptive system, from primary afferents through the cerebral cortex, strongly modulated by the interactions of ascending and descending pathway (Head and Holmes, 1911; May, 2007). At the level of the forebrain, it has become apparent that no one region in the cerebrum is responsible for our feelings of pain, instead a complex network of reciprocally interconnected regions of the cerebrum respond to noxious stimuli. Our feelings and emotions related to pain are an emergent property of this distributed neural network, termed the pain matrix (Ingvar, 1999; Fig. 15.16). Three separate but interconnected systems for generating the emergent feelings of pain have been defined in this distributed network:

1. A sensory-discriminative system that codes pain location and intensity
2. An affective-motivational system that encodes the suffering associated with the feelings of pain.
3. A cognitive-behavioral system that encodes our conscious behavior to a painful stimulus or to an ongoing painful experience.

The somatosensory cortices on the postcentral gyrus are involved in encoding intensity, temporal and spatial aspects of nociception and thereby functions mainly in the sensory-discriminative zone. Conversely, the anterior cingulate cortex plays a role in the affective-emotional component, as well as in pain-related anxiety and attention. The insula, through its interaction with the autonomic nervous system, appears to be mediating both affective-motivational and sensory-discriminative aspects of pain perception. The prefrontal cortex,

Figure 15-16 The pain neuromatrix takes nociceptive input from the spinal cord (or trigeminal system) and converts into a feeling associated with emotions. (Used with permission from the Willard/Carreiro collection.)

while not having intensity-coding properties, devotes significant amount of processing to the cognitive and emotional introspections and planning strategies underlying efforts to cope with the pain. Finally, the amygdala has emerged as the junction point for anxiety and depression, the negative aspects of pain, sensitizing to past pains and coloring out reception of future painful stimuli.

Pain perception is now clearly distinguished from nociception by the significant engagement of brain regions critical to sensory, affective, and evaluative assessments (Turk et al., 1993; Jerome, 1993). These areas involve:

1. Selectively reviewing all information at the onset of pain.
2. Retaining various aspects of the information to be analyzed and organized into meaningful patterns (i.e., “pain matrix”).
3. Comparing this noxious stimulus information to pain information already catalogued in short- and long-term memory.
4. Transmitting recognized pain patterns to specific brain appraisal systems, including those responsible for attaching affect and meaning to the experience; and those responsible for translating the pain experience into behaviors, musculoskeletal reactions, and problem solving routines.
5. Selecting and executing various problem-solving strategies in an effort to adapt and cope with pain.

These pain strategies both influence and are influenced by the patient’s neuromusculoskeletal environment.

The Endogenous Pain Control Systems

In response to injury, our body can suppress the transmission of nociceptive information through the spinal cord thus facilitating our ability to focus on escape and survival. Then, when safe to do so, reverse the situation by enhancing nociceptive transmission thereby facilitating protective guarding of the injured structure. To accomplish this control, our brain has the ability to modulate activity in the spinal cord, regulating the amount of information that is allowed to rise to consciousness. Descending pathways of brainstem origin and involving such neurotransmitters as serotonin and norepinephrine among others perform modulation of the dorsal horn and spinal trigeminal nucleus (Mayer and Price, 1976; Fields and Basbaum, 1978); as such these pathways form an endogenous and powerful antinociceptive system (Basbaum and Fields, 1978). Ascending nociceptive information reaches areas in the medulla, rostral pons, and midbrain; in turn these areas can initiate a complex descending pain control system capable of significantly modifying signal transmission in the dorsal horn. This descending system is named for its major nuclei in the brain stem: the periaqueductal gray-rostral medulla- dorsal horn (PAG-RM-DH) system.

This PAG-RM-DH system is under dynamic top-down modulation by brain mechanisms that are associated with anticipation and other cognitive and affective factors. When activated, the descending brainstem pain control systems can dampen pain sensation and inhibit behavior reactions typically evoked by nociception (Fields et al., 2006). This type of pain suppression can permit the use of an injured body part on an emergency basis. Such events are reported in combat situation as well as in competitive athletic events and other high-stakes crisis situations. In this way, the endogenous pain control system can represent a very adaptive behavior.

In addition to its descending control, the PAG-RM-DH system is also capable of enhancing our sensitivity to pain, an event that can also be protective in some situations (Fields et al., 2006). By promoting activities that limit aggravation of the painful area, through immobilization or other protective measures, these

systems may have a positive effect on healing. Therefore, enhancing the neurotransmission of nociception and the associated perception of pain may serve an adaptive role. Unfortunately, an extended period of pain facilitation or diminished pain inhibition may no longer be serving an obvious adaptive function and in fact creating excess suffering.

A second, descending pain control system has been identified (reviewed in Le Bars, 2002). Unlike the PAG-RM-DH system, when this second system is activated by primary afferent fiber discharge, it provides a diffuse blanket of inhibition over the entire spinal cord, with the exception of the segment that is stimulated. This second system is termed Diffuse Noxious Inhibitory Controls (DNIC). Once DNIC has been initiated, a second nociceptive stimulus at a distance in the body from the first is blunted in its affect on the spinal cord. The neural pathways utilized in DNIC are separate from those of the PAG-RM-DH and involve the subnucleus reticularis dorsalis in the medulla. However, like the PAG-RM-DH system, DNIC is modulated by multiple supraspinal mechanisms. DNIC has been demonstrated in humans and appears to have similar effects in males than females (France and Suchowiecki, 1999), despite the fact that men generally have a higher threshold for pain than women. In women, DNIC was demonstrated to vary somewhat during the menstrual cycle, being most effective during the ovulatory phase (Tousignant-Laflamme and Marchand, 2009).

The observation that at least some of the pain modulation system can facilitate nociceptive transmission as well as inhibit it at the spinal or trigeminal level, coupled with the knowledge that multiple forebrain areas, especially those long felt to be located in the limbic system, exert a strong regulation over these pathways, gives rise to some very intriguing possibilities. Complex supraspinal networks, influenced by emotions and hormones, could be responsible for enhancing as well as suppressing our feeling of pain from a noxious stimulus. Thus, the social and psychological context of the injury along with the degree of anticipation and anxiety as well as the individual's past experience with similar or related stimuli and their current body physiology may have a lot to do with that individual's ultimate response to a noxious stimulus.

Finally, it is important to note that what has been described as "descending endogenous pain control pathways" may be only a specific function of a much more broad-based system controlling numerous aspects of the spinal cord. It has been long known that areas in the brainstem, closely related to those involved in pain modulation, control the functions of the spinal components of the autonomic nervous system as well as the activity of motoneurons in the ventral horns (reviewed in Mason, 2005). Thus, the so-described pain control system may be an integral component of a larger brainstem system controlling spinal facilitation in general.

Pain Perception

There is a significant distinction between nociception and pain perception. Nociception occurs at the peripheral nerve, spinal cord, and brainstem level. It facilitates spinal cord and brainstem circuits, triggering reflexes and unconscious adaptive behavior. Conversely, pain perception begins with the activation of thalamocortical circuitry. The initial stages of pain perception most likely involve the primary and secondary somatic sensory cortical areas, but then rapidly spread outward on the pain matrix to engage numerous other regions such as the insula, anterior cingulate, amygdala, and prefrontal cortex as previously described. The perception of pain is a construct (Chapman, 2005) that emerges

from the sum total of activity in this matrix and not a specific property of anyone region. The brain scans a pain threat or the potentially painful event for recognizable patterns in an effort to attach meaning and emotions and to generate strategies to problem solve. Each component of the cortical pain matrix provides aspects of the physiological, emotional, and cognitive response. The native activity in each of these cortical regions is strongly colored by the sum total of previous experience, such as past pains, emotional events—in essence—the baggage of life. It follows then that experience of a given pain and the subsequent emotional reactions that it generates may differ significantly between individuals.

At this point, it is important to distinguish between what is termed acute pain and the more ominous state termed chronic pain. Acute pain, also termed physiological pain or *eudynia* (good pain) occurs when a noxious stimulus is present. Peripheral nerve and central systems in the spinal cord, brainstem, and forebrain can sensitize and ramp-up activity, but acute pain will remit with the natural course of tissue repair. In contrast, chronic pain, also termed surgical pain or *maldynia* (bad pain) is pain that is still present 3 to 6 months following the expected natural healing of the injured tissue. In this way, chronic pain represents dysregulation in the normal sensitization systems either at a peripheral nerve, spinal cord, brainstem or forebrain level. From these observations, two significant conclusions can be made. First, chronic pain is a pathology representing altered neuronal activity—such as neuronal cell death—in multiple areas including possibly prefrontal cortex, more so than simply prolonged nociceptive activity triggered by peripheral generators. Second, the longer patients are exposed to chronic pain, the more sensitization mechanisms are stressed and falter leading to greater pain scenarios. Clinically, this means that the longer patients experience chronic pain patterns, the more intense these patterns will become and the harder it will be to ameliorate these pain syndromes.

Pain Behaviors and Problem-Solving Processes

Problem solving implies that humans have the capacity to identify and incorporate potentially useful stimuli, to translate and transform the information received from the stimuli into meaningful patterns, and to use these patterns in forming an optimal response. As the individual thinks about the factors surrounding a painful or damaging event, reasoning and learning are taking place. The individual quickly learns to anticipate damaging events and makes adjustments to optimize their chances for adaptation, new learning, and long-term survival (Sanders, 2002). Historically, the basic need to successfully anticipate and avoid potential tissue-damaging events has set the stage for considerable complex thinking and innovative problem solving. Humans have evolved to become quite good at anticipating, avoiding, or minimizing pain. When these skills are augmented with the ability to create symbols for communication, and to share language, reasoning, and abstract thinking, the result is the capacity for minimizing tissue damage and avoiding persistent pain and new learning.

Persistent pain, as has been documented, can lead to spinal cord excitability, brain reorganization, and self-perpetuating neuronal activity. The psychosocial consequences include anxiety, depression, and a reduction in quality of life (Melzack, 1993). The osteopathic physician often sees a patient who continually seeks medical attention in search of any treatment that will either interrupt the pain signal or help them manage the impact of the pain on their lifestyle. Without pain control, the patient suffers, and the suffering continues until the threat has passed. Pain and suffering form a dynamic-plastic system; dynamic in that the pain matrix

continually responds to nociception, and plastic in that it also continually changes as a result of nociception. The constant resynthesis of pain information, coupled with the constant cognitive-emotional appraisals, positions the individuals to either suffer or learn and adapt (Jerome, 1993).

The philosophy of whole-person, health-oriented care that underwrites the Osteopathic profession provides a unique opportunity to help the patient suffering from chronic pain. Pain expression is closely tied to the condition of the musculoskeletal system and thereby acts as a bridge between the body and the mind. This bridge is a two-way street allowing the emergent activity in the mind to influence the physical condition of the musculoskeletal system as well.

Thoughts, Feeling, and Words

When nociception reaches the thalamocortical level and reaches consciousness as pain, thoughts, feelings and words are put to the event, conscious memories form, and behavior adaptations occur. Continuous nociception and activation of past pain memories encourage the assignment of words to pain experiences; lumping a large variety of pain experiences into pain beliefs that form the basis for future thoughts, feelings, behaviors and the problem-solving strategies employed in response to the pain experience. Emotional appraisals of the pain become highly charged when the pain is perceived as having a significant personal impact on function and quality of life. This becomes especially apparent when there is little or no understanding of the origin of the pain or of the future course of the pain.

The emotional appraisal process at the onset of pain begins with orienting and startle reflexes, and feelings of arousal, preparing the individual to engage in more focused attention. Further appraisal might determine that the noxious stimulus is not harming tissue but hurts, and this may cause some anxiety and irritability. If the appraisal concludes that some harm is also occurring, one may develop a feeling of fear about the impact and meaning of the pain. This process can lead to “catastrophizing” about horrible consequences coming from the pain situation (Sullivan et al., 2001; Turk and Monarch, 2002). Pain perception and cortical activity can vary with the patient’s degree of vigilance or their perspective on pain, catastrophizing (Seminowicz and Davis, 2006).

In either case, there is generalized musculoskeletal tension, autonomic arousal, and visceral and motor responses, such as those that would be called on to fight or flee. If a person is unable to take any action, they may feel anger and want to fight or sadness from a sense of loss of control because they can’t stop the pain or run from it. Over time, the loss of control and decline in personal mastery over the pain leads to depression.

If the pain extends beyond normal healing time, 3 to 6 months leading to the diagnosis of chronic pain (Merskey and Bogduk, 1994), the patient makes further more global appraisals in an effort to understand the overall biopsychosocial effect of their pain on function and quality of life. Emotions attached to this global appraisal include shame, fostered by a sense that one has failed to reach social cultural standards for mastering and living with chronic pain; or guilt, fostered by a sense that one has transgressed personal, family, and/or group member’s expectations for adequately coping with pain. As a result of these ongoing cognitive-emotional appraisals, new behaviors are selected, more emotions are labeled and linked to painful musculoskeletal sensations, and the experience of pain and suffering reaches full expression, often through the musculoskeletal system.

Pain and Stress

The neural and endocrine linkage between the nociceptive system and the stress-response system is very strong (Schulkin, 2003a). Both systems operate on a feed-forward mechanism that is adaptive in nature. Neither the stress-response axis, nor the pain-response system has an established set-point around which it operates; thus, when activated, both are open-ended responses that meet the current definition for an allostatic event (Schulkin, 2003a). Both systems offer mechanisms that are protective in the short term or acute response. Acute pain and acute stress are symptoms of a problem that has occurred and that typically will resolve. Both systems can become pathologic (disease) when prolonged. Chronic pain and chronic stress represent diseases that no longer are responding to a triggering stimulus but have taken on a life of their own in the patient.

Both the pain response system and the stress response system have long-loop, slow feedback control system that attempt to reestablish the normal homeostatic rhythms of the body once the nociceptive event or the stressor remits. Destruction of these long-loop control systems through excitotoxic pathologic mechanisms is known to occur. This breakdown in control results in an inability to downregulate either the pain response or the stress response or both (Lee et al., 2002; Schulkin, 2003a; Schulkin, 2003b). In essence, both systems are stuck in the “on” position. In addition, long-term exposure to activity in either or both chronic pain and chronic stress system can result in the onset of depression. Indeed, there is strong crossover between each system. Patients with chronic pain chronically activate the stress response system, often resulting in the onset of depression, while those caught in a chronic stress response are more inclined to develop chronic pain as well (Magni et al., 1994).

Allostatic Mechanisms

Pain—and the stress it creates in the body and brain—is, in essence, an allostatic process influenced by a complex network (i.e., pain matrix) of cortical and subcortical brain structures. All levels of the nociceptive system are capable of an allostatic (feed-forward) response to noxious stimuli. At the level of PANs, peripheral sensitization can occur, in a feed-forward process, enhancing the activity of the fiber. In the spinal cord, central sensitization occurs, again in a feed-forward process, creating regions of segmental facilitation. Similar facilitation also occurs, again using feed-forward mechanisms, in the forebrain areas such as the amygdala. At this level, emotional experiences surrounding the painful event can facilitate amygdaloid activity, resulting in enhanced fear memories and increased drive on the neuroendocrine systems of the hypothalamus and midbrain. These systems increase the production and release of norepinephrine and cortisol resulting in an enhanced protective response to arousal-provoking stimuli such as pain. While such a response may be highly protective in the short-term situation, long-term exposure to allostatic mechanisms is known to be pathologic to numerous body systems thus predisposing one to physiological dysregulation (Chapman et al., 2008) as well as to such psychological states as depression and anxiety. Viewed in this light, chronic pain is the end product or disease that occurs in the nociceptive system when a normal allostatic response such as acute pain exceeds its control systems and becomes fixed in a pathologic state.

Keen understanding of pain from the peripheral generation of a nociceptive signal to its conversion into a painful feeling in the forebrain is necessary to provide a framework for managing somatic dysfunction. The person in pain is more than a biologic event; he or

she is a thinking, feeling individual capable of sophisticated problem solving. Such a person, when confronted with chronic pain, actively seeks information, makes decisions, and attempts to put forth their best effort possible in adapting to the painful condition. Osteopathic treatment is aimed at taking the patient beyond the symptom of pain by exploring and treating factors in the patient's life that appropriately modified will facilitate recovery, prevent the reoccurrence of chronic pain, and improve their health and inherent recuperative and restorative powers.

KEY CONCEPTS

- Pain is an unpleasant sensory and emotional experience. Acute pain is a symptom; chronic pain is a disease.
- The pain neuromatrix is nested in the central nervous system, where modulation, transmission, and transduction of noxious stimulation occur.
- The musculoskeletal, immune, neurologic, and endocrine (MINE) systems interact as one “supersystem” in response to nociception.
- Body unity and structure/function interrelationships guide osteopathic thinking regarding chronic pain management.
- Stress dysregulates the MINE supersystem, predisposing one to chronic pain.
- Chronic pain results from a sustained loss of a system’s ability to function normally with regard to its own self-regulation and/or its normal regulatory role interacting with other systems.
- Osteopathic assessment of chronic pain is dynamic, patient focused, and comprehensive.
- Osteopathic pain management integrates the five models as the standard of care for pain management.

INTRODUCTION

The National Institute of Health describes pain as a leading public health problem affecting more than 75 million Americans, more than the number of people with diabetes, heart disease, and cancer combined (1). This translates into 70 million health care visits a year, making pain a leading cause for health care utilization (2). In a large study of primary care practices, 50% of patients regularly reported experiencing pain and associated dysfunction. Health care utilization for chronic pain patients is *five times* that of those without chronic pain (3).

In the evaluation and management of patients with chronic pain, osteopathic medicine offers a particularly illustrative example of its unique diagnostic and therapeutic potential. The principles that have defined osteopathic philosophy and practices can be readily recognized as central to the process of diagnosis and treatment of patients with chronic pain.

In osteopathic medicine, the emphasis is placed on evaluating, not just the painful region of the patient, but the “person who is in pain”; taking into consideration the general health of their body, their relations with family and close associates, as well as their cultural background. In this manner, the pain syndrome is seen as nested in ever-expanding circles of influence. Each element in this nested array represents a diagnostic vector capable of affecting other elements, at every other level (Fig. 16.1).

Chronic pain management has been formally studied only since the late 20th century. In that time, we have come to understand profound influence that noxious peripheral stimuli can have on the musculoskeletal, immune, and endocrine systems as well as the central nervous system (CNS). In the spinal cord, brainstem and forebrain regions, synaptic organization and function can change rapidly, in response to acute nociceptive input (4). Such changes can range from the molecular, to the gross, structural levels, involving alterations in gene expression and protein synthesis. These immediate responses can be transient or long term, and, unfortunately, given the right circumstances, can become permanent. Certainly, one of the most profound findings in the recent research on pain is the dynamic or plastic nature of this beast and its pervasive influence on body physiology and behavior (5).

Therefore, it is important to keep in mind, when evaluating a patient in pain, that the process is dynamic and may rapidly evolve in catastrophic directions.

Detailed and repeated examinations are required to monitor the situation. Treatment protocols must have both a strong evidence-based grounding and the confidence of the patient in order to succeed (6). Finally, the irony involved in evaluating a patient in pain is that for the patient this is a first-person subjective experience, strongly colored by prior experience, that the physician is attempting to convert into a third-person investigation, for the purpose of diagnosis and the design of an appropriate treatment and management regimen.

Pain is an unpleasant sensory and emotional experience. In 1982, the subcommittee on Taxonomy of the International Association for the Study of Pain (IASP) redefined pain by integrating both physiological and psychological components. This definition was published in *Pain* (IASP) (7) as well as in the *Proceedings of the 3rd World Congress on Pain* (8).

Pain: An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.

Note: Pain is always subjective. Each individual learns the application of the word through experiences related to injury in early life. Pain is the experience that we associate with actual or potential tissue damage. It is always unpleasant and therefore an emotional experience. Many people report pain in the absence of tissue damage or any pathophysiological cause; usually, this happens for psychological reasons. This definition avoids tying pain to the stimulus. Activity induced in the nociceptor and nociceptive pathways by noxious stimulus is not pain, which is always a psychological state.

The following policy statement on pain was adopted by the American Osteopathic Association’s House of Delegates in 1997 and reviewed in 2002 and 2005. Chronic pain means “a pain state in which the cause of the pain cannot be removed or otherwise definitively treated and which in the generally accepted course of

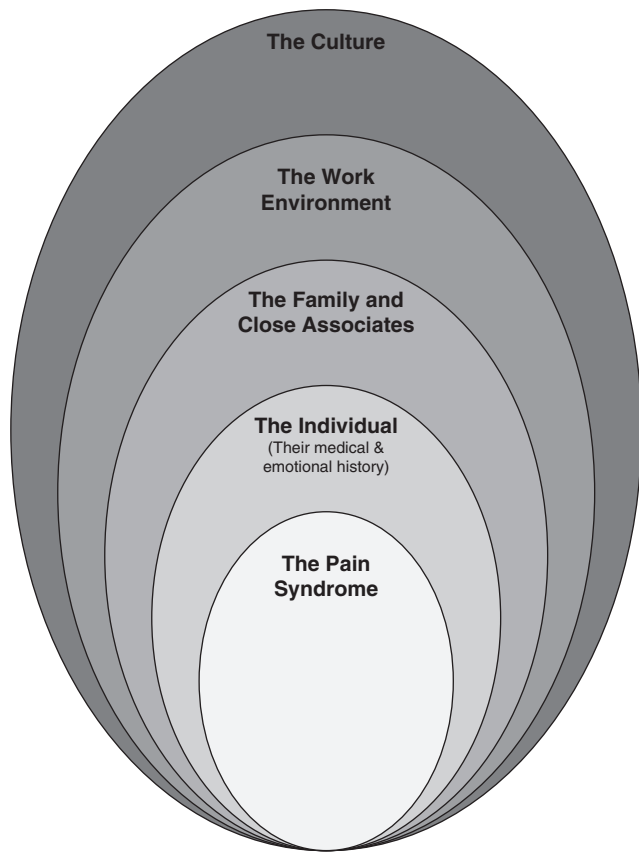

Figure 16-1 The nested spheres of influence on the pain syndrome.

medical practice, no relief or cure of the cause of the pain is possible or none has been found after reasonable efforts” (9,10). Osteopathic physicians recognize a duty and a responsibility to treat patients suffering from chronic pain. Certainly, the differences between acute pain and chronic pain represent qualitatively different experiences for both patient and clinician.

In this chapter, we learned that nociception is related to the process of detecting real or potential tissue damage. Specialized A-delta and C fibers (nociceptors) respond to a variety of noxious stimuli. They convert the chemical, mechanical, or thermal stimuli into altered neuronal activity. This is largely transmitted to the dorsal horn in segment derived, organized, receptive patterns. The nociceptor responses themselves are affected by local chemical and neural activity. In their normal state, they respond to energies capable of damaging cells. In abnormal states, they can demonstrate altered response characteristics associated with hyperalgesia and painful responses to noninjurious stimuli, known as allodynia. Nociception can be disrupted or enhanced by descending modulation from the brain and brainstem. In chronic pain, there is a bias toward greater nociceptive facilitation and less inhibition.

Pain is the response to nociception. When the system is healthy, it represents nociceptor-driven activity in the spinal cord and brain. When the system is not healthy, it may represent impaired function of the peripheral nervous system (PNS) or CNS. Pain may be experienced even when there is no noxious stimulus (i.e., phantom limb pain) (11).

Therefore, pain is a perception. This perception is part of a greater pain experience.

Suffering is a negative affective experience and response to pain. It is seen in association with pain and other psychic states (i.e., “a broken bone can cause pain... while the suffering of a broken

heart may often be inconsolable”). Suffering is associated with activity in specific brain regions. It, too, is under the influence of ascending and descending influences. It is a feeling. This feeling is part of a greater pain experience. It frequently leads to pain behaviors. Often, it is this suffering that is the primary concern driving a patient to seek health care.

Acute pain is a symptom. Acute pain is usually associated with a well-defined biological cause and a rapid onset that alerts you to the possibility of tissue damage. It usually vanishes as healing occurs. Acute pain follows an injury to the body and implies a natural healing process of short duration. It is only expected to persist as long as the tissue pathology itself. Acute pain is often, but not always, associated with objective physical signs of:

- Increased cardiac rate
- Increased systolic and diastolic blood pressure
- Increased pupil diameter
- Striated muscle tension
- Decreased gut motility
- Decreased salivary flow
- Decreased superficial capillary flow
- Fear and/or anxiety
- Releases of glycogen, adrenaline, and noradrenaline

These are collectively understood as the alarm response and the secondary stages of resistance/healing that can lead to recovery. These changes in nociceptive activity have been assumed to be roughly proportional to the intensity of a noxious stimulus. The enormous biologic value of acute pain is to promote a rapid orientation to the noxious stimulus, and, to promote reactions to minimize or escape the damage being done by the noxious stimulus. Some pain fosters rest, protection, and care of the injured area during healing, thereby promoting recuperation. In other situations, acute pain can be suppressed temporarily in the service of a greater circumstance. These examples can be seen on the battlefield, the athletic field, and in emergency, crisis situations as anyone might experience (11).

The overall behavioral signs of acute pain are agitation and the emerging flight-or-fight reaction. Patients with acute pain are anxious about the pain’s intensity, meaning, and impact on themselves and their lifestyles (12). This is rapidly followed by the resistance phase during which the organism resists a compromise of homeostasis. Through allostatic actions of the integrated musculoskeletal (M), immune (I), neural (N), and endocrine (E) systems, the person is led toward recovery.

Unfortunately, and rather often, pain persists after initial healing. It may persist after all conventional medical treatments and drugs have been tried to little or no avail. A constant barrage of erratic nociceptive impulses into the brain provides no new or useful information, but the adverse signal continues to reach consciousness. As an example, a patient with a failed back surgery 2 years postoperatively does not need to experience pain every time he moves his spine to remind him that he has scar tissue, adhesions, and functional changes in the structure of his back. Since he is no longer in the acute healing phase, the information provided by this type of repetitive noxious stimulation may lead to central sensitization, with musculoskeletal, immunologic, neurologic, endocrinologic disturbances, and abnormalities of regional cerebral blood flow (13) and metabolism.

Chronic pain is a disease that can affect both the structure and the function of the CNS (14). Pain patients imaged with functional magnetic resonance imaging (f-MRI), positron emission tomography (PET), single-photon emission computed tomography (SPECT), and magnetoencephalography (MEG) have revealed changes in neural processing that differentiates chronic pain from acute pain (15–17).

In patients with irritable bowel syndrome (18) with chronic pain, there is cortical thinning, and cell loss in the anterior cingulate cortex and anterior insula. Similar changes are also seen in chronic tension headache (22) and chronic back pain (4). In addition, effects are seen on thalamic and prefrontal gray matter density, as well as on ascending and descending pain-modulating pathways (19). In the fibromyalgia syndrome, there is an altered sensitivity to stimulation, with sensitization in pain-related neural activity (20). In migraine sufferers, there has been a reported thickening of the somatosensory cortex (21).

It is also reasonable to consider that a person's inherent structural/functional neural capacity may predispose them to the development of chronic pain. Genetically determined or acquired disturbances in the neural circuitry affecting neurotransmitter production and metabolism, receptor morphology and function, ion channel structure and function, disturbances of the neurons, their cell bodies and metabolism, their axons, their transmission properties, their structure and function, the tracts in which they run, the nuclei that they form, and their neuronal/glial interactions, all help create a pain neuromatrix.

The pain neuromatrix is nested in the CNS, where modulation, transmission, and transduction of noxious stimulation occur. At the basic biochemical level, when noxious stimulation of muscle afferent C fibers is prolonged and persistent, excitatory amino acid and neurotransmitters are released in greater amounts and for longer periods (23), the resulting activation of *N*-methyl-D-aspartate (NMDA) receptors and the release of substance P, both centrally and peripherally, lead to hyperexcitability of PNS and CNS neurons with expansion of the size of the painful area beyond the original site of damage. This peripheral and central sensitization, the enlargement of peripheral pain receptor fields (24), allows noxious sensations to be experienced as more painful (hyperalgesia) (25) and even non-noxious sensations as painful (allodynia).

Primary hyperalgesia occurs at the site of tissue damage as an increased sensitivity to heat or mechanical stimulation. This primary hyperalgesia is due to peripheral sensitization (26). That is one way in which a healthy peripheral nerve can be chronically activated at its periphery. For heat, it has been linked to sensitization of the peripheral terminals of the primary pain afferents (27). The primary afferent can also be sensitized by descending noradrenergic and serotonergic systems that work directly, in the spinal cord, on the primary afferent's central terminals (presynaptic) and on the segmental interneurons to increase their sensitivity in chronic pain states. *Secondary hyperalgesia* occurs around the site of tissue damage, manifesting as an increased sensitivity to mechanical stimulation only. This secondary hyperalgesia is due to central sensitization. It is in this enlarged receptive field that mechanical stimulation elicits abnormally increased responses from second-order afferents in the spinal cord to normal afferent input. It is, in part, NMDA receptor mediated. It appears to be related to increased synaptic efficacy, which is molecularly similar to long-term potentiation (LTP). This represents a form of intercellular learning. It, too, is subject to descending modulation of both inhibitory and excitatory influences.

The lateral system ascends to the lateral thalamus, synapses, and projects to the primary and secondary somatosensory cortex and the insular cortex. The insular cortex and claustrum appear to represent a site of major sensory modality convergence. It is largely associated with the discriminative aspects of stimulus quality, intensity, location, and duration.

The medial system projects to the brainstem and ultimately to the medial thalamus. It sends projections to the anterior cingulate cortex. The insular and anterior cingulate cortex project to

the amygdala and then to the brainstem. From the brainstem, projections can be ascending and descending. The descending projections can inhibit and disinhibit the activities in the spinal cord and lower brain stem and in this way contribute to primary and secondary hyperalgesia.

The medial nociceptive system has been associated with general arousal, emotional, autonomic, motor responses, leading the drive to end the painful problem. Here, then, afferent sensory information is linked to efferent autonomic and gross motor actions of defense and avoidance. This activity may be studied with objective measures of chemical levels, neural activity, and gross behaviors.

The cognitive evaluation occurs in view of past experience, memory, and expectation and is cortically and subcortically mediated. The way a person feels and thinks about their pain condition actually can affect the way they process and cope with pain. Cognitive elements promote modulation of the medial and lateral ascending nociceptive systems and provide a connection to the conscious experience.

The endogenous opioid system is richly represented at all levels of the neuraxis involved in pain processing. It is part of the parallel distributed and integrated endogenous system for relieving pain. It is part of the medicine chest to which A.T. Still referred. It, however, can be inadequate in states of chronic pain. Ironically, the long-term use of exogenous opioids, usually from the doctor, can inhibit the body's capacity to respond to pain. The chronicity of pain is associated with structural and functional changes at multiple levels of the neuraxis (4). It can involve changes in excitability, lowered thresholds and higher gain in the system, changes in receptors, channel-mediated changes, and second messenger effects, transduction and translational effects at the cellular level, and changes in synaptic efficacy (14). This form of LTP is part of the neural basis for learning, known as *plasticity*. Plasticity means that the nervous system has the capacity to change its structure in response to environmental demands (28,29). Maladaptive plasticity (4,30) at several levels of the nervous system is the biology behind the continuation of pain long after the original offending event has passed, depriving pain of its functional role of protection, withdrawal, adaptation, and functional recovery (4,31,32). Plasticity can also be influenced by and can certainly influence the development of depression and anxiety (27,39).

When pain results in the activation of peripheral nociceptive afferents, there is tremendous activity in the brain. It is clear that pain perception requires a brain. "No brain, no pain." Proceeding from the peripheral receptive fields associated with the pain, there is an activation of limbic, autonomic, brainstem, and spinal cord networks of modulation (33–36).

Parallel neural networks of processing pain information are responsible for the pain behaviors resulting from the peripheral activation of nociceptors (12,38). These parallel networks are always represented in some ratio to each other. The ratio varies as the *symptoms* of acute pain become the *disease* of chronic pain (37).

Finally, it is important for the osteopathic physician to recognize that a systems network understanding of chronic pain would not be complete without consideration of the structural/functional *interactions* of the musculoskeletal, immune, neurologic, and endocrine (MINE) systems in response to nociception. *The MINE systems interact as one "supersystem" in response to nociception.*

Chapman talks about a system of "reciprocal, neural, endocrine, and immune interactions" (36) in the human response to pain and stress. In this, he posits a coherent model of interacting systems with global and local features. From there, complex pain behaviors emerge as immune (I), neurologic (N), and endocrine (E) interactions (i.e., INE system). Chapman's comprehensive, systematic

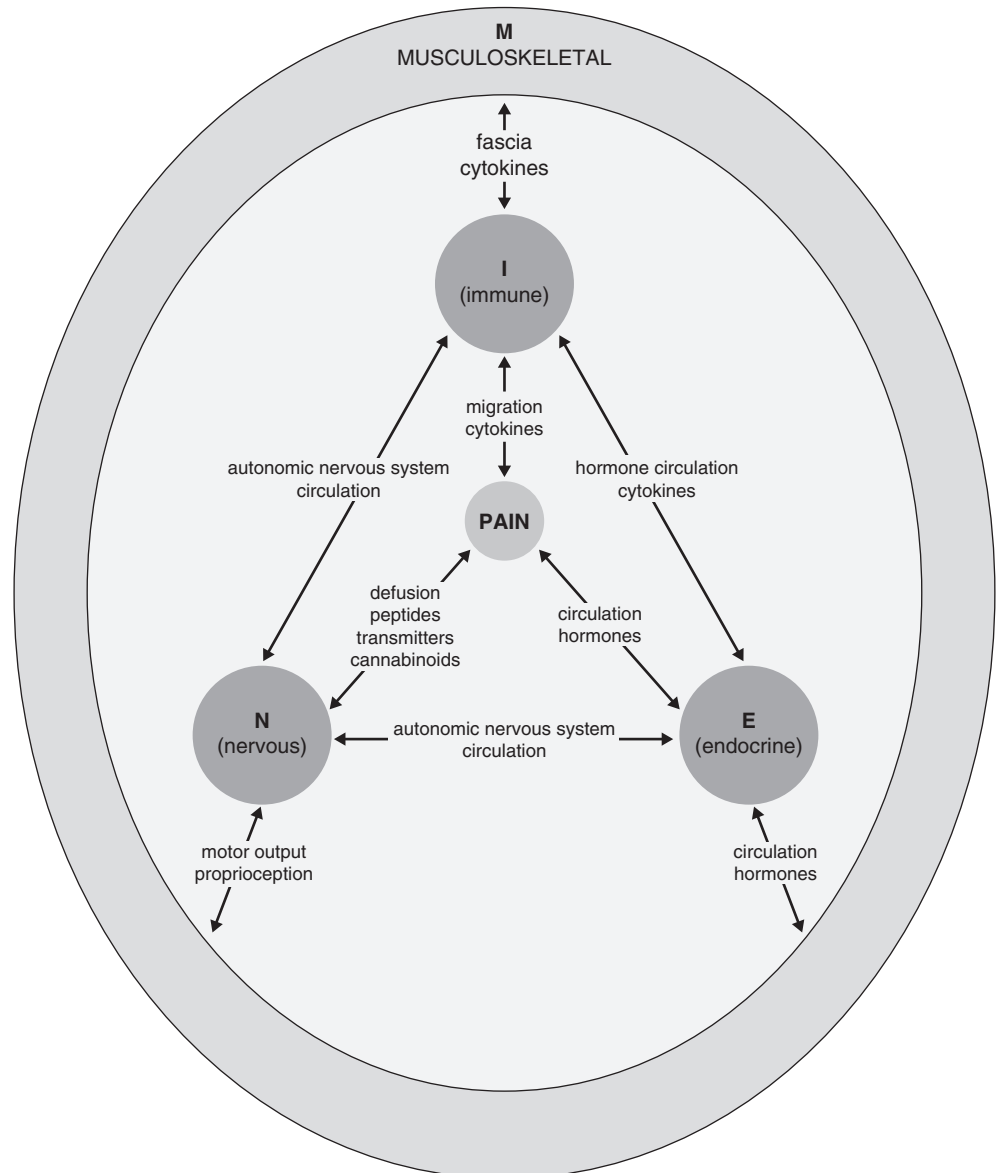

review of the immune-neural-endocrine systems as they respond to pain and stress is a clear elaboration of principles, which are characteristic of osteopathic medical thinking. This, then, joins the works of Denslow and Korr, as further demonstration of the underlying biologic, anatomic, and physiologic substrata of human functioning. When Chapman describes his INE system, he calls it a “nested system.” It provides a nest for the INE systems and is itself nested in a larger, more complex system. That is, it is nested, nurtured and nurturing, defended and defending a greater system. This greater system is the neuromusculoskeletal system whose activity is crucial to our survival. The neuromusculoskeletal system “enables us to respond to, interact with, and even alter, the external environment. Through its activity, our needs are expressed and met. It is through the use of our neuromusculoskeletal system by which we define our niche as a unique species on the planet” (ECOP, 2000).

The reciprocal interactions of these four systems—musculoskeletal (M), immune (I), neurologic (N), and endocrine (E)—as they interact in response to nociception form a *MINE system* that is continually adjusting to incoming information from both internal and external environments.

Many of the behavioral responses of the MINE system can be observed and measured. The behaviors occur at levels of scale, from the molecular to the cellular, to the whole human level. The responses represent both incoming information about the outer world and outward directed responses designed to meet and satisfy the needs and drives of that person to decrease their pain. The four individual systems that comprise the MINE system demonstrate feedback effects that can be both facilitating and inhibiting. They show connection, through their common shared receptors and their associated ligands. Neurotransmitters, peptides, hormones, cytokines, and endocannabinoids are the biochemical messengers, responsible for some of the interactive crosstalk between these four systems.

The final pain effects of the MINE system interactions vary depending on where, when, and how they are expressed and reinforced by the environment. Pain inhibitory or excitatory systems and MINE feedback and feed-forward mechanisms are all at work. Though elements within each individual MINE system can be reduced to relatively simple observable physical/chemical activity, their coordinated interactive efforts create a more complex system of observable pain behaviors.

Figure 16-2 MINE supersystem in response to nonceptive input.

For example, measurements can be made of afferent nociceptive activity in primary afferent neurons, ascending secondary afferents, brainstem, subcortical and cortical neurons; hormone levels and endocrine activity; and immune system expression of cytokines. These are the simple activities. The fight or flight response, the endocrine aspect of stress response, and the inflammatory reaction are examples of more complex pain behavior. Even more complex is the individual's ability to recognize danger and avoid it and run or fight as needed. The ability to fight off infection, the ability to recover from abuse or trauma, or the capacity to suffer are representative behaviors of even greater complexity. These coordinated complex whole-body behaviors are based upon simple principles occurring at every level of the system.

Dysregulation within the MINE system also has individual components that can be measured, modeled, and understood. The multitude of possible states and phases, for each of the four systems, from the level of the atomic, to the whole human, represent all the possibilities for healing or obstruction. "Remove all obstruction; and when it's intelligently done, nature will kindly do the rest." (A.T. Still)

The human pain system is thus characterized as dynamic. The dynamics of these systems are very sensitive to initial nociceptive conditions. That is, even though many parameters can be measured and monitored, in the face of apparent deterministic anatomic, physiologic, and pathophysiologic principles, there is still an inherent unpredictability. Because there is such sensitivity to nociception, one must be able to account for and manage every circumstance at every scale, at every moment. This is obviously not possible with chronic pain. Furthermore, slight variations or perturbations in one or another system can result in exponential expression or change from that perturbation. Therefore, with nociception, there is unpredictability. Pain behaviors in the patient often appear random, nonlinear, or chaotic; yet these behaviors are characteristic for dynamic systems. Complexity and emergence of chronic pain behaviors, in this complex pain system, is natural. *Body unity and structure/function interrelationships guide osteopathic thinking regarding chronic pain management.*

Each of the MINE subsidiary systems has an inherent capacity for self-regulation, self-learning, and health maintenance. Any of these subsidiary systems can also break down. Chronic pain, therefore, is likely an effect or consequence of system breakdowns or dysregulation.

Sometimes it is easy to understand why a patient might be hurting and other times it is less easy to explain how a particular set of circumstances might result in a patient's unique pain expression and experience. Understanding this dynamic pain system's extreme sensitivity to initial and/or prolonged nociceptive conditions makes it understandable that some people will become chronically painful (36).

The idea of holistic, interactive, nested systems, such as the MINE supersystem, is an idea consistent with osteopathic philosophy. The MINE system has properties greater than the sum of its individual subsidiary systems. The MINE system explains how individuals are able to live and adapt, respond to, and survive stressful pain situations and how they can mount a defensive response to a stressor/pain crisis, recover from that response, survive, and maintain health. The four systems themselves are interdependent, show reciprocity of structure and function, demonstrate self-regulation, and produce and maintain the necessary biologic products to sustain their own continued existence. *Homeostasis serves to regulate the internal resources ready to be called upon when stressed by pain.* From a system's analysis, homeostasis exists as an attractor, or basin of attraction within which the body maintains its internal milieu.

Allostasis is the set of adaptive reactions that help the individual maintain homeostasis in the face of any number of stressors. Pain, trauma, illness, aging, excess or deficiency can all call forth a stress response. This is a mobilization of internal resources to meet stressor challenges. First, there is an alarm response, which is accompanied by both immediate stressor resistance and a slower forming recovery response. In fact, a critical part of the recovery response is its ability to down-regulate the pain defensive response when the threat is over. This avoids overactivity of the defensive catabolic responses of active resistance and permits self-mediated recovery and return to anabolic conditions. The defensive response turns itself on, and then turns itself off, when it is appropriate. If the stressor prevails, exhaustion results. If the individual prevails, recovery occurs. The range of an individual's collective biopsychosocial responses, as well as their ability to tolerate pain intrusion and still maintain homeostasis, helps to define their level of health.

Failure to self-manage pain symptoms might occur if the defensive response is inadequate or excessive. An inadequate or excessive recovery response is associated with clinical symptoms as seen in chronic pain, especially in the musculoskeletal system. *The musculoskeletal system is ultimately involved in all pain processes and management.*

One thing essential to understanding the MINE system is an appreciation of the musculoskeletal (M) system. The musculoskeletal system is particularly available for observation and palpatory evaluation. It is the system within which the INE systems are nested. It executes the flight or the fight, and maneuvers in the external world to secure the necessary objects of sustenance, food, drink, breath, and through movement it allows seeking behaviors, interpersonal behaviors, and collectively communal behaviors. It, too, is built upon basic behaviors reiterated at cellular, tissue, and organism levels. This system, too, shows feedback, and feed-forward mechanisms. The musculoskeletal system is interactive with the other systems, not only through a common chemical language but also through a system of mechanical linkages that can be shown to have transduction, transmission, and response capability in effecting pain coping behaviors (39).

Mechanical transducers include muscle, tendon, ligament, bone, fascia, and fibroblast. The transmission occurs along planes of physical connection. The patterns of connection can be described as mechanical, anatomical, neurological, or biomolecular. The effects may include skeletal muscle behavior, whether segmental, regional, or global. They may be seen in coordinated and patterned motor system responses. They may be seen in the transformation of fibroblasts to myofibroblasts when they are under mechanical stress (39). Similarly, the behavior of bone in response to stress loading is a dynamic process. Certainly, the musculoskeletal system is body wide in its presence and in its purpose. From the cytoskeleton to the integrins to the intercellular connective tissues, from the osteon to the bones, from the myofibril to the muscle groups, from the local fascia to the entire body of fascia, there is reiteration in every scale. There is complexity and there is predictability in the musculoskeletal system. It is a part of the body's essential response to pain and stress. The musculoskeletal system interacts with the immune system, nervous system, and the endocrine system, not to mention, the respiratory, circulatory, digestive, and eliminative systems.

Stress dysregulates the MINE, predisposing one to chronic pain—dysregulation in the MINE system's ability to respond to stress, at any of its component sites, or its numerous interfaces compromises one's overall ability to heal or recover from pain/stress. Whether from extraordinary stress, compounding comorbidities, confounding social stressors, or intrinsic system vulnerability, nociception can create dysregulation and become chronic pain.

The musculoskeletal system responds to pain/stress. It is the active agent of fight and flight, and why muscles tense, contract with a purpose, and relax, when the stress has passed. The musculoskeletal system affects the nervous system through the proprioceptive stream of information that complements the flow of nociceptive afferent information. The musculoskeletal system affects the endocrine system through its complex relationship with the SMA and hypothalamic-pituitary-adrenal (HPA) systems. The musculoskeletal system affects the immune system particularly by enabling the movement of cells and their products, along the fascial networks, which are responsible for mounting immune responses.

The immune system responds to pain/stress with an inflammatory response. The combined effects of cytokines, lymphoid tissue, and immune active cells are to focus attention on internal directed vigilance. Tissue trauma elicits an elaboration of immune active molecules at the site of trauma and systemically, to trigger both the acute, inflammatory, phase reaction at the site of injury, and a more global acute phase reaction, which has been dubbed, the “sickness response” (i.e., see Chapter 10: Somatic Dysfunction). Proinflammatory cytokines and immune cell (lymphocytes, granulocytes, neutrophils, and macrophages) are “circulated” through blood vessels, lymphatics, and along fascial networks.

The immune system interacts with the nervous system. Nociceptor activation causes release of substance P and neurokinin A at the site of the disturbance. These are immune stimulating neuropeptides. The neurogenic inflammation is a part of the initiating mechanism and propagation of the immune defensive response. This inflammatory response is sensitive to sympathetic enhancement from primary nociceptor activation. The immune system interfaces with the endocrine system. This is accomplished largely by cytokines, such as interleukins 1 and 6, and their receptors that are found throughout the HPA and the sympathetic-adrenal-medullary (SAM). The immune system affects the musculoskeletal system via the structure and function of tissues that are responding to potential invasion. These are local, mechanical, anatomic, and neurologic, in their pattern of organized, coordinated involvement. Features of tissue texture abnormalities, both acute and chronic, can be associated with the primary pain response of reactive nervous, immune, and endocrine systems.

The nervous system responds to pain/stress. In a bidirectional manner, tissue trauma, anticipated or perceived, elicits transduction of the threat into an information signal, transmission of that information, and effecting of a response, adaptive in nature. When wounds occur and primary afferent nociceptors (PAN's) are aroused, their signal activity increases, and they contribute to their own peripheral responsivity, by producing peripheral neurogenic inflammation in concert with the immune system. These nociceptors and immune system elements show connectivity in the periphery, where they participate in the acute inflammatory reaction, a part of the acute phase reaction. Peripheral sensitization is the result, with additional neural contribution from the sympathetic mediated peripheral effects.

Dorsal horn (central) sensitization refers to the lowered threshold and increased responsiveness, which occurs in secondary afferents from severe or protracted nociceptive stimulation. It occurs by glutamate and NMDA receptor mechanisms. There are inhibitory and excitatory influences from segmental, polysegmental, and descending mechanisms, which help determine the afferent sensitivity of ascending transmission. Central connections in the thalamus, hypothalamus, locus coeruleus (LC), solitary nucleus (visceral and somatic convergence), amygdala, periaqueductal gray (PAG), and the cerebellum are the sites of relay and response of the ascending neural message. Further projection to the insula and anterior

cingulate cortex appears to represent convergent sites for affective (amygdala), motivational (LC), and primary sensory processing. Multiple sensory modalities are integrated and coordinated. Of course, the somatosensory cortex is activated. Descending influences may be inhibitory or excitatory. The presence of inadequate inhibition or excessive excitation can explain a circumstance in which chronic pain may develop.

In the alarm response, a stage of defensive arousal, the hypothalamus, amygdala (affective intensity), and PAG (pain modulation) are engaged. They coordinate sensory input with emotional content and cognitive meaning with the goal of driving behaviors that favor survival. They are connected with higher-order cortical structures and lower-order brainstem and subcortical elements to foster learning and ultimate mastery.

The nervous system's alarm response affects the endocrine system via the HPA axis and the SAM axis. The nervous system also affects the immune system. The vagus nerve has an afferent role and an efferent role in mediating inflammatory responses by modulating cytokine levels. The nervous system affects the musculoskeletal system. Acutely, in stress it shunts blood to the skeletal muscles and away from the viscera (sympathetic). In recovery, it shifts to a resting state, decreasing skeletal muscle shunting, and becomes more supportive of visceral, vegetative processes (parasympathetic).

The endocrine system is seen to respond to stress in fast defensive arousal and in the slower process of recovery. Hormone variably affects the nervous system. At the level of the LC, noradrenergic engagement occurs. Through the HPA, the hypothalamic periventricular nucleus and the pituitary, adrenal effects are reinforced or restrained. Corticotrophin-releasing hormone (CRH), pro-opiomelanocortin, as a precursor for adrenocorticotrophic hormone, and glucocorticoids, are involved in a feedback-dependent response system. This affects adrenocortical behavior through glucocorticoid (cortisol) release. The LC, noradrenergic axis, affects adrenomedullary behavior through release of epinephrine, norepinephrine, and neuropeptide Y. Through the effects of CRH and its receptors CRH-1 and CRH-2, the endocrine system initiates defensive arousal and recovery, respectively. It affects the immune system through its effects on cytokines. HPA axis activation affects the cytokines differentially at times encouraging inflammation, other times encouraging recovery and resolution of inflammation. It affects the musculoskeletal system. Through an activated sympathetic state of arousal, there is shunting of blood to the necessary fight or flight participants. This is the musculoskeletal system.

Other nested systems responding to stress include the visceral, arterial, venous lymphatic, and respiratory/circulatory systems. These nested systems are also intra-active and interactive. The majority of their communication is via the holistic musculoskeletal, circulatory, and nervous systems. They share many of the same properties and demonstrate similar feedback and feed-forward modulation. The feed-forward aspect allows the ability to mount a rapidly accelerating and amplified response when needed. The feedback aspect is part of a process of deceleration that helps control the acute defensive reactions and prevent their excesses. Excesses or deficiencies, in positive and negative feedback, create the potential for dysregulation. These dysregulatory mechanisms can also be related to the problem of chronic pain. This can occur when the fast immediate arousal state does not yield to the slow response recovery phase, or when the response to the stressor fails to readjust to the normal level after the stress has passed. Hypervigilance and hyperreactivity continue as the system, using McEwen's metaphor, fails to hear the all-clear signal (28) and back off. It can occur when the classic changes in cortisol and HPA axis regulation fail to occur. Disturbances in the coordination of the elements involved in

the MINE system can result in circumstances predisposing to chronic pain.

Chronic pain results from a sustained loss of a system's ability to function normally with regards to its own self-regulation and/or its normal regulatory role interacting with other systems.

Impaired connectivity of the neuromusculoskeletal system, the autonomic nervous system, the LC, the endocrine, HPA and SMA axes, and the immune cytokines can lead to pain system dysregulation. Coordination of the MINE system is disrupted when the mechanisms of interaction are impaired. This can lead to an inadequate recovery. In this same vein, the system and its set points can be altered by experience such as seen in both posttraumatic stress disorder (PTSD) (40,41) and in chronic pain.

Autonomic dysregulation is first manifested by loss of inter-r-wave intervals on ECG. This electrophysiologic variable typically fluctuates in association with inhalation and exhalation. Its variability is modulated by vagal nerve activity and reflects the balance of sympathetic and parasympathetic activity. Its presence is a sign of health and stress-managing capacity. Its absence is a sign of autonomic dysregulation and portends a lesser capacity to respond and recover from stress.

Sensory dysregulation can lead to chronic pain. Excessive facilitation, as in the phenomenon of wind-up, can lead to a sensitized state and chronic pain. Deficient inhibition at any level of the neuraxis can lead to a chronic pain predisposition.

The Default Mode Network (DMN dysregulation) of Raichle shows changes of function and structural distribution of brain activity in patients with chronic pain compared to healthy controls (42). The neuroendocrine and biochemical systems, and their set point changes, contribute to the suffering and misery associated with chronic pain. It is as though these patients continue to experience the memory of pain and are unable to stop.

Endocrine dysregulations, as it affects the HPA axis and cortisol release, can be measured and correlated with diurnal fluctuations and in the response to dexamethasone suppression and/or corticotrophin stimulation. This informs the clinician as regards the inherent endocrine capacity to respond to stress. When disturbed, as in depression, it can lead to an increased incidence of dysregulation and chronic pain.

