Physician: Seated to the right side of the head of the treatment table

Procedure

1. Pass your caudad arm beneath the patient's neck with your hand adjacent to the opposite shoulder (Fig. 50.55)
2. Gently, using your more cephalad hand, roll the patient's head along your arm from your fingers toward your elbow, until it is rotated 45 to 60 degrees from the midline
3. Allow the patient's head to drop over your forearm, placing the anterolateral cervical musculature on stretch. (You may have to raise your elbow slightly off the table.)
4. Slowly, roll the head slightly further through the soft tissue restrictive barrier, simultaneously pressing the head gently down toward the table. Hold this position for a second and release, allowing the head to rise and roll back to just inside the restrictive barrier
5. This technique is applied slowly and rhythmically gradually increasing the amount of stretch
6. Continue this technique for 3 to 5 minutes
7. Success of the technique is determined by reassessing freedom of motion of the first and second ribs, and by repalpating the previously hypertonic scalene musculature. Success is in part determined by reassessing the patient's symptoms

Articulatory Technique

Rib Raising: Seated Position

Diagnosis

Restriction of motion of ribs 2 to 6. Motion will be created through traction on the pectoralis major muscle. (Motion may be imparted indirectly to rib 1 via its clavicular relations and ribs 7 to 10 through the attachments of the serratus anterior muscle.)

Treatment Position

Patient: Seated on the side or end of the treatment table.

Physician: Standing facing the patient with one foot behind the other.

Procedure

1. Instruct the patient to cross his or her arms, hooking their thumbs into the antecubital fossae (Fig. 50.56)
2. Reach under the patients arms with both your hands, then pass them over the patient's shoulders
3. Make contact with the pads of your fingers at the level of the second costotransverse articulation, just lateral to that same joint

Figure 50-56 Rib raising—seated position.

Note: At each rib level, you will want to position the pads of your fingers between the costotransverse articulation and the angle of the rib.

4. Lean your weight onto your back foot, drawing the patient toward you. The patient's forearms should translate forward, parallel to the floor. At the same time, this should permit the shoulders to drop, increasing the tension on the pectoral musculature and drawing the anterior aspect of the ribs cephalad
5. Simultaneously press forward with the pads of your fingers to create a gapping pressure at the costotransverse articulations
6. Hold this position for 1 second, then release, allowing your weight to transfer to the more anterior foot, and the patient to spring back to a more upright position
7. Move the pads of your fingers down one rib level and repeat. Continue this stepwise down the rib cage until you can no longer comfortably reach the rib levels (usually in the range of ribs 6 to 8)
8. Reverse the procedure, working your way back up the rib cage until you again reach the second rib
9. Success of the technique is determined by retesting motion of the previously restricted costal levels

739.9 Abdominal: Other Somatic Dysfunction

Soft Tissue Technique

Lateral Abdominal Wall

Diagnosis

Hypertonicity of the lateral abdominal wall musculature

Type of Soft Tissue Technique

Perpendicular traction/parallel traction

(This depends upon which muscle layer you wish to talk about.)

Treatment Position

Patient: Prone

Physician: Standing at the side of the table on the side opposite the hypertonic musculature

Figure 50-57 Lateral abdominal wall.

Procedure

1. Wrap your cephalad hand around the lateral abdominal wall. Make your palmar contact as complete as possible (Fig. 50.57)
2. Place your caudad hand on the iliac crest with the heel of your hand near the posterior superior iliac spine
3. Draw the abdominal wall toward you, simultaneously increasing the pressure on the iliac crest to maintain the pelvis in place
4. Hold this position for a second, then release, allowing the abdominal musculature to draw back to its position just inside the restrictive barrier
5. Reposition your hand slightly on the abdominal wall and repeat
6. Continue steps 3 to 5 rhythmically for 3 to 5 minutes
7. Success of the technique is determined by repalpatting the previously hypertonic abdominal muscles

Articulatory Technique

Liver Articulation

Note: In this technique, the liver is considered to articulate with the diaphragm. Inflammatory conditions involving the liver may result in adherence of the liver to the diaphragm with subsequent restriction of diaphragmatic and lower right costal motion

Diagnosis

Restriction of hepatic motion relative to the diaphragm

Treatment Position

Patient: Seated on the side of the treatment table

Physician: Standing behind the seated patient

Procedure

1. Reach under the patient's arms and bring your finger pads into contact with the abdominal wall 1.5 to 2 in. below the right costal margin (Fig. 50.58)
2. Have the patient slump back against you, relaxing the abdominal wall
3. Exert a posterior pressure with the pads of all of your fingers and then curl them upward against the inferior surface of the anterior edge of the liver
4. Instruct the patient to take a deep breath
5. Follow the liver edge as it glides slightly down and forward with downward motion of the diaphragm

Figure 50-58 A, B. Liver articulation.

6. Instruct your patient to exhale. Again follow the liver edge as it glides superiorly and posteriorly with upward motion of the diaphragm
7. Increase your pressure against the liver margin and instruct the patient to breathe deeply again. Try not to allow the liver to move
8. Instruct the patient to exhale and follow the liver as it moves with exhalation
9. Repeat steps 7 and 8 until no further increase in liver motion is palpable
10. Success of the technique is determined by reassessing diaphragmatic and right lower costal motion

SUMMARY

Both soft tissue and articulatory techniques span a wide range of force levels and are therefore adaptable to a wide variety of patient types and problems, making them two of the most versatile treatment forms available. These techniques are often used to decrease muscle tension and increase joint mobility prior to use of high-velocity low-amplitude thrust techniques. They can be used alone, or in combination with any other manipulative technique.

KEY CONCEPTS

- The lymphatic system plays a major role in numerous homeostatic mechanisms of the body.
- The lymphatic system is particularly vulnerable to fascial dysfunction in the region of the superior thoracic inlet.
- Initial draining of the lymphatic system must always be done through terminal areas.
- The risk-to-benefit ratio for lymphatic techniques is quite good. No known significant complications have resulted from osteopathic lymphatic treatment to date. Clinical judgment, however, should always be used when prescribing treatment for a patient in any disease state.

CASE STUDY

Pregnant Medical Transcriptionist With Finger Swelling and Tingling:

This chapter documents numerous benefits that could be derived from thoughtful osteopathic care centered about the respiratory-circulatory model and the systematic, sequential application of

local, regional and systemic “lymphatic” osteopathic manipulative treatment (OMT) to facilitate fluid homeostasis.

Initial Case Presentation:

After 14 years at the same job without complaint, a 32-year-old transcriptionist now presents with 6-week progressive numbness and tingling in her right (dominant) hand. Awakening her nearly every night, the distribution of her dysesthesiae includes her thumb and the next 2½ digits. For the last month, she has had difficulty opening jars and has nearly dropped objects. Gravida I, para 0-0-0-1 and early in her second trimester, she takes no medications or nutritional supplements other than a prenatal vitamin.

Findings:

Her right thenar eminence appears smaller than the left and manifests reduced grip strength; all fingers on the right hand are puffy. On the right, positive neurological tests include Phalen’s (at 20 seconds) and Tinel’s (just distal to the wrist’s flexor crease). There are no other historical or physical findings to indicate thyroid disorder, cervical radiculopathy, diabetes, vascular disease, or other significant health issue.

The common compensatory pattern (CCP) of Zink is violated by her superior thoracic inlet that prefers rotation and sidebending to the left. She has tender fullness in the right supraclavicular region and posterior axillary fold; in the supine position, her shallow, rapid breaths are seen to extend only half-way down to the umbilicus. Spinal palpatory reveals only grade I severity, Fryette type-I somatic dysfunctions; no Chapman points or collateral ganglion findings were identified. She has a right posterior radial head. Active myofascial trigger points (MTrPs) are palpated in the right pronator teres and in several forearm and finger flexor muscles.

Electromyography (EMG) consisting of nerve conduction studies (NCS) with needle examination confirmed moderate severity median entrapment neuropathy at the wrist with positive sensory and motor NCS but no fibrillation potentials in the thenar eminence; it also ruled out a concomitant cervical radiculopathy.

This case and its discussion at the end of the chapter were chosen to illustrate the rationale and manual components associated with applying the respiratory-circulatory model. The ultimate result of the OMT portion of her care in this regard included reduction of upper extremity edema, resolution of the signs and symptoms of her carpal tunnel syndrome (CTS), and increased function in both her arm and several other systems.

INTRODUCTION

The lymphatic system plays a major role in numerous homeostatic mechanisms of the body; it transports fats to the blood from digestive processes, facilitates immune function, is a vital component of the overall circulatory system of the body, and assists the body in removing interstitial tissue fluid and plasma proteins that accumulate as a result of tissue metabolism, inflammation, infection, trauma, or system dysfunction. For these reasons, a coordinated, systematic approach known as the “Respiratory-Circulatory model” and a number of lymphatic treatment techniques have been used clinically by osteopathic professionals to treat patients with a various conditions such as edema and infection. This model is indicative of one of the “structure-function framework” approaches commonly employed by osteopathic practitioners in their objective and subjective interpretation of the physical findings that lead to rational diagnoses and treatment. It also codifies a systemic osteopathic approach to deliver treatment that specifically and effectively accomplishes lymphaticovenous homeostatic goals; it may even provide useful respiratory-circulatory strategies aimed toward enhancing intrinsic, host-maintained health levels.

In order to systematically set and initiate clinical goals applying the “Respiratory-Circulatory model,” osteopathic physicians incorporate a number of important principles that influence both the choice of OMT techniques and the order of their application.

History—Systematic

The cells, which make up our body, have an internal environment also. The fluid matrix of it must be free of 'pollution.' Waste products of tissue metabolism must be constantly carried away by the veins and lymphatics. The health and life of cells and therefore the whole body depend on it—J. Gordon, Zink, DO, F.A.A.O. (1).

The lymphatic system, which is integral to the understanding of health and disease, was accurately first described as a system by Olaf Rudbeck (Sweden) in 1653 (2). The osteopathic profession, from its onset, embraced the importance of the lymphatic system and attempted to document its role in health. A. T. Still emphasized that diagnosis of the fascia and treatment of the lymphatic system was vital for maintaining health and treating disease (3); therefore, in 1898, his faculty in Kirksville used skiagraphy (an early form of x-ray) to research the distribution of the vascular and lymphatic systems (4).

Later, one of Still's students, Frederic Millard, D.O., researched the structure and functions of the lymphatic system and published *Applied Anatomy of the Lymphatics* in 1922 (5). The first DO to specifically describe physical examination of fluid and lymphatic status (6,7), Millard based aspects of his surgical versus nonsurgical recommendations on the state in which he found the lymph nodes. He noted that the lymph vessels were “pliable and readily compressed”; that “for every congested tissue there is a corresponding lymph disturbance”; and that “attempts to clear the lymph stream before clearing the edema in the clavicular regions is to over-tax the general lymph stream and cause profound reactions” (8) In addition, Millard also described a series of “lymphatic drainage” techniques (9–11) while admonishing the osteopathic practitioner to “never work over an enlarged or indurated lymph node,” advocating instead to “free the efferents and the lymph will drain” (12).

J. Gordon Zink, D.O., F.A.A.O., acknowledging the work of Millard as his major inspiration, expanded the approach by popularizing the concept that “respiration and circulation are unifiable functions” (13), and that, for homeostasis, eternal respiration determines internal respiration. Zink's influence and teaching led to the profession's general adoption of the “Respiratory-Circulatory” model and

acceptance of technique sequences designed to enhance cellular level health (internal respiration) by maximizing external respiration. In his extensive teaching of the respiratory-circulatory model, Zink placed special emphasis on the fascial restrictions that limited venous and lymphatic return, the value of creating pressure differentials in the body cavities for effective venous-lymphatic flow, and the central importance of the thoracoabdominopelvic pump in the maintenance of lymphatic homeostasis (14–16). While the idea that respiration affected venous return was known at this time, it was only quantified and confirmed with Doppler studies in the 1980s (17).

Specific lymphatic treatments outside the osteopathic profession were first defined and described by Emil Vodder, a French Ph.D. in the 1930 and consisted largely of manual lymph drainage (18). Based upon manual therapies for draining lymphedema, Vodder method was developed further in Europe during the 1960s and applied to the treatment of lymphedema patients, as a part of Complex Decongestive Therapy (Complex Decongestive Therapy). Schools teaching therapists and physicians to perform the Vodder technique opened in the 1970s about the same time that Zink was popularizing a codified approach for osteopathic physicians to enhance the lymphatics.

Zink, and subsequently Bruno Chikly, M.D., described diagnostic sites for identification of regional lymphatic dysfunction (sites of “terminal lymphatic drainage”) (19–21) and integrated concepts from osteopathy in the cranial field. In addition, Zink specifically linked “primary and secondary respiration” by talking about the “craniosternosacral mechanism”; as a consequence of his attempts to raise awareness of this approach, osteopathic students fondly referred to Zink as the “lymphomaniac.”

History—Osteopathic Lymphatic Technique

If we think ... and say that disease is only too much dirt in the wheels of life, then we see that Nature takes this method to wash out the dirt. ... Let the lymphatics always receive and discharge naturally, if so we have no substance detained long enough to produce fermentation, fever, sickness, and death. We strike at the source of life and death when we go to the lymphatics. ... Thus it behooves us to handle them (the lymphatics) with wisdom and tenderness, for by and from them, a withered limb, organ, or any division of the body receives what we call reconstruction, or is builded anew—A. T. Still (22).

Still preferred that his students create techniques to accomplish clinical goals, that is, techniques based upon their knowledge of anatomy rather than a memorized maneuver. (“I am not here to teach a bunch of parrots,” he wrote) (23). Probably for this reason, the lymphatic techniques used by Still as early as the 1870s were not described by his students until later (24). Nonetheless, some specific osteopathic lymphatic techniques, using a few minutes of local manual pumping to reduce swelling in and around organs (such as the pressure-sensitive liver), were described in the profession's literature as early as 1898 (25).

Like that over the liver, rhythmic manual pumping over the spleen (a secondary lymphoid organ) was described and researched very early in the osteopathic profession; as it is even today. Clement A. Whiting, D.O., studied the effects of using splenic pump on immune function in 1910 (22) as did M.A. Lane, D.O. in 1920 (26), and Yale Castlio, D.O., and Louise Ferris-Smith, D.O., in the 1930s (27,28). Research, using modern methods to investigate lymphatic pump techniques to enhance immune function began again in earnest with the work of Measel (29,30) in the 1980s and continues today with funding from both NIH and the osteopathic profession. (Modern research outcomes are discussed later in this chapter.)

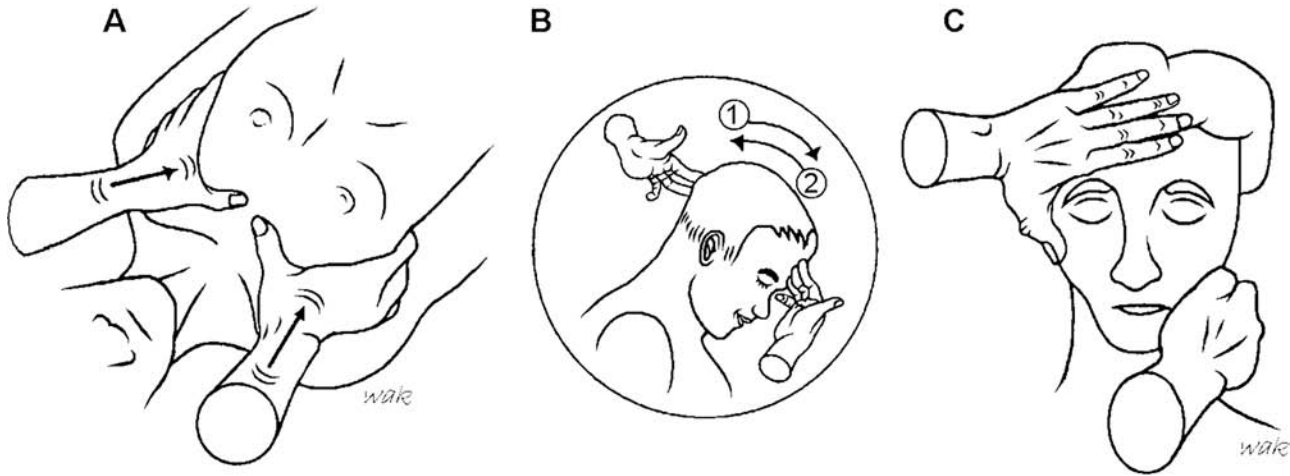

Figure 51-1 Examples of OMT techniques designed to move venous and/or lymphatic fluids.

Osteopathic techniques expanded to the use of muscle pumps and respiratory pumps; each enhancing normal homeostatic mechanisms to move fluids in the vascular-lymphatic system. C. Earl Miller in 1926 first described and then researched the effects of the classic thoracic lymphatic pump along with other lymphatic approaches (Fig. 51.1A) (31,32). T.J. Ruddy, M.D., D.O., developed a muscle pump system called “Rapid Rhythmic Resistive Duction” for treating lymphatic congestion in multiple areas (especially the head and neck) (33) that was the precursor to later development of muscle energy techniques (Fig. 51.1B). William Galbreath, DO, described the Galbreath technique, a method for mobilizing lymphatic fluid in the mandibular region and for draining accumulated fluid from the middle ear in 1929 (Fig. 51.1C) (34,35).

Another student of A. T. Still, D.O., and a contemporary of Millard, D.O., William Garner Sutherland, D.O., also focused on fluid diagnosis and treatment. Best known for his contributions to osteopathy in the cranial field, Sutherland emphasized the definition of Webster’s definition of “fluctuation” as “the movement of a fluid within a natural or artificial cavity and observed by palpation or percussion” (36). The techniques he described and taught within the profession were simple and effective. He noted, “With the method I described of facilitating the movement of lymph and controlling the Tide by bringing the fluctuation to the short rhythmic period, you have the interchange of all the fluids of the body” (37).

The lymphatics were postulated by osteopathic practitioners to play a diagnostic and therapeutic role in visceral function. For example, Frank Chapman, D.O., another student of Still, elucidated a series of so-called neurolymphatic reflexes believed to correspond to visceral structures in the 1930s. These so-called Chapman’s Reflexes (see “Chapman’s Approach” in Chapter 52) are now more typically described as secondary tissue texture changes associated with viscerosomatic reflexes in a distribution associated with the sympathetic nervous system.

When all is said and done, Sutherland offered the most cogent insight, as true now as it was then:

The science of Osteopathy is simple. You realize you are a mechanic of the fluids of the body as well as of the skeletal system (38).

STRUCTURE AND FUNCTION

Lymph and the structures making up the lymphatic system comprise approximately 3% of the body’s total weight. Lymphatic structures may be divided into the lymphatic collecting system and

the organized lymph tissue. In this chapter, organized lymph tissue includes the following structures (Fig. 51.2):

- Spleen
- Liver
- Thymus
- Tonsil
- Vermiform appendix
- Lymphoid tissues in the gastrointestinal and pulmonary tracts
- Lymph nodes

Lymph and the lymphatic system cleanse, purify, and defend the body; they also play a role in absorbing and transporting nutrients and maintaining fluid balance (Table 51.1).

Structural Components of Lymphatic System

Embryology

The lymphatics, along with other components of the immune system, begin to develop by the end of the fifth week and make significant and observable progress around the 20th week of gestation.

Lymphatic vessels, lymph nodes, the spleen, and myeloid tissue (the tissue in bone marrow responsible for production of various classes of blood cells, including lymph cells) all develop from lateral plate mesoderm. In contrast, both the thymus and the epithelial components of the tonsils differentiate from foregut endoderm.

Lymphatic vessels may arise from two different developmental trajectories; they can either form contingently as an outgrowth of the venous system or independently but still in close association with veins to create numerous lymphaticovenous connections throughout the body. Like blood vessels, large lymphatic vessels develop an endothelial lining and are capable of releasing nanomolar levels of nitric oxide (NO) by upregulating transcription of endothelial NO synthase (eNOS). They have a distinctive vasculature structure including a discontinuous basement membrane, open endothelial junctions, anchoring filaments, valves, and intrinsic contractility; features that both share similarities to and contrast with the blood vasculature.

Masses of lymphocytes accumulate about lymphatic vessels and organize as lymph nodes. The spleen is composed of somewhat similar tissue, but its channels are supplied with blood rather than lymph.

Continued lymphangiogenesis occurs after tissue damage and in pathological states such as myocardial infarction. The “driving force” for new lymphatic vessel development is the need for organized interstitial fluid flow homeostasis (39).

Figure 51-2 Organized lymphoid tissues and lymph nodes.

TABLE 51.1

Functions of the Lymphatic System in Regard to Homeostasis

Purification/cleansing of tissues

- Lymph bathes all body organs and cleanses extracellular space.
- Lymph is delivered to lymph nodes which act as purifying filters to remove waste (particulate matter, exudates, bacteria, etc.)
- Along with the fluid in lymph, waste products, proteins, postinjury biochemical by-products, etc. are removed.

Maintaining fluid balance

Daily about 30 L fluid moves from capillaries to the interstitial spaces.

- ~ 90% back into blood capillaries
- ~ 10% (3L) drains into lymphatic channels
- Fluid overload: Lymphatic system protects against damage

Lymphatics also return ~50% of plasma proteins diffusing out of vascular system (high molecular weight).

Defense/immunology

With so much contact with the body, the lymphatics provide a first-line defense against infection. The lymphatics carry antigen to the lymph nodes where the immune response is initiated.

Aging, lymphatics, and the immune system

- Immune system begins development at ~20 wk of gestation
- At birth, the immune system is still immature but lymphoid tissue is plentiful during infancy and increases in amount until 6–9 y of age.
- At puberty, the immune system matures; lymphoid tissues slowly regress until 15–16 years of age.
- Barring autoimmune dysfunction or disorders such as AIDS, lymphoid tissue and immune function levels are stable through most of the adult lifespan.
- In the geriatric patient, the system may decline to the point where they cannot mount a fever (silent infections).

Nutrition

Villi of small intestines absorb large amounts of long chain fats, chylomicrons, and cholesterol

After fatty meals, the thoracic duct may contain 2% fat; lymph-fat "chyle" changes color from clear yellow to milky white

Organized Lymph Tissues

The **spleen** is the largest single mass of lymphoid tissue in the body. This pressure-sensitive organ abuts the diaphragm, which provides movement from its inherent respiratory-circulatory activity that is important for the employment of its homeostatic function. The spleen can be detected deep to the left 9th to 11th ribs and can be located by percussion of the area for splenic dullness. In the absence of splenomegaly, the spleen should not be palpable or percussible below the costal margin. Functionally, the spleen destroys deformed or damaged red blood cells, clears particulate antigens and microorganisms (particularly poorly organized bacteria), and synthesizes immunoglobulin.

Half of the body's lymph is formed in the **liver**, which also has a functional role in the purging bacteria from the body. The liver, similar to the spleen, is also a pressure-sensitive organ abutting the diaphragm. Unless there is hepatomegaly, the liver's edge is palpable at approximately the right costal margin. The liver's venous-lymphatic drainage is shared between the gallbladder and the pancreas with the former serving as this region's "gatekeeper" to venous and lymphatic drainage.

In infancy, the **thymus** is a relatively large organ that peaks in size at age 2 years. It serves to provide immunologically potent cells needed to develop mature immune cells. It is also a preprocessing site for T-lymphocyte immune cells. After puberty, in adulthood, it involutes and is replaced by fatty tissue.

The palatine, lingual, and pharyngeal **tonsils** are organized lymph tissues that are considered to be important to the child, but nonessential in adult immunologic function. In early life, they provide cells that are essential to building immunity. The **verruiform appendix** is also additional organized lymph tissue that is viewed as nonessential to adult immune function.

There are two types of **visceral lymphoid tissues**, pulmonary and small intestinal. Pulmonary lymphoid tissues aid in the filtration of particulate matter and toxins from the lungs. The small intestinal mucosal lymphoid tissues (Peyer patches and lacteals) have an autonomic innervation stemming from the enteric nervous system (including the Auerbach and Meissner plexi).

Finally, there are 400 to 450 superficial and deep **lymph nodes** that differ from other organized lymphatic tissues because they are

dispersed along the lymphatic vessels where they filter lymph and to synthesize lymphocytes. The lymph nodes might be the most highly organized of all lymphoid tissues (Fig. 51.2B)—with nodal reticuloendothelial cells to phagocytize bacteria, particulate matter, and cell fragments and with germinal centers to manufacture lymphocytes that enter the lymph as it passes through the node. The **superficial nodes** are located in subcutaneous connective tissues accompanying superficial veins and drain into three main groups: cervical, axillary, and inguinal. They receive lymph from skin and deeper tissues of the head, neck, and extremities. The **deep nodes** (Fig. 51.2A) drain into a system of collecting channels/trunks.

Lymphatic Vessels

With the exception of the brain, spinal cord, epidermis (including hair and nails), the endomysium of muscle and cartilage, bone marrow, and selected portions of the peripheral nerves—all of which are perfused by minute interstitial conduits or by direct diffusion—lymph channels are disseminated throughout the entire body. The lymph channels begin as blind endothelial tubes or capillaries composed of a single layer of leaky squamous epithelium that is supported by anchoring filaments (Fig. 51.3A); this site is associated with the formation phase of lymph.

The lymphatic collectors are approximately 100 to 600 μm in diameter and consist primarily of chains of muscular units called "lymphangions" (Fig. 51.3B), which possess two-leaflet bicuspid valves. Described as little "lymphatic hearts" (40), lymphangions work much like the body's heart pacemakers, contracting regularly throughout the lymphatic system (lymphangiomotricity) and moving lymph in peristaltic waves. From the tunica media to the tunica externa, these muscular units have extensive autonomic (sympathetic and parasympathetic) innervation, which is somewhat similar to the alpha and beta receptor system found in blood vessels.

Peripheral lymph capillaries join to form capillary plexes that, in turn, form larger paired trunks that will eventually feed into either the right or left thoracic ducts (Fig. 51.4). On their way to the thoracic ducts, superficial lymph vessels follow the course of the superficial veins and lymph nodes and drain into deep lymphatic channels; deep lymphatic vessels follow the deep veins and deep

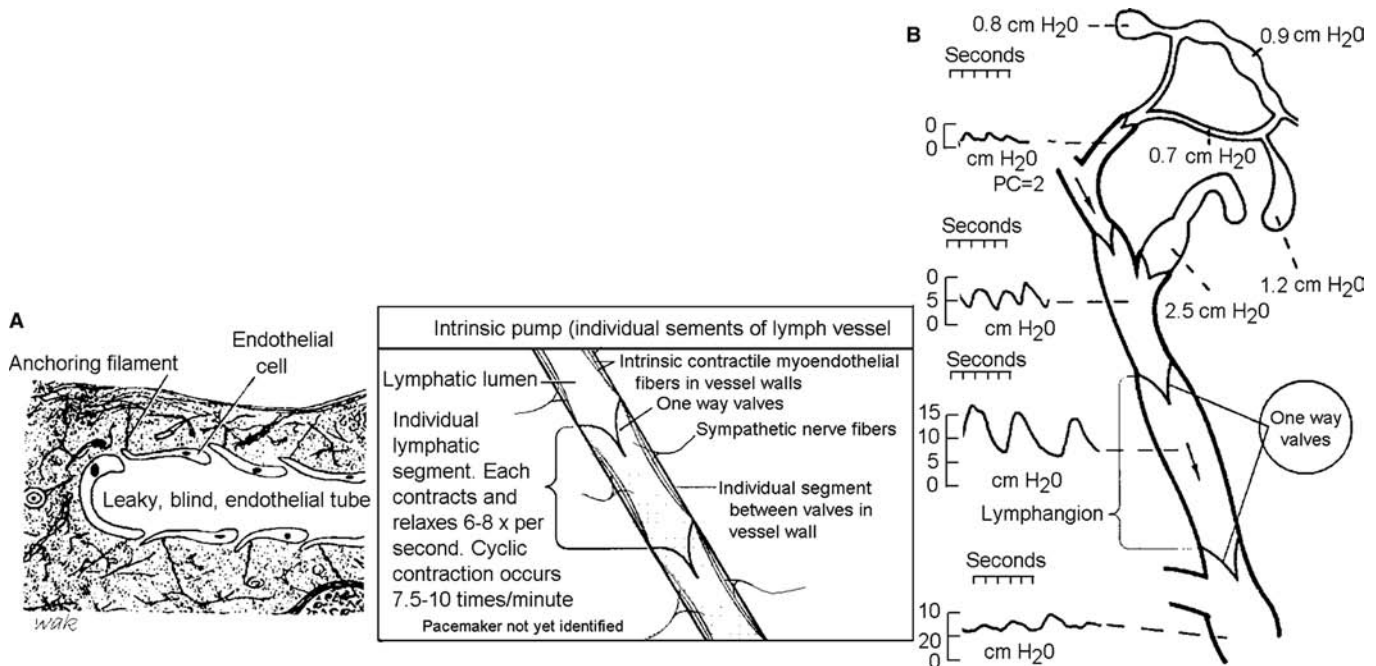

Figure 51-3 Lymphatic collection system: Terminal, lymphangion, vessels, and ducts.