Immune system dysregulation is exemplified in the complex relation of Th1, proinflammatory, and Th2, anti-inflammatory cytokines. Th1/Th2 ratios can be measured and can be quantified as a sign of dysregulation. Glucocorticoids and catecholamines can locally stimulate Th1 changes, but globally have a Th2 effect. This suggests that they can promote local inflammation while maintaining generalized, opposing, anti-inflammatory effects. An inadequacy of Th1 response, as seen in the chronically stressed, may reflect a compromised ability to respond to stress.

A pattern of objective clinical signs (115) also emerges with dysregulation as the patient in chronic pain now reports:

- Sleep disturbance
- Decreased libido
- Irritability
- Depression
- Decreased activity level
- Deterioration in interpersonal relationships
- Change in work status
- Increased preoccupation with health and physical function

Over time, patients in chronic pain become hypervigilant to all incoming stimuli, their behavior regresses, and they demand pain control from the medical community at any cost. The environment around the patient in chronic pain also often reinforces these

ongoing pain behaviors. The pain behaviors are expressed through the musculoskeletal system and are integrated into the patient's lifestyle.

Every aspect of human life is acted out by the body's muscles and joints...These are the body parts that act together to transmit and modify force and motion...Everything man does to express his aspirations and convictions can be perceived by others only through his bearing and demeanor and utterances, and these are composites of myriads of finely controlled motions.

—L.M. Korr

The end result is that chronic pain becomes the focal point of the individual's life. This leads to demoralization and suffering. The outcome of dysregulation is the refractory, enduring pain experience commonly referred to as the "chronic pain syndrome."

The person in pain expresses structural changes and functional disturbances, associated with their unique thoughts, feelings, and pain behaviors, through the musculoskeletal and visceral systems. Immunologic, neurologic, and endocrine systems are also continually responding to the moment-by-moment changes of the musculoskeletal system, in response to prolonged pain. With this rich afferent input of the musculoskeletal system into the CNS, it is inevitable that continuous redundant pain has profound consequences on the patient's mind, body, and spirit.

An osteopathic model of pain goes beyond the biological level of sensory modalities and neurological transmissions to include dynamic interactions among and within the mind, body, spirit, and social environment to describe each patient's unique pain presentation (131). For the osteopathically trained physician, pain is more than sensation and perception (Fig. 16.3).

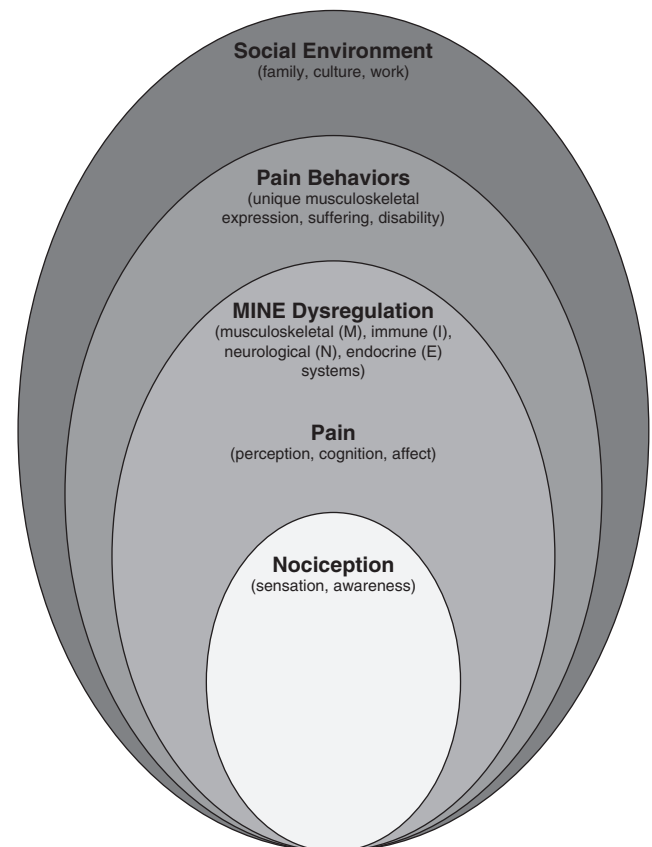

Figure 16-3 Osteopathic model of pain.

It is fundamentally recognized that nociception sets in motion a conscious awareness of discomfort, thoughts, emotions, and dysregulation of the MINE systems, which are displayed throughout the musculoskeletal system. Over time, the social environment (i.e., family, culture, work, etc.) responds to the pain, suffering, and system dysregulation to further shape and reinforce each unique and highly individualized aspect of the pain presentation (132,133). This model, which builds on the biopsychosocial model (134) and Loesers conceptual model of pain (135), emphasizes the critical role of system dysregulation (Chapman, 2008). And also more importantly, it recognizes the central role of the neuromusculoskeletal system that “is ultimately involved in all pathophysiological processes, regardless of where or how they originate.” (ECOP, 2000).

Osteopathic assessment of chronic pain is dynamic, patient focused, and comprehensive.

Osteopathic evaluation includes a complete biopsychosocial history, physical examination, osteopathic structural examination, and follow-up visits for both reassessment of the pain management plan and review of the patients’ pain scores and functional capacities (43) (see also Table 16.1).

TABLE 16.1

Investigations to Support History and Physical Examination

Categories of Tests	Examples of Tests
Psychometric testing	Formal neuropsychologic evaluation, McGill Pain Questionnaire (MPQ)
Diagnostic imaging	X-ray, computerized tomography (CT), MRI
Functional diagnostic imaging	Isotope scan, PET, blood oxygen level dependent-MRI (BOLD-MRI), fluoro-deoxyglucose-PET (FDG-PET), O2-PET, ultrasound (US)
Neurophysiologic testing	Electroencephalography (EEG), MEG, electromyography (EMG), nerve conduction velocity (NCV), evoked potentials (EP), quantitative sensory testing, vibration threshold
Fluid testing (serology)	Blood, urine, feces, cerebrospinal fluid (CSF)
Tissue testing (histology)	Nerve biopsy, tissue biopsy
Cellular testing (cytology)	Morphology, function, energy, transformation
Molecular testing	Immunologic, hormonal, neurotransmitters
Genetic testing	HLA testing, inherited disorders
Diagnostic anesthetic blockade	Nerve blocks, facet blocks, epidural blocks

Patients and their individualized pain management programs are routinely evaluated for benefits and side effects of treatment, and impact on activities of daily living (ADL). These are regularly queried and appropriately documented. The physician interprets these data through their medical knowledge and formulates a description of the patient in biopsychosocial terms, that is an integrated biological, psychological, and social diagnosis (44,45).

The osteopathic physician recognizes that the palpatory examination provides clues to the underlying pain generators. Pain generators may be confirmed by an effective therapeutic response, even temporarily, to manual correction (OMT). “Somatic dysfunction may be causative, reflective, reactive or perpetuating, or a combination (43).” In summary, osteopathic thinking requires more than assessing somatic dysfunction and relying on pain intensity scores. Comprehensive osteopathic care for chronic pain takes into account patient’s moods, beliefs about pain, coping efforts, resources, response of the family members, and the impact of pain on the patient’s functional quality of life (QOL). The patient reporting the pain must be evaluated, not just the pain (46).

The general medical history holds many keys to understanding chronic pain. The past medical history includes a childhood and early life history, a history of previous or current medical conditions and trauma (41). Of particular importance is a history of dysregulations of the musculoskeletal system, immunologic system, nervous system, and endocrine system (i.e., MINE system).

Active listening is essential for both understanding pain and developing trust. Chronic pain management begins with careful listening and observations, is followed by the physician-guided examination, and is completed with the review of historical record. The patient is seen as a whole person affected by many spheres of influence. They have sought your help because their health and sense of well-being is challenged. They hurt. What they have tried on their own for pain has failed. They often fear the worst, or they fear you’ll find nothing wrong and tell them the pain is in their “head.”

The simple message is “I know you have pain. I believe that your pain is real. I want to know all about you and the pain you are experiencing. I will treat your pain in parallel with the necessary investigations to exclude serious underlying pathology. The goal is to identify the reasons for the pain to restore function and to reduce your pain to the lowest possible level.”

A common mnemonic of PQRST (pain, quality, radiation, severity, temporal) is a good starting point for the focused pain history.

Pain: Most frequently used pain assessments are single-item Verbal Rating Scales with 0 being “no pain” and 10 being “unbearable pain.” These assessments rely on patients’ self-reported experience of pain intensity or unpleasantness. A great deal of information is available about the psychometric qualities and properties of these single-item numeric rating scales. A systematic review of clinical and randomized controlled clinical trials shows them to be reliable and valid (46).

In addition to pain scores’ intensity, multidimensional measurements of affective response, coping, function, and QOL and analgesic use allow a more comprehensive approach to measuring pain and function (46). These measures are designed to assess ability to engage in functional activities such as walking, sitting, lifting, performing ADL, and an overall sense of satisfaction and QOL.

Quality: One of the most frequently used pain assessment instruments is the McGill Pain Questionnaire (MPQ) (70–72). This instrument has three parts including a descriptive scale (pain intensity), a front and back of a drawing of a

human figure on which patients indicate the location of their pain, and a pain-rating index based on patient selection of adjectives from 20 categories of words reflecting sensory, affective, and cognitive components of pain. The MPQ provides a great deal of information in less than 5 minutes (Fig. 16.4) with good test/retest reliability (66–69).

Radiation: where is the pain, and to where does it travel or refer? (see pain drawing on MPQ). Look for dermatome patterns, peripheral nerve distribution patterns, or CNS patterns.

Severity (intensity): how bad it is; sometimes the pain intensity score and behavioral observations can be corroborating or contradicting, (i.e., 10/10 but the patient looks comfortable. or 2/10 and they look dreadful).

Temporal (intensity and duration): Another useful clinical parameter of pain assessment is a pain, intensity—time curve. These can be graphed. Basically, over a 24-hour period of time, how does the pain wax and wane? This line of questioning can be valuable. For example, a subarachnoid hemorrhage is likely to produce severe pain rapidly; meningitis may take hours or days to reach maximum intensity, while a muscle tension headache patient may describe maximal pain continuously.

The graph can include the temporal characteristic of pain resolution. Over what period of time does the pain diminish and to what degree? The pain of trigeminal neuralgia comes like a lightning bolt and typically goes away in a matter of seconds to minutes. Cluster headache crescendos rapidly and while severe is usually gone within 1 to 3 hours.

Pain of neuropathy is commonly constant, reported as worse when the patient is trying to relax or sleep, yet gets better when

distracted. It is important to know how the pain returns and with what temporal characteristics. The peristaltic rhythm of colonic pain, the morning stiffness of osteoarthritis, or pain associated with menses are examples of temporal aspects.

It is useful to understand and classify pain by its intensity and persistence over time. This can lead to differential diagnoses based on differential anatomy, physiology, and pathology (Table 16.2).

The patient is queried regarding the *impact on their affective state*. What is their mood? Are they depressed, worried, angry, or fearful and what is the history of these feelings? To what degree and in what ways is the patient suffering? What is the *impact on their cognitive state*? (Use Pain Coping Skills) What is their self-image and, how has it been affected by pain? What is the *impact on the patient's ADL*? Are they able to eat, dress, wash, and toilet? Can they do the shopping, cooking, and cleaning? Are they able to work? Are they completely unable to work, do they have a limited ability to work, are they on disability? Are they seeking disability? Has there been an effect on their mobility? Can they walk, bend, stand, sit, or lie without pain? Can they exercise? What do they do for exercise and has it changed because of their pain? Has this affected how they view themselves or how they feel? How has this affected their nutrition? Have they lost their appetite, are they not eating adequately, has it affected the availability of healthy food choices, or are there physical impediments to eating? *Lifestyle changes* and *high-risk choices* such as increased alcohol use, drug use, lack of exercise, and comfort eating are other important factors (see Chapter 32: Health Promotion).

How is their *sleep*? Do they have trouble falling asleep, staying asleep, staying awake, or getting enough sleep? Do they feel refreshed after sleeping?

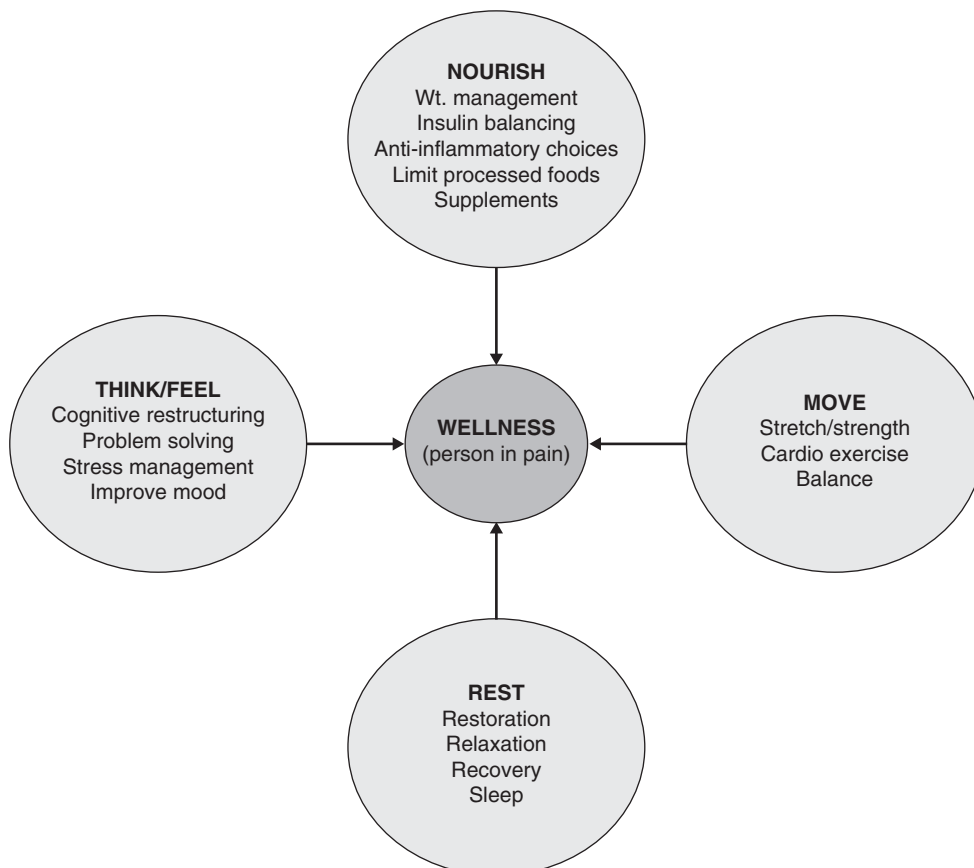

Figure 16-4 Wellness is appreciated through multiple interacting systems.

TABLE 16.2

Assessment/Diagnosis: Temporally Defined

Temporal Character	Clinical Examples
Acute	Trauma, illness
Acute, recurring	Migraine
Subacute	Longer-lasting insult or time to resolution
Chronic	Low back pain, neck pain, daily headache, fibromyalgia, irritable bowel syndrome
Chronic, progressive	Malignancy, degenerative, inflammatory
Chronic with acute recurrences	Spondylosis

What is the impact on their *family* life? How have the family dynamics and interpersonal relationships been affected? Is there a family history that is relevant? Are there family members with migraine, degenerative disc disease, connective tissue disease, substance abuse, or other abuses? Who are the caregivers? What is the impact on the *community*? Has there been a change in the patient's role in the community? Do they derive care giving from the community? What is the cultural stigma or stereotype associated with admitting, showing, or seeking treatment for pain? What are the *economic implications* of their pain? Are they missing work, losing wages, receiving or seeking disability payments? What is their degree of health care utilization? Are they seeking *medicolegal* redress?

What are the *environmental stressors*? Is there poverty, malnutrition, dysfunctional living circumstances, toxic exposure, substance abuse, high-risk behaviors?

Ultimately, the behavioral model assesses the pain and its impact on the patient's *QOL*.

The osteopathic physician is uniquely trained to evaluate the musculoskeletal system. Through observation, palpation, and motion testing, key information is gathered. The neurological/musculoskeletal system is known as reflector and effector of the entire organism and all its systems. The combination of this information with the general physical exam and appropriate evidence-based test results provides the osteopathic physician with a comprehensive data set. This allows for a most complete biopsychosocial evaluation of pain, physical functioning, system dysregulations, and adaptive response patterns.

The osteopathic physical examination is patient focused and solution oriented. It can allow a connection to the patient, otherwise unavailable. The musculoskeletal system is not just for securing a diagnosis. It provides an avenue for treatment that can target the nociceptors, the pain experience, the suffering, and the pain behaviors. Armed with the knowledge of anatomy, physiology, and pathologic physiology, a dynamic, interactive, systems analysis can be made. Specific diagnostic considerations include ongoing tissue injury, effects of neurologic processing, presence and degree of suffering, cognitive and affective disruptions, musculoskeletal manifestations, as well as premorbid, and subsequent, adaptive responses. The diagnostic systems analysis will typically describe multiple axes of dysfunction. This leads directly to an integrated diagnostic assessment and an active treatment plan (Table 16.3).

TABLE 16.3

Assessment/Diagnosis: Location Defined

Anatomic Location	Clinical Examples
Visceral	Liver, lung
Vascular	Large vessel, small vessel
Muscular	Muscle, myofascial pain syndrome
Skeletal	Bone, joint, capsule, ligament, tendon
Nervous system	Cortical, thalamic, brain stem, spinal cord, peripheral nerve, autonomic nervous system
Other	Skin, eyes, ears, nose, mouth

The formal biomechanical/musculoskeletal examination is integral to osteopathic medicine.

Besides the obvious orthopedic aspects of the examination, the characteristic evaluation for static asymmetry, tissue texture abnormalities, and restriction of motion has become an integral part of the osteopathic examination. Static asymmetry looks at posture, spinal curvature, and limb asymmetry. Tissue texture abnormalities and motion restrictions can be examined for in local, regional, and even global fashion. The important thing is to be doing this part of the examination mindful of what the patient's major pain complaints might be. Be sure to examine where it hurts. How does it look, how does it feel, how does it move? Knowing exactly where it hurts also suggests any number of associated mechanical, anatomical, and neurological associations, visceral and somatic, that can augment the biomechanical examination and its contribution to a comprehensive diagnosis. Patients in pain are sometimes not touched by their doctors. Sometimes, their painful areas are not directly examined and, as a result, their complaints are not fully understood, and the physician's formulations believed (Table 16.4).

The Neurologic Model

The neurological examination is particularly relevant in evaluating patients in pain. This is designed to ferret out those patients with irritation of a previously healthy nervous system from those with disorders of the nervous system that might be predisposing to painful states.

Always when evaluating the holistic nervous system, both peripheral and central, the questions to be answered are, is there something wrong, where is it localized, and what is causing it?

It begins with an evaluation of the patient's level of arousal and content of their consciousness. Are they bright and alert, or are they dull and sluggish? Are they making sense? Are they delirious, demented, or encephalopathic? Have they taken too much medication or do they have encephalitis? Are they mood appropriate to their complaints?

Particular attention to the cranial nerves is obviously appropriate in pain complaints of the head, face, and the special sensory organs. The eyes, ears, nose, and mouth are known to be richly innervated and very sensitive. Smell, sight, eye movements, facial strength, facial sensation, hearing, taste, speech, and swallowing are all evaluable (Table 16.5).

TABLE 16.4

Assessment/Diagnosis: Pathophysiology Defined

Pathologic Process	Clinical Examples
Malignant	Primary, metastatic, para-neoplastic
Degenerative	Trauma, wear and tear, apoptotic
Inflammatory	Immune mediated, organ effects
Immunologic	Antibodies, interleukins, tumor necrosis factor, etc.
Respiratory, circulatory	Local, regional, global
Energy, metabolic	Local, regional, global
Endocrine	Hormones, releasing factors
Infection	Local, regional, global
Somatic dysfunction	Local, regional, global
Trauma	Severity, complexity
Neurogenic	Neoplasm, infarction, demyelination, trauma, infection, degenerative, migraine
Psychogenic	Somatoform, depression, anxiety, hypervigilance, personality disorder, malingering, catastrophizing

Sensory Examination

Sensory testing is designed to evaluate the peripheral nerves, which lead to spinothalamic and dorsal column pathways, from their peripheral elements to their central pathways and connections. Further testing is aimed at evaluating cortical and subcortical components of sensory processing. Obviously, in pain conditions, sensory processing is hugely relevant. An attempt to recognize a pattern of sensory dysfunction is sought. Is there altered sensation in the territory of a peripheral nerve or is it the territory of a nerve root with dermatomal features? Do the small fibers that respond to pinprick and temperature react differently than the larger fibers that respond to touch, vibration, and proprioception? Sometimes, this can point to a disorder of the peripheral nerves such as a small fiber neuropathy. These conditions are known to have association with peripheral neuropathic pain. Is there a sensory level suggestive of a spinal cord etiology? Is there a hemisomatic distribution of sensory changes suggesting a central source? Are there dissociations of sensory deficits? For example, is there loss of pain and temperature with preservation of touch as in syringomyelia? Is there loss of pain and temperature on one side of the body with loss of touch on the other as in hemisection lesions of the spinal cord? Are there deficits in touch and proprioception with sparing of pinprick sensation, as in dorsal column disorders such as vitamin B₁₂ deficiency or multiple sclerosis? Does the sensory loss include the face on one side and the arm and leg on the other side suggestive of brain-stem pathology? Or, does the sensory loss involve the face, arm, and leg on the same side suggesting a disorder at the level of the thalamus or sensory cortex? These central lesions have long been

TABLE 16.5

Management of Nociceptive Activity

Type of Intervention	Clinical Examples
OMT	Direct, indirect
Anesthesia	Local, regional, sympathetic
Medication, systemic	NSAID, opiates, pregabalin, gabapentin, lamotrigine, acetaminophen
Medication, local	Lidocaine, NSAID, OTC topical
Surgery	Removal, repair, restoration, ablation, stimulation
Biofeedback	EMG, temperature, galvanic skin response (GSR), EEG
Physical therapy	Heat, cold, laser, ultrasound, electrical stimulation, traction, exercise, balance
Acupuncture	With or without electrical stimulation, local, systemic

known to be cause for central pain syndromes, such as thalamic pain syndrome, or parietal pain syndrome. Whether from cerebral infarction, neoplasm, trauma, or demyelinating disease, they can represent vexing conditions to manage.

Armed with a pin, tuning fork, and wisp of cotton, the sensory evaluation is pursued. Not just patterned disturbances are relevant. Sometimes, the patients response themselves are illuminating. Do they have allodynia, hyperpathia, or hyperalgesia indicating unusual sensitivity to stimuli? Or, do they have sensory loss in areas that are reported as painful, so-called, anesthesia dolorosa? Do they complain of pain in parts they no longer have, as in phantom pain syndrome? Do they have dissociations between their ability to feel and localize painful stimuli and their ability to manifest appropriate affect or cognitive correlates? This can be seen in some of the cerebral hemispheric disorders.

It is particularly important to assess the sensory status in the area or areas of complaint. Is it normal or abnormal? If abnormal, is it more or less sensitive? Is there indifference? If the sensory exam is abnormal, do the sensory findings correlate with the pain in some way? Is there a pattern of sensory loss suggesting a neurological localization?

Motor Examination

The motor examination begins with the casual examination while the patient walks into your office, moves about your examination room, describes their pain problem, participates in the examination process, passively and actively. Because pain is at least part of the problem, a particular eye toward the patient's signs of protective behaviors, such as limping or hobbling, is made. Looking for and documenting signs of suffering, such as grimacing, moaning, or crying, is done. Sad, anxious, angry affective behaviors are part of the casual motor examination, as are observations of the cognitive behavioral manifestations, like resigned, slumped/shouldered, head drooped, slow moving postural adjustments. This, by the way, is an important opportunity to broaden your osteopathic impressions

TABLE 16.6

Management of Pain Perception

Type of Intervention	Clinical Examples
OMT	Direct, indirect
Education	Information about pain and self-management
Exercise	Stretch, balance, strengthen
Medication	Opiates, TCA, NSRI, cannabinoids
Cognitive and behavioral therapies	Insight, hypnosis, relaxation training Operant and respondent conditioning

regarding the entirety of the burden that has befallen the patient (Table 16.6).

The formal testing of the motor system includes passive tests of motor tone looking for flaccidity, spasticity, or rigidity, as well as atrophy, or fasciculations. In patients with pain, there may be guarding, which must be considered. Likewise, in active testing of strength, pain may limit effort or willingness to exert a particular action or many different actions. This is best recorded as pain limited strength testing. Testing for strength can be done both regionally and locally. So, while testing general arm and leg raising, grip and toe wiggle, may be enough for a screening exam, sometimes a meticulous muscle-by-muscle, limb-by-limb, and trunk exam must be conducted, particularly, if there are pain complaints, associated with symptoms of weakness, cramping, spasms that can be localized. In those cases, the more thorough version of motor examination is mandated (Table 16.7).

Furthering the motor examination requires tests of the reflexive properties of the body. These include the segmental, monosynaptic myotatic reflexes. These tendon reflexes can be obtained from most myotendinous junctions, but are usually tested at elbow, wrist, hand, knee, and ankle. Their hypo- or hyper-reactivity must be ascertained. Is there a pattern to the reflex and motor findings?

Is there a problem in the muscles generally with proximal weakness and normal reflexes? Do they have distal weakness and reflex loss due to neuropathy? Do they have weakness of one side of the body involving the leg, arm, and face with hyperactive reflexes on that same side suggesting a CNS disorder?

Some reflexes are usually not present in adults and are considered pathologic when present.

Plantar responses that are extensor, thumbs that flex with middle finger flicking are signs of upper motor neuron deficiency.

Palms that grasp when stroked, chins that twitch when the palm is stroked, loss of extinction to glabellar tapping, rooting and sucking signs are generally hemispheric deficiency signs.

Somewhere, you are also collating this information with what you have already obtained in the mental, cranial nerve, and sensory exams.

Cerebellar/Motor Examination

The cerebellar testing includes an assessment of gait and posture, coordination, and balance. The cerebellum has great capacity for

TABLE 16.7

Management of Suffering

Type of Intervention	Clinical Examples
OMT	Direct, indirect
Cognitive and behavioral therapy	Psychotherapy, cognitive restructuring, hypnosis, imagery, relaxation
Relaxation	Biofeedback, progressive relaxation
Breathing exercise	Yoga, tai chi, diaphragmatic breathing
Medication	Opiates, antidepressants, anticonvulsants
Surgery	Ablation, deep brain stimulation

learning and remembering and mostly what it learns is how to balance and move. In general, signs of imbalance are just that. They are signs of imbalance in the body proper. Balance is what we seek, when we seek health.

The patient stands, walks, eyes open, eyes closed, along an imaginary tight rope. They stand on one leg; they touch their finger to their nose and their heel to their shin. Rapidly alternating motions can be tested, including finger and foot tapping. The qualities of their speech and eye movements are assessed.

Fifty percent of the neurons of the CNS are in the cerebellum, which occupies only 10% of its volume. It has a prominent role in the nervous system's contribution to health or disease. Its activities are, for the most part, not consciously appreciated. It is becoming clear that the cerebellum is involved in all manner of dysfunctions, including pain and somatic dysfunction.

Autonomic Model

Autonomic testing has largely been performed earlier in the examination. The heart rate, respiratory rate, blood pressure, state of the pupils, tears and saliva, color and temperature of the limbs, associated sudomotor activity, sweaty and clammy features have likely been noticed by now. The presence of goose flesh due to piloerection or skin mottling has already been observed during the general physical but here is reformulated in the context of overall autonomic behavior. Is the pattern sympathetic driven, sympathetic exhausted, or parasympathetic in nature? Is it generalized or regional?

The evaluation of the skin provides the most external opportunity for evaluation and can lead to important observations about regional, dermatomal, or local problems. The tuft of hair over the midline lower back may overlie a neural tube closure defect like a spina bifida. The blistered rash over a single dermatome can be the presentation of Herpes zoster or shingles. It is noteworthy that for the skin to be evaluated, in fact for an adequate examination to be performed, the patient must be disrobed. With modesty and respect, patients should be undressed, gowned, and examined.

The fascial system, another of the body's holistic systems, is an organizing tissue like no other. It is continuous from top to bottom, front to back, inside to outside. It invests every tissue type, from its outer most coverings to its deepest cellular structures. In its investments, it is found to be continuous. Current research has now revealed intracellular and intercellular linkage through this same

fascial system. Connective tissue, collagen, integrins, cytoskeletons are the levels of scale in which the reiterated properties of mesodermal derivatives serve as a principal organizer for the multitude of the body's structures and functions. As a mechanical force transducer, a mechanical force transmitter, and an effector tissue, the fascial system impacts immunologic, neurologic, and endocrinologic, and, of course, musculoskeletal functions and structures. Its many functions will be discussed elsewhere, but its evaluation in patients suffering pain can be uniquely rewarding. It can reveal biomechanical linkages between internal and external structures as well as information regarding the patient's unique constellation of painful parts.

The Respiratory/Circulatory Model

The respiratory/circulatory testing demands a thorough examination of both the cellular and the whole-body adequacy of oxygen, blood, lymph, interstitial fluid, and cerebrospinal fluid dynamics. Good health requires the maintenance of adequate arterial, venous, lymphatic, cerebrospinal, and interstitial fluid dynamics. The cardiovascular exam evaluates the very essence of circulatory function, from the pump to the pipes. Every region must be considered for the adequacy of its blood supply and the health of its components. Is there leg pain from claudication? Is it due to peripheral vascular disease? Is it due to neurogenic claudication, as a result of spinal stenosis?

Is their head pain associated with an indurated, tender superficial temporal artery? Is their acute low back pain (LBP) associated with an abdominal bruit and loss of pedal pulses? This is one of the holistic systems of the body that reaches every single cell and influences every single function. The "rule of the artery" must always be considered.

In some texts, the respiratory system is considered as part of a cardiorespiratory system. But it merits its own consideration as another of the holistic systems of the body. The adequacy of breath, the dependence on adequate oxygenation, again, can be seen to affect every organ, every system, every cell and cellular function. The examination considers the patient's color, their respiratory effort and capacity, as well as its adequacy. Signs of chronic insufficiency like clubbing of the fingers raise concerns for more widespread problems. Ultimately, the adequacy of the cardiorespiratory system is vital to the essential well being of the individual. In managing pain, optimization of respiratory and circulatory structure and function is critical. Of course, this involves auscultation, palpation, and observation of the thoracic space. Examination of the heart, lungs, lymphatic structures, great and small vessels, diaphragm, and thoracic inlet comprise the test.

There are palpable reactions of the musculoskeletal system to stress/pain (see Chapter 14 The Physiology of Touch). Touching the patient's pain is more than a euphemism. It is an experience for doctor and patient alike. It is an opportunity to validate a patient-centered subjective experience with more objective physical data. As a clinician, you will always feel more confident in diagnosis when you have been able to reproduce the patient's symptoms. This is not always possible even with a meticulous and comprehensive examination. Sometimes, the examination process is straightforward; other times, it remains elusive. Patients themselves feel better understood when they are examined and touched in ways that inform the examiner regarding the nature of their pain. Understanding the generators and mechanisms of a painful process enhances the therapeutic options. Therefore, understanding what actions exacerbate or initiate the pain is essential. Ask the patient to demonstrate the behaviors, positions, movements, and activities that influence their pain. Pay attention to what worsens and what improves the symptoms.

At some point in the examination, if it has not already occurred, provocative testing is pursued. This means attempting to reproduce or aggravate the pain. If the clinical scenario suggests nerve root compression, then intervertebral foraminal compression with vertebral side ending and extension may exacerbate the nerve root symptoms. Straight leg raising that causes pain to radiate down the leg suggests nerve/nerve root entrapment that is affected by neurofascial stretch. Compression or traction on peripheral nerves that reproduces symptoms can be diagnostic of conditions like thoracic outlet syndrome, carpal tunnel syndrome, cubital tunnel syndrome, tarsal tunnel syndrome, or piriformis syndrome. Skeletal percussion can help identify a bony source of pain, as in fracture or metastasis. Visceral palpation can identify a visceral source of pain.

Palpation of the myofascial system, systematically seeking tender points, can reveal the trigger points of myofascial pain syndrome, Chapman's points of neurolymphatic dysfunction, the muscles, tendons, ligaments, skeletal, and connective tissue generators of pain.

At times, the relationship between the tender points and the pain complaint is obvious. They sprain their ankle and their talofibular ligament is tender. Other times it is less obvious; their appendix is inflamed and their abdominal wall is tender. The relationship of the tender places and the pain complaints is usually related to their segmental, autonomic, and central relations.

The pattern of tenderness may reveal patterns of musculoskeletal involvement that involve multiple structures. This pattern can be analyzed to reveal whole-body patterns of strain and trauma. This is an example of forensic Osteopathy. This provides an opportunity to correlate the patterns of dysfunction with the biomechanical/musculoskeletal behaviors of origin. This can reveal the traumatic vectors of strain.

Even more important than the attempts to increase pain are the efforts to reduce pain. Besides asking the patient to demonstrate what helps, maneuvers such as distraction or compression are performed. Attention to the functional anatomy and neurology of the maneuvers can reveal keys to diagnosis as well as treatment. OMT, as will be described in greater detail in this text, is a uniquely osteopathic approach to this process. For example, the confirmation of a cervical origin to a headache by relieving it using manual cervical distraction provides useful diagnostic information. In addition, it provides critical understanding that can be translated into therapeutic strategy (Table 16.8).

Behavioral Model

The psychological examination has been ongoing and largely done by now. Has the patient been anxious, tense, fearful, angry, worried, or depressed? Are they catastrophizing (50–53) about their pain? Is their belief in their pain so firmly maintained as to disagree with logic or rational argument? Do they fear pain (54–56), or movement (i.e., kinesiophobia) (57–59) and avoid activity? Patients who catastrophically (mis)interpret their pain are prone to become fearful and consequently engage in protection (e.g., escape/avoidance) behaviors, such as guarding and resting. Paradoxically, these behaviors may increase pain and pain disability rather than reducing them (60). There are a large number of patients with musculoskeletal pain who avoid physical activities unnecessarily because of the fear that movement can be harmful. As a result of inactivity and withdrawing, they feel helpless, have little initiative to comply, and find themselves depressed (39). *Pain sets in a still joint. Depression sets in a still person.* "Motion is a basic function of life" (ECOP). In fact, prolonged bed rest is no longer recommended for the management of LBP; it is ineffective and may even delay recovery. Recent guidelines encourage the patient to continue to stay active, continue

TABLE 16.8

Pain-Related Behavior Management

Type of Intervention	Clinical Examples
OMT	Direct, indirect
Meditation	Mindfulness meditation, self-hypnosis
Visual imagery	Guided, self-guided. Distraction and visualization training
Behavioral therapies	Functional recovery programs (Fordyce), operant conditioning, interdisciplinary pain programs
Exercise	Healthy activity, prescribed stretch, strengthening, endurance, balance training

ordinary activities, and work as normal, and this leads to faster recovery and lower risk of chronic pain and disability (61,62).

The osteopathic physician remembers that pain is a complex, subjective perceptual phenomenon with intensity, quality, time course, personal impact, and meaning—“That you assess the person, not just see the pain” (63). Persons experiencing nociception display a large range of reactions that are indicative of pain, distress, fear, anger, depression and/or suffering. Their autonomic arousal, muscle tension, endocrine, immune, and neurologic reactions add to the pain behaviors (Table 16.9). The pain behaviors further develop and change through learning and are molded by past painful experiences (64,65).

It is important not to mistake these pain behaviors as being synonymous with malingering. Malingering is a conscious purposeful effort to defraud and fake symptoms of pain for financial and/or emotional gain. In many cases, chronic pain behaviors do not automatically correlate with conscious deception, but rather they are behaviors that are unintended and result either from unrelieved pain or environmental reinforcement. Most patients who display pain behaviors are not aware of them nor are they consciously motivated to obtain reinforcements from others. There is little support for the contention of outright faking of pain or that the process of malingering is widespread (63).

Formulation and Execution of Osteopathic Pain Management

It has been our contention that proper therapy depends upon a proper diagnosis. That is why in a chapter titled Chronic Pain Management, so much emphasis and time has been devoted to assessment. We have learned that the diagnostic process is multivariate and it is reasonable to conclude that therapeutic plans are best conceived as offering benefit at multiple levels. Our diagnosis must include relevant medical diagnoses, including medical, affective, cognitive, and behavioral comorbidities. It must include an understanding of the involved nociceptive mechanisms, peripheral and central. Finally, our diagnosis must include an understanding of the biopsychosocial impact on the patients' function and QOL. Our targets, therefore, are the peripheral, spinal, and forebrain structures and their functions. They include

TABLE 16.9

Behavioral Indication of Pain

Anatomic Location	Clinical Examples
Vocalizations	Sighs, moans, crying, pleading
Facial expressions	<ul style="list-style-type: none"> • Brow bulge • Eye squeeze • Nasolabial furrow • Horizontal mouth
Motor activity	<ul style="list-style-type: none"> • Bulging, creasing and/or vertical furrows above and between eyebrows • Lowering and drawing together of the eyebrows (squeezing and bulging of eyelids) • Pulling upward and deepening • A distinct horizontal stretch/pull at the corners of the mouth
Disposition	Slow movement Avoidance of activity for fear of pain
Body postures, gesturing	Irritable, withdrawn, sad, aggressive
Behaviors to avoid pain	<ul style="list-style-type: none"> • Limping or distorted gait • Rubbing or supporting the affected area • Frequent position changes • Rigid posture, guarded movement • Inactivity and rest to avoid pain • Excessive use of medication/health care system • Social withdrawal/reduction of ADLs • Outward symbols of distress (self-prescribed collars, canes, braces) • Addictions

Adapted from Turk (133). *Psychological Approaches to Pain Management: A Practitioners Handbook*. 2nd. Ed. New York: Guilford; 2002.

the MINE systems. Additional targets include comorbidities, psychiatric, social, behavioral, and medical. In all patients, with or without chronic pain, general advice is offered regarding proper nutrition, levels of activity and exercise, on sleep and rest, as well as the importance of creating and maintaining thoughts of wellness (122).

The Osteopathic Pain Management Plan is Evidence Based and Comprehensive

Osteopathic treatment decisions are based on systematic reviews and evidence-based considerations. (For current reviews, see The American Pain Society [APS] and the American College of

Physicians systematic reviews, utilizing both the Oxman criteria and the Cochrane Database [In *Ann Intern Med* 2007;147(7):492–504]). Their therapeutic prescription, after reviewing all the evidence on nonpharmacologic therapies for chronic pain (>4 weeks duration) when compared to placebo, sham, or no treatment found *good evidence* for spinal manipulation, exercise, cognitive-behavioral therapy, and interdisciplinary rehabilitation. The only nonpharmacological therapies with *fair-to-good evidence* of efficacy for acute pain (<4 weeks duration) are superficial heat and spinal manipulation. The choice and sequencing of these therapies and the methods of tailoring therapy to the unique individual patient is the true art of osteopathic care.

The therapeutic plan is aimed at removing noxious influences, at any level or location. Concurrently, efforts at optimizing structure and function are the objective goals for moving toward health. The inherent vitality and capacity for wellness of the patient is the focus for therapy. From the molecular, cellular, systemic, and regional perspectives, therapeutic strategies are conceived. They are often stratified. First, we will try treatment A and if not successful will change to treatment B. They are typically multifaceted. Sometimes, they are additive and even synergistic. In this way, they represent a microcosmic, multidisciplinary, therapeutic plan. Of course, in some situations, multiple different health care providers are involved in delivering and coordinating the plan. This represents the macrocosmic interdisciplinary therapeutic team.

In some cases, there is clear synergy of therapies. The total amount of therapeutic efficacy is greater than the sum of the individual therapeutic efforts. Likewise, the idea that interdisciplinary management can offer synergistic therapeutic opportunities has led to the creation of interdisciplinary pain management centers treating both pain and disability.

The osteopathic mission through both OMT and the doctor-patient relationship is to restore postural and mechanical alignments, manage fascial strain, and tissue texture changes to encourage the patient's innate ability to heal (116,117). Osteopathic thinking has long considered pain as a symptom closely linked to somatic dysfunction. In addition to neuromuscular factors *triggering nociception* and the initial report of pain, biopsychosocial factors often *worsen and perpetuate* pain. Osteopathic physicians need to approach patients in chronic pain with support and empathy while drawing heavily from the expertise of their pain specialist colleagues. Caring for chronic pain often warrants an interdisciplinary approach blending osteopathic thinking and the best evidence-based knowledge about biopsychosocial treatments (73,74). The goal is to assist the patients internal healing and their ability to mount a homeostatic response. Each therapeutic prescription needs to be individualized.

Biopsychosocial Interventions Decrease Suffering

Much of the disabling nature of chronic pain thus stems from cognitive and affective factors and cannot be explained by objective physical measures alone (75,76). Osteopathic interventions are biopsychosocial and they target nociception in an attempt to decrease distress and increase functioning (77,78). Four systematic reviews (79–82) and a recent meta-analysis (83) of random controlled trials (RCTs) of specific measurement domains such as pain expression, functional activity level, health-related QOL, and depression substantiates the efficacy of treating the psychological factors of chronic pain.

Specifically, these RCTs showed cognitive behavioral treatments (Table 16.10) were *moderately superior* to no treatment, placebo, and wait-list controls. Positive effects of psychological

TABLE 16.10

Common Components of Cognitive Behavioral Treatment of Chronic Pain

Strategy	Focus of Treatment
Cognitive restructuring	Self-statement reanalysis to change pain, distressing thoughts, and decrease anxiety
Challenging irrational beliefs	Catastrophizing, all or none thinking, negative predicting, selectively focusing on pain, over generalizations, jumping to conclusions, fatalistic viewpoints
Motivating patients	Reduce social isolation, improve communication and problem-solving skills and outcome expectancy
Desensitize patients	Pacing activities, goal setting, muscular relaxation training
Reinforce activity	Operant and respondent conditioning
Teach self-management	Breathing techniques, bio-feedback, imagery training, distraction techniques
Educate on mind/body/spirit	To understand body unity and our inherent capacity for self-regulation, self-learning, and the importance of healthy lifestyle choices
Relapse prevention	Pain coping skills, support groups, family interventions, caregiver support/education, breakthrough pain rescue planning

interventions when compared to these various control groups were noted for pain intensity, pain-related interference, health-related QOL, and depression. Both cognitive and behavioral and self-regulatory treatments were specifically found to be efficacious in decreasing suffering (83).

The robust nature of these studies should encourage confidence in the osteopathic physician as they advise and counsel the chronic pain patient in the areas of pain catastrophizing (84), fear avoidance (85), managing psychiatric comorbidities (76), reinforcing pain relevant conversations (86), and the promotion of pain self-management and self-healing (87). *The strength of osteopathic medicine in managing chronic pain comes through talk and touch. Nothing can be more powerful.*

Exercise is Treatment for Chronic Pain

The body is made to move. At every stage of life and health, there is a range of activity that can be realized. There is a minimum,

and there is a maximum. Within this window of physicality is the domain of exercise and conditioning. Outside of this window is the realm of atrophy and injury.

In 2003, the Center for Disease Control (CDC) presented information on over 200,000 individuals in the United States and found less than half engage in activities that fulfill the CDC's minimal recommendations for exercise (88). Females were significantly less active than males, and their activity levels were also found to be progressively lower with age (89).

Exercise significantly enhances physical and psychological health (90–91), contributes to antidepressant and anxiolytic effects (92–97), and benefits sleep (69,90). Prescriptive exercises can begin to teach the patient to think about health-oriented behaviors. Exercise affects posture, balance, flexibility, strength, and coordinates movement to promote the optimal structure and function. Over time, exercise promotes lessening of tension and stress as the patient learns to support their own health. This has impact on the Respiratory/Circulatory, and Metabolic/Energy systems.

Metaregression analysis found the best outcomes for exercise incorporating the following elements (98):

- Individualized regimens
- Supervision
- Stretching
- Strengthening

When exercise included these features, compared to no treatment, pain scores went down nearly 20% and functions scores improved by 60%! The standard exercise course includes educating the patient, clearly defined goals, a program of 30 minutes performed twice daily and beginning with low-stress activities (walking, aquatic exercise, stationary bike with rest breaks), and encouraging self-management. (99).

Relaxation exercises can also be taught along with exercise when anxiety, fear of movement or pain, and chronic muscle tension interfere with performances (100–102).

OMT can provide further solace and comfort while the patient is in your hands (102,104). It is likely that maladaptive pain states can be partially characterized by excessive suffering (105). To this end, making the patients calm allows the intrinsic systems to function more optimally.

Suffering can be relieved, at least temporarily. The reduction of suffering is part of the process of altering pathologic activity in the limbic and autonomic domain. Once the lack of value of suffering has been realized, like getting the attention of those around, including caregivers and health professionals, its value quickly diminishes.

Osteopathic medicine is at its most essential level a mechanism for changing pain-related behaviors (116,117). From the OMT effects on segmental, regional, and global neuromusculoskeletal activity, to its calming limbic and autonomic effects, it is attempting to change behaviors. At the whole-person level, OMT affords the patient an opportunity to feel better. Even if only transient, OMT permits the patient a glimpse of their capacity for having less pain.

Educating the patient to gain understanding and self-manage pain is therapeutic. Enabling the patient to understand their pain generators and pain management strategies allows a patient to self-manage their symptoms. The patient is empowered by accurately understanding the causes, treatments, and prognoses relative their pain. This is education.

Active listening skills (see Part II: Approach to Patient) and sound advice can help the patient maintain a reality-based expectation for course and outcome. Patient education can be conducted

one on one, but is typically carried out in small group sessions (eight to ten patients). Clinical trials show this group model helping to increase activity levels and effectively applying pain self-management skills (106). In addition, pain support groups are an extremely powerful and low-cost strategy for educating large numbers of patients with chronic pain (107). The goal is to help patients cope with and adjust to their pain and condition. In support groups, patients reconceptualize the meaning of their pain, their cognitive and emotional appraisals, and problem-solving strategies (108). They review how their pain impacts themselves and their lifestyle and identify the events in the environment that reinforce their pain behaviors and musculoskeletal reactions. If not taught in a group therapy model, the following concepts form at least an outline for teaching coping strategies within the doctor–patient relationship. These concepts are also the foundational ideas for the advice given to the pain patient on how to think about and manage their pain (37). Patients who have to “live with their pain” are taught to hold the following ideas as true:

1. My pain is real. It occurs in my body, I have a reaction to it in my head.
2. I accept that I may need, outside help to control my pain, and I refuse to quit or give in to the pain and the deterioration it causes.
3. At times my pain has had an overwhelming influence on my life, but I believe that I can choose how I react to it.
4. My best efforts and those of the medical community have not stopped my pain. This is not necessarily a fault of mine or a shortcoming of medicine. I will no longer fight with myself about this or blame medicine. No fight, no blame.
5. I will recognize some aspects of my coping with pain that I am doing well, and will also admit to myself mistakes that I have made.
6. I will forgive myself unconditionally for my past mistakes and forgive others whom I perceive are responsible for my pain and troubles.
7. I will fix any mistakes I've made struggling to live with the pain.
8. I will go forward with hope that the pain will someday pass or be relieved; and, at the same time, recognize that I have to cope with the pain that I have.
9. I will strive for higher goals, making pain a side issue, to be managed as necessary.
10. I now recognize there is more to my life than struggling with pain.
11. With this knowledge, I will separate myself from my pain management program or doctor, with the complete understanding that I may return at any time.
12. I understand that I have more important goals in my life than coping with pain and I will strive toward them as my mission.

Remembering that “Pain runs in front of the skillful surgeon’s scalpel or anesthesiologist’s needle;” a laudable goal, if possible, is to find and block nociception.

To control acute pain, anesthetic blockade of neural transmission to virtually any part of the body can temporarily be achieved by direct application of local anesthetics (nerve blocks), such as procaine, lidocaine, tetracaine, or bupivacaine. In some severe cases, substances that destroy neural tissue can be injected (neurolytic block) in an effort to permanently obliterate the neural transmission mechanisms.

Diagnostically, nerve blocks determine specific pathways of involvement that aid in the differential diagnosis, of the site or transmission mechanisms, of a given pain. Prognostically,

they partially predict the probable effectiveness of neurolytic or neurosurgical procedures. Interestingly, the pain-relieving effects of local anesthetics can often exceed the duration of the chemical blockade of neural transmission. The reason for this is not completely understood. It might be a result of decreasing sympathetic reflexes and skeletal muscle tension. Perhaps it results from the creation of pain-free time during which the patient can restructure their cognitive and emotional processing routines or learn new behavior patterns that help in coping with pain. The treatment of acute pain adequately may help prevent some cases of chronic pain. For example, the use of topical anesthesia before starting an IV, the use of adequate local anesthesia before an invasive procedure, the use of nitrous oxide with dental procedures, all represent ways of preventing the unnecessary experience of pain.

Treating the symptom (nociception) alone rarely leads to lasting results. Dysregulation in the MINE systems, and pain-induced changes in thinking, feelings, and behaviors must be addressed, often in an interdisciplinary team approach.

In some cases, chronic pain medication can be seen as a helpful measure. Chronic pain requires chronic care. Medications for chronic pain involve three main categories:

1. Nonopioid analgesics: aspirin, salicylate salts, acetaminophen, and nonsteroidal anti-inflammatory drugs (NSAIDs)
2. Opioid analgesics
3. Analgesic adjuvants

These drugs are prescribed according to the World Health Organization's analgesic ladder (108). It involves choosing among these three groups based primarily on pain intensity. Many mild-to-moderate acute pains readily respond to nonopioid analgesics alone; they are the obvious first choice. Some moderate-to-severe pains may require combining the nonopioid analgesics with a low-dose opioid preparation, the second step in the analgesic ladder. The third step is the addition of a *time-released* opioid preparation to the nonopioid analgesics. At any of these three steps, analgesic adjuvants might also be useful.

The APS and the IASP outline a number of important concepts to remember when choosing drugs to manage chronic pain:

1. Analgesia should be integrated into a comprehensive patient evaluation and management plan.
2. The emotional and cognitive aspects of pain must be recognized and treated.
3. Individualize route, dosage, and schedule.
4. Administer analgesics on a regularly predetermined time schedule.
5. Recognize and treat side effects.
6. Do not use placebos to assess nature of pain.
7. Watch for development of tolerance.
8. Use analgesic adjuvants.
9. Block pain transmission whenever possible.
10. Consider a multimodality approach that applies both pharmacologic and nonpharmacologic therapies.

These organizations are a constant source of updated information on the rapidly changing pharmacologic knowledge base regarding pain control with drugs. (See the section "Resources" at the end of this chapter for contact information.)

It is important to remember, that for chronic pain, management with medication "as needed" is often insufficient. Adequate management of ongoing pain is better accomplished using time-contingent, long-acting medications with adequate medication for breakthrough pain (118). This also frees the patient from constantly thinking about how much pain they have and wondering if and

when they should be medicating. This therefore is another example of the potential use of preventive pain management principles.

When narcotics are a part of the medication regimen especially at the end-of-life care (119,120), special communication and contracting between physician and patient also becomes necessary. Monitoring benefits, side effects, and possible inappropriate drug use becomes a part of the standard osteopathic pain management (121). Finally, one must remember that opioids can also activate pronociceptive mechanisms creating *opioid-induced hyperalgesia* (129) through distinct cellular mechanisms such as spinal dynorphin, glutamatergic activity, and descending facilitation (125,126). Diminished opioid analgesic efficacy may be opioid tolerance, increased nociception, and/or opioid-induced pain sensitivity (127). These complex pain management patients may require opioid rotation, adding adjunctive medications, combining an NMDA-receptor antagonist, or a trial of opioid tapering (126–129).

Interdisciplinary rehabilitation is the osteopathic standard of care for complex chronic pain management. The APS and the American College of Physicians recently released the clinical practice guidelines for treating back pain, and recommended *interdisciplinary rehabilitation* and exercise therapy for chronic LBP patients (99). The advantages and benefits of an interdisciplinary approach to managing pain, especially when it is chronic, are well documented (81). Treatment in interdisciplinary pain rehabilitation programs is considered the premier treatment for chronic pain (82,106,124). As reported by Flor et al. (73), behavioral outcomes, including return to work, were significantly better, for interdisciplinary, compared with unimodal treatments. Their analyses extend these findings by demonstrating that interdisciplinary treatments were superior to other treatments at improving work-related outcomes at both short-term and long-term follow-up. Using local treatments to reduce noxious stimulation can be multidimensional. Physical measures such as heat and cold, topical agents, local injections of anesthetics, acupuncture, and electrical stimulation (TENS) all can be seen as affecting nociception locally. Systemic medications that have local effects include NSAIDs, narcotics, channel and receptor blockade (sodium, calcium, glutamate), and the expanding list of anti-inflammatory agents targeting recently discovered elements of the inflammatory cascade (tumor necrosis factor, leukotrienes, interleukins, etc.) As the nociceptive signal is processed rostrally, additional sites of intervention become available.