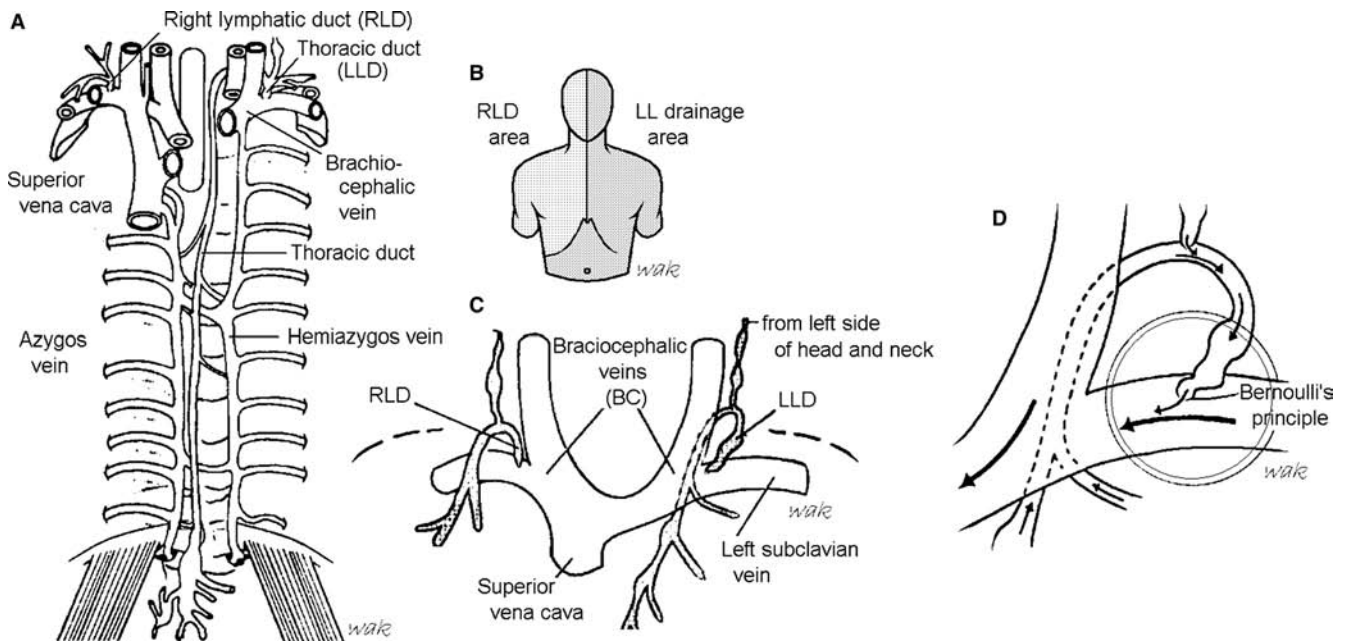

Figure 51-4 Terminal drainage phase: Lymphatic ducts, drainage regions, and Bernoulli principle.

lymph nodes that subsequently drain the deep structures of the neck, the perineum and pelvis, the abdomen and the thorax. These deep channels lie around all major organs of the body.

A distinct, centimeter-long right lymphatic duct (RLD) can be found in 20% of patients and will cross the anterior scalene muscle to empty into the region of the jugulosubclavian vein junction. In 80% of patients, the three major right-sided drainage trunks (right jugular, right subclavian, and right bronchopulmonary trunks) will empty here through two to three openings. There are semilunar valves at the lymphaticovenous juncture to prevent venous blood from refluxing into the RLD. The right side receives drainage from right side of the head and neck, right upper extremity, right chest, heart, and lungs with the possible exception of the left upper lobe. (Fig. 51.4B).

The left-sided thoracic duct (LLD) is the largest lymphatic channel in the body; it extends 38 to 45 cm in length from the first lumbar vertebra to the root of the neck. This thoracic duct drains lymph from the left arm and left side of the neck and head, thorax, upper abdomen (to umbilicus) as well as both sides of the abdomen below the umbilicus and both of the lower limbs. The LLD arises either from the confluence of several lymph trunks on the posterior abdominal wall or, in 20% of patients, from these lymph trunks draining into the cisterna chyli. The cisterna chyli, when present, is anterior to L1-2. The LLD then passes through the aortic opening in the diaphragm at the T12 level. It ascends in the posterior mediastinum to the right of the midline between the descending aorta (to its left) and the azygos vein (to its right). When the thoracic duct reaches the horizontal plane at the level of the sternal angle (T4), it inclines to the left. It then passes out of the thoracic cage into the neck through Sibson fascia, which covers this “superior thoracic inlet” and merges with scalene fascia, and then turns to pass a second time through the same fascia back into the chest cage where it terminates in either the junction of the left internal jugular or subclavian (brachiocephalic) veins. Before it terminates, the duct receives the left jugular trunk (draining lymph from left head and neck) and left subclavian trunk draining the left upper extremity).

The one-way valve that prevents venous blood from entering the LLD is under sympathetic control as is the smooth muscle in the wall of the LLD. It should be generally noted that large lymphatic vessels are affected by both autonomic control, which

facilitates peristalsis, and upregulation of eNOS activity from the endothelial shearing forces caused by lymphatic movement (41).

Lymph Fluid

Lymphatic fluid (lymph) contains the cells produced in the lymph nodes as well as the fluid, electrolytes, small proteins, and cells that leak out of arterial capillaries into the blind-ended lymphatic capillaries. The primary cells in lymph are lymphocytes (2,000 to 20,000/mm in the thoracic duct). There are also macrophages and foreign antigens; bacteria and viruses found in peripheral lymph prior to being filtered are brought in close contact with the lymphatic immune cells. Lymph also carries clotting factors and after meals lymph coming from the left thoracic duct will carry chyle that is richly laden with emulsified water-soluble fats.

Increased capillary permeability as occurs in various inflammatory and infectious conditions allows fluid and proteins to escape into the interstitial tissues. These, along with the debris and by-products secondarily produced, must be removed by the lymphatic system. The inflammatory process will progress through a proliferative phase.

Lymphatic Physiology and Homeostatic Mechanisms

A plan for management of lymphatic stasis is based on the understanding of the mechanics of lymph formation and its propulsion. There are three lymph phases: (1) formation, (2) vascular, and (3) terminal.

The **formation phase** (Fig. 51.5) consists of the movement of extracellular fluid into blind endothelial tubes. This is not as automatic as it might sound. Circulatory forces (the hydrostatic and osmotic gradients, which produce capillary exchange) dissipate almost immediately beyond the edge of the vessel. Furthermore, Starling forces do not account for the movement of fluid through the interstitial matrix (gel) where **cellular respiration** takes place.

By the time fluid reaches these blind end pouches, a small uphill gradient must be overcome before lymph can form. This means that *motion* (including inherent tissue movements and fluctuation of extracellular fluid) is a vital interstitial mechanism that promotes interstitial interchange and thereby facilitates cellular respiration.

Figure 51-5 Formation phase involved in cellular respiration and lymph formation.

Lymphatics are adapted to utilize motion for the formation phase of lymph. Anchoring filaments attached to each of the endothelial cells (see Fig. 51.3A) produce a change in volume with alternating movements in the local interstitial tissue. With this structure, overlapping endothelial cells allow the ebb and flow of fluid fluctuation from the interstitium into the lymphatic system. Motion opens access to lymphatics; swelling increases the opening, and up to a certain point the anchoring filaments prevent collapse of the thin-walled capillaries. Unfortunately, too much swelling closes the initial lymphatic entry sites. So, a major limiting factor for overall lymphatic homeostasis is the movement of lymphatic fluid into the blind endothelial sacs and the initial lymphatic tubules during the formation phase.

The **vascular phase** consists of the movement of lymph through the lymphatic vessels (see Fig. 51.4). In this phase, the lymphangion is the functional unit with its smooth muscle, valves, and intrinsic peristalsis being under autonomic control.

The **lymphangion** can generate enough pressure to account for intravascular lymph movement (see Fig. 51.3B). Additionally, lymphatic propulsion from the vessels themselves is homeostatically accomplished with the help of muscle pumps, respiratory motion, and intrinsic movement of the viscera (such as the intestines). One-way valves encourage propulsion toward the heart. The walls of the lymphangion segments between the valves contain smooth muscle fibers; distention of the walls in these segments produces stimulation of stretch receptors resulting in rhythmic peristaltic waves that effectively move lymph toward the heart.

Unfortunately, the vascular phase can become dysfunctional with increased tissue tension and somatic dysfunction. Here, the thinnest-walled vessels, the lymphatics, are the first vascular structures affected by fascial dysfunction or torsion.

The lymphatic system is particularly vulnerable to fascial dysfunction in the region of the superior thoracic inlet. The vulnerability of the vascular phase of lymphatic function is most likely at this site because the thoracic duct must pass through this fascial diaphragm (Sibson fascia) twice before discharging lymph back in to the central cardiovascular system. Recalling the contiguous nature of the scalene and Sibson fascia in this region, congestion is especially prominent when coexisting with scalene muscular hypertonicity.

In the vascular phase, the large lymph vessels may also become dysfunctional with sympatheticotonia, which impairs both their

peristalsis and the sympathetically controlled valves between the thoracic ducts and the venous system. Here too, trigger points in the scalene muscles are purported to also cause dysfunction by reflexly impeding thoracic duct peristalsis (42).

The **terminal drainage phase** refers to lymphatic drainage into regional collection sites for eventual drainage into the thoracic ducts and subsequently into the subclavian vein (see Fig. 51.4). These junctures are under sympathetic control. The diaphragm, Sibson fascia, and the superior thoracic inlet are once again key areas for terminal lymphatic drainage from all regions. As Millard noted, "The lymph stream must always be drained first through terminal areas. Attempts to clear the lymph stream before clearing the edema in the clavicular regions over-tax the general lymph stream and cause profound reactions."

Zink, who popularized the respiratory-circulatory model, referred to certain palpable sites of "terminal lymphatic drainage" dysfunction that could be used clinically to identify the first regional signs of compromised lymphatic homeostasis in this phase. These terminal sites include (Fig. 51.6):

- Supraclavicular for the region of the head and neck
- Posterior axillary fold for each respective upper extremity
- Subxiphoid for the abdominal region
- Inguinal for each respective lower extremity

In the respiratory-circulatory model, 35% to 60% of the drainage through the thoracic duct is said to be accounted for by various pumping activities associated with the act of respiration; external respiration determining internal respiration. The two main respiratory elements in this regard include the mechanical pump created by the diaphragmatic crura on the cisterna chyli and the Venturi Effect (Bernoulli Principle), which acts both as a "suction pump" and factor to reduce the outflow pressure against which lymph must drain (see Fig. 51.4D).

Quoting the Venturi effect, Zink linked venous with lymphatic return in the respiratory-circulatory model. He described a "**Warmth Provocative Test**" used to identify areas of spinal somatic dysfunction that he postulated were significant enough to impede effective segmental venous return (Fig. 51.7). Segmental or systemic, the model predicts that the greater the venous return, the greater the lymphatic return.

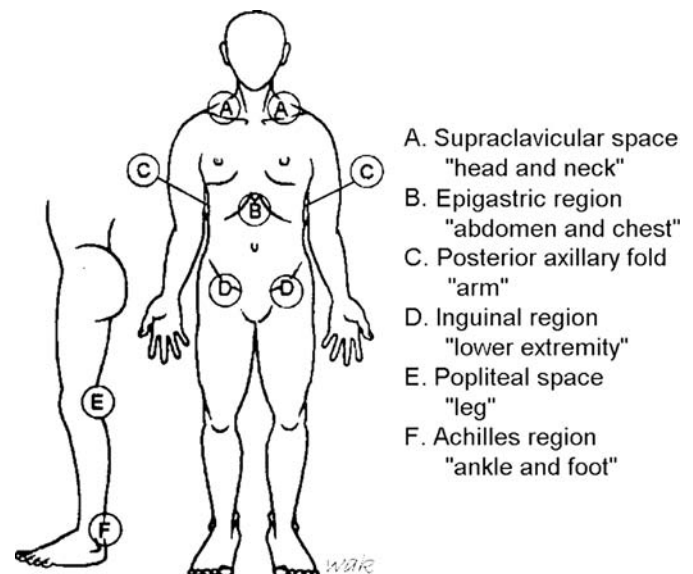

Figure 51-6 Palpation sites for terminal lymphatic drainage dysfunction from body regions.

Figure 51-7 Zink “Warmth Provocative” test for a significant somatic dysfunction using the respiratory-circulatory model.

IMPLEMENTING THE RESPIRATORY-CIRCULATORY MODEL

The respiratory-circulatory model concerns itself with the maintenance and enhancement of extra- and intracellular environments through the unimpeded delivery of oxygen and nutrients and the removal of cellular waste products. In this model, the clinical goal is to identify and remove key tissue stresses interfering with the flow or circulation of body fluids in order to positively affect tissue health (43). Therapeutic application of OMT, as determined by this model, addresses somatic dysfunction affecting respiratory mechanics, circulation, and the flow of body fluids. Many of the techniques used in this model are designed to enhance the homeostatic mechanisms associated with the lymphatic system, and these are therefore sometimes broadly referred to as “lymphatic techniques” even though they may have other roles and other mechanisms.

Lymphatic techniques are those which are designed to remove impediments to lymphatic circulation and promote and augment the flow of lymph. The purpose of so-called lymphatic treatments is to improve the functional capacity of the lymphatic system, which

includes maintenance of fluid balance in the body, purification and cleansing of tissues, and enhancement of immune response. As the lymphatic system is also involved in tissue nutrition and the absorption of macronutrients from the gastrointestinal tract and interstitial fluids, treatments enhancing lymphatic function can theoretically improve tissue nutrition.

Indications and Contraindications

With the foregoing aspects in mind, general indications for use of lymphatic treatment techniques within the framework of the respiratory-circulatory model include:

- Acute somatic dysfunction
- Sprains, strains
- Edema, tissue congestion, or lymphatic/venous stasis
- Pregnancy (Fig. 51.8)
- Infection
- Inflammation
- Pathologies with significant venous and/or lymphatic congestion.

The respiratory-circulatory approach is one of three arms used in the treatment of systemic dysfunction wherein coordinated, directed osteopathic manipulative treatment provides homeostatic enhancement (44). (The other two are strategies and techniques to modify sympathetic and parasympathetic activity—see ANS-Related Chapters 10 and 11). Examples of systemic implication can be found in Table 51.2 (45).

There are few absolute systemic contraindications to the approach other than conditions such as anuria (if the patient is not on dialysis) or in an area of necrotizing fasciitis. That said, clinical judgment must be used in employing lymphatic techniques with particular attention directed toward the patient’s diagnosis, clinical condition, and medical therapy. It is obvious that local issues (such as a fracture at the sites where a given technique might transmit force) must be considered when deciding on any treatment approach. These and other pragmatic factors influence choice of the appropriate technique, site, dose, duration, and frequency of treatment.

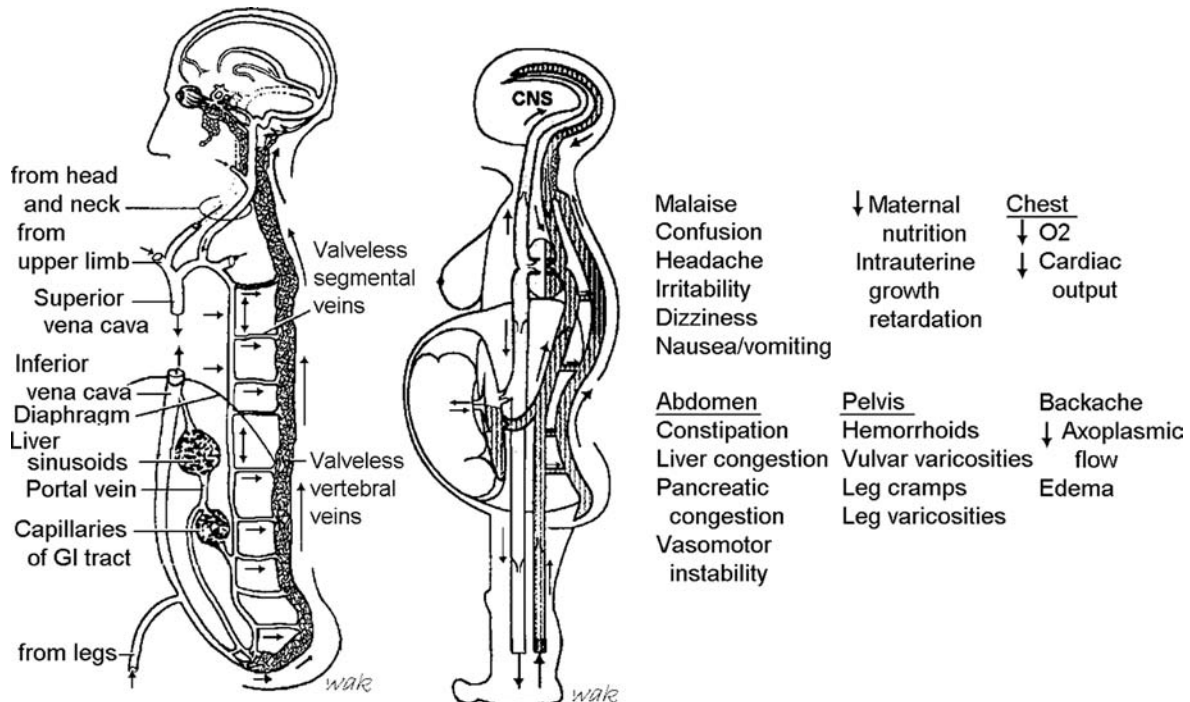

Figure 51-8 Congestive phase of pregnancy.

TABLE 51.2

Lymphatic Homeostatic Concerns in Systemic Disease and Dysfunction (Synopsis of Osteopathic Considerations in Systemic Dysfunction)

Systemic Region or Patient Population	Examples of Pathologies or Homeostatic Concerns
Eyes-ears-nose-throat (right side of head and neck drain to right thoracic duct; left side to the left thoracic duct)	<ul style="list-style-type: none"> • Glaucoma linkage to fluid drainage of eye • Endolymphatic hydrops ("glaucoma of the ear") • Meniere's: Fibrosis of edematous fluids in the endolymphatic duct • Foreign body (or wax) against the eardrum (vagal stimulation) may cause rapid shallow breathing (thereby compromising effectiveness of the respiratory-circulatory model) • Lymph node pattern helpful in noting site of inflammation/infection
Upper respiratory tract	<ul style="list-style-type: none"> • Tissue congestion increases "misery index" in URTI and decreases medication tissue distribution • Lymph node pattern helpful in noting site of inflammation/infection; also type of infection (viral vs bacterial infection: posterior cervical chain > anterior cervical chain)
Lower respiratory tract (Pleural sac and lung tissues drain to pretracheal nodes and then to the RLD)	<ul style="list-style-type: none"> • Minor diaphragm flattening decreases efficacy of respiratory-circulatory pump affecting all body systems • Flattened diaphragm in COPD changes contraction of the diaphragm from inhalation into exhalation • Increased fluids or infection in alveoli stimulate vagal afferents that reflexly decrease the depth of respiration • Coughing often leads to exhalation rib dysfunction → chest cage respiratory efficacy • COPD often leads to barrel chest, rigid chest cage mechanics with flattened diaphragm and hypertonicity in secondary muscles of respiration (especially sternocleidomastoid)
Cardiovascular conditions (heart and mediastinum drain to the right thoracic duct)	<p>CHF → pulmonary edema with secondary rapid, shallow breathing (due to stimulation of vagal afferents in alveoli) as well as hepatomegaly (nonfriable type); electrolyte imbalance from peripherally sequestered fluid plays role in CHF morbidity; increases lymphatic functional demand up to 40x resting capacity</p> <ul style="list-style-type: none"> • Thoracic duct dilation (up to 16x normal) may occur with additional backflow of lymphatic fluid; dilated thoracic duct may leak leading to ascites • Vagal stimulation from posterior-inferior wall myocardial infarctions may decrease depth of respirations • Impaired lymphatic drainage from myocardium causes EKG abnormalities similar to sick sinus syndrome as well as arrhythmias, diminished SA node automaticity, AV irritability and slowed AV conduction; increased mortality and morbidity from myocardial infarctions; increased colonization of bacteria in heart and valves • Prolonged lymphatic impairment to heart → endomyocardial fibrosis and endomyocardial fibroelastosis • Lymphatic drainage of vascular wall plays postulated role in atherosclerosis • Recognize for use of pectoral muscles that 60% of coronary artery/ cardiac disease patients have pectoralis major trigger points • Superior mediastinum and the superior thoracic inlet anatomic boundaries are the same <p>Hypertension increases peripheral lymph production</p>
Gastrointestinal tract	<ul style="list-style-type: none"> • Irritation of the diaphragm by inflammation or perforation of Upper GI structures may cause diaphragmatic hypertonicity (and C3-5 referral) that decreases efficacy of the respiratory-circulatory model • Irritation of the stomach's vagal receptors may cause decreased depth of respiration (rapid shallow breathing results)

(continued)

TABLE 51.2 (Continued)

	<ul style="list-style-type: none"> • Gall bladder and pancreas share same lymphatic drainage pathways; compromise of drainage increases risk of pancreatitis resulting from gall bladder disorder • Poor lymphatic function decreases absorption and distribution of nutrients from the gut (especially those that are fat soluble) • Increased tissue congestion in and around the bowel leads to bloating, more symptomatic pain in irritable bowel syndrome, increased fibrosis in colitis and Crohn disorders; fatigue, constipation and/or diarrhea, pain, and cramps • Decreased medication distribution, accumulation of active drugs and drug by-products in congested tissues, and reduced supply available to other needy tissues; accumulation of toxic by-products normally managed by the liver • Some upper gastrointestinal surgical procedures irritate the diaphragm (retractors or free air introduced in endoscopic procedures) → decreased diaphragmatic respiratory efficacy
Genitourinary tract	<ul style="list-style-type: none"> • Renal lymphatics drain capsule and parenchyma of kidney acting as a “safety valve” aiding in clearance of waste products as well as fluid, electrolytes, infectious, and drug byproducts • Lymphatic drainage maintains needed oncotic gradient for countercurrent salt/water exchange in kidneys; impaired lymphatics increase oncotic pressure and decreases ability of kidney to concentrate urine • In acute ureteral obstruction, renal hilar lymph flow increases 300% • Capsular lymphatics dilate to prevent renal damage in hydronephrosis • Pelvic congestion (in conjunction with hormonal basis) → dysmenorrheal, premenstrual syndrome, ovarian cysts, backache-headache-bloating of PMS, emotional instability and depression • Prostatic congestion decreases distribution of prostatic medications (if used) and may play a role in chronic nonbacterial prostatitis
OB patients	<ul style="list-style-type: none"> • Congestive phase is 28–36 weeks of gestation—partly mechanical, partly hormonal, partly biological • Breast engorgement (day 3 primipara or day 2 multipara) responds well to treatment of lymphaticovenous drainage of breasts
Pediatric patients	Heightened immune responsiveness suggests need to inform caregivers that lymphatic techniques intended to increase immune function may generate significant pyrogens and increase fever transiently (hours)
Geriatric patients	<ul style="list-style-type: none"> • Diminished immune function may not be as responsive to lymphatic techniques to improve immune response • Increased venous and lymphatic stasis of dependency and more common in the aged patient may cause misinterpretation of congestive findings as secondary to an acute or other local pathological process
Rheumatological patients	<ul style="list-style-type: none"> • Lymphatics remove waste products and immune complexes out of the region of inflamed joints; congested joints are more painful and have less synovial distribution of anti-inflammatory or disease-modifying medications • Swelling with poor lymphatic drainage leads to fibrosis around joints and further decreases range of motion • Tendons are very rich in lymphatics; tenosynovitis responds well to lymphatic techniques

Source: Kuchera M, Kuchera W. *Osteopathic Considerations in Systemic Function*. Columbus, OH: Greyden Press, 1994.

Relative contraindications to certain techniques exist; however, they are specific to the respiratory-circulatory model and certain lymphatic treatment techniques. These include the following examples:

- **Cancer:** There is some concern about enhancing lymphatic flow based upon potential lymphatic spread of cancerous cells rather than activating the immune system. Advocates point out the value of exercise in a number of cancerous conditions that is known to increase lymphatic flow. Because, to date, no risks of lymphatic treatment on patients with cancer have been demonstrated, judicious use in select cancer patients is supported by most authorities
- **Certain infections:** Splenic pump and hepatic pump techniques are probably contraindicated in Infectious mononucleosis patients or any patient who may have a fragile hepatosplenomegaly. The approach (especially applied directly over infected tissues or nodes) must be used with caution if at all in patients with overwhelming bacterial infections and an associated risk of dissemination or chronic infections that have a risk of reactivation (abscess, chronic osteomyelitis)
- **Certain circulatory disorders** (venous obstructions, embolism, hemorrhage) or **coagulopathies** (including patients on anticoagulants): For example, a technique like the Dalrymple pedal pump should be avoided if a patient has positive Homan or Moses signs or any other indication of deep vein thrombosis in one of his or her lower extremities

Safety and Efficacy

The risk-to-benefit ratio for lymphatic techniques is quite good. No known significant complications have resulted from osteopathic lymphatic treatment to date and multiple published studies have documented the efficacy of various lymphatic treatments. Nonetheless, clinical judgment should always be used when prescribing treatment for a patient in any disease state.

For example, in recognition of the highly effective immune function in the majority of the pediatric population, be sure to warn caregivers that a lymphatic treatment approach may transiently increase their child's fever; this being a normal response to the pyrogens produced in fighting infection. Treatment of the fever may or may not be necessary depending upon its level and duration.

Finally, a special comment will be made here regarding the safety of returning fluids back into an already fluid-overloaded condition such as that found in a patient with congestive heart failure (CHF). In such a state, the thoracic duct may be dilated sixteen times its normal size; subsequent leakage can cause ascites and congestive backflow can compromise other organs (e.g., pulmonary edema or hepatomegaly). In a study of severe CHF

patients where death was imminent, a surgical shunt was created between the thoracic duct and venous system; the clinical outcome was stabilization (fluid-electrolyte improvement) within 24 hours (46). This has been offered to suggest that homeostatic lymphatic fluid return will not overload the system even in severe CHF (47).