OMT throughout the stages of treatment, as a strategy, can address primary causes and secondary manifestations, and in so doing, can enhance healing capacity. It fosters an individualization of treatment designed to influence health restoration, recovery, and disease prevention. Using palpatory, diagnostics, and therapeutics, the customized therapeutic program can be furthered.

Special considerations arise when there is damage to the peripheral or CNS. The traditional treatments may be less effective as the nature of the pathophysiology is different. Peripheral blockade with local anesthetics, affecting sodium channels, anticonvulsants with effects on glutamate and NMDA transmission, SNRI antidepressants, affecting NE and 5-HT, opiates, and all the rest are possibly well-timed, coordinated options in an evolving interdisciplinary treatment plan.

In this interdisciplinary model, the patient, as leader, in partnership with the physician creates a health care team. Through the use of appropriate consultants and caregivers, coordinated pain management can be delivered. Consulting physicians in pain management, anesthesiology, psychiatry, osteopathic manipulative medicine, physiatry, orthopedics, neurosurgery, general surgery, gynecology, oncology, EENT, neurology, internal medicine, endocrinology,

immunology, pharmacology, addictionology, behavioral medicine, sleep medicine, or any other subspecialty required is part of the process of team building. Coordinated nursing services are also appropriate when medical acuity or complexity requires a protracted need for health services. This includes patients hospitalized in pain centers, outpatient pain management centers, primary care-based pain management programs, and medical appliance-related health care (intrathecal or epidural pumps, implanted brain and spinal cord stimulators, etc.).

The fact that anything ever heals is a reminder of the miracle of life.

From a simple paper cut that heals without much thought to a pelvic fracture that requires surgery and thoughtful rehabilitation, there is represented a spectrum of the ongoing manifestation of one of Osteopathy's guiding principles. A broken bone is likely to heal relatively quickly in a healthy person. A sprained ankle might take longer to heal if the patient is misbehaving or suffers with comorbidities that interfere with healing. A more serious injury, with greater tissue injury, or with more systems or sites of involvement is likely to take longer to rehabilitate, even in a healthy person. Most healing is less than perfect, leaving its mark, a scar, a memory on the mind, on the body and on the spirit.

By integrating the five models, the osteopathic perspective seeks to restore optimal structural and functional relations. A comprehensive palpatory examination and a review of psychological factors is required for chronic pain management (43). We know the neuromusculoskeletal system is the primary source of a number of neck, low back, spinal, and extremity pain problems. Here, again, is a setting where OMT can be of particular therapeutic value.

Recently, the APS and the American College of Physicians clinical practice guidelines recommend heat, spinal manipulation, and time to allow the natural healing processes to occur (83), as mainstays for treatment of LBP. Neck and low back syndromes are often related to disturbances of muscle, tendon, ligament, joint capsule, joint, or disc. Appropriate use of OMT can encourage healing and health maintenance. Other examples exist (see Part III: Problem-Based Osteopathic Patient Management). By optimizing structure and function the patient course can be positively affected.

In chronic pain states, whether primary or secondary, there are always manifestations of somatic dysfunction, compensatory structural adaptations, and altered sense of self-confidence for healing. OMT, at this level, is useful by promoting afferent reduction through direct and indirect techniques, muscle relaxation, and improved mobility. This includes attempts at balancing muscle tension and identifying and treating pain generating compensatory musculoskeletal processes. For example, a patient with a limp, from a musculoskeletal or neurologic pathology, may secondarily develop LBP. Treating the back pain helps treat the compensatory process and may suggest preventive strategies. This treats aspects of the pain arising remotely.

When there is ongoing tissue damage or inflammation, efforts to reduce the destructive or inflammatory process is a first step in pain management. This might include OMT, medications, systemic and topical, physical modalities like, heat, cold, traction, compression, TENS, acupuncture, biofeedback, rest, and positioning for comfort. This leads to general recommendations regarding behaviors best suited to recuperation. This can include specific exercises and restrictions, both for daily life and work. It would include advice about sleep and rest requirements. It might invoke a conversation about nutritional optimization as it relates to wellness. This includes a discussion of supplements, foods, herbs, and medications.

Medications have a role in helping the body manage its nociceptive load. Anti-inflammatory agents, immunosuppressants, glutamate antagonists and NMDA receptor antagonists, opiates, NSRI antidepressants, topical anesthetics and anti-inflammatory agents, even intrathecal and intraventricular administration of medication may be useful depending on the circumstance.

There are times when surgical intervention, removing the inflamed gallbladder, decompressing the nerve root, etc., is the clear and best option. Anesthesiologic interventions like trigger point injections, nerve blocks, sympathetic blocks, even spinal cord stimulators can be of selective utility. Now, we also have deep brain stimulation as an extreme option for extreme circumstances. Surgical procedures can influence the suffering aspect of pain and leave the pain experience otherwise intact. Through ablation and deep brain stimulation of structures like the thalamus, hypothalamus, and amygdala, this can be accomplished. Due to its invasive nature, it is usually reserved for patients with malignant clinical courses. Still it is the patient who must be up to the healing process (Table 16.11) to fully benefit. (For an excellent review of presurgical psychological screening and pain outcome (109)).

The ultimate goal of chronic pain management is, "Wellness," fostered by self-regulation, self-healing, and health maintenance. This notion of wellness refers to the balance and recuperative capacity of an individual (Fig. 16.5). It takes into effect inherited constitution, acquired conditions through illness, injury, and abuse, as well as the restorative and healthful aspects of an individual. Their nutrition, exercise regimen, sleep habits, state of mind, support system, and willingness to enter into health-oriented partnerships with doctors and others help determine their reservoir for health (123). This includes their ability to recover from or successfully live with a variety of chronic conditions. It reflects the vulnerability of any given individual to develop pathology in response to a variety of stressors. These pathologies can manifest as organ pathology, musculoskeletal dysfunction, and/or system dysregulation.

Osteopathic chronic pain management is a true art and true science. Chronic pain, like so many other conditions, cannot be cured. Patients can learn to live successfully in spite of chronic pain. This requires the patient and practitioner forming a therapeutic alliance; a partnership for health. In this context, medical investigations can be conducted, psychologic and sociologic information can be

TABLE 16.11

Psychological Factors that Interfere with Pain Relief

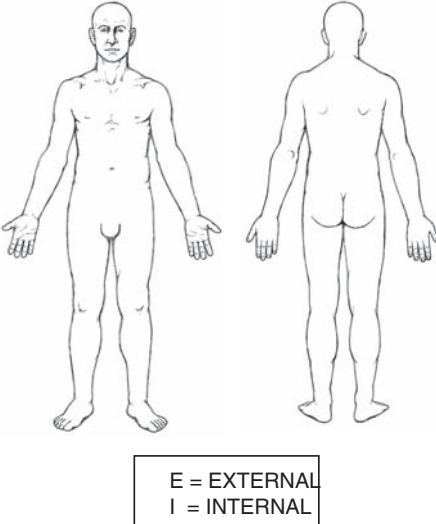

Number of failed surgeries

Length of pain duration
History of smoking/alcohol overuse/medication failures
Job dissatisfaction/disability payments
Unhealthy food choices/obesity
Stress, anxiety, fear or panic associated with pain
Personality disorders, hypervigilance, somatization
Catastrophic misinterpretations of bodily sensations
Fear of movement, lack of exercise
History of physical, emotional, sexual abuse
Insomnia, nonrestorative sleep

Figure 16-5 McGill Pain Questionnaire.

gathered, all in an effort to educate the patient and the practitioner. Treating begins by educating the patient about their unique constitutional predisposition, heredity, effects of trauma and illness, and lingering learned behavioral/neurophysiologic traits on how they contribute to their burden of pain. Then, in healing fashion, this information is slowly reformulated into a workbook of health-restoring activities. This workbook includes counsel on nutrition, exercise, rest and sleep, and mental attitude. This advice is included with recommendations regarding traditional medical care, traditional osteopathic manipulative medical care, and whatever care of the future whose evidence-based value is yet to be proved.

With our growing knowledge of the MINE correlates of chronic pain experience and behavior, we can offer a more comprehensive, individualized program for traveling toward wellness. Whether it is nanobot delivery/repair systems or new biochemically targeted molecules, we are prepared to critically evaluate biomedical research of the future, as well as the past and present. Utilizing the osteopathic precepts of *self-healing* and a *self-contained medicine chest*, we and our patient are drawn toward interventions that encourage the expansion and enhancement of these inherent capacities.

Recognizing the primacy of structure/function reciprocity and having the neuromusculoskeletal system readily accessible for evaluation enable osteopathic physicians to enjoy unique access to biologically relevant physical diagnostic information, thereby creating a more complete patient-centered evaluation. As a logical corollary, it also allows an avenue of OMT intervention that is uniquely well tailored and therapeutically useful to the chronic pain patient.

Pain management tests the skills of all physicians. Whether it is the symptom of acute pain or the disease of chronic pain, proper management is dependent on proper assessment. The more multifactorial and biopsychosocial the evaluation can be and the more comprehensive and patient focused the treatment plan, the greater the decrease in reported pain scores and the better the QOL at 2-year follow-up (81–85). Being comprehensive and incorporating the five models (see Chapters 1 and 5) assures the patient feels heard and thoroughly understood. At many levels, the patient feels “touched” by the osteopathic physician.

As an important aside, this collaborative doctor–patient relationship allows the osteopathic *physician* to participate in the patients’ healing process and in so doing to help to heal themselves. Physicians are certainly not immune to the problems of chronic pain. In this way, the focus of caring for one’s self is encouraged, which is generally not well supported at the professional or institutional level.

In summary, the physician’s goal is to restore both physical functioning and adaptive musculoskeletal responses through the simultaneous use of physiological and psychological interventions (110). When managing chronic pain, it is routine to use osteopathic manipulative techniques (104), exercise, sleep, nutritional, and psychological counseling. Combining the five models into a comprehensive treatment approach increases the chances of a successful outcome (103,111). A treatment plan that simultaneously addresses the biological, psychological, and social factors of chronic pain is more likely to succeed and decreases chronic pain perception and behavior (111–114).

Pain is the most common element in the symptoms presented to physicians. But as so eloquently stated by John Loeser (105):

It is *suffering*, not pain, that brings patients into doctor’s offices in hopes of finding relief. Astounding developments in our understanding of the mechanisms of nociception should not cause us to lose sight of our patients’ goals. Chronic pain is far more than

a sensory process. We must maintain the biopsychosocial model of chronic pain if we are to provide effective health care to our patients. Understanding the components of pain facilitates this goal. Suffering is an emergent property of the human brain and is dependent upon consciousness. It too is worthy of study by scientists and of concern to clinicians.

Successful management of chronic pain depends on much more than knowledge. Knowledge must be teamed with keen observation, patience, and compassion. Many physicians have come to believe that treating chronic pain and suffering, with all its biopsychosocial elements, reflects both the true art and the true science of osteopathic medicine.

This is truly a labor of body, mind, and spirit.

Psychoneuroimmunology—Basic Mechanisms

DAVID A. BARON, ROSE J. JULIUS, AND FRANK H. WILLARD

KEY CONCEPTS

- Psychoneuroimmunology (PNI) is the study of the interaction between psychological processes, the nervous system, and the immune system of the human body.
- While clinical observations have noted the dynamic interplay between the nervous, endocrine, and immune systems in homeostasis regulation and stress adaptation, it was not until the 20th century that research has formally investigated these mechanisms.
- Osteopathic philosophy and principles emphasize the unity between the structure and the function of multiple body systems. The osteopathic physician is best suited to appreciate and study the interplay between the different systems of the body and behavior, health, and disease.
- Understanding the basic functions and mechanisms of the HPA axis, the central and peripheral nervous systems, is key to elucidating the processes through which the PNI systems integrate to affect health and disease.
- Stress impacts the body's endocrine, immune, central, and peripheral nervous systems, with direct influences on individuals' health and disease susceptibility. Furthermore, stress reduction can improve overall health and well-being.
- Depression and anxiety symptoms are commonly comorbid with many chronic physical diseases. These psychiatric symptoms can complicate the physical illnesses and increase morbidity and mortality. The osteopathic physician should maintain a low threshold for treatment of depressive and anxiety symptoms.
- Many somatic illnesses have behavioral and psychological manifestations. The osteopathic physician should be aware of these in order to properly diagnose and treat patients.

INTRODUCTION

Psychoneuroimmunology (PNI) conceptualizes the brain, endocrine, and immune functioning as an interactive supersystem. As Rubinow first pointed out (new ref), the immune, neuroendocrine, and central nervous systems (CNSs) are all stimulus-response systems that are similar in the functions they subservise and tightly integrated in their actions. The reciprocal regulatory effects of these systems provide a basis (but not proof) for the belief that brain-behavior-endocrine-immune interactions are clinically relevant and not reducible to characteristics of component systems.

At the core of PNI research is a demonstration of the interconnectedness of the body, mind, and behavior, and its impact on health and disease. Basic PNI principles stress the hardwiring of emotions to the body's physiologic functions. The CNS, autonomic, the endocrine, and the immune system all contribute to the body's inherent work in regulating and trying to maintain homeostasis. Pert et al. (2) first suggest that the intimate integration of these three systems warrants their consideration as a single system. All three systems can function as sensory and effector organs, recognizing foreign antigen and other incoming physiologic signals. All three also transmit signals as part of their basic function. The immune response can be modulated by input from nervous and neuroendocrine systems. The high degree of similarity and integration between these systems is sensible due to the fact that their common task is to preserve homeostasis and assure consistency and integrity of body cells and tissues, for which integration and regulatory redundancy is an obligation (1). The more research elucidates the mechanisms through which these complex systems interact, the further advances can be made in the diagnosis and treatment of disease and in the promotion of health.

HISTORY OF PSYCHONEUROIMMUNOLOGY RESEARCH

Despite centuries of interest, clinical observation, and anecdotal reports, research on the complex interactions between the CNS, the endocrine, and the immune system has only taken place in modern medicine. This in part is due to the lack of an understanding of the complexities of immune functioning and limited availability of biologic probes to observe and measure the impact of one system on another. Walter Cannon, a physiology professor at Harvard University, coined the term *homeostasis* to reflect the need of the organism for regulation and balance of all its systems. He conducted research with animals, noting that affective states such as psychological distress, anxiety, and rage were associated with cessation of the movements of the stomach. His findings were published in 1911 in a book titled *The Mechanical Factors of Digestion*. Hans Seyle would continue to expand on Cannon's early work, studying the physiologic adaptation of animals to stress. Through his research, he ultimately developed a clinical model for adaptation to stress, consisting of three stages: a brief alarm reaction, prolonged resistance, and a terminal stage of exhaustion and death (3).

George F. Solomon (4), M.D. ultimately coined the term *psychoneuroimmunology* in 1964, in his paper, "Emotions, Immunity, and Disease: A Speculative Integration." In this paper, Solomon offers a theoretical explanation of how emotional states can diminish immunocompetence, ultimately resulting in physical disease. These speculations were of significant interest to the mental health community. However, they did not enjoy a similar level of acceptance by the medical community as a whole and especially not by immunologists. Without data derived from well-controlled research studies, the consensus was that something as

imprecise and variable as emotion could not impact on a seemingly hard-wired physiologic process like immune function. No reasonable explanation existed for how these systems could communicate with each other.

Despite repeated reports of illness following a significant stressor, nothing more substantial than observation and anecdotal reports existed to convince the nonbelievers. Ader (5) made an accidental finding that immunosuppression could be classically conditioned in mice, by pairing taste aversion (saccharine) with an immunosuppressive medication (cyclophosphamide). He conditioned rats by using saccharine combined with cyclophosphamide. When given to the rats, the elixir induced nausea and suppressed the rats' immunity. Ultimately, Ader gave the rats saccharine alone, and this neurologic signaling via taste was able to stimulate immune suppression. These findings ignited research interest in PNI. For the first time, direct evidence demonstrated the potential for external manipulation of the immune system. Intriguing questions followed. If immunologic response could be behaviorally conditioned to turn off, could it be conditioned to turn on? Could this help explain why the patient, who shortly after giving up the will to live, dies or conversely why some patients refuse to succumb and ultimately defy the odds to survive life-threatening illness? These and related questions stimulated PNI research.

In addition to stress-induced immune suppression, altered immune functioning has been reported in patients with mood disorders and other psychiatric syndromes. The Greek physician, Galen, reported the relationship between clinical depression and physical illness in the second century c.e. He observed that melancholic (depressed) women were especially susceptible to breast cancer. In an effort to replicate and further explain this observation, Levy et al. (6) measured natural killer (NK) cell activity (a measure of immune function) and psychological stress in women with breast cancer. They found NK activity to be a reliable and valid predictor of the patient's prognosis relative to their lymph node status. In a separate study, these same authors reported that 51% of baseline NK activity changes could be accounted for by assessing a patient's adjustment to diagnoses, depressive symptoms, and perceived lack of social support. They concluded, based on multiple clinical trials, that differences in NK cell activity and overall prognosis could be predictably determined by assessing baseline stress, as measured by emotional adjustment, depression or fatigue, and lack of social supports.

Alterations in immune function were demonstrated in patients with psychotic illnesses as early as the 1940s (7). Early studies in the 1970s also reported an increase in the prevalence of herpes simplex virus in patients with psychotic depression when compared with age-matched nondepressed controls. Unfortunately, these early studies did not monitor any specific immune parameters. This research and findings would be replicated in a similar fashion in future PNI research as it applies to stress, mood disorders, and clinical outcomes.

OSTEOPATHIC PHILOSOPHY AND PSYCHONEUROIMMUNOLOGY

The concept of PNI was the central theme of A.T. Still's original theories that formed the basis of the Osteopathic philosophy. Still was ahead of his time in postulating that the body communicated with itself and that the CNS was integral to the somato-visceral, visceral-somatic response. Still opened the first Osteopathic psychiatric hospital, the Still-Hildreth Clinic in Missouri in 1916. Although not yet recognized as an area of clinical investigation at that time, core PNI concepts were prominent in the proposed

etiology and treatment of the patients treated at the clinic. Essentially, a broad-based appreciation of inextricable structural and functional relationships between somatic dysfunction, hormonal systems, central and peripheral nervous system, and resultant mood and behavior formed the rationale for explaining symptom onset and treatment interventions. The idea that the brain could be the target organ of hormonal fluctuation occurring in other parts of the body would later be described as hormonal neuromodulation.

PSYCHONEUROIMMUNOLOGY MECHANISMS

PNI mechanisms are founded on some core clinical observations and research findings:

- The autonomic nervous system, particularly the sympathetic nervous system (SNS), directly innervates lymph organs and tissues. The SNS can change blood flow/supply to lymphoid tissue.
- Immune cells have receptors for neurotransmitters such as norepinephrine, which is released from sympathetic nerve terminals. This allows the SNS to directly affect immune functioning.
- Immune cells also have receptors for hormones.
- As elucidated by Pert, neuropeptides are present on the cell walls in the CNS as well as in the immune system (2).
- Cytokines made by immune cells, such as macrophages, can directly act on the nervous system.
- Cytokine receptors are expressed in the CNS as well as in the periphery.
- Stress impacts the immune, nervous, and endocrine systems.

These clinical observations generate support for the idea that nervous, endocrine, and immune systems can interact, in part, through neuropeptides and neurotransmitters and more generally that psychological effects and physical health are intricately linked.

The structure and function of the HPA axis is thought to be central to the physiologic response of the body to stress, as its activation occurs in response to stress. Part of the HPA axis response to stimuli involves the release of cortisol, ACTH, and corticotropin-releasing hormone (CRH). The stimulation and release of these mediators has CNS effects on arousal, sensory processing, stimulus habituation, pain, sleep, and memory, and depends on whether the stressor is acute or chronic. Chronic increases in cortisol can also have multiple physiologic effects, including hyperglycemia, increased visceral adipose, increased blood pressure, decreased bone density, and increased lipids. The response of the HPA axis is also modulated by the autonomic nervous system, which works to maintain homeostasis through the sympathetic branch, regulating arousal, and parasympathetic branch, regulating relaxation. Often when the HPA axis is stimulated together with the SNS during a stressor, the result is a diminished immune response (8). Reactions of the HPA axis and the nervous system in response to stress have been demonstrated as risk factors for diseases such as viral infection and autoimmune diseases (9).

The HPA axis is also stimulated in the process of inflammation. Macrophages generate numerous proinflammatory cytokines, such as interleukin (IL)-2, IL-6, IL-1, IL-10, tumor necrosis factor- α and interferon-gamma (INF- γ), in response to stress. These cytokines in turn stimulate ACTH and cortisol secretion. These same cytokines are active in the brain and the periphery. When cytokines are released in response to stress and inflammation, the effect on the body is weakness, malaise, sleep and appetite disturbances, and difficulties with memory and concentration. Proinflammatory cytokines also cause serotonin levels to be decreased within the CNS, by increasing its enzymatic turnover (10).

The HPA axis, the nervous system, and the interaction of the two are disturbed in disorders of chronic inflammation, such as rheumatoid arthritis and systemic lupus erythematosus (SLE) (11). Persistent inflammation is linked with a multitude of diseases, including heart disease, arthritis, renal and pulmonary disease, diabetes, infection, and cancer. Cytokines and IL-6 stimulate the production of C-reactive protein (CRP), an important risk factor in heart disease (12). In fact, Ridker et al. (12) found a 2.6 increase in risk of death among individuals with high CRP and IL-6 levels. IL-6 and other inflammatory cytokines have also been implicated in muscle wasting, osteoporosis, and arthritis. INF- α has been shown to increase anxiety-like behaviors in rhesus monkeys and to induce ACTH and cortisol (13).

CRH has been studied as another key mediator between the central nervous, endocrine, and immune systems. It is a major regulator of the HPA axis, the autonomic nervous system, and the immune system and is widely distributed in the brain and the periphery of the body. CRH dosed in the CNS has been shown to cause decreases in immune responses in numerous studies, including immunoglobulin M (IgM) and IgG levels (14–16). CRH receptors in the amygdala are associated with immune response (17).

In collaboration with the immune and endocrine systems, the nervous system is known to mediate the body's response to stress in a multitude of ways. First, as mentioned above, autonomic nerves directly innervate lymphoid tissue, including the spleen. Second, lymphoid cells have B-adrenergic specific receptors. The SNS stimulates and potentiates immune responses to inflammation and infection through β_2 adrenergic receptors and neuropeptides, such as neuropeptide Y (18). Cole et al. (19) demonstrated that activation of the SNS accelerates HIV replication and progression. Wilder (20) demonstrated that sympathetic activity exacerbates arthritis in rats. Kuis (21) found that evidence for disturbed sympathetic activity in response to stress has a negative impact on juvenile idiopathic arthritis.

THE EFFECTS OF STRESS ON HEALTH AND DISEASE

The arrival of a good circus consisting of clowns is a greater benefit upon the health of a town than that of twenty Asses laden with drugs.

—Dr. Thomas Sydenham

Throughout history, medical researchers and clinicians have observed and reported the effect of stress on health and disease. Stress impacts multiple body systems, the behaviors and the health of the individual, with implications for morbidity and mortality. Despite the general acceptance of this concept by health care providers, it is difficult to define stress and its impact on health and disease. Early concepts focused on stress being a force of universality, acting on a passive body, with all organisms reacting in a similar way to the disruption. More modern concepts emphasize stress not as a universally experienced phenomenon, but rather that experienced uniquely by every individual. Research to date has shown that an individual's reaction to stress is dependent on a myriad of factors, including the type of stress, chronicity of the stress, genetic predisposition, health status, psychological factors, coping strategies, and the interplay between all these variables.

The role of stress, the stress response, and health is a central concept in PNI research. The idea that emotional stress is a biologic phenomenon that has a modulatory effect on immune functioning, and ultimately health, has historically not been fully accepted by the medical community. Over the last few decades, significant discoveries and clinically meaningful advances have been made by

PNI investigators. Researchers at Temple University's Center for Substance Abuse Research have reported provocative findings suggesting chemokines function as neurotransmitters within the CNS (22,23). These findings further demonstrate how emotional stress, which impacts the immune response system including chemokines, may directly affect central neuronal functioning via synaptic transmission modulation. As this area of investigation continues to progress and the extant literature grows, a critical question is the direct impact of emotional stress on physical health. When does a down-regulation of immunocompetency result in the actual onset, of exacerbation, of disease? How much of an immune alteration is required before susceptibility to physical illness is more likely to occur? Translational research in this area has yet to answer these highly relevant clinical questions. The answer is most assuredly as complex as the interaction between stress and immunomodulation. The intricate nature of this interaction is further complicated by epigenomic phenomena and the concept of context dependency. In addition, recent preclinical investigations have demonstrated that stress resilience is biologically mediated, but can be altered through nonbiological interventions. This was highlighted by Meili and colleagues who discovered stress resilience in rat pups could be altered as a result of maternal overgrooming. The overgroomed pups not only increased their stress resistance but also bred more stress-resistant pups themselves compared to genetically similar siblings.

Psychological distress arises when a person perceives that imposed demands have exceeded their ability to cope with them. There is a significant physiologic response to stress, and this response further impacts the ability to cope both physically and psychologically with the stressor. The response also directly impacts an individual's objective physical and mental health, with effects on disease incidence, morbidity, and mortality. Early PNI research using animal models linked stress with acute infections and inflammation. Rasmussen et al. (24) and others found that mice subjected to psychological stress were at increased risk of developing herpes simplex virus infections. Amkraut et al. (25) and others also demonstrated that psychologically stressed rats were more susceptible to developing adjuvant-induced arthritis.

Specific immunologic mechanisms have been demonstrated to mediate the body's immune response to stress. In the early 1980s, Kiecolt-Glaser published a series of prospective studies examining the effects of emotional stress on the function of the immune system. Kiecolt-Glaser et al. (26) measured NK cell activity, γ -interferon (INF- γ) production by lymphocytes, stimulated with concanavalin A and mitogen responses in medical students prior to important examinations. Medical students stressed by examinations had poorer immunity and were thus susceptible to active herpesvirus infection (27). The results of these studies demonstrated that emotional stress did in fact have a measurable negative effect on the immune system. NK cell activity has been further studied by many as a key factor in the body's response to stress and infection. A robust response should be seen in NK cell activity when pathogens and/or non-self-entities are recognized by the body. Numerous studies have demonstrated a decrease in NK cell activity in response to severe life stress (28).

Would the results from research in acute infections and stress be similar in studies of patients with chronic illness? Castes et al. (29) conducted a prospective study of 35 asthmatic children to evaluate the impact of a psychosocial intervention on immune function. The immune measures studied were NK cell number and activity, IL-2 (30), and leukocyte affinity for IgE receptors (an important marker related to asthma attacks). Clinical outcomes assessed included the number of asthma attacks, use of bronchodilators,

and overall pulmonary improvement in pulmonary functioning during the psychosocial interventions, as compared to the six months before entry into the study. In fact, surface markers for IgE in the children receiving the psychosocial interventions became similar to nonasthmatic children. Smyth et al. (31) report similar findings in adults with asthma and rheumatoid arthritis. These well-designed clinical trials offer preliminary data supporting the hypothesis that psychosocial stress can and does affect immune functioning and ultimately wellness.

A more recent view of the relationship between PNI and cancer by Kiecolt-Glaser (32) reports “substantial evidence from both healthy populations under stress as well as individuals with cancer associated psychological stress for immune deregulation and that stress may also enhance carcinogenesis and through alterations in DNA repair and or apoptosis.” The study concludes that psychological and behavioral factors could influence the incidence and progression of cancer through psychosocial influences on immune function. Decreased NK cell activity has been recognized in patients with cancer under stress (33), and a reduced NK cell activity has been linked to diminished capacity to resist tumor suppression in animals.

Severity of the stressor is an important variable in terms of the body’s reaction to the stimulus. Loss of a spouse or other significant other is considered one of the most severe psychological stressors. Research has demonstrated decreases in immune function, specifically mitogen-induced lymphocyte proliferation among individuals who have lost spouses (34,35).

Just as type of stressor is important to the overall response of the neuroendocrine system on the body, so too does the individual’s perception of and reaction to the stressor work in mediating the body’s response. Irwin et al. (36) demonstrated that the severity of affective symptoms in response to psychologic stressors correlates with the NK cell activity, that is, those with a greater severity of affective symptoms such as depression have greater decreases in NK cell activity. Greater levels of perceived stress and depressive symptoms have been shown to predict susceptibility to infection with viruses such as the rhinovirus (37) as well as delays in wound healing (11).

Chronicity of the stressor is also relevant to understanding the different physiologic responses on the body. One study showed that while an initial response to a stressor (in this study foot shock) is immune suppression, repeat exposure to the stressor elicited immune enhancement, and this process was mediated by central CRH (38). Other research demonstrates activation of the immune system in response to acute stress and an inhibition of immune responses under exposure to chronic stress. Chronic stress of caring for a loved one with Alzheimer dementia is associated with delays in wound healing and in long-term immune changes.

Since it is established that stress significantly influences immunity, an important next research question is *Can stress-reduction mediate the body’s immune response?* In one important study, students who were taught relaxation training had a significant increase in NK cell activity compared to students who had not received stress-reduction training. This was the first well-controlled clinical human study that demonstrated evidence of immune enhancement resulting from a psychological intervention (39). Not only did stress reduction improve immune response, but students who were not taught stress-reduction techniques self-reported an increase in infectious illness symptoms around exam time (24). These provocative experiments clearly demonstrated an effect in otherwise healthy subjects. Another study showed that relaxation interventions decreased inflammatory response (40). Additionally, research in cancer patients has demonstrated longer survival

time and improved immune function among patients enrolled in support and psychoeducation groups (41,42).

MOOD DISORDERS AND IMMUNE FUNCTION

A merry heart doeth good like a medicine but a broken spirit dries the bones.

—Galen

Immunologic alterations have been reported in a number of psychiatric disorders. Schleifer et al. (43) demonstrated that depressed patients have a decreased number of peripheral T cells compared with those of nondepressed control subjects. Their data suggest that the functional activity of lymphocytes, as well as the number of circulating immunocompetent cells, is reduced in patients with clinical depression. They also speculate that the altered immune functioning in patients with depression might be related to the severity of their depressive symptoms. Indeed, patients with depression have also been found to have decreases in NK cell activity in several studies (44,45). Affective symptoms such as depression and anxiety appear to stimulate proinflammatory cytokines such as IL-6 (46).

Depression is a common comorbidity in many physical illnesses. Research has documented prevalence rates of depression among patients with a variety of chronic medical conditions, often higher than in the general population. Table 17.1 highlights these prevalence rates. Not only are many diseases associated with an onset of clinical depression and anxiety, but depression and anxiety symptoms themselves can be significant risk factors for the progression of many diseases, with effects on morbidity and mortality (47). Depressive symptoms are associated with lower immune responses, such as lower T lymphocyte counts, along with higher

TABLE 17.1

Prevalence of Depression in Patients with Comorbid Medical Illness

Comorbid Medical Illness	Prevalence Rate (%)
Cardiac disease	17–27
Cerebrovascular disease	14–19
Alzheimer disease	30–50
Parkinson disease	4–75
Epilepsy	
Recurrent	20–55
Controlled	3–9
Diabetes	
Self-reported	26
Diagnostic interview	9
Cancer	22–29
HIV/AIDS	5–20
Pain	30–54
Obesity	20–30
General population	10.3

rates of infection (9). La Via et al. (48) demonstrated that among patients with generalized anxiety, symptom severity was correlated with immune suppression and increased disability from upper respiratory infection. Severity of anxiety symptoms has also been associated with decreased NK cell activity (46).

Depression as a clinical syndrome, as well as depressive symptoms, has been shown to impact morbidity and mortality related to cardiovascular health. Cardiovascular disease risk is increased significantly among patients with depression (47). Also, the prevalence of depression among patients with cerebrovascular and cardiac disease is higher than that in the general population. As Evans et al. (47) point out, the prevalence of depression may be even higher, as many patients with cardiovascular disease have symptoms that may not meet criteria for a diagnosis of major depression, but that are clinically significant. These subsyndromal symptoms still may impact morbidity and mortality in these patients. Frasure-Smith et al. (49) conducted a large prospective study of patients' status post acute coronary syndrome and monitored them for depressive symptoms as well as inflammatory markers. Findings demonstrated that depressive symptoms were risk factors for further cardiac morbidity, and that a higher level of CRP was also a risk factor. In another longitudinal prospective study of over 5,000 elderly men and women, Arbelaez et al. (50) found that greater depressive symptoms were associated with an increased risk of ischemic stroke. Depression is postulated to exert its physiologic effects on cardiovascular health by influencing inflammation of vessels, increasing platelet activation, promoting hypercoagulability, changing autonomic function (decreased heart rate variability and increased QT), and increasing in plasma cortisol (47).

Given the documented association between depression and cardiovascular morbidity and mortality, one might consider a low threshold for treatment of depressive and anxiety symptoms in this context. The trial, Enhancing Recovery In Coronary Heart Disease Patients (ENRICH), demonstrated safety for SSRI treatment in the context of cardiac disease. Future research will focus on potential cardioprotective benefits SSRI may have, hypothesized to be beneficial due to their assumed inherent antiplatelet activity.

Depression is also an associated risk factor for diabetes morbidity and mortality (47). Depressed patients may be less adherent to medications, placing them at risk for higher blood glucose levels and associated progression of the disease (51). Additionally, depression, through its effects on the HPA axis, can promote insulin resistance and inflammation.

Much research has investigated the association between depression and cancer. In addition to having possible depression as a result of coping with the psychological and physical aspects of their diagnosis and treatments, studies have suggested that affective symptoms may decrease survival time (52) and increase mortality (53). There is even some suggestion that stress may lead to an increased risk of cancer (47).

Lowering the threshold for treatment of comorbid depression is warranted given the association between depression, its symptoms, and many other physical illnesses. To date, research has attempted to document the safety and efficacy of using antidepressants in the context of many physical comorbid conditions.

SOMATIC CONDITIONS WITH BEHAVIORAL AND PSYCHIATRIC MANIFESTATIONS

Many somatic illnesses have behavioral and psychological manifestations. While not all the mechanisms are clearly understood, the presentation and associations of somatic conditions with behavioral and psychiatric manifestations highlight the interconnectedness between physical and mental health, and relate strongly to PNI

concepts. For example, Stein (54) reports behavioral pathology and neuropsychiatric impairment of patients with autoimmune and viral conditions associated with SLE and multiple sclerosis (MS). In turn, stress can also aggravate the symptoms associated with many of these and other conditions. Stress has been shown to predict CD4 cell loss in HIV. Table 17.2 highlights some somatic pathology with psychiatric manifestations. It is important for the osteopathic physician to be especially mindful of these conditions in the assessment and diagnosis of patients.

HEALTH BEHAVIORS

Health behaviors clearly influence the physical responses of the body, with implications for health and disease. Behaviors such as tobacco smoking, drug dependence, and sleep deprivation have been shown to further decrease the body's immunity independent of other factors such as depressive symptoms, and that many of these behaviors interact synergistically with depression to cause greater decreases in immunity than either factor alone (18). Chronic sleep deprivation may stimulate the SNS and the HPA axis (55). As well, partial sleep deprivation during a single night was demonstrated by Irwin et al. (56) to produce a reduction in NK activity. Kripke et al. (57) demonstrated increased mortality associated with poor sleep.

RELEVANCE OF PSYCHONEUROIMMUNOLOGY TO MEDICAL PRACTICE

Why is PNI an important topic for study? The implications of research in this area are paramount for the diagnosis and treatment of patients with a myriad of chief complaints and diagnoses. Particularly, mental health issues are often ignored or viewed as unimportant for treating physically ill patients. Most of medical education focuses on the diagnosis and treatment of so-called organic pathologic conditions. Yet, PNI research underscores that all illness, regardless of whether its manifestation is physical or mental, is organic. Psychosocial issues, while often seen as separate

TABLE 17.2

and distinct from biologic concerns, directly influence multiple body systems and impact the health and disease of the individual. To put in context the need to understand this interplay, consider the following facts:

- Emotionally distressed patients visit their doctors more than nondistressed patients.
- Emotionally distressed patients are hospitalized more often than nondistressed patients.
- Emotionally distressed patients have greater morbidity and mortality than nondistressed patients and generally poorer health outcomes for many physical diagnoses.
- People with emotional distress commonly visit their doctors with physical symptoms and complaints, never reporting psychological symptoms.
- Emotional distress and other psychological issues directly impact patient adherence to medications and other biologic treatments.
- Nearly two thirds of all physician visits fail to confirm a biologic diagnosis.
- Numerous biologic diseases can manifest themselves with psychiatric symptoms.
- Medical illness can precipitate emotional distress, which complicates medical treatment and increases medical costs.
- Emotional distress often goes unrecognized and untreated in medical encounters.
- Appropriate mental health treatment reduces emotional distress, medical utilization, and costs.
- Savings from reduced medical costs can offset the cost of providing mental health treatment and stress-reduction training, which may result in lower overall health care costs.

In everyday medical practice, both in inpatient and outpatient settings, these facts are often ignored, leading to a striking mismatch between the true needs of patients and the health care services delivered. The result is less effective care, frustration for both patient and physician, and the waste of ever-shrinking health care resources. Worse, it can lead to dangerous misdiagnosis of patients, with disastrous health consequences, including disability and death. If nothing else, PNI research underscores the need to assess patients' emotional distress. Osteopathic physicians in particular are likely to encounter patients with musculoskeletal complaints with a component of stress contributing to their illness. Eliciting information from patients on their stressors, their perception of their stress level (see Chapter 19) along with their current mood and mental state, making appropriate referrals and recommending appropriate stress-management techniques, will positively impact their overall health, improving disease and disability. For patients suffering from ongoing illness, identifying and addressing these issues may improve their response to other somatic treatments.

CASE VIGNETTES

Case 1

A 47-year-old woman presents to your office complaining of frequent low back pain, headaches, poor sleep, and a cold she "just cannot kick." The patient has been in your practice for 12 years and has enjoyed good health. She lives a healthy lifestyle, watches her diet, exercises regularly, does not smoke or drink in excess, and comes in yearly for a physical. Her routine labs are normal. Her physical exam reveals musculoskeletal tension in her lumbar, midthoracic, and cervical regions. The remainder of her physical exam is unremarkable, except for mild congestion in

her lungs and a nonproductive cough. She appears more stressed than usual, and when questioned admits to ongoing marital discord and trouble with her teenage son. She also reports failing health in the parents and concerns over their ability to care for themselves much longer. She reports feeling tired most of the time and rarely gets a restful night's sleep. It takes her up to three hours to fall asleep due to worrying about her life circumstances. She does not meet diagnostic criteria for depression or generalized anxiety disorder.

Discussion

This patient's physical complaints are real and likely related to the chronic emotional stress she is experiencing. Although immunologic measures were not attained, an appropriate treatment strategy would include OMT for her musculoskeletal complaints, conservative symptomatic treatment of her pulmonary symptoms, analgesics as needed for her headache (if not relieved by cervical OMT), and a stress-reduction strategy focusing on coping skills to deal with her stressful life issues (marriage, son, and parents). Special attention should be paid to normalizing her sleep. Chronic initial insomnia (difficulty falling asleep) is commonly associated with life stress and often responds to effective stress management. Disruptive and diminished sleep can play an important role in contributing to physical pain and susceptibility to organic pathology.

Case 2

A 58-year-old man, who has been your patient for the past 6 years, suffers an acute myocardial infarction. He survives the event and is being stabilized in the coronary care unit (CCU). You have treated the patient for depression in the past with antidepressant medication and referred him for psychotherapy. Although he was compliant with his medications, he never followed up on referrals for therapy. When you visit him in the CCU, he is very depressed and convinced he is going to die. He is hopeless, helpless, and expresses guilt over not being a good husband or father. Your attempts to cheer him up are unsuccessful. You inform his cardiologist of his history of Major Depression and restart his antidepressant medication and arrange for a psychiatry consult while in the CCU.

Discussion

It is critically important to address the patient's depression. Major depression is a major, independent risk factor for mortality in patients with cardiac disease. The precise mechanism for the increased morbidity and mortality is not fully known. However, the extant literature is robust and well replicated in confirming this clinical association. All physicians treating patient with cardiac disease should routinely screen for depression.

PATIENT EDUCATION

...I can trust the principles that I believe are found in the human body. I find what is necessary for the health, comfort, happiness of man, the passions, and all else. Nothing is needed but plain, ordinary diet and exercise.

—A.T. Still

The physician should emphasize the importance of lifestyle alterations such as cutting down on caffeine, maintaining a healthy diet, quitting smoking, and exercising regularly. Other stress-reduction strategies can be tailored to the patient's lifestyle and can be a key component to disease prevention. It is the responsibility of physicians

to educate their patients about the importance of maintaining a healthy lifestyle. Make patients aware of target organs and areas particularly vulnerable to stress, such as the heart, kidney, gastrointestinal tract, and musculoskeletal system. Some patients with chronic medical conditions should be educated on the potential associated psychological consequences of their condition and the physician should be regularly screening for these. Patient counseling should also include protecting patients from claims of miracle cures or unsound, potentially dangerous interventions, such as unproven megavitamin therapies.

Virtually all adult patients have some awareness of the noxious effects of chronic stress on overall health. The lay media and press are replete with stories on the importance of stress reduction, and the ill effects of the stressful times we live in. As physicians, it is important to teach patients to first identify emotional stress, particularly chronic low-grade stress that often goes unidentified. By the time a patient acknowledges their inability to manage their life stress, adverse health consequences have already been set in motion. Stress may be self-medicated with alcohol or drugs, which results in additional health problems. It is important for physicians to give patients the "permission" to discuss stress, as they may be reluctant to address these issues as not having medical relevance.

Osteopathic philosophy highlights the importance of treating the whole patient, not just diseased or dysfunctional organs. Every physical complaint should be evaluated as context dependent, that is, how does the current life setting impact on the symptom presentation? The field of PNI demonstrates the need to evaluate stress as an important factor in the etiology and treatment of disease.

CONCLUSIONS

Our understanding of the intricate complexity of the body, its individual systems, and their interconnectedness, is rapidly expanding. Since the first edition of this text in 1997, significant advances have been made in understanding the basic mechanisms of PNI. Early clinical observation is rapidly becoming scientifically proven fact. As with other core osteopathic concepts, the key to continued acceptance in the medical community, and ultimately to the enhancement of health of patients, is the study of and adherence to the principles of methodologically sound scientific research. PNI research has demonstrated that the CNS is in direct and constant bidirectional communication with the immune and endocrine systems. The goal of future research is to better understand their "language" and how to identify and manipulate it to promote health and treat disease. The challenge of the next generation of osteopathic researchers and clinicians is to continue to investigate and to expand on the work of this exciting and important field.

KEY CONCEPTS

- Empathy for stress-related problems and their many manifestations
- Stress and related somatic complaints, including those related to somatic dysfunction
- Signs and symptoms of depression
- Signs and symptoms of anxiety
- Signs and symptoms of alcohol abuse
- Signs and symptoms of insomnia
- Adaptive methods for coping with stress
- Overview of treatment techniques
- Impact of the doctor/patient relationship

DEFINITION OF STRESS

Stress is a condition experienced when the physical, mental, emotional, or social environment makes unwanted inescapable demands. These demands exceed resources and create a sense of powerlessness and inability to control the stressor or effect change.

The person under stress responds as a unit (i.e., mind, body, and spirit) and coordinates an adaptive response to the stressor. The main physiological components of the stress system response are activation of the hypothalamic—pituitary—adrenal (HPA) axis, autonomic nervous system arousal, and adrenalin secretion in the “fight or flight” response. Being aroused by stress provides a biologic advantage that enables the individual to rapidly respond to danger. Historically, the stress system response enhanced survival and adaptive responses. We ignored a pain, fought back, ran to safety on broken bones, and scrambled to the top of the food chain.

Osteopathic philosophy teaches us that damaging stress levels are reached when perceived threats or dangers upset the biopsychosocial balance. Prolonged hypersympathetic activity can be deleterious to health and can facilitate disease. Thoughts, emotions, and behaviors in response to stressors are in a blended and complex relationship that can affect both anatomy (structure) and physiology (function).

Seyle (1) first described these interdependent processes of responding to stress as the general adaptation syndrome. Seyle believed that our response to stress was a specific syndrome following certain patterns and affecting specific organs. Stress itself could be induced by a variety of internal or external stimuli.

When patients are continually stressed, they move through three response stages. First, there is a startle response and orientating reflex as the patient becomes aware of the stress and is biologically alarmed. Adrenal, cardiovascular, respiratory, and musculoskeletal functions increase.

Next is an attempt to cope and problem-solve biologically, psychologically, and socially. The patient mobilizes all resources to meet and resist the stressor. If the patient is successful, mastery and learning occur. If the patient fails, he or she becomes exhausted physically, mentally, and emotionally.

The third stage, exhaustion, is what the osteopathic physician sees clinically as a variety of dysfunctional signs and symptoms

affecting any and all organ systems. As coping responses fail, the exhaustion depletes adaptive reserves and resistance disappears. Patients then experience somatic dysfunction and present themselves to the primary physician requesting treatment for symptoms of stress-related problems.

In primary care, stress-induced somatic complaints are the mechanisms underlying the symptoms for 20% to 35% of all patients seeking treatment from physicians (2,3). In the United States, more than 33% of the population is susceptible to acute or chronic stress and the physical and psychological disorders caused by stress (4). Studies in several populations have also found that 10% of patients account for about 30% of primary care visits (5,6). These high utilizers of medical services represent a group of patients who have physical disease *as well* as concomitant distress (7).

The onset of stress-related illness is a complex phenomenon that incorporates the tissue pathology (musculoskeletal abnormalities), psychosocial and behavioral response to that physical insult, and the environmental factors that maintain or reinforce that disability (even after the initial cause has been resolved). A significant portion of the variance in an individual response to any disease outcome is accounted for by the manner of behavior and emotional response to the stress of the illness (8). In fact, the majority of today’s health woes—obesity, cancer, and anxiety disorders to heart disease, hypertension, and adult-onset diabetes—are actually relatively new “diseases of civilization” brought on by our behavioral choices and mind-body interactions.

Our current understanding of stress-induced illnesses suggests that these processes are a complex interplay between genetic physiologic, environmental, and behavioral factors that influence health and disease. Behavioral mechanisms can alter the nervous system, endocrine system, and immune system, directly influencing health. Diet, exercise, drugs, alcohol, and tobacco use, along with a variety of other behaviors, also modify disease progression and/or disease risk (see Chapter 32). Finally, behaviors directly related to seeking or avoiding medical care also have important consequences on prevention, early detection, and adherence with medical regimens.

This chapter presents a framework for understanding and clinical management of stress-related illness. It includes guidelines

for the cognitive/behavioral management of the effects of stress related to:

- Anxiety
- Depression
- Alcohol abuse
- Insomnia

CONCEPTUALIZING STRESS

No life is without stress. There are, however, adaptive and maladaptive manners of coping, even under the most stressful circumstances. Although there are many events that can happen in our lives that are completely unexpected, many of life's difficulties can be anticipated and managed effectively. Many people accept high levels of stress in their lives but do not appreciate the high price they pay. Medical research has shown that a life lived in chronic stress can trigger and activate psychophysiological disorders such as hypertension, peptic ulcer disease, and coronary artery disease (9). In essence, a feed-forward loop is established where each added consequence of stress becomes a factor in raising the levels of stress.

More recent research in psychoneuroimmunology shows a relationship between stress and attenuation of immune responses (see Chapter 17). Mental health researchers have long known that

stress plays a strong role in various forms of anxiety and depressive disorders, as well as in many forms of substance use and abuse.

Most recently, stress has been conceptualized as an organism's nonspecific response in an attempt to adapt to demands. Those demands can cover the spectrum of psychological, social, and physiological functioning. Even ordinary day-to-day events, whether seen as positive or negative, involve adoption to change. The concept of adoption to change now dominates current thinking about stress. In 1967, Holmes and Rahe verified the stress of adaptation (10). They developed a scale and assigned points to 43 common life events to develop a stable and objective point of reference. They were not concerned with how people interpreted or felt about these events but merely with whether they happened. They demonstrated that the greater number of points a person scored over a 1-year period, the greater the probability of illness occurring within the next 2 years. Later research determined that if the person assessed the event as a negative life experience, the impact was more severe (11). Based on these findings, the preventive implications are clear. Although a number of stress scales are now available, the Holmes & Rahe Social Readjustment Scale remains one of the most highly validated and widely used (Table 18.1). This scale can be easily incorporated into medical practice and used liberally to help patients assess their judgments and vulnerabilities based both on the stressful event and their perception (positive or negative) of the event and develop increasingly effective anticipatory coping strategies.

TABLE 18.1

Social Readjustment Scale

Life Events	Holmes Points
1 Death of spouse	100
2 Divorce	73
3 Marital Separation	65
4 Jail term	63
5 Death of close family member	63
6 Personal injury of illness	53
7 Marriage	50
8 Fired from job	47
9 Marital reconciliation	45
10 Retirement	45
11 Change in health of family member	44
12 Pregnancy	40
13 Sex difficulties	39
14 Having a baby	39
15 Business readjustment	39
16 Change in financial state	38
17 Death of a close friend	37
18 Change to different line of work	36
19 Change in number of arguments with spouse	35
20 Mortgage large in relationship to income	31
21 Foreclosure of mortgage or loan	30

22 Change in responsibilities in work	29
23 Son or daughter leaving home	29
24 Trouble with in-laws	29
25 Outstanding personal achievement	28
26 Spouse begins or stops work	26
27 Begin or end school	26
28 Change in living conditions	25
29 Change in personal habits	24
30 Trouble with boss	23
31 Change in work hours or conditions	20
32 Change in residence	20
33 Change in schools	20
34 Change in church activities	19
35 Change in recreation	19
36 Change in social activities	18
37 Small mortgage in relation to income	17
38 Change in sleeping habits	16
39 Change in number of family get-togethers	15
40 Change in eating habits	13
41 Vacation	13
42 Christmas	12
43 Minor violations of the law	11

Stress can also be self-generated. The “type A personality” first described by Friedman and Rosenman has now become a household word (12). Although it has been argued excessively as to whether the “type A personality” is a feature of coronary artery disease, the adaptive style of a person with type A characteristics can hardly be envied. Research beyond Friedman & Rosenman’s seminal work indicates that competitiveness, impatience, and difficulty dealing with anger and hostility are the core characteristics of people prone to coronary artery disease. It might be difficult to completely alter these maladaptive styles, but counseling and education can modify them to the point where a patient’s risks are significantly lowered (13).

Change the Stressor

Before seeking medical treatment, the patient probably has already tried to change the stressor without much success. In this situation, casual advice usually doesn’t work, even when coming from a physician. Compliance with physician advice is low, particularly in the current climate of health care delivery where the pace is hectic and often impersonal. As patients shift between physicians and insurance plans in a managed care environment, the personal relationships once forged between physician and patient disappear. Trusting relationships are difficult to establish under these circumstances, increasing the likelihood that professional advice will go unheeded.

Many patients who come to a primary care setting are looking for help with stress-related symptoms. A primary care, osteopathically oriented approach assesses all the disturbing psychosocial and organic problems, including the neuromusculoskeletal elements, so that a long-term treatment strategy can be developed. In such cases, after a detailed history is taken and complete physical examination, the treatment strategy incorporates all elements of the osteopathic philosophy. It includes:

- Palpatory diagnosis
- Manipulative treatment
- Exercise, diet, smoking, alcohol, drug cessation
- Appropriate medication
- Coping strategy education

There is a palpable reaction of the musculoskeletal system to stress whether from inside the body or from environmental or social influences. When hands-on procedures are used to identify stress-induced somatic dysfunction, the experienced osteopathic practitioner can determine whether the observed pattern of somatic dysfunction is associated with primary neuromusculoskeletal dysfunction, contribution from somatovisceral or viscerosomatic components, or a more complex behavioral dysfunction. Designing all aspects of treatment to include modification of the biopsychosocial causes and maladaptive responses to stress is important. The primary care physician must constantly be aware that clinically evident stress reflects two realities:

1. A patient’s response to stress-inducing events produces biopsychosocial consequences.
2. A patient’s long-term stress management style is an important factor determining health or disease and an area in which the physician must intervene for long-term adaptive change.