Principles of Diagnosis

Use of the respiratory-circulatory model or of lymphatic techniques in a coordinated systematic manner is based upon determining how much the patient would benefit relative to their risk of their application:

1. **Indications/risk-to-benefit ratio:** Obtain a history and physical examination relating to swelling, organ dysfunction and disease, shortness of breath, areas of swelling or puffiness, tissue trauma, and infection. Knowing whether a given pathological condition has a significant lymphatic component is helpful in deciding the degree of emphasis on the respiratory-circulatory model and the use of lymphatic techniques. Palpable tension, tenderness or ticklishness, or full, boggy tissue texture changes in the regional terminal lymphatic drainage sites are particularly useful in determining if regional tissue congestion exists (see Fig. 51.6). The initial history and examination should also cover possible absolute and relative contraindications for the use of lymphatic techniques
2. **Central myofascial pathways:** Palpate anatomical transition zones and consider the fascial compensated or noncompensated patterns described by Zink (Fig. 51.9) to describe common fascial restrictions such as torsion or rotational patterns, which may cause restriction of lymphatic flow. Restriction in any direction or pattern indicates dysfunction; however, a pattern of fascial motion restrictions that does not alternate in direction for adjacent regions is considered to be "uncompensated" or "traumatic" and is often a cause of congestive symptoms and an indication for treatment under this model. Even compensated patterns of fascial somatic dysfunction may cause symptoms; however, this is especially true in patients who are restricted to bed rest where the peripheral muscular pumps normally activated by walking fail to simultaneously alter the relationships between adjacent regions to permit free fluid flow. Other key myofascial somatic dysfunctions that can be associated with general reduction in lymphatic flow include trigger points in the scalene muscles
3. **Fluid pumps:** Observe and palpate muscular and fascial diaphragmatic function including thoracic inlet restrictions, for conditions that may limit lymphatic flow. In the supine position, the motion of respiration should be seen to extend all the way to the pubic symphysis in a patient who is breathing passively and in a nonselfconscious manner; failure to do so could

Figure 51-9 Regional diagnosis and transition zone relationship to the four major transverse diaphragms.

be interpreted as a need to address improvement of thoracic diaphragm function. Likewise, the pelvic diaphragm should be palpated. It should normally move passively and synchronously with the thoracic diaphragm and exhibit equal tension to the medial wall of both ischio-rectal fossae. A poorly functioning thoracic diaphragm that does not respond to redoming OMT or treatment of the inferior thoracic outlet may warrant diagnosis and treatment of any C3-5 (phrenic) somatic dysfunction. Attempts to “redome” the pelvic floor with OMT should follow treatment of any bony-articular pelvic somatic dysfunctions

4. *Spinal Involvement*: After treatment of the central pathways and diaphragms, compression of the abdominal region by the physician’s hand should create a uniform sensation of warmth down to the sacrum—Zink “Warmth Provocative test” (48) (see Fig. 51.7). A spinal area perceived to be warmer than others may be interpreted as a site of somatic dysfunction requiring treatment to maximize fluid return. Other key somatic dysfunctions interfering with the respiratory-circulatory model would include those thoracic, rib, and sternal dysfunctions that restrict motion of the chest cage (secondary respiration) and cranial base, C2 somatic dysfunction, and sacral somatic dysfunctions that restrict the depth of respiration (primary respiratory mechanism)
5. *Peripheral/Regional pathways*: Evaluate sites of terminal lymphatic drainage associated with early regional lymphatic congestion (see Fig. 51.6). Congestion in the terminal lymphatic drainage sites may constitute an indication for comprehensive treatment using the respiratory-circulatory model. Palpate other regional and local tissues to evaluate the presence of congestion and excess fluid in the interstitial tissues. This helps identify the region that might benefit from local fluid techniques as a last step in this model’s protocol

Principles of Treatment

Treatment protocols using this model are typically designed to (1) remove impediments to lymphatic flow, (2) enhance mechanisms involved in respiratory-circulatory homeostasis, (3) extrinsically augment the flow of lymph and other immune system elements, and (4) further mobilize lymphatic fluids from local or regional tissues that would benefit from decongestion. These are summarized in Table 51.2.

Theoretically, all manipulative treatments can influence the lymphatic system through change in muscle tone, myofascial pathways, neural reflexes, autonomic tone, and effects of respiration. Certain osteopathic techniques however have been long identified as “lymphatic techniques” because of their efficiency and efficacy. Some of these techniques are postulated to remove somatic dysfunctions that interfere with various motions needed for lymph formation or lymph flow, others to remove key somatic dysfunctions that impede flow between or through somatic structures, and yet others do not remove somatic dysfunction but rather are considered to augment homeostatic mechanisms important in respiration and circulation.

Proposed Mechanisms of Treatment

To improve treatment outcomes, different strategies might be selected to enhance homeostatic mechanisms specifically linked to the different phases of lymphatic function (see Figs. 51.3 to 51.5). For example:

- Any OMT technique that improves *local tissue motion* should enhance the *lymph formation phase*, consequently reducing

edema and improving cellular level nutrition. While tensegrity principles suggest that this can be indirectly accomplished with almost any technique that removes somatic dysfunction throughout the body, the most effective choice should be specific local manual techniques that include oscillatory movement, various manual techniques focused upon the soft (myofascial) tissues, or any addition of a host of energy-transmitting physical therapy modalities (such as pulsed ultrasound or Fulford percussion hammer) that could increase local tissue motion

- Application of other types of ancillary modalities such as rest, ice, compression, and elevation during acute edematous states should be properly timed to limit local swelling (to prevent it from overwhelming the local homeostatic mechanisms allowing entry into the blind-end lymphatic capillaries) and otherwise remove impediments to the *lymph formation phase*
- Several OMT treatments affect lymphatic channels as they travel between fascial layers or body regions. Any treatment that reduces myofascial restriction can theoretically improve lymphatic flow by optimizing the *vascular phase* and thereby increasing the efficacy of intrinsic lymphatic pumps. Myofascial release (MFR), balanced ligamentous tension, and ligamentous articular strain techniques would seem to be especially suited to removing such local and regional fascial obstructions
- Also numerous OMT treatment forms employ direct external forces that serve to act as extrinsic pumps that mobilize lymphatic fluid in the *vascular phase*. Some of these treatments improve the lymph flow by applying external pressure (soft tissue effleurage, massage, petrissage, etc.), whereas others remove somatic dysfunction that generally restricts fluid or employs directed muscle energy OMT to speed propulsion using muscle pumps. This latter mechanism is especially effective in the periphery when combined with Ruddy Rapid Resistive Duction OMT where contraction-relaxation rates may be two to three times the normal heart pulsation. (See as an example Ruddy technique using the sternocleidomastoid muscle.) Significant increases in lymphatic flow rates in the thoracic duct have been measured as well using both the muscle pumps involved in exercise and the passive pressure changes of various lymphatic pump OMT techniques (Fig. 51.10A)
- Osteopathic treatment that seeks to enhance the efficacy of respiratory mechanisms (primary and secondary) in order to maximize venous and lymphatic return during either the *vascular* or the *terminal phase* typically focuses upon improving diaphragm or chest cage functions. (See as an example: thoracic diaphragm release technique, Fig. 51.10B.) Such respiratory approaches to circulation function largely through amplifying rhythmic pressure changes between compartments as well as the previously mentioned Bernoulli principle
- Lymphatic pump manipulative techniques are also used over the spleen, liver, chest cage, or from the feet. The direct motion against the tissues could affect the *formation phase*; the systemic and rhythmic pumping could affect the *vascular phase*; and the additional pressure changes in intra-abdominal and intrathoracic cavities could affect the *terminal phase*. (See as examples: splenic pump and Dalrymple pedal pump, respectively.)

Other mechanisms of action for OMT have been postulated and are worthy of exploration. For example, the role of eNOS is of particular interest because of the mechanics of the lymphatic pumps. The intermittent movement associated with the previously mentioned Dalrymple pedal lymphatic pump has the potential to increase shear stress on the vascular endothelium (Fig. 51.10C). Such shear stresses applied at twice the typical heart rate were

Figure 51-10 A. Mobilization of immune cells as a postulated mechanism for lymphatic pump OMT. B. Pressure changes, Bernoulli principle, and relationship between internal and external respiration as a postulated mechanisms for diaphragmatic lymphatic pump techniques. C. Upregulation of endothelial NO as a postulated mechanism for some of the action of OMT.

postulated to release an increased amount of NO (through upregulation of eNOS) from the blood vessels (49,50); a mechanism of action that has been postulated to account for many of the benefits of OMT (51). Release of NO through the same mechanism of action has similarly been postulated as an underlying mechanism for many of the benefits attributed to exercise (52). Interestingly, NO is not only produced in the walls of blood vessels but produced in the luminal wall of lymphatic vessels as well (53). This suggests that physiologic levels of NO produced by lymphatic endothelium may play a role in regulating lymphatic vascular tone.

As more is learned about the mechanisms of action for various OMT techniques, additional strategies may be found for the existing techniques as well as being able to finetune the frequency and duration of their application in order to accomplish the desired goals.

Evidence-Based Physiological Outcomes of Treatment

A wide range of lymphatic drainage techniques have been shown to be effective in reducing pain, edema, and tissue turgor secondary to numerous traumatically induced inflammatory processes. Furthermore, evidence is growing for the use of manual techniques and exercise to enhance immune function. Regardless of the professional degree of the healthcare practitioner, a growing number of techniques ranging from massage (including effleurage and

petrissage) (54) to indirect OMT (such as counterstrain) (55,56) to mechanical tissue movement (such a vibration) (57) to exercise strategies have each been documented to accomplish particular physiological responses.

For many decades, it has been known that scarring or thickening of tissues might occur after trauma if only water is resorbed and interstitial proteins remain; poorly rehabilitated ankle sprains with thickening of the Achilles tendon is one example of this. Efficient lymphatic drainage facilitates removal of the proteins in edematous states and might effectively prevent this problem. Furthermore, removal of inflammatory cytokines and the subsequent resolution of the pain and sequelae associated with an inflammatory process depend on efficient lymphatic drainage. The evidence base for movement, early ambulation, use of compressive wraps to limit initial swelling, elevation to allow the effect of gravity to improve lymphatic drainage and various lymphatic drainage manual methods from those of Vodder to those of the massage therapists is extensive (58,59).

The osteopathic respiratory-circulatory model also depends upon the role of OMT to improve the compliance of the chest wall, diaphragmatic excursion, and efficacy of the respiratory process generally. Here, the logic is convincing but less extensive evidence has been published concerning the application. Nonetheless, examples of the evidence-base here include demonstration that restriction of chest wall excursion limits forced expiratory vital capacity

and forced expiratory volume in 1 second (60) while treatment of chest wall somatic dysfunction with OMT has been shown to increase chest expansion, O₂ saturation, increase total lung capacity, and improve vital capacity as much as incentive spirometry or more (61–63). In patients with chronic obstructive pulmonary disease (COPD), manual treatment of the chest wall to increase respiratory efficacy has been shown “chest wall gymnastics” (64,65), and by osteopathic physicians using OMT (61).

With respect to immune function and the lymphatic model, a significant amount of documentation has been made in the last few decades and, based upon the emphasis of currently funded research in the osteopathic profession, tremendous advances are immediately ahead. It has been noted that the production of lymphocytes is increased greatly as lymph passes through the nodes. Research indicates that T-lymphocytes remain approximately 30 minutes in the blood circulation, about 5 to 6 hours in the spleen, and 20 hours in the lymphatic vascular system (66).

In the early 1980s, Measel (67) conducted experiments testing immune response in healthy individuals using the classic thoracic (Miller) pump technique. He found a greater immune response to several subserotypes of pneumococcal polysaccharide in the treatment group relative to the control group. Since that study, several other groups have looked at immune function in response to different lymphatic pumps in isolation.

For example, in 39 healthy subjects provided with hepatitis B vaccine, one study (68) found a faster rise in antibody titers in those who also had lymphatic and splenic pump techniques three times weekly for 2 weeks compared to the control group. By 13 weeks, 50% of treated subjects versus only 16% of controls achieved protective antibody titers and at all points in time after 6 weeks, the antihepatitis titers in the treatment group were higher than in the control. However, by the end of the study period, both groups had similar numbers of individuals with protective antibody titers. In a different study using splenic pump alone in nursing home residents, the researchers failed to show improved influenza vaccine antibody titers after the use of splenic pump, but did document a reduction in antibiotic use during the influenza season (69).

Recent research studies conducted at the Osteopathic Research Center (ORC) located at the University of North Texas Health Sciences Center—Texas College of Osteopathic Medicine (UNTHSC-TCOM) clearly support the claim that lymphatic pump OMT techniques (thoracic or abdominal) are capable of enhancing both lymphatic flow and leukocyte flux. Innovative protocols employing dogs with surgically cannulated thoracic ducts were designed to answer the question of “How much lymph could a lymph pump pump if a lymph pump could pump lymph?” (70) The model (see Fig. 51.10A) permitted the researchers to directly measure approximately a three-fold increase in thoracic duct lymph flow as well as a five to seven-fold increase in the number of active immune cells per milliliter of lymph in response to the lymphatic pumps; similar to the increases seen in exercise. Researchers at the ORC are now studying the impact of lymphatic pump in reducing morbidity and mortality in rats infected with highly pathogenic pneumonia-causing bacteria as well as others with carcinomas in the lungs.

Using a human model at the Philadelphia College of Osteopathic Medicine (PCOM), researchers at the Human Performance and Biomechanics Laboratory of the Center for Chronic Disorders of Aging demonstrated that using the Dalrymple pump created significant increases in NO at levels consistent with those expected from eNOS release (71) (see Fig. 51.10B). Furthermore, NO levels from this passive intervention were consistent with those levels produced by moderately intense exercise. Researchers at this site

are investigating the impact of pedal lymphatic pump OMT on NO levels and other parameters in subjects with conditions ranging from fibromyalgia syndrome to Parkinson disease. Preliminary studies performed collaboratively by these PCOM and UNTHSC-TCOM researchers using real-time NO probes in dogs have shown this biomarker to rise and fall in venous blood and thoracic duct lymph with each respiration and to be increased with application of a lymphatic pump maneuver.

At this point in time, there are also calls for osteopathic research based upon around the respiratory-circulatory model ranging from studies to reduce postmastectomy lymphedema (72,73) to those to reduce mortality risk in any future influenza pandemic (74).

Treatment Technique Order (Integrated into the Respiratory-Circulatory Model)

Following a common-sense order for most fluid systems, the order of the techniques used in the respiratory-circulatory model might be summarized by the following series of statements:

First open the pathways for fluid to flow; then turn on their thoracoabdominopelvic pump to its normal operating level. If you have congestion, turn the pumps up to “high” to clear any backflow in the system. When the backflow is cleared, then new fluid from targeted areas can be moved into the drainage system.

With this simple mechanical process in mind, the order of integrating choices from the varying broad categories of “lymphatic treatment” techniques proceeds roughly in the order of the following goals:

- (Goal 1) open myofascial pathways at transition areas of the body
- (Goal 2) maximize normal diaphragmatic motions
- (Goal 3) increase pressure differentials or transmit motion in order to pump or otherwise augment fluid flow beyond normal levels, and
- (Goal 4) mobilize targeted tissue fluids into the lymphaticovenous system

Examples of these techniques appear in Tables 51.3 to 51.6 and are subdivided with relationship to each stepwise goal. Following each portion of the table, a few descriptive step-by-step techniques are offered to supplement the figures or provide alternative methods.

(Step/Goal 1) Techniques for Freeing Lymphatic Pathways

The lymph stream must always be drained first through terminal areas. Attempts to clear the lymph stream before clearing the edema in the clavicular regions (thoracic inlet) is to over-tax the general lymph stream and cause profound reactions.—F. P. Millard, D.O. (75).

In the respiratory-circulatory model popularized by Zink, D.O., the first step of care should be to open the major fascial pathways (see Fig. 51.9). The four key sites used in diagnosis and treatment of this clinical goal are the:

1. Craniocervical junction
2. Cervicothoracic junction
3. Thoracolumbar junction
4. Lumbopelvic junction

These are transitional areas where anatomic structure changes (several related to transverse diaphragms between the regions). Therefore, these are the areas where function first changes.

TABLE 51.3

Integration into a Sequenced Respiratory-Circulatory Model Approach: Lymphatic Techniques to Open Pathways and Remove Restriction to Flow

Manipulative Approaches	Comments
Regional OMT of Zink's transitional areas <ul style="list-style-type: none"> • Craniocervical junction release • Cervicothoracic junction (superior thoracic inlet: T1-4, R1-2, manubrium) • Thoracolumbar junction (inferior thoracic outlet) • Lumbopelvic junction 	Direct or indirect method OMT as appropriate to either the regions involved or to the separate structures contributing to the structure-function of the region (see Fig. 51.11 for Regional handholds adaptable to MFR, BLT, or muscle energy OMT techniques)
Sibson fascial release (helps to add OMT to scalenes and ribs 1 and 2)	Indirect or direct
Soft tissue techniques <ul style="list-style-type: none"> • Kneading—stretching • Direct MFR • Indirect MFR • Tapotement • Petrissage • Fascial unwinding • Fulford percussion hammer release • Directed self-stretching techniques/exercises 	Specific technique less important than the goals of limiting entrapment and providing freedom for free lymphaticovenous flow; petrissage excellent at scar sites; fascial unwinding or Fulford percussion OMT excellent post trauma as in an MVA <i>Note: In the extremities, these techniques may follow "out-of-order" ... often just prior to the last step</i>
Anterior and posterior axillary fold techniques	Important in upper extremity lymphatic drainage; anterior fold—pectoral traction combination also increases lymph flow (see later)
Extremity popliteal fossa release (spread) Direct MFR (extension ME may be added)	Improves pathway from foot, ankle, and lower leg
Other considerations include: <ul style="list-style-type: none"> • Treatment of the first rib and clavicle and scalenes including the targeted regionalized soft tissue pathways described in the fourth section earlier rather than later 	Depending upon the amount of congestion and other clinical factors, treatment sequence may vary here
Manipulative Approaches	
Other preparatory OMT may include: <ul style="list-style-type: none"> • For thoracoabdominal diaphragm: OMT to C3-5 or phrenic; OMT lower rib attachments (esp R12) and quadratus lumborum; psoas or even hip also may affect • For pelvic diaphragm: OMT to innominate, sacral, pubic somatic dysfunctions may be needed first • Reducing exaggerated sagittal plane posture also affects both diaphragms—through quadratus lumborum and psoas as well as the posterior L1-2-(3) attachments for the thoracoabdominal diaphragm, but also for the pelvic diaphragm tension placed on the pelvic floor by gravity and the counter-rotation within the pelvis (see Chapter 36) 	
Thoracic diaphragm "redoming"/indirect release	
Thoracic diaphragm "redoming"/direct release	
Ischiorectal fossa technique for the pelvic diaphragm	

If perfection is not possible (no somatic dysfunction), Zink noted that the natural homeostatic inclination of the patient was to develop an alternating pattern at the four transitional areas. The most common pattern involved the pelvis rotating to the right, thoracolumbar junction to the left, upper thoracic inlet area rotating to the right, and the occipitoatlantal region rotating to the left.

He described this pattern, seen in 80% of normal individuals, as the "CCP." The uncommon pattern (seen in 20%) has the opposite alternating fascial pattern.

Traumatically induced and/or highly dysfunctional fascial patterns were felt to significantly compromise the ability of the body to move venous or lymphatic fluids. Uncompensated patterns are

Integration Into a Sequenced Respiratory-Circulatory Model Approach: Lymphatic Techniques to Maximize Diaphragmatic Functions

Manipulative Approaches	Comments
Thoracic diaphragm “redoming”: direct or indirect release	For the thoracoabdominal diaphragm to respond, consider also: OMT to C3-5 or phrenic; OMT lower rib attachments (esp R12) and quadratus lumborum; psoas or even hip also may affect function
Ischiorectal fossa technique for the pelvic diaphragm	For pelvic diaphragm: OMT to innominate, sacral, pubic somatic dysfunctions may be needed first
Other preparatory OMT may include:	Reducing exaggerated sagittal plane posture also affects both diaphragms—through quadratus lumborum and psoas as well as the posterior L1-2-(3) attachments for the thoracoabdominal diaphragm, but also for the pelvic diaphragm tension placed on the pelvic floor by gravity and the counter-rotation within the pelvis (see Chapter 36: Postural Model)

TABLE 51.5

Integration into a Sequenced Respiratory-Circulatory Model Approach: Lymphatic Techniques to Accentuate Lymphatic Return and Augment Lymphatic Pumps

Manipulative Approaches	Comments
Thoracic pump—with and without modifications <ul style="list-style-type: none"> • Classic thoracic (Miller) pump: Takes advantage of rhythmic added passive recoil from chest wall for greater pressure differentials with each pumping motion • Atelectasis modification: Takes advantage of periodic sudden “explosive” recoil to refill collapsed alveoli • Pulmonary toilet variation: Takes advantage of continuous superimposed vibratory motion to mobilize secretions 	Usual large amplitude component uses inherent respiratory rate for about 2 min; superimposed vibratory rate typically about 120/min. <ul style="list-style-type: none"> • Atelectasis variation contraindicated in emphysema patients (with hyperinflated blebs) • Avoid aspiration of secretions as well as gum or other intraoral objects
Splenic pumps <ul style="list-style-type: none"> • Immune function: Adult and pediatric versions • Also good for left lower lobe pneumonia • Abdominal pump version below costal margin 	(See text for relative contraindications such as splenomegaly; Usual rate = 120/min for 2 min)
Liver pump: In reducing toxicity (a variation called the “liver flip” involves a quick release after taking up the passive range of the chest wall and may be useful in right lower lobe pneumonia with adhesion)	(See text for relative contraindications such as hepatomegaly)
Pedal (Dalrymple) pump	Usually 120/min for 2 min; (see relative contraindications in conditions such as deep vein thrombosis)
Ruddy rapid resistive duction (muscle pump) techniques <ul style="list-style-type: none"> • Specific or grouped isometric muscle pump against resistance moves fluid through one-way valves • Holding angle of the rib while patient intermittently activates/relaxes specific muscles attached to the rib(s) in question may be used to treat specific ribs and to improve rib cage dysfunction generally 	Principle the same for all regions; rate typically twice the heart rate; muscle effort energy is minimal
Rib raising—seated and supine	

(continued)

TABLE 51.5 (Continued)

Pectoral traction	
Proximal lymphatic duct siphon technique and/or fluctuation at the distal cisterna chyli	
CV4 ("Compression of fourth Ventricle")	Links primary respiratory mechanism to secondary respiration; CV4 often results in slower, deeper respirations and empirically enhances fluid movement out of the body
Nasal sinus drainage and pump	Sometimes this is performed at the end of a sinus treatment
Exercise-Induced muscle pumps	OMT to prepare the body for certain exercise types is recommended; placing exercise in the context of the Respiratory-Circulatory model is a very effective physician-patient decision for maintaining gains started in the office or hospital
<ul style="list-style-type: none"> • Generally moves fluids with total body exercise (postulated mechanisms include muscle pump effect on one-way valves, enhanced depth of respiration, and/or release of eNOS) • Specific group muscle exercises my target tissues for drainage • Certain impact exercises (e.g., mini-trampoline) may be better for interregional pressure changes and eNOS release than nonimpact types 	

TABLE 51.6

Integration into a Sequenced Respiratory-Circulatory Model Approach: Lymphatic Techniques to Mobilize Local Lymphatic Congestion

Manipulative Approaches	Comments
Mobilization (general and focused) from the head and neck region <ul style="list-style-type: none"> • Soft tissue OMT: Anterior cervical arches and hyoid • Soft tissues OMT: Lateral and posterior cervical tissues • Soft tissue, Ruddy OMT or counterstrain of the sternocleidomastoid ms • Submandibular and jugulodigastric drainage OMT • Mandibular and Eustachian drainage (Galbreath) OMT • Auricular drainage OMT 	While some of these techniques could arguably be included in the first stage of opening pathways, they are usually performed either after that first step or at the end prior to effleurage depending on the degree of congestion
Mobilization (general and focused) from the upper extremity <ul style="list-style-type: none"> • Posterior axillary fold technique • Shoulder girdle OMT with goals of free clavicular and scapulocostal motions • Ulnoradial interosseous membrane release (LAS or BMT) • Removal of scalene and upper extremity MTrPs (etc.) causing entrapments 	
Mobilization (general and focused) from the lower extremity <ul style="list-style-type: none"> • Fascial unwinding of the lower extremity • Tibiofibular interosseous membrane release • Removal of lower extremity MTrPs (etc.) causing entrapments 	
Mobilization (focused) from the gastrointestinal tract	
Mobilization (focused) exercise from the uterus/pelvis <ul style="list-style-type: none"> • Uterine (Marion Clark) drainage exercise 	Usually taught to do at home as self-exercise
Soft tissue OMT for fluid movement <ul style="list-style-type: none"> • Effleurage • Tapotement • Lateral fluid fluctuation (transmitted vibration) 	After finding a BLT or BMT position, a lateral fluid fluctuation in any area may be introduced with greatly enhanced tissue reaction (e.g., adding oscillatory supination-pronation while performing the radioulnar interosseous membrane technique)

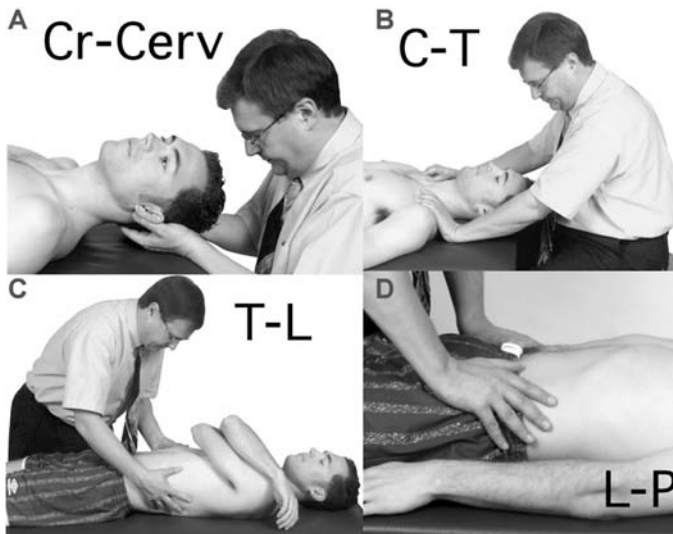

Figure 51-11 Hand placement for MFR or BLT to correct regional somatic dysfunctions compromising fluid drainage at the transition zones/major transverse diaphragms.

defined by the palpatory finding of even one nonalternating fascial preference between adjacent regions.

Many alternatives for opening fascial pathways exist to the indirect methods offered in Figure 51.11. Direct release method techniques for these transitional regions (and their transverse diaphragms) can also be supplied using the same hand placement and simply varying the level and type of the tissues contacted as well as the direction, tension, and type of release. An example for direct release of the very important superior thoracic inlet is offered as follows.

Direct Method Treatment of the Superior Thoracic Inlet (Cervicothoracic Diaphragm)

Example: Assume that the fascia at the patient's thoracic inlet has been diagnosed as being regionally S_L , R_L .

Position: Patient is supine with arms across the chest (or comfortably along side) and the physician is seated at the head of the table.

Activating Force(s): Direct MFR, direct balanced regional ligamentous articular strain (or an adaptation for direct muscle energy) OMT:

1. Physician's hands are placed on the shoulders with fingers on the anterior chest wall below the clavicle and thumbs posterior behind the 1st to 2nd ribs
2. Physician applies caudad pressure to take the patient's right shoulder to its restrictive barrier (Inlet S_R)
3. While maintaining the right shoulder caudad pressure, the physician's left hand moves the patient's shoulder anteriorly and to the right to its restrictive barrier as the left hand contact simultaneously moves the patient's right shoulder posterior and medially (R_R). (The hands move simultaneously like turning a car's steering wheel.)
4. The patient is asked to take a deep breath in and out as the physician resists motion except for the direction described earlier

Continue until there is a myofascial or ligamentous release—depending upon the desired depth of the targeted tissues—resulting in equal right and left sidebending as well as equal right and left rotation. (If no release is sensed, it is possible to have the patient attempt to turn away from the barrier against resistance using standard

postisometric muscle energy steps.) Opening drainage pathways for the extremities may follow the opening of the transitional core regions in Step/Goal 1 (listed in Table 51.3 earlier); however, often when there is a lot of systemic congestion (as is the case for this chapter's pregnant transcriptionist), then this component is placed later in the series. Thus, opening local pathways for the extremities or a particular visceral structure may take place *after* core diaphragms are working (Step/Goal 2) and even *after* central congestion has been cleared (Step/Goal 3).

In mild cases, opening these more distal pathways can be done in conjunction with opening the core pathways.

(Step/Goal 2) Techniques for “Redoming” or Otherwise Maximizing Function of the Diaphragms

When the thoracoabdominal diaphragm contracts, it does so around its central tendon. It descends because of the stabilization offered largely by the quadratus lumborum muscle that stabilizes the 12th rib, a lower attachment of the diaphragm. A “flattened diaphragm” does not displace as much volume and is therefore a less effective pump (see Fig. 51.10B). In fact, in some conditions, the diaphragm is so flattened that it becomes a muscle of *exhalation* as it pulls the 11th and 12th calipered ribs medially.

In approaching the thoracoabdominal diaphragm with OMT, it is also helpful to recognize the posterior attachments of the crus of the diaphragm to L1-2-3 and lower ribs, the myofascial relationships of the diaphragm with the quadratus lumborum and psoas muscles, and the fascial continuity of the deep fascia of the abdomen and that underlying the diaphragm. Likewise in approaching the pelvic diaphragm, bony attachment and myofascial trigger-points should be considered.

Table 51.4 presents lymphatic techniques for maximizing diaphragmatic function.

Two techniques are offered as examples for the thoracolumbar diaphragm; these are extensions of the previously mentioned inferior thoracic outlet techniques. Direct or indirect techniques that begin by using the handhold (themselves very effective for releasing the inferior thoracic outlet or thoracolumbar region) shown in Figure 51.11C can be transitioned into a thoracoabdominal diaphragm technique by simply concentrating on function and release of the diaphragmatic elements noted in steps 4 and 6 of the direct MFR technique.