Change Response to Stress

Significant stress-related conditions are often found in primary care outpatients (14–16). By changing the patient’s response to

stress, one immediately treats some of the autonomic components of stress-related somatic dysfunction and their antecedents, which can be so impactful on the patient’s general health. Success is more likely when physicians educate patients, guide and mentor their adaptation, and teach them coping and stress-mastery skills. In a primary care practice, diagnosis begins by accurately reviewing four of the most common behavioral consequences of stress:

- Depression
- Anxiety
- Substance abuse
- Insomnia

When the exact diagnosis is made, carefully inform the patient and then guide him or her through a process of problem identification and problem solving designed to either relieve or cope with the stress. The remainder of this chapter reviews these four stress-induced problem areas from a cognitive behavioral standpoint. Emphasis is on rapid techniques for diagnosis and on specific strategies to be employed within the doctor-patient relationship.

DEPRESSION

Feeling “down” is a universal experience. Being sad or “blue” accompanies disappointments, setbacks, or losses in life. The depressed mood usually lasts a short time and passes. For some people, however, the sadness becomes intense and long lasting, coloring every aspect of their existence. The future seems hopeless. They see the world as an overwhelming place in which they are unable to concentrate, sleep, or solve the routine problems of life.

In the United States, the problem of clinical depression is monumental. Clinical depression results in the hospitalization of 6% of all women and 3% of all men, with 15% of all who are severely clinically depressed eventually committing suicide (17,18). There is emerging evidence that depressed patients have a significant loss of cells in the prefrontal cortex, a brain area important in discerning reward versus punishment, in shifting mood from one state to the other, and in exerting cortical restraint on the amygdala fear system through the HPA axis and the sympathetic nervous system. An increase in cortisol and norepinephrine secretion represents a highly adverse biochemical environment, a condition that is likely to contribute to many different adverse outcomes, including increased visceral fat, insulin resistance, increased inflammation, enhanced blood coagulation, deficient fibrinolysis, decreased bone formation, and increased bone resorption.

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)* (19) and the *Guidelines for Detection and Diagnosis in Primary Care* categorize mental health diagnoses. The word “depression” refers to a syndrome in which a variety of signs and symptoms occur. Typically, there is a change from previous adequate emotional functioning to a depressed mood and a loss of pleasure in life’s usual activities. The depressed person feels sad or empty most of the time and often experiences impairment in interpersonal, social, or occupational functioning. Conceptually, these symptoms may be grouped as disturbances in:

- Emotions (depressed mood, loss of interests/pleasure, worthlessness or guilt).
- Ideation (worthlessness/guilt, death/suicide).
- Neurovegetative or somatic symptoms (sleep, appetite/weight, psychomotor, energy, concentration).

If five or more of these symptoms are present for more than 2 weeks, a diagnosis of *major depressive disorder* is considered. The diagnosis

TABLE 18.2

Structured Interview Questions for Depression^a**For the last 2 weeks, have you had any of the following problems nearly every day?**

1. Trouble falling or staying asleep, or sleeping too much?	YES	NO
2. Feeling tired or having little energy?	YES	NO
3. Poor appetite or overeating?	YES	NO
4. Little interest or pleasure in doing things?	YES	NO
5. Feeling down, depressed, or hopeless?	YES	NO
6. Feeling bad about yourself, or that you are a failure or have let yourself or your family down?	YES	NO
7. Trouble concentrating on things, such as reading the newspaper or watching television?	YES	NO
8. Being so fidgety or restless that you were moving around a lot more than usual? If No: What about the opposite—moving or speaking so slowly that other people could have noticed?	YES	NO
9. In the last 2 weeks, have you had thoughts that you would be better off dead or of hurting yourself in some way? (Tell me about it.)	YES	NO

SCORING: If five or more of Nos. 1 to 9 are yes, one of which is No. 4 or 5, then consider *major depressive disorder*. If the condition has persisted over the last 2 years and the patient reports that it was hard to do their work, take care of things at home, or get along with other people, then consider *dysthymia*.

^aPrimary care evaluation for mental disorders (Prime-MD).

Source: From Spitzer RL, Williams JB. *PRIME-MD Clinical Evaluation Guide*. New York, NY: Biometrics Research, New York State Psychiatric Institute, 1994, with permission.

becomes *dysthymia* if over the last 2 years the patient reports having felt these symptoms and says that for more than half of that time it was hard to work, take care of simple things at home, or get along with people. These symptoms (all but depressed mood) may be more readily recalled using the mnemonic “SIG: E CAPS” (i.e., “prescribe energy capsules”): Sleep, Interest, Guilt, Energy, Concentration, Appetite, Psychomotor, and Suicide.

Measurement of Depression

The diagnosis and management of depression in a patient can be facilitated through numerous self-administered inventories, such as the Zung Depression Scale (20,21), the Beck Depression Inventories (22,23), and the MMPI Depression Scale (24,25). These inventories provide reliable and valid measures of the severity of depression. The patient can initially be tested for a baseline measure and then repeatedly tested with the same instrument to measure progress. More recently developed structured interviews such as the PHQ-9 (26,27) allow one to quickly (i.e., in 8.4 minutes) determine the presence of pivotal signs and symptoms (Table 18.2). The PHQ-9 is a 9-item self-report instrument assessing the nine symptoms of DSM-IV major depression, which is feasible to use, reliable, and valid in primary care settings (28). The PHQ-9 establishes the clinical diagnosis of depression and does not require further confirmation. This allows the clinician more time to be spent on patient education and negotiation of the treatment plan. The PHQ-9 sum score can also be used to track the severity of patient symptoms over time (29).

Medical disorders with intrusive symptoms of depression must also be ruled out (Table 18.3). Unfortunately, there is no evidence to support routine laboratory testing in the diagnosis of depression. Complete blood count (CBC), a basic chemistry profile, liver function tests, TSH, Rapid plasma reagin (RPR), B₁₂, and folate levels are only helpful when underlying medical conditions are suspected. This situation is made more complex by the fact that depression

has also been reported as a serious adverse effect of more than 100 commonly prescribed drugs (Table 18.4).

Tricyclic antidepressants and serotonin reuptake inhibitors are the gold standards for initiating management of many serious, possibly organic, depressions (30,31). Recoveries are often dramatic as the patient reverts to predepression levels of functioning. Given the distribution of depression in the population and the long-term treatment protocols used in management, primary care physicians are exposed to a tremendous amount of publicity and marketing from pharmaceutical companies to manage the symptoms of depression with their various products.

Cognitive Behavioral Factors in Depression

Depression in response to stress can be well understood within the framework of learning theory (32). Deficits in social skills can set the stage for unrewarding social, vocational, and personal relationships causing subsequent feelings of depression. Studies with animals and humans exposed over time to inescapable stress have shown that the subjects failed to demonstrate simple behaviors to escape or avoid the stress and subsequent punishment (33,34). In a laboratory setting, when exposed to inescapable electric shock, dogs and humans felt helpless and both suffered from naturally occurring depression. Human and animal groups showed similar response patterns of passivity, slowed learning, impaired problem solving, and loss of appetite. Their inability to stop the stressor or to escape from the stressor initiates cognitive processes that lead to a sense of powerlessness. Victims of inescapable stress lower their future expectations for control over stress and have measurably lower self-esteem and lower motivation.

Beck (23,32,35) describes negative schemas as a learned maladaptive thinking process that often leads to depression. When faced with stressful events, some patients routinely employ negative views of themselves and their abilities (i.e., negative schemas) and are dominated by themes of failure and personal inadequacies.

TABLE 18.3

Medical Illnesses and Conditions with Intrinsic Symptoms of Depression

Parkinson disease
Normal pressure hydrocephalus
Multiple sclerosis/stroke
Brain tumors (temporal lobe)
Adrenal insufficiency syndrome
Hyperparathyroidism
Vitamin B ₁₂ or iron deficiency
Serum sodium or potassium reductions
Hypercalcemia
Cancer
Metal (thallium, mercury) intoxication
Chronic pain and disease (i.e., fibromyalgia, diabetes mellitus)
A common symptom in geriatric populations
20%–24% of medical inpatients
Neurologic disorders (i.e., related to abnormal catecholamines or indoleamine metabolism)
Cardiac disease
Serious medical injury (i.e., spinal cord, end-stage renal disease)
Dementia, head trauma, seizure disorders

Source: From Derogatis LR, Wise TN. *Anxiety and Depressive Disorders in the Medical Patient. Clinical Practice No. 4.* Washington, DC: American Psychiatric Press, 1989:121, with permission.

They have learned to expect their performance to be worse than that of others, and view the world as an overwhelming place, laden with burdens, and filled with excessive demands and daily defeats.

Over time, negative depression themes become stable, long-standing thought patterns creating downward cognitive spirals. Once the pattern begins, the patient will organize new experiences as depressing and selectively direct attention to the negative aspects of current and future stressors. Thus, these depression-prone patients perceive the present as depressing, remember the past the same way, and respond to the future in a fixed, negative manner, independent of what occurs in their environments.

There are six basic cognitive errors in logic that a patient learns over time (Table 18.5). Insight into these faulty reasoning patterns is helpful for some depressed patients. Patients who respond positively to cognitive therapy by changing their patterns of thought, appear to have sustained benefits; the risk of relapse over one year was lower than that of patients who had responded to medications and were then switched to placebo (36). Osteopathically trained physicians routinely work with their patients' cognitive stress coping styles in addition to pharmacologically managing their depressive symptomatology. Drug therapy and cognitive behavioral treatments augment and complement one another in patients diagnosed with major clinical depression; administering these strategies simultaneously yields a superior result (37–40).

ANXIETY

Chronic anxiety is a generalized state of apprehension in response to stress. The chronically threatened individual will eventually begin to experience *distress* in everyday situations that would not normally have elicited such reactions in the past. An anxious reaction is a basic, genetically programmed human response to a real or imagined threatening stressor. The biologic changes elicited by an anxious reaction have specific adaptive survival value in their acute state. They represent alertness and arousal responses for better behavioral and biologic focusing and coping with the threat. It is when feelings of anxiety becomes dysregulated and a constant part of the patient's life that a state of pathology occurs.

An anxious reaction represents one of several built-in stress programs that patients can use to adapt to and cope with new

TABLE 18.5

Faulty Reasoning Patterns Noted in Depression-prone Patients

Arbitrary inference—drawing a specific conclusion in the absence of evidence to support the conclusion.

Selective abstraction—drawing a conclusion based on a detail taken out of context.

Overgeneralization—drawing a broad, global conclusion on the basis of one or more isolated pieces of information.

Magnification and minimization—exaggerating the significance of negative events and minimizing the significance of positive events.

Personalization—relating external events to oneself when there is no realistic basis for making such a connection.

Absolutistic, dichotomous thinking—placing all experiences in one of two opposite categories.

threats in their environment. Physically, anxiety is a state of fear with especially strong manifestations in the hypothalamic, sympathetic, autonomic, adrenal, and reticular neuroendocrine networks orchestrated from such forebrain limbic structures as the amygdala. Chronic anxiety is a maladaptive response to a stressful stimuli primarily involving the neurotransmitters norepinephrine, serotonin, and gamma-aminobutyric acid (GABA). Research has also focused upon possible HPA axis abnormalities and the potential role of cholecystokinin (41). Imaging studies in patients with GAD have shown differences in regional brain activity. As an example, one report using positron emission topography measurements found high relative metabolic rates in parts of the occipital, temporal, and frontal lobes, and cerebellum, during a passive viewing task in patients with anxiety relative to normal control subjects (42). Experienced osteopathic physicians soon learn that chronic exposure to anxiety-inducing stress without adequate coping strategies often involve irrational cognitive appraisals of threats that, in turn, can lead to further and commonly excessive anticipatory anxiety.

Lifetime prevalence rates for anxiety based on DSM IV criteria are estimated at 4.1% (43). The prevalence is estimated to be 8% in the primary-care setting (44). The number of office visits with a recorded anxiety disorder diagnosis increased from 9.5 million in 1985 to 11.2 million per year in 1994 and 12.3 million per year in 1998 (16). Twice as many women as men have the disorder (43,45).

Anxiolytic benzodiazepines are among the most commonly prescribed medications in the United States, and primary care physicians write 85% of these prescriptions. Unfortunately, the diagnosis of anxiety is complicated by the fact that anxiety is often not the patient's chief complaint. Rather, patients experiencing anxiety generally complain of physical problems (46). Primary care physicians often focus exclusively on these physical symptoms, failing to note that the patient's complaints are really created by unreported

or unrecognized anxiety and chronic autonomic arousal including disturbed sleep-wake cycles.

Further complicating the situation is the fact that some medical problems magnify the state of anxiety. Table 18.6 lists medical disorders and conditions associated with high amounts of anxiety. Laboratory studies to consider include a CBC, chemistry panel, serum thyrotropin (TSH) (47), urinalysis, electrocardiogram (in patients over 40 with chest pain or palpitations), and any other specific studies required to diagnose a suspected medical cause of anxiety. Urine or serum toxicology measurements of drug levels can be obtained for drugs or medications suspected in the etiology of anxiety.

Measurement of Anxiety

Anxiety inventories such as the state-trait anxiety inventory (48) and anxiety subscales of the MMPI-2 (24,25) measure individual differences in anxiety susceptibility and the patient's tendency to perceive a wide range of situations as threatening. The inventories also measure the patient's reported response to these situations with associated activation and arousal of the autonomic nervous system, an important index of the anxiety state.

These measurements can also be routinely collected in the primary care setting. A seven-item anxiety questionnaire (GAD-7) has been developed and validated in a primary care setting (Table 18.7) (49). GAD-7 is a patient self-assessment tool that can facilitate screening. It is important that positive results from the test (a score of 8 or higher) should be followed by clinician interview to establish the diagnosis of generalized anxiety disorder (GAD). The GAD-7 tool has been validated to screen for generalized anxiety, as well as for other types of anxiety (panic disorder, social anxiety disorder, and posttraumatic stress disorder [44]). Additionally, a shorter version of the GAD-7 (referred to as the GAD-2), using only its first two items of the original test and employing a cutoff score of 3 or more to initiate further evaluation, may be equally sensitive to the GAD-7 (44).

TABLE 18.7

Structured Interview Questions for Generalized Anxiety Disorder (GAD-7)

1. Have you felt nervous, anxious, or on edge on more than half the days in the last month?	YES	NO
In the last month, have you <i>often</i> been bothered by any of these problems?		
2. Feeling restless so that it is hard to sit still?	4. Muscle tension, aches, or soreness?	6. Trouble concentrating on things, such as reading a book or watching TV?
3. Getting tired very easily?	5. Trouble falling asleep or staying asleep?	7. Becoming easily annoyed or irritated?
8. Are three or more of Nos. 2–7 checked?	YES	NO
9. In the last month, have these problems made it hard for you to do your work, take care of things at home, or get along with other people?	YES	NO
10. In the last 6 months, have you been worrying a <i>great deal</i> about <i>different things</i> , and has this been on more than half the days in the last 6 months? (Count as yes only if yes to both.)	YES	NO
11. When you are worrying this way, do you find that you can't stop?	YES	NO
12. These current anxiety symptoms are <i>not</i> due to the biologic effects of a physical disorder, medication, or other drug?	YES	NO

SCORING: Yes to 1, 8, 9, 10, 11, and 12 constitutes a probable diagnosis of *generalized anxiety disorder*.

Anxiety Treatments

An osteopathically oriented approach for managing anxiety involves treating both the physical symptoms of chronic fear and the mechanisms of learned and reinforced maladaptive arousal in response to prolonged stress. Benzodiazepines can be prescribed to reduce the paralyzing anxiety associated with a clear external stressor. These are most effective if prescribed on a *temporary* emergency basis with the goal of preventing dependence and iatrogenic withdrawal anxiety when medications are stopped. Thus, one should avoid chronic use of these pharmaceuticals. Physical symptoms can also be controlled by muscular relaxation training, controlled diaphragmatic breathing, and biofeedback (50,51). Structural examination and manipulative treatment should be used to assure appropriate function of the respiratory muscles. Supportive therapy and cognitive behavioral therapy (CBT) are frequently recommended as first-line psychological treatment for GAD. A meta-analysis found CBT to be effective in reducing symptoms in patients with GAD (22). CBT in primary care settings that have integrated mental health resources are particularly effective (52). Osteopathic care attempts to reduce anxiety by enhancing coping abilities, providing interpersonal support, and training the patient to reduce learned anxiety associated with stress while also establishing and maintaining normalized function of the somatic system.

Also, general measures to improve coping ability such as a healthy diet, moderate exercise, weight control, and mobilizing a support system of family and friends can set the stage for effective long-term anxiety management. Positive outcomes of the proposed treatment will result when the primary care physician enters collaborative management relationships with anxious patients. The goal of these relationships is to alleviate overly aroused patients' fears as they learn new coping styles.

ALCOHOL USE AND DEPENDENCE

The use of alcohol as a coping strategy is uniquely human. As our society becomes more complex and ambiguous, more patients use alcohol to manage stress. Medical care for alcohol abuse has become routine work in primary care practice (53–55). The reported use and abuse of intoxicating chemicals that alter the physiology of the body and the central nervous system dates back to the ancient Egyptian papyri and the Greek amphitheater at Delphi. Alcohol abuse and dependency have become a self-medication strategy for stress that is socially tolerated and modeled for our children. Approximately 10% of Americans (10 million people) abuse alcohol (56). A survey of mental health and substance abuse disorders in nearly 20,000 American adults found a 13.5% lifetime prevalence rate for alcohol abuse or dependence (57,58). Alcohol abuse and dependence runs in families (59). First-degree relatives have a three- to fourfold higher prevalence compared with the general population; this number is twofold higher in identical twins of alcohol-dependent individuals (60,61).

Alcohol as Response to Stress

The excessive use of alcohol accounts for a wide spectrum of health and social problems. Alcohol plays a casual or a contributing role in deaths resulting from accidents, homicides, and suicides, as well as diseases such as cirrhosis and cancer. Beyond the negative effects on individuals with alcoholism, the disorder also has been estimated to negatively affect the lives and health of many other people. Alcohol abuse is implicated in 50% of all divorces, in 45% to 68% of spouse abuse cases, and in up to 38% of child abuse cases. Alcohol abuse is especially harmful during

pregnancy. Fetuses can be seriously harmed by alcohol. Fetal alcohol syndrome is now one of the three leading causes of prenatal mental retardation in the United States, and it is completely preventable.

In low concentrations, alcohol depresses the brain's neuronal and synaptic transmission systems, including inhibitory center. These depressant effects create three self-reinforcing psychological and behavioral patterns:

- Euphoria effects
- Disinhibiting effects
- Anxiety-relieving effects

Initial euphoria effects reflect central nervous system sedation, temporarily increasing self-esteem, courage, and confidence. To the alcoholic, these disinhibiting and anxiety-relieving effects seem almost magical.

As dependence and abuse develop, biologically, alcohol acts as an antagonist at *N*-methyl-D-aspartate receptors and as a facilitator at GABA receptors. It also interacts with multiple other neurotransmitter systems in the brain such as the endogenous opioid, serotonin, and ultimately dopamine systems (62,63). Corticotropin-releasing factor, which is involved in stress responses, may play a role in mediating alcohol enhancement of GABA neurotransmission and thus could be involved in the relationship between stress and alcohol abuse (64).

The National Council on Alcoholism and Drug Dependence and The American Society of Addiction Medicine define alcoholism as a primary chronic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations (65). The disease is often progressive and fatal. It is characterized by impaired control over drinking, preoccupation with the drug alcohol, use of alcohol despite adverse consequences, and distortion of thinking, most notably denial. Each of these symptoms may be continuous or periodic.

A person who abuses alcohol rarely changes these maladaptive behaviors without strong, consistent, systematic, and long-term treatment. The first step involves accurate diagnosis so that the appropriate treatment can follow. A number of useful examiner and self-administered questionnaires are available, but the most useful diagnostic screen consists of four simple questions. The screen's acronym, CAGE, comes from the critical word in each question (66):

1. Have you ever tried to *Cut* down on your drinking?
2. Are you *Angry* or *Annoyed* when people ask you about your drinking?
3. Do you ever feel *Guilty* about your drinking?
4. Do you ever take a morning *Eye* opener?

One positive response suggests the possibility of alcoholism and merits further exploration. Two positive answers make the likelihood of alcoholism extremely high. Three positive responses to questions 1 through 3, or a single positive response to question 4, is most likely diagnostic for the condition. The helpful features of these questions are their simplicity, sensitivity, and efficiency. These questions take under two minutes to ask and they should be included in every initial ambulatory and hospital admission workup.

Alcohol abuse often is a symptom of psychiatric illness, most commonly anxiety and mood disorders. The ubiquity, social acceptance, and relative low cost of alcoholic beverages make drinking an effective short-term and maladaptive long-term manner of self-medication. If the alcohol problem is a primary disorder

(alcohol-related disorder, *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition [DSM-IV]) (67), substance abuse treatment alone suffices. If the alcohol problem is secondary to a psychiatric disorder (dual diagnosis), specific attention to the underlying illness must be addressed simultaneously with the substance abuse disorder. The most useful recent method to diagnose psychiatric disorders efficiently and accurately in an ambulatory care setting is the Prime-MD (Primary Care Evaluation of Mental Disorders) (68). Prime-MD is a well-validated and highly reliable questionnaire that screens for psychiatric disorders (see Table 18.8). Patients fill out a questionnaire and the physician then discusses with the patient any positively endorsed symptoms. The questionnaire is specific for most of the common psychiatric disorders presenting to primary care practice, including mood, anxiety, somatoform concerns, and alcohol-related problems.

If a psychiatric disorder is coexistent with alcoholism, referral for psychiatric consultation and comanagement is strongly recommended. Compulsory inpatient treatment followed by close monitoring for incipient relapse yields the best results (69).

Alcohol as Cause of Further Stress

Once alcohol use becomes a primary stress management strategy, a cascade of further physical and psychosocial stressors will follow (Table 18.9). Evidence of brain plasticity and atrophy (shrinkage) has also been documented in various imaging studies of addicts with results indicating that frontal lobes, limbic system, and cerebellum are particularly vulnerable to damage and dysfunction. Atrophy of the brain contributes to transient or persistent loss of memory, diminished cognitive ability, and compromised reasoning and decision making, depending upon which brain areas are affected and severity and duration of chronic substance abuse (64,70,71). With abstinence, maintained for more than 6 months, partial function may return, but studies have shown that full recovery of these compromised structures is usually not attained.

Alcohol might have been initially used to manage stress, but disruption in work, personal, and social relationships, and isolation are the final consequences. The urgent need to drink concentrates the patient's remaining energies on securing and ingesting alcohol. Denial, minimization, and self-deception are used to explain the alcoholic's deterioration, especially when discussing alcohol use with the primary care physician. When the patient's self-esteem or prominence in the community is at risk, lying, evasion, and other manipulative behaviors emerge as strategies to avoid admitting the problem to the primary care physician and to others. At the point of threatened or actual loss of job, family, home, or health, the physician may intervene and encourage the patient to enter an alcohol treatment program.

Primary care physicians normally refer patients with recurrent alcoholism who need active motivational counseling that treats the biopsychosocial components of addiction (see Table 18.10). Alcohol abuse is a chronic, relapsing disease, and these patients often require consistent interventions by the primary care physicians. The recent research has shown that 5 to 15 minutes of motivational counseling can reduce heavy drinking by 25% (72,73). The recovering alcoholic will need a physician's guidance (Table 18.11) and family support to learn to face life's stressors without the use of intoxicants. With support from the physician, the family, and a peer support group, the patient can change his or her maladaptive stress management style and abstain from alcohol (55,74).

TABLE 18.8

Structured Interview to Elicit Information on Probable Alcohol Abuse/Dependence

Opening Inquiries:

Have ... you thought you should cut down on your drinking? Why?

Has ... someone complained about your drinking? Who? Why?

Do ... you feel guilty or upset about your drinking? Why?

Have ... you had five or more drinks in a single day in the past month?

How often have you had that much to drink in the past 6 months?

Has that caused any problems?

1. Has a doctor ever suggested that you stop drinking because of a problem with your health? (Count as yes if patient has continued to drink in the last 6 months after doctor suggested stopping.)	YES	NO
--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	-----	----

Have any of the following happened to you *more than one time* in the last 6 months?

2. Were you drinking, high from alcohol, or hung over while you were working, going to school, or taking care of other responsibilities?	YES	NO
------------------------------------------------------------------------------------------------------------------------------------------	-----	----

3. What about missing or being late for work, school, or other responsibilities because you were drinking or hung over?	YES	NO
-------------------------------------------------------------------------------------------------------------------------	-----	----

4. What about having a problem getting along with other people while you were drinking?	YES	NO
-----------------------------------------------------------------------------------------	-----	----

5. What about driving a car after having several drinks or after drinking too much?	YES	NO
-------------------------------------------------------------------------------------	-----	----

SCORING: Yes to most questions. (Consider responses to opening inquiries and other information known about the patient, such as information obtained from a family member.)

OSTEOPATHIC MANIPULATIVE TREATMENT

Osteopathic Manipulative Therapy

The musculoskeletal components of the stress response are important when considering manipulation as a modality for stress management. The musculoskeletal system is the physical expression of emotions and feelings (ECOP, 2000). In patients with prolonged depression, anxiety, or fear, those parts of the body that are used to express these emotions tend to have increased tone, altered

biomechanics, and lack efficient postural mechanics. Conversely, in the face of altered connective tissues of the parts of the body involved with the expression of a particular emotion, there is often inability of the patient to adequately express or communicate that emotion. While applying OMT, many physicians have encountered emotional releases as the connective tissues begin to regain their functions (ECOP, 2000).

The physician may also encounter lifestyle choices, attitudes, and habits that directly affect the musculoskeletal system. They include poor sleeping habits and chemical dependency (i.e., alcohol abuse causing fatty degeneration and atrophy of the muscle), and the physician may learn about high-risk behaviors, sociocultural values, and views of health and disease that interfere with or

Physician Tasks

The tasks of the physician are to

- Develop a strong relationship built on trust
- Make the diagnosis of alcoholism compassionately
- Elicit the support of family and friends
- Refer the alcoholic to a recognized recovery program
- Reinforce the stress management techniques

facilitate the adaptive response to stressors. Counseling, problem solving, and education are at the core of complete and comprehensive osteopathic stress management.

Cognitive Behavioral Counseling

Systematic review of English-language studies listed in Medline (through November 2006) and the Cochrane Database of Systematic Reviews (2006, issue 4) identified ample evidence supporting the use of cognitive-behavioral counseling (75) for relief of both the stress of chronic pain and depression (76–79). Cognitive therapy assumes that a patient's misconceptions and attitudes about the world and themselves precede and produce symptoms such as anxiety and depression. Therapy identifies habitual ways in which patients distort information (e.g., automatic thoughts) and teaches patients to identify, evaluate, and respond to their dysfunctional thoughts

and beliefs, using a variety of techniques to change thinking, mood, and behavior (See Chapter 16; Table 16.10). Cognitive therapy is a structured, goal-oriented, problem-focused, and time-limited intervention. This active approach involving principles of learning, help the patient develop new and adaptive ways of behaving. Treatment also attempts to alter behavior by systematically changing the environment that produces the behavior; such behavioral changes are believed to lead to changes in thoughts and emotions.

The osteopathic physician employs all their interpersonal skills (see Part II, Approach to the Patient), to elicit information on the patients perceptions of stressors but more importantly, the thoughts, feelings, and behaviors that contribute to lifestyle choices and stress-related symptoms (Fig. 18.1). As a clinician, on average you will perform 200,000 patient interviews during your career (80). The goal is to elicit personal and symptom data, and through an osteopathic health oriented approach, formulate a description of the patients stress-related symptoms and the biopsychosocial factors involved (81,82). The next step is to interpret and synthesize this information along with laboratory and physical/palpation assessments to formulate the biopsychosocial description, a diagnosis and recommendations for treatment (83,84).

Problem Solving

Many patients need to construct understandable and easy-to-explain models of the complex interaction of stressful factors in their environment to effectively cope with stress. The physician must provide the patient with simplified models of how the world works and which steps must be taken to problem solve stress. Many patients like to use simple models to increase their understanding of health problems and the subtle and complex factors surrounding

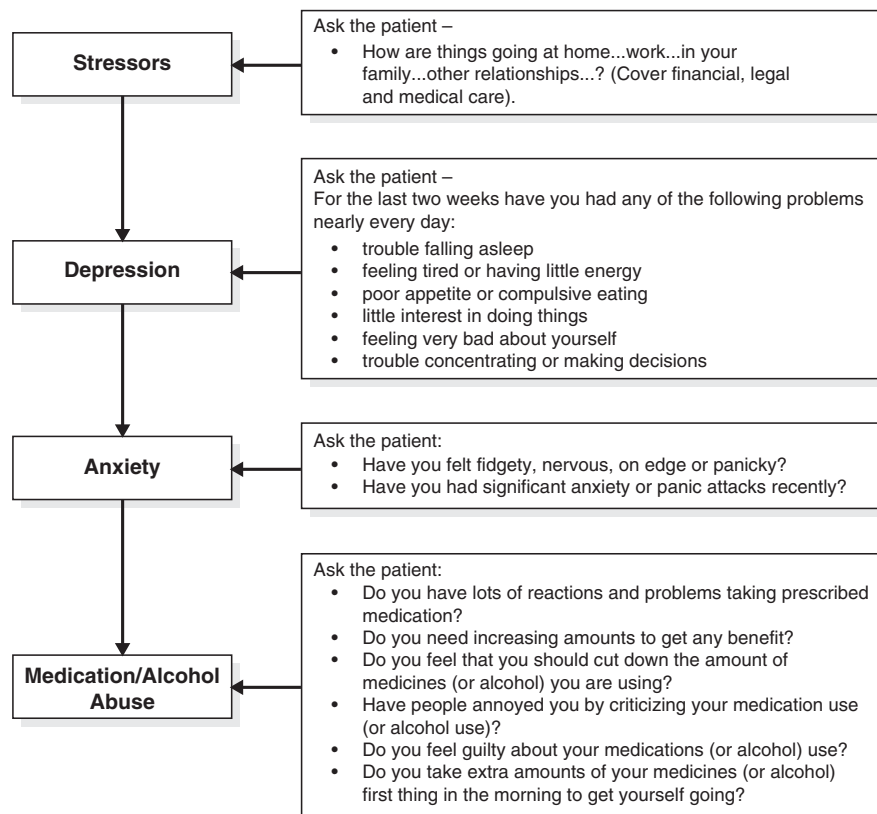

Figure 18-1 Stress evaluation steps.

the risks posed by a stressor. Setting the stage for decreased anxiety and adaptive coping is as easy as taking a moment to listen to the patient's conceptual model of the stressors in his or her life. From there, the physician in a collaborative relationship can offer concrete explanations of the stressors and the risks imposed sharing expert knowledge with the patient (85). One example is telling a patient with back pain that he or she has degenerative disc disease and osteoarthritis. Stated as such this can sound intimidating and hopeless; however, to help the patient understand the diagnosis, the physician can describe the condition from the patient's perspective. Thus, in this example, the patient's diagnosis could be described as "an aging back with stiffness that can be treated in many ways."

Patient Education

Knowledge gives a sense of control and can powerfully mitigate stress (83,84). Education provides patients with information about their diagnosis, its treatment, how to recognize signs of relapse, relapse prevention, and strategies to cope with the reality of prolonged stress. Patients can be given a sense that they can cope by learning to anticipate a potential stressor. The perception that a stressor can be accurately anticipated or stopped increases one's range of problem-solving possibilities and consequent feelings of control. By giving a patient information about stressors before the patient's exposure to them, researchers have reduced the threatening appraisals made when the stressor is experienced. Studies have determined that the stress of surgery or of common medical procedures can be reduced by giving patients accurate expectations, particularly in terms of pain and recovery time. In essence, through adequate patient education and the development of appropriate coping skills, the inescapable stress becomes escapable, the unmanageable stress becomes manageable, and the patient regains control over their life.

Assertiveness Training

The physician often teaches assertiveness and problem-solving techniques. These techniques are most effective with individuals who experience stress as a result of difficulties in self-expression. A lack of appropriate interpersonal skills exacerbates stress-related physical symptoms. For example, an overwhelmingly demanding boss or spouse may be a common cause of stress-related symptoms seen in a primary care setting. By teaching verbal strategies to more effectively deal with excessive and unfair demands, patients learn new and more effective coping behaviors.

Insomnia Management

In the United States, approximately 10 million people consult their health care provider annually for sleep disorders, with half receiving prescriptions for sleeping medications. Epidemiologic studies suggest that 20% to 35% of respondents describe sleep problems as severe or constant for as long as 14 years; however, other health problems are commonly identified as the primary complaint (86). Persistent insomnia is not life threatening. When compared with good sleepers, however, insomniacs experience more (87,88) somatic complaints, anxiety, depression, and have a greater propensity for alcohol and other substance abuse.

An inability to remain asleep is most common initial presentation; this is soon followed by difficulty falling asleep and then by abnormal early morning awakening. Typically, insomniacs are chronically aroused autonomically (anxious), or cognitively distressed and unable to stop thinking and worrying at bed time.

They worry about not getting to sleep and then are too aroused at bedtime to sleep. This worrying leads to fears that they will have poor daytime performance if they cannot make themselves sleep. This initiates a vicious downward cycle, insomnia begets more insomnia and leads to poor learned sleep habits and routines that further exacerbate the insomnia. When insomnia lasts more than 3 weeks, it becomes ingrained and requires specific behavioral strategies to counteract the learned aspects of the insomnia. Current strategies that can mitigate the insomnia include such things as relaxation therapies, stimulus control, distraction techniques, and sleep hygiene education. Evidence from clinical trials and meta-analysis suggests that these sleep habit strategies for insomnia are as effective as sedative hypnotics for acute treatment and more effective for long-term therapy (89,90). CBT for insomnia typically involves visits over six to eight weeks and can be administered in group format (91). Effectiveness has even been shown for patients with insomnia associated with medical and psychiatric disorders (93), and for older patients and chronic hypnotic users (93). A review of evidence-based treatments for insomnia found that 70% to 80% of patients with chronic insomnia showed benefit from sleep habit strategies (94).

Insomnia can be managed effectively by teaching sleep hygiene techniques that employ a variety of sleep habit strategies (Table 18.12). These techniques form the foundation for the guidance that the osteopathically trained physician gives to the patient. When sleep is restored, the patient feels more alert, and there are fewer stress-related somatic complaints. Patients practicing good sleep habits also report improved concentration, better problem solving, and more effective management of their stress.

Augmenting sleep habit strategies with medication for sleep during short intervals is another method used to manage insomnia. A prescription for exercise and a muscular relaxation training tape to be used in the evening hours will also promote better sleep. All this, coupled with encouragement by the osteopathic physician who functions both as educator and guide, will alleviate insomnia.

TABLE 18.12

Good Sleep Habits

Get up about the same time every day, regardless of when you go to bed.

Go to bed only when sleepy.

Establish relaxing presleep rituals.

Exercise regularly and keep active.

Organize your day around regular times for eating and outdoor activities with regular exposure to bright light, which synchronizes circadian cycles.

Avoid caffeine, nicotine, alcohol, excessive warmth, and hunger at bed time.

If you nap, try to nap at the same time every day.

When laying down to sleep, relax all your muscles, particularly your face and jaw, and breath slowly and evenly.

If you do not fall asleep in 20 minutes, get back up and return to bed when sleepy.

Muscular Relaxation

Progressive relaxation is based on the premise that muscle tension is closely related to anxiety. Individuals feel a significant reduction in experienced anxiety as their tense muscles are taught to relax. The teaching of progressive muscular relaxation skills follows a standard procedure. The individual practices muscle relaxation after he or she decides which muscle groups are tense. For example, the individual is instructed to tighten his or her jaw and notice a pattern of feeling strain in these muscles. After maintaining the tension for approximately 10 seconds, the subject is instructed to let the muscle group completely relax, and then to notice a difference in sensation as the places that were previously tense and strained relax. After a few minutes of relaxation, repeat the sequence. The main goal of the training program is to teach individuals what it feels like to relax each muscle group and to provide practice in achieving greater relaxation. Once the individual can discriminate the pattern of tension in a particular muscle group, omit the instruction to tense before relaxing. Instead, the individual must relax the muscle from the present level of tension. The original relaxation procedure required months of training with hundreds of trained muscle sites. Clinical practice employs a much more abbreviated form of training and is easy to teach to the patient in a primary care setting.

Biofeedback

In biofeedback paradigms, the individual is taught to use physiologic monitoring equipment to perceive physiologic processes. Once the physiological process is perceptible, the individual is taught to monitor the process. By receiving auditory or visual feedback, one learns about the close relationship between mind and body. The availability of sensitive recording devices for home use has made it possible to work on these skills in a more organized and regular manner. There are a number of systematic and well-controlled outcome studies that show the clinical effectiveness of Electromyographic Biofeedback (95–97). Temperature biofeedback, which is also receiving positive support in the literature, has been shown to control Raynaud phenomena and migraine headaches. From an osteopathic perspective, biofeedback makes it possible to extend voluntary control over some elements of somatic dysfunction by decreasing arousal responses affecting somatic and viscerosomatic reflex activities. Learning to master these responses helps develop a sense of control and improves confidence in one's self-healing abilities.

Social Support

One of the major factors attenuating stress is an effective system of psychosocial support. The physician should conceptualize a patient's support system as a network of expanding concentric circles with the patient's closest confidant at the center. This social network gives a person the feeling that he or she is valued and cared about. The idea that people need to be surrounded by groups of people who provide love and a sense of belonging is not new. The patient needs help to identify mentors and significant others in his or her environment whom he or she can trust and with whom he or she can share feelings. The importance of having person(s) in whom we can confide cannot be overemphasized in buffering the effects of life stress. Most times, this central confidant is a spouse or best friend, or it could be anyone who demonstrates care, concern, and respect for feelings and opinions. This confidant serves the preventive role of ensuring that all burdens and troubles can be shared. A system of support ranges from the confidence of having

trusted advice available when planning a predicted transition to the comfort and nurturing of friends, neighbors, and community during an unforeseen tragedy. Confidants also help professionals, such as the clergy or physicians, to provide assistance. The osteopathic physician assumes an important role by providing this help and counseling the stressed patient. Referrals to self-help groups in the community such as Alanon and Recovery, Inc. can help to reduce the patient's self-absorption. Participation in these groups also leads to the development of outside interests that are compatible with a lifestyle free of addictions. Last, but certainly not least, religious faith provides the opportunity for a spiritual confidant. Patients for whom a spiritual dimension to life is important derive great comfort and benefit from their belief in power and meaning beyond what can be known in life in the world. Physicians should not underestimate the positive healing power of spiritual belief systems.

Spiritual Support

For patients undergoing elective open heart surgery for coronary artery disease, those experiencing strength or comfort from their spiritual feelings are three times more likely to survive than are those without spiritual support. Those who participate in social and community groups (such as local school programs, senior centers, historical societies, etc.) also have three times the survival rate of those who do not take part in social activity. A 1995 study (98) involving 232 patients over age 55 found that seniors who had both "protective factors," that is, spiritual and social support, enjoyed a 10-fold increase in survival. The amount or type of spiritual or social activity did not matter as much as the *participation, comfort, and support derived from the activity* (98). Why and how spiritual feelings and social support extend life after open heart surgery is not understood. There are many studies corroborating this health-enhancing, life-prolonging effect in a variety of circumstances and population groups. It is well documented, for example, that Mormons (both clergy and devout members) have extremely long life expectancies. The physiologic mechanisms behind longevity, health, and social support are not well understood, however (see Chapter 30, "Integration of Mind/Spirit").

Group Support

Encourage your patient to become involved in settings and groups of people who are coping with stress. This can lead to new patterns of coping behaviors. For example, patients with intractable pain fear physical movement. Having them attend a group aquatic exercise program lets them observe others, perhaps older or in poorer health than themselves, moving without damage or injury. This vicarious learning lessens the patient's apprehension when the painful area is moved. In managed care population studies, group sessions for identified high utilizing distressed patients, including education, social support, and coping skills, as well as an opportunity to individually interact with a physician after the session, improved patient satisfaction and led to lower costs for hospitalization, as well as fewer emergency department visits and subspecialty referrals (7,99).

CONCLUSIONS

The osteopathically trained physician has many available tools to employ a broad approach to stress-related problems, including varieties of somatic dysfunction. Anxiety, depression, insomnia, and drug and alcohol abuse are common symptoms seen in

primary care offices. Osteopathic management can be practiced in three ways:

1. By treating symptoms as they are reported and observed.
2. By giving advice on managing stressors.
3. By guiding and mentoring stress-related responses toward positive coping behaviors and strategies (the most rewarding).

Successful diagnosis depends on the understanding the interaction of the biopsychosocial factors that lead to stress-induced problems. Successful treatment depends on giving clear explanations so that the patient understands the mechanisms that perpetuate his or her distress. The long-term goal to assist the patient toward self-mastery and self-healing through a collaborative doctor—patient relationship based on treating the whole person—mind, body, and spirit.

Life Stages—Basic Mechanisms

JED MAGEN, ALYSE LEY, DEBRA WAGENAAR, AND STEVE SCHEINTHAL

KEY CONCEPTS

- Human development involves the complex interaction of biological influences and environmental effects.
- Infants come equipped with preprogrammed capabilities that have evolved to maximize survivability.
- Adolescence marks a time of profound biobehavioral shifts with reorganization of cognitive, emotional, and biologic functioning.
- The definition of adulthood and the transition to geriatric status is fluid.
- While we often tend to view elderly individuals as a homogeneous group, there are actually tremendous variations in the physical and emotional aspects of aging.
- The definition of “older adult” depends upon the context in which it is given. Age-related changes begin by the third or fourth decade of life.
- The major focus of geriatric care is optimizing function, avoiding institutionalization, and maintaining the older adult in the community.
- A mental status examination is a part of thorough geriatric evaluation.

Human development involves the complex interaction of biological influences and environmental effects. From the time of conception through death, the individual continuously develops. The process of development and the phases of development, however, follow a paradigm that is discontinuous. Transitions from one phase of development to another are characterized by “biobehavioral shifts” (1). These times of transition involve relatively abrupt reorganizations of biologic, cognitive, affective, and social characteristics resulting in more complex behaviors and abilities by the organism (2). Recent studies have demonstrated that the dramatic physiologic and “psychological competencies” that occur in early development, especially during the first two years of life, are temporally correlated with the anatomic, biochemical, and physiologic changes occurring in the brain (3).

The timing and genesis of a biobehavioral shift is mediated by and dependent upon the expression, repression, and depression of genes that are themselves both environmentally and biologically influenced. Phenotype is the observable physical or biochemical characteristics of an organism as determined by both genetic makeup and environmental influences. Cells can modulate functions in response to internal and environmental factors. The theory of “phenotypic plasticity” explains the ability of a specific environmental stressor to alter the phenotypic expression of a gene (4). Defects in plasticity alter genes and stem cell processes leading to many forms of cancer (5,6). From an evolutionary perspective, organisms continuously attempt to manipulate their environment in ways that are beneficial to them. An abnormality in development resulting in a disorder or disease process may be an adaptive response to an environmental stressor. The influence of genes in early development may also result in a disease process in later development. For example, gene and prenatal environmental interactions are correlated with adult health, including the risk of coronary artery disease and type 2 diabetes (7). Genes not only impact physiologic mechanisms resulting in disease, they also shape psychological developmental outcomes. Serotonin transporter promoter polymorphism, or the variation in serotonin transporter genes, is linked to

temperament, antisocial behavior, and substance abuse disorders among adolescents (8).

The move from childhood to adolescence is a particularly cogent example of a “biobehavioral shift.” Puberty is associated with an upsurge in sexuality with very different behaviors toward the opposite sex, for example, an increase in aggression and striking physical changes and cognitive changes (9). Relationships during adolescence transform from a family-centered focus to a peer relations focus. Adolescence also marks a change in the epidemiology of various disorders. Illustrating this change, the sex ratio for depression changes from 1:1 to a larger predominance in females.

PRENATAL PERIOD

Rapid development during the prenatal period is influenced by multiple factors. Embryogenesis is affected by the complex interactions between genes and the intrauterine environment. Genetic predispositions are determined by maternal and paternal gene composition prior to conception. The association between maternal age and the increased risk of chromosomal abnormalities such as trisomy 21 has long been established. Paternal age also appears to contribute to the etiology of birth defects, including heart, gastrointestinal, and musculoskeletal defects, as well as chromosomal abnormalities (10).

In utero environmental factors, such as exposure to alcohol, drugs, maternal malnutrition, and maternal stress, influence prenatal growth and development. Cigarette smoking and malnutrition are associated with decreased fetal growth and low birth weight. Alcohol exposure can result in fetal alcohol syndrome, which occurs in 1 in 500 to 1,000 live births, and includes characteristic facial features, mental retardation, behavioral abnormalities, and language delays (11). There is now evidence that fetal alcohol exposure should be considered in the pathogenesis of some cases of attention deficit hyperactivity disorder (ADHD), depressive disorder, oppositional defiant disorder, conduct disorder, and specific phobia (12). Maternal wellbeing is essential to fetal growth and development. Multiple studies have demonstrated the influence

of maternal psychopathological symptoms and the impact on the developing fetus. Untreated depression during pregnancy has been linked to preeclampsia, spontaneous abortion, early labor, bleeding during gestation, small fetal size, low birth weight, preterm delivery, increased neonatal care unit admissions, and elevated cortisol levels in the neonate (13). Prenatal exposure has also been linked to early childhood behavior disorders. Children born to mothers who endured intimate partner violence during pregnancy have significantly more behavioral disorders than their counterparts (14). Prenatal stress has been implicated as an important factor in the neurodevelopment of cognitive abilities and fearfulness during infancy (15).

Attachment begins prior to infancy. As the embryo completes its transition into a fetus and the fetus develops into the neonate, mothers and other family members undergo an emotional transformation. In preparation for childbirth and caring for the infant, mothers often become preoccupied with herself and the pregnancy. This phenomenon is especially pronounced after fetal movement is detected. Fathers may initially experience attachment when viewing their fetus through sonographic examination or when they can feel fetal movement through the mother's abdomen. Complications such as preterm delivery can adversely affect the infant and the developing relationship with parents. The complex measures used to sustain premature infants oftentimes make it difficult for parents to develop attachments to their infant. Parents may not perceive the infant responding to them as a term infant would. This lack of reciprocal interaction can begin to shape the infant-parent interaction and add to complications in growth and development, sometimes leading to later behavioral difficulties. The neonatal care unit is not an atmosphere that fosters the parent child dyad. Parents of preterm children are often unable to feed or care for their infant in the usual ways. Preterm infants are at risk for severe neurological and physical disabilities as well as eating disorders, ADHD, learning disabilities, visual-motor disorders, and language impairment. The stress of preterm delivery and adjustment to caring for a medically ill child places the mother-infant relationship in jeopardy. Early family support and intervention while the infant is in the hospital and during the transition home help to decrease stress and the risk of maternal depression, thereby increasing positive mother-child interactions (16,17).

INFANCY

On the 18th day of gestation, the nervous system begins to develop (114). Brain growth and development in the fetus proceeds in a predictable manner from the brainstem to the cerebral cortex (18). At birth, the gross anatomical structure of the brain is nearly identical to the adult brain, but the complex neural connections and pathways will continue to develop until adulthood. The limited capacity of the female pelvis to accommodate the fetal head forces brain growth to continue outside the uterus. Given this limit on brain size, infants are equipped with only those capabilities needed for survival. The brainstem is almost fully functional in the newborn but the forebrain and limbic structures are immature by comparison (19). Infants come equipped with preprogrammed capabilities that have evolved to maximize survivability. Adaptive reflexes including rooting, sucking, grasping, and Moro allow the infant to feed and maintain close contact with the caregiver. Less overt capabilities are also present in the infant at birth. Newborns engage in complex visual activities. They scan patterns by means of eye movements going back and forth across edges (20). At birth, infants discriminate their mother's voice from the voice of others. Between one and four months of age, infants gain

the ability to discriminate speech sounds (21). These and other abilities allow infants to participate in the dyadic interaction with the primary caregiver known as attachment. These innate preprogrammed behaviors and capabilities are critical in the attachment process. Attachment can be defined as "an enduring emotional bond uniting one person with another" (22). Preprogrammed behaviors and predispositions of the infant serve to help develop a secure attachment between the infant and care giver, allowing optimal psychosocial development to take place. Instinctive caregiver behaviors also contribute to the attachment process. Caregivers tend to hold infants at a distance maximizing face-to-face contact, engage in exaggerated greeting behaviors, and imitate infants' facial and vocal expressions. All these behaviors promote attachment (24). Newborns reciprocate by making eye contact and vocalizing. The temporal relationship that exists between the neurobiological development of the brain and the emergence of more complex behaviors is evident in the acquisition of developmental milestones that allow the infant to participate in more complex interactions with caregivers and their environment. The appearance of a social smile by eight weeks helps to engage the caregiver, thereby promoting the reciprocal relationship. By 2 to 3 months, preprogrammed neonatal reflexes begin to disappear allowing the emergence of more complex abilities. Cortical inhibition of the brainstem causes the palmer reflex to recede and spontaneous crying becomes less prominent. Simultaneously, the hippocampus and surrounding structures develop the sophistication to permit the beginnings of recognition memory, allowing the infant for the first time to store events from the immediate past, thereby promoting the infant caregiver relationship. Working memory, the ability to compare past and present, emerges in the form of stranger and separation anxiety develops at approximately 7 to 10 months of age and coincides with the maturation of the prefrontal cortex, hippocampus, limbic system and the integration of the hypothalamic-pituitary axis (25).

New behaviors that elicit stimulation from caretakers conversely contribute to brain growth and development in infants. The brain grows most rapidly during the first year of life. Glucose use in the cerebral cortex rises from birth to 4 years; at age 4 it is twice that of the adult. During the first two years of life, there is tremendous growth and proliferation of neurons, axons, dendrites, and synapses. As time passes, these complex networks are pruned in part based upon how actively they are used (26). This "use it or lose it" phenomenon partly accounts for the smaller brain growth seen in cases of deprivation. Failure to thrive is typified by infants who do not demonstrate appropriate growth or achievement of developmental milestones. This diagnosis can be divided into two categories based on whether the etiology is organic or environmental. The earliest sign of failure to thrive is often the lack of a social smile. This is the direct result of the inability to achieve a relationship with the caretaker that involves handling and positive interaction. There is experimental evidence that touch, in part, operates as a soothing mechanism in animals by activating brain opiates (27). This mechanism may be operative in the therapeutic effects of osteopathic manipulative medicine.

The importance of closeness and touch is well documented in the literature on breast feeding and developmental outcomes. Breast milk provides multiple health, nutritional, and immunologic benefits as well as the perfect natural setting for bonding and attachment to take place. Breast feeding has also been implicated in the earlier development of language and motor skills (28). A growing body of research indicates that breast feeding is associated with increased cognitive abilities and later academic achievement (29). The long-chain polyunsaturated fatty acids,

docosaheptaenoic acid and arachidonic acid, found in human milk are essential in the growth and development of the central nervous system (CNS). Many studies suggest that the fatty acids found in breast milk confer long-term benefits as well. Early infancy and childhood nutrition are linked to diabetes and atherosclerosis in adulthood (30,31).

Infancy is a critical time for attachment and bonding. Decreases in the normal expected quantity or quality of stimulation as seen in post partum depression may have profound effects on the development of the infant. Infants of depressed mothers exhibit dysregulated neurobiological rhythms including elevated norepinephrine and cortisol levels, decreased vagal tone, and right frontal EEG activation. They show lower scores on the Bayley Scale for infant development and growth delays up to 12 months (32). Maternal impairment during infancy may have lasting effects throughout childhood. Post partum depression has been linked to emotional, cognitive, and behavioral disorders in infants and children (33). An analysis of the literature on child behavior demonstrates the

negative effect of post partum depression on “later distractibility, antisocial and neurotic behavior” that may continue until age 5. The degree of cognitive and behavioral effects on the child is directly correlated to the severity and duration of the depressive episode in the mother (34).