Direct MFR to Open the Inferior Thoracic Outlet and Redome the Thoracoabdominal Diaphragm (see Fig. 51.11C)

Example: Assume that the region prefers sidebending and rotation left and that the diaphragm does not move as well on the left. Patient is supine with the patient standing on either side.

1. Position the lower ribs and thoracic cage to the “feather-edge” of the direct rotation barrier by moving both hands together to rotate to the patient's right
2. Add left translation with both hands simultaneously to create a right sidebending
3. Fine tune until the direct myofascial and ligamentous articular strain creep phenomenon begins (direct MFR/LAS)
4. At this point as the creep continues, shift attention to the diaphragm as the patient breathes. Add additional compression to the hemidiaphragm that moves most (in this example, the right moves best)
5. As the patient exhales, continue to follow the MFR/LAS release process (SB and rotate right more fully)
6. As the patient inhales, resist the most functional hemidiaphragm

- Repeat steps 5 and 6 until diaphragmatic excursion begins on the poorly functioning side and the MFR/LAS release sensation is complete. Recheck with deep inhalation and exhalation for symmetry and functional excursion

Also, consider using the alternative anteroposterior hold to apply an indirect diaphragmatic redoming technique that has the advantage of being able to address the quadratus lumborum, psoas, and thoracolumbar lordotic curve as well. This technique is described as follows:

Indirect MMF to Redome the Thoracoabdominal Diaphragm

Example same as earlier and the same positions for physician and patient. For this technique:

- Place one hand posteriorly to cup the L1-3 vertebral column (posterior diaphragmatic attachments) with fingers contacting paraspinal muscles on one side and the heel of the hand contacting the opposite muscles
- Place fingers of the anterior hand to broadly contact the subxiphoid region compressing to sense the deep anterior abdominal fascia that is continuous with the fascia lining the undersurface of the diaphragm
- Rotate one hand clockwise and opposite hand counterclockwise (whichever is indicated by testing fascial drag) to the point of indirect balanced tension
- Fine tune balance by adding any superior-inferior and left-right translation between hands (moving in opposite directions) to establish full balance between the hands
- Follow the release with normal respiration continuously maintaining the balance point until a release occurs in both hands

Multiple options for this vital area guarantee success when either the patient's status or presence of a surgical site might prevent a different technique.

(Step/Goal 3) Techniques to Accentuate Lymphatic Return and/or to Augment Lymphatic Pumps

This therapeutic step is all about changing pressures to move fluids through vessels with one-way valves, to enhance the siphon pump, or to transmit pressure changes into pressure-sensitive organs such as the liver or spleen. Typically, most pumps are performed at a rate of 120 beats/min and for the duration of 2 minutes.

Table 51.5 presents lymphatic techniques for accentuation of lymphatic return and augmentation of lymphatic pumps.

An interesting and effective fluid augmentation technique associated with this step is directed at the thoracic duct itself. A one-way valve is located at the proximal end of the thoracic duct. The thoracic duct can be stimulated at its proximal or its distal ends by directed, transmitted vibrations. Dr. Sutherland likened the thoracic duct to a siphon, indicating a functional turn at its superior end, allowing it to drain downward into the venous junction of the brachial and subclavian veins. The thoracic duct may be stimulated with a transmitted vibration at its proximal and distal ends.

Vibratory Methods for Treatment of the Thoracic Duct

Position: The patient is supine with knees flexed and feet on the table. The physician stands at the right side of the patient.

From the Distal End

- Physician contacts the patient's upper right abdominal quadrant with one hand just below the costal margin and may reinforce this hand with the other hand.

- A gentle, rhythmic vibration is instituted and directed toward the cisternal chyle. (This would be toward a midpoint of a line extending from the xiphoid process to the umbilicus.)

Toward the Proximal End

- The physician's palm contacts the patient's left thorax over the second or third intercostal space at the midclavicular line and that hand is reinforced with the other hand.
- A gentle, rhythmic vibration is instituted and directed posteriorly, laterally, and superiorly toward the junction of the thoracic duct to the left brachiocephalic vein.)

End point: A palpable sense of decongestion of tissues.

(Step/Goal 4): Mobilizing Targeted Lymphaticovenous Congestion

In the final goal, after the pathways are open and the body's homeostatic mechanisms are moving fluids, the osteopathic physician may select OMT techniques that decongest specifically targeted tissues. This step may incorporate manual lymphatic drainage techniques from other systems (such as the direct, light superficial effleurage strokes to move fluids through one-way valves toward the heart), the use of muscle pumping techniques (such as were packaged by Ruddy), gentle lateral fluctuation of fluids (as suggested by Sutherland), local MFR applied to the local somatic tissues, various visceral and mesenteric lifts applied to the viscera (76,77), or activation of reflex mechanisms to promote fluid movement.

Table 51.6 presents lymphatic techniques for mobilizing local lymphatic congestion.

The posterior axillary fold technique offers what Dr. Zink refers to as the "gateway to the upper extremity" (78). The mechanism of action for this technique has been postulated (79) to be reflex, autonomic, lymphatic, or a combination of parts of each. Palpation of the posterior and anterior axillary folds for evidence of myofascial dysfunction is clinically important in assessing the degree of lymphatic dysfunction affecting the upper extremities and/or breasts. The posterior axillary fold is the location of palpable myofascial points in the subscapularis, teres major, and latissimus dorsi muscles. It is also the site of terminal lymphatic drainage dysfunction for the upper extremities. Zink discusses diagnosis and treatment of this region to relieve lymphatic congestion in the upper extremity. Those findings closely parallel the palpatory and clinical findings described independently by Travell and Simons (80), using myofascial points located in the posterior axillary fold. Points higher in the posterior axillary fold correlate predominantly with shoulder referral, although lower points refer distally. Both Zink and Travell report that treatment of myofascial dysfunction in this area results in reduction of swelling, joint dysfunction, and dysesthesia. Likewise, appropriate treatment of anterior axillary fold dysfunction results in reduction of breast tenderness and congestive changes attributed to entrapment of breast lymphatics traveling around and through the pectoralis muscle toward the subclavicular lymph nodes (81).

Posterior Axillary Fold Technique

This technique is useful in patients who have increased lymphatic congestion of the upper extremity, as may occur in patients with shoulder discomfort, hand and/or arm paresthesias, patients with cool clammy hands, or patients who have had a radical mastectomy. It should probably be preceded by rib raising techniques or paraspinal inhibition to the patient's T1-8 thoracic region to calm segmental facilitation and insure that the large lymphatics are optimally functioning. This technique may also be used to treat tender

myofascial points in the posterior axillary fold muscles. The more congested the tissues, the more tenderness there will be during the initial treatment with this treatment technique. **Note:** *This technique will be difficult to initiate in patients who are excessively ticklish, although thereafter it is “uncomfortable” enough generally to overwhelm the tickle.*

Position: The patient is supine and the physician stands or sits by the patient’s shoulder and faces the patient’s head on the side that is to be treated:

1. Physician caudad hand grasps the patient’s posterior axillary fold with the thumb anteriorly and the fingers posteriorly. The total lateral length of the thumb and the index finger is snug against the patient’s rib cage
2. The physician reinforces this grip of the caudad hand with the fingers and thumb of the cephalad hand
3. A steady, gentle, firm, squeezing pressure is applied through the entire length of the physician’s thumb and held for about 10 to 15 seconds
4. The fingers are moved from the cephalad end toward the caudal end of the axillary fold and step 3 is repeated. This is repeated until the entire posterior axillary fold has been treated

Successful treatment: The patient, when asked, will feel warmth, not only in the arm but also to the finger tips, as good vascular flow is re-established. This warmth can be increased by having the patient clench and unclench the fist because this activates the peripheral muscular lymphatic pumps.

Lateral Fluctuation at the Forearm

This technique capitalizes on the use of motion in moving fluid out of the interstitial tissues into the blind lymphatics. As with all such local fluid mobilization techniques, pathways will have already have been cleared prior to using this technique. Note that for upper extremity OMT, the ulna is treated prior to the radius that is, in turn, treated prior to the wrist. If considered, LAS or BLT techniques for the interosseous membrane between the radius and the ulna could then be added. Lateral fluctuation of the forearm or effleurage is usually the last technique applied in applying the respiratory-circulatory model to this region.

Position: The patient is seated and the operator is seated and facing the patient:

1. Physician grasps the patient’s hand as if to shake hands
2. The patient’s elbow is supported by the other hand and the patient’s elbow is flexed 90 degrees
3. Physician supinates and pronates the forearm until the position of greatest ligamentous balance is palpated
4. From this position of balance, the physician institutes a small rhythmic supination/pronation excursion that is continued during the entire treatment

Follow-Up and Self-Treatment Prescriptions

Neither the physician nor the patient should be surprised if a compensatory fascial somatic dysfunction pattern returns between clinic visits—few individuals are perfectly symmetrical. They can be informed that with normal walking activities, such alternating patterns are periodically aligned to permit fluid drainage. On the other hand, in hospitalized patients or individuals who are extremely sedentary, even compensatory fascial patterns may lead to symptomatic congestion and these individuals benefit from

periodic treatment using the protocols discussed in Tables 51.3 to 51.6. Additionally, after a traumatic injury, core pathways may assume nonalternating, noncompensatory patterns compromising the respiratory-circulatory mechanism systemically or local pathways may be compromised leading to local congestive phenomena. Such symptomatic processes often benefit from osteopathic care using this model.

Patients may be educated to maximize their own respiratory-circulatory homeostatic mechanisms or to help prevent its dysfunction. These are important osteopathic goals designed to help patients raise their own health level or to be empowered to participate in their own ongoing care in a chronic condition. This may also be preventative in the previously mentioned sedentary individuals to keep them from needing to be “patients.”

Depending upon the clinical situation, specific self-stretching exercises can be provided. The physician may choose to focus the patient on exercises that maintain open drainage pathways or exercises that are more general (systemic).

CASE STUDY (CONTINUED)

PREGNANT PATIENT WITH CARPAL TUNNEL SYNDROME

Initial Case Presentation:

After 14 years at the same job without complaint, a 32-year-old transcriptionist now presents with 6-week progressive numbness and tingling in her right (dominant) hand. Awakening her nearly every night, the distribution of her dysesthesiae includes her thumb and the next 2½ digits. For the last month she has had difficulty opening jars and has nearly dropped objects. Gravida I, para 0-0-0-1 and early in her second trimester, she takes no medications or nutritional supplements other than a prenatal vitamin. *The distribution of the numbness and weakness coupled with an almost pathognomonic night-wakening symptom is classic for CTS, a median entrapment neuropathy at the wrist.*

CTS occurs more commonly in individuals with (a) biomechanical risk factors (e.g., overuse on the computer, square wrists, forearm somatic dysfunction including triggerpoints, etc.); (b) neurological risk factors (e.g., double crush conditions including cervical radiculopathy or dysfunction, scalene entrapment, etc.); (c) hormonal risk factors (e.g., hypothyroidism, diabetes, etc.); and (d) fluid overload/edema (e.g., pregnancy) to name just a few causes bearing on the choice of osteopathic model that might be selected.

Findings:

Her right thenar eminence appears smaller than the left and manifests reduced grip strength; all fingers on the right hand are puffy. On the right, positive neurological tests include Phalen’s (at 20 seconds) and Tinel’s (just distal to the wrist’s flexor crease). There are no other historical or physical findings to indicate thyroid disorder, cervical radiculopathy, diabetes, vascular disease, or other significant health issue.

The common compensatory pattern of Zink is violated by her superior thoracic inlet that prefers rotation and sidebending to the left. She has tender fullness in the right supraclavicular region and posterior axillary fold; in the supine position, her shallow, rapid breaths are seen to extend only half-way down to the umbilicus. Spinal palpatory reveals only grade I severity, Fryette type-I somatic dysfunctions; no Chapman points or collateral ganglion findings were identified. She has a right

posterior radial head. Active MTrPs are palpated in the right pronator teres and in several forearm and finger flexor muscles.

EMG consisting of NCS with needle examination confirmed moderate severity median entrapment neuropathy at the wrist with positive sensory and motor NCS but no fibrillation potentials in the thenar eminence; it also ruled out a concomitant cervical radiculopathy. *The presence of both sensory and motor problems suggests that this problem is probably at least moderate in severity and that treatment is warranted. The EMG confirms this but without fibrillation potentials indicates that conservative management is possible in this case. The EMG also ruled out a cervical radiculopathy as might coexist in a low, but significant percentage of cases and could itself predispose that extremity to MTrPs.*

Coupled with several ruled-out risk factors, her pregnancy (including edema, signs of terminal lymphatic drainage dysfunction, poorly effective respiration, and multiple somatic dysfunctions impeding both optimal fluid return and optimal biomechanical efficiency) suggests that the optimal first conservative step might be a combination of applying the respiratory-circulatory model in conjunction with a biomechanical/ergonomical approach.

OVERVIEW OF APPROACH WITH OMT

Thus, while the findings in this particular case confirmed a neurological manifestational pathology, they also suggested that majority of the dysfunctional components (and perhaps the structural changes themselves) were related to overwhelming the patient's underlying myofascial and fluid homeostatic mechanisms. It was therefore determined that this particular case would best be "primarily" addressed conservatively by applying the **Respiratory-Circulatory model** instead of the **Neurological model** and emphasizing education and exercises derived from the **Biomechanical model**.

The primary goals selected for this particular pregnant transcriptionist included correcting somatic dysfunction (1) to remove pathway impediments to fluid return and (2) to maximize the use of respiratory and muscle pumps to augment that return. Additional goals to empower her through education to reduce ergonomic stress while self-exercising to keep fluid pathways open were also felt to be needed. The resultant homeostatic improvement in her ability to manage systemic fluid changes (seen in pregnancy) simultaneously with local edema (that may have resulted from overuse and trigger points associated with her job) eliminated her CTS symptoms and, in this case, modified several of the pathogenic causes of median entrapment so that self-healing mechanisms could take over.

Care in this case consisted of OMT at each of her remaining prenatal visits (employing from those techniques listed later only as needed to accomplish the clinical goals of the respiratory-circulatory model) and asking her to take a short rest with forearm-wrist stretches every few hours. This simple regimen successfully resolved her symptoms after the second visit even as she continued to work. After vaginal delivery and 1 month of maternity leave, she returned to work. Her thenar eminence on the right returned to normal and she had no further hand symptoms. With clinical improvement, she refused to repeat the EMG and she remained empowered with her prior education concerning wise ergonomics, self-stretch exercises for the neck and forearm, and breathing exercises (which also helped calm her "biopsychosocial" stressors that were related to being a working mom with a new child). She now seeks OMT occasionally "when she feels overly stressed at work" but is ultimately responsible for her own health.

AUGMENTING THE FLOW AND MOBILIZING REGIONAL CONGESTION

Pectoral Traction

BLT/BMT with Lateral Fluctuation of Arm

EXERCISE PRESCRIPTION FOR PATIENT

Self-Stretch (83,85)

EVIDENCE-BASED OUTCOMES OF OTM IN CTS CASES

Numerous osteopathic trials have been conducted in the care of patients with CTS (86–90). Sucher has even demonstrated the efficacy of the exercises recommended earlier in "opening" the carpal tunnel in cadaveric specimens (91). Currently, a large-scale study funded with NIH funding is underway at the ORC in Texas. (See Chapter 43 in this text for more information concerning CTS.)

COMMENT ON OTHER OSTEOPATHIC MODELS THAT COULD HAVE BEEN INVOLVED IN THIS CASE

Neurological Model:

Screening diagnosis identified the primary pathology to be related to probable median entrapment neuropathy at the wrist consistent with a unilateral CTS. However, there was no additional evidence of C5–C8 neural involvement as might exist from cervical disk disease, cervical ribs, scalene triggerpoints or entrapment, or significant cervical somatic dysfunction that might lead to a "double crush syndrome" augmenting CTS symptoms or to confusion with the sensory and motor supply of the hand. Furthermore, no segmental facilitation from viscera sharing the upper extremity's sympathetic segments (T2–8) was seen. In other cases of CTS, OMT to augment sensory, motor, and autonomic homeostasis might be the primary management strategy. Increased sympathetic tone decreases blood flow to the upper extremity, reduces the ability of large lymphatics to move fluid, and can play a role in the development of what was formerly called "reflex sympathetic dystrophy" but is now referred to as "complex regional pain syndrome." There is definitely an overlap between the respiratory-circulatory model and the neurological model

Biomechanical Model:

In pregnancy, many postural and biomechanical changes take place. Increasing sagittal plane curves have their effects on the transverse diaphragms and create additional myofascial forces all of which can overlap with the respiratory-circulatory model. From an ergonomic perspective, pregnant women often will modify how they perform tasks based upon growing uterine impediments to bending or positioning themselves to perform certain work tasks or activities of daily living,

Metabolic-Energy Model:

Hypothyroidism is more common in pregnancy and causes thickening of connective tissue that can predispose to CTS (up to 10% of bilateral CTS patients may have myxedema). The relaxin circulating in the pregnant patient may also interact

with the postural and biomechanical model through changes in tensegrity. While the former was not a problem in this case, myxedema would need to be addressed prior to effectively applying the respiratory-circulatory model and the relaxin component in a pregnant patient influences choices of OMT techniques to use regardless of the model.

Behavioral Model:

This model mentioned the impact that respiratory instruction had in enhancing calmness and focus post-partum. (It did not mention the use of focused breathing this patient performed during her labor as a distraction from the pain of delivery). Optimal respiratory-circulatory homeostasis has a number of benefits important in the behavioral model including reduction of pain and anxiety by decreasing venous congestion around the central nervous system and enhancing the quality of sleep. Conversely, patients with heavy biopsychosocial stressors often have muscle tension and shallow breathing that compromise optimal respiratory-circulatory function.

In summary, an osteopathic approach to an individual case may not follow a single model, but identifying which model might have a primary impact permits the osteopathic practitioner to better focus his or her treatment plan in a time-efficient and effective manner. The outcome of applying the osteopathic respiratory-circulatory model to the chief complaint in this case accomplished much more than reduction of edema and thereby reduction of the signs and symptoms of “carpal tunnel syndrome.”

Representative Models

DENNIS J. DOWLING

This chapter contains a number of manipulative interventions currently practiced and taught by osteopathic physicians. Unlike the manipulative models presented in Chapters 45 to 51 inclusive, the models described in this chapter are not uniformly taught at all colleges of osteopathic medicine. The premises of the models are rationally based on accepted scientific principles. Their inclusion in this chapter demonstrates varying expressions of manipulative intervention within the somatic dysfunction diagnostic terminology developed by the osteopathic medical profession.

The contemporary approaches covered in this chapter include the following:

- A. Balanced Ligamentous Tension and Ligamentous Articular Strain
- B. Facilitated Positional Release
- C. Progressive Inhibition of Neuromuscular Structures
- D. Functional Technique
- E. Visceral Manipulation
- F. Still Technique
- G. Chapman's Approach
- H. Fulford Percussion

52A

Balanced Ligamentous Tension and Ligamentous Articular Strain

WM. THOMAS CROW

KEY CONCEPT

In this section, emphasis is placed on the role of ligaments in maintaining articular dysfunction. The cardinal principles of this approach are three: disengagement of the dysfunctional area (compression/decompression), exaggeration of the dysfunctional pattern (returning to the original position of injury), and balanced tension of ligaments (maintained until release). Retracing the path of injury via ligamentous tension and strain is done anatomically and facilitated by respiratory cooperation of the patient.

CASE STUDY

A 50-year-old male complains of pain in the left hip. It started several weeks ago after climbing six flights of stairs at work. The pain is worse in flexion and going up stairs. He tolerates going down stairs easier. The pain radiates from the groin mainly into the left thigh region. However, he is more functional and can bear weight on his left leg. Rest makes it better. It is worse at the end of the day than in the morning. Advil relieves most of his pain but it is now causing him some "stomach burn."

OBJECTIVE

Physical exam is normal except as follows. Neurological—no focal sensory or motor deficits, reflexes symmetrical. Less hypersensitivity to touch noted in the S1 S2 distribution. M/S muscle spasm noted in the L adductors. His gait is antalgic.

ASSESSMENT

719.45 JOINT PAIN-PELVIS

728.85 SPASM OF MUSCLE

Plan:

OMT to region

OSTEOPATHIC STRUCTURAL EXAM AND TREATMENT NOTE

Patient was found to have tenderness, asymmetry, restriction of range of motion, and tissue texture changes in the following areas:

Lumbar Spine:

Lumbar paraspinal muscles tight bilateral, L4–5 RLSRL

Sacrum and Innominates:

Posterior sacrum—left. **Inferior** pubic symphysis shear—right, Tight piriformis—left

Pelvis:

Adductors restricted in extension

739.4 SOMAT DYSFUNC SACRAL REG

739.5 SOMAT DYSFUNC PELVIC REG

739.3 SOMAT DYSFUNC LUMBAR REG

Plan:

Osteopathic manip, 3 to 4 body regn

PT treated with ligamentous articular strain (LAS) and balanced ligamentous tension (BLT) techniques. PT tolerated procedure well. No complications. Rest and ice to areas, if needed. He may continue to use **Tylenol** 1 PRN pain. Increase in PO fluids \times 24–48 hours

INTRODUCTION

Balanced ligamentous and balanced membranous tension to treat LASs were concepts of Dr. Andrew Taylor Still. William G. Sutherland, D.O., a student of Still, reinforced these concepts in his teaching. Rebecca and Howard Lippincott wrote the principles and techniques down and subsequently published them as the "Osteopathic

Technique of Wm. G. Sutherland” in the 1949 *Year Book of the Academy of Applied Osteopathy* (1). Dr. Anne Wales in the Northeast called what she was doing BLT techniques and Rollin Becker in Dallas called it LAS techniques. The terms come from the above-mentioned article where it states “Osteopathic lesions are strains of the tissues of the body. When they involve joints it is the ligaments that are primarily affected so the term ‘ligamentous articular strain’ is the one preferred by Dr. Sutherland. The ligaments of a joint are normally on a balanced, reciprocal tension and seldom if ever are they completely relaxed throughout the normal range of movement... Since it is the ligaments that are primarily involved in the maintenance of the lesion it is they, not muscular leverage, that are used as the main agency for reduction.... This is the point of balanced tension” (1).

HISTORY

At the time that Dr. Sutherland received his osteopathic training at Kirksville, Dr. Still was still supervising the instruction given at the college. The principles that were taught had to conform exactly to his concept. Dr. Sutherland made good use of every opportunity to learn and understand them and has adhered closely in his thinking and practice to Dr. Still’s principles throughout his professional career. “In consequence, the technique which he presented to us is a reflection of the clear vision of our founder” (2). During this course, Sutherland related the following: “Dr. Still gave me a lesson one day along with the rest of our class. A member of our class had stepped on a rusty nail. All the appropriate surgical management and cleansing had been used, but it would not heal. It began to look an angry red, so we called in the Old Doctor. He said, ‘You damn fools!’ and we were. We had not stopped to consider that when the patient stepped on that nail he drew his leg up away from it. The lasting problem was not the nail or the original wound; it was what occurred in the sudden jerk of the patient that caused a membranous strain between the fibula and the tibia (3). Sutherland’s student H. A. Lippincott, D.O., elaborated on this: “Since it is the ligaments that are primarily involved in the maintenance of the lesion it is they, not muscular leverage that are used as the main agency for reduction. The articulation is carried in the direction of the lesion position as far as is necessary to cause tension of the weakened elements of the ligamentous structure to be equal to or slight in excess of the tension of those that are not strained. This is the point of balanced tension. Forcing the articulation back and away from the direction of lesion strains the ligaments that are normal and unopposed, and if it is done with thrust or jerks there is a definite possibility of separating fibers of ligaments from their bony attachments. When the tension is properly balanced the respiratory or muscular cooperation of the patient is employed to overcome the resistance of the defense mechanism of the body to the release of the lesion” (1). Sutherland is best remembered for his application of osteopathic techniques for the cranium and sacrum. However, it is clear that he had learned from Dr. Still techniques for treating the whole body, and was only expounding more on an area that was receiving insufficient attention at that time, that is, the motion of the individual bones in the cranium. This is why Sutherland, later in his life, held that he had just pulled back a veil so that others could see more clearly.

While LAS techniques may not be the only techniques used by Drs. Still and Sutherland, they are the ones that both of them described. For example, Dr. Still wrote: “Without going into detail further, I will say that all dislocations, partial or complete, can be adjusted by this rule: First loosen the dislocated end from other tissues, then gently bring it back to its original place” (4).

Carl Phillip McConnell, D.O., M.D., who had been treated by Still and was on the faculty at the American School of Osteopa-

thy, described Still’s treatment technique in his book, *The Practice of Osteopathy*, by writing “Disengage the articular points that have become locked. Reduce the dislocation by retracing the path along which the parts were dislocated. One can readily see that a dislocated ball and socket joint could be reduced only by the dislocated bone retracing the path through which it left its socket as the capsular ligament would at once prevent its returning to the socket by any path other than that taken when dislocated. This applies to all dislocations to a greater or lesser extent” (5).

In 1917, Edythe Ashmore wrote that there were two methods commonly employed by osteopaths in the correction of lesions, the older of which is the traction method, the latter the direct method or thrust (6). In a footnote, she wrote: “The term ‘direct’ is preferred for the reason that the imitators of osteopathy have given to the word ‘thrust’ an objectionable meaning of harshness” (6). As noted previously, the older method is now known as LAS techniques, while the newer methods refer to high velocity–low amplitude techniques. Of the former, she wrote: “Those who employ the traction method secure the relaxation of the tissues about the articulation by what has been termed exaggeration of the lesion, a motion in the direction of the forcible movement which produced the lesion, as if its purpose were to increase the deformity. C.P. McConnell states that this disengages the tissues that are holding the parts in the abnormal position. The exaggeration is held, traction made upon the joint, replacement initiated and then completed by reversal of the forces” (6).

RECIPROCAL TENSION

Sutherland coined the terms “reciprocal tension ligaments” and “reciprocal tension mechanism” to describe the role of ligaments in joints (3). An example of this is the wrist as it moves into flexion displacing the distal row of carpal bones toward the dorsal surface of the arm. During extension the reverse occurs. Each bone then rotates as the group is moved. The tension of the carpal ligaments remains constant and constantly shifts its balance. This is a key concept in Dr. Sutherland’s approach.

The type of motion which may occur at any given articulation is determined by the shape of the joint surfaces, the position of the ligaments, and the forces of the muscles acting upon the joint. Ligaments do not stretch and contract as muscles do; consequently, the tension in a ligament has very little variation. The tension distributed throughout the ligaments of any given joint is balanced. In normal movements, as the joint changes position, the relationships between the joint’s ligaments also change, but the total tension within the ligamentous articular mechanism does not. The distribution of tension between the ligaments is altered, however, when the joint is affected by injury, inflammation, and/or mechanical forces. This is what happens in somatic dysfunction. The distribution and vector of tension within any given ligament will change according to the position of strain in the joint. However, the shared tension within the ligamentous articular mechanism of any given joint remains constant as long as the ligament is not damaged. This has been called a reciprocal tension mechanism. Of course, the balance within the ligamentous articular mechanism can be strained if the joint is inappropriately moved beyond its physiologic range of motion. In the former case, it is the balance of tension, which is distorted. In the latter case, the fibers of the ligament are subjected to microscopic tears and stretch. While this (the latter case) will most assuredly result in a strain to the balance of the articular ligaments, the ligaments do not need to be disrupted for the balance to be distorted. The distortion in balance is a mechanical strain, which may or may not involve an anatomical one. In any somatic dysfunction, there is always a strain.

H.A. Lippincott, D.O., describes LAS as “Osteopathic lesions are strains of the tissues of the body. When they involve joints, it is the ligaments that are primarily affected so the term ‘ligamentous articular strain’ is the one preferred by Dr. Sutherland. The ligaments of a joint are normally on a balanced, reciprocal tension and seldom if ever are they completely relaxed throughout the normal range of movement. When the motion is carried beyond that range, the tension is unbalanced and the elements of the ligamentous structure that limit motion in that direction are strained and weakened. The lesion is maintained by the overbalance of the reciprocal tension by the elements that have not been strained. This locks the articular mechanism or prevents its free and normal movement. The unbalanced tension causes the bones to assume a position that is nearer that in which the strain was produced than would be the case if the tension were normal, and the weakened part of the ligaments permits motion in the direction of the lesion in excess of normal. The range of movement in the opposite direction is limited by the more firm and unopposed tension of the elements which had not been strained” (1).