Adaptability, the ability to modulate and change behaviors in conjunction with the environment, is an important attribute in both infants and caregivers. For example, a parent who is unable to remain calm and soothe an irritable, cranky infant is likely to have an infant who is in fact irritable and crying most of the time. The situation, sometimes labeled as colic, may be the result of a mismatch between what the parent is able to provide and what the child needs. Competent caregivers are able to modulate their infant’s arousal caused by displeasure, fear, or frustration by calming the infant and returning him or her to a tolerable emotional state. Given at least average parenting, most infants are able to obtain the stimulation and nurturance needed from the environment to progress developmentally (35,36).

Age	Gross Motor	Fine Motor	Language	Social
1 month	Elevates head momentarily from prone position	Tight fist grasp	Responds to sounds	Prefers the human face
3 months	Steadily holds head up in midline	Hands held open at rest, reaches for objects	Coos	Anticipates feeding
4–5 months	Rolls over	Hand-to-hand transfer	Laughs	Visually explores environment
6 months	Sits up	Raking grasp	Babbles	Stranger recognition
9 months	Crawls, pulls self to standing position	Immature pincer grasp, holds bottle	Waves bye-bye, understands “no”	Plays games “pat a cake”
12 months	Walks	Mature pincer grasp	Uses single words	Begins to imitate actions
18 months	Runs	Scribbles, three block tower	Combines two words	Copies parent tasks
24 months	Walks up/down steps	Draws a line, removes shoes and pants, seven block tower	Follows two-step commands, uses two-word sentences	Parallel play
3 years	Rides tricycle	Draws circle, undresses self completely	Vocabulary at least 250 words, uses three word sentences	Gender identity, full name and age
4 years	Jumps, hops on one foot, alternates feet going up and down stairs	Draws square or plus sign, dresses self completely	Knows songs, poems, and colors	Plays cooperatively with others
5 years	Skips, jumps over object	Draws triangle	Writes name, some letters, and numbers	Plays games and understands rules

AGE 1 TO 5

Prominent language, motor, social, and emotional changes develop between the ages of one and five. The abundant number of synapses and continued growth and proliferation of neural connections in the first 2 years is demonstrated in the rapid acquisition of developmental skills and milestones. Expressive language becomes evident by the end of the first year. Receptive language exceeds expressive language until approximately the age of 4 to 5. The child’s language progresses from cooing (3 to 6 months) and babbling (6 to 18 months) to single words (12 months). The appearance

of single words between the age of 8 and 18 months marks a transition after which time there is rapid acquisition of words (37). At this age, children also begin to walk allowing them to explore their environment more independently. A sense of one’s own body also begins to emerge in a coherent way. Gender identity appears to be set by age two and a half (38). As the children gain motor and language skills, a sense of self and independence develops. With increasing self-reliance and a developing ability to understand and evaluate social situations comes the appearance of behavior that differs from those desired by the parents. The suddenly-less-than-compliant

2- to 3-year-old has entered the “terrible twos,” a period often marked by a strong need for autonomy that often leads to oppositionality. Consistent and calm limit setting often helps parents navigate through this sometimes challenging time.

Children in the United States become interested in toilet training between age 2½ and 4. Most children in the United States are trained by age 3. Readiness for toilet training is based upon social-emotional skills, the acquisition of motor skills and sphincter control. Intensive toilet training prior to 27 months of age is not associated with earlier completion of training and is likely to take significantly longer to master (39). It is important not to develop a battle of will around toileting issues. Healthy children with complicated toilet training more often are found to have constipation and difficult temperaments (40).

The toddler and preschool years are often complicated by the introduction of a new sibling. Many children will feel displaced by this intruder. It is not unusual for children to oscillate between excitement and anger. Children often displace anger onto inanimate objects such as toys. Regressive behaviors including bedwetting, thumb sucking, or oppositionality may be observed. Opportunities to be alone with parents, to engage in pleasurable activities, and to safely displace anger are essential.

Parenting is crucial in the growth and development of children. Children who are exposed to adverse events during early childhood may be impacted for life. Child Protective Services investigated 3.5 million cases (5% of all children in the United States) of child abuse or neglect in 2004. The majority of abuse cases and deaths from child maltreatment occur in children under the age of 4 (41). Children who are abused or neglected in early life suffer enduring behavioral and neurobiological consequences. At a minimum, they appear to have increased vulnerability for psychiatric disorders (42). Abuse is correlated with a host of maladaptive behaviors and psychiatric difficulties in young children, including personal and academic difficulties, aggression, suicidal behavior, risk taking, and diagnosable psychiatric disorders (43). Recent literature suggests that exposure to early childhood abuse and/or neglect may alter brain structure and function. Exposure to abuse is associated with EEG abnormalities, alterations in the corpus callosum, and decreased synapse density and volume in the hippocampus. There appear to be critical periods during early childhood when discrete brain regions are most sensitive to stress and likely to be altered (44). Early maltreatment has a dramatic impact on the developing hypothalamic-pituitary axis. Child abuse has long-term consequences on basal cortisol levels and the ability of the Hypothalamic Pituitary Adrenal (HPA) axis to respond to stress (45).

SCHOOL AGE CHILD

Generally, children from school age to puberty are considered to be school age or latency age children. The major tasks of this period are cognitive development and socialization. Central experiences for children during this period are the family and school. Attendance at preschool or public school may be a child's first experience with adults other than parents. A premium is placed in this setting on the ability to interact in socially appropriate ways with other children and adults. Rapid advances in interactional abilities take place. Children begin to learn strategies for continuing interactions and for reengaging after rejection and failure in groups. Self-concept and internalization of self-identity is heavily dependent on these early experiences in school. Cognitively, Jean Piaget noted that young school age children are dominated by “centration.” They tend to view events as happening to them or in some way being affected by them. For example, children in this age group who experience parental divorce usually think that they, in some way,

caused the divorce. It is not unusual to see increases in depression, oppositional, and angry behaviors and declines in school grades as a result. Objects also tend to be measured and defined by only a few of several possible dimensions and may be classified in idiosyncratic ways. Children may measure the volume of a column of water exclusively by its height or width without taking into account changes in both parameters (46). Piaget termed this preoperational thinking. Children who learn how to recognize constant qualities or quantities of material even when the material changes shape or color are said to have achieved the concrete operational level.

This is also a time period when personality is rapidly developing and changing. A 6 year old is very different cognitively, socially, and emotionally from a 10 year old. There is always debate about what the major influences on personality are. Table 19.1 lists those thought to be most important. We have discussed temperament in an earlier section of this chapter. Basic components of parenting include consistency and limit setting. The importance of parenting is reflected in the numbers of programs developed to help parents with these kinds of skills. Most do not have any experimental verification. One well-known model that seems to have empirical validity has been used in schools and by mental health professionals for over 30 years. The Love and Logic model (Charles Fey, Ph.D.) (<http://www.loveandlogic.com/>) postulates that (1) children learn the best lessons when they're given a task and allowed to make their own choices (and fail) when the cost of failure is still small; and (2) that the children's failures must be coupled with love and empathy from their parents and teachers. The California Evidence-Based Clearinghouse for Child Welfare reports no research studies that document efficacy. Expressed emotion (EE) is a concept that, in contrast, is well studied in many different populations. EE consists of parental critical comments, hostility, and overcontrol. High levels of criticism especially have been correlated with poorer outcomes in children with physical disabilities and psychopathology (47,48). School quality seems to be related to both academic achievement and to healthy personality development. The way children relate to peers is important in overall adjustment. Students who had good relationships with teachers and peers did better in terms of engaging in school emotionally and behaviorally (49). There is good evidence that on balance, birth order affects intellectual performance (50) and personality characteristics within the family constellation, but perhaps not outside the family (51). It has been pointed out that the protests of the 1960s resulted in a cohort of individuals who are less likely to listen to authority and to follow social conventions (52).

TABLE 19.2

Common Psychiatric Disorders in School Age Children

Separation anxiety disorder
Attention deficit hyperactivity disorder
Learning disorders
Oppositional defiant disorder

Psychiatric disorders as listed in Table 19.2 commonly begin in this age group. Depressive disorders are present but are less common. Children date the onset of internalizing disorders like depression earlier than their parents so that when identified, depression and anxiety disorders have likely been present for a longer time. On the other hand, parents and children agree about the timing of onset of externalizing disorders like oppositional defiant disorder (53).

It appears that childhood behavioral disorders are fairly stable into adolescence, so that the presence of a behavior disorder in childhood is predictive of disorder into adolescence (54). Importantly for adults, it appears that most lifetime psychiatric disorders first appear in childhood (53). This makes identification of psychiatric disorders in children critically important for treatment and prevention. In one survey of 1,060 pediatric practices, approximately 16% of patients were identified with psychiatric disorders and 55% of parents who reported a psychiatric disorder did not report discussing it with their pediatrician (55). Rates of use of mental health services for children are lower than indicated based on rates of disorder (56). Based on this and other data, identification and referral for children and adolescents with psychiatric disorders is a problem. Primary care practitioners can improve identification by using parent- and patient-completed standardized questionnaires they can then review (57). Table 19.3 lists some of these questionnaires.

ADOLESCENCE

Adolescence marks a time of profound biobehavioral shifts with reorganization of cognitive, emotional, and biologic functioning. Adolescence generally coincides with the onset of puberty. In females, breast budding precedes menarche by about 1 year (58). In males, the onset of puberty is marked by pubic hair and penile growth (58).

Strengths and difficulties questionnaire

The initiation and onset of puberty illustrates the complex interplay of genes and environment. The initiation of puberty is under control of multiple genes (59), and it is estimated that genes account for about 75% of the variation in time of onset of puberty (60). Consider, however, that female athletes tend to have delayed menarche based on body fat levels determined by diet and exercise. This illustrates the complex interplay of genetic and environmental factors.

Cognitive and social-emotional factors are extremely important during this time period. Cognitively, adolescents move from the state of concrete operations to formal operational processes (47). They begin to grasp highly abstract concepts and manipulate them. They develop the ability to use deductive and inductive reasoning to solve problems.

Development of these executive functions is related to marked changes in brain growth and organization that occur in adolescence. There may be a critical period for brain growth and development during this time. The prefrontal cortex and limbic systems undergo extensive reorganization. Dopaminergic and serotonergic inputs increase to frontal lobes, and there is an increase in gray matter volume resulting, in part, in greater frustration tolerance and better ability to delay impulses. There appears to be overproduction of neurons and synapses early in adolescence and pruning later on. As in earlier childhood, the amount, types, and quality of interaction and stimulation probably heavily influence this remodeling/production/pruning process (61). For example, tasks of selective attention, working memory, and problem solving improve consistently during this period and correlate with frontal cortical synaptic pruning and myelination (62). Drugs or injuries related to sensation seeking can cause profound behavioral and neurobiological distortions affecting the rest of life. Some studies show that in animals, adolescent brains are uniquely sensitive to alcohol (63).

Perhaps the hallmark of adolescence is the process of separation-individuation (64). Adolescents develop a relatively stable adult personality structure that tends to endure and as part of the process, they gradually separate from their family. Many factors contribute to and interact with this critical developmental process. Cognitively, adolescents can now conceive of a larger world and others outside their family as being relevant and important. Their peer group begins to be more important than parents regarding matters like dress, opinion, and in numerous other ways. They are overwhelmingly concerned with relationships with the same and opposite sex. This is not accidental or only determined by cultural norms. Adolescents use these new relationship abilities and their newly developed ability to think independently in order to separate from their family, build an increasingly independent lifestyle, and develop a character structure capable of self-regulation and independent action. Most adolescents have some conflict with their parents around at least a few things, and this may even enhance the process. However, viewing this time as a developmental period of turbulence does not seem to be true for a substantial number of adolescents. Offer and colleagues (65) documented a large group of male adolescents who seemed to go through this period of time in a "continuous growth" mode. They found little evidence of conflict or turmoil with family members, and this group was able to integrate various experiences of adolescence and to accept cultural and societal norms without conflict.

Some adolescents separate in maladaptive ways. Individuals who engage in delinquent acts are in part choosing an alternative path of separation from the family. There is also good evidence for gene-environment interactions related to some maladaptive behaviors. For example, Nilsson and colleagues report that individuals with the short variant of the MAO-A gene and who had

been maltreated or abused or who came from families with poor relationships showed the highest scores on alcohol-related problems (66). Another group reported in 2007 that in a sample of males referred for forensic assessment, high adversity in child impacted later life violence only if the short form of the serotonin transporter gene was present (67). These studies demonstrate that one has to have both the gene and the environmental insult to develop the maladaptive behaviors described.

Individuals with chronic diseases may need more care and may not be able to become as independent as quickly as peers. In reaction, they may become neglectful of diets or insulin injections or other care needs. Adolescent diabetics with frequent ketoacidotic episodes might be engaging in a maneuver to express independence in the only way easily available. The opposite also occurs. Some adolescents never really separate and remain childish and enmeshed with parents. College and professional education can extend adolescent-like dependency into the 20s and 30s with continuing financial dependence on parents. This pattern may be particularly pertinent to medical students.

Other patterns of progression through adolescence occur. That which we consider normative is, in part, culture bound. In some cultures, preadolescent and early adolescent male homosexuality in normative and does not seem to result in large numbers of homosexual adults. In a number of cultures, there is a sharp demarcation between adolescence and adulthood with rites of passage.

Hamburg (68) comments that the fundamental requirements for healthy adolescent development are:

1. finding a valued place in a constructive group
2. learning how to form close, durable human relationships
3. feeling a sense of worth as in individual
4. achieving a reliable basis for making informed choices
5. knowing how to use the support systems available to them
6. expressing constructive curiosity and exploratory behavior
7. believing in a promising future with real opportunities
8. finding ways to be useful to others
9. learning to live respectfully with others in circumstances democratic pluralism
10. cultivating the inquiring and problem-solving skills that serve lifelong learning and adaptability

Practitioners seeing adolescents should be supportive of normal developmental processes. Seeing adolescents alone for at least a part of the medical visit is important and supports the process of separation-individuation.⁵²

ADULT DEVELOPMENT

The definition of adulthood and the transition to geriatric status is fluid. For instance, medical students often have a prolonged period of dependency on others due to the length of training without opportunity to be employed. One is earning money while in residency, but is still in many ways a trainee. The transition to independent wage earner is gradual. Meanwhile, medical students and residents are often establishing families, having children, and acquiring all the other traditional trappings of independent adult life.

Furthermore, individuals progress through life stages at different rates. A 35-year-old woman may be a new mother, or in some settings, a new grandmother.

Personality is generally quite stable in adulthood. This should not be taken to mean that there are no changes. An individual at age 30 is certainly going to be different from the same individual at 40 or 50. However, change is much more gradual than in

younger age groups. A sudden personality change is grounds for suspecting CNS disease. For instance, a patient who presents with the development of depression at age 52 with no history of psychiatric disorder, or a patient who begins to make impulsive decisions and sexually inappropriate comments needs to be worked up medically for space-occupying lesions as well as neurodegenerative disorders.

Eric Erickson's psychosocial stages of development in adulthood include:

1. Intimacy versus Isolation: Developing a cooperative, close, and supportive relationship with a spouse or significant other, often leading to starting a family, is a major task. Negotiating between parents around who does what at home and who takes care of the children at what times are major issues in a society where often both spouses work. Nontraditional family settings with a single parent or two parents of the same sex are more and more common and present their own challenges related to intimacy, childcare, and support.
2. Generativity versus Stagnation: A concern for and active involvement in guiding the next generation is a characteristic of individuals who achieve generativity. People who are generative also have fulfilling work and relationships. Contrast this lifestyle and values to persons who are without intimate relationships and who dislike their work and are waiting to retire.
3. Integrity or Ego Integrity versus Despair: This stage is discussed under geriatrics below.

One of the few studies to look at long-term aging followed several groups of men and women over a 60-year period. George Vaillant describes six factors in middle age (50) that have seem to be correlated with getting to age 80:

- Having a warm marriage
- Possessing adaptive coping strategies
- Not smoking heavily
- Not abusing alcohol
- Getting ample exercise
- Not being overweight

These people are more likely going to be the "happy well," people "who subjectively enjoy their lives and are objectively healthy" (69). Physicians see these people less often in their offices than the worried well or those who have debilitating chronic illnesses.

GERIATRICS

Introduction

Aging is a diverse, complex phenomenon that requires the physician become aware of both normal and pathological changes associated with it. The osteopathic physician's holistic perspective is especially advantageous in helping geriatric patients with complex medical, psychosocial, and end-of-life issues. While we often tend to view elderly individuals as a homogeneous group, there are actually tremendous variations in the physical and emotional aspects of aging. To this end, physicians must be aware of the normal and pathological changes linked to late-life development. Osteopathic physicians bring a comprehensive patient view and manual medicine skills that are tremendously valuable when treating chronic diseases and associated musculoskeletal disorders that are so often seen in elderly individuals.

The definition of "older adult" depends upon the context in which it is given. The establishment of Medicare in 1965 provided the cut off at age 65, an age at which individuals could receive full Medicare and Social Security benefits. Gerontologists have used a

broader definition, considering age 60 the beginning of late life. In contrast, some cultures equate the term “old” with what the western world would consider middle age, that is, age 45. However, more recently geriatricians have divided late life into young old (age 65 to 75), older-old (age 75 to 85) and old-old (age 85+) (70).

The 2000 U.S. Census reports that 12.4% of the U.S. population is over age 65. Among the older population, those “old-old” age 85 years plus showed the highest percentage increase, moving from 3.1 million to 4.2 million adults nationally. In 2000, there were over 50,000 centenarians living in the United States, suggesting increasing longevity for our oldest citizens (71). Centenarians are expected to exceed 1 million by 2040. Of note, by 2030, the older population is expected to double from 2000 census figures, increasing to 71.5 million people (72). The oldest living adult was Jeanne Calment, who died in 1997 at age 122 in France (73).

Cellular Changes Associated with Aging

There are a number of possible explanations for why cells decline resulting in aging of the organism. Although no single theory is generally accepted, researchers currently view the impact of environment upon genetic substrate as a possible reason for such variability in the aging process.

Hayflick limit purports that genes do not drive the aging process, but the general loss of molecular fidelity does. There are a finite number of cell divisions possible. This theory explains that aging is the result of changes that occur in molecules that have existed at one time with no age changes. Aging is considered a molecular disorder with an escalating loss of molecular fidelity that ultimately exceeds repair and turnover capacity and increases vulnerability to pathology or age-associated disease (74).

Telomere shortening is another theory of cellular aging. Telomeres serve to camouflage chromosome ends from the DNA damage response machinery. Telomerase activity is required to maintain telomeres. One consequence of telomere dysfunction is cellular senescence, a permanent growth arrest state. The introduction of telomerase is proposed as a method to combat ageing via cell therapy and a possible method to regenerate tissue (75).

The free radical theory of aging by Harman proposes that reactive oxygen species are a cause of aging. Chronic states of oxidative stress exist in cells even under normal conditions. However, an imbalance leads to a steady-state accumulation of oxidative damage in a variety of macromolecules that increases during aging, resulting in a progressive loss in the functional efficiency of various cellular processes (76).

Genes may also impact the aging process. Developmental genetics theorists propose that aging is genetically programmed and controlled by influences in the second half of life. Both oxidative stress and DNA methylation are possible regulators of gene expression. Examples of genetic influences in aging are Apolipoprotein (ApoE-4) in the development of Alzheimer disease and coronary heart disease and longevity (77).

Inflammation may be linked to cellular aging. A large number of studies have documented changes in Zinc metabolism in experimental animal models of acute and chronic inflammation and in human chronic inflammatory diseases. In particular, modification of zinc plasma concentration as well as intracellular disturbance of antioxidant intracellular pathways have been found associated to age-related inflammatory diseases, like atherosclerosis. Zinc deficiency in individuals genetically predisposed to a dysregulation of inflammation response may play a crucial role in causing adverse events and in reducing the probability of successful aging (78).

Other aging theories focus on inflammation and evolution. Chronic inflammatory conditions (as demonstrated by increased homocysteine and plasma cholesterol levels) may shorten the lifespan by causing cellular damage and diverting resources (79). Evolutionary theories include the notion that genes that are adaptive in early life may be harmful later in life when natural selection is not operative.

Physical Changes Associated with Aging

Age-related changes begin by the third or the fourth decade of life. Physical changes appear to happen earlier and more dramatically than do psychological changes. Although previously considered a constant phenomenon, genetic research offers another explanation, namely that individual genes impact the rate of aging decline (80).

Body Composition Changes

Throughout life, there are three specific periods in which there is notable increase in fat mass, specifically early in life, during pregnancy and lactation, and with aging. The increase in body fat and decrease in lean body mass and body water seen in aging may be protective from an evolutionary standpoint, providing body calorie reserves to withstand periods of illness (81). Total and central body fat increase with aging.

Because of these changes in total body fat, drugs that are lipid soluble may have prolonged half-lives in the elderly. This alternation in pharmacokinetics with aging must be accounted for when prescribing or evaluating treatment regimes in this population. For example, while diazepam (Valium) has a half-life of 20 hours in a 20-year old, due to increased fat storage the half-life in an 80 year old may be 80 to 100 hours (82).

Skin Changes

Skin changes are well-known markers of aging. The skin loses its elasticity and sagging appears. Wrinkles increase significantly during the second half of life. Other changes include the loss of subcutaneous fat, sweat glands, and increased capillary fragility. Chronic inflammation also appears strongly linked to many preventable and treatable skin diseases and conditions such as visible skin aging. Mucocutaneous inflammation may be the final common pathway of many systemic and mucocutaneous diseases (83). Sex steroids modulate epidermal and dermal thickness as well as immune system function, and changes in these hormonal levels with aging and/or disease processes alter skin surface pH, quality of wound healing, and propensity to develop autoimmune disease, thereby significantly influencing potential for infection and other disease states (84).

Skin issues become increasingly important in the elderly. These include bruising, skin tears, changes in body temperature regulation, and pressure sores (85). Adequate nutrition and mineral supplementation, management of shear forces, body positioning, and physical health are a few of the many critical components of good skin care management in late life.

Sensory Changes

Hearing and vision decline with normal aging. Ophthalmic changes include loss of elasticity of the lens resulting in presbyopia. Many older adults experience a variety of visual perceptual problems resulting from aging-related changes in the optics of the eye and degeneration of the visual neural pathways. These problems consist of impairments in visual acuity, contrast sensitivity, color discrimination, temporal sensitivity, motion perception, peripheral visual

field sensitivity, and visual processing speed (86). Visual changes can make it more difficult to read, encouraging older adults to use back lighting as well as large print materials to accommodate to these changes.

Hearing diminishes with well-documented loss of auditory neurons and cochlear hairs (87). The resulting presbycusis (a decreased ability to hear high-pitched sounds) can also lead to misunderstanding of information and conversations. It becomes increasingly difficult to hear conversation with background ambient noise, making conversation in a crowd quite difficult. Paranoia may result from misunderstanding and sensory loss. An older adult may withdraw from social situations as a way to deal with hearing loss or ensuing paranoia. Accepting the need for hearing aids can be a slow process for some older adults who experience denial of their problem.

Taste and smell change with aging. In general, both young and elderly confuse salty and sour much more than they confuse sweet and sour (88). Changes in taste can impact diet and nutrition, causing decreased food intake and enjoyment in eating. The sense of smell is more impaired by aging than is the sense of taste (89). As with taste, if smell is impaired the older adult may be less likely to enjoy the smell of food and the impact of smell on digestion and appetite.

Brain Changes

Age-related neuronal dysfunction, which must underlie observed decline in cognitive function, probably involves a host of other subtle changes within the cortex that could include alterations in receptors, loss of dendrites, and spines and myelin dystrophy, as well as the alterations in synaptic transmission (90). Loss of brain weight with cerebral atrophy has been demonstrated on MRI. Both whole brain metabolism and frontal lobe metabolism decrease significantly with age (38% and 42%, respectively), whereas cerebellar metabolism does not show a significant decline with age (91). Many elderly individuals demonstrate increased time to recall memories. On the whole, it is important to know that memory loss and dementia are never normal parts of the aging process.

Musculoskeletal Changes

Age-related changes to the musculoskeletal system have tremendous impact on the older adult. Muscles achieve peak force in women in their 40s and then force trends downward for those in their 50s and 60s, with significant reductions by the 70s. Tactile acuity, vibration sensitivity, and joint position sense for a non-weight-bearing toe-matching task were significantly reduced by the 40s or 50s, with further reductions by either the 60s or 70s (92). In addition, decreased muscle mass and demineralization contribute to falls and to fractures as well as spontaneous compression and stress fractures. Decreased mobility and the pain of osteoarthritis can lead to social isolation and the inability to complete activities of daily living (ADLs). The osteopathic physician's holistic philosophy and manipulative therapy skills are well suited for addressing musculoskeletal issues.

Cardiopulmonary Changes

Calcification and sclerosis of arteries and heart valves can affect blood pressure and hemodynamic response to exertion. The main changes in the cardiovascular system include loss of large artery compliance, dysfunction of some of the systems modulating resistance vessel tone, increased activity of the sympathetic nervous system, and reduced hemodynamic responses to inotropic agents (93). These changes may contribute to fatigue, decreased endurance and depression.

The structural changes associated with the pulmonary system and aging include chest wall and thoracic spine deformities that impair total respiratory system compliance leading to increase work of breathing. The lung parenchyma loses its supporting structure causing dilation of air spaces: "senile emphysema." Respiratory muscle strength decreases with age and can impair effective cough, which is important for airway clearance. The lung matures by age 20 to 25 years, and thereafter aging is associated with progressive decline in lung function. The alveolar dead space increases with age, affecting arterial oxygen without impairing carbon dioxide elimination (94). There is a decline in alveolar surface area, a decrease in vital capacity, and a decrease in the partial pressure of arterial oxygen. These changes may contribute to the experience of shortness of breath, a significant cause for the new onset of anxiety in the older patient.

Liver Changes

Several age-related changes in the liver have been documented, including (a) a decline in liver volume, (b) an increase in the hepatic dense body compartment (lipofuscin), (c) moderate declines in the Phase I metabolism of certain drugs, (d) shifts in the expression of a variety of proteins, and (e) diminished hepatobiliary functions. Other more subtle changes (e.g., muted responses to oxidative stress, reduced expression of growth regulatory genes, diminished rates of DNA repair, telomere shortening) may contribute to reduced hepatic regenerative capacity, shorter post-liver transplant survival, and increased susceptibility to certain liver diseases in the elderly (95). Overall liver mass decreases. As liver function decreases with decreasing drug clearance, older adults are increasingly at risk for delirium and increased drug-drug interactions. The osteopathic physician working with an older adult should be aware of decreased liver clearance with many drugs and anticipate the CNS effects of prescribed medications.

Renal Changes

The function of the kidney as well as its morphology changes markedly with age. The glomerular filtration rate falls progressively, independent of overt pathology. Glomerular, vascular, and accompanying parenchymal changes occur (96). The number of nephrons is reduced and creatinine clearance declines. This impacts the kidney's ability to clear drugs. Care must be taken when prescribing drugs that are cleared through the kidney as drug toxicity may result quite rapidly. In addition, as chronic kidney disease is quite prevalent in late life, special care should be taken with drug prescribing and dosing to avoid kidney-related drug toxicity.

Immunologic Changes

With increasing age, the competence of the immune system to fight infections and tumors declines. Age-dependent changes have been mostly described for human CD8 T cells (97). Antibody production decreases and autoantibodies increase with age. These changes may account for the higher rate of infection, autoimmune disease, and perhaps malignancy with age.

Psychological Changes Associated with Aging

Late life has been described as a season of change and loss. Older adults are faced with a variety of predictable losses including retirement, reduction in income, loss of spouse, death of friends and peers, loss of health, and change of living environment. The elder may experience a shift from an internal locus of control to an external one, as many life changes occur outside of one's control.

A number of developmental theorists have addressed the psychological issues associated with aging. Erickson identified the last stage of aging as “integrity vs. despair.” In this stage, the older adult is faced with looking back on their life and determining meaning and value in their history. Regrets for mistakes, losses and life events left undone can create bitterness and frustration. Erickson believes that successful resolution of this stage results in wisdom.

High levels of extraversion and low levels of neuroticism are associated with reduced risk of mortality in old age and that these associations are mediated in part by personality-related patterns of cognitive, social, and physical activity (98). Older adults who are more outgoing may be able to weather the changes associated with late life more flexibly than those who are more introverted. Anxiety also appears to play a role in survival in that elders with low levels of anxiety appear to survive longer than those with high levels of anxiety.

Comprehensive Geriatric Assessment

The major focus of geriatric care is optimizing function, avoiding institutionalization, and maintaining the older adult in the community. The geriatric multidisciplinary assessment is defined as a multidimensional interdisciplinary process focused on determining a frail elderly person’s medical, psychological, and functional capacity in order to develop a coordinated and integrated plan for treatment and long-term follow-up (99). Team members may include a geriatrician, nurse practitioner, social worker, dietician, pharmacist, psychiatrist, physical therapists, and other medical specialties. The domains addressed in a comprehensive geriatric assessment include competency and communication, functional status, physical status, nutrition, mobility, symptoms and distress, psychological/social status, spiritual issues, care services, and quality of life (100).

Components of the Medical Assessment

Geriatric patients need a thorough medical assessment as in no other age group is the interface of physical, behavioral, and social issues so great. The presentation of a variety of disorders may be different in a young versus older population; physicians should be mindful of these differences. Examples include abdominal pain from a ruptured diverticuli that presents as often with less pain and less inflammation in an older adult when compared to a younger person. Depression may present as memory changes for an older adult, less likely in a younger person. Drug interactions can be more serious for older adults, both because of the multiple medications many older adults take as well as the drug interactions that may occur.

Older adults may under report symptoms, perhaps due to embarrassment or misconceptions about normal aging. Before beginning the history, physicians should determine if there are any significant deficits of vision, hearing, or cognition that may impact the patient’s ability to relate their story. Physicians often have to spend more time with patients because of cognitive slowing and a lengthy life history. Other informants such as children or care providers should be interviewed since they may be able to provide another perspective on patient functioning or problems. Informants should be encouraged to bring an accurate list of the patient’s medications as medication adherence/confusion may prove to be a key element of the comprehensive geriatric assessment.

Table 19.4 outlines those issues that should be a component of the geriatric assessment. Unlike other age groups, the geriatric patient should be assessed for ADLs such as dressing, toileting, bathing, continence, feeding, and transferring. Independent activities of daily living should also be assessed including housekeeping, laundry, finances, cooking, medication management, transportation,

TABLE 19.4

Components of the History in a Geriatric Assessment

- Dentition/dentures
- Feeding difficulties
- Hearing status
- Vision status
- Bowel and bladder control
- Nutrition
- Infections
- Osteoporosis
- Status of feed/gait
- Fall risk
- Osteoporosis
- Decubitus ulcers
- Mood/affect
- Thought process and memory
- Advanced directives
- Abuse
- Medications and polypharmacy issues

and telephone use. The elder’s ability to complete these is essential information needed to help determine the level of care that is needed from independent living to residential care.

A number of assessment instruments can be helpful in obtaining history from the patient. For falls and gait issues, the “Get-up and go” test (101) can be a helpful assessment of balance and ambulation issues (Table 19.5).

The geriatric patient should have a physical exam as part of their geriatric assessment. The components of the physical exam are not unlike those of a younger adult with special attention being focused on issues associated with aging. The osteopathic physician should be mindful of modesty issues with older adults and sensitively examine in a warm comfortable environment. Table 19.6 outlines issues to focus on with respect to each area of the physical exam.

A mental status examination is a part of thorough geriatric evaluation. Appearance can inform the clinician about self-neglect and

TABLE 19.5

The Get-up and Go Test

Initial check:

All older persons who report a single fall should be observed as they:

- From a sitting position, stand without using their arms for support
- Walk several paces, turn and return to the chair
- Sit back in the chair without using their arms for support

Note: Individuals who have difficulty or demonstrate unsteadiness performing this test require further assessment.

TABLE 19.6

Key Components of the Geriatric Physical Examination

Vital signs

- Assess for orthostatic hypotension (Blood pressure sitting and standing)
- Assess temperature
- Monitor weight with each visit

Skin

- Evaluate for common skin lesions in aging including lentigo, senile keratosis, senile purpura, pressure sores, or evidence of falls

Head

- Assess vision and eye movements, evidence for cataracts
- Assess hearing
- Evaluate skull for trauma with a history of falls
- Examine patient for cerumen impacting ear canal
- Auscultate for carotid bruits

Cardiopulmonary system

- Evaluate for systolic ejection murmurs (common secondary to aortic valve changes associated with aging)
- Presence of peripheral pulses
- Assessment for leg edema
- Auscultate for bibasilar rales and possible atelectasis secondary to immobility

Abdomen

- Assess hernias
- Deep palpation for aortic size
- Palpate for enlarged bladder
- Rectal examination and assessment for stool in blood
- Prostate exam in men

Musculoskeletal

- Evaluate gait
- Assess posture
- Range of motion of upper and lower extremities
- Feet evaluation for ulcers and nail care
- Osteopathic structural evaluation of muscle and joint for somatic dysfunction

Neurological exam

- Evaluate vibration (may be normal in older adults)
- Reflexes (ankle reflex may be absent in normal older adult)
- Observe for asymmetrical test results (could be suggestive of stroke)
- Mini-Mental State Exam to evaluate cognition (Table 19.4)

TABLE 19.7

The Geriatric Depression Scale

Scoring system: Answers indicating depression are highlighted. Each bold faced answer counts as one (1) point.

1. Are you basically satisfied with your life?	yes/ no
2. Have you dropped any of your activities and interests?	yes /no
3. Do you feel that your life is empty?	yes /no
4. Do you often get bored?	yes /no
5. Are you in good spirits most of the time?	yes/ no
6. Are you afraid that something bad is going to happen to you?	yes /no
7. Do you feel happy most of the time?	yes/ no
8. Do you often feel helpless?	yes /no
9. Do you prefer to stay in your room rather than going out?	yes /no
10. Do you feel you have more problems with memory than most?	yes /no
11. Do you think it is wonderful to be alive?	yes/ no
12. DO you feel worthless the way you are now?	yes /no
13. Do you feel full of energy?	yes/ no
14. Do you feel that your situation is hopeless?	yes /no
15. Do you think that most people are better off than you?	yes /no

Score > 5 = Probable Depression Score_____.

dementia issues. Orientation and short-term memory assessment are invaluable tools to understand whether a patient will be able to live independently and comply with complex medical treatments. Mood assessment is critical to evaluate for any level of depression that may impair functioning or quality of life. The Geriatric Depression Scale (102) (Table 19.7) can be used for older adults without cognitive impairment. For patients with cognitive decline in which one suspects dementia, the Cornell Scale for Depression in Dementia (103) may be used to assess the cognitively impaired patient for depression (Table 19.8).

Likewise, evaluating the patient for thought disorder is vital to help understand the clarity of thinking process and the patient's ability to participate in their care. The neurological exam should periodically include a standardized cognitive assessment (Table 19.9). The Mini-mental state exam (MMSE) (104) is one such cognitive exam frequently used both as a baseline and an outcomes measure of cognitive decline.

Pathologic Changes Associated with Aging

Humans are social animals. Late life is fraught with losses and changes to the social support network. Social networks work as buffers for stresses and moderate losses. Older adults who lose their social networks due to death, changes in location or illness tend to not do

TABLE 19.8

The Cornell Scale for Depression in Dementia

a	0	1	2	
				A. Mood-related signs
				1. Anxiety: anxious expression, rumination, worrying
				2. Sadness: sad expression, sad voice, tearfulness
				3. Lack of reaction to present events
				4. Irritability: annoyed, short tempered
				B. Behavioral disturbance
				5. Agitation: restlessness, hand wringing, hair pulling
				6. Retardation: slow movements, slow speech, slow reactions
				7. Multiple physical complains (score 0 if gastrointestinal symptoms only)
				8. Loss of interest: less involved in usual activities (score only if change occurred acutely, i.e., in <1 month)
				C. Physical signs
				9. Appetite loss: eating less than usual
				10. Weight loss (score 2 if >5 lb in 1 month)
				11. Lack of energy: fatigues easily, unable to sustain activities
				D. Cyclic functions
				12. Diurnal variation of mood: symptoms worse in the morning
				13. Difficulty falling asleep: Later than usual for this individual
				14. Multiple awakenings during sleep
				15. Early morning awakening: earlier than usual for this individual
				E. Ideational disturbance
				16. Suicidal: feels life is not worth living
				17. Poor self-esteem: self-blame, self-deprecation, feelings of failure
				18. Pessimism: anticipation of the worst
				19. Mood congruent delusions: delusions of poverty, illness, or loss

Score _____ score > 12 = Probable Depression Score.

Ratings should be based on symptoms and signs occurring during the week before interview. No score should be given if symptoms result from physical disability or illness

Scoring system: a, unable to evaluate; 0, absent; 1, mild to intermittent; and 2, severe.

as well physically or psychologically as those adults whose lives are more stable. Assessing the older adult’s social network is critical to understanding the nature and scope of support around them as this may impact their ability to function. The osteopathic physician will want to understand other components of support including financial and physical status. This is critical to help the patient access appropriate services as well as to guide treatment and therapy decisions. A team approach is likely to be helpful in collecting this information and providing more interventions than any single health professional may be. Even with a strong social and financial support system in place, the older adult may be more vulnerable to a number of issues including depression, anxiety, dementia, and psychosis.

Depression

Depression is prevalent in late life. Although many older adults present with subsyndromal depressive symptoms that may not meet DSM-IV-TR criteria for major depression, depression continues to impact functioning significantly in late life. Increased somatic symptoms may be present for some older adults, leading to somatization and a focus on bodily functions. Eight to twenty percent of older adults in the community and up to 37% in primary

care settings suffer from depressive symptoms (105). Table 19.10 describes the symptoms associated with major and minor depression (106) in the elderly.

Suicide risk is also high. Being male as well as having mental illness (particularly depression), physical illness, and interpersonal discord are all risk factors for suicide in the elderly (107). To this end, a thorough evaluation of mood and suicidal ideation should be done with the older patient including the use of a thorough psychiatric examination to obtain information about the patient’s current presentation, history, diagnosis, and to recognize suicide risk factors therein; the necessity of asking very specific questions about suicidal ideation, intent, plans, and attempts; the process of making an estimation of the patient’s level of suicide risk is explained; and the use of modifiable risk and protective factors as the basis for treatment planning (108).

When older adults consider suicide, they choose the most lethal means and do not tell their physician prior to their attempts. Older patients may not realize or acknowledge that they are depressed. In fact, many patients will deny that they are depressed yet admit to symptoms of hopelessness, decreased energy, anhedonia, sleep changes, and changes in appetite. Other etiologies must also be considered including iatrogenic causes for depression, recent loss (spouse, children, friends, and pets) and advancing medical illnesses.

TABLE 19.9

Mini-Mental State Exam

Orientation	Maximum Score
1. What is the (year) (season) (date)(day)(month)?	5
2. Where are we? (state)(country)(town)(hospital)(floor)	5
Registration	
As the patient if you may test his memory. Then say the names of three unrelated objects, clearly and slowly. After you have said all three, ask him to repeat. This first repetition determines the score (0–3) but keep saying them until he can repeat all three, up to six trials.	3
Attention and calculation	
Ask the patient to begin with 100 and count backward by 7, stop after 5 subtractions (93,86,79,72,65). If the patient cannot do serial 7s, ask him to spell the word WORLD backwards.	5
Recall	3
Ask the patient to recall the three items repeated above.	
Language	2
Naming: Show the patient a wristwatch and pencil and ask the name.	
Repetition: Repeat the phrase “No ifs, ands, or buts” after you.	1
3-Stage Command: Give the patient a blank paper and ask him to take the paper in his right hand, fold it in half, and put it on the floor. One point for each part correctly executed.	3
Reading: On a blank page of paper print “CLOSE YOUR EYES.” Ask the patient to do what it says.	1
Writing: Give the patient a blank piece of paper and ask him to write a sentence that must contain a subject and a verb.	1
Copying: Ask the patient to copy the figure of intersecting pentagons. All 10 angles must be present and 2 must intersect to form a four-sided figure.	1
SCORING:	
MAXIMUM 30	
Mild impairment MMSE >21; Moderate MMSE 10–20; Severe MMSE <9.	

Depression is treatable in late life and should not be considered merely a normal reaction to loss. Antidepressants may be helpful for the neurovegetative signs of depression such as sleep disturbance, weight changes, and depressed mood. However, because of decreased renal and liver clearance, antidepressant dosages used should be one half to one third of a younger adult's dosage to eliminate the possibility of toxicity. A variety of selective serotonin reuptake inhibitors or noradrenergic-serotonergic reuptake inhibitors may be used safely in the elderly. Frequent visits with the physician to both monitor for side effects and provide encouragement in waiting for antidepressant response (which may take 6 to 12 weeks) is encouraged.

Psychotherapy is helpful in managing depression as old age is fraught with a number of losses. Cognitive behavioral, interpersonal, and supportive therapies are helpful for the older adult (109). Used in combination with antidepressant medication, psychotherapy can provide additional help in dealing with the adjustment to life changes as well as problem solving.

Anxiety

There is significant overlap between depression and anxiety in late life. Anxiety may manifest itself as panic, generalized anxiety, or

simple phobias of theft or loss. Feeling nervous or restless may be signs of anxiety, but in the older patient anxiety is very closely tied to medical illness. Pulmonary disorders such as chronic obstructive pulmonary disease can create hypoxia and mimic the signs and symptoms of anxiety. Cardiac disease has also been associated with anxiety in older adults (110).

Although often used, benzodiazepines can be highly problematic for older individuals. This class of drug is associated with falls, delirium, and even depression. A better choice to manage anxiety is the use of a selective serotonin reuptake inhibitor. Benzodiazepine use should be short term and of low potency in order to reduce risks associated with these medications.

Cognitive behavioral therapy has been demonstrated to be highly effective for the management of anxiety (111). Learning to deal with irrational thoughts, developing strategies for replacing negative thoughts with positive ones, and helping a patient find solutions for overwhelming worries are all practical functions of psychotherapy.

Dementia

Dementia is a syndrome of brain deterioration characterized by short-term memory loss, disorientation, word-finding difficulties,

TABLE 19.10

Symptoms Associated with Major and Minor Depression

Major depressive disorder

- Depressed or irritable mood for >2 weeks
- Five or more of the following symptoms >2 weeks that impair social, occupational or other important areas of functioning:
 - a. diminished interest or pleasure
 - b. significant weight change
 - c. insomnia or hypersomnia
 - d. psychomotor agitation or retardation
 - e. fatigue
 - f. feelings of worthlessness or guilt
 - g. diminished ability to concentrate
 - h. recurrent thoughts of death

Minor depression

Presence of 2–5 symptoms of major depressive disorder. In addition, these symptoms may also be associated with minor depression:

- Increased somatic preoccupation
- Anergic, anhedonia
- Isolation
- Pessimistic attitude
- Fatigue
- Increased emotional sensitivity
- Increased mood reactivity

apraxia, and agnosia with significant functional decline. It is estimated that currently around 24 million people have dementia in the world, with the number being projected to double every 20 years, and that 60% of dementia patients live in developing countries, with the proportion being raised to more than 70% by 2040 (112). Patients with dementia require increased caregiving supervision and care because of their memory loss.

A number of behavioral issues can arise with dementia. These include psychosis, depression, agitation, and physical aggression. Personality changes may also result making docile individuals premorbidly aggressive or paranoid. These behavioral issues can be particularly troublesome to caregivers and are the place where the osteopathic physician, considering the impact of mind-body-environment, can help provide psychoeducation, behavioral strategies to minimize excessive stimulation, and support for the family caregivers (113).

Pharmacological treatment for the management of dementia currently includes acetylcholinesterase and glutamate inhibitors (114). Antidepressants can be helpful in the management of depression in dementia. Atypical antipsychotics have been used in the management of agitation and psychosis in dementia; however, they have recently come under scrutiny for increased risk of cerebrovascular risk and sudden death (115).

Delirium

Delirium is characterized by an acute confusional state, usually fairly sudden in nature, in which the patient has fluctuating sensorium,

attentional deficits, waxing and waning levels of alertness, and intermittent psychosis. Delirium is common in the elderly and its manifestation may be frightening for family members witnessing an abrupt change in the patient. Delirium may result from many sources including medications (anesthetics, pain medications), infection, electrolyte imbalance, hypoxia, and sensory loss.

Systematic detection and intervention programs and special nursing care appeared to add large benefits to traditional medical care in young and old surgical patients and modest benefits in elderly medical patients (116). Special attention to sensory loss such as hearing or vision may help target interventions (hearing aids, glasses) that can reduce the risk for the development of delirium (117). Osteopathic physicians should work to identify those medical and environmental causes for delirium. Providing psychoeducation to caregivers and family is also an important component in trying to aggressively anticipate the problem of delirium in the older adult.

Psychosis

Older schizophrenics have more multiple medical problems as a result of chronic illnesses due to poor lifestyle choices as well as lack of health care. Often, these individuals are frail and may be suffering from cardiac or pulmonary diseases. These illnesses may hamper the pharmacokinetics of antipsychotic medications they are using to manage their psychosis. Elderly patients may be at greater risk for tardive dyskinesia and parkinsonian side effects of antipsychotic medications (118).

Psychosis may result from schizophrenia, mood disorders, or organic etiologies. Since new onset psychosis in older individuals is much more likely to be related to an organic etiology, it requires a thorough medical workup. Schizophrenics may also develop dementia. In addition, older adults with premorbid schizoid or schizotypal personality disorders may develop late-life schizophrenia.

PART

II

The Patient Encounter

This page intentionally left blank.

KEY CONCEPTS

- In the initial patient encounter, the establishment of rapport with the patient is equally important as the historical information that is gathered.
- There are several clinical issues that represent public health problems of such magnitude that all physicians must participate in the detection and treatment of these disorders; these include cancer, hypertension, hypercholesterolemia, obesity, and overweight.
- Patient management is most effective if the patient is assessed in the largest possible context. Besides their personal life and family relationships, this includes cultural, socioeconomic, and religious/spiritual issues.
- Part of the “art” of medicine is the ability to apply guidelines developed for millions of people to the individual patient whom the physician is treating at the moment.
- Patient-centered care is easier to talk about than it is to implement. However, like many other things in medicine, it is a teachable skill and one that can be learned.

INTRODUCTION

The first encounter with a patient is the culmination of medical training and the fulfillment of clinical practice. As J. Willis Hurst (1) explains, the purpose of the initial history and physical evaluation is to gain information and, just as importantly, to establish a bond between the patient and the physician (1).

With the increasing availability of sophisticated, accurate, and expensive diagnostic tests, physicians in training typically devote a large amount of time to learn about these studies. As a consequence, an emphasis on the approach to the patient at the bedside has been diminished. Physicians who train to perform surgical or other interventional procedures recognize that a certain minimum number are required for proficiency. In the same way, a minimum number of bedside examinations are necessary for proficiency.

The information to be gathered on each patient is appropriate for the context of that evaluation. For a new patient visit in a primary care office or a patient hospitalized in a general medical or surgical ward, the standard patient history and physical examination is appropriate. The subspecialty evaluation, such as the presentation to an ophthalmologist, urologic surgeon, or specialist in sports medicine, may be much more focused.

KEY ASPECTS OF PATIENT EVALUATION

Because there are many fine references on bedside patient evaluation, this section of the textbook does not attempt to recreate that content; rather, it will emphasize unheralded aspects of the patient evaluation that warrant more attention. These include the evaluation of the musculoskeletal system in the context of the public health perspective of clinical problems in this area (Chapter 21: Public Health Aspects: screening and prevention and Chapter 22: The Musculoskeletal Component), an assessment of the influences of the environment (Chapter 23: Environmental Issues), and an evaluation of the patient in the context of complementary and alternative medicine and nonosteopathic forms of manual medicine (Chapter 24: Interface of Osteopathic Medicine with Complementary and Manual Medicine Practitioners).

Presently, members of the Educational Council on Osteopathic Principles promote the use of five models to be used in patient

assessment and treatment, including the biomechanical, respiratory/circulatory, neurologic, metabolic-energy, and behavioral or biopsychosocial models. These form the organizing principles for the basic science and clinical chapters of this textbook.

Regardless of the presenting complaint of the patient and irrespective of the specialty interest of the health care provider, all physicians have some inherent obligations. For example, some clinical problems occur with such a magnitude that all physicians need to be involved. Examples include hypertension, which affects an estimated 42 million Americans; hypercholesterolemia, affecting 100 million Americans; and obesity and overweight, which affect two third of all Americans. Likewise, diabetes and cancer are such prevalent public health problems that physicians need to be vigilant for manifestations of these disorders. Some problems, such as vaccinations for influenza for the elderly, require that every encounter with the patient become an opportunity for intervention (Chapter 30: Life Cycles—Health Promotion). This is the basis for hospital-based initiatives to provide influenza and pneumococcal vaccinations for all appropriate patients admitted to the hospital.

PATIENT RAPPORT

The information that is gathered as part of the initial patient evaluation is considered in the context of establishing osteopathic medical care. Consider the influence of context in the following four examples of patients with chest pain:

- A 38-year-old man who is in danger of losing his home to foreclosure begins to experience chest pain after he is laid off from his job.
- A 67-year-old man has experienced typical effort angina at progressively lower levels of exertion over the past 4 weeks; he is awakened from his sleep with chest pain at 2 AM.
- A 67-year-old woman indulged in an unusually opulent feast with lots of fatty food and alcohol; she is awakened from her sleep with chest pain at 2 AM.
- An 84-year-old woman with lung cancer metastatic to bone, brain, and adrenal glands comes to the hospital with chest pain.

It should be obvious that the context of the patient presentation means that we cannot take a “one-size-fits-all” approach to chest pain, since the above patients have chest pain related, respectively, to stress/anxiety, unstable angina, gastroesophageal reflux, and chest pain that may be cardiac in the setting of end-stage lung cancer.

More often, the context of the patient evaluation involves subtleties that can only be discerned after careful evaluation. The development of rapport with the patient is critical to this approach, as are the principles for patient care (2) that identify the patient as the focus for care. There are tools that can be used to assist physicians in developing rapport; perhaps the most important of these is professionalism, which seeks to raise the standard of physician behavior, while enhancing that individual’s sensitivity to cultural, socioeconomic, and religious differences (Chapter 26: Professionalism). In addition, the awareness of the importance of the mind-body relationship can open new avenues to understanding the patient’s presenting complaint and provide insight into working collaboratively with the patient to resolve health problems (Chapter 27: Mind-Body Medicine). The role of spirit in health care is discussed much more widely than it is understood. This section explores that consideration and offers a few concrete points to assist in expansion of patient care into this arena (Chapter 28: Spirituality and Health Care).

DECISION MAKING AND EVIDENCE

After collection of information on a patient and with the establishment of appropriate rapport, the physician is then ready to embark on medical decision making. As with any other aspect of health care, decision making (also called clinical problem solving) is based on principles that have been validated and can be taught to newcomers to the field. A portion of this section of the textbook is devoted to an explication of medical decision making (Chapter 25: Clinical Decision Making).

Implementation of the patient care plan is multifaceted. The goal is to base that care plan on clinical evidence derived from well-designed and well-conducted research trials (Chapter 32: Evidence-Based Medicine). In one sense, clinical evidence is like a net. When used properly, it is a safety net that sustains the physician and his/her practice and supports him/her in terms of the many pressures that confront physicians in medical care. However, it can also be a net that holds one down. Physicians are expected to meet the standard of evidence-based medicine, and failure to do so is constraining and increases the potential for malpractice liability.

Finally, evidence-based medicine presents a challenge in terms of keeping the focus on the individual patient. Scientific evidence must be based on sufficient numbers of patients to generate meaningful information. At the moment of the patient encounter, however, there is just one person who matters: the patient. There is often a significant challenge of discernment, to define the manner in which your decision making is properly formed by the research literature.