FASCIA

Still looked to the fascia for the source of disease (4). Strains in the fascia not only pull bones out of position and impinge on nerves, vessels, and lymphatics but also impede the flow of the interstitial fluid. At the 1998 Cranial Academy Conference, the osteopathic anatomist Frank Willard, Ph.D., stated that the fascia should be defined and studied as a system unto itself and not simply as an obscuring material hiding more important tissues (7). From an embryological standpoint, fascia, bone, and all the connective tissues arise from the mesenchyme.

CONNECTIVE TISSUE

Connective tissue makes up about 16 percent of the body’s weight and stores approximately 25% of the body’s total water. It forms the biological building blocks of the skin, muscles, nerve sheaths, tendons, ligaments, fascia, blood vessels, joint capsules, periosteum, aponeuroses, bones, adipose tissue, and cartilage and the framework for the internal organs (8). Connective tissue, with a special emphasis on fascia for our purposes here, has unique deformative characteristics. The fascia derives its unique characteristics from its viscosity and elasticity, both of which are changed by manipulation to reinstate homeostasis in the body. Being viscoelastic in nature, the fascia has both permanent (viscous) and temporary (elastic) deformation characteristics (9,10). In addition, fascia has a plastic component that allows for permanent elongation and a mechanical component that allows it to contract; thus, the fascia and bones deform in the same four ways. Wolff law states: “Every change in form and function of a bone, or in its function alone, is followed by certain definite changes in its internal architecture and secondary alterations in its external conformations, for example, bone is laid down along lines of stress” (11).

This process apparently also applies to the fascia and all connective tissue.

CRIMPING

If there are abnormal stresses found in the collagen that makes up the tendons and ligaments, then the tendons and ligaments will be deformed and their basic functions will be affected. Tendons attach muscle fibers to bones and transmit muscle forces, and the ligaments check excess motion of the joints and guide joint motion (12). Ligaments have a less consistent parallel arrangement of collagen than tendons (13). The orientation of the ligament takes on an undulating configuration known as the crimp, which allows the

ligament to work like a spring and which is an essential function of normal ligaments. Upon injury to the ligament, the spring will be straightened, causing the ligament to function improperly.

IMMOBILIZATION

Scientific studies have shown that fascia and connective tissue have certain biochemical and physiologic responses to immobilization. Most of the currently available research is on animals, which may limit its application to the human population. Nevertheless, in the studies on animal connective tissues, laboratory animals were immobilized for various periods of time and then examined at different time intervals (14).

BIOCHEMICAL CHANGES SECONDARY TO IMMOBILIZATION

Fibrofatty infiltrates were found in the capsular folds and recesses, and the longer the joint was immobilized, the greater the amount of infiltration (15–17). There was a loss of water and of glycosaminoglycans in the ground substance, a lubricant found between the collagen fibers, which are the primary connective tissue fibers that compose the fascia. Collagen fiber lubrication is associated with the maintenance of a critical interfiber distance, which has to be maintained between the fibers in order for them to move smoothly. When this distance is not maintained, microadhesions form and new collagen is then laid down in a haphazard manner (15). Immobilization for >12 weeks resulted in an overall loss of collagen since its rate of degradation exceeded its rate of synthesis under these circumstances (16). Joint contracture occurs as the result of remodeling and shortening of connective tissues when connective tissue is immobilized in the presence of inflammatory exudates. When a limb is immobilized in the absence of inflammatory exudates, no contracture occurs. In addition, biochemical changes are noted (17,18).

PHYSIOLOGICAL CHANGES SECONDARY TO IMMOBILIZATION

The force needed to move an immobilized joint is ten times that of a normal joint. After several repetitions, the amount of force required to move the immobilized joint is reduced to three times that of a normal joint. Over time, the joint will usually regain normal joint mobility (19). Manipulation of experimentally immobilized rat knees by either high velocity techniques or range of motion resulted in the rupture of macroadhesions and the restoration of partial joint mobility. Movement restores the normal histological makeup of the connective tissue, but the chances of obtaining optimum results decrease as the immobilization period increases (19). All periarticular connective tissues responded in the same manner. Ligament and capsule surrounding the fascia all have the same basic response to immobilization. Manual manipulation of the tissues causes a reversal of effects, provided manipulation was done within three months of immobilization (17).

Every cell in the body is surrounded by fascia that fuse together to make bigger sheets of fascia. Eventually, these fuse together to form tendons and ligaments. When you look at the smallest fibers of a muscle, it is still surrounded by fascia. It is like plastic bags within plastic bags within plastic bags. It is through pressure on these “plastic bags” that we are causing a change in the body. Pascal law states that “Pressure applied to a liquid at rest from any point is transmitted equally in all directions” (20). The human body consists of many closed fluid systems like the plastic bags that respond exactly as predicted by Pascal principle, that is, an

increase in the pressure of fluid in one of the plastic bags will distribute its pressure to other portions of the body.

The effects of the hydrodynamic fluctuation of body fluids restore motion and life to “dead spots,” or somatic dysfunctions, changing the structure of the tissues. Research has shown that changes in the structure of the tissues of the body alter the structure of the cytoskeleton, which in turn can actually alter gene expression and cellular metabolism (21). Therefore, we believe that we can bring about significant change on all levels by manipulating the tissues of the body. This concept is echoed in the osteopathic literature.

Every organ in the body exhibits the phenomenon of pulsations or rhythmic action which is incessantly active, dynamic, and highly mobile, resulting in forward, backward, sideways, and rotational fluid movement (19). These pulsations appear to be ubiquitous. They propel the extra cellular fluids into and across the semipermeable membranes of cells everywhere and deliver nutrients and remove metabolic waste products even from synovial spaces, bursae, and other nonvascular compartments. Every cell membrane of the body is continuously and rhythmically bathed with these essential fluids in a fashion similar to the ebb and flow of the ocean upon the beach.

Fluid dynamics, joint physiology, fascia, and vectors of injury may look on the surface to be unrelated, but, on a deeper level, are found to be closely connected. As osteopaths, we are interested in continuously advancing our skills and studying the interrelatedness of biomechanics. As you expand your knowledge of osteopathy, you will move from a view of the human body as a skeleton, with other tissues hanging on as it were, to a view of the body as a moving, living organism with a skeleton found within it. As a result, your attention will move from bones and joints to the fascia and fluid dynamics. It is important to understand the scientific principles upon which these techniques are based in order to apply them most successfully. If you understand the principles, you can then create your own techniques.

PRINCIPLES OF CORRECTIVE TECHNIQUE

Look at a somatic dysfunction as an impediment to the flow of the interstitial fluid. The fluid moves around areas of dysfunction like a stream flows around a stone. The goal of your treatment is to remove the stone and let the stream flow through unimpeded. Take that which you palpate as hard and make it soft. When you feel the flow come through the dysfunctional area, your treatment of that area is complete.

Once an area of dysfunction has been located, compress or decompress the joint or fascial plane to disengage the injury so that the displaced bone can be moved. (This is similar to pushing in the clutch on a car to shift gears.) Then carry the injured part in the direction of least resistance, returning it to the original position to which it was forced during the injury. Carrying the injury the way it wants to go is an indirect method of treatment and is also one that follows the direction of the somatic dysfunction. Remember that just after the initial injury, the injured part sprang back toward a normal position but was caught in limbo—part way between the position of the injury and the normal functional position. So, when correcting the injury, you must carry the injured part back to the exact position of injury and maintain that position until the body rebalances all the connective tissue surrounding the dysfunction, and draws the part back to its normal functional physiologic position. This can be done using a direct technique, an indirect technique, or a combination of indirect and direct methods.

It is the act of disengagement, exaggeration, and balance that makes the techniques work. These are the three basic components to remember when utilizing LAS techniques: disengage, exaggerate, and balance:

1. **Disengage:** Compress or decompress the joint or fascial plane, increasing the pressure or traction until you are able to move the injured part
2. **Exaggerate:** Carry the injured part back to the original position of injury by, for example, rotating, flexing, “side bending,” or “side shifting” until the balance point or still point is found. For example, if the right ankle is slightly inverted, you exaggerate the position of the ankle by taking it into a more inverted position, which is how the injury occurred originally
3. **Balance:** Maintain the area of dysfunction in the position of injury, that is, the balance point or still point, until a release occurs. The bone will move slightly farther in the direction of exaggeration. It then will move back to its normal functional position as the cranial rhythmic impulse or tide returns through the tissues that were injured. Once the correction has occurred, the injured ligaments will start their 3-month healing process

LAS Hip Technique

Symptoms/diagnosis: Hip pain, often due to a force transferred up from the lower extremity or a fall directly on the hip

Procedure (Fig. 52A.1):

Roll the knee medially to raise the symptomatic hip slightly off the table. Place the thenar eminence of your hand farthest from table between the greater trochanter and the table. Place the patient's knee in the fossa just below your coracoid process on the side nearest the patient to control the distal femur. Grasp the medial proximal aspect of the femur close to the femoral head with the index, middle finger, and thumb of your other hand. Use your shoulder to increase or decrease the flexion at the hip and to slightly internally or externally rotate the femur. The patient's foot is dangling just off the table. Compress the hip slightly anteriorly and medially with your thenar eminence on the greater trochanter. With your medial hand grasping the femur close to the femoral head, generate pressure posteriorly and laterally with your middle finger, index finger,

Figure 52A-1 Las technique for the hip. (From LAS by William Thomas Crow and Conrad Speece. Used with permission of Eastland Press.)

and thumb. Using your shoulder, locate the direction of balanced tension in the hip by slightly increasing or decreasing the flexion of the femur and slightly internally or externally rotating the femur. Balance the forces at the hip joint from all three contact points. When the release occurs, the connective tissue surrounding the head of the femur will readjust itself, all three vectors of force will “melt,” and the femur will move back to its functional physiologic position.

Active range of motion is assessed with the patient standing facing the physician, and the physician slowly moving the patient’s foot into internal and external rotation. Restriction of active motion is noted by assessing movement at the pelvis. The treatment is performed with the patient sitting facing the physician. The leg to be treated is crossed so that the ankle rests over the contralateral knee.

Treatment for Externally Rotated Legs

The physician places one hand upon the medial aspect of the femur near the femoral neck to externally rotate the femur. The other hand grasps the patient’s knee. The physician establishes a point of balance between the femoral head and the acetabulum. The patient also places his or her hands upon his or her knee. The patient holds the knee down and laterally while rotating the body away from the leg and backward.

Treatment for Internally Rotated Legs

In this instance, the physician’s handhold is more proximal so that there is less torque at the acetabulum. The physician establishes a point of balance between the femoral head and the acetabulum. The patient draws the knee medially and upward while rotating forward and toward the affected side.

52B

Facilitated Positional Release

DENNIS J. DOWLING

KEY CONCEPT

In this section, emphasis is placed on decreasing muscle hypertonicity involved in the maintenance of articular dysfunction. The dysfunctional region is initially placed in a relatively neutral position. Activating force of compression, traction, or torsion is applied to effect immediate release of tissue tension, articular restriction, or both. Subsequent positioning into resistance seeks to affect larger (regional) muscle groups or smaller (intrinsic) deep muscles involved in joint mobility.

CASE STUDY

The patient is a 48-year-old female who presented to the osteopathic physician’s office with several complaints of chronic lower back pain, neck pain, left shoulder pain, and frequent headaches. She described these as originating in her early twenties with no noted precipitating event, but all of the symptoms

have been gradually increasing over the years. The most recent symptom to appear has been intermittent radiating of pain and tingling from the left lower back to the left buttock and sometimes the left lower leg. The level of pain is a 3 to 4/10 pain and is worse in the morning after awakening. She has been married for 25 years, has three children, and works full time as a librarian. She describes that she is happy and satisfied in her private

and professional life. In her free time, she exercises and does volunteer work at her church both of which she states helps often, but always, with her symptoms. She has been seen by several physicians and health practitioners, including orthopedists, a neurologist, a rheumatologist, physical therapists, massage therapist, an acupuncturist, and a nutritionist. The massage therapy has helped but was only of short benefit. Radiological findings included some mild degenerative changes in the cervical and lumbar spinal regions with a paracentral herniated disc on the left at L4-5. Neurophysiological (EMG/NCS) only demonstrated some involvement of the L5 paraspinal muscles. Blood serology has been negative. She has been prescribed a tricyclic antidepressant, a specific serotonin reuptake inhibitor, gabapentin, various nonsteroidal anti-inflammatories, muscle relaxants, and narcotic analogue medications. She discontinued all of the medications either because of side effects or ineffectiveness. She does occasionally take acetaminophen for her headaches, which she describes as tightness at the back of her head radiating to her temple area. She denies any aura or other symptoms associated with the headaches. She denies any other constitutional symptoms, is up to date with her gynecological, breast, and physical examinations, is not menopausal, is monogamous, and utilizes barrier methods for birth control. Her bone density studies have revealed minimal osteopenia. She has no known allergies, has never smoked or used recreational drugs, has only one to two glasses of wine per week, and has never had surgery. Her only hospitalizations were for her pregnancies, which were all full term and resulted in spontaneous vaginal deliveries. Family history is essentially negative with only a positive with her father's controlled hypertension.

On physical examination, the patient is a well-nourished, well-developed woman who appears to be younger than her stated age and is in no apparent distress. Gait and posture are normal. Regional demonstrates full range of motion and equal with the exception of reduced left shoulder flexion/abduction/internal rotation, lumbar side bending and rotation to the right, and cervical side bending and rotation to the right. Standing and seated flexion tests, straight leg-raising, and Spurling compression tests are negative. Motor strength is 5/5, reflexes are 2/4, and sensory is intact for touch/sharp/dull and is symmetrical throughout. The rest of the physical examination is benign and noncontributory. Specific structural findings include: left trapezius spasm, C3 ES_LR_L, C7 FS_LR_L, elevated first rib on the left, T6 FS_LR_L lumbar paravertebral muscle spasm on the right, latissimus dorsi muscle spasm on the left, L3 ES_LR_L, and L4 FS_LR_L. A mild flexion pattern with a CRI of 8 was noted and the sacrum and pelvis were symmetrical and mobile. Diagnoses of cervical, rib, thoracic and lumbar somatic dysfunctions; lumbar herniated disc; lumbar radiculopathy; and lumbar and cervical strain and sprain were made. The shoulder pain and restriction of motion were determined to not be directly related to shoulder restriction or pathology but were secondary to the spasms of the trapezius and latissimus muscles and the cervical and rib segmental dysfunctions. The patient was treated primarily with soft tissue and facilitated positional release (FPR) techniques. After the first treatment, she described that the pain was a 1 to 2/10, less frequent, and she was having less frequent headaches. The course of treatment resulted in weekly treatments for three weeks, and then biweekly, followed by monthly intervals.

HISTORY

In the 1980s, Stanley Schiowitz, D.O., F.A.A.O., was an associate dean and chairman of the Department of Osteopathic Principles and Practices (OPP) at the New York College of Osteopathic Medicine. His clinic practice on campus gave the undergraduate OPP fellows a great opportunity to practice osteopathic manipulation under the supervision of an experienced practitioner. Time after time, they would describe the same experience: Dr. Schiowitz would enter the treatment room after each had treated a patient, they would describe some finding or restriction that was recalcitrant to treatment, Dr. Schiowitz would perform some quick maneuver that was unfamiliar to them, the patient would be improved, and Dr. Schiowitz would quickly exit to go see other patients. As they exchanged notes on what they observed and mimicked some of his treatments, the group found that they were able to successfully perform them. Whenever possible, Dr. Schiowitz taught them one on one or in small groups. It appeared that he had a cohesive approach for treatment that was, as of that time, nameless and without explanation. In order to record the description in the "Progress" section of the SOAP note, the OPP fellows would use the letters "IO" ("Instant Osteopathy") as an abbreviation. Because of his busy practice and time limitations, Dr. Schiowitz sought out and adapted methods of treatment that were rapid and effective and based on anatomical and physiological principles. Some of his students have remarked that he had to develop a quick approach to treatment since he couldn't stay in one place for 90 seconds. He has admitted that he may have seen some practitioners using some elements or on very specific diagnoses but not in a globally designed system. By 1990, Dr. Schiowitz had formulated the treatment to the extent that it was published in the JAOA (1) and taught at national meetings. The OPP fellows and some faculty members became his earliest table trainers at some of these sessions.

FPR is primarily an indirect method of treatment as has been published. Actually, as practiced by Dr. Schiowitz and those whom he has directly taught, FPR is a mixed indirect followed by direct treatment. The physician initially places the region or somatic dysfunction into a position between flexion and extension to approach the neutral position as defined by Fryette (2). An activating force, compression, traction, or torsion, is then applied to facilitate an immediate release of tissue tension, joint motion restriction, or both. This is followed by placing the region into its directions of dysfunction for a few seconds and then repositioned, if desired, in the barrier directions followed by rediagnosis. This latter aspect, the positioning into the barriers, brings FPR into greater resemblance with the Still technique (3). The goals of treatment are to decrease muscle hypertonicity that maintains somatic dysfunction whether by affecting larger regional groups or by modifying smaller more intrinsic deep muscles, which are involved in joint mobility.

FPR as a technique is easily applied, effective, and time efficient. Often, patients report immediate relief of tension and/or tenderness and restoration of function. Because treatment of specific dysfunctions is accomplished in seconds, repeat application can be attempted or other methods of treatment can be subsequently applied.

THEORY

Korr (4) wrote that the immobility of a lesioned segment was initiated or maintained by increased gain in gamma motor neuron activity of the muscles of that segment. The gamma motor

neurons specifically innervate the intrinsic muscles, the muscle spindle apparatus that act as sensors for overall muscle tonicity. When a gamma motor neuron stimulates a muscle spindle, such as a nuclear bag fiber, the fiber shortens in length and the stretch receptor, either annulospiral or flower spray, becomes more sensitive to stretch than it was previously. Even if the overall extrinsic muscle is in a rest position, the length-sensing nerve fibers of the muscle spindles may be sending signals back to the spinal cord, which in turn stimulate alpha motor neuron fibers innervating the same muscles. In effect, the muscle may remain in tension even in a so-called neutral position and may worsen with further stretching. Bailey (5) proposed that this high gain-set of the muscle spindle results in changes of the soft tissues that are characteristic of somatic dysfunction. Because of these aspects, FPR is an indirect form of osteopathic manipulation in which the patient remains passive throughout treatment.

Carew's (6) discussion of the feedback mechanism of the muscle spindle stretch reflex indicated that compressing muscles into more than the neutral position results in an inverse spindle output. The afferent excitatory input to the spinal cord through the Group Ia and II fibers is eliminated. This results in a "quieting" of the gamma motor gain to the spindle, reduction of the stretch stimuli, and resultant elimination of the reflex activation of the alpha motor neuron. The tension and hypertonicity of the extrafusal muscle fibers is reset.

Specific diagnosis in three planes is required for accurate treatment with FPR. The primary step in the application of FPR is the placement of the region of somatic dysfunction into its neutral position. This unloads the joints and may also affect both proprioceptive and nociceptive elements. The dysfunction can then respond more easily and rapidly to the applied therapeutic position, motion, and force. For the spine, the articular facets are placed into an idling position between the flexed and the extended extremes. A facilitating force, typically compression and/or torsion, is applied and maintained throughout the treatment. Generally, initial soft tissue relaxation is noted at this time. Using the triplanar diagnosis, further positioning of the somatic dysfunction is applied into all of the directions of relative freedom. Further easing of the dysfunction occurs at this point. This position is held for approximately 5 seconds after which the region is restored to neutral. In practice, Dr. Schiowitz often followed neutral by bringing the dysfunction into the barrier directions and then returned the region again to neutral. The dysfunction is then reassessed. The tension that was noted in the area is most typically is gone or at least reduced. Joint motion symmetry increases after treatment with the FPR modality if the etiology or maintenance of the dysfunction is due to muscular hypertonicity. If the asymmetry of joint motion is caused by other factors, such as arthritic or other degenerative changes, congenital malformation, meniscoid or synovial entrapment or ligamentous damage, the joint may remain restricted. Other modalities of osteopathic manipulation or repeated treatment with FPR may be necessary to complete treatment of the dysfunction.

DIAGNOSIS

The diagnostic methods used to determine somatic dysfunction can vary. The use of FPR treatment procedures does not require special diagnostic tests unique to FPR. However, diagnosis is a prerequisite to treatment. Mennell (7) has described a method of skin rolling. Mitchell et al. (8) have used the coupled motion of vertebrae as described by Fryette to conduct roto scoliosis testing, while

Johnston (9) incorporates a method of scanning and screening to progressively narrow the findings to specific diagnoses.

Schiowitz utilizes a very rapid method of diagnosis that incorporates the introduction of small motions to test all cardinal planes of motion. The appreciated palpatory response indicating relative freedom and resistance results in a specific diagnosis. For superficial muscular diagnosis, the physician places the pads of his fingers on the area of dysfunction and determines elements of Sensitivity, Tissue Texture Changes, Asymmetry, and Restriction of Motion (S-T-A-R) (10). This can be accomplished in seconds and the FPR treatment applied. For specific segmental dysfunction, the physician introduces motion in all three planes by alternating forces in opposite directions. In the spine, the pads of the fingers apply anterior force to create rotation both to the left and to the right. When pressure is placed on the right transverse process, it creates a slight left rotation. Segmental dysfunctions will have directions of relative ease and restriction with the direction of restriction demonstrating greater resistance to the applied pressure and the freedom allowing less. Lateral motion, or side bending in the spine, is tested by applying pressure to deviate one transverse process into a more cephalad direction and the opposite side simultaneously into the caudad direction. Relative ease and restriction to the forces are noted and the opposite directions are tested. Sagittal planar motions of flexion and extension require observation of the resistance to anterior deviation of one vertebra with the next lower one. The pads of the fingers are pressed anteriorly on the superior surfaces of the upper vertebra's transverse processes for flexion and on the inferior surfaces for extension. The combination of all findings results in a triplanar diagnosis of segmental dysfunction. For the extremities, similar methods are utilized to determine flexion-extension, abduction-adduction, and rotation. The directions of ease will be the ones that will be introduced immediately after placing the joint into neutral and adding the facilitating force.

Using a combination of methods can further increase the accuracy of the diagnosis and therefore the treatment.

TREATMENT

FPR treatment can be used to address at abnormal superficial tissue texture as well as influence the deep intrinsic muscles involved in segmental joint mobility. When it is a clear diagnostic differentiation as to which is primarily involved in the somatic dysfunction, the superficial soft tissue changes should be initially treated. If the dysfunction persists after this treatment, FPR should then be directed toward treatment of the deeper muscular component involved in the specific joint motion restriction. FPR is primarily an indirect technique that requires the patient to remain passive. However, sometimes the patient can assist initially into attaining a neutral position, the physician braces the patient, and then the patient relaxes. The technique can be adapted to treat the patient in a supine, prone, side-lying, or upright position.

Tissue Texture Change Treatment

1. The physician monitors the region to be treated
2. The anteroposterior spinal curve of the treatment area is flattened. This position places that region of the spine into an idling position, which shortens and softens associated muscle. A palpatory softening is customarily noted immediately. The lordoses of the lumbar and cervical regions are slightly flexed while the thoracic spine is extended. When treating the patient

- in the supine or prone positions, pillows can be used to attain approximation of neutral
3. A facilitating force is applied. This may be compression, torsion, or a combination of the two. At times, traction may be used with or without torsion
 4. The physician places the patient (patient's musculature) into a relaxed position. This usually requires approximating the origins and insertions by further compression and/or torsion. Additional softening is often noted
 5. The position is held for 3 to 5 seconds and then all facilitating forces are released
 6. The patient's condition is reevaluated. In some cases, passive stretch can be introduced

Intervertebral Motion Restriction Treatment

The same basic procedures are used to address intervertebral motion restrictions, with the additional requirement that the physician place the vertebra into a position that allows freedom of motion in all planes. For the cervical spine, the patient can be treated in the seated position but more frequently in the supine position. The thoracic and lumbar regions are typically treated in the seated or prone positions, but the techniques can be adapted for side-lying positions:

1. The dysfunction is monitored continuously
2. The lordosis or kyphosis is flattened
3. A facilitating force, either compression, torsion, or a combination is applied specifically to the monitored dysfunction. Often, regional tension decreases immediately
4. The directions of the somatic dysfunction are added just to the level of the dysfunction. Further relaxation is noted. The sequencing can be varied depending on the skill and experience of the physician. In fact, motion into all directions can be applied simultaneously rather than in a stepwise fashion. Some clinicians have even found the treatment effective by placing the dysfunction into neutral, applying the directions of relative freedom, and then adding the facilitating force
5. The position is held for 3 to 5 seconds, the facilitating forces are released, and the region is returned to neutral
6. The dysfunction is reevaluated. When appropriate, movement can be introduced into the barrier directions

SIDE EFFECTS AND CONTRAINDICATIONS

There are few contraindications and most are relative in nature in the clinical application of FPR. If the patient is not able to tolerate the positioning or experiences discomfort, either alternative positioning of the region or alternative techniques should be used. FPR to the cervical region approximates a Spurling maneuver and if the patient experiences radicular pain, then repositioning or traction may be used. Lumbar techniques may put torsion into knees or hips that have degenerative changes or prosthetics. Performing lumbar discogenic treatment would be contraindicated with a patient who has had a hip replacement as the external rotation and torque forces may possibly disarticulate the joint. The same can be said for the use of the first rib technique with patients with shoulder pathology. The compression and twisting involved with the treatment may exacerbate conditions where there are new or chronic shoulder dislocations or separations. Any recent history trauma of any region should raise suspicion of fracture or dislocation. Compression, even the relatively small forces used in FPR, may make a stable fracture unstable. Accurate diagnosis and integration of clinical knowledge

should direct the use of any intervention with osteopathic manipulation. Caution but not contradiction should be used in case of osteoporosis, malignancy, rheumatological disorders, congenital malformations, stenosis, or other clinical diseases.

Generally, patients experience relief and few side effects when treated with FPR. As with any other treatment, there may be transient fatigue, soreness, or stiffness due primarily to restoration of circulation to previously dysfunctional tissue and release of muscular waste products. In rare cases, the patient experiences these discomforts on subsequent treatments.

SUMMARY

FPR is an easily administered, nontraumatic, and efficient technique. When it is properly performed, the patient often reports immediate relief of point tenderness and restoration of function. If complete normalization is not achieved, it can be repeated, or other methods of treatment can be applied immediately. This can mean treatments lasting a few minutes that can be easily incorporated into a busy clinical, non-manipulative specialist practice. Although primarily axial procedures have been described in this chapter, it is possible to use FPR for other regions of articular and soft tissue dysfunction.

DIAGNOSES AND TECHNIQUES

739.1-Cervical

Soft tissue treatment.

Findings

Posterior cervical muscle hypertonicity (soft-tissue texture abnormalities).

Patient Position

Supine on the table; the patient's head is beyond the end of the table, resting on a pillow on the physician's lap.

Procedure

1. The patient is supine and the physician sits at the head of the table (Fig. 52B.1)
2. The physician cradles the patient's neck in the palm of his hand utilizing the hand that is on the opposite side of the dysfunctional region. When treating the left side, the right hand is used.

Figure 52B-1 Cervical soft tissue technique.

- The pad of the index or other finger acts as both monitoring finger and fulcrum, on the contralateral muscular spasm
3. The physician's other hand is placed on the top of the patient's head. This hand then straightens the patient's cervical lordosis by slightly forward bending the neck
 4. Using the hand that is on the top of the patient's head, the physician applies a compressive facilitating force to the neck, through the patient's head and sufficient enough to be appreciated and to create a relaxation of the tissue noted at the monitored location
 5. Maintaining the compressive force, extension is introduced to the neck to the level of the monitoring finger. This should cause a further relaxation of the tissue being treated
 6. Side bending and rotation, usually toward the side of the tense tissues, are added to the point that the tissues continue to soften
 7. The position is maintained for 3 to 5 seconds before returning the neck slowly to a neutral position
 8. The tissue being treated is reevaluated. A mild stretch can be applied into the barrier directions can be added while monitoring the tissue tension

Note: If tissue changes are found anteriorly, flexion instead is usually required. Some muscles, such as the sternocleidomastoid, have side-bending and rotation components in opposite directions. Knowledge of anatomy determines the direction that muscles must be placed into their individual shortened positions as determined by palpation and tissue response. Careful localization of the component motions of forward/backward bending, side bending/rotation, and compression to the area of tissue texture change will result in faster and more efficient results.

Cervical Segmental Somatic Dysfunction

Findings

C3 ES_LR_L and C7 FS_LR_L.

Patient Position

Supine, with the patient's head beyond the end of the table, resting on a pillow on the physician's lap.

Procedure

1. The physician sits at the head of the table (Fig. 52B.2)
2. The physician cradles the patient's neck in the palm of his hand. When treating the left side, the right hand is used. The pad of a finger monitors posterior to the left articular pillar of C3

Figure 52B-2 Typical cervical C3 ES_LR_L left technique.

3. The physician's other hand is placed on the top of the patient's head. This hand then introduces straightening the patient's cervical lordosis by slightly flexing the neck down to the level of the monitoring finger on C3. This is the neutral component
4. The physician's hand on the top of the patient's head adds a compressive force directed through the head to the neck until noted at the monitored level
5. The physician adds slight extension to the neck through the level of the monitored C3 while maintaining the compression
6. The relative freedom of motion of the somatic dysfunction is added by side bending C3 to the left by introducing a translatory force to the right through your monitoring finger
7. Rotation of the head and neck only through the level of C3 is added. This places C3 into all three planes of freedom of motion
8. This position is held for 3 to 5 seconds and then the physician slowly returns the neck to neutral
9. The C3 motion freedoms and restrictions are reevaluated. Improved range of motion into the barrier directions can be applied

Note: If the diagnosis is flexion rather than extension (C7 FS_LR_L), step 5 is replaced by adding flexion through the level of C7 rather than adding extension. Similarly, if the diagnosis is one of right side bending and right rotation, the appropriate adjustments should be made to engage these relative freedoms.

This procedure to dysfunctions of the suboccipital area can be specifically applied to the occipitoatlantoid articulation. The flexion or extension component can be localized by introducing a nodding motion to the skull. Any further flexion or extension of the cervical spine is nonspecific. The typical and restrictive motions of the occipitoatlantoid joint involves side bending and rotation in opposite in opposite directions. The appropriate directions of relative freedom should be used.

739.2-Thoracic

Thoracic segmental somatic dysfunction.

Findings

T6 FS_LR_L.

Patient Position

The patient is seated on the end of the table.

Procedure

1. The physician stands behind and to the side of the dysfunction to be treated (in the T6 FS_LR_L somatic dysfunction as in the current case, this is to the left of the patient) (Fig. 52B.3)
2. The physician monitors at the left T6 transverse process with his right hand. The palm of the hand can be used to support the region during the next step
3. Although FPR is a passive technique, attaining a neutral position in the seated position requires patient cooperation. The patient is asked to sit up as straight as possible and push his or her chest forward. This will straighten the thoracic kyphosis and add to the initial neutral component
4. The physician places his left axilla over the patient's left shoulder. This should be as close to the cervicothoracic junction as is possible. The physician's forearm is placed across the patient's chest and his left hand should grasp the patient's right shoulder
5. The physician adds a downward compressive force through his left axilla onto the patient's left shoulder. This both adds the facilitating force and introduces a localized left side bending down through to the level of the monitoring finger at T6

Figure 52B-3 Thoracic spine T6 FS_LR_L technique, seated.

6. Flexion to the level of T6 is added by pulling forward on both of the patient's shoulders while maintaining the side bending
7. The physician rotates the patient's thoracic spine to the left down through the level of T6 by pulling the right shoulder forward
8. The position is held for 3 to 5 seconds, and then the patient is slowly returned to a neutral position
9. The somatic dysfunction is reassessed. Improved range of motion into the barrier directions can be applied

Note: If the diagnosis is extension rather than flexion (T6 ES_LR_L), the flexion in step 6 is replaced adding extension instead through the level of T6. This is accomplished by the physician pulling the shoulders backward. Similarly, if the diagnosis is side bending and rotation is to the right, the appropriate adjustments into the relative freedoms of the somatic dysfunction are made. If the somatic dysfunction is a neutral group curve, neither flexion nor extension is used. The physician stands on the side of the curve concavity, the side-bending side, and monitors at the apex of the curve. Adjustments are applied in order that the side bending and rotation are achieved in the opposite directions.

Alternative Thoracic Segmental Somatic Dysfunction (Extension Dysfunctions), Prone

Findings
T6 ES_LR_L.

Patient Position

The patient is prone, with pillows beneath the abdomen and head. This creates a flattening of the thoracic kyphosis. The patient's arms are placed at his sides.

Procedure

1. The physician stands at the side of the table opposite to the somatic dysfunction. For T6 ES_LR_L, the physician stands at the right side of the patient (Fig. 52B.4)

Figure 52B-4 Thoracic spine T8 ESRRR technique, prone.

2. The physician palpates and monitors the T6 posterior left transverse process with the fingers of his right hand
3. The physician's left hand grasps the patient's left shoulder. The patient's entire shoulder should be held with your fingers placed on the superior and lateral portion of the shoulder
4. The patient's left shoulder is compressed medially toward the spine (this flattens the spine in the anteroposterior plane) and then toward the patient's feet (this compressive force creates left side bending). The combination of forces creates a force vector that is parallel to the patient's thoracic spine
5. Some extension of the spine is created through the level of T6 by maintaining traction on the shoulder as the patient's shoulder is lifted from the table, until motion can be palpated at the level of the monitoring fingers
6. To create greater extension, the physician stands up straighter, pulling the patient's shoulder further posteriorly. This also creates some additional left rotation down through the level of T6

Figure 52B-5 Discogenic pain syndrome treatment.

Figure 52B-6 Treatment for first rib. **A.** First rib elevated on left. **B.** Internal rotation and flexion introduced. **C.** Adduction and circumduction added.

7. This position is held for 3 to 5 seconds, and then the patient's shoulder and thoracic region are slowly returned to the neutral position
8. The T6 somatic dysfunction is then reevaluated

Note: If the diagnosis is a flexion somatic dysfunction, FPR is more easily accomplished with the patient in the seated position as described previously.

739.3-Lumbar

Discogenic pain syndrome treatment.

Findings

Left lumbar disk herniation or bulge with left radiculitis.

Position

The patient is prone, close to the left edge of the table, with a sufficient number of pillows beneath the abdomen to cause flattening of the lumbar lordosis.

Procedure

1. The physician sits on a rolling stool at the (left) side of table of the dysfunction, with the physician's thighs parallel to the table, at the level of the patient's pelvis, facing the patient's head (Fig. 52B.5)
2. The physician monitors the posterior transverse process (left) of the level to be treated (L4-5) with a finger of the (right) hand that is closer to the patient

3. The physician uses his nonmonitoring (left) hand to grasp the patient's (left) knee and flex the patient's (left) hip and knee on the involved side
4. The physician places the patient's upper leg across his anterior thighs. This creates abduction and external rotation. The patient's lower leg is lateral to the physician's thighs and the physician grasps the patient's (left) ankle
5. The physician localizes motion to the involved segment by moving the patient's upper leg in a cephalad direction. It is easiest to do this by rolling the stool closer to the head of the table
6. The physician raises his outer (left) knee by lifting his heel off the floor. The physician pushes the lateral part of his (left) knee into the popliteal fossa of the patient's (left) knee. This creates a traction force that can be modified, as the physician further raises and moves his knee laterally, until motion is palpated at his monitoring finger. The physician's knee is now at the medial surface of the popliteal fossa of the patient's knee and the medial surface of the knee and acts as a fulcrum for the rest of the technique
7. The physician uses his nonmonitoring (left) hand to push the patient's (left) lower leg toward the floor until motion is palpated at his monitoring finger. There may be a slight amount of tension noted at the monitored location. Often, the patient will state that the symptoms are reduced while in this position
8. The position is held for 3 to 5 seconds until there is a sudden release of the somatic dysfunction and then the patient is slowly returned to the initial position
9. The lumbar region is reevaluated

739.8-Rib

First Rib

Findings

First rib elevated on left.

Patient Position

The patient is supine.

Procedure

1. The physician stands on the side of the elevated rib. In the current example, this is to the left of the patient. The physician faces toward the head of the table (Fig. 52B.6)
2. The physician places the monitoring finger of the hand that is closer to the patient (left hand for an elevated left first rib) over the posterior portion of the elevated first rib. The finger serves

- primarily as a monitoring component. The physician's forearm serves as a fulcrum for some of the subsequent steps
3. The physician's other (right) hand grasps the patient's left elbow. The shoulder is flexed to approximately 90 degrees and abducted slightly (10 to 20 degrees) from the vertical. This should be adjusted until the tissues soften maximally (Fig. 52B.6A)
4. A compressive force is introduced through the patient's left elbow directed toward the monitoring finger (Fig. 52B.6B)
5. Slight further flexion of the patient's shoulder is introduced by the physician deviating the patient's elbow more cephalad. This causes the patient's forearm to abut the physician's forearm and introduces some internal rotation into the shoulder. The absolute position should be determined by the relaxation of the monitored rib soft tissue
6. The position is held for 3 to 5 seconds
7. While maintaining the compressive force and the internal rotation, the physician adducts and further internally rotates the patient's upper arm. To complete the treatment, the physician circumducts the patient's arm through a curving motion and back into a neutral position alongside his torso (Fig. 52B.6C)
8. The first is reevaluated

52C

Progressive Inhibition of Neuromuscular Structures

DENNIS J. DOWLING

KEY CONCEPT

In this section, emphasis is placed on decreasing tissue tonicity. Clinical symptoms are assumed to be directly related to increased dysfunctional tone. A steady pressure (constant mild/moderate force) is applied to regions of dysfunction. The relationship between musculoskeletal structures and underlying visceral organs is also considered. In order to achieve efficacy and accuracy, a thorough knowledge of the typical and variant courses of nerves, fascial bands, and muscles is required. This knowledge must be augmented by clinical decision-making skills.

CASE STUDY

The author had headaches as a teenager and was brought by his parents for treatment to the family physician. Most of the treatments that were offered had a limited impact or had very undesirable side effects. Accompanying the cephalgia were other apparently related symptoms: a boring pain of the right eye; increased lacrimation; right-sided facial pain; nasal congestion; and scalp sensitivity. There was also frequent suboccipital pain that appeared to be related in onset to the periorbital pain, although no direct connection was apparent. Eventually, common precipitating events leading to the symptoms were discerned: prolonged reading; eyestrain due to exposure to bright sunlight; and dehydration. There were no sensory deficits. Some symptoms could occur independently and were usually worsened by stress. Having little knowledge of anatomy at the time, the author attempted self-treatment involving the application of manual pressure to various locations of the head. Pressing painful sites appeared to bring about only temporary relief when any were pressed singly. The pain could recur almost immediately after release of the pressure. Adjacent regions of the scalp also developed sensitivity during or after release of pressure. Eventually, some patterns appeared to develop as these secondary and even subsequent points became unmasked. The most successful approach appeared to be the sequential treatment of a series of points.

Much later, as an osteopathic student and physician, the author began to integrate osteopathic manipulative medicine theory along with personal clinical observations in the utilization of treatment of these apparently linear patterns. The method of self-treatment was converted into a treatment modality and taught to other students of osteopathy. Gradually, the rationale as well as further expansion of use of this specialized inhibitory technique beyond treatment of headaches became clearer (1). Some similarities and differences were noted in relationship to other manipulative methods of point or applied pressure techniques.

INHIBITION

Progressive Inhibition of Neuromuscular Structures (PINS) is most closely related to the osteopathic modality of inhibition. The *Glossary of Osteopathic Terminology* states that inhibition is "...a term that describes steady pressure to soft tissues to effect relaxation and normalize reflex activity" (2). The "steady pressure to soft tissues" is perhaps one of the oldest methods of manual treatment, regardless of the name applied. Classically, inhibition is a constant mild-to-moderate amount of force exerted by the fingers, elbow, knee, or even foot on regions of hypertonic muscle. Even though the patient's presenting complaint may be of pain or decreased function, the objective of the treatment is to decrease the tonicity of the tissues. Any symptoms that the patient has are assumed to be directly related to this increased dysfunctional tone (3). Larger, more superficial muscles are the most easily identified whether they are in the normal-relaxed or hypertonic states. Regional muscles can be selected and treated individually or in pairs. Typically, the patient is treated in either the supine or the prone positions. This may facilitate the process by reducing the use of some muscles for positional support of the trunk and neck. As an example, the trapezius, can be easily located in the cervical, shoulder, and upper thoracic regions. Some portion of the muscle can be grasped, pressed,

or pinched. A hypertonic muscle is commonly found to be firmer than the same muscle on the opposite side of the body and perhaps more than its antagonist. This finding, and perhaps greater sensitivity or tenderness, are noted as the pressure is introduced. As long as the applied pressure remains constant, the structures should reflexively relax. Attempts should be made to avoid altering the position or amount of pressure, as these will more likely be stimulatory.

In regard to inhibition, the relationship between musculoskeletal structures and the underlying visceral organs should also be considered. These organs receive innervations from the same spinal cord segment levels that service the skin, bones, joints, ligaments, and muscles. The sympathetic chain lies just anterior to the rib heads and dysfunction of the vertebral or rib joints may result in increased stimulation to related structures, visceral, and musculoskeletal (4). Acute responses to increased sympathetic activity are the same as to any new injury: redness (rubor), pain (dolor), swelling (tumor), heat (calor), and decreased function (functio laesa) (5). More superficial structures such as the skin and subcutaneous tissue may have a "doughy" consistency and the pain noted by the patient would be typically sharp and throbbing. Chronic sympathetic hyperactivity in the absence of adequate treatment and/or recovery demonstrates altered signs and symptoms: the muscles may feel fibrotic ("ropy"); the skin is thinner, paler, and cooler; and pain responses can range from relative insensitivity ("anesthetic") to altered sensitivity ("paresthesia") to hypersensitivity. The pressure provided by the application of a modality, such as inhibition, may result in a transitory increase in the palpatory findings or symptoms followed by reduction of some or all of these components can be readily appreciated. When the visceral organs are the primary dysfunction, the persistence or recurrence of a musculoskeletal somatic dysfunction may indicate the viscerosomatic reflex. When a musculoskeletal injury is the etiology, manipulative treatment may result in a more persistent reduction or elimination of all pathological components.

Inhibitory techniques have a different visceral focus in the suboccipital and sacral regions. Rather than a sympathetic effect, the parasympathetic system predominates. Somatic dysfunction of the upper cervical, occipital, and sacral regions may reflect or result in prolonged inappropriate parasympathetic activity. Inhibitory treatment results in reduction of increased regional musculoskeletal tone and congestion, and theoretically downregulates the more internal mechanisms.

A thorough understanding of the structure and function of all of the factors related to somatic dysfunction is necessary in guiding accurate treatment with Inhibitory and PINS treatments. When correlated with somatic dysfunction findings, treatment patterns may be moved about several locations with the intent upon reducing all of the relevant dysfunctions.

When Andrew Taylor Still was a young man suffering from chronic headaches, he treated himself with a rope-swing by lowering the rope to a few inches above the ground. A blanket was slung across it and he positioned his neck with the base of the skull on this support and subsequently fell asleep. He awakened refreshed and pain-free. Whether intentionally or inadvertently, his self-treatment appears to represent an inhibitory treatment as much as a positional intervention (6). Despite an aversion to defining specific types of treatment in his writings, Dr. Still included some descriptions of both inhibition and stimulation methods (7).

Some of Dr. Still's early students likewise described inhibitory techniques as well as a rationale for their use. In his book, *A Manual of Osteopathy*, Eduard Goetz, D.O., described and

illustrated Readership will be largely nonosteopathic, so we must not assume familiarity with Still so a brief background as to who he was would be helpful if you wish to keep this reference in inhibition for various conditions, both somatic and visceral (8). The accompanying photographs in this small handbook clearly demonstrate and detail inhibitory treatment of several regions. Of special note are the orbital and suboccipital regions of the head. A few minutes of pressure applied individually to each of these points was recommended.

A more extensive description appears in *The Principles of Osteopathy* by Dain L. Tasker, D.O. (9). Dr. Tasker described the rationale as to the effectiveness of inhibitory techniques, especially since inhibition appeared to be a natural phenomenon. Bodily functions such as defecation and urination could not come under conscious and unconscious control without the adapted or learned ability to perform inhibition. In discussing the effectiveness of externally applied inhibitory pressure directed toward decreasing hyperactivity, as is applied by an osteopathic physician, he stated that it is not the surface pressure that is effective but the initiation or alteration of the reflex arc that subsequently occurs. The initial response to the placing a pressure is, in effect, a form of stimulation since it is impacting on the soft tissue. However, steadily applied pressure results in a diminution of the stimulation and a resultant inhibition of the region sets in motion a lessening of the dysfunction. These may bring about some alterations both deep to and distant from the location of the applied pressure. In citing Hilton law "that the skin, muscles and synovial membrane of a joint, or the skin, muscles of the abdomen and contents covered by peritoneum, are innervated from the same segment of the cord," Tasker states that the "overstimulation" caused by inhibition results in diminution or elimination of the overreactivity.

An Expansion of His Rationale Here Would Be Good

Osteopathic Point and/or Pressure Techniques

Many types of passive direct and indirect systems of osteopathic treatment of somatic dysfunction exist. Some standard points and diagnoses are used as fulcrums and/or monitoring locations in practically all of these modalities. Constant palpation at these points is one of the best means for an osteopathic physician to experience feedback and monitor the success of the treatment when performing Jones' strain-counterstrain treatment (10–12). Often, the patient can likewise appreciate the alteration. The muscle spindle sensory organ is embedded into the larger extrafusal muscle. The sensory ends of nerve fibers to these small muscles are stimulated by stretch of any kind, whether it is static or dynamic. The result is a single spinal segment increase in alpha motorneuron activity, which results in contraction of the whole extrafusal muscle. As a means of preventing overstretching of the soft tissue, it is quite successful and should decrease as soon as the danger retreats. However, if the region is underprepared or overwhelmed, the reflex can persist longer than is appropriate. The signals from the spindle continue to fire as if the tissue were being too rapidly stretched or overstretched even though the overall length of the muscle may be normal or relatively short. The sensitivity of a "tender point" reflects increased underlying activity. The external pressure at the tender point often elicits the complaint while the positioning during strain-counterstrain technique shortens the whole muscle. This allows the spindle reflex mechanism to be reset and the sensitivity disappears.

Facilitated positional release (FPR) (13) is similar in many respects to strain-counterstrain. It differs in its use of an activating force, usually compression or torsion, after initially positioning

the region in neutral. Strain-counterstrain is a form of positional release while FPR utilizes an additional facilitating force. Both strain-counterstrain and FPR theoretically utilize the same neurophysiological mechanism, the muscle spindle. Richard Van Buskirk, Ph.D., D.O., F.A.A.O., also attributes the muscle spindle as the core activator that is treated by the Still technique (14). It shares many similar applications to strain-counterstrain and FPR. Based on his recovery of components of the technique on the writings of Charles Hazzard, D.O., (15) as well as Dr. Still himself, Dr. Van Buskirk describes the technique as initially utilizing the palpatory diagnosis of dysfunctions to place the region into the freedoms. Finally, the osteopathic physician introduces movement past the neutral point into the barrier directions. This low-velocity, relatively low-amplitude articular movement toward the barriers follows the positional treatment into the freedoms.

In the spinal regions, functional technique (16) utilizes diagnostic points to define the somatic dysfunction that exists at that level relative to its two adjoining vertebrae, the one above and the one below. Detection of somatic dysfunction is typically made by percussion and more specific testing to scan and screen the regions. Elaine Wallace, D.O., developed Torque unwinding, (17) she utilizes constructs whereby the body is imagined as a collection of adjacent or overlapping cubes. Theoretically, injuries direct forces into a whole "cube" that is typically in a state of torsion during the process. When the patient is twisted, the initial vector force may be straight, but the resultant pathway becomes arched or more twisted as the person and region straightens. In this manner, the fascia acts more colloid-like with disruption and a tissue memory of the force in the form of adaptation. Torque unwinding treatment involves the introduction of oscillating rhythmic balancing pressures directed centrally from two diametrically opposed theoretical cube faces. The intent is for the therapeutic forces to counteract the residual traumatic ones. Other variations of myofascial or fascial release techniques (18,19) that utilize point contacts as references, contact points, and/or diagnostic reflections occur in the osteopathic literature. Trigger band technique, as described by Steven Typaldos, D.O., (20) is a method of treating the pathological crosslinkages of fascial bands by exerting deep pressure along certain connective tissue pathways. Chaitow (21,22) describes neuromuscular technique that consists mostly of point localization and pressure followed by deep stroking and/or rolling of the tissue.

Chapman's point treatment (23) reflects a neurological/endocrine/lymphatic alteration reflected to specific points on the surface that should raise suspicion of a possibly latent visceral correlate. Some of the specific mapped points are similar in location and correlation to those of acupuncture.

Nonosteopathic Point and/or Pressure Systems

Cyriax method (24), Trigger point therapy (25,26), acupressure (27,28), reflexology, Rolfing, and Shiatsu (29,30) bear some similarities to typical inhibition and stimulatory techniques. The practitioner provides the treatment in each by pressing the patient's soft tissue.

The British medical orthopedist James Cyriax, M.D., practiced joint mobilization and massage and utilized a pinching technique on several locations. Trigger point therapy, developed by Janet Travell, M.D., maps out the relationship between a remote referral region and a damaged myofascial nexus. The methods of treatment can include manual pressure, dry needling, or a combination of anesthetic and/or steroid agents injected into the trigger point. A vapocoolant spray can be directed from the trigger point toward the referral zone in another form of the treatment. An apparent

variant of the trigger point concept, Bonnie Prudden Myotherapy, consists of primary points, as well as satellite points. Both types of points are treated for short intervals several times per day over several sessions (31,32). Stretching may also be incorporated in either Bonnie Prudden myotherapy or trigger point therapy.

Acupressure utilizes surface points that represent reflections of energy or chi forces within the body aligned along meridians by specific point locations. The technique generally involves the application of pressure as well as circular motions. When treated with acupuncture needles, the practitioner may also burn incense or apply electricity to the outer tip of the acupuncture needles.

Ida Rolf, Ph.D., developed the eponymous system, Rolfing (33). Sometimes known as “Dr. Elbow,” because of her use of that region to apply pressure, she proposed utilizing deeply applied forces on regions of the body. The actual amount of force applied in this modality exceeds that which is commonly employed in osteopathic inhibition. There is a great deal of emphasis placed on approximating ideal symmetry and alignment. Followers of Dr. Rolf made some alterations to the technique and integrated them into other modalities involving movement patterns (Hellerwork, Aston-Patterning).

One of the oldest forms of manual therapy, Shiatsu, attempts to reduce the amount of the tissue tension present. Although typically brief in duration, the amount of force can be quite intense. Specific treatment patterns are utilized for certain conditions. Reflexology also relates energetic or visceral components to resonant areas located on the hands, feet, and ear. As with acupuncture, the name of the organ is related more to a theoretical functional contribution to the integrity or energy component of the organ than the actual physical structure of the viscera.

PINS Method

PINS requires an osteopathic physician’s capability to utilize anatomical and clinical knowledge to determine involved structures and sequence of treatment in the localization of points and the application of pressure in a logical fashion to treat persistent or resistant dysfunction. The osteopathic physician must have a thorough knowledge of the typical and variant courses of nerves, fascial bands, and muscles and augmented by clinical decision-making skills for efficacy and accuracy. This may involve the treatment of contiguous muscles, addressing the overlapping zones where more than one involved nerve, muscle, or fascial tissue may be contributing to the persistence of somatic dysfunction, and the development of a sequencing of **PINS** treatment. It is not as simple as locating a single sensitive point. Any patient can point to a location that hurts or that is sensitive to pressure. Shoulder pain can originate in the glenohumeral joint and specific treatment can be successful in increasing mobility and decreasing discomfort. However, when that is unsuccessful, more of the same treatment may not be the answer and this may prove frustrating to both the patient and the doctor. If the restrictions of motion of the shoulder involve the combination of flexion, abduction, and external rotation as well as reduction of scapulothoracic motion with freedoms in the opposite directions, the latissimus dorsi may be in spasm. It attaches in the bicipital groove of the humerus, pulls the arm into extension, internal rotation, and adduction, the motions directly opposite the restrictions. Treatment may have to go beyond this focus by including the upper ribs, pectoralis muscles, lower cervical spine, clavicle, thoracic spine, lumbar spine, pelvis, and lower extremity in the process. Fascial planes, and therefore fascial stresses, must also be considered.

In **PINS**, patients can offer feedback. They participate in the treatment by describing the amount of pain or other sensitivity

at the palpated areas. As the treatment proceeds, the osteopathic physician takes note of the tissue changes that occur, as well as the integration of the patient’s subjective experience. **PINS** can be used before or after other methods of treatment, manipulative or otherwise, as part of a comprehensive treatment regimen.

Procedure

The development of an appropriate and specific diagnostic and treatment protocol using **PINS** requires the following:

1. In most cases, the patient should be lying supine or prone. This is to allow postural muscles to be in a fairly relaxed state. However, treatment can be done with the patient seated or standing in some regions of the body
2. The osteopathic physician stands or sits near the region to be treated. The fingers of both hands should be able to contact the patient comfortably and accurately
3. Examine the patient. Determine any relationship between the patient’s symptoms, somatic dysfunctions, and the soft tissue findings
4. Determine the components of the somatic dysfunction. The mnemonic “S-T-A-R” (34) can be used to track the different aspects:
 - (a) Inquire about **[S] Sensitivity changes**. These are the patient’s subjective responses to palpation. These can include tenderness, numbness, radiation, warmth, irritation, throbbing, etc
 - (b) Locate **[T] Tissue texture changes**. They can be chronic (prolonged blanching of the skin, ropy or fibrous texture of the muscles and fascia, coolness, dryness, vascular changes) or acute (increased redness, swelling and edema, moist, and/or increased temperature). Palpation may initially worsen this component
 - (c) **[A] Asymmetry** can be noted by visual inspection or by palpatory examination. The so-called nondysfunctional side is used as the standard of expected form. Theoretically, an imaginary line down the middle of the body should reveal symmetry of one side to the other in a nondysfunctional condition
 - (d) Perhaps the most important determinant of somatic dysfunction is **[R] Restriction of Motion**. Restriction can be by quantity (number of degrees of motion), quality (i.e., stiffness, tremors, cogwheel rigidity, extraneous movement, etc.)
5. The site of subjective complaints of pain can be deceptive and may not help in the actual localization of the etiology. As an indicator that there is a problem, pain is fairly reliable. Tight muscles on one side may be relatively pain free while the contralateral stretched muscles may be more “attention-seeking.” Symptoms may distract treatment from the more needy locations. Pain, or any other symptom, tells that there is a problem but may or may not correlate with the dysfunction
6. Locate a “primary sensitive” point by examination of the tissue in the region of the patient’s complaint. If a significant one is not found, then knowledge of anatomical relationships is used to widen the search to adjacent areas
7. Using knowledge of anatomical structures, another point is located. This may be designated as the “end point” for **PINS** treatment purposes. It is located either distally or proximally to the primary point in a structure that links the two points. Having a thorough working knowledge and understanding of muscle origins/insertions, nerve and vascular pathways, and ligamentous attachments is a good beginning in determining

this pair of points. If the primary point is at a muscular origin, the end point may be at the insertion, or vice versa. Sometimes, one or the other point is located in the belly of the muscle. In that case, exploration of both ends of the attachments to bone may reveal the location of an end point. Ligaments, which are generally shorter and more fibrous, have points that are probably also fairly close to one another. Keep in mind that fascia encompasses all structures and the path between one point and another may seem to cross other structures. The more specialized the fascia, the more palpable and tendinous it is. Tracing superficial and deep pathways of nerves is useful when determining paths that apparently do not correlate with the other structures. Primary and end points may be found where a nerve passes out of a foramen, between or through muscles, or around bony protrusions. Sometimes, if more than one nerve innervates a region, the primary point can be found at the beginning of one nerve and the end point at the beginning of the other. In the case of nerve distribution of an extremity, one point will typically be found closer to the body, while the other will be closer to the end of the extremity. There are no exhaustive maps of points and sensitive point locations. There is no substitution for an excellent working knowledge of anatomy. The designated primary point will most likely be nearer to the patient's symptoms. The end point may also elicit the patient's presenting symptoms but usually to a lesser extent. Since the entire structure is in dysfunction, all intervening points between the primary and the end points must be addressed. In any case, the first steps are to make a determination of the two ends of the pattern. A patient's complaints of apparently unrelated regions of the body being related may give a clue as to the location of some components. Assuming that their knowledge of anatomy is small, it is left to the osteopathic physician to draw the conclusions necessary to begin treatment

8. Determining the two points is obviously critical to the outcome and this process of selection needs to be very clear—other than the supraorbital point described below
9. For the purpose of proceeding in a logical fashion, the point that is more sensitive is designated as the “primary.” To put this in more easily understood language for the patient, the

primary point is addressed as the “first point.” Both you and the patient can consider the other point, which is found on the other extreme, as the “end point.” Table 52C.1 provides examples of primary and end points

10. Determine a muscular, fascial, and/or neurological pathway between the primary sensitive point and the end point. The line may be curved rather than straight. The direction of treatment may be from distal to proximal, medial to lateral, anterior to posterior, or vice versa
11. An understanding of the connection between the two points using knowledge of anatomy is necessary, especially
 - (a) Nerve innervation:
 - (i) Direct connections (The connection of a point near the antecubital region of the elbow to a point along the middle of the forearm near the wrist-median nerve.)
 - (ii) Consider overlap or “watershed regions” of innervation. (The ophthalmic division of the trigeminal nerve travels from the supraorbital notch over the frontal region and to the top of the head.) The greater occipital nerve exits the suboccipital region in the occipital sulcus and travels over the occiput to the top of the head. They overlap in the scalp is near the vertex
 - (b) Muscle origins and insertions:
 - (i) Typical (A sensitive point may be found at the medial aspect of the clavicle and another found at the mastoid process representing involvement of the sternocleidomastoid muscle.)
 - (ii) Overlap (The location of a sensitive point on the superior anterior chest may involve intercostals muscles, pectoralis major, and/or pectoralis minor.)
 - (iii) Contiguity (The tensor fascia lata and iliotibial band actually form a continuity for two possible tender points located, respectively, at the greater trochanter and the fibular head. If a terminal point was actually found near the lateral malleolus instead of the fibular head, then there might be a tensor fascia lata, iliotibial band, peroneal muscle connection.)
 - (c) Fascia:
 - (i) Specialized (Interosseous ligaments are actually specialized fascia connecting the radius and ulna in

TABLE 52C.1

Primary Points, End Points, Connections, and Clinical Conditions

Primary Point	Endpoint	Connection	Clinical Condition
(a) Supraorbital notch	Suboccipital region	Frontalis-occipitalis muscles Trigeminal-greater occipital nerves (Fig. 52C.1)	Tension Headache Chronic daily headache Migraine headache
(b) Superior medial scapular border	Base of occiput	Levator scapula (Fig. 52C.2)	Cervicalgia
(c) Greater trochanter of femur	Fibular head	Iliotibial band (Fig. 52C.3)	Hip pain Knee pain
(d) Sternum at second rib	Coracoid process	Pectoralis minor (Fig. 52C.4)	Chest pain
(e) Gluteal region	Greater trochanter popliteal region	Piriformis muscle (Fig. 52C.5) Sciatic nerve (Figure 52C.6)	Hip pain Sciatica
(f) Xiphoid process	Pubic ramus	Rectus abdominus (Fig. 52C.7)	Abdominal pain nausea
(g) Antecubital region	Wrist	Median nerve (Fig. 52C.8)	Carpal tunnel syndrome Double crush syndrome

- the arm, and the fibula and tibia in the leg. Consider their involvement if a pattern appears to overly their locations.)
- (ii) Septums (Even though it is mostly muscular, the diaphragm has fascial components including the central tendon and crus of the diaphragm. It supports and separates. Points found around the lower costal cartilage, the 12th rib, and T10-12 and may represent a diaphragmatic involvement.)
 - (iii) Overlaps (The common thoracolumbar fascia in the back acts as an attachment for muscles such as the latissimus dorsi and overlaps muscles such as the quadratus lumborum, iliocostalis, and other erector spinae muscles.) Points may be found anywhere within the region and may extend to the lateral edge of the 12th rib (quadratus lumborum) or even

to the bicipital groove of the humerus (latissimus dorsi.)