PATIENT-CENTERED CARE

The issue of patient-centered care touches on a core osteopathic premise. To focus on the patient is more difficult than it might appear at first glance. Frequently, it is not considered as part of the approach to the patient interview or to medical decision making. Physicians, by nature, are goal oriented. To stop and assess the patient’s values may appear to disrupt the flow of information gathering and development of the patient care plan. A chapter in this section (Chapter 29: Patient-Centered Model) offers both

Seven Aphorisms for the Successful Physician

1. *Distinguish between a goal and a guideline.* A goal is a guiding principle that we may or may not attain, similar to the North Star, which can lead us, but we may never get there. An example of a goal in osteopathic medicine is “treatment of the whole person.” The individual person presenting for health care is far too complex for any one physician to fully understand every aspect of that individual. Still, we do our best to maintain a holistic approach. In contrast, a practice guideline is a statement developed by an expert group based on the best available medical evidence. Physicians are expected to adhere to guidelines and to fulfill those requirements.
2. *Maintain a focus.* Sometimes you will hear a physician say that he or she performed a “comprehensive” history and physical examination. Even if a truly comprehensive exam existed, it would often be inappropriate. A physician should be capable of a general evaluation of the patient. Then, as specific concerns arise, a detailed, complete assessment can be made in that one area. For example, a full assessment of each of the cranial nerves is unnecessary in the assessment of a patient complaining of chest pain, but some basic evaluation of the neurologic status is necessary in all patients.
3. *The patient is the hero.* Many physicians gladly accept the expressions of praise and gratitude offered by patients and their family members. Some even accept the description of “heroic.” But the reality is that the patient is the hero. Frequently, they come to the health care system with life-threatening medical problems or with the fear that they have these problems. Patients who have advanced heart disease, unrelenting gastrointestinal problems, or cancer are expected to arrive for their appointments on time, be polite, respond respectfully, tolerate physicians who are late, and maintain good cheer in the face of crippling health care costs. The fact that many of them still have time to bring in home-cooked pies or cookies and to send thank-you notes is really remarkable.
4. *Poor historians are outnumbered by poor history takers.* Patients often come to the health care encounter in a frightened state, and typically they don’t know what information the physician needs. Because of this, their answers can be vague and even misleading. It is the physician’s job to provide leadership during the interview process. Clearly, there is a delicate balance between providing direction and also giving plenty of opportunity for thoughtful, careful listening.
5. *Be brief.* It’s big world out there. There is a lot to learn, and there is a lot to do. Use your time well. Learn to distinguish what is important and what is urgent.
6. *In medicine, there is no finish line.* Although there are many mileposts in the practice of medicine, there is really no stopping point. In terms of physician education, milestones can be the basic science and clinical science aspects of medical school, postgraduate training, and then specialty programs. Because the world of medicine and science advances so rapidly, physician education must be an active, continuous process. Likewise, a patient is seen on day one, and their clinical course develops by the time the patient is seen in follow up. Each patient encounter represents the opportunity to integrate developments in the patient’s clinical course with new information that

(continued)

is available. Even when a patient dies, the finish line is not clear cut: there are still issues to handle in terms of providing consolation and solace for the family.

7. *Our patients have much to teach us.* How did the great clinicians become so? One has to suspect that they did not go through life committing the same mistakes time again. Instead, they were present in each moment, taking the opportunity to adjust their medical practice to the changing circumstances of their patients and to new developments in medical science.

philosophical and practical points to address this topic. Patient-centered care also becomes especially clear when decision making must be conducted in the context of end-of-life decisions (Chapter 31: End of Life Care).

Finally, there is the issue of documentation. One institution puts this in a grand context: “In God We Trust. All others must document.” Behind this glib statement is the recognition that, if events are not documented, there may be no evidence that they

happened. Younger members of the medical profession frequently spend a good deal of time documenting information that is not needed and failing to document information that becomes the foundation of the conclusions and care plans that they propose. Several tools are available to assist the physician, including the time-tested problem list and, more recently, the electronic health record. Box 20.1 presents useful aphorisms for this purpose.

The patient encounter is the most fulfilling aspect of being a doctor. It might be considered to be the litmus test of who we are. This includes the position as a physician, a professional, and as a person. It gives us the chance to live every day from a new perspective, since all of us change every day: the patient, the field of medicine, and, of course, each of us. Try to savor the experience!

2. Rogers FJ, Glover J, D'Alonzo GE, et al. Proposed Tenets of Osteopathic Medicine and Principles for Patient Care, *J Am Osteopath Assoc* 2002; 102:63–65.

KEY CONCEPTS

- A host of factors impact the development, incidence, and prevalence of disease and illness among the population.
- We, as a society, must act collectively to assure the conditions in which people can be healthy.
- Public health functions include assessment and monitoring of health, formulation of public policies, and ensuring access to appropriate and cost-effective care.
- Advocation of concepts of public health with utilization of the principles of osteopathic medicine will further our ability to enhance the health and well-being of all patients.
- The desirable results of efforts of public health and osteopathic medical practice include longevity with health and the elimination of health disparities.

INTRODUCTION

There is sometimes a perception that a discipline like osteopathic medicine, which prides itself on its holistic approach to health care, thrives on its own merit. Evidence, however, shows that without the strides made through public health concepts and practices, all medical fields would not exist as we know them today. In the later 19th century, Andrew Taylor Still, the founder of osteopathic medicine, established four basic principles as the basis for the profession's philosophy and practice. More recently, in 2002, a multidisciplinary ad hoc committee of osteopathic clinicians and researchers proposed an updated set for these tenets of osteopathic medicine and associated principles of patient care that are to reflect the relevance of scientific approach to care. These proposed tenets and principles found by Rogers et al. are:

Tenets:

1. A person is the product of dynamic interaction between body, mind, and spirit.
2. An inherent property of this dynamic interaction is the capacity of the individual for the maintenance of health and recovery from disease.
3. Many forces, both intrinsic and extrinsic to the person, can challenge this inherent capacity and contribute to the onset of illness.
4. The musculoskeletal system significantly influences the individual's ability to restore this inherent capacity and therefore to resist disease processes.

Principles:

1. The patient is the focus for health care.
2. The patient has the primary responsibility for his or her health.
3. An effective treatment program for patient care is founded on these tenets.

These tenets and principles form the overarching ideology and the basis for the use of structural diagnosis and osteopathic manipulative medicine.

Through education rooted in these principles, evidence-based practice, and diligent doctor-patient partnerships, osteopathic physicians, particularly primary care specialists, provide exceptional and holistic care to their patients. In the early 1800s, medical practice

became centered on various developments achieved through public and community health efforts. Since the early 14th century, simple acts such as hand washing and proper management of human waste have produced significant impacts on the health of individuals as well as reducing the adverse effects that communicable diseases have on the population at large. Today, although public health efforts seem to be relegated to the background of medical practice, they have remained important facets in managing the health of global communities.

Recognized as a leading figure in the early development of public health in America, Winslow (1920) described public health as "the science and art of preventing disease, prolonging life and promoting physical health and efficiency through organized community efforts for the sanitation of the environment, the control of community infections, the education of the individual in principles of personal hygiene, the organization of medical and nursing science for the early diagnosis and preventive treatment of disease, and the development of the social machinery which will ensure to every individual in the community a standard of living adequately for the maintenance of health" (Winslow, 1920). Over the years, components such as research for diseases, injury prevention, and promotion of healthier lifestyles were added to encompass the totality of the field. In 1988, the Institute of Medicine published a landmark report titled "The Future of Public Health in the 21st Century" and defined public health as "What we, as a society, do collectively to assure the conditions in which people can be healthy." Therefore, activities that include organized community efforts to identify, prevent, and counter threats to the health of the public and improve the health and well-being of people can be categorized as public health.

CORE FUNCTIONS OF PUBLIC HEALTH

The three core functions of public health include:

1. Assessing and monitoring the health of communities and populations at risk to identify health problems and priorities
2. Formulating public policies designed to solve identified local and national health problems and priorities
3. Ensuring that all populations have access to appropriate and cost-effective care, including health promotion and disease prevention services, and evaluating the effectiveness of that care

Many of the dramatic achievements of public health in the 20th century have contributed to the improvement of the quality of life of people globally and resulted in increased life expectancy, reduction in infant and child mortality, and elimination of many communicable and infectious diseases in many industrialized nations.

While doctors usually treat individual patients one-on-one for a specific disease or injury, public health practice requires that professionals monitor and diagnose the health concerns of entire communities and promote healthy behavior and practices to ensure that populations stay healthy.

However, the prevalence of certain chronic diseases, such as diabetes, hypertension, and cardiovascular disorders, as well as the recent occurrences of certain communicable illnesses like SARS, Ebola Fever, HIV/AIDS, and methicillin-resistant staphylococcus aureus, Norovirus and the H1N1 influenza infections, signal the need for a paradigm shift in the overall evaluation and management of many patients especially on a community basis.

TRENDS IN POPULATION MEDICINE

The recent trends in population medicine today show that in America:

- There is increasing racial and ethnic diversity.
- Life expectancy of the population continues to increase.
- People are getting more involved in their own health care and seeking alternative ways to manage their health while demanding more from their physicians.
- More people today are living with some form of chronic disease such as hypertension, diabetes, heart disease, cancer, Chronic Obstructive Pulmonary Disease, or chronic pain.
- There are increasing numbers of people without health insurance coverage.
- There are increasing concerns about real or perceived threats associated with natural disasters, massive biohazard accidents, and terrorist acts that could have a significant impact on the health of the community.

These trends should motivate physicians to become more aware and more involved in disease prevention, health maintenance, promotion of healthy lifestyles, and emergency preparedness for their patients. In 2006, a report by the U.S. Centers for Disease Control and Prevention (CDC) indicated the alarming rise in the numbers of Americans suffering with chronic diseases such as diabetes type 2, a disease that remains the leading cause of adult blindness, lower-limb amputation, kidney disease, blindness, and nerve damage, thereby contributing significantly to health policy issues and public health concerns. The CDC also reports that a majority of the top ten causes of mortality in the United States are due to preventable illnesses. The study, "Measuring the health of Nations" conducted by the London School of Hygiene and Tropical Medicine, ranks the United States the nation with the highest in the rate of preventable deaths among 19 most industrialized nations when comparing matters about health status and morbidity (Nolte and McKee, 2008). According to this study, more than 100,000 Americans die each year from lack of timely and effective medical care. The study focused on how a variety of conditions including diet, lifestyle, and various preventable and treatable chronic diseases and risk factors contribute to mortality rates. Of the 19 nations studied, the United States is the only one without universal health care coverage yet spends significantly more money in health care services than any of the other countries. Other studies have shown similar findings and conclusions (Danaei et al., 2009).

The results of this study raise an important question regarding what this nation and the health care system can do not only to improve these statistics but also to energize the health of the population in general. Health care reform, modifications in clinical practice, and fostering positive lifestyle changes may be necessary to achieve this goal.

A critical look at the osteopathic medicine reveals significant similarities of prevention, holism, and community inclusion between its tenets and the philosophical approach to public health. The basic principle of osteopathic medicine recognizes the important connections and the inseparable link between the physical, mental, emotional, and spiritual factors in the maintenance of optimal functioning in the context of the individual, family, and society.

In addition to their medical education, skills, and talents, there exists a wide range of resources and tools that help osteopathic physicians to successfully integrate and apply various procedures, including osteopathic manual medicine, in their practices in order to foster health promotion, disease prevention, early diagnosis, timely treatment, and standard of care that are based on clinical evidence.

To become fully conversant with these methods, physicians, particularly those who provide general medical care in the primary care of their patients, may have to make some changes in the methodologies of their practices. Osteopathic medical students will need to learn and think differently regarding the way health care services are delivered as well.

THE PATIENT ENCOUNTER

Currently, the patient encounter consists of the individual patient-centered approach: an approach to providing health care and occasional comprehensive primary care for people of all ages and medical conditions. It is a way for a physician-led medical practice, chosen by the patient or insurer, to integrate health care services for that patient. Frequently, the patient confronts episodic sporadic care within a complex and confusing health care system associated with referrals, insurance rejections, copay requirements among other regulations.

The Healthy People 2010 concept challenges individuals, communities, and professionals to take specific steps to ensure that good health, as well as long life, is enjoyed by all. The two overarching goals of the Healthy People 2010 are:

- **Goal 1: Increase Quality and Years of Healthy Life:** designed to help individuals of all ages increase life expectancy and improve their quality of life.
- **Goal 2: Eliminate Health Disparities:** designed to foster the elimination of health disparities among different segments of the population thereby improving community health and health for all.

While the Healthy People proposes the improvement of health for all, it targets two primary concerns: (a) specific chronic illnesses and (b) the health of vulnerable populations that focus on specific health indicators to be used in measuring the health of the nation over the 10-year span of its existence (2000–2010). The ten specific health indicators, listed below, are termed The Leading Health Indicators and reflect the major health concerns in the United States at the beginning of the 21st century. These indicators were selected on the basis of their ability to motivate action, the availability of data to measure progress, their contribution to disease process, morbidity and mortality, and their longitudinal importance as public health issues.

The leading health indicators are:

- Physical activity
- Overweight and obesity
- Tobacco use
- Substance abuse
- Responsible sexual behavior
- Mental health
- Injury and violence
- Environmental quality
- Immunization
- Access to health care

Physicians are encouraged to review the needs of individual patients they see, as well as those of the populations in the communities they serve to determine which specific health recommendations to implement in their practices. While each patient is unique, there are certain basic examination and screening procedures that should be performed for each patient as a part of the overall health care service.

What to do for Each Adult Patient at Every Visit

The management of a patient at each visit can determine the potential of early diagnosis of disease and thereby contribute significant to health care outcomes. These recommendations are provided partly to help establish standard of patient care and also to provide guidance in record keeping in order to monitor changes and further take corrective clinical action. While these recommendations assist physicians in making clinical decisions regarding the care of their patients, they cannot be substituted for the individual judgment brought to each clinical situation by the physician based on his/her knowledge, expertise, and experience. As with all clinical matters, they reflect the best understanding of the science of medicine in the regular management of patients and in the provision of care that are valuable in health maintenance, early diagnosis of disease, or considerations in health status changes. These recommendations are to be carried out regardless of the specialty of the physician. Variations on recommendations relating to pediatric patients are not discussed in this chapter.

The following health indices should be recorded at each visit:

- **Vitals:** BP, pulse, temperature, respiration, weight;
- **Presenting complaint(s):** medical history as relates to the complaint(s), past occurrences, quality, differences and similarities of symptoms, and any management thereof;
- **Medications/and changes:** prescribed, over-the-counter, herbs, vitamins, and other supplements—compliance with recommendations, appropriate use, abuse, and misuse;
- **Functional Status:** ability to perform activities of daily living, including emotional and physical aspects;
- **Review of Lifestyle Behaviors and Activities:** smoking, regular exercise, nutritional factors, rest, meditation, job, family life;
- **Other Changes:** including consultations with other health care providers for secondary or tertiary care.

What to do for Adult Patients Annually

Despite lack of evidence to support annual physical exams for asymptomatic adults, patients report considerable enthusiasm for such exams. While many physicians may consider this an essential aspect of health maintenance for their patients, research has shown that only specific patients, particularly those with manageable chronic illnesses, should receive yearly medical check-ups. Healthy individuals with minimal or no risk factors, and those with documented healthy lifestyles can be monitored less frequently.

Effective monitoring of all patients requires the implementation of evidence-based clinical medicine. Pediatric procedures should be followed accordingly.

Items for the Annual Patient Screening and Evaluation include:

- Review of vaccinations and immunizations
- Healthy lifestyles evaluation
- Motor vehicle safety
- Safe workplaces

REVIEW OF VACCINATIONS AND IMMUNIZATIONS

Each patient's yearly evaluation should include a review of their vaccination/immunization status to determine the needs of the patient for protection against communicable diseases and potentially preventable epidemics. Appropriately timed adult and childhood immunizations can reduce or prevent morbidity and mortality related to illnesses such as influenza, pneumococcal infection, hepatitis B, diphtheria, tetanus, measles, mumps, and rubella. Vaccination of adults at risk for various communicable and infectious diseases can reduce the expenses associated with preventable causes of adult morbidity and mortality. While diphtheria, tetanus, measles, mumps, and rubella affect children at a higher rate than adults, the wide scope of positive results of childhood immunizations has shown that morbidity and mortality attributable to these preventable illnesses can also be substantially reduced by selective immunization of at-risk adults.

HEALTHY LIFESTYLES EVALUATION

Items to consider in the Healthy LifeStyles Evaluation include tobacco use, alcohol abuse and misuse, exercise, coping with stress, and diet and weight maintenance.

TOBACCO USE STATUS

The use of tobacco products—cigarettes, cigars, and chewing tobacco—should be monitored and recorded in the patient's chart and reviewed annually. Since the recognition of the health hazards of tobacco use, U.S. surgeon generals as far back as 1957 have given reports on the health risks associated with tobacco and further emphasized the causal relationship between smoking and lung cancer. In 2004, the U.S. Department of Health and Human Services reported an increase in averted deaths due to the multiple factors of government policy on smoking, public health focused attention on smoking cessation, and the decreased use of tobacco in all its forms, which improved the understanding of the health hazards associated with smoking and the use of tobacco products.

ALCOHOL ABUSE AND MISUSE

While the use of alcohol in moderation has been found to have beneficial effects on cognition and the cardiovascular system (Mayo Clinic.com); (Galani et al., 2000) excessive drinking can lead to serious health problems and even sudden death. Therefore, obtaining information about the drinking habits of the patient is useful in determining the need for intervention if abuse or misuse of alcohol is suspected.

EXERCISE

It is well known in the medicine that part of a healthy lifestyle includes regular physical activities. There are known merits of exercise such as preventing chronic health conditions, boosting confidence

and self-esteem, improving the immune system, enhancing overall well-being maintaining weight and supporting the body structure, and many others. According to a Mayo Clinic report, these benefits exist regardless of age, gender, or physical ability. The report further maintains that exercise has positive influence on almost every body function and subsequently can reduce the incidence and prevalence of diseases that result in significant morbidity and mortality.

COPING WITH STRESS

Stress has both positive and negative effects on the body. The body's reaction to stress, particularly in the long term, can trigger the development of serious illnesses or even make an existing physical or mental condition worse. Some researchers such as Astin et al. (2003) and Pelletier (2004) support these assertions and further recommend evidence-based mind-body intervention modalities for patients. The chapter on Mind-Body Interactions is a good follow-up reading.

DIET AND WEIGHT MAINTENANCE

Recent studies by Avenell et al. (2004) and O'Brien et al. (2004) have shown that obesity is a major public health problem in adults and a significant growing issue in children. In light of the current obesity crisis, prevention of weight gain and better weight maintenance are critical. Therefore, inquiring and reviewing diet, weight management and maintenance are important facets of the regular patient encounter.

MOTOR VEHICLE SAFETY

Improvements in motor vehicle safety have contributed to large reductions in motor vehicle-related deaths (Harfst and Marshaw, 1990). While these improvements include engineering efforts to make both vehicles and highways safer, additional successful efforts of personal behaviors regarding use of safety belts, child safety seats, and increased use of motorcycle helmets, designated driver, and reduced speed limits have had positive impacts on injuries and deaths related to vehicular use.

SAFE WORKPLACES

Common work-related health injuries and illnesses such as coal workers' pneumoconiosis (black lung), and asbestosis, and repetitive stress injuries have been significantly reduced since the emergence of the policies for safer workplaces, use of ergonomically structured work stations, and the monitoring of work hours and the work environment. It is, however, necessary to review the patient's work environment and any potential hazards that might contribute to occupational-related injuries.

RECOMMENDATIONS FOR PREVENTIVE SERVICES

In view of the constantly changing and challenging bulk of medical literature on patient care and management, the U.S. Preventive Services Task Force (USPSTF) (1996) recently provided a guide on which clinical judgment can be made regarding intervention and treatment protocols.

Recommendation Categories

These recommendations were developed with consideration of overall costs, patient preferences, and the quality of the overall evidence for a service on a three-point scale of good, fair, and poor (Table 21.1).

TABLE 21.1

U.S. Preventive Services Task Force Recommendation Categories

Category	Description
SR/A	Strongly recommend: Good quality evidence exists which demonstrates substantial net benefit over harm; the intervention is perceived to be cost-effective and acceptable to nearly all patients.
R/B	Recommend: Although evidence exists which demonstrates net benefit, either the benefit is only moderate in magnitude or the evidence supporting a substantial benefit is only fair. The intervention is perceived to be cost-effective and acceptable to most patients.
NR/C	No recommendation either for or against: Either good or fair evidence exist of at least a small net benefit. Cost-effectiveness may not be known or patients may be divided about acceptability of the intervention.
RA/D	Recommend against: Good or fair evidence which demonstrates no net benefit over harm.
I	Insufficient evidence to recommend either for or against: No evidence of even fair quality exists or the existing evidence is conflicting.

Strength of Recommendations

The USPSTF grades its recommendations according to one of five classifications (A, B, C, D, and I) reflecting the strength of evidence and magnitude of net benefit (benefits minus harms). These classifications represent gradation of the strongest evidence (A) to (I) where research has shown insufficient evidence of any derivable benefits. In addition, the USPSTF provides a 3-point scale (good, fair, and poor) for determining the quality of evidence to support the above recommendations.

A new approach to patient care, the "Medical Home" system was proposed several years ago by physicians who were looking for different and better ways to deliver health services, improve quality of care, and also receive appropriate remuneration. The new paradigm asserts that with burgeoning health care costs, increasing number of the uninsured, and the health care burden associated with retirees and the "baby boomers," there is dissatisfaction among patients, physicians, insurers, and the public in general about the way the current health care systems function. Initially suggested by the American Academy of Pediatrics in 1992, "Medical Home" recommends a major fundamental shift from the patient-centered care to the family-centered care that fosters an accessible, multidisciplinary, culturally effective, compassionate, continuous, coordinated, and comprehensive method of care delivery with the concept of relationship building. In early 2007, several medical groups, including

the American Osteopathic Association, the American Academy of Family Practice, and the American College of Physicians, joined in endorsing this system. The Medical Home guidelines consist of six index domains: Organizational Capacity, Chronic Condition Management, Care Coordination, Community Outreach, Data management, and Quality Improvement. While some physicians especially those in solo medical practices may find it challenging to systematically apply the Medical Home concept, its principles reflect the philosophical approaches found in both osteopathic medicine and public health. Some modifications and flexibility within this system might make it appealing to more physicians.

The Doctor's Role

In addition to having the expertise to provide standard of care, the doctor will also need to be a communicator of information in succinct and clear ways, a facilitator and coordinator of the gamut of services that the patient requires, and further act as an advocate and coach inspiring the patient to work toward achieving better health. Physicians need to understand that patients expect to be treated promptly, courteously, and correctly. They expect their care to be personalized and communicated to them in terms they understand. These practices can reflect positive and effective relationships between the patients and their doctors.

The Patient's Role

As the U.S. health care system continues to evolve and change, patients and their families seem to be taking more active roles in their own health care. It is becoming more and more essential that patients actively partner with their physicians and also take more responsibility for understanding their care, proactively advocate for themselves, engage in open dialogue and communication with their doctor, and become knowledgeable in their own health profiles. Given these circumstances, the patient becomes an active participant in his/her own health care and by extension in the health care of those that depend on them. The patient's role thereby complements and supports the role of the physician. As research reminds us (Steinbrook, 2006a,b), the concept of personal responsibility in health care is that by following healthy lifestyles (exercising, maintaining a healthy weight, and not smoking) and complying with good judgment (keeping appointments, heeding physicians' advice, and using a hospital emergency department only for emergencies), people can enjoy better health, improved quality of life, and greater longevity at a more reasonable cost.

Society's Role

There are many examples of initiatives that are meant to promote personal responsibility. The World Health Organization no longer hires persons who smoke, suck, chew, or snuff any tobacco product, although it will still recruit people "who do not have a healthy lifestyle." In several US states and local communities, laws have been enacted to restrict smoking in public areas such as restaurants, hospitals, and schools. Airlines no longer permit smoking during flight, initially due the efforts of the flight attendants who wanted to minimize their exposure to cigarette fumes and finally by public regulations that ratified the ban.

SUMMARY

The key to successful preventative and curative treatment of patients is to first understand that a host of factors impact the development, incidence, and prevalence of disease and illness among the population. How we, as physicians, interact with the patient is essential to good clinical management and the outcomes. The application of

established preventive measures as advocated through the concepts of public health coupled with the utilization of the principles of osteopathic medicine will further our ability to enhance the health and well-being of all patients. It is in this way that the tenets of osteopathic medicine can be sustained.

KEY CONCEPTS

- Juxtaposing the viewpoints of public health and individual patient care with the musculoskeletal system and its varied disorders demonstrates their impact and burden on the health care system.
- A recent shift from static structural diagnosis to a dynamic patient concept is the guide for assessment of the “three fundamental pillars” of health care.
- Appreciation of the primary role of the musculoskeletal system in health and disease is fundamental to the philosophy and approach to the patient of the osteopathic system of care.
- Central tools of osteopathic management approaches include the use of refined functional examinations and the application of specific osteopathic manipulative interventions.
- Recent public health initiatives and prevention strategies have targeted chronic disorders having significant musculoskeletal consequences of major functional loss.
- Physiologic mechanisms viewed from the perspective of somatic dysfunction facilitate osteopathic management within an integrated musculoskeletal approach.

INTRODUCTION

The musculoskeletal system continues to play a central role in the osteopathic paradigm of patient care ever since its inception at the end of the nineteenth century. As osteopathic medicine has grown from a virtually purely “hands-on” profession of healers to a present-day system much akin to the orthodox allopathic model of disease and pathology, its uniqueness and distinctiveness have been challenged in most recent years. According to the World Health Organization (2003), “...although the diseases that kill attract much of the public’s attention, musculoskeletal or rheumatic diseases are the major cause of morbidity throughout the world, having a substantial influence on health and quality of life, and inflicting an enormous burden of cost on health systems ...” With many assumptions remaining about the profession and its practitioners, we want to take a closer look at the osteopathic approach to the individual patient from a musculoskeletal perspective, while viewing it as one that is embedded in and guided by the greater challenges of public health and health policy at the same time.

Musculoskeletal Function and Burden: Perspectives of Public Health and Medical Care

Musculoskeletal or rheumatic conditions include over 150 diseases, disorders, or syndromes. These are progressive and painful conditions that present as a leading cause of morbidity and disability, giving rise to enormous health care expenditures and loss of work (2). Musculoskeletal conditions account for more disability and more costs to the U.S. health care system than any other condition (3). The musculoskeletal conditions with greatest impact on society include rheumatoid arthritis, osteoarthritis, osteoporosis, spinal disorders, and severe limb trauma (2).

Low back pain is the most prevalent of the spinal disorder group and is treated most commonly in the primary health care setting (4). This condition presents with significant disability among young adults, leading to not only considerable personal challenges but also to a large societal burden in all developed. Low

back pain is thought of primarily as a self-limiting problem with a spontaneous recovery in those who experience their first activity-related episode. Nonetheless, about 40% of patients with low back pain have recurrences within 6 months, and up to 60% have recurrences within 1 year (5). Furthermore, with the increasing age of the population, this burden will not only increase but is expected to become a major challenge to society at large. In addition, when coupled to the shift in lifestyle toward greater activity in the very same population, there is greater risk of injury, abuse, and overuse.

The Shift from Structure to Function

The central focus in musculoskeletal care in recent years has prominently shifted away from a symptom- or a disease-based description of disability *toward* the concept of *function*. This change is innately reflected in the adoption of the current operative term of “musculoskeletal system,” as it goes beyond one specific physician’s specialty of care, say orthopedics, neurology, or rheumatology, for instance. The new emphasis in the musculoskeletal system is *away* from a static structural description toward an understanding of abilities and health rather than disability. Thus, medicine has been moving away from “linear” or purely anatomic disease classifications, typically utilized in the orthodox medical model to a dynamic, interactive system. This reflects the desire to integrate human functioning within a larger context, based on the biopsychosocial model (6). This system, in which activity is the center of consideration, is represented in Figure 22.1 and Table 22.1.

For the purposes of this chapter, it is helpful to recall that a particular disorder or set of disorders can be approached vis-à-vis two fundamental perspectives:

1. the Public Health Domain
2. the Health Care Domain

The mission of public health is to promote physical and mental health, prevent disease, injury, and disability, and to protect the public from environmental hazards (7). The public health domain is distinct from health care in that public health focuses on the

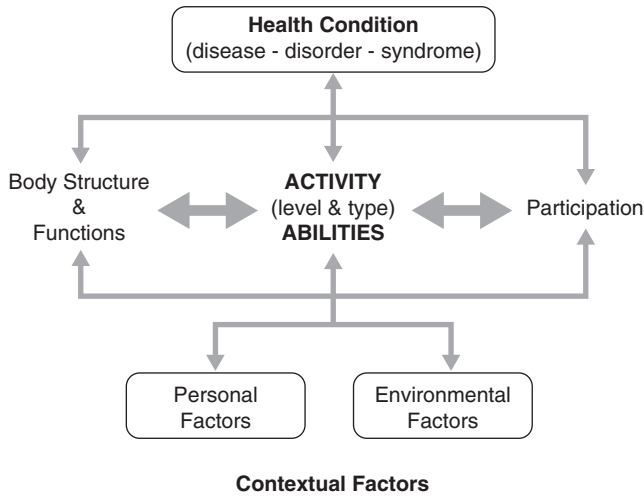

Figure 22-1 Activity level and type are the center of a functional approach to the patient, where structure and function interact on one level, while at the same time, personal and environmental factors play into the entire patient situation as well as the disease process itself. (Modified from Public Health Functions Steering Committee, "Public Health in America," U. S. Department of Health and Human Services, June 1995, accessed August 28, 2008. Available at: <http://www.health.gov/phfunctions/public.htm>.; WHO [2002].)

prevention of disease within populations, while health care focuses on the treatment of disease in individuals (8). With a common vision of ensuring good health and often pursuing overlapping strategies to achieve this vision, there exists no consensus on the precise boundaries between the two disciplines (8). This is a point worth remembering, especially when considering the three fundamental axes making up the *health policy equation* that guide the entire health system, namely, access, quality, and cost (Fig. 22.2).

PUBLIC HEALTH ASPECTS OF MUSCULOSKELETAL DISORDERS

Currently in the United States, more than 30% of the entire population is affected by musculoskeletal problems that require medical care. This figure alone represents an increase by more than two percentage points over the past decade (9), indicative of a prevalence of more than 11.5 million people. While musculoskeletal diseases rarely are a cause of death and do not have the high visibility of conditions such as heart problems, respiratory problems, and cancer, they are nonetheless much more prevalent and are a major cause of pain and reduced quality of life (10). In 2005 alone, 107.7 million adults, that is one in two aged 18 and over, reported suffering from a musculoskeletal condition lasting three months or longer during the prior year. This is nearly twice the number who reported any other medical condition (9). In addition, nearly 15% of the adults aged 18 and older are reported to be unable to perform at least one common activity, such as self-care, walking, or rising from a chair, on a regular basis due to their musculoskeletal condition (9). Table 22.2 compares the diseases with high mortality with those that lead to significant disability (self-reported), with the latter having a significant impact on disability and function, and thus contributing in the USA to significant health care expenses.

The annual direct and indirect costs of nearly US\$ 850 billion for musculoskeletal care represent 7.7% of the gross domestic product (GDP) of the United States (9), corresponding to nearly half of the entire health care costs in the United States. These figures are particularly impressive when realizing that the future health expenditures will dramatically rise even more as a result of factors that are *directly linked* to the musculoskeletal system. These factors include *intensity of care* (longer life span, greater prevalence of chronic disease) and aging of the population, especially when the baby boomer generation (persons born between 1946 and 1964) enters the Medicare program in 2011, shifting a significant burden to the public sector (9).

TABLE 22.1

Functional Approach to the Patient

Health Condition	Intervention/Medical Care	Prevention/Public Health
Health Condition (disease, disorder, or syndrome)	Medical treatment/care Medication(s)	Health Promotion Nutrition Immunization Exercise
Impairment	Medical treatment/care Manual medicine approaches/manipulation Medication(s) Surgery	Prevention of further functional deterioration or development of further activity limitations
Activity limitation	Assistive devices Personal assistance Rehabilitative intervention/treatment	Preventive rehabilitation Prevention of the development of participation restrictions
Participation restriction	Accommodation Public education Antidiscrimination laws Universal design	Environmental change Employment strategies Accessible services Universal design Lobbying for change

Source: Modified from WHO (2002). Definitions used in the bio-psycho-social function model and indicating how the different levels of disability are linked to the different levels of approaches: intervention (e.g., medical care) and prevention (e.g., public health sector).

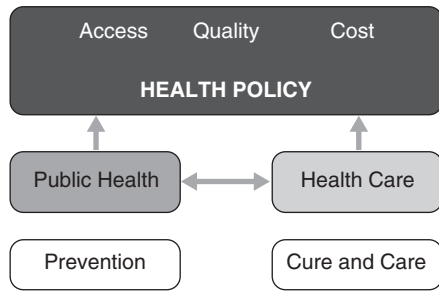

Figure 22-2 Health Policy as shaped by the three “pillars” of access, quality, and cost of health care issues. The public health sector deals primarily with prevention, and the individualized patient health care sector (e.g., hospitals, clinics, doctors’ offices, etc.) deals with the care and cure of disease or disorders. However, the borders between the two often overlap and may be blurry.

Musculoskeletal health care utilization and the economic costs of musculoskeletal diseases are the focus of a recent comprehensive monograph published by the American Academy of Orthopaedic Surgery (9). The report highlights and substantiates the growing impact and burden musculoskeletal problems will have on both the health care industry and on the individual patient. A brief review of the reported findings will be presented here to address some of the major considerations such as (a) musculoskeletal disease prevalence, (b) musculoskeletal health care utilization, (c) musculoskeletal medical care expenditures, and (d) impact of musculoskeletal diseases on the U.S. economy.

Prevalence

Between nearly 90 million people and 108 million people reported musculoskeletal conditions as a primary health concern during the 2002–2005 period (9). When including people in whom the musculoskeletal disease is a byproduct of another condition, nearly 50% (46.6%) of the population reported some musculoskeletal disease (135.6 million people) (9). Figure 22.3 shows prevalence of musculoskeletal diseases and percentage of total population, United States, 1996–2004.

Utilization

Persons with musculoskeletal conditions account for a rather large share of health care utilization. Since 1999 to 2001, utilization has been increasing steadily, especially that associated with the consumption of prescription medication, which is twice the amount in the 2002–2004 as compared with the 1996–1998 interval.

Expenditures

Overall, the total average *individual* expenditure rose by 23% from \$4,751 in the 1996–1998 interval to \$5,824 (9). The aggregate total expenditures increased by nearly \$150 billion from 361.0 billion to a total of \$ 510.0 billion during this time frame, corresponding to a more than 40% increase. Within a 6-year period, it is noteworthy that the percentage of the GDP represented by expenses associated with MSK disease has risen from 4.4% (1996–1998 aggregates) to 4.6% (2002–2004 aggregate numbers).

TABLE 22.2

Causes of Death and Disability in the United States (2006)

Most Common Causes of Death in the United States* (2006)	Main Causes of Disability Among U.S. Adults Over 18 Years of Age**
Disease of the heart (28.5% of total)	Arthritis or rheumatism (19% of total)
Cancer/malignancy (22.8% of total)	Back or spine problems (16.8% of total)
Stroke/cerebrovascular accident (6.7% of total)	Circulatory/heart trouble (6.6% of total)
Chronic lower respiratory diseases (5.1% of total)	Lung or respiratory trouble (4.9% of total)
Accidents (nonintentional injuries) (4.4% of total)	Mental or emotional problems (4.9% of total)
Diabetes Mellitus (3.0% of total)	Diabetes (4.5% of total)
Alzheimer disease (2.7% of total)	Deafness/hearing problems (4.2% of total)
Influenza and Pneumonia (2.4% of total)	Stiffness of deformity of limbs/extremities (3.6% of total)
Nephritis/kidney diseases (1.7% of total)	Blindness or vision problems (3.2% of total)
Septicemia (1.4% of total)	Stroke (2.4% of total)
Intentional self-harm/suicide (1.3% of total)	Cancer (2.2% of total)
Chronic liver disease (1.1% of total)	Broken bone/fracture (2.1% of total)
Primary hypertension/hypertensive renal disease (0.8% of total)	High blood pressure (1.9% of total)
Parkinson disease (0.7% of total)	Mental retardation (1.5% of total)
Homicide (0.7% of total)	Senility/Dementia/Alzheimer disease (1.1% of total)

Note: The table compares the most common causes of death in the United States in descending order and the main causes of self-reported disability of adults older than 18 years of age in the United States.

Sources: Mortality figures (left column): http://www.cdc.gov.nchs/data/nvsr/nvsr57/nvsr57_14.pdf and for disability figures (right column): <http://www.cdc.gov/mmwr/preview/mmwrhtm/mm5816a2.htm#tab1>

Figure 22-3 Prevalence of musculoskeletal diseases and percentage of total population, United States, 1996–2004. While the 2% increase in prevalence between the 1996–1998 and 2002–2004 time intervals appears rather modest, it reflects an increase of nearly 12 million people in the same time frame. (Modified after reference WHO Technical Report Series. The burden of musculoskeletal conditions at the start of the new millennium. Available at: http://whqlibdoc.who.int/trs/WHO_TRS_919.pdf, accessed August 24, 2009.)

Economic Impact

The direct total costs for all four conditions studied (e.g., gout, osteoarthritis, rheumatoid arthritis, spine disorders) including earning losses are highest for those associated with disorders of the spine, followed by those associated with osteoarthritis and allied disorders, gout, and rheumatoid arthritis (9). When further including with spine disorders, the total costs for spine care amounted to \$120 billion US\$, which is nearly three times that used for treatment of osteoarthritis and allied disorders, and nearly four times that used for treatment of gout or rheumatoid disease each (9).

PUBLIC HEALTH INITIATIVES AND PREVENTION STRATEGIES

The monumental impact of musculoskeletal conditions worldwide is now recognized by the United Nations, the World Health Organization, World Bank, and numerous governments throughout the world through support of the Bone and Joint Decade 2000 to 2010 initiative (9,11).

Realization of the impact from bone and joint disorders on society, the health care system, and on the individual, combined with the awareness that resources need to be more efficiently used, culminated in the proposal for the “Decade of the Bone and Joint from 2000 to 2010” (12). The Bone and Joint Decade 2000–2010 aims to improve the health-related quality of life for persons with musculoskeletal disorders by working in partnership with all stakeholders to raise awareness, identify needs, empower patients, promote cost-effective prevention and treatment, and advance understanding through education and research to improve prevention and treatment (13). The major areas of focus are osteoporosis, rheumatoid arthritis, back pain, and musculoskeletal trauma (13).

Drawing on a number of major documents produced by various national and international groups over the last few years, an international task force of the Bone and Joint Decade came together to develop standards for the care of acute and chronic musculoskeletal pain (14). The group’s document is a product of the World Health Organization Collaborative Centre for Evidence-Based Health Care in Musculoskeletal Disorders (15) that has set forth the following three goals:

1. To identify barriers and facilitators that affect successful implementation of health strategies for better musculoskeletal health
2. To identify the costs of musculoskeletal conditions and develop economic models for cost-effectiveness

3. To monitor for ongoing activities relating to musculoskeletal conditions etiology, prevention, and treatment

Another recent example of successful international collaborative efforts is reflected in a series of publications on the topic of neck pain and its burden on the health care sector as published in the journal *Spine* (16). The authors who made up the working group actually developed a new conceptual model for the evaluation and treatment of neck pain and then presented a new classification system based on a “domain approach” to neck pain by using “axes” of diagnostic categorization similar to a system used in the psychiatry/psychology literature (16).

With respect to manipulative and exercise therapy for neck pain, the group’s best evidence synthesis suggests that such therapies are more effective than alternative strategies for patients with neck pain. Their recommendations for future efforts include studies of noninvasive interventions for patients with radicular symptoms and on the design and evaluation of neck pain prevention strategies (17).

THE OSTEOPATHIC PERSPECTIVE—APPROACH: REAL AND PERCEIVED BENEFITS

In the United States, Osteopathic Medicine is described as a complete system of medical care with the philosophy of treating the whole person, not just symptoms (28). Currently, there are more than 60,000 osteopathic physicians (D.O.—Doctor of Osteopathic Medicine) reflecting a significant growth in numbers in the recent years (18).

DOs may use all accepted methods of treatment, including drugs and surgery, while they place special emphasis on the body’s musculoskeletal system, preventive medicine, and holistic patient care (19). With about half of DOs practicing in general or family medicine, general internal medicine, or general pediatrics, they are most likely to be primary care specialists although they can be found in all specialties (19).

It would seem plausible to hypothesize that osteopathic medicine, by virtue of its medical education and philosophical underpinnings, is uniquely positioned to provide a comprehensive medical and manipulative perspective to a variety of medical disorders in general, and musculoskeletal problems in particular. The remainder of this chapter will take a closer look at the current supportive evidence of such claims. Of interest in the discussion will be the concept of the “art of osteopathic medicine,” which provides satisfactory patient care even in situations where there is no “published evidence.”

According to Cypess (1983), low back pain was the most common reason for office visits to osteopathic physicians based on the 1977–1978 National Ambulatory Medical Care Surveys (NAMCS) (20).

Subsequently, based on the NAMCS of nearly 40,000 ambulatory care visits to osteopathic physicians, Koch and McLemore report in 1987 (21) that “although office-based DOs gave ample evidence of their prominent concern with the musculoskeletal system, this concern did not appear to dominate their office practice.” The closest counterpart to osteopathic office care was found in the care provided in the offices of MDs in general or family practice. Most DOs in office practice were best characterized as generalists who brought the added dimension of a specialized philosophy and training to the conduct of their professional tasks. With respect to musculoskeletal disease, the same authors found that DOs were more focally involved with injuries and musculoskeletal disease, conditions which, according to prior NAMCS studies, were among the most likely to be associated with symptomatic pain (22,23).

This allowed Koch and McLemore to further conclude that apparently, the use of manipulative therapy “reduced the perceived need for pain medication, albeit to an unknown extent” (20). The following patient and physician characteristics were specifically reported: “The DO’s special concern for the musculoskeletal system is evident in the finding that back symptoms were the major reason for a patient visit. Back and neck symptoms alone motivated about 1 of every 10 visits to the osteopathic physician.”

More recently, Licciardone and Herron (23) report that a majority of those patients who visit an osteopathic physician receive treatment for musculoskeletal disorders. Furthermore, based on a national telephone survey, Licciardone further reports in 2003 (25), that a majority of those patients who visit a DO also receive spinal manipulation. Among those persons who reported being life time users (16% of the respondents), 84% received primary care, while 52% reported receiving osteopathic manipulative treatment (OMT) and 25% received specialty care.

Musculoskeletal Disorders, Health Care Access, Cost, and Quality

The Osteopathic Survey of Health Care in America (OSTEO-SURV II), a national random telephone survey, confirmed that most patients visiting osteopathic physicians (52% in the 1998 and 2000 administrations) continue to seek treatment for musculoskeletal conditions (25).

In the United States, osteopathic physicians, allopathic general and family physicians, chiropractors, orthopedic surgeons, and other medical specialists are the main providers of low back pain care. Millions of office visits per year are attributed to low back pain, and almost half of the visits may involve spinal manipulation provided by osteopathic physicians or chiropractors (25).

With respect to the quality component of the health care equation, it is noted that unlike treatment modalities offered by many allopathic physicians, including orthopedic surgeons and neurosurgeons, and spinal manipulation provided by chiropractors, OMT can be readily integrated with other primary health care services when patients visit osteopathic physicians (26).

Considering that the majority of low back pain is mechanical, consideration should be given to the nonspecific low back pain as a multifactorial problem, yet all the while considering the “sprain/strain” model to be more reflective of somatic/segmental dysfunction (27).

Osteopathic Structural Examination

The primary goal in the osteopathic management of a patient with a particular condition, especially with a musculoskeletal component

(as the presenting or the associated phenomenon), is to view the influences of posture, regional, and segmental dysfunctions upon the entire organism or specific body regions. The goal of the osteopathic structural examination (OSE), which searches for functional aberrations within the musculoskeletal system, is to determine the presence of one or multiple segmentally related somatic dysfunction(s) and its/their relevance within the overall clinical presentation. Perhaps the greatest contribution from the osteopathic manipulative approach and integrative thought is the evaluation of a diagnostic and therapeutic framework defining the various dysfunctions that affect the musculoskeletal system, with a goal of restoring maximal function within postural balance (28).

The OSE has as the primary goal the determination and specification of the entity known as somatic dysfunction (ICD 9:739). The examination routine builds upon and is integrated into the standard neuro-orthopedic and medical examination routine. By using the OSE, the physician is able to obtain information about the tissues and body regions otherwise not available through the standard medical exam or diagnostic imaging or laboratory studies.

The OSE takes on special consideration in the musculoskeletal system and also is important when dealing with nonmusculoskeletal issues, especially when mediated through viscerosomatic reflexes.

A Rational Approach to the Patient

In order to maximize the individual person’s functional capacity, osteopathic medicine’s philosophical and practical approach has always emphasized the individual’s capacity for self-healing when appropriately guided and fostered, including the use of manual medicine approaches. Thus, so it appears, osteopathic medicine has inherently “practiced” medicine using the biopsychosocial model throughout. More research is needed that will look at such factors as cost-effectiveness, impact, outcomes, and expediency of care as provided by medical providers, and osteopathic physicians, in particular. The “standard” research methods, however, may not suffice. New tools or approaches to the study of functional abilities as well as impairments and disabilities are needed in order to fully “catch” the multilayered effects a fully integrated hands-on approach has within the medical setting (29).

With the growing international collaborative efforts, it is becoming evident that what should guide patient management is a comprehensive and patient-centered approach based on the best available evidence. In addition to recommending specific evidence-based practices for neck pain, the members of the *Bone and Joint Decade 2000–2010 Task Force on Neck Pain and Its Associated Disorders* performed an analysis of their own group’s activities and “internal workings” in a “Self-Study of Values, Beliefs, and Conflict of Interest,” which led to a set of “Guiding Principles” (30). From this, it is apparent that such guiding principles are helpful, if not necessary, in advancing sound consensus.

Musculoskeletal Issues and Medical Diagnoses

Of growing recent interest to clinicians and basic science researchers alike are the often surprising interrelationships that have been observed to exist between many nonmusculoskeletal and musculoskeletal conditions as well as particular medical issues related to various musculoskeletal problems.

When a patient enters the osteopathic physician’s office, the musculoskeletal component assumes a central role for either of the two following reasons or a combination of both:

1. The presenting complaint is related to the musculoskeletal system.
2. The presenting complaint is a medical issue that is accompanied by musculoskeletal issues.

The physician skilled in both aspects, that is one having achieved a well-educated understanding of both the full spectrum of medical care *and* the musculoskeletal system, is best situated to determine the most appropriate patient-specific approach.

Organic Versus Musculoskeletal Pain

AN INTERESTING CASE

A woman in her early 60s was referred for osteopathic manipulation by her internist because of unresolved upper and midback pain of several weeks' duration. Laboratory and radiographic studies had been unremarkable. The history revealed a "strain" after the patient had picked up her granddaughter. Initial osteopathic evaluation revealed no localizing neurologic deficits or other "red flags" but found both chronic and acute tissue changes in the midthoracic region. The patient received myofascial trigger point injections with Lidocaine and OMT in the first visit.

In her follow-up visit one week later, the patient reported that the presenting pain had completely disappeared after the initial treatment, only to return "like gang-busters" 2 to 3 hours after the injection. Follow-up examination revealed more acute soft-tissue changes and somatic dysfunctions, prompting the contact of the patient's internist to rule out viscerosomatic disease.

The MRI of the spine revealed a space-occupying lesion in the thorax, which by biopsy turned out to be a mesothelioma. The patient succumbed approximately 6 months later.

Organic pain may mimic musculoskeletal pain. The more common organ-system related pain syndromes that present as either pseudospine pain or pain referred to various regions of the axial skeleton and/or the extremities include the following (29):

- *Cancer and the entire body system*—85% of patients who have bone cancer report pain; 50% of patients who have breast cancer report pain; and approximately 40% of patients who have lung or gastrointestinal cancer report pain.
- *Cardiovascular disease* that may present with pain mimicking musculoskeletal disease include abdominal aortic aneurysm, angina, myocardial infarction, pericarditis, and mitral valve prolapse.
- *Lung diseases* include such entities as a pulmonary embolus, pneumonia, and tracheobronchial pain.
- *Gastrointestinal diseases* include cholecystitis, duodenal ulcer, irritable bowel syndrome, and pancreatitis, among others.
- Symptoms/signs related to the *genitourinary system* include sources such as cystitis, nephrolithiasis, and prostatitis.
- *Gynecologic* considerations include endometriosis, pelvic inflammatory disease, and ectopic pregnancy, as well as cancer.

Recent research advances in the basic and clinical sciences have shown in the care of the patient with diabetes, for instance, that the skeleton is more than the support and biomechanical "connector organ" of the body, as it is "actually an endocrine organ," which produces hormones that act outside of bone (31). The spine is now believed to influence the body's insulin and glucose levels. For instance, Osteocalcin, a hormone released by bone cells, is reported to direct the pancreas to produce more insulin: all the while it is thought to signal fat cells to increase their sensitivity to insulin (31).

The Patient Visit: Cardinal Questions

From a direct and practical medical management standpoint, in the evaluation of a patient with a musculoskeletal issue, there are

four cardinal questions that need to be answered in each clinical situation, especially when associated with apparent or true medical emergencies involving complaints of pain, stiffness, or swelling affecting the spine and joints of the extremities.

1. Is there a systemic organic disease that could explain the symptoms?

This question would lead to the appropriately targeted medical evaluation of the patient ruling out the prominent "red flags." The osteopathic physician's medical education allows her/him to easily integrate the "red flag thinking" into the standard medical examination. The OSE may provide immediate clues for diagnosis (e.g., presence of viscerosomatic reflexes) and osteopathic treatment may provide information about prognosis in response to manipulative treatment that may be provided as an adjunct or primary treatment intervention for a particular situation.

2. Are the symptoms due to neurologic deficits that are becoming progressively worse (e.g., low back pain, with worsening leg pain and loss of bowel and/or bladder control, for instance, in cauda equina syndrome)?

In this case, surgical referral is then most likely indicated.

3. Are there social or psychological stress factors that influence or worsen the patient's pain perception (e.g., impending job loss, family discord, prolonged disability, loss of function), both vocationally and avocationally that may have precipitated psychological issues?

4. Is there a history of major trauma—even if remote?

This question includes trauma that may have required hospitalization in the past, for instance. Of significance is any report in which the patient volunteers the information that the "wind has been knocked" out of him/her. If there is such a history, it may imply longstanding adaptive or compensatory changes in the entire musculoskeletal system such that areas of "stress" are created throughout the body, which may cause symptoms "away" (centripetal from) the location of original injury. For instance, a patient with shoulder pain may present with a pelvic dysfunction that had never been detected, and vice versa, leading to all sorts of muscle, fascial, articular, and capsular changes that may create an "individualized" pain presentation.

Integrated Osteopathic Evaluation and Management

The aim of individual patient management is to comprehensively address both the patient's pain and his/her functional deficits and, using best medical practice, to work toward goals that are determined in partnership between patient and physician (32). Both the patient's vocational and avocational interests must be taken into account when developing a management plan. Furthermore, it is prudent to build projections of time frames according to which one would expect certain improvements to occur in order to allow monitoring patient progress. It should be remembered that even when best care is rendered, patient expectations and preferences may affect outcome (33).

Manual medicine treatment may assume an integral role in the management of the various musculoskeletal disorders or particular presentations. This is especially true when the approach to the individual patient is appropriately coordinated within the entire patient medical management process; from obtaining a meaningful history to integrating a structural/functional musculoskeletal examination, and implementing a comprehensive treatment plan with appropriate follow-up, all the while determining specific medical and functionally meaningful end points.