- (d) Ligamentous attachments:
 - (i) Typical (The attachments of either end of the collateral ligaments in the elbow and knee can be considered.)
 - (ii) Relationships to muscles (Specific points can be found on the superior or lateral C7 spinous process,

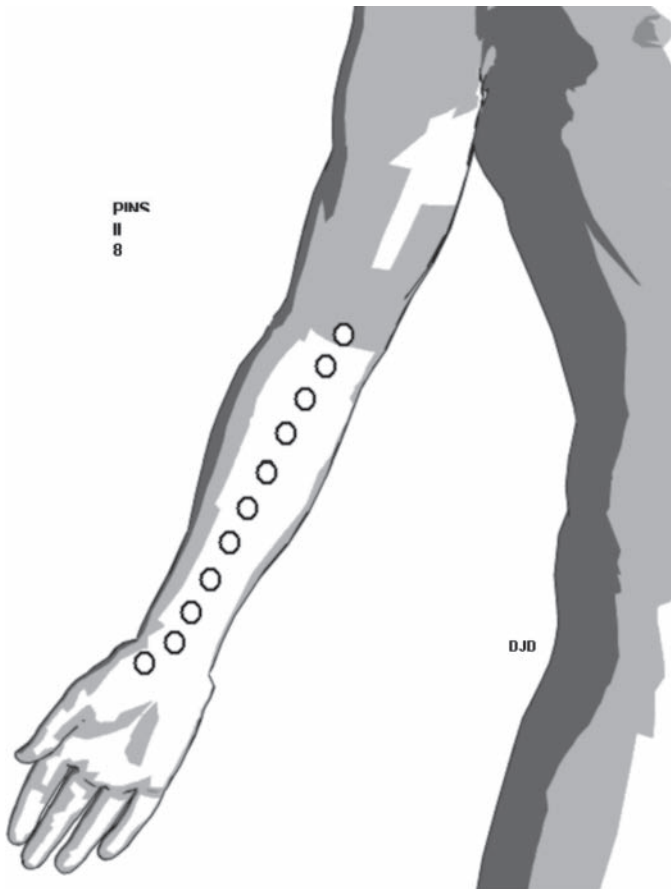

Figure 52C-8 Primary point: antecubital region; endpoint: wrist; connection: median nerve.

- and the base of the occiput may represent spinalis muscles or the nuchal ligament.)
- (iii) Relationships to nerves (The flexor retinaculum and palmar aponeurosis of the hand are related to the median nerve in the forearm. These, in turn, are related to attachments with at least four (pisiform, hamate, scaphoid, and trapezium) of the retinaculum as well.)
- (e) Bones (They and their components should be considered as connective tissue as well.):
- (i) Construction of joints (Joint capsules connect two or more bones. At the elbow and the knee, the capsules are stronger and reinforced on their medial and lateral surfaces by collateral ligaments. The anterior and posterior surfaces are relatively weaker and may tighten or loosen in one extreme of motion or the other. Points may occur in the middle of the capsule and at the bony attachments.)
- (ii) Lever action (Muscle tendons and ligaments attach to bony prominences. Because of the forces placed upon them, they enlarge into tubercles, trochanters, and other processes. Points located at tendinous insertions may theoretically also represent a contribution from the bony attachments.)
- (f) Vascular (They and their components should be considered as connective tissue as well.):
- (i) Arteries (Some large arteries travel long distances within the extremities and are responsible for the

overall nutrition to the surrounding tissue. It should also be noted that the sympathetic nerves travel with and modify the constriction of the arteries such as occurs in Raynaud's syndrome and complex regional pain syndromes.)

- (ii) Veins (The superficial veins often travel with structures such as the nerves. However, care should be taken when addressing vascular structures with PINS or inhibition as there are the possibilities of thrombi and/or phlebitis.)
12. Press both the primary point and the end point simultaneously using the pad region of a finger on each hand (Fig. 52C.9). (Again, for the sake of simplicity, identify the primary point as the "first point" for the patient.) The pressure exerted is a few ounces. It should be enough to elicit the patient's symptoms and should be applied equally on both points. The patient may experience a mild to moderate increase in sensitivity initially. Also, note the soft tissue response to the initial pressure:
- (a) Acute dysfunctions may be more sensitive than chronic ones. A muscle that has been hypertonic will usually be more sensitive to pressure than the same muscle on the contralateral side
- (b) Chronic hypertonic muscles will usually be larger than those on the contralateral side:
- (i) Larger muscles do not necessarily indicate dysfunction. Asymmetric use, where there is preference with one side being used more, will result in the dominant side becoming typically larger. An enlarged muscle does not necessarily mean that there is a dysfunction

Figure 52C-9 Press both the primary point and end point simultaneously using the pad region of a finger on each hand.

- (ii) Whether dysfunctional or not, frequently used muscles or ones in chronic dysfunction may not be quite so sensitive to pressure. This may be due to the chronicity of usage and histological alterations
 - (a) Both sides can be simultaneously dysfunctional. One side may be more symptomatic than the other. The more dysfunctional tissue should be treated first and then the other is reexamined, and then treated as well, if necessary
 - (b) A firmer muscle is probably in greater dysfunction
13. Exert the same amount of pressure on both the primary and end points:
- (a) Patients may assume that the point that a more sensitive location is being pressed harder. They should be reassured that the reason for the asymmetry is the greater dysfunction or hyperactivity of the involved tissue
 - (b) Patients may direct the practitioner that they can tolerate greater pressure. This does not accelerate the treatment. It is not necessary to increase the amount of pressure and may even be counterproductive
 - (c) Pain or tenderness may not be the only sensations experienced due to the applied pressure. The patient may report other sensations. They can occur alone or in combination with pain
14. Maintain constant pressure on the location of the end point throughout the treatment. Initiate pressure on the point with greater sensitivity (primary point). Request that the patient report what they are feeling. When inhibition is utilized properly, any increase in sensitivity at a sensitive point will most probably be transient. There is also a typical rapid decrease in sensitivity as the tissue accommodates to the irritation of the inhibition. Ultimately, it may totally disappear. The duration can vary from several seconds to minutes
15. Maintain contact with the primary point for 20 to 30 seconds before seeking any subsequent points:
- (a) One finger remains on the primary point and another finger of the same hand is used to locate a “secondary point.” If the middle finger is on the primary point, then the index finger is used to palpate the secondary point (Fig. 52C.10)
 - (b) The search for a secondary point begins approximately 2 to 3 cm away from the primary point along an imaginary line connecting the primary and end points. This will typically follow the predicted course of an anatomical structure (innervating nerve, along the direction of the muscle fibers, bone, blood vessel, or following fascial planes). Because of the variable nature of the structures, the actual location of a secondary point may be along an arc that occurs 2 to 3 cm into the direction of the endpoint
 - (c) Identify the secondary point as “the second point” for the patient
16. Exert equal pressure onto both the primary and the secondary points while maintaining the constant pressure on the end point
17. Request that the patient determine which of the two points (primary vs. secondary or “first vs. second”) is more sensitive:
- (a) To make it simpler for the patient, a phrase such as, “I am pressing on two points that are close together. Please tell me which of the two, the “first” or the “second” is more sensitive,” can be used
 - (b) Give example of the dialogue—what does the practitioner say to the patient? (“I am going to press on another point, close to where my right middle finger is pressing now, and I want you, etc.) If the second point is more or equally sensitive as compared to the first:

Figure 52C-10 One finger remains on the primary point. Use another finger of the same hand to locate a “secondary point.” If the middle finger is on the primary point, then use the index finger to palpate the secondary point.

- (i) Relieve the pressure from the first (primary) point and then remove it entirely
 - (ii) Maintain constant pressure on the new, second (secondary) sensitive point for an additional 20 to 30 seconds
 - (iii) It is not necessary to wait for the sensitivity at any point to be completely abated before moving on to the next point. It is more important that each subsequent point is more sensitive than the prior one.
 - (iv) There can be both increased tension and sensitivity in the new secondary point. With practice, the “secondary” points can be located by palpatory sense of tension alone. A return to a lower level of sensitivity and response baseline usually occurs after a few seconds. The amount of time depends on the soft tissue response
- (c) Certain points may require further inhibition before progress can be made. After doing so, a new secondary point may be located where previously there was less sensitivity. If the original or a subsequent “first point” persists as the more sensitive of the two points:
- (v) Maintain pressure at the location of the primary point for an additional 20 to 30 seconds; and/or
 - (vi) Move the finger that was locating the secondary point more laterally or medially from the connecting line. A located new secondary point should have at

least the same sensitivity, if not more, as the primary point. (The anatomical structure, whether muscle, nerve, or fascia, which is being inhibited, may have slight variations in the specific course in this individual.)

- (vii) Once a secondary point, that is equally or more sensitive, is located, relieve pressure from the primary point and maintain on the new secondary point as described above
 - (viii) The secondary point then becomes the new “first” point in the continuing sequence of treatment toward the endpoint
18. Inhibit the endpoint with constant pressure with a finger of the other hand throughout. The patient will often forget that this point is being treated. As the anchor for the dysfunctional tissue, continuous treatment is necessary. It may lose sensitivity during the course of treatment
 19. Repeat the process until an ultimate “second” point is located 2 cm from the end point
 20. Once the two final points have been treated with inhibition, determine the amount of dysfunction that persists, especially at the endpoint location. It may have become significantly reduced or may disappear totally
 21. All of the intervening points are part of the dysfunction. This is the reason that there can be persistence of symptoms when the area of the primary point (chief complaint) is treated by another method. It is not so much that it is not a part of the problem but rather one component in a “reverberating circuit.”
 22. Occasionally, pressure on one of the intervening points between the primary and end points results in a recurrence of the chief complaint, radiation of symptoms from this point toward the endpoint, the primary point or both. This is actually a good indication of the continuity of the dysfunction and the need for this thorough treatment
 23. Another modality of treatment can be used if the dysfunction, including the endpoint, remains persistent. The endpoint and overall dysfunction may now be easier to treat than previously. FPR, strain-counterstrain, muscle energy, balanced ligamentous tension techniques, or some other modality may be used. The use of HVLA that was difficult to perform before may now be easier. Guidelines for determining the choice include:
 - (a) The persistence of the dysfunction or related components after treatment
 - (b) The ability of the practitioner to perform other modalities of treatment
 - (c) The need or capability of the patient to tolerate additional treatment
 24. The conclusion of manipulative treatment for the session should be based on the findings for the individual. It should not be based solely on the patient’s subjective complaints. Overtreatment can cause as many problems as undertreatment
 25. Patients may limit types of treatment based on prior experience or misconceptions. They may have had a reaction to previous treatments or they may have had no previous difficulties but have developed a dislike for a particular modality (i.e., “popping” secondary to HVLA). Attempting to coerce a patient to allow certain forms of treatment would be counterproductive to the therapeutic relationship. In many locales, it could be considered illegal as well (i.e., battery)
 26. The somatic dysfunction is always reassessed
 27. Despite a relatively comfortable treatment, there may be a posttreatment reaction. The patient should be informed that

some treatment reactions can include transient soreness, aches, and fatigue. In some patients who are prone to bruising, or when there are certain other predisposing factors (i.e., medication), ecchymoses may occur. If excessive pressure has been used, it can also occur. Generally, all such side effects resolve in 24 to 48 hours

Possible Mechanism of Action. One of the important components of that distinguishes inhibitory contact from a stimulatory one is the use of a low level, but constant, amount of pressure applied to a dysfunctional tissue. A contact of this type may initiate accommodation or habituation over time even though the initial effect may be irritating. The patient may be acutely sensitive at first with complaints of increased pain, sensitivity, pressure, or some other sensation. These reactions decrease and may disappear altogether as the system adapts (35). Part of this reduction in awareness may be from the screening mechanisms provided by the reticular formation. The body accommodates to other stimuli, such as the relative nonawareness of body contact with eyeglasses, tight belts, stiff clothing, uncomfortable shoes, as well as constant background auditory and visual stimuli. This sensory filtering process may also involve the spinal cord acting as a mediator or as a “brake” when sensory overload (36) occurs. Some stimuli remain relatively subliminal if not of sufficient quality, duration, or quantity.

Some effects may include pressure or contact as a counterirritant. Instead of actually inhibiting they act as stimulation to the neighboring tissue, thus reducing the sensitivity of the original tender point. Scratching in the region of an itch would be one such example. Rapid conducting large nerve afferents gate transmission in the dorsal horn of the spinal cord with collateral fibers in the substantia gelatinosa or adjacent interneurons inhibiting the transmission of pain to the central nervous system via the spinothalamic tract (37).

Relative ischemia has also been proposed as a theory. Muscle maintained in prolonged contraction produces metabolites and waste products from the local tissue damage (38). Impaired circulation also occurs concomitantly with hyperemia and congestion. Some of the substances also have vasoactive effects, which theoretically address tissue injury. Trophic and fibrotic changes may occur if the injury persists. Normally, the overlying skin shows a brief blanching followed by redness. This typically fades when normal but may persist when the tissue is damaged for a prolonged time. It appears that the use of therapeutic pressure may add temporarily to the ischemia. This does not initially make intuitive sense when considering the amount of nutrient deprivation. However, the increased ischemia may reduce the capacity of the nociceptive receptors to process information. Hyperemia may also occur once this pressure is removed, resulting in the flushing of the waste products from the location.

A muscle in dysfunction may appear to be in its neutral position but may still be hypertonic. Further stretch from the relatively shortened length increases activity of the muscle spindle mechanisms and will result in a reflexive and prolonged contraction. This is a means of protection (39,40–42). Slow stretching of the type applied during inhibition introduces a gentle stretch while allowing the resetting of the stretch receptors (43). Only a small amount of the tissue may be challenged without upsetting the whole structure. Once the small, localized component is overwhelmed, any affected adjacent area can subsequently be inhibited with similar results. Inhibition in general, and PINS in particular, may be very effective methods to deal with a series of irritated pieces. The osteopathic physician may treat the entire dysfunction by progressively treating all of the involved elements.

The Golgi tendon organ is a sensory mechanism that becomes relatively stretched during muscular contraction where the overall length of the muscle does not change. When a critical amount of tension occurs, increased Golgi tendon organ activity brings about reflex relaxation of the muscle as a whole. An inhibitory interneuron between the afferent nerve ending in the spinal cord and the alpha motorneuron bring about sudden, almost complete muscular relaxation. The pressure from an osteopathic physician's fingers may create an initial stretch that results in transient contraction. This is then followed by resultant relaxation (44).

Contraindications and Side Effects

There appear to be few contraindications and side effects with the use of PINS. Pressure should not be exerted onto localized inflammations, abscesses, or infections as the integrity of the skin or walled infections may be compromised.

SUMMARY

PINS represents a unique variant of the more traditional approach to using inhibition as well as a means of discovering the ways in which dysfunction occurs and is maintained. It can be used solely or in combination with other methods of osteopathic manipulation. The effect of other treatment modalities can be enhanced by the use of PINS.

Using PINS does require an investment of time. When it appears that other typical interventions are of limited success with recalcitrant dysfunctions, alternative means must be used. However, when this occurs, the time necessary to perform PINS would be worth the effort.

52D

Functional Technique

WILLIAM L. JOHNSTON (1921–2003)

KEY CONCEPT

In this section, emphasis is placed on input (physician) palpated and evaluated at the segmental level. The sense of ease (compliance) and bind (increasing palpable resistance) is used to interpret the motion input. Opposite asymmetries (above and below) a segmental level is referred to as *mirror-image motion asymmetry*. Effective treatment is accomplished through the delivery of a smooth torsion arc of therapeutic motion. The component of visceral influence is recognized through the concepts of lack of accord and linkage. Both provide information directly relevant to treatment.

HISTORICAL PERSPECTIVES

To engage the term *functional technique*, one needs to sense the stimulus driving its initial development in the early 1950s. Within the osteopathic discipline, there was a growing recognition that *motor function* had a broader conceptual framework than just bony relationships, with their structural configuration relatively confined to joints, and to concepts for motion of one bone on the bone below. To open up this conceptual model, it was necessary to give increasing attention to the physiologic aspects and clinical manifestations of motor control. For a mobile system, specific directions of regional motion tests were becoming effective in delineating positive diagnostic signs of dysfunctional behaviors, both regional and segmental. Within these broader functional parameters, motion tests would supply promising tools for application in clinical practice and osteopathic research.

To engage the term *indirect*, as a method of manipulation, one needs to refer back to the early 1900s. In the history of osteopathy, information derived from palpatory examination had led to the development of a classification for methods of manipulation. Development of the terms *direct*, and *indirect*, gave recognition to the specific directions of motion forces used in osteopathic manipulative procedures. A brief look at 100 years of professional history indicates a significant struggle regarding the issue of terminology. The controversy involves two areas:

1. Verbalizing palpatory findings in the musculoskeletal system
2. Conceptualizing models for palpable findings, for example: the use of bony malposition at a joint, to depict a local area of segmental dysfunction (referred to in the past as a *lesion*, the *Still lesion*, or *osteopathic lesion*)

Difficulties with terminology create problems for communication about the clinical signs of musculoskeletal dysfunctions. To describe a direct manipulative technique for segmental dysfunction, initial concepts of somatic dysfunction focused on joint restriction and direct forces to encounter and overcome restriction; this fit the layperson's concept of "putting the bone back in place." Other techniques did not directly encounter the restriction yet still overcame restricted

movement. Such manipulative procedures did not fit the concept of the direct method. They did use motion and maneuvers in the opposite direction of the restriction effectively, however, and were given the term *indirect*. Owing to the fact that they seem to defy positional relationships and joint concepts, indirect methods are often set aside. Since they do not fit with those earlier models of thought, they continue to present a special challenge for instruction.

Several early osteopathic practitioners expressed these issues. Edythe F. Ashmore, a faculty member at the American College of Osteopathy in Kirksville, Missouri, wrote the first textbook on the mechanics of osteopathy in 1915. She stated:

There are two methods commonly employed by osteopaths in the correction of lesions the older of which is the traction method, the later the direct method or thrust.* Those who employ the traction method secure the relaxation of the tissues about the articulation by what has been termed exaggeration of the lesion, a motion in the direction of the forcible movement which produced the lesion, as if its purpose were to increase the deformity. The exaggeration is held, traction made upon the joint, replacement initiated and then completed by reversal of the forces.†

The direct method consists in the application of a precisely directed force toward a bony prominence during the process of putting the articulation or lesion through the spinal movement, which is the reversal of that which produced the lesion.

*The term "direct" is preferred for the reason that the imitators of osteopathy have given the word "thrust" an objectionable meaning of harshness.

†This method is the more difficult of the two and for the instruction of students does not find favor with the author (1).

Ashmore's footnotes about terminology and instructional problems are particularly illuminating. The limited concepts implied by the expressions *exaggerating the lesion* and *reversal of that* [movement] *which produced the lesion* remained in use for many years. The direction of restricted movement was even then becoming a determinant for methods of manipulative technique and their classification as direct and indirect.

Carl P. McConnell, D.O., was another osteopathic pioneer who actively contributed to osteopathic literature from 1905 to 1938. He commented:

So, striving to get the bones in normal position, per se, or perhaps to keep them in position, is simply hopeless. In this regard, the bony item is simply an idol, and a similar idol could be made of the muscles, and so forth (2).

McConnell also wrote:

Precision of method follows definiteness of diagnosis. It is evident that there are many ways of applying the same mechanical principles. But ease and effectiveness should be the goal of operative activity. In adjusting lesions it is obvious that a method which retraces the path of the lesion with a minimum of irritation is highly desirable (3).

McConnell's orientation was still on *the path of the lesion*, but this was tempered by a growing discomfort with using bony position or any single anatomic structure as the key to conceptualizing about areas of musculoskeletal dysfunction.

By 1923, in *Principles and Practice of Osteopathy*, C. Harrison Downing (4) went a step further in describing restriction at a lesioned segment. He referred to the fact that, when testing a physiologic motion, the lesioned segment becomes more restricted going in one direction. He added that the restriction decreases in the opposite direction and *apparently disappears*. Keeping his motion testing procedure as a frame of reference, Downing provided palpatory information about the restriction *decreasing*, in a direction opposite to the direction of restricted motion. These new facts sometimes supported the concepts centered on the joint and bony description of malposition, and sometimes did not.

By 1949, Howard A. Lippincott reported on the osteopathic technique of William G. Sutherland as follows:

The articulation is carried in the direction of the lesion, exaggerating the lesion position as far as is necessary to cause the tension of the weakened elements of the ligamentous structure to be equal to or slightly in excess of the tension of those that were not strained. This is the point of balanced tension. When the tension is properly balanced, the respiratory or muscular cooperation of the patient is employed to overcome the resistance of the defense mechanism of the body to the release of the lesion (5).

This described an indirect method of treatment, but the anatomic construct was more *ligamentous*. The *point of balanced tension* (also referred to as *the point of balanced ligamentous tension*) became the significant phrase used to describe techniques where the physician palpated throughout the procedure and continually adjusted treatment to the changing tissue tensions. Descriptive terminology still relied mainly on a positional orientation to express this important feedback of palpable information during motion. *Balance and hold* became another phrase to describe indirect techniques, but this phrase fails to point out the continued balancing carried out by the physician in response to the tissues changing.

In the early 1940s at the Chicago College of Osteopathy, indirect diagnostic skills were a part of students' formal training. This involved instructing students regarding the diagnosis of directions of motion that would initially relax the tissues, and their application in combined techniques. In Boston, by 1944, some very prominent physician teachers in the New England area had already been applying indirect methods extensively in their practices; however, the difficulty in communicating these skills was still a problem.

In the 1940s, the Academy of Applied Osteopathy (now known as the American Academy of Osteopathy) initiated a national program of education to improve the clinical skills of physicians, for those proficiencies in practice that can be achieved with continual application of Still's principles. This was done through the implementation of postgraduate instruction. Harold Hoover was a part of this effort. His classification of direct and indirect manipulative methods included the following:

1. Direct technique: the method of moving one bone or segment of the articular lesion directly to a normal relationship with its neighbor. This is accomplished against the resistance of tissues and fluids maintaining the abnormal relationship.
2. Indirect technique: the method of moving one bone or segment slightly in the direction away from the direction of correction until the resistance of holding tissues and fluids is partially overcome and the tensions are bilaterally balanced, then allowing the released ligaments and muscles themselves to aid in pulling the part toward normal. Other body forces, including that of respiration, may be employed (6).

Hoover's experiences with both of these methods of manipulation were beginning to channel his major interest toward the indirect (7). Recognizing a functional model, he was reporting on his use of palpatory tests, palpable findings, and manipulative procedures, especially those of the clinically effective indirect method. He often introduced his functional approaches in seminars. His presentation in New England in 1951 initiated an era of development in the New England Academy of Osteopathy. Biannual study sessions, led by Charles Bowles, resulted in a series of three publications entitled *A Functional Orientation for Technic*.

In his initial report, Bowles wrote:

This was not the birth of a new entity in osteopathy, but simply a new type of measuring stick for evaluating the Still lesion as a process of aberrated function ... our functional investigation had become formalized by using the pattern of a demand-response transaction, instituting motion demands (which could be named) with a motive hand, down to, and through a given segment, while assessing the motion response of this given segment through a palpatory listening hand. To best understand, follow, and control this demand-response transaction therapeutically at a segmental level, certain specific insights seem necessary, namely:

1. An understanding of typical motion demands and a system of annotation that makes them easily communicable between operators
2. An understanding of responses that allows an accurate reporting and a useful evaluation of the specific demand-response transaction taking place currently under the fingertips of the palpating or "listening hand" during manipulation
3. An understanding of criteria for lesioned and nonlesioned performance, that is, in terms of functional adequacy

Thus, the significant functional information about vertebral motion or restriction is not so much that there is motion or restriction, but rather how these motions and restrictions change, and under what circumstances, and in response to what demands.

It is the response information that eventually guides functional technic (8).

It should be noted that these comments by Bowles are in contrast to guides based on anatomic *concepts*, and bony, muscular, or ligamentous relations.

By 1961, Lippincott was expressing educational concerns similar to those of Ashmore. He reported student confusion, as well as practice trends, that were leading him to analyze and clarify the various methods of correcting lesions. In *Basic Principles of Osteopathic Technique*, he reported:

It is evident that Dr. Still treated his patients carefully, with due consideration for the delicacy and the welfare of the tissues beneath his fingers. It is also evident that he imparted to the students who

came under his supervision this wholesome respect for the tissues, the structures, and their functioning. Then, after the turn of the century, it became popular with many of the vigorous and enthusiastic young doctors to treat with vigor and enthusiasm. They developed techniques that would produce a “pop” regardless of the force required to produce it. This gave them a sense of accomplishment but it also gave osteopathy a reputation for being rough, painful, and even dangerous, a stigma that still persists among the uninformed. Within a decade or two the trend turned back toward more careful and intelligent, but perhaps less spectacular methods. The result is a wealth of technical procedures representing varied approaches to the correction of osteopathic lesions. It is a decided advantage for the physician to have at his command a variety of methods whereby he can meet the needs of each individual patient (9).