As shown in Table 22.3, the OSE thus builds upon and refines findings elicited in the standard neuro-orthopedic examination by using specific manual medicine approaches (56), by:

1. Paying specific attention to findings of asymmetry in posture, regional, and segmental regions
2. Determining both the degree and the quality of motion abnormalities/restrictions or hypermobility
3. Eliciting abnormal soft-tissue findings in muscle and fascial structures
4. Eliciting specific findings through controlled provocative testing

TABLE 22.3

The OSE Embedded in the Standard Patient Visit Routine Based on the Problem-oriented SOAP-format Approach

Subjective	Patient's Chief Complaint Pain—Loss of Function—Lifestyle Changes	Physician Activity/Task
	<ol style="list-style-type: none"> 1. History of present illness 2. Detailed pain history and medical history 3. Functional history/loss of function 4. Is there sinister organic pathology ("red flags") <ol style="list-style-type: none"> a. nonmusculoskeletal related history b. musculoskeletal related history 5. Any history of trauma? Recent vs. remote 6. Review of systems, social, family history, medication use, allergies, prior interventions/studies, etc. 	Standard Medical Interview and questions (including stress and stressors) Osteopathic considerations <ol style="list-style-type: none"> a. trauma, even if remote b. work habits (vocational) c. avocational components (hobbies, etc.) d. stress and stressors (unit/function/outcome) e. any "mechanical issues" that could contribute or exacerbate an underlying/associated medical issue f. patient goals and why he/she came to the visit
Objective	Standard Neuro-Orthopedic Exam	Physician Activity/Task
	<ol style="list-style-type: none"> 1. "LOOK": General Inspection Gait—posture—deformities—skin 2. "FEEL": Palpation of gross structures 3. "MOVE": Range of motion (quantity) 4. Neuro exam: Sensory-motor examination 5. Special tests: Provocative tests 6. Adjunct studies: Laboratory/Imaging/Neurodiagnostics 	Appropriate Exams/evaluation Standard medical exams Osteopathic Integration using the structural examination routine—to be correlated with the other findings KEY element: Integration of structural OMM exam into the entire clinical scenario (contextual)
	Osteopathic Structural Exam Screen—Scan—Segmental Exam	
	<ol style="list-style-type: none"> 1. "LOOK": Specific joints, spine and tissues after general exam 2. "FEEL": Detailed tissue/joint palpation 3. "Move": Segmental/joint specific motion testing; quality and quantity 4. Function: Muscles and Fasciae/"Points" 5. Specific tests: Provocative testing of specific joints/regions 	
Assessment	Diagnosis—Assessment—Clinical Impression	Physician Activity/Task
	<ol style="list-style-type: none"> 1. Structural level: "organic" 2. Functional level: "dysfunction" 3. Pain perception level: pain and behavior 	<ol style="list-style-type: none"> 1. RATIONALE for which studies are essential/helpful — and which might be "superfluous" 2. RATIONALE for the correlation of osteopathic diagnostic findings to the clinical presentation 3. RATIONALE as to what techniques are indicated and contraindicated 4. RATIONALE as to what patient goals and physician goals would need to be prioritized and what outcome is expected in what time frame 5. Provides the framework of what additional information is essential to have and how to obtain it
Plan	Treatment—Planning—Management	
	<ol style="list-style-type: none"> 1. Comprehensive, patient-specific planning and time projections 2. Setting meaningful functional goals 3. Periodic reevaluation with appropriate parameters to monitor progress or lack thereof 	

5. Helping select the appropriate additional diagnostic studies as indicated by the patient's presentation and specifically defined patient and physician goals with specific outcomes and time frames in mind

The key is that the presenting complaints and findings per each visit's assessment should be reviewed anew and monitored on an ongoing basis and compared with the initially set patient-physician goal so as to allow meaningful monitoring of the progress or lack thereof. The patient's pain should be assessed within the greater context of patient expectations and elicited goals. Patients may be "ok to live with some pain," as long as they can do what they want or need to do.

SUMMARY

The incidence of musculoskeletal problem in the general population is so high that a typical patient is likely to have MSK problems in addition to the other medical issues. Neck and back pain are among the leading source for cost generation in the United States, and there is no change for the better predicted given the aging of the population. The cost associated with the diagnostic and therapeutic management of chronic musculoskeletal diseases or disorders is expected to continue to rise. Musculoskeletal disorders have a profound effect on aging and lifestyle and vice versa. Consideration of the role that somatic dysfunction plays in the musculoskeletal system may provide improvement in quality, cost, and access to care. The osteopathic physician is able to positively influence the (a) access, (b) quality, and (c) cost dimensions *directly*. Osteopathic physicians are well prepared to take on the challenge of muscle and bone disorders, especially when considering the duality of either (A) medical issues that are accompanied by musculoskeletal issues or (B) musculoskeletal issues that are accompanied by medical problems. The ability of treating both simultaneously should enhance access, quality, and cost through a best-practice approach.

KEY CONCEPTS

- Environmental health is the field of science that studies how the environment influences human health and disease.
- When a patient presents with signs and symptoms of disease that is difficult to successfully treat, you as the clinician should go back to the patient's history and make sure you included a complete environmental history.

INTRODUCTION

Our environment is made up of all the things around us. It can be broken down into our natural world such as air, water, and earth, and our man-made world such as our homes, buildings related to work, pollution, and chemicals. Our environment includes the foods we eat, the clothes we wear, and even our socioeconomic status. As human beings, we have an intimate relationship with our environment. We cannot be separated from the food and water we eat and drink, or the environment in which we live. Too often, we take environmental issues for granted and dismiss them as a factor in health. As a physician, it is vitally important to remember these aspects when evaluating patients. An environmental history is a key component to obtaining an accurate picture of your patient's complete health status. You are your environment.

THE INTERACTION OF GENETICS AND ENVIRONMENT

Some liken the role of genetics in your overall health as a loaded gun, and the environment as the actual trigger. Patients often ask themselves the "why me" question. How is it possible for one person to smoke like a chimney for years and never develop lung cancer, and another individual who smokes significantly less yet develops lung cancer? Current research is leading scientists to believe that factors in our environment, such as pollution and man-made chemicals, as well as naturally occurring gases and radiation may be setting us up for disease (1). The National Academy of Science has reported that as much as 25% of developmental disabilities may be caused by environmental factors.

A study in 2006 evaluated the effects of polychlorinated biphenyls (PCBs) on the cognitive function of adolescents. The study found that there were "significant correlations between serum PCB concentrations and three subtest scores: delayed recall index ($p = 0.019$), long-term retrieval ($p = 0.004$), and comprehension knowledge ($p = 0.043$). These subtle negative effects provide a warning that more serious effects could occur from greater exposure to environmental PCBs" (2). PCBs were banned in the 1970s, but they are classified as persistent organic pollutants that bioaccumulate in mammals. They were used in many everyday items such as wood flooring, adhesives, and paints to name just a few. Thus, many homes and buildings that were built with the use of PCB-contaminated items continue to be a health threat, especially to those of lower socioeconomic status (3). If we do not ask our patients about their environment, we will miss important epidemiological information that will help us diagnosis, treat, and, more importantly, prevent disease.

ENVIRONMENT AS THE TRIGGER FOR DISEASE DEVELOPMENT

Several common environmental factors can impact health (4–7), as shown in Table 23.1.

Examples of work-related environmental diseases include:

- Carpal tunnel syndrome
- Hearing loss
- Vibrational trauma
- Musculoskeletal pain
- Asbestosis/pleural plaques

Examples of environmental diseases related to chemical/biological/radiation sources include:

- Birth defects
- Cancer
- Dermatitis
- Emphysema
- Fertility problems
- Lead/mercury poisoning
- Nervous system disorders
- Vision problems
- Waterborne diseases
- Kidney/liver disease
- Asthma
- Allergies

PATIENT HISTORY

When taking a social history of your patient, it is imperative to include an environmental history that includes both occupational and nonoccupational information. Specific questions will give you the detailed information you need to properly evaluate and care for your patients.

Keep in mind that chemicals leave residue behind even outdoors. Children and pets crawl on floors and play outside, and young children place almost everything in their mouths. We tend to have close contact with our pets and they often sleep with us; thus, a pet could contaminate our indoor living spaces. Most patients are not aware of what kinds of chemicals are in their home-cleaning products or pesticides, or the chemicals used where they work. All employers are mandated by the government to maintain a Material Safety Data Sheet (MSDS) that is accessible to all employees giving a complete list of all chemicals used in the workplace. Patients should be encouraged to maintain a file with a copy of the MSDS from all of their jobs (8).

TABLE 23.1

Examples of Environmental Health Factors

Natural world	Air	Water	Soil	Chemical	Biological	Social
Examples						
Dust	Radon gas	Mercury	Arsenic	Mold	Fungi	Pollen
Man-made world	Structures: home and work	Schools	Farms	Factories	Community buildings	Roads
	Transportation: public and private	Land	Waste management	Pollution	Chemicals	
Examples						
Organophosphates	Pharmaceuticals	Latex	Asbestos	Epoxy resins	Cigarette smoke	Carbon monoxide
Lead paint	PCBs	Noise	Pesticides	Ozone		

NONOCCUPATIONAL AND OCCUPATIONAL ENVIRONMENTAL HEALTH HISTORY

Begin asking questions systematically. The questions apply to pediatric, adult, and geriatric patients. You need to ask specific questions as most patients are unlikely to realize that environmental information could be pertinent to their problem. Box 23.1 provides a sample of some of the key questions to ask your patients. It is not intended to be a comprehensive list of all possible questions. Your general history should have the majority of your open-ended questions. An environmental history should be focused on the details; be a detective.

Key Questions in an Environmental Health History

- Is the problem acute or chronic?
- Are the symptoms worse when at home or work?
- What chemicals are used in and outside the home (e.g., pesticides, paints, solvents, glue, cleaners, etc.)?
- Do any of the chemicals have a warning label (such as “Do not use around small children or pets”)?
- Is the home near any manufacturing companies? If so, what kind?
- Does a family member work around chemicals? If so, what are the chemicals?
- Are any of the household pets sick?
- Does anyone else in the home or neighborhood have the same symptoms?
- Is there peeling paint around the home or in the neighborhood? Are there abandoned buildings accessible to the children?
- Is there new construction in or around the home?
- Are medications and chemicals out of reach of children?
- Has there been any recent water leakage in the home? Is there black mold growing on walls?
- What protective equipment is used when handling chemicals in and outside the home? Are these chemicals used around pets or children’s toys?

(continued)

- Have there been visitors to the home from another country? Has there been travel outside the country?
- Has the home been tested for carbon monoxide or radon gas?
- Does anyone smoke in or around the home?
- Do you use well water?
- Is the patient eating a strict vegan diet?

Focused Occupational History Questions

- Type of work: current and past 10 years
- Chemical or radiological exposures
- If there are chemicals in the workplace, does the patient have a copy of the MSDS?
- If working with or around chemicals, what protective gear does the patient use?
- If working with or around chemicals, does the patient shower at work and change clothes before going home?
- Does the patient work in manufacturing? If so, what kind?
- Does the patient work outside? If so, in what capacity?
- Is any machinery used (e.g., heavy, loud, grinding vibrational, etc.)?
- If working with or around machinery, what kind of protective equipment is used?
- Does the patient work with animals? If so, what kind?

CASE VIGNETTE: ENVIRONMENTAL ILLNESS

Mary is a 40-year-old health care worker who is in good health with a medical history of only reactive airway disease (RAD). She reports to the clinic with chief complaints of new-onset shortness of breath, nonproductive cough, and wheezing that started 3 weeks ago. She denies any other symptoms. She states that she has not had a flare-up of her RAD for over 5 years. Her RAD is known to be triggered by dust mites, mold, and dog dander. She admits to trying allergy medication and an albuterol inhaler without significant improvement in her symptoms. The patient reports that she moved into a new house 3 weeks ago, that is a new construction home. It has been professionally cleaned three times, but her symptoms seem to

be getting worse. She reports that she has attempted to “dust proof” her new house (hardwood floors, no drapes, dust mite covers on her pillows and mattress, air purifier in her bedroom). She has a cat that does not go outside.

Physical examination reveals normal vital signs. The remainder of the exam was normal except for; head exam revealed dark circles (allergic shiners) under each eye. Nasal and throat exam revealed boggy and pale nasal mucosa with clear drainage and cobblestoning of the posterior pharynx. On pulmonary evaluation, the patient had both inspiratory and expiratory wheezing. The remainder of the lung exam was normal.

Investigation of the patient’s new home revealed an access panel in her bedroom closet that connected to the room for the washer and dryer. When the panel was removed black mold (stachybotryis) was found covering all of the inner drywall in the access space. A professional mold removal company was hired to eradicate the mold. The patient’s symptoms completely resolved after the space was cleaned.

Resources Box

There are many resources to assist the practicing clinician with understanding the impact of environmental issues on health. The Toxicity and Exposure Assessment for Children’s Health (TEACH), is a Web site run by the EPA that contains summaries of scientific literature and U.S. Regulations regarding children’s environmental health currently focusing on 18 known chemicals of health concern (www.epa.gov/teach/). Many information portals can be accessed through the EPA Web site. Other useful sites are The National Center for Environmental Assessment (NCEA), www.cfpub.epa.gov/ncea/, The National Institute for Occupational Safety and Health (NIOSH), www.cdc.gov/niosh/, National Institute of Environmental Health Sciences (NIEHS) www.niehs.nih.gov/, and The Centers for Disease Control and Prevention, www.cdc.gov/Environmental/.

Patient Education: Easy Steps to Personal Environmental Health

As a physician, your job is not only to diagnose and treat medical problems, but also to educate patients on how to prevent health problems in the first place. Below you will find some important tips to help you educate patients on how to maintain good health.

1. Read labels on house and garden chemicals. Crosscontamination is common and can lead to accidental self-poisonings. Patients should carefully follow instructions on the handling of chemicals especially around children and pets. Use gloves, masks, and eye protection when recommended. When possible use nontoxic, biodegradable products in and around the home.
2. Turn down the volume. Noise pollution is real and can cause permanent hearing damage. Use ear plugs when working with loud equipment and when attending loud concerts (9).
3. Use a carbon monoxide detector in your home. Carbon monoxide can leak from faulty heaters and is produced from the exhaust of cars. Detectors are inexpensive and easy to install.
4. Know the hazards of your job. All businesses are required to have an MSDS file of the known chemicals used on a job site. Encourage patients to ask their employer for a copy of this information to include with their chart.
5. Immediately deal with any water leakage in the home. Look for any signs of mold (commonly found in wet areas around washing machines, windows, and bathrooms). Remove all mold from your home (10).
6. Keep chemicals and medications out of reach of children. Use child-proof locks on all accessible cabinets that contain household cleaners/chemicals.
7. Don’t smoke/don’t allow others to smoke around you. There are over 4,000 known chemicals in tobacco smoke, and it is a known carcinogen.
8. Allergy sufferers and asthmatics should consider using an air purifier in their homes. Use dust mite covers on pillows and bedding. Avoid being outside, and exercising outside when air pollution levels are rated as high; this is especially important for young children with asthma (11–15).
9. Wash your hands. Many diseases such as the common cold, flu, and diarrheal diseases are passed passively by people touching bacteria- or virus-laden objects, and then introducing those pathogens into their own system, or contaminating venues affecting many people, such as a food buffet. Hand washing after using the bathroom or changing an infant’s diaper is common knowledge, but reminding your patients can be helpful. Alcohol-based hand sanitizers and plain soap and water will kill the majority of these pathogens.
10. Be careful with the use of pesticides around and in your home. Extreme caution should be used when applying insect repellents to children. They should never be applied over open wounds, or directly to the face or hands. Use the smallest amount possible, and never under clothing.
11. Use sun block. Apply according to instructions and repeat the application if remaining outdoors for an extended period of time or after getting wet. Even waterproof sunscreens need to be reapplied after prolonged time in the water. Use age-appropriate sun block.
12. Eat a healthy balanced diet with plenty of fresh fruits and vegetables. If a patient is eating a strict vegan diet, supplements may be needed to get all the basic nutrients required, especially for young children. Vegetable protein can be less bioavailable than animal protein sources. The average adult should be getting approximately 0.9 g of protein per day per kilogram of weight, and the protein sources used should be able to provide all of the essential amino acids needed.
13. Use caution when visiting the beach. It can pose serious health threats to the young, old, and those with a compromised immune system from contaminated water. Patients should always pay attention to signs for beach closures due to pollution and bacterial contamination (16).
14. Grow plants. Plants have been shown to help reduce toxins in the environment, and they make and release oxygen into the air.

SUMMARY

Every individual on this planet is impacted by their environment. Sometimes that impact moves us toward health, and sometimes toward illness. A complete patient history, taking into account the potential environmental impact, along with a thorough physical exam will give you the information you need to come up with a functional differential diagnosis. Every patient encounter is an opportunity to counsel patients on how to improve their quality of life. Always include “Patient Education” on environmental issues; it will go a long way toward helping your patients have the happy healthy life they deserve.

Osteopathic Medicine within the Spectrum of Allopathic Medicine and Alternative Therapies

JOHN M. MCPARTLAND

KEY CONCEPTS

- The primary care physician (PCP) works with an interdisciplinary health team that includes allied health professionals (e.g., nurses, dentists, physical therapists, etc.) as well as practitioners of complementary and alternative medicine (CAM), such as acupuncturists, naturopaths, and massage therapists.
- Osteopathic physicians are uniquely poised to integrate osteopathic principles and practices with the care provided by allopathic physicians and CAM practitioners, creating a system of integrative medicine.
- Sources of reliable information regarding the risks and benefits (safety and efficacy) of CAM therapies are available. The physician should develop guidelines for choosing local CAM practitioners and formulate a referral strategy.

INTRODUCTION

Treating the person as a whole includes the whole of the patient's "health care team." Interacting with other providers becomes imperative when the osteopathic physician serves as the primary care physician (PCP). Since the majority of osteopathic physicians serve as PCPs, this chapter comes from the PCP perspective. The patient's interdisciplinary health team includes physicians (osteopathic and allopathic) and allied health professionals such as nurses, dentists, podiatrists, physical therapists, occupational therapists, psychologists, social workers, counselors, and registered home health aides. Patients frequently employ complementary and alternative medicine (CAM) practitioners, such as chiropractors, naturopaths, acupuncturists, homeopaths, midwives, and massage therapists. Lastly, patients may self-prescribe Over The Counter (OTC) drugs, dietary supplements, and medicinal herb preparations. The physician must obtain a history of the patient's CAM practitioners and self-prescribed CAM modalities, and document that history. Patients frequently fail to disclose CAM use, so the physician should make specific queries regarding CAM. The patient's attitudes toward other practitioners can be gauged by verbal and nonverbal clues (e.g., tone of voice, body posture, eye contact). Ask the patient or a family member to bring in all pharmaceuticals and nutraceuticals for review.

Osteopathic physicians are uniquely poised to integrate osteopathic principles and practices (OPP) with the care provided by allopathic physicians and CAM practitioners, creating a system of *integrative medicine*. This chapter describes the interactions between osteopathic physicians, allopathic practitioners, and CAM health care providers, delivered within a historical context. For a book-length description of these interactions, see Gevitz (2004).

Allopathic Medicine

Allopaths were initially forbidden to associate with osteopaths or accept patient referrals from osteopaths. Finally in 1961, the AMA Judicial Council deemed it ethical for MDs to work with DOs. After the AMA quit attacking osteopathy, it tried co-opting the profession by assimilation. This danger loomed in the California merger debacle during the 1960s. Another act of integration by the AMA—the sanctioning of mixed-staff hospitals—contributed

to the decline of osteopathic hospitals. Of the 127 osteopathic hospitals accredited by the American Osteopathic Association (AOA) in 1974, only 59 remained in 1999 (Gevitz, 2004). A new assimilation threat began in 1968 when the AMA opened its residency programs to DOs. Thus, association and assimilation have posed a double-edged sword. Will the integration of OPP with allopathic medicine endanger our unique osteopathic identity? Dr. Still was wary of integration, "Medicine and osteopathy as therapeutic agencies have nothing in common either theoretically or practically, and only an inconsistent physician will attempt to practice both" (Still, 1903).

Nevertheless, within Dr. Still's lifetime, osteopathic physicians began integrating OPP with allopathic approaches. Arguably, some allopathic approaches may inform and reinforce OPP. Certainly, the integration of reductionist allopathic research methods by J. Stedman Denslow, D.O., led to breakthroughs in understanding the "osteopathic lesion" or somatic dysfunction. These advances, in turn, sped innovations in osteopathic manipulative treatment (OMT), such as the development of muscle energy technique (MET), functional and counterstrain techniques, and even (at least in part) osteopathy in the cranial field. The allopathically derived philosophy of "evidence-based medicine" has been embraced by many osteopathic physicians (see Chapter 32).

In contrast, J. Martin Littlejohn exported Dr. Still's staunch antiallopathic paradigm to England. He established the British School of Osteopathy (BSO) in 1915. One may speculate that "carrying the torch of osteopathy" by spurning allopathic-flavored advancements hampered osteopathic evolution in England. Indeed, when this author introduced MET into the curriculum at the New Zealand osteopathic school in 2001, former BSO faculty in New Zealand were unfamiliar with many MET concepts. The former BSO personnel taught articular techniques and were inexperienced in counterstrain, myofascial release, and many cranial concepts.

As American DOs have integrated allopathic approaches, some American allopaths have adopted OPP approaches. Holistic medicine has become an allopathic specialty! The American Board of Holistic Medicine was established in 1996 and currently seeks affiliation with the American Board of Medical Specialties. Allopathic physicians have long employed manipulative treatment as a procedure. In 1955, an AMA committee that investigated

osteopathic education had reported, “The use of manipulative therapy is decreasing in colleges of osteopathy and is increasing in the orthopedic and physiatry departments of medical schools” (Cline, 1955). Ironically, many osteopathic physicians use OMT-style techniques developed by allopaths, such as Travell and Simons’ approaches to myofascial triggerpoints (Kuchera and McPartland, 2002). *Principles of Manual Medicine*, 3rd ed., by Philip Greenman, a well-regarded osteopathic text, highlights proprioceptive rehabilitation developed by Vladimir Janda, M.D. (to whom that book is dedicated).

COMPLEMENTARY AND ALTERNATIVE MEDICINE

Widespread American use of CAM promoted federal funding of the Office of Alternative Medicine (OAM) in 1991, which soon enlarged into the National Center for CAM (NCCAM). NCCAM defines CAM as a group of diverse medical and health care systems, practices, and products that are not presently considered to be part of conventional medicine. The list of what is considered to be CAM changes continually, as therapies that are proven to be safe and effective become adopted into conventional health care and as new approaches to health care emerge (NCCAM, 2007). Many CAM practices employ manipulative and body-based techniques (McPartland and Miller, 1999).

Is osteopathic medicine alternative? This debate has raged in the *Journal of the American Medical Association (JAMA)* and the *Journal of the American Osteopathic Association (JAOA)* (McPartland, 1999a,b). After the AMA dropped osteopathy from its list of medical cults in 1961, DOs lost their “alternative” identity in many people’s minds. One of the first comprehensive reference works on alternative medicine did not mention osteopathic medicine in its otherwise encyclopedic coverage of CAM modalities (Bauman et al., 1978). To show how osteopathic medicine straddles the divide between allopathic medicine and CAM, the NCCAM classifies osteopathic physicians as “conventional medical providers,” while it designates OMT as a CAM technique (NCCAM, 2007).

The AOA initially distanced itself from the OAM and NCCAM. In 1995, the First International Congress on Alternative and Complementary Medicine featured an “osteopathy workshop” led by an allopathic physician, Peter Bower, M.D. The AOA changed its position in 2001, and the Bureau of Osteopathic Clinical Education and Research facilitated research collaborations with NCCAM. NCCAM has awarded multiple grants to the Osteopathic Research Center.

RELATIONS WITH CHIROPRACTORS

The AMA waged a fierce war against chiropractic, the largest CAM profession. The chiropractic profession eventually countered with a federal antitrust suit, which the AMA lost in 1990 and paid damages. Early osteopaths distrusted chiropractors, calling them plagiarists. The AOA teamed with the AMA to defeat the initial chiropractic-licensing bills (Norman, 1912). The DOs softened their stance, however, and by the 1980s DOs were granting hospital privileges to chiropractors at Doctors Hospital in Detroit and the Seattle Osteopathic Hospital (Wardwell, 1992). Research collaborations between osteopathic colleges and chiropractic schools began in 1993 (McPartland et al., 1997). In 2005, the AOA officially recognized that chiropractors, naturopaths, acupuncturists, homeopaths, and numerous other nonphysician clinicians have unique and valid roles in health care (AOA, 2007). The very existence of this chapter you are reading attests to the acceptance of CAM by AOA leadership.

REFERRAL PATTERNS

Interactions between providers, in the form of referrals and consultations, necessitate effective communication. Residency programs provide training in the physician-to-physician referral process. Web-accessible primers are available (e.g., Harris, 1998). The consultation letter from an osteopathic specialist to an allopathic PCP calls for particular attention; referring physicians may be hypersensitive to perceived arrogance by a consultant (Greene et al., 2006). OMT specialists have a special opportunity to provide evidence-based education in their consultation letters. Consultation letters can be improved by including problem lists, patient-centered assessments, prognostic statements, contingency plans, and the clear enunciation of consultants’ reasoning behind further tests and changes to current management (Scott et al., 2004). Use of structured letter templates may facilitate the consistent inclusion of key information to referring physicians.

Increasing use of CAM makes it crucial that the physician formulate a referral strategy both clinically sound and ethically appropriate. The physician’s first step is with the patient, fostering open communication and a nonthreatening environment, enabling the patient to enlist the physician as an ally. Choosing a CAM modality requires a balance between the patient’s preferences and evidence to the contrary. A framework for choosing a CAM modality was developed by Adams et al. (2002). The major relevant issues included the severity and acuteness of illness; the curability of the illness by conventional forms of treatment; the associated side effects of the conventional treatment; the evidence of efficacy and safety of the desired CAM treatment; the level of understanding of risks and benefits of the CAM treatment combined with the patient’s knowing and voluntary acceptance of those risks; and the patient’s persistence of intention to use CAM therapies.

Once a specific CAM modality has been chosen, the next step is finding the right practitioner. Considerations include patient recommendations, advice from colleagues, and verification of the CAM practitioner’s licensure. In the absence of licensure requirements, the PCP should open a dialog with the practitioner and ask about duration of training, CAM certification, and membership in professional societies (Frenkel and Borkan, 2003). Collaborating with CAM practitioners in a professional manner will be in the patient’s best interests. The PCP who refers a patient to a CAM practitioner is responsible for ensuring the practitioner’s competency and safety. With time, the PCP will develop a list of trusted CAM practitioners in the community. The PCP should monitor the results of the referral and schedule periodic reviews with the patient. Additional guidelines for choosing CAM practitioners are available (see the NCCAM and Rosenthal Center Web sites cited below). Fully integrated clinics and hospitals need to establish policies governing CAM practitioners’ credentialing and hiring, scope of practice, informed consent, and malpractice liability (Cohen et al., 2005).

The final consideration is cost. CAM therapies are rarely reimbursed by third-party payors. Few CAM modalities are included in the *Resource-Based Relative Value Scale (RBRVS)*, which Medicare and Health Maintenance Organization (HMOs) use to determine provider reimbursement schedules. And listing in the *RBRVS* does not guarantee reimbursement; OMT gained inclusion in 1998, but OMT specialists still struggle with some private insurers and managed care entities. Most third-party payors accept claims from chiropractors. The FDA stopped classifying acupuncture needles as “experimental devices,” thus facilitating reimbursement. Homeopathy and herbal medicine consultations may be reimbursed if the practitioner is licensed as a physician or holding another license allowing the prescription of drugs.

EVALUATING CAM USE

Your patient may have already seen a CAM practitioner, or taken herbal compounds, or ask for advice regarding information gleaned from the Internet. Providing advice regarding CAM practitioners follows the steps described above and further behooves the osteopathic physician to become acquainted with CAM practitioners in the area. Recommending source material regarding herbal medicines and other CAM modalities can be more problematic. Books become outdated and Web sites are ephemeral. Some of the best-known references written by CAM “authorities” are frighteningly biased (McPartland, 1998).

Herbal remedies and dietary supplements may be the most important CAM modalities to understand, because they act pharmacologically and may interact with conventional medications. In contrast, homeopathic remedies employ an “energetic” activating force, rather than a pharmacologic one, and will not crossreact with medications (albeit indirectly, if they ill-advisedly replace allopathic medications). Attitudes toward herbal remedies are often polarized into two extremes: some people believe that herbs are simultaneously *dangerous* and *clinically ineffective* (in other words, all side effect and no benefit). Other people naïvely believe that herbs are *always curative* and *incapable of causing harm* (all benefit and no side effects). Of course, neither extreme is true. Perhaps the best evidence-based text for busy physicians is *The 5-Minute Herb & Dietary Supplement Consult* (Fugh-Berman, 2003).

Although Web sites can be ephemeral things, reliable online sources of information regarding CAM modalities include:

- NCCAM (<http://nccam.nih.gov/>),
- Cochrane Collaboration (www.cochranelibrary.com/clibhome/clib.htm),
- Bandolier (www.medicines.ox.ac.uk/bandolier/),
- Clinical Evidence (www.clinicalevidence.com/ceweb/conditions/index.jsp),
- TRIP Database (www.tripdatabase.com/),
- Rosenthal Center (www.rosenthal.hs.columbia.edu/),
- PubMed (www.ncbi.nlm.nih.gov/sites/entrez).

Several of these sources are proprietary and require subscription fees, so access may be an issue. PubMed may be insufficient as a stand-alone search engine for retrieval of CAM information; McPartland and Pruitt (2000) showed that PubMed yielded only a third of published clinical trials regarding saw palmetto that were located in an expanded literature search. Nevertheless, using PubMed as a search engine may be preferable to general search engine portals (e.g., Google), which typically access low-level pages that are not peer reviewed. The Internet is saturated with both good and bad health information, and studies have shown that consumers are not good judges of quality (Greenberg et al., 2004). Judging the accuracy of CAM information is uniquely challenging because CAM is generally not supported by biomedical literature. Some Internet sites clearly state they have instituted peer review processes, and these sites are preferable.

SUMMARY

In *Medical Economics*, a physician with both MD and DC degrees proclaimed, “The most valuable degree is one I don’t have: the DO... They have it all: pharmacology, surgery, and manipulation” (Gilley, 1989). Osteopathic medicine has grown in recognition and prestige, especially within the past 30 years. Osteopathic practitioners now find themselves where several worlds collide. One world, allopathic medicine, holds sway with its pharmaceutical- and

government-funded dominance. Yet at the same time, allopathic practitioners are losing the confidence of the American public. Another world, CAM, generates little gravitational force within the “medical-industrial complex,” but a rising number of Americans trust and support CAM practitioners. Osteopathic physicians are uniquely prepared to integrate allopathic medicine and CAM within our unique OPP art and science.

KEY CONCEPTS

- The former “art” of practicing medicine has given way to the more modern “clinical decision making.”
- This transition represents a comprehensive process of evaluation, testing, resource utilization, and demonstration of treatment effectiveness.
- The extensive evaluation and treatment options of today were not available to our predecessors.
- The physician impact on the health care system requires knowledge of and attention to the reimbursement process.
- Physicians are increasingly asked to demonstrate improvement and outcomes in practice and within the health care system.

INTRODUCTION

Let us begin with a few questions that we will attempt to answer as this chapter progresses. Is clinical decision making the same as making a diagnosis? If not, then what is clinical decision making? How is clinical decision making today different from the past? How do the daily activities of a physician impact clinical decision making?

Probably no aspect of a practicing physician’s day is more important than decision making, yet it is perhaps least studied by members of the profession. Although an increasingly important part of medical practice, few physicians have any type of formal training in the decision-making process (1). Despite this, reality is that our daily choices as physicians drive outcomes related to quality, safety, and cost.

TEACHING DECISION MAKING

It can be difficult to teach decision making in a way that makes for an interesting classroom experience. This should not come as a surprise given the topic is not “the stuff” that makes medicine or surgery interesting. For most trainees, a practical approach emerges during residency, as few individuals have an interest in regularly applying rigorous methods to or mastering the conceptual theories behind clinical decision making.

There is little evidence to support that practicing physicians read about or take courses on decision making. In fact, few continuing medical education courses teach critical thinking skills. Experience alone appears to account for the improvement in decision making by individual physicians that occurs over time. A three-question survey was recently conducted of thirty career emergency medicine physicians who work in a setting where decision-making complexity and level of uncertainty are potentially the highest in medicine (1). The survey asked about the last time they read a journal article or book explicitly on decision making, if they read the *Journal of Medical Decision Making*, and how important they thought decision making was in their practice. The results are found in Box 25.1.

Clinical decision making is the effective use of information to implement an effective plan of care. Quite simply, it is the “critical thinking” or processing of information that comes after a stimulus (the patient presentation) and before a response (the testing and/or

treatment). This is shown in Figure 25.1, along with what is likely the most common question asked by a physician, “What is happening with this patient?” The information gained from the time-honored completion of a proper history and physical examination is combined with what is learned from other forms of testing and evaluation to guide the development of a final plan of care based upon available forms of treatment. Indeed, clinical decision making encompasses the “art” of making a diagnosis and beyond that it considers the effective use of resources and implementation of the right treatment.

Consider for a moment the expansion of medical and surgical capabilities over the last century. Sir William Osler has been quoted as saying that a patient’s history alone can solve many problems encountered in medicine, and this was likely true at the time. In the late nineteenth century, the “art” of making a diagnosis was essentially limited to information elicited from a patient’s history and findings gathered during a physical examination. Few reliable tests existed and effective therapies were virtually nonexistent for most conditions.

The practice of medicine has changed dramatically since the days of Dr. Osler, and concerns exist about inadequacies in the training process that has changed far less during the same time period (2). Today, there are at least 26 major specialties in medicine and surgery with a vast number of sub-specialty areas recognized or under development. As a result, methods developed to teach clinical decision making must to some degree be applicable across specialties, requiring us to identify elements common to each.

The potential exists for every physician encountering a patient to have a different perspective on how best to approach clinical decision making. Consider for a moment the story of the six blind men and the elephant (Fig. 25.2). There are many versions of this tale, but the essence is that a group of blind men are asked to describe an elephant using only their sense of touch. Although each man describes well the specific part of the animal he touches, the final picture when the descriptions are combined looks little if anything like an elephant. This old story suggests that reality may be viewed differently depending upon one’s perspective.

How often is this true when practicing medicine? It is easy to become focused upon a problem from only one perspective, yours. Such focus limits your ability to solve problems. Perhaps this fact alone supports osteopathic belief regarding the need for a more holistic approach to health care.

Results of Physician Survey Regarding Decision Making

- **Question 1—when was the last time you read a journal article or book explicitly on decision making?**
 - within the last 6 months: 0%
 - within the last year: 0%
 - within the last 5 years: 20%
 - not since residency training: 80%
- **Question 2—do you read the journal *Medical Decision Making*?**
 - yes 3%
 - no 97%
- **Question 3—how important is decision making to your practice?**
 - not very important 0%
 - moderately important 0%
 - very important 100%

There appear to be three critical questions involved with the clinical decision-making process that impact all physicians regardless of their specialty. What is the nature of the problem—acute or chronic? What is the severity of the problem? What information is or is not necessary to appropriately diagnose and treat the problem?

Attempts have been made to loosely describe levels of decision making in medicine (Table 25.1). Such attempts are based upon the complexity of the presenting problem with consideration to the required knowledge and involved skills. Consider for a moment the emergency physician faced with decision making that typically occurs in an acute setting. He or she will likely have limited information and significant time constraints when making a diagnosis. This is a direct contrast to the office-based rheumatologist who will most likely make decisions about subacute or chronic processes. Such a physician will usually have more extensive information at hand and the potential luxury of multiple visits to arrive at a diagnosis and treatment plan. The severity of the problem may be equal for both patients, but the path taken to problem solve will be quite different. A physician whose practice tends to deal with patients described by levels five and six may prefer or be required to use a different method of decision making than one whose patients tend to be described by level two or three.

This suggests that a single method of clinical decision making does not exist. The situation and degree of uncertainty will drive the approach taken by the physician (1). The problem will in

general be seen by the treating physician from his or her perspective dependent upon training and experience.

In order to be effective, physicians must be aware of how different forms of decision making impact their specific type of practice, the types of errors commonly seen with each form, and the methods to improve their decision-making skills. It is however not enough to teach physicians what to do as part of some methodical process; we must also teach them what not to do and what to avoid.

The medical education process is undergoing its first major change in almost 100 years (2). Work-hour limitations have recently been placed upon trainees in the United States and abroad. It remains unclear how such changes will impact the resident training process and clinical decision making in the future. The time spent in the operating room has been reduced as a result of the 80-hour work week rule, replaced in many cases by other nonclinical activities (3). The requirements for internal medicine training have changed as well, reflecting decreased inpatient continuity from the limited work hours. Residency training program changes include increased time for ambulatory training, enhanced didactics, and developing skills lab experiences. A decrease in the amount of time spent providing actual patient care may require that we develop new ways to teach decision making. Traditionally, we have relied upon immersion learning within a time-served apprenticeship as the primary method for resident development (3). This is being replaced in almost all teaching facilities by a more formal, structured, competency-based training program.

The work hour limitation reflects a perceived need to protect the public from error as a result of faulty decision making. Quality indicators do exist for some specialties to suggest that workloads exist above which error is more likely to occur. Specifically, such a threshold has been identified in the specialty of radiology with regard to the number of abdominal CT cases interpreted by a physician per day (4). Because of these types of examples, Pat Croskerry, M.D., Ph.D., an expert in the field of decision making, has suggested that the successful decision maker may become the well-rested physician working in an optimized workplace, who is not driven by a pressure to perform, is aware of the most common forms of error and bias, and is able to blend intuition and analysis to the task at hand.

OSTEOPATHIC THOUGHT

What is osteopathic thought and how does it impact clinical decision making?

One of the early concepts taught to osteopathic medical students is the need to avoid focusing on the obvious problem before you as a clinician, and to instead focus on what is often not so

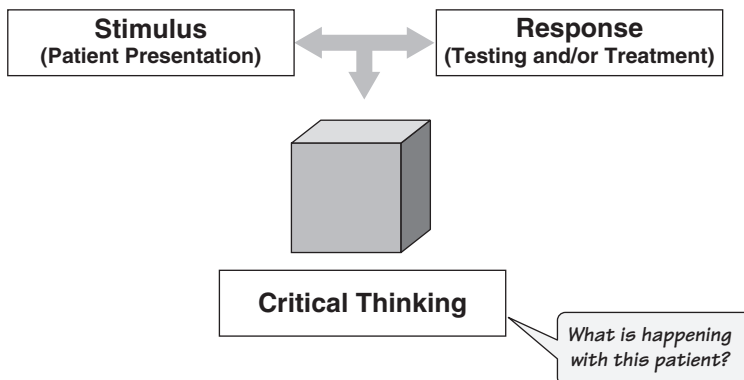

Figure 25-1 Clinical decision making, based upon Stephen R. Covey's *The 7 Habits of Highly Effective People*, 1989.

Figure 25-2 The parable of the Six Blind Men and the Elephant.

obvious. This might be stated as, “don’t treat the symptom, find and treat the cause.”

Our founder Andrew Taylor Still expressed this in another way when he said, “The object of the physician is to find health, anyone can find disease.” A conscious choice to make clinical decisions in a manner that promotes and maintains health requires a different thought process than one focused upon treating symptoms and the effect of disease.

It is critical we remember this perspective when developing the patient–physician relationship. The complaint bringing a patient to us may be far different from an unspoken problem actually troubling them. The need to investigate further (and actually doing so) provides us with an opportunity to identify and treat

something that might otherwise have been missed. There are however a variety of threats to the patient–physician relationship in this current health care environment, including managed care, litigation, decreasing resources, and loss of privacy (5). All of these (and undoubtedly more) have the potential to shift our perspective away from the goal of making good clinical decisions designed to assist our patients with maintenance of their own health. Our decisions and behaviors often send a hidden message that we are treating a disease, offsetting the effects of illness or overcoming bad behaviors, when indeed we should be providing the tools necessary to achieve and maintain an optimum state of health. As an example, consider what a patient imagines an inhaler containing a medication to treat COPD to do when prescribed. Do they believe the inhaler provides them a way to offset the effects of smoking and that the medication is in fact a cure for their problem? In such a case, our message must be clear that the medication is only a bandage covering up the problem by limiting symptoms. The real intervention is the lifestyle change leading to smoking cessation.

Three distinct components are often used to identify the domains within which an osteopathic physician operates. These domains are mind, body, and spirit. Their intersection likely represents what is termed osteopathic thought (Fig 25.3).

It has been suggested that an osteopathic physician should build upon the proposed new tenets of osteopathic medicine when developing an effective plan of care. Simultaneously while doing so, he/she should incorporate evidence-based medicine (EBM), optimize the patient’s natural healing capacity, address the primary cause of disease and emphasize health maintenance and disease prevention (5).

It is tempting in the need to be efficient with our time to focus only upon the needs of the body, but research clearly shows that a failure to address underlying mental illness, such as depression, in a patient with chronic disease results in a less-than-optimal outcome (6,7). Such patients are often less compliant and present with varied and less common symptoms, complicating the decision-making process. Although it may be argued by some that treating within the domain of the mind is not their responsibility, it is just as easily argued that professional behavior dictates proper referral and follow-up on subsequent visits as critical to achieving best outcomes. Consultation with another physician for management of mental illness may indeed help to control the primary disease, although arguments can be made about division of care among specialists being less optimal than primary care by one physician.

TABLE 25.1

Levels of Decision Making in Medicine

Level	
1	self-evident problem with clear-cut treatment
2	self-evident problem with limited thought about treatment
3	simple problem, requires linear thought with essentially clear-cut decision making
4	narrow differential diagnosis to presenting problem requiring limited medical knowledge and use of testing
5	broad differential diagnosis to presenting problem requiring moderate medical knowledge and more extensive use of testing
6	very broad differential diagnosis to presenting problem requiring complex medical knowledge and extensive use of testing
7	life-threatening problem + any of the above levels

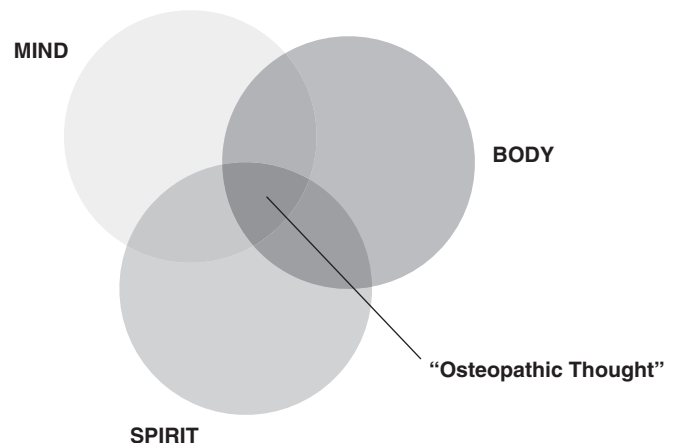

Figure 25-3 Identifying the origin of osteopathic thought.

With regard to the domain of the human spirit, failure to identify the underlying beliefs of a patient may mean a lost opportunity to recognize the critical support systems they are missing or may make it difficult to understand their decisions about testing, procedures or treatment. The end result is that our ability to make effective clinical decisions can be compromised without adequate information.

At least one small study has suggested that communication differences exist between osteopathic and allopathic physicians (8). It is possible these communication differences represent one effect of osteopathic thought. The major differences identified in the *Journal of the American Osteopathic Association* study were associated with psychosocial aspects of patient care. Addressing these critical areas during a patient encounter may help to provide a more complete “picture” as we begin the process of clinical decision making. In fact, the simple act of asking questions or addressing issues of a psychosocial nature may result in an opportunity to provide more complete and comprehensive health care through the development of a stronger patient-physician relationship. Proper research may demonstrate that “osteopathic thought” results in more effective resource utilization for our health care system and improved outcomes for our patients.

The osteopathic approach to patient care is a more complete one if we maintain an ongoing awareness of this mind-body-spirit connection. The primary difference appears to be the amount and type of information gained by thinking within the osteopathic paradigm. Simply put, osteopathic thought creates a different perspective from which our critical thinking takes place.

DEVELOPMENT OF CLINICAL DECISION MAKING

Use your five senses...learn to see, learn to hear, learn to feel, learn to smell and know that by practice alone you can become expert.
—Sir William Osler

For those who argue the practice of medicine can be reduced to branching algorithms, making it pure science to be practiced by an individual using a handheld computer, others note that clinical decision making is an art, blending and balancing science with physician senses.

It is virtually impossible to write about or teach a single method of decision making and expect that it can be applied by every physician and in all types of clinical encounters. Each of the recognized processes has some kind of limitation dependent upon the clinical situation. It is more likely that at any given time a physician may need to call upon one or more of these different processes to deal with an individual patient. However, all too often as a result of constraints placed upon us by a busy practice, shortcuts in decision making become a significant part of physician behavior.

A balancing of physician senses is an important part of the clinical decision-making process. These senses are developed over time and represent tools that are always with us during a patient

encounter. The three most important senses are sound, sight, and touch. The first two are critical to the rapid analysis often required of physicians in determining whether a given patient is “sick or not sick” (9). Such an analysis will often guide what kind of a search must follow to elicit additional information and arrive at a treatment plan.

Consider for a moment how hearing can be a critical part of the patient encounter and decision-making process. Is their voice weak? Do they speak rapidly? Does their speech pattern suggest an inability to form cohesive thoughts? From such information we begin to formulate our first thoughts about what is wrong with the patient. The habitual use of empathic listening skills is likely to affect our thinking process as well and as a result provide a better understanding of the patient before us.

Sight is important to identify any number of patient characteristics. Does the patient appear to be in pain? Do they appear anxious? How are they dressed? What is their breathing pattern? Do they engage your gaze or do they look away? Visual sense is a basic part of the physical exam. It contributes to our documentation about the general appearance of the patient and our subsequent decisions.

Although sound and sight can provide us with a significant amount of information about a patient, touch provides a unique opportunity to expand our perspective on diagnosis and to develop the patient-physician relationship. Like our ears and eyes, our hands are readily available to help provide information about a patient. Palpation as a skill is learned early in medical school and is employed in a variety of ways including joint evaluation, point of maximal cardiac impulse, and establishing the presence or the absence of organ enlargement. These are common components of the basic physical examination, but we cannot as osteopathic physicians forget the role of the structural evaluation, perhaps identifying an otherwise unrecognized viscerosomatic reflex. In an effort to save time, the structural exam is often limited or even worse overlooked, an act that may limit our ability to fully integrate osteopathic thought into patient care.

The development of clinical decision-making skills is a continuously evolving process with at least three defined stages—the medical student, the resident, and the experienced clinician (Fig. 25.4).

The student focuses heavily upon what has been termed the hypothetico-deductive method. A very structured pattern is learned and applied to obtaining the history, completing the physical examination, ordering tests, and arriving at a decision (10). Each step guides the next. Early in residency this same pattern is used, but as experience is gained another form of decision making emerges parallel with the hypothetico-deductive method. It is known as pattern recognition or template matching. This form of thinking seems to represent simultaneous information gathering and decision making. It is as if the physician chooses a likely diagnosis based upon expanded use of the senses already described. With the exception of complex cases, pattern recognition often becomes the dominant form of decision making for the experienced physician.

Figure 25-4 Development of the decision-making process.

Effective decision making requires us to be flexible and avoid becoming locked into pattern recognition alone. An over-reliance upon pattern recognition may result in misdiagnosis. It is associated with certain types of errors the clinician should be aware of when making decisions. Unfortunately, the time constraints of practice often force pattern recognition to become dominant. Oddly, this happens at the same time it is demanded we use resource wisely and make choices to limit risk of litigation from malpractice. The “well-calibrated” physician therefore needs to balance their thinking process with task uncertainty (1). Ultimately, the chosen approach must optimize quality and safety for the patient.

It is also important to note that there may be additional methods of decision making across the various medical specialties. Surgical decision making may be somewhat different as a result of the environment within which a surgeon functions. A skilled (developed) surgeon must have situation awareness and be able to rapidly choose appropriate courses of action (3).

It is unlikely that an experienced physician will make a significant shift in his or her decision-making process without some force motivating the behavior change. This directly reflects that a “hard-wiring” of behavior takes place over time and reduces the likelihood that meaningful change will occur. The practicing physician is also faced with other constraints that limit the possibility of change, time being among the most obvious. An understanding of how experienced physicians think combined with the appropriate use of incentives and application of cognitive forcing strategies might help with the development of continuing medical education designed to improve their decision-making process (11). Such an effort is completely different than that required to promote the development of good decision-making skills among medical students, who are yet to become “hard-wired.”

COMMUNICATION SKILLS

Clinical decision-making and physician communication skills are closely linked. In fact, good decision making is aided by a strong doctor-patient relationship. The astute clinician readily recognizes that each visit is a new opportunity to question, listen and observe (10).

Attention to the interpersonal component of human communication extends our interaction during a patient encounter to include an understanding of the involved emotions. Such an approach directly reflects what has previously been described as “osteopathic thought” and its attendant association with the psychosocial aspects of patient care. It is necessary that awareness exists of both the emotions of the patient and the physician. A patient detecting a disinterested physician is likely to limit the information provided or may alter their responses in order to answer what they perceive the physician wants to hear (10).

The development and utilization of empathic listening is critical, as a good history still remains the backbone of the decision-making process. Tests should never be substituted for this basic component of patient care hoping that the results will provide the answer. Such an approach is potentially harmful to the patient and wasteful to the health care system (10).

Listening must follow a proper line of questioning. Open-ended questions are far more likely to result in patient-centered answers and are less likely to be leading (10). Permitting the patient an adequate amount of time to tell their story is critical. Some sources have demonstrated that on average physicians stop listening to a patient within eighteen seconds after they have started to speak (12). Limiting the patient as a primary resource for information can easily result in error from misuse of “availability” or

the tendency to judge the likelihood of an event by the ease with which relevant examples come to mind (10,13). By way of example, a physician might rapidly decide without adequate information that a patient with cough and fever has influenza, determining this because he has seen four other similar cases throughout the day. This is an example of a heuristic. Heuristics, what otherwise might be thought of as rules of thumb, intuitions, abbreviations, simple judgments and short cuts, are often part of dynamic decision making and represent a form of pattern recognition or template matching (1).

There is growing recommendation to involve the patient in his or her own treatment plan by including them more actively in the decision-making process. This is thought to be important to optimize outcomes and has come to be known as patient-centered care. It requires that we undertake an effort to understand what the patient wants or desires in addition to helping them understand what we are proposing. A patient may view very differently their participation with the decision-making process from that desired by physicians; thus, their involvement should be delineated as the patient-physician relationship is established (14).

There is one other important aspect of communication skills to be considered as it may affect the decision-making process. Physicians must often interact with each other in order to gain additional information that is needed to make a diagnosis and develop a plan of care. This requires an ability to listen and question in a manner that promotes cooperative patient care. When considering collaborative decision making among physicians, there are two factors that can influence the process. These are prediscussion knowledge of the patient and problem and an awareness of each other's knowledge and talents (15).

ERROR AND CLINICAL DECISION MAKING

Despite public perception from legal advertising, errors in diagnosis (misdiagnosis) actually happen in only a minority of cases. Based upon autopsy data, this has been estimated at 15% by A.S. Elstein (10,16). Keep in mind that misdiagnosis is something different from medical mistakes, which are primarily errors of action (10). The majority of errors in diagnosis are due to flaws in physician thinking.

Significant performance variability has been demonstrated among physicians as a whole and within a given specialty. At least one study of radiologists conducted by E. James Potchen, M.D., at Michigan State University demonstrated a variability in agreement of 20% between physicians interpreting a series of sixty chest x-rays (10,17). A 5% to 10% variability was noted when the same radiologist was compared using his or her own interpretation on two separate occasions. The potential “miss rate” was substantially higher depending upon whether the radiologist was asked to “rule-in” or “rule-out” a diagnosis. It might be assumed that the variability represents a difference in the decision-making process associated with a request to find versus to exclude an abnormality. This once again reminds us that perspective affects decision making.

The medical profession has been less than responsive to the concept of admitting error (18). Unfortunately, the ability to do so is critical to successful process improvement. Dealing proactively with error may help us to understand and avoid certain pitfalls associated with time-honored practices used to establish a diagnosis.

Heuristics have been previously defined. The use of heuristics developed as a necessity in medicine and was the approach used by our predecessors when no evidence existed for treatment (1). Clinical problem solving at the time was dependent upon expertise

and the needs of the patient. It is only since the advent of rigorous scientific research, especially the development of randomized controlled trials (RCTs), that evidence supporting decision making has emerged. Unfortunately, many variables exist that impact our ability to make good decisions despite the presence of strong evidence supporting any given treatment plan (1).

The term “cognitive disposition to respond” (CDR) has been proposed as an alternative to words with negative connotations such as error, bias, sanction, and fallacy (1). A CDR represents those actions or behaviors likely to have an impact upon the decision-making process, and over 30 types have been identified (1). Examples of these are found in Box 25.2, demonstrating the somewhat whimsical names that have in some cases been applied. Explanations of these are available in work by Croskerry (1) or in the AHRQ glossary (19).

Many of these CDRs are derived from three metaheuristics: representativeness, availability, and anchoring (1). Availability has been previously defined. Representativeness occurs when physician thinking is overly influenced by what is typically true, failing to consider possibilities that contradict their mental template of a disease and attributing symptoms to the wrong cause (19). Anchoring occurs when physicians allow first impressions to exert excessive influence upon the diagnostic process. Although we are taught in training to “trust our first impressions,” the bias occurs if we continue to maintain a diagnosis as accurate even when there is evidence to the contrary (19).

The duration of medical practice, gender of the physician, and the type of specialty under consideration may all be associated with certain types of CDR and differences in approach to decision making. Knowledge-based, skill-based, and rule-based errors occur with greater or lesser frequency at different points in a physician's career (1). It has already been stated that emotions can affect our decisions, but what about known personality types? The various medical specialties are associated with personality differences (1). Surgeons have been shown to make decisions about undertaking surgery even when information to the contrary is provided to them (1,20). Certain CDRs have been shown to occur more frequently among women than men suggesting that gender contributes to the decision-making process as well (1,21).

CDRs That May Influence Clinical Decision Making

- Aggregate bias
- Gambler's fallacy
- Premature closure
- Anchoring
- Gender bias
- Psych-out error
- Anticipated regret
- Hindsight bias
- Representativeness restraint
- Ascertainment bias
- Ignoring negative evidence
- Search satisfying
- Availability
- Multiple alternatives bias
- Sutton's slip
- Base-rate neglect
- Omission bias
- Triage cueing
- Commission bias
- Order effects
- Unpacking principle
- Confirmation bias
- Outcome bias
- Vertical line failure
- Diagnosis momentum
- Overconfidence bias
- Visceral bias
- Ego bias
- Playing the odds
- Ying-Yang out
- Fundamental attribution error
- Posterior probability error
- Zebra retreat

It is quite possible that certain CDRs are already hard-wired in the development phase of decision making (1). If so, cognitive forcing strategies might be developed to heighten the awareness of medical students and physicians, potentially teaching ways to avoid predictable problems. Simulation and rehearsal are evolving activities at all levels of medical education that may help us with this process. Simulation and rehearsal programming typically includes a debriefing session that is used to review and learn from performance. The “debrief” session is critical to promote behavior change and accelerate learning. During such sessions, it is possible to focus upon observed CDRs.

HYPOTHETICODEDUCTIVE REASONING

This form of reasoning might be looked upon as a “paper” form of problem solving. Because this method can be time consuming, it is most useful in the classroom for training purposes, but under the right conditions, it also has its place in clinical practice (9).

The most likely situation for this method of decision making to be employed is a nonurgent consultation where a complex diagnosis presents itself. Unfortunately, the health care environment we exist in today discourages long visits with patients (both due to patient volume and financial constraints) and limits practical use of this approach in daily clinical practice. Decision making involving the development of hypotheses is best employed when there is more time or less risk involved allowing for the development of several responses or options (1).

Hypothetico deductive reasoning represents linear thinking during which a diagnosis is established as part of a progressive exercise in logic. When compared to pattern recognition, this form of clinical decision making begins by asking the question, “What might this be” instead of making the statement, “I know what this is.”

This method is commonly employed by trainees where a high degree of uncertainty exists about a diagnosis. The linear thought process allows the trainee to investigate the case and break it into manageable pieces. It is also employed by experienced consultants when the complexity of a case is high. This is especially true if the consultant desires to avoid diagnosis momentum (22). Diagnosis momentum is the tendency to assume that the diagnosis made by previous physicians is correct and then building upon their decisions, potentially propagating established errors.

This form of reasoning integrates Bayes' theorem within the context of the clinical decision-making process. It requires that we have a sense of probability as to the diagnosis under consideration and as to the proper interpretation of test results. Each diagnosis has its own initial probability based on its prevalence. Understanding the concept of prevalence is crucial, because common diseases automatically have a greater initial likelihood than uncommon diseases (23). At least some understanding of sensitivity/specificity and positive and negative predictive values is required in order that test be used appropriately. Such simple biostatistics help to guide steps in the decision-making process by collecting information in a purposeful and logical sequence.

By using Bayes' theorem, hypothetico deductive reasoning takes relevant information and estimates the probabilities for a wide range of diagnoses (23). It does this repetitively and sequentially as new information is added, eventually leading to the development of what is commonly termed the “differential diagnosis.” The process often begins even before the patient is seen, driven by available history, documented chart information, and support staff comments (23).

Consider the following example. A 60-year-old male presents with blue lips and fingers. A series of questions begins to arrive at

a diagnosis and develop a treatment plan. The response to each question or result of each test guides the next step. The physician might begin by trying to determine if the finding represents a life-threatening condition. He may ask the patient if he is short of breath, suspecting that a breathing disorder is causing cyanosis to be present. This might be followed by a question to determine if he smokes. A negative response may change the line of questioning, asking next if he has chest pain. While this historical information is obtained, pulse oximetry is found to be normal, prompting the physician to ask how the patient long his lips and fingers have been blue. When the patient responds, "Only since preparing the blueberry pie I just gave to your staff," the line of questioning changes and the importance of good staff communication becomes obvious.

TEMPLATE MATCHING

Template matching represents a "real-time" process with regard to physician decision making. It is most useful at the bedside and especially in urgent situations. It is often visual in nature, although historical information contributes to the decision as well (10). Essentially, the physician is asking, "What does the picture presented by this patient best fit?"

Template or pattern matching is nonlinear reasoning in that "thinking" about the diagnosis begins from the start of the patient encounter (10). The physician is likely to exclaim an almost immediate, "I know what this is" (even if not spoken) instead of undertaking a deeper inquiry to ask, "What might this be?" As such, this is a form of forward reasoning or arriving at a decision even before all information has been gathered (9).

This process relies heavily upon use of shortcuts or what has been previously described as "heuristics." It is acquired rather than taught, meaning that some degree of clinical expertise must be present to incorporate intuition as part of the process (23). The result frames a patient within a certain clinical context. This "pre-establishing" of a diagnosis may lead to certain kinds of errors and less than desirable outcomes in more complex cases.

As an example, think again about the 60-year-old male presenting with blue lips and fingers. If the evaluating physician reacts using minimal critical thinking, suspecting profound hypoxemia as a cause of the cyanosis, a completely different pathway might be followed. The patient might immediately be placed on oxygen and testing undertaken before all the necessary information is accumulated, in this case learning that the effect is the result of having made a fresh blueberry pie. The "preestablishing" of a diagnosis delays identifying the real cause of the patient's presentation, adds cost to the system, and places the patient at risk from unnecessary testing.

Pattern recognition as a form of decision making may lead to a higher rate of error. Such errors can be primary or secondary in nature (22). A primary framing error results from a physician's own flawed decision making from excessive use of shortcuts. A secondary framing error results from a physician accepting and carrying forward an existing diagnosis based upon the decision making of a colleague.

ALGORITHMS

Algorithms have been suggested by quality improvement experts as a means to overcome weaknesses in the health care system as a result of studies suggesting that educational efforts alone do not change physician practice behavior (24,25). The algorithms serve as a form of reminder, helping to guide the clinical decision-making process.

Until recently, these algorithms were added to the practicing physicians approach to patient care as a means to improve outcomes for a variety of inpatient and outpatient conditions.

Now some medical schools have chosen to incorporate a curriculum that focuses upon the use of algorithms to develop in-depth clinical decision-making skills in medical students. The most common presenting signs and symptoms are used as a starting point for patient evaluation.

At least one osteopathic medical school has elected to teach from a curriculum based upon the 120 most common presenting signs and symptoms (26). This clinical presentation model, originally developed in Canada, is now being used by ATSU's School of Osteopathic Medicine in Arizona (27). Each clinical presentation is associated with an algorithm developed to assist the learner toward a diagnosis. Such an approach does create a methodical thought process if followed without shortcuts.

Algorithms use decision trees, typically branching pathways of yes/no and present/absent, to guide the physician through the evaluation process. "Real-time" and "paper" decision making are combined when using algorithms, and it is quite easy to develop computer assistance for this type of process. Both forward and backward reasoning may be included, concurrently recognizing patterns and developing hypotheses.

This type of decision making is commonly promoted by third-party payers believing that it improves outcomes and reduces waste by decreasing over-utilization.

EVIDENCE-BASED MEDICINE IN CLINICAL DECISION-MAKING

Weigh evidence and [do] not go beyond it.
—Sir William Osler

The development and promotion of EBM principles has introduced yet another approach to clinical decision making. Unfortunately, many physicians in practice appear to misunderstand the potential power of this form of problem solving as they have been exposed to a somewhat skewed version of EBM often promoted by third-party payers. EBM is more than just the identification and use of best evidence. EBM in fact provides a framework for identifying best practices by finding and using best evidence, considering clinical experience and circumstance, and incorporating patient interests when undertaking decision making (28).

Perhaps for the physician, these elements of EBM can be thought of as the legs of a stool (Fig. 25.5). The role of the clinician is to balance these legs in a manner that promotes a best practice. Clinical expertise represents individual experience and recall of collective outcomes. Distant events tend to be less remembered while recent events tend to be more remembered, and bad events are more likely to be remembered versus routine good outcomes. Few

Figure 25-5 Best practice as represented by a level stool with four equal legs.

physicians can objectively ask and assess themselves with regard to the question—how am I performing? (2). This is likely because our selective memory skews the impact of clinical expertise.

Best evidence represents primarily the physician's fund of medical knowledge. This means that best evidence tends to be limited by our individual cognitive abilities and by the always and fast changing world of medical research. While patient interests may seem easiest to understand, we must be aware that strong communication skills are required to obtain information, then adequately educate and inform them about choices and options.

Clinical context or situation is unique for every case and can alter our decision-making process. Best practice can also be defined by the intersection of the four major aspects of EBM (Fig. 25.6). No one aspect alone is capable of defining a best practice.

Evidence as derived from a variety of research sources represents probability (29). Higher levels of evidence as based upon predetermined grading systems can be considered to have greater validity in the decision-making process. Those with the highest levels should in fact stimulate a physician to change practice habits when identified. In general, best evidence utilizes specific information about populations and generalizes it to the individual patient.

Evidence stands in direct contrast to the inference or logic that must be applied when considering clinical context in the decision-making process (29). This is especially true in the practice of surgery, where an individual case may require unexpected and immediate consideration of best practices, expertise and patient interest if an intraoperative emergency arises. Rigorous data from RCTs or other forms of research are often unavailable in such circumstances (29). There is no good method associated with teaching this process. It requires the application of general knowledge to a specific situation.

Clinical experience calls upon the progressive development of a personal reference source for measuring when and how to apply specific evidence, while patient interest may ultimately determine whether or not our decision-making process is applicable to a given situation.

Consider the following example with regard to these four elements of the EBM decision-making process:

An 88-year-old male presents with acute blood loss from a lower GI bleed. The patient has a history of coronary artery disease and complains of anginal chest discomfort. His hemoglobin

is 6.0 gm/dL. Best evidence supports the use of blood products to increase oxygen carrying capacity, and clinical experience tells us that use of blood products in this case will likely be of benefit. When you request permission to administer packed red blood cells, the patient informs you he is a Jehovah Witness and unwilling to accept blood products as part of his treatment. Based upon his religious beliefs it is unlikely you will convince him otherwise; thus, in this clinical situation an alternative decision will be required. This results in a return to "point A" of the process. It will require the development of a new clinical question and a new search for best evidence to support another approach to treatment. Since this new treatment may be unfamiliar to you (meaning that you have little clinical experience), patient interest becomes critical in the decision-making process as a result of the specific clinical situation.

Patient safety and quality outcomes are driving forces behind the practice of EBM.

IMPACT OF TECHNOLOGY AND RESOURCE UTILIZATION

Perhaps no area of medicine has been impacted more by technology and the third-party payer system than the physician-patient relationship. The strength and nature of this relationship greatly impacts our approach to clinical decision making, yet it is being challenged on several fronts.

Resource utilization is a new concept faced by practitioners when making decisions about patient care. It requires that we attune ourselves to the value of information gained from a given procedure and treatment while considering the demands placed upon the overall health care system. The greater the intensity of the problem and the longer its duration the greater are the demands upon the health care system.

The most basic approach to patient care and clinical decision making begins with a simple timeline. This timeline has only two points—the beginning of the problem (disease development) and the end of the problem (disease resolution). The duration of the problem (length of the timeline) and other critical points between the beginning and the end (such as onset of symptoms) is unique for each patient and disease process. However, this simple linear model of patient care no longer exists, requiring an expansion of our thinking process in order to be highly successful as a practitioner today. In the current health care environment, clinical decision

Figure 25-6 Identifying the components of best practice for optimal decision making.

making is impacted by at least three major elements of resource utilization and these are:

1. Overall outcome for the patient
2. Timing of intervention or treatment
3. Effects upon the health care system

Each of these elements represents a different axis of the decision-making process, potentially creating a three-dimensional framework in which a physician must learn to operate (Fig. 25.7). As described by this framework, there are only two optimum pathways to follow in clinical decision making. These are:

- Doing something that results in a good outcome and a positive system effect
- Not doing something that results in a good outcome and a positive system effect

This three-dimensional thinking is radically different from the decision-making process of physicians trained prior to the advent of managed care and pay for performance. Although we cannot lose sight of the dictum, “first do no harm,” there are clearly other factors that become important when making decisions about patient care in today’s health care environment.

We have progressed from linear thought to this complex arrangement in a relatively short period of time. Initially, our primary interest as physicians relied upon clinical expertise and patient interest. To these have been added best evidence and system interests as well. Although decision making resulting in a good outcome for the patient should still be our primary goal, it is quite possible to be censured for failing to recognize our impact upon the system. In fact, this awareness of our impact upon the “system” is the basis of the systems-based practice competency domain described by the ACGME and AOA as something to be mastered by a resident prior to graduation. Hopefully, this demand will better prepare future graduates to function effectively in practice.

Clinical decision support systems (CDSSs) are interactive computer programs designed to assist physicians with decision-making tasks. The concept is not new, going back to the 1950s before the right technology existed. Based upon a definition proposed by Dr. Robert Hayward of the Centre for Health Evidence, CDSSs link health observations with health knowledge to influence health choices by clinicians for improved care. Such systems can assist with decisions about when we should or should not do something over the course of patient evaluation and care.

Although CDSS may help to limit the adverse impact of our decisions upon the health care system, they should not be a replacement for physician judgment and should not override the primary importance of our role to assist patients to find a state of optimum health.

One other aspect of technology to impact our decision-making process is the sheer volume of information available to us today as a result of the internet and electronic publishing methods. Keep in mind that more information is not always better information. A significant amount of material published is of little use to the average practitioner and a large portion of it is not what we would call “evidence-based,” thus raising questions about its usefulness in daily practice.

It is important that we learn to access information from highly valid sources, hopefully filtering relevant from irrelevant in the process. Point-of-care resources are under development that will eventually make possible the almost immediate access to useful filtered information that can impact the decision-making process in a real-time manner.

CLINICAL REASONING FOR OSTEOPATHIC PHYSICIANS

Clinical reasoning for osteopathic physicians (CROPs) is a modern and unique approach to decision making. It was created using various aspects of existing approaches to problem solving with the goal of assisting physicians with decision making in the current health care environment.

CROP requires that certain good habits become “hard-wired” into physician behaviors for life. These behaviors represent the AOA domains of competency and are based upon the model of patient care promoted by the new tenets of osteopathic medicine. It is here that “osteopathic thought” can be used to create a unique approach to decision making for osteopathic physicians, thus setting them apart from their allopathic counterparts.

What is different about CROP? It accepts that there is no one right way to make clinical decisions, yet provides in itself a structured framework for decision making. Its basis is found in the work of Stephen R. Covey, Ph.D. In his highly acclaimed work, *The Seven Habits of Highly Effective People*, Dr. Covey published what has become an internationally recognized approach to effecting change on a personal level (30). This change focuses upon the development of good habits or what we might think of as “hard-wired” behaviors. It is highly applicable to the practice of medicine, and for our purposes may be thought of as suggestions to help develop the habits of highly effective physicians. What are the involved steps to “hard-wire” behaviors?

Dr. Covey describes the “maturity continuum” as the central process in his approach (30). This maturity continuum, when considered and practiced regularly, is the framework for “hard-wiring” the desired behaviors. The maturity continuum is made up of seven elements, all of which are applicable to the decision-making process of clinical reasoning. For the purpose of developing effective practice habits the sequence has been altered slightly from the original publication. These seven elements are:

1. Seek first to understand then to be understood
2. Be proactive
3. Begin with the end in mind
4. Put first things first
5. Think “win-win”
6. Synergize
7. Sharpen the saw

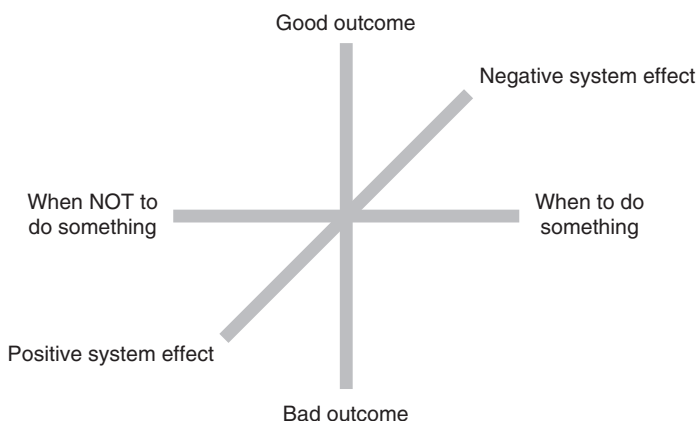

Figure 25-7 Resource utilization elements impacting decision making.

“Seek first to understand then to be understood” occupies the position of central importance in CROP as it is felt to represent the need to develop a strong patient–physician relationship. As previously expressed, this relationship is considered to be critical to the decision-making process. This is the point where empathic listening and speaking become important, as well as the need to be aware of the emotions involved during the patient encounter (the physician’s and the patient’s). This is the foundation for all of the elements that follow. The component of EBM reflecting patient interest is identified while developing this element during first and subsequent encounters. It is based upon a mastery of the competency domains of professionalism and communication/interpersonal skills.

To “be proactive” represents the critical need to maintain and apply current medical knowledge. It requires not only that physicians maintain a commitment to lifelong learning and incorporate evolving technology or treatments into their practices, but also that they not lose focus upon the osteopathic principles we believe are important to maintaining health. To “be proactive” infers that we make decisions in a methodical manner and work to avoid reactive practices that waste resources and potentially result in less-than-optimal outcomes for our patients. This requires an awareness of best evidence within the context of practicing EBM. It is based upon a mastery of the competency domains of medical knowledge and practice-based learning.

“Begin with the end in mind” represents the needs to understand and communicate the anticipated outcomes and endpoints of any planned treatment. As physicians, we should always understand the desired effect of selected treatments. One way of doing this is to become comfortable with the basic statistical concepts of number needed to treat/harm and positive/negative predictive values. Understanding these values and incorporating them into our clinical decision-making process expands the communication possibilities with our patients. This element is based upon a mastery of the competency domains of medical knowledge and communication/interpersonal skills.

To “Put first things first” represents the need to develop a linear or sequential plan of care. No plan can foresee every need of the individual patient, but population-based studies describe for us the behavior of most acute and chronic problems. Understanding that these often follow a similar path can help us to determine the points at which testing and treatment are best undertaken. This requires the development of clinical expertise within the context of practicing EBM. This element is based upon a mastery of the competency domains of medical knowledge and practice-based learning.

Think “win-win” represents a consideration of the impact our decisions have upon the patient, the practice, and the health care system as a whole. Although it is important to remember that the needs of our patient at the moment must always come first, today it is also important to consider how our decisions affect the patient and the system over time. Such consideration to the rationale use of health care services may help to prevent rationing in the future and in fact may provide physicians with the means to maintain greater autonomy over decision making. This “win-win” paradigm should be considered across the spectrum of decision making from the most basic (whether or not to use an antibiotic) to the most complex (whether or not to start dialysis in a dying patient) choices. This element is based upon a mastery of the competency domain of systems-based practice.

“Synergize” represents the need to view decision making within the context of a team, calling effectively upon other physicians and professionals who contribute to positive outcomes for patients.

The concept of synergy helps us to understand the strengths of the evolving health care team that provides care for patients. It is quite important that physicians (especially the primary physician) maintain a central role as members of this team. All team members should understand that a “project” requires a manager (the physician) to be successful. The idea of patient care viewed as a “project” while initially foreign is actually quite accurate. Project management is defined by cost, time, features, and quality. Indeed, effective clinical decision making requires an awareness of these same components. The function of the physician on the team is critical to balancing a desired outcome (quality and features) with effective use of resources (cost and time). This element is based upon a mastery of the competency domain of systems-based practice.

“Sharpen the saw” is the last element of the maturity continuum. It represents the need for us to maintain our own health if we are to provide proper care to our patients. We are all aware that rapid changes are taking place in the health care environment. For example, the demand upon radiologists has been particularly disturbing as the number of images they view per day rises dramatically, possibly creating a less-than-safe working environment in some facilities (31,32). As previously noted, Croskerry has suggested that the successful decision maker of the future may be one who has an optimized workplace, is well rested, and is not driven by pressure to perform. This element is based upon a mastery of the competency domain of professionalism.

Each of the elements of the maturity continuum represents strong professional behaviors that if practiced habitually can augment the decision-making process. The elements are summarized in Table 25.2. They provide a “hard-wired” template to follow whether dealing with the easiest or the most difficult of cases. The first four elements represent our independent growth as physicians. The remaining three elements recognize that we as physicians are a small part of a greater whole, promoting the concept of interdependence in order to improve patient care. In this manner of thinking, effective patient care as a competency domain results from the mastery and application of all the other domains.

The practice of these habits is critical to the next component of CROP. Physicians must be aware of certain “root activities” where repetitive clinical decision making is prominent. In order to be effective, a physician must also “hard-wire” his or her approach to each of these “root activities” including:

- Admitting a patient
- Caring for a patient
- Discharging a patient
- Dealing with unexpected outcomes
- Communicating with patients, families, and colleagues
- Accessing and using information

Applying a “hard-wired” template to each of these “root activities” provides the greatest opportunity for a successful clinical practice, including a positive impact upon patient safety and quality outcomes.

Once these behaviors and templates are in place, certain primary elements of medical knowledge are required to support good decision making within the context of the CROP concept. These elements should drive our learning process both in medical school and subsequently as practicing physicians. The capable physician should possess a knowledge base that includes the elements listed in Box 25.3.

A strong understanding of disease behavior, especially chronic disease, is essential. This means an awareness of what happens from the point of disease development to the final outcome. The natural history of chronic disease has been previously described and assists

TABLE 25.2

Association of the Covey “Habits,” Desirable Decision-Making Behaviors, and the Seven AOA Competency Domains

Covey Habit to be “Hard-wired”	Desirable Impact on Decision-Making Behavior
	Associated AOA Competency Domain
Seek first to understand, then to be understood	Creates strong physician–patient and physician–physician relationships based upon “osteopathic thought”
Be proactive	Communication and interpersonal skills, professionalism, patient care Encourages use of current best practices and incorporation of recommended treatment guidelines
Begin with the end in mind	Medical knowledge, practice-based learning and improvement, professionalism, patient care Undertakes testing or treatment with clear goals and defines expected outcomes for patients
Put first things first	Medical knowledge, communication and interpersonal skills, practice-based learning and improvement, patient care Develops and sequentially carries out well-defined treatment plans
Think win-win	Medical knowledge, practice-based learning and improvement, patient care Understands and becomes a part of the health care system by solving problems for patients, physicians, and the community
Synergize	Systems-based practice Draws upon the strength of fellow physicians and diverse support staff to create a safe environment providing quality patient care
Sharpen the saw	Systems-based practice Recognizes the need to take care of “self” and others by being well rested, optimizing the workplace, and avoiding excessive pressure to perform
	Professionalism

us with this process (Fig. 25.8). Understand that the divisions listed are artificial, but they do provide a generalization of the expected changes over time (23). Appropriate questions must be asked during the clinical decision-making process to recognize where the patient is at any given time with regard to the various stages. Such “thinking” is easily done within the context of timelines and with consideration to several questions:

- How is this disease or problem expected to behave?
- How is treatment expected to work?
- How much improvement do I expect?
- What variations have I seen previously?
- How do outcomes compare to expectations?

Elements of a Capable Physician’s Knowledge Base

- Recognizing signs and symptoms or at-risk populations
- Utilizing available screening or diagnostics
- Understanding the course of illness/complaint or natural history of disease
- Adapting therapeutic guidelines
- Undertaking the right procedure or treatment at the right time
- Identifying desired outcomes and endpoints

As osteopathic physicians, our approach to patient care should also include proper attention to psychosocial issues that impact illness and decision making. Maintaining an awareness of the mind-body-spirit connection defines a central core for the successful practice of osteopathic medicine.

The final critical component of CROP is the development of the differential diagnosis. The list of possible diagnoses for any patient may be very limited or it may be very extensive. If we are

Figure 25-8 Natural history of chronic disease. (Adapted from Rosen P, et al. *Emergency Medicine Concepts and Clinical Practice*. St. Louis, MO: MosbyYearBook, Inc., 1998.)

Differential Diagnosis Descriptors

- **Rule out Dx**—this is the most important diagnostic possibility and represents the greatest potential risk to the patient
- **Probable Dx**—this is the most likely alternative to the primary diagnosis under consideration
- **Possible DX**—this is a closely related alternative, but even less likely based upon presenting information
- **Consider Dx**—this is a possible mimic of the apparent diagnosis and represents variable risk dependent upon many factors; the ability to recognize that it is not the likely diagnosis expands our thought process and our understanding of the patient we are evaluating

not careful, this important step in the “thinking” process can overutilize pattern recognition, resulting in a limited list of possible diagnoses.

Certain descriptors (Box 25.4) are useful for trainees during the previously described “development phase” of clinical decision making to assist with the construction of a differential diagnosis. These same descriptors can also be used to expand the practicing physician’s list of possible diagnoses after clinical decision-making practices have been “hard-wired.” As such, they can be applied as a cognitive forcing strategy to drive change in the “developed” clinician when performance is less than optimal.

It has been said that the physician of the future will not be successful because of what he or she knows, but rather he or she will be successful because of how they access and use information (33). As we have previously commented, the use of CDSSs and algorithms can successfully replace certain tasks that have traditionally been under the control of the physician. Our place as decision makers will rely upon an ability to problem solve using methods that cannot be replaced by a microprocessor.

CROP is a means to accomplish this role in a successful fashion because of the way it expands our view of decision making. CROP permits us to merge advanced forms of evaluation and technology into a basic process that has little cost, is easy to learn, and has been shown under other conditions (business, leadership, and education) to be reproducible in a variety of settings (30). The “hard-wired” behaviors are with us at all times, unlike CDSSs that are expensive and may not always be available.

In summary, CROP consists of five very specific components that if considered regularly provide a strong basis for effective decision making beyond the simple desire to reach a diagnosis. These five steps include:

1. The physician should develop a “hard-wired” template for thinking comprehensively about decision making (the effective physician habits)
2. The physician should develop a “hard-wired” template to approach the repetitive activities of practice (the “root activities”)
3. The physician should develop the primary elements of medical knowledge to better understand disease states, using this as a foundation to be built upon through lifelong learning (the “capability concept”)
4. The physician should develop a strong understanding of expected disease behavior (awareness of the natural history of disease)
5. The physician should utilize cognitive forcing strategies to expand the differential diagnosis for a problem under evaluation (the use of differential diagnosis descriptors)

Figure 25-9 Natural history of chronic disease. (Adapted from Rosen P, et al. *Emergency Medicine Concepts and Clinical Practice*. St. Louis, MO: MosbyYearBook, Inc., 1998.)

Perhaps if we are able to utilize this approach habitually in our decision-making process we will one day find that our health care system becomes less reactive to medical problems and instead approaches evaluation and treatment in a proactive manner. Such an approach is consistent with both primary care and osteopathic principles. Several studies have shown differences in resource utilization and patient outcomes in areas of the country where such practices are emphasized (34). This suggests that the goals of high-quality patient care and optimal resource utilization are not incompatible. Reactive care is in general costly and offered under crisis situations that well-planned decision making carried out in a longitudinal and methodical fashion might help to avoid (Fig. 25.9).

DOCUMENTATION

One final topic remains to be discussed that is closely related to clinical decision making. It directly impacts our ability to be reimbursed as physicians and is critical to the practice of medicine in the present health care system. The topic is medical decision-making as defined by the third-party payer, specifically the Centers for Medicare and Medicaid Services (CMS) under guidelines produced during the 1990s.

The process of clinical decision-making that we have outlined in this chapter requires translation from our minds to paper in order to create a billable situation for our practices and a permanent record of our actions. The “thought” associated with clinical decision making can be extensive and the associated documentation can easily become overwhelming. It is therefore important to have at least some understanding of the current documentation guidelines as they pertain to medical decision making. This short section is not meant to substitute for extensive works on this topic, but rather to provide a summary of how documentation should be undertaken to express the “thinking” process physicians utilize during a patient encounter.

To begin, it is important to point out that many authorities consider documentation of medical decision making to be the true test for determining the evaluation and management (E/M) level associated with a specific patient encounter. The content of an H&P can be easily upcoded, especially since the development of electronic medical record systems. Complexity of the medical decision-making process and the nature of the presenting medical problem therefore become the most heavily weighted factors determining the E/M service (35). It is important then that we

provide adequate evidence within the written document to support the level of E/M service billed.

There are essentially four levels of complexity associated with medical decision making accepted by third-party payers. These are straightforward, low, moderate, and high (36). In addition, there is specific terminology associated with the three main variables contributing to the level of a claim. These three variables are the number of potential diagnoses and management options, the amount and complexity of data to be reviewed, and the associated risk of complication, morbidity, or mortality. To simplify these variables, it might be said that they represent uncertainty, data, and risk (35).

Uncertainty represents a number of things when converting our thoughts into writing. These include the number of problems dealt with during an encounter, how uncertain the physician is about the diagnosis, the number of options for managing the diagnoses, and how uncertain the physician is about which management option to choose (35).

The spectrum of diagnostic uncertainty can be expressed as:

- An already diagnosed problem that is improved or resolved/resolving
- An already diagnosed problem that is inadequately controlled, worsening, or failing to change
- An identified but undiagnosed problem for which the H&P is adequate to establish a diagnosis
- An identified but undiagnosed problem for which additional information is needed

Since documentation of uncertainty relies upon diagnostic possibilities it is important to consider this spectrum, as the level of complexity for billing purposes shifts from straightforward to high based upon these descriptions (35). A single diagnosis involving a stable condition cannot be considered as more than “minimal” based upon the aforementioned spectrum, whereas a new complaint requiring further evaluation significantly elevates the level of uncertainty.

It is best that physicians document what was done to acquire needed information. This should be obvious from the written plan, and at the very least a minimal comment should be added to describe why any testing was ordered (35). Documentation should also be present that addresses the initiation of or any change in treatment (35).

Data as a variable represent a review of information other than that gained from the H&P. This includes test results ordered during the evaluation that you will have to interpret, old records or history from another source (such as family), any discussion with other treating physicians, and personal review of available test data (such as looking at imaging studies).

Risk represents danger posed to the patient resulting from their interaction with the health care system. It does not reflect malpractice risk or risk to the physician and staff. It includes risk associated with the presenting problem(s), any diagnostic procedures requested and management options chosen (35). When developing the risk variable of medical decision making, you should always consider and document co-morbidities and the urgency of the problem. Specific documentation should be included about any planned surgical or invasive procedures. In general, risk is related to the episode being documented and not the long-term risk associated with a diagnosis (35). Risk determination should be based upon what may happen during and immediately following any treatment or testing. Of interest in the stratification process, any visit involving a prescription drug represents at least moderate risk.

How do we use this information in a meaningful fashion?

The problem-oriented medical system described by Lawrence Weed, M.D., nearly 50 years ago is an excellent method for

documentation (9). Although the system as a whole has failed to be adopted for a variety of reasons, one component, the SOAP note (an acronym standing for subjective, objective, assessment, and plan) provides a meaningful way to record the patient encounter. Following detailed documentation of the history and physical using accepted CMS guidelines, the documentation of assessment (including a differential diagnosis) and plan easily provides what is needed to meet the requirements of the third-party payers. The assessment should outline the diagnostic possibilities, while the plan should reflect data review (completed or to be accomplished) and risk (based upon the documented testing or treatment). While some physicians choose to separate their assessment and plan others choose to document their plan immediately following each element of the assessment.

Conversion of our thoughts into written words is critical not only to the reimbursement process but also for successful communication between health care professionals. The record of our decision-making process when clear and understandable assists staff and other consultants, enhances transfer of care, reduces inefficiencies in the system, and may help to prevent error.

SUMMARY

We began this chapter by asking a few questions about clinical decision making and then attempting to provide answers to those questions within the various sections. Modern clinical decision making expands greatly upon what has previously been called the “art of making a diagnosis.” It is a comprehensive process reflecting not only evaluation and testing, but also resource utilization and treatment effectiveness. One primary difference in clinical decision making today is the extensive evaluation and treatment options that were not available to our predecessors. Of particular note, clinical decision making now requires that we pay attention to the reimbursement process (pay-for-performance) and the impact we have upon the health care system.

Physicians are progressively being asked to show how they are undertaking methods to improve their practice behavior and outcomes (practice-based learning) and how to perform optimally within the health care system (systems-based practice). These two domains of competency directly impact clinical decision making. The development of Good Medical Practice-USA by the National Alliance for Physician Competence has caused the Federation of State Medical Boards to suggest reform of the physician licensure/relicensure process (37). Such changes will hopefully encourage continuing medical education by physicians to better understand how the decision-making process impacts them, their patients, and the health care system as a whole.

In conclusion, probably no other part of a physician’s day is more important than the process of clinical decision making. A reasonable attempt by physicians to understand the most common methods of decision making and the errors associated with each can have an impact upon misdiagnosis (safety) and outcomes (quality).

KEY CONCEPTS

- As a group, physicians are granted status, autonomy, and the ability to self-regulate.
- A traditional societal contract expects the application of knowledge and skills to benefit individuals and society.
- Additional challenges to professionalism have arisen in the digital age: internet applications, electronic mail, and social networking Web sites.
- Andrew Taylor still taught that each person should be treated as a unique individual, not as a disease entity. Osteopathic physicians have consistently maintained this thought as the core of their professionalism.
- Professionalism is a personal journey for each osteopathic physician's understanding of how to demonstrate attributes of knowledge, skill, altruism, and duty.

INTRODUCTION

Osteopathic physicians have valued professionalism since the days of A.T. Still. Some authors have suggested that medical professionalism is the cornerstone of the societal contract between the physicians and the public (Whitcomb, 2007). As a group, physicians are granted a status, ability to self-regulate, and to be autonomous in exchange for an expectation that they will use their knowledge and skills to benefit individuals and society. Although there is consensus about the importance of professionalism, descriptions of it vary widely. Each author or organization tends to have a slightly different notion of how professionalism should be defined and the characteristics that comprise it.

To add to the complexity, expectations for professional behavior tend to evolve over the professional life cycle of an osteopathic physician, and recent research is providing greater insight into how subtle differences in demonstrations of professionalism impact patient relationships and outcomes. Additional challenges to professionalism have arisen in the digital age as internet applications, electronic mail, and social networking Web sites have become increasingly popular among physicians (Farnan et al., 2008). For all of these reasons, this is an opportune time to take a systematic look at professionalism as it relates to osteopathic physicians.

Professionalism and Osteopathic Philosophy

Although many of the foundations for osteopathic medicine defined by Still were mechanical in nature, he also taught that each person should be treated as a unique individual, not as a disease entity (Seffinger et al., 2003). A pioneer of holistic health, he developed the four key principles of osteopathic philosophy, one of which being that the person is a unity of body, mind, and spirit. The importance for the osteopathic physician to be mindful of the uniqueness of individual patient needs and the need to maintain a humble attitude when approaching the application of medicine is summarized in Still's basic premise: "It is the patient who gets well, and not the practitioner or the treatment that makes them well" (Seffinger et al., 2003).

The Osteopathic Oath (modified from the Hippocratic Oath in 1938), shown in Box 26.1, also places the health and needs of the patient as the central focus of care; as well as the importance of maintaining the general welfare of the community.

In 2002, the *Journal of the American Osteopathic Association* published a set of principles for patient care to accompany the proposed tenets of osteopathic medicine. These tenets and principles were developed by a multidisciplinary ad hoc committee under the leadership of Felix Rogers, D.O. (Rogers et al., 2002).

The principles of patient care are:

1. The patient is the focus for health care.
2. The patient has the primary responsibility for his or her health.
3. An effective treatment program for patient care is founded on the tenets of osteopathic medicine and
 - incorporates evidence-based guidelines,
 - optimizes the patient's natural healing capacity,
 - addresses the primary cause of disease, and
 - emphasizes health maintenance and disease prevention.

These recently defined principles of patient care further enhance the osteopathic physician's understanding of how to demonstrate the professional attributes of knowledge, skill, altruism, and duty.

Professionalism in the Preclinical Years

At time of matriculation, most osteopathic medical students are typically given some type of document that outlines student rights and responsibilities and communicated expectations about professionalism. For example, at Michigan State University, COM students are "expected to demonstrate academic professionalism and honesty, and to maintain the highest standards of integrity according to a code of honor that embodies a spirit of mutual trust and intellectual honesty" (Michigan State University College of Osteopathic Medicine website, n.d.). Though such guidance is an important beginning, it must be recognized as being unique to the values and culture of the organization that authored them. These early forms of guidance also tend to make a medical student's initial glimpse at professionalism relatively narrow because it relates specifically to one's role as a student and focuses upon academic honesty.

The guidance offered by medical schools on professionalism has been recently expanded as more schools are broadening their institutional policies to specifically address what students should and should not post online (Chretien et al., 2009).

In 2001, the Accreditation Council for Graduate Medical Education ("ACGME") began the "Outcome Project," a long-term

The Osteopathic Oath

“I do hereby affirm my loyalty to the profession I am about to enter.

I will be mindful always of my great responsibility to preserve the health and the life of my patients, to retain their confidence and respect both as a physician and a friend who will guard their secrets with scrupulous honor and fidelity, to perform faithfully my professional duties, to employ only those recognized methods of treatment consistent with good judgment and with my skill and ability, keeping in mind always nature’s laws and the body’s inherent capacity for recovery.

I will be ever vigilant in aiding in the general welfare of the community, sustaining its laws and institutions, not engaging in those practices which will in any way bring shame or discredit upon myself or my profession.

I will give no drugs for deadly purposes to any person, though it may be asked of me.

I will endeavor to work in accord with my colleagues in a spirit of progressive cooperation and never by word or by act cast imputations upon them or their rightful practices.

I will look with respect and esteem upon all those who have taught me my art.

To my college I will be loyal and strive always for its best interests and for the interests of the students who will come after me.

I will be ever alert to further the application of basic biologic truths to the healing arts and to develop the principles of osteopathy which were first enunciated by Andrew Taylor Still”

(American Osteopathic Association Web site, n.d.).

initiative with increasing emphasis on educational outcomes. Professionalism is one of the general competencies outlined in the Outcome Project described as “a commitment to carrying out professional responsibilities, adherence to ethical principles, and sensitivity to a diverse patient population.” They have developed excellent educational resources to aid residency programs and physicians in teaching and assessing professionalism (ACGME Outcome Project Website, n.d.).

The American Osteopathic Association (AOA) quickly followed suit in adopting core competencies. In the AOA version, the six competency areas were accompanied by an additional one: OPP. The AOA also provided more detailed guidance on the core competency of professionalism, adding several required elements to assist in understanding (Box 26.2).

In this guidance from AOA, professionalism encompasses patient advocacy, ethics, collaborative relationships with colleagues; ongoing learning; sensitivity to diverse patient populations; self-health; honesty; confidentiality; and compassion among other things.

Along with graduate medical education, osteopathic medical schools have been required to incorporate the core competencies. Consequently, as medical school progresses, each COM is obligated to teach and evaluate professionalism along with all the other seven required core competency areas. As this occurs, additional descriptors are brought to bear in an effort to accurately capture professionalism so that it can be effectively taught, reviewed, and evaluated. Accrediting bodies and specialty groups contribute additional information by offering their own interpretations and professionalism becomes larger, encompassing a variety of areas beyond the purely academic.

The taxonomy lists for professionalism are abundant and daunting. As shown in Table 26.1, there are many different descriptors

Core Competency of Professionalism

Competency 5: PROFESSIONALISM

DEFINITION

Residents are expected to uphold the Osteopathic Oath in the conduct of their professional activities that promote advocacy of patient welfare, adherence to ethical principles, collaboration with health professionals, life-long learning, and sensitivity to a diverse patient population. Residents should be cognizant of their own physical and mental health in order to effectively care for patients.

REQUIRED ELEMENTS

1. Demonstrate respect for patients and families and advocate for the primacy of patient’s welfare and autonomy.

Suggested methodology to achieve compliance:

- a. Present an honest representation of a patient’s medical status and the implications of informed consent to medical treatment plans.
- b. Maintain a patient’s confidentiality and demonstrate proper fulfillment of the physician’s role in the doctor–patient relationship.
- c. Commitment to an appropriate and nonexploitive relationship with patients.
- d. Inform patients accurately of the risks associated with medical research projects, the potential consequences of treatment plans, and the realities of medical errors in medicine.
- e. Treat the terminally ill with compassion in the management of pain, palliative care, and preparation for death.
- f. Participate in course/program (compliance and end of life). Workshops, lectures, bedside, and clinic/office teaching
- g. Role modeling behavior

AOA Report of the Core Competency Task Force (2003)

of professionalism such as honesty, trust, fairness, respect, personal accountability, altruism, competence, skill, integrity, commitment to excellence (Inui, 2003). Some of these descriptors are objective and amenable to measurement; however, some of them are arguably subjective, difficult to quantify, and open to varied interpretation.

Although we all agree “good physicians” should embody these virtues, the challenge arises with how we should educate, apply, and measure such traits when professionalism (like beauty) is in the eye of the beholder. It is much like trying to teach and quantify love. We as humans agree that love exists, but we have yet been able to establish a tool with which to measure it. Certainly, many attributes of professionalism such as knowledge, academic honesty, and accountability can be identified and measured during the

preclinical years in the academic “course work” setting. However, the true labor of professionalism becomes apparent with the onset of clerkship training and continues to unfold for the duration of the osteopathic physician’s clinical career.

Professionalism in the Clerkship and Residency Years

Multiple organizations have offered differing definitions of professionalism. In his landmark publication on professionalism “A Flag in the Wind: Educating for Professionalism in Medicine,” Thomas Inui, MD, has condensed the work from the Association of American Medical Colleges (AAMCs) Medical School Objective Project defining the “attributes of the good physician as falling into four large domains—being knowledgeable, skillful, altruistic

and dutiful” (2003). The expanded description for each attribute is summarized below:

- Knowledgeable (scientific method, biomedicine)
- Skillful (clinical skills, reasoning, condition managing, communication)
- Altruistic (respect, compassion, ethical probity, honesty, avoidance of conflicts of interest)
- Dutiful (population health, advocacy, and outreach to improve nonbiologic determinants of health, prevention, information management, health systems management) (Inui, 2003)

Medical schools and professional organizations have striven to develop meaningful curricula and evaluation tools to help physicians produce clinicians who will understand and fulfill such societal expectations.

Yet, it must be recognized that the early clinical experiences that medical students encounter in clerkships can be disquieting. They may find themselves thrust into situations where decision making is driven more by insurance restrictions than doing what is best for the patient. When this occurs, they will witness the frustration of their mentors and role models. Quickly, medical students realize that although they are taught that professionalism is important and highly valued, embodying it consistently in clinical situations is not simple or easy at all. Some authors have reported that such early clinical experiences may actually contribute to a decline in empathy (Newton et al., 2008) and moral development during the medical school years (Patenaude et al., 2003). Based on such findings, some authors have voiced concern that more should be done to prevent deterioration during the clinical years in medical school (Branch, 2000; Self et al., 1998).

In a recent article published in *Academic Medicine* 2007, medical students who are “immersed in learning professionalism, observe that most of the professionalism literature missed the mark” (Brainard and Brislen, 2007). These authors indicate that there is a “hidden curriculum” in the actual practice of medicine that places such issues as efficiency, productivity, or academic hierarchy ahead of the patient’s needs. The accompanying cynicism and despair many medical students and physicians describe in response to the “hidden curriculum” are reflections of a grieving process.

The increased use of social networking among the technically savvy medical students can also be problematic. “Medical students may not be aware of how online posting can reflect negatively on medical professionalism or jeopardize their careers.” (Chretien et al., 2009) The authors suggested including a digital media component in the formal professionalism curriculum to help the student manage their “digital footprint.” (Chretien et al., 2009; Gorindo and Groves, 2008).

All of this information should be a serious wake-up call for physicians. It is imperative that we examine the expectations we place on medical students, the impact of their clinical experiences, and what we might do differently to lessen or reverse these negative influences as much as possible.

Professionalism and the Staff Physician

Once a physician has completed residency, obtained certification, and become established in practice, professionalism becomes codified in daily activities. Epstein (2002) wrote “Professional competence is the habitual and judicious use of communication, knowledge, technical skills, clinical reasoning, emotions, values and reflection in daily practice for the benefit of the individual and the community being served.” This expansive description captures the multifaceted demands of professionalism in daily practice

and the intention that such activities will enable the physician to benefit society through his or her work. Although all of these aspects are important to professionalism, much has recently been learned in the areas of communication and physician self-awareness, and these areas are summarized below.

Communication Skills

Communication is one of the primary skills for an osteopathic physician’s effectiveness in the “art” of medicine. These skills help to elicit a patient’s story, promote rapport, influence patients’ understanding, compliance, and emotional well-being (Novack et al., 1992). Historically, communication skills were considered to be a “soft” science, something physicians developed “at patients’ bedsides, in their rounds as residents, and as students at the elbows of master clinicians” (Traveline et al., 2005). Currently, it is appreciated that many of these skills can be taught and, consequently, this is a focus of learning early in medical school so that baseline skills are present prior to contact with actual patients.

Published literature has long shown the value of effective physician-patient communication on improving health outcomes of common clinical conditions such as headache, hypertension, diabetes, and anxiety (Stewart, 1995). Research has affirmed the importance of communication skills and their effect on health care outcomes for racial and ethnic groups (Ashton et al., 2003); gays and lesbians (Harrison, 1996); and the functionally illiterate (Williams, 2002). Low patient satisfaction scores for hospitalists and emergency department physicians have been documented when communication skills are deficient. Some work has been done on developing targeted sets of communication skills expressly to assist physicians and when implemented, there are indications that this does improve those satisfaction scores (Keller et al., 2002).

Empathy has been measured as a neurobiological response in studies using positron emission tomography. This chapter suggests that “the physicians’ use of empathy warrants consideration as a clinical procedure” because of the features of having “a medical indication; a skilled interpersonal performance requiring emotional labor; and an attempted improvement in the patient’s psychobiology” (Adler, 2007). Adler (2007) indicates further that the benefits of affective attunement help the patient to feel understood, but also benefit the physician for they foster a deeper understanding of the patient’s unique situation and clinical presentation.

As technology has advanced, electronic mail has become readily available as a potential tool for communication between the patient and physician, but ethical, legal, and clinical concerns have been raised about the use of e-mail (Luo et al., 2009) Guidelines for clinical use of e-mail are now available through several organizations such as the American Medical Association.

However important communication may be for special situations, a case could be made that in our current practice environment, improved communication skills are important for all physicians—now more than ever before. In busy practices, physicians face emotionally charged situations, crisis decision making, family contacts, conflicting interests, and much more on a daily basis. Improved listening and communication skills can be a tremendous benefit to an individual physician in addressing such issues, in boundary setting, and in clarifying expectations.

Physician Personal Awareness

Because physicians use themselves as instruments of diagnosis and therapy, it can be extremely valuable for a physician to have an insight into how his or her personality, life experiences, and feelings

can impact interactions with patients, families, and other professionals (Novack et al., 1992). In Novack et al.'s (1992) article "Calibrating the Physician," a number of studies are discussed which evaluate factors impacting doctor-patient communication such as the physician's core beliefs, family of origin, gender issues, and sociocultural influences.

In addition, studies have documented a general drop in physician satisfaction most prominent in areas with a high penetration of managed care (Gallagher and Levinson, 2004). In one longitudinal observational study, Murphy et al. (2001) reported a decline in the patient rating of their doctor's communication and interpersonal skills over a 3-year period of time. The authors suggested that possible factors driving this decline might include the distractions of organizational restructuring, mergers, and pressures to increase productivity without compromising standards of care. All of these examples are commonplace in health care environment today.

Consequences of Lack of Professionalism

Just as outstanding physicians are recognized by their continuous professionalism, the absence of professional behaviors can be a signal that an individual practitioner is at risk for problems.

Papadakis et al. (2005) have published a number of studies extrapolating behavior patterns observed in medical students and their associated risks for future disciplinary actions by medical boards. The three types of unprofessional behavior categories that were significantly associated with disciplinary actions were (a) irresponsibility, (b) diminished capacity for self-improvement, and (c) poor initiative (Teherani et al., 2005). Examples of unprofessional conduct included observed behaviors such as unreliable attendance at clinic, lack of follow-up on activities related to patient care, argumentativeness, failure to accept constructive criticism, lack of motivation, and poor attitude. A list of the most frequent subsequent violations that lead to disciplinary action on the part of state medical boards included use of drugs or alcohol, incompetence, negligence, conviction for a crime, and also unprofessional conduct (Teherani et al., 2005).

A case-controlled descriptive design study was published that established a relationship between psychological indices as measured by the California Psychological Inventory ("CPI") with measures of professionalism during medical school (Hodgson et al., 2007). The CPI was administered at time of matriculation. The authors indicated that those physicians who demonstrated unprofessional behavior in medical school tended to score significantly lower on four CPI scales. Low scores on the four CPI scales indicated the following patterns of behavioral deficits: responsibility (self-indulgent, lack of discipline), communality (unconventional, changeable, and moody), well

-being (perceived unfair treatment, health, or personal problems), and rule respecting (rebellious, cynical). Finally, it has been recognized that physicians who receive a disproportionate number of patient complaints and subsequent malpractice claims often struggle with interpersonal behaviors such as establishing rapport, expectation management, and communication effectiveness (Hickson et al., 2002).

Professionalism—A Lifelong Personal Commitment

There are an abundance of suggestions for enhancing education for professionalism from medical schools and professional organizations. The remainder of this chapter will be devoted to providing practical resources for individual physicians to incorporate into their lifelong implementation plan for professionalism. The

suggestions below are organized according to the attributes of professionalism provided in Table 26.1.

Knowledge and Skills

The continuing medical education requirements of licensing agencies and certifying boards provide the structure for maintaining some form of lifelong learning. Current clinical knowledge status is also regularly assessed through periodic specialty certification boards. Participating and receiving feedback from hospital quality assurance programs also promotes the ongoing outcome measurement of clinical skills application. Many hospitals have opportunities for participation in peer review, M&M conferences, grand rounds, and other activities that enable the practicing physician to keep abreast of knowledge and skills in his/her clinical specialty area.

Individual practitioners can become more self-aware of their personality and communication preferences by taking the Myers-Briggs Type Indicator personality questionnaire, a process that provides many helpful insights. Keirse (1998) and Meyers (1980) have expanded on the concepts of personality preferences in their books. Deborah Tannen, Ph.D., is a professor in linguistics and has published a number of useful books and journal articles on gender communication patterns (Tannen, 1990).

Increased understanding of religious and cultural differences may be obtained from attending local college classes, community programs, and/or online resources. Volunteering to help patients and families with understanding medical information in the context of their own cultural and religious issues may also be a very valuable source of personal learning.