During the 1960s and 1970s, the steadfastness of positional concepts continued to be reflected in the development of new techniques. In 1964, Lawrence H. Jones published his original article, “Spontaneous Release by Positioning,” introducing the technique for manipulative treatment called *strain/counterstrain*. Dr. Jones questioned:

Is the muscular tension arranged so as to splint this joint, to prevent it from moving back into its eccentric position? No! The muscular tension resists any position away from the extreme position in which the lesioning occurred. Even the severest lesions will readily tolerate being returned to the position in which lesion formation originally occurred, and only to this position. When the joint is returned to this position (indirect), the muscles promptly and gratefully relax (10).

Since 1969, and possibly starting during the Bowles initiative in New England in 1955, interest has grown in relation to motor function, with a focus on the application of motion tests and palpable findings for descriptive clinical research. A test pattern of passive gross motions evolved with standards relevant to the six elementary directions of the body’s movement (Figs. 52D.1 and 52D.2). These motions are as follows:

- Flexion/extension
- Side bending

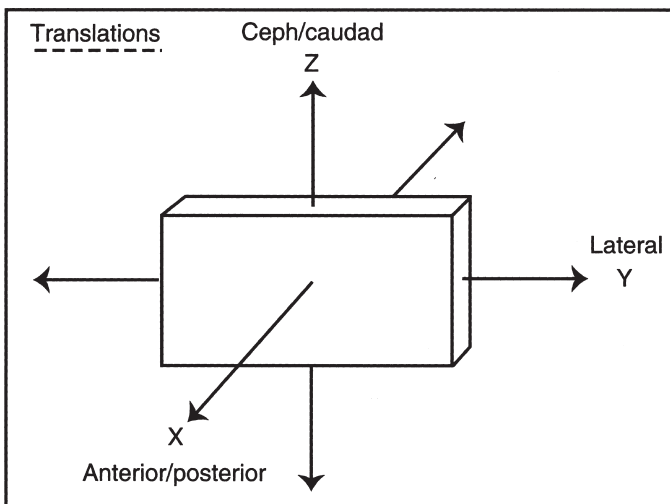

Figure 52D-1 Coordinate system to illustrate straight-line directions of movement used to describe translatory motion tests. (From Johnston WL. Segmental definition, part I: a focal point for diagnosis of somatic dysfunction. JAOA 1988;88:99–105, with permission.)

Figure 52D-2 Coordinate system to illustrate directions of movement about axes used to describe rotary motion tests. (From Johnston WL. Segmental definition, part I: a focal point for diagnosis of somatic dysfunction. JAOA 1988;88:99–105, with permission.)

- Rotation
- Translation from side to side
- Translation anteriorly/posteriorly
- Translation cephalad/caudad (traction/compression)

This test pattern allows implementation of an organized diagnostic process for describing the motor characteristics of neuromusculoskeletal dysfunctions. Investigations (11) using this test pattern have been advancing our knowledge about functional aspects of both regional and segmental somatic dysfunction, as follows:

1. Passive gross motion tests provide a means to attain baseline palpatory information in medical problem solving for a mobile system:
 - Examining *regional* motor performance (12)
 - Locating *segmental* motor defects (13,14)
 - Characterizing *the specifics of a segment’s motor dysfunction* as a basis for designing manipulative interventions to address somatic dysfunction (15–17)
2. Segmental somatic dysfunction is a complete asymmetry of its elementary motion functions: three rotary, three straight-line translatory, and respiratory (18). (Respiratory was the seventh function, and takes under consideration the demands of inhalation and exhalation on motor function.) Palpable recordable cues evident in response to these motion tests provide seven possible descriptors for the motion characteristics of each motor defect.
3. A fundamental unit of segmental somatic dysfunction (16,19) consists of a three-segment complex, as illustrated in Figure 52D.3. A central asymmetric segment is the primary defect. Mirror-image (opposing) motion asymmetries are present at the adjacent segments, above and below. (These are secondary and adaptive, implying a basis in somatosomatic reflex activity.)

Figure 52D-3 Schematic representation of three mobile columns in thoracic region, with a three-segment unit of dysfunction in vertebral column. X, location of primary functional defect at T2, with resistance to shoulder/trunk rotation to right (*short, solid arrow, with bar representing sense of resistance*). In adjacent T1 and T3 segments, mirror-image resistance to left rotation is secondary (*short, solid arrows without bars*). Longer, open arrows without bars at each level represent sense of compliance with motion and a greater range of motion in directions opposite to directions of limited mobility. (From Johnston WL. Somatic manifestations in renal disease: a clinical research study. JAOA 1987;87:22–35, with permission.)

Figure 52D-4 Schematic representation of two primary motor asymmetries at T2 spinal level, indicated by X in vertebral and adjacent left costal columns. Arrows with bars at T2 spinal level indicate resistance in both columns to right rotation of shoulders/trunk. Secondary mirror-image asymmetries of restricted motor function are indicated at T1 and T3 spinal levels by bars on arrows for left rotation that is (again) present in both columns.

4. A different organizational principle operates when primary defects are identified at a midline vertebra and an adjacent rib at the same spinal level with *identical* motion asymmetries; this contrasts with the *opposing* asymmetries presented by mirror images (20). An example is illustrated in Figure 52D.4 at T2 and left rib 2. Accompanying this primary defect at the T2 level, note that there still are secondary mirror-image asymmetries at the adjacent segments above and below in both the midline vertebral and left costal columns. Clinical research (21) has supported the premise that visceral afferents contribute to this characteristic configuration of two segmental units, vertebra and rib, *linked* in similar primary motion asymmetries at the same spinal level.

This preceding historical perspective puts one in mind of the classic tale of the blind men and the elephant, with each man describing the elephant according to the part being touched. From clinical palpatory experience, asymmetry (*A*) of joint position, restriction (*R*) of motion, and tissue texture changes (*T*) are expressed in the mnemonic acronym ART. Tenderness (*T*) has recently been added to the acronym, making it TART, with the first “T” representing tenderness. Each of the last three has emerged as a palpable sign of segmental somatic dysfunction, where motor function is asymmetric and its manifestations are present in structure, motion, and tissue. The functional characteristics of motor asymmetry emerge primarily from motion tests. These characteristics provide detailed descriptors to implement differential diagnosis and also establish basis for the classification of methods of manipulation as direct and indirect.

FUNCTIONAL TECHNIQUE

The term *functional technique* refers to osteopathic manipulative procedures that apply palpatory information gained from tests for motor function, although the term is often applied inappropriately as a general synonym for *indirect*. To be specific, in functional manipulative procedures, the palpable information regarding all six degrees of freedom and respiration is used to address the dysfunctional aspects of segmental behavior. Passive gross motion testing identifies motion symmetry/asymmetry at an individual mobile segment. If you can, temporarily set aside the interpretation of palpatory information about mobility in a format for static concepts of joint position—for example, a posterior transverse process. Instead, criteria for determining a mobile segment’s behavior and its resistance to or compliance with opposing directions of specifically induced passive *regional* motion tests are applied. The demonstration in Figure 52D.5 illustrates a single axial motion test introduced through the shoulders and trunk in rotation to the right. With the patient seated and arms folded, right rotation of shoulders and trunk is introduced by the physician’s right hand at the patient’s right elbow. The fingers of the left hand monitor bilaterally the *immediate* response of paravertebral tissues overlying T6 transverse processes. To compare for response to rotation left, the operator stands to the left and the hand positions are reversed. Finding asymmetric behavior at T6, one can report resistance encountered at T6, for example, during shoulder trunk rotation right. (The test and the criterion are explicit, and the finding becomes clear in relation to the test used to elicit it, thereby attending to scientific method for first-order reporting.) This is in contrast to applying *local*, pressure prone at T6, encountering increased resistance to pressure on the left versus the right, and then reporting a posterior

Figure 52D-5 Single axial motion test of shoulders and trunk in rotation to right. (From Johnston WL. Segmental definition, part I: a focal point for diagnosis of somatic dysfunction. *JAOA* 1988;88:99–105, with permission.)

left transverse process, with limited rotation to the right of T6 on T7 within the concept of a joint.

As illustrated in Figure 52D.6 for symmetric behavior, the initial resting level of minimal muscle tone or tension at point X reflects the natural palpable resistance that the operator's fingertips sense as they lightly contact tissues overlying the bony segment at rest. Point X also illustrates there is palpable symmetry in a segment's initial compliance to move right and left with no rise on the tone scale at the initiation of movement. Indicated also is the normally increasing resistance to range as motion approaches a physiologic and an anatomic barrier.

Start with a compression test. The compression test is the application of pressure through the fingers to sense any *increased* tissue tension at one segment compared with adjacent segments. Even at rest, a compression test of a *dysfunctional* segment will register the local increased resistance of that segment's deep musculature; this can be illustrated as an elevation to X1 on a tone scale (Fig. 52D.7). The fingertips mark the site of the increased resistance to pressure.

The segment's tissue tension in the marked area changes *immediately* on initiation of each passive motion test. Palpatory cues reflect the immediately increasing resistance to pressure in one direction (in this example, to the right), while in the opposing direction they reflect an immediate sense of decreasing resistance to

Figure 52D-6 Symmetric response to motion at a nonlesioned thoracic segment where only axial rotation is represented. Shown are equal initial compliance to right (R) and left (L), and then increasing resistance toward an equidistant final anatomic end point. (From Johnston WL. Segmental definition, part I: a focal point for diagnosis of somatic dysfunction. *JAOA* 1988;88:99–105, with permission.)

Figure 52D-7 Asymmetric behavior at a dysfunctional (lesioned) segment. (From Johnston WL. Segmental definition, part I: a focal point for diagnosis of somatic dysfunction. *JAOA* 1988;88:99–105, with permission.)

pressure (i.e., a decreasing tension with increasing ease of motion). These palpable changes provide an indicator of asymmetric motor function, to monitor not only during diagnosis to guide accuracy, but also during treatment to guide efficacy in the return to symmetric motor function. Treatment with functional technique is a distinctive application of an indirect method of manipulation. Well-defined directions of passive motion are combined *in their initial stages of increasing ease*. A particular phase of active respiration also increases this sense of ease in movement. As the responses to each precise elementary direction of increasing ease are summed up, the reduced tissue tension signals a rapidly improving motor function palpable at the fingertips.

Guidelines

Certain procedural aspects of functional technique help to ensure success in the application of an indirect method of manipulation for segmental dysfunction (22):

1. The initial introduction of motion in any one elementary direction is small (not range), with minimal forces applied.

2. Motion directions are toward a sense of *immediately increasing ease*. This response manifests a decreasing sense of resistance to pressure at fingers monitoring the tense dysfunctional segment (at the same time, motions are away from the opposing direction in which increasing resistance is encountered).
3. Single elements of rotary and translatory directions are combined, effecting the control of an eventual smooth torsion arc for body movement. The order of introduction of these elements is not important.
4. The final step of the functional procedure involves request for a specific direction of active respiration, whichever direction (inhalation or exhalation) contributes further to the increasing ease. For example, if inhalation, the request is for the subject to take a deep breath *slowly* and hold it briefly.
5. This respiratory interval, adding to a continuous feedback of decreasing resistance, allows the operator to fine-tune the combination of translatory and rotary directions. The objective is to reach a sense of release of tissue tension at the fingertips, which are continually monitoring response at the dysfunctional segment.
6. The release of restraint in the motor mechanism allows a return to midline resting, unobstructed by any sense of the resistance previously encountered in the return direction.

A successful outcome is signaled by a sensed release of the segmental tissues' holding forces, which then allows a free return to a resting position, and a new tissue tone at rest. The segment's new functional symmetry is evident in the responses to further motion retesting. Increased resistance in response to directions previously limited is no longer encountered.

Examples of applying this functional method of palpatory diagnosis and manipulative treatment are presented under "Examples of Functional Technique" later in this chapter. To memorize any technique for use as a manipulative procedure, without recreating each of the steps outlined above, this would be inappropriate and probably clinically ineffective. Bowles (23) stated, "It is ... the response information that eventually guides functional technic." Therefore, at a mobile segment, focus attention on the following:

1. The criteria for symmetric and asymmetric motor function
2. The orientation of motion testing to the palpable findings of bony and tissue tension expressed at a dysfunctional mobile segment
3. The way that response at your fingertips, to each direction of motion test, guides not only diagnosis but also the development of each individual manipulative procedure

Conceptual Basis

The following phrases reveal the static positional concepts that emerged during osteopathy's early professional history:

Describing the lesion as a bone out of place
Exaggerating the lesion position
Retracing the path of the lesion
Noting the position in which the lesion occurred
Stacking positions to balance the tension

Bowles' comments about demand/response transactions and the motor coordination necessary for each bone to be in the right place at the right time during demands for body movement strongly indicate that he was moving beyond static positional concepts. His conceptual bias for motor function called for the recognition of a mobile system and mobile segments, patterned

to act in concert with one another. Each mobile segment is a bone with articular surfaces for movement and adnexal tissues under motor control; together, they respond to precise functional demands to:

1. Maintain postural position
2. Carry out active movements
3. Allow passive movement

For Bowles, functional diagnosis and technique were "unique in accuracy and universal in nontraumatic application" (24).

Currently there is widespread recognition, but still limited understanding, of the neural control of these motor dynamics. In 1978, Stein (25) reviewed principles emerging from studies of the properties of interneurons and their application to the organization of the body's motor patterns. Fundamental concepts of command neurons and pattern generators furnished a baseline for continuing research in this field. This growing knowledge about neural networks and motor control systems has been reviewed by Getting (26). Atsuta et al.'s research presents an ongoing example (27). In areas where motion tests detect signs of segmental motor asymmetry, somatic proprioceptive and nociceptive afferents (sensory impulses) acting through feedback loops effect adaptive changes in motor patterns. These changes are palpable as a three-segment unit of segmental dysfunction, which describes a basic unit of defective and adapted function.

During functional technique, the release of holding forces (using minimal force) and the return to motor symmetry have been expressed as follows (28):

At the moment when the release of resistance forces is sensed, the response (conceptually) appears to be the result of a matching in movement function, in which the local segmental control becomes appropriate to the current, overall movement—a matching of adequacy in physiologic response to specific motion demand. The return to local controlled compliance of the mobile segment within the whole complex movement restores the opportunity for adequate part-to-whole functional relations of this segment within the mobile system.

Basic knowledge about proprioceptor and nociceptor stimuli as a source of reflex communication from somatic tissues to other somatic tissues is well established (29). Even at rest, in response to only gravity and positional demands, the palpable findings of bony irregularity and increased resistance of muscular tissue to pressure at dysfunctional segments reflect ongoing stimulation of proprioceptor sensors. During movement, these palpable cues to the traffic on afferent pathways are highly erratic, since in some directions of ease they decrease whereas in opposing directions of resistance they increase.

The sheer immediacy of the changes palpated during motion testing and treatment suggests the moment-to-moment afferent monitoring by numerous muscle spindle stretch receptors and the resulting efferent control of muscle contraction/relaxation as a physiologic basis for interpreting the response to osteopathic manipulation being reported here (28).

At vertebral levels where segmental motion asymmetry is present, the physical stress of daily demands for movement and positioning accounts for a major increase in somatic sensory afferent impulses reaching the spinal cord (30). A concept of *afferent reduction* has application where the palpable sense of decreasing resistance, monitored throughout a functional manipulative procedure, successfully restores symmetric motor function.

EXAMPLES OF FUNCTIONAL TECHNIQUE

Thoracic, Lumbar, and Sacral Regions: Seated

The method described in the following example of functional technique (17) is applicable in the thoracic, lumbar, or sacral spinal regions.

Findings

This patient has a dysfunctional T6 segment, locally resisting regional rotation of shoulders and trunk to the right. Additional findings on shoulder/trunk rotation tests indicate that the increasing ease in rotation left at T6 is accompanied by *resistance* to rotation left at T5 and T7. Other rotary motion tests reveal initial increasing ease at T6 to side bending left and to extension, and to initial *inhalation* on respiratory testing. These directions are resisted at T5 and T7. In the next test (Fig. 52D.8A), the physician initiates right side bending of the trunk with moderate caudally directed force through the right hand, which is on the patient's right shoulder. The fingers of the physician's left hand monitor the response at T6. In the second test (Fig. 52D.8B), trunk flexion and extension are initiated, being careful not to introduce translatory aspects of movement (e.g., the patient is maintained in midline of the intersection of midcoronal and sagittal planes). Slightly relaxed slumping supported by the physician's left arm initiates flexion. Reversal of this rotary direction (about the y -axis of Fig. 52D.2) initiates extension. The physician's right fingers compare responses to these opposing directions of motion.

Position

The patient is in the seated position. As indicated in Figure 52D.9, the physician's left arm is over the left shoulder and under the right shoulder of the patient to allow easy introduction of side bending left and rotation left in the following functional application of an indirect method of manipulation.

Treatment Procedure

1. Hold the patient to provide control in side bending left, rotation left, and extension in a smooth torsional arc. Each of these directions will begin to diminish the local tissue resistance being monitored at T6 during the manipulative procedure.
2. Using slight shifting of postural forces to control movement of the patient's body, three translatory tests can be completed. In Figure 52D.10A, with patient's hips relatively fixed by sitting position, a slight shift in the physician's body weight to the right and then to the left allows comparison of response of T6 to lateral translations of the patient's trunk. In Figure 52D.10B, a slight shift in the physician's weight controls patient's shoulders and trunk, relative to the pelvis, to initiate anterior and then posterior translation motions for testing response at T6. In Figure 52D.10C, for testing cephalad/caudad directions, the physician initiates slight lifting cephalad through the patient's shoulders and trunk, and then caudad by applying mild body compression; the segment's responses to opposing directions are monitored by the physician's right hand.

Figure 52D-8 Additional rotary motion tests. **A.** Physician initiates right side bending of trunk. **B.** Trunk flexion and extension. (From Johnston WL. Segmental definition, part II: application of an indirect method in osteopathic manipulative treatment. *JAOA* 1988;88:211–217, with permission.)

Figure 52D-9 Positioning of patient and physician to facilitate initial introduction of combined three rotary components toward a sense of increasing compliance (ease) in extension, left side bending, and left rotation. (From Johnston WL. Segmental definition, part II: application of an indirect method in osteopathic manipulative treatment. *JAOA* 1988;88:211–217, with permission.)

In this example, movements are added with increasing ease in translations to the left, anterior, and cephalad. Testing had indicated increasing resistance in each opposing translatory direction. Initial introduction of each appropriate direction is more important than extent of range in any one direction alone.

3. The final component is to direct a slow inhalation by the patient. The additional element of increasing ease promotes an eventual release of the holding tensions at the dysfunctional segment. The release allows return to a central resting position without encountering the previous resistance in these opposing directions.
4. Following successful release, retesting confirms a return to compliance and symmetry in response throughout the T5–7 area.

Cervical Region

In this example, the cervical region is examined initially in the seated position, followed by treatment in the supine position.

Findings

The first cervical vertebra (atlas) is limited in head and neck rotation left.

Diagnostic Procedure

Position No. 1

The patient is seated; the practitioner stands behind the patient.

1. With the left hand, contact the frontal-parietal region, palm frontal, with fingerpads at the right, thumb at the left
2. For the rotation test, introduce motion with the left hand. The right hand monitors for restricted motion response to the rotation left, with the third fingerpad of the right hand at the right, thumb at the left, and overlying the facet processes. (Hand placements are reversed to monitor the associated limitations in rotation right at occiput and at C2.)

Position No. 2

The patient is supine; the physician sits at the head of the table as shown in Figure 52D.11.

Positioning of the physician's arms with elbows supported on the knees provides comfortable support of the patient's occiput in the palms of the physician, who then monitors response to introduced motion. The third fingertips overlie cervical articular facets at C1 bilaterally to monitor response. As rotary motion tests continue, C1 responds with initial increasing ease in side bending right and flexion. During respiration, exhalation is easier.

Treatment Procedure

1. (the patient is supine) To small amounts of each of the three directions of rotary ease, add translatory components (of the head in relation to the trunk) in straight-line directions of increasing ease to the left, posterior, and caudal approximation. (Translatory testing in this example has indicated increasing resistance in each opposing direction.)
2. The increasing ease accumulating at C1 during the initial introduction of these six specific elements of motion is enhanced during a directed exhalation
3. The smooth torsion pathway for final release of tissue tension allows an easy return to a central resting position
4. Reexamination in the seated position should reveal a return to symmetry in response to head/neck rotation tests including the occiput, C1, and C2

Costal Region

When diagnosing the motor functions of ribs, it is significant to recognize that their elementary function is respiratory. Ribs also function, however, within the context of routine gross body movements that involve the thoracic spine and cage. Therefore, rib function is examined with the patient in the seated position with fingertip contact over the rib angle to monitor a rib's response to the spinal test pattern of elementary passive gross movements (rotations and translations), as well as active respiration. In principle, costal mobile units also function in association with movement of the upper extremities. Recognizing their intermediary role in so much of the body's movement suggests that costal dysfunctions may show more complex characteristics of motor asymmetry because they have one major motor function (inspiratory/expiratory)

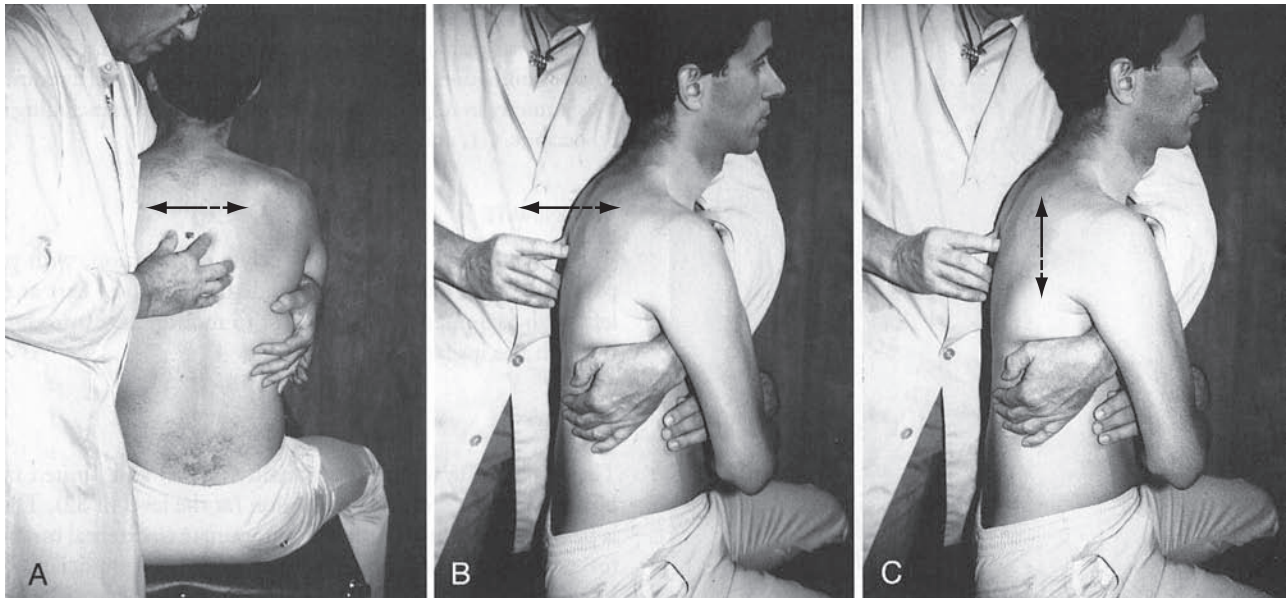

Figure 52D-10 Translatory motion tests. **A.** Patient in sitting position for comparison of response of T6 to lateral translations of trunk. **B.** Shift in physician's weight initiates anterior and then posterior motion testing at T6. **C.** Testing cephalad/caudad directions. (From Johnston WL. Segmental definition, part II: application of an indirect method in osteopathic manipulative treatment. *JAOA* 1988;88:211–217, with permission.)

Figure 52D-11 Supine position for cervical technique.

and two subsidiary motor roles active in trunk and appendicular movement.

This complexity becomes evident when the palpatory characteristics of costal motor asymmetries are identified. There appears to be an element of simplicity, however, in the manner in which that asymmetry is organized. The primary movement of the ribs occurs in inhalation and exhalation. It is this respiratory primacy that appears to dictate the remaining characteristics of the total motor asymmetry when a rib becomes dysfunctional.

For example, if a primary costal defect is freer during exhalation and resists inhalation, this respiratory feature distinctively patterns the motor dysfunction of that rib. This becomes apparent when tested through the shoulders and trunk, with the patient seated, and through the ipsilateral arm with the patient in the lateral recumbent position. However, if the dysfunctional rib is freer during inhalation and resists exhalation, then the asymmetric pattern

of this rib's motor function is largely reversed from that of the preceding (exhalation) example.

Ribs are also involved in asymmetric motor function associated with afferent input from visceral disease. This distinctive category of a viscerosomatic component needs consideration separate from the two dysfunctions to be detailed here. They arise more strictly from the physical stresses incurred in this somatic region.

The following two examples illustrate the most common kinds of dysfunction in the rib cage (essentially somatic in origin, rather than visceral). One shows elementary limitation on exhalation; one is limited in inhalation. The predominance of bucket-handle or pump-handle motion during the inspiratory and expiratory function varies throughout the rib cage and is not considered in these examples. Instead, each example is concerned with monitoring a rib's response to specific demands for rotary and translatory aspects of passive motion tests. These are introduced through the shoulders and trunk of the seated patient and through the ipsilateral upper extremity when the patient is in the lateral recumbent position. Each example of treatment has two procedural components, one seated and one side lying.

Findings in Example 1

The right rib 3 resists *exhalation*. It predictably resists shoulder/trunk rotation left and side bending left in the seated position, monitored with the right fingertips overlying the rib angle. Testing adjacent ribs above and below demonstrates mirror-image asymmetries if right rib 3 is the primary functional defect.

Procedure No. 1: Concurrent Diagnosis and Treatment: Through the Trunk

1. Standing at the right of the seated patient, monitor directions of increasing ease of motion with the left fingers (Fig. 52D.12)
2. The right arm is over the patient's right shoulder and under the left to control initiation of motions through shoulders and trunk during side bending and rotation to the right (Fig. 52D.12A)

Figure 52D-12 Example 1: Right rib 3 resists exhalation. **A.** In seated position, motions introduced through the shoulder/trunk. **B.** In left side-lying position, motions introduced through the right arm.

3. Tissue tension and limited mobility continue to improve during initial introduction of backward bending and translations to the right and anterior. (They worsen during flexion and translations to the left and posterior.)
4. Direct the patient to inhale slowly and hold the inhalation phase momentarily as directions of motion are carefully combined in a smooth torsion arc of movement. This promotes a release and return to a central resting position
5. Retest shoulder/trunk movements, seated, to assess return to symmetry of these motion components

Procedure No. 2: Concurrent Diagnosis and Treatment: Through the Upper Extremity

1. The patient is in a left lateral recumbent position. Stand in front of the patient with the patient's right upper arm supported just cephalad to the elbow, as shown in Figure 52D.12B, on the physician's left forearm. The patient's right hand hangs toward the floor
2. The right fingers overlie the tissue tension/restriction identified at the rib angle and monitor respiratory motion to confirm continuing resistance to exhalation
3. Palpate for response to motion tests introduced through the patient's right arm. Typical findings include resistance to external rotation (about the long axis of the humerus), abduction, and cephalad movements
4. In the treatment procedure, monitor increasing ease to internal rotation, adduction, and caudad movements during a directed slow inhalation phase of the patient
5. Following a successful release, retest the arm motion components in the side-lying position
6. Following successful release in each of these two treatment components at right rib 3 resisting exhalation, retesting throughout right ribs 2, 3, and 4 confirms return to functional symmetry in this area of the rib cage

Findings in Example 2

Right rib 3 resists *inhalation*. During diagnostic testing, stand on the right to test rotation to the right, and on the left to test rotation to the left. The right rib 3 resisting inhalation predictably resists shoulder/trunk rotation right and side bending right. This is monitored with the left fingertips overlying the rib angle. Testing adjacent ribs above and below demonstrates mirror-image motion asymmetries, if the right rib 3 is the site of the primary dysfunction.

Procedure No. 1: Concurrent Diagnosis and Treatment: Through the Trunk

1. Standing at the left of the seated patient, monitor directions of increasing ease of motion with the right fingers (Fig. 52D.13)
2. The left arm is over the patient's left shoulder and under the right shoulder to control initiation of motions through the shoulders and trunk during side bending left and rotation to the left, as shown in Figure 52D.13A
3. Tissue tension and limited mobility continue to improve as you allow initial slouched flexion over the left arm support and translate to the right and posterior. (They worsen during backward bending and translations to the left and anterior.)
4. Direct the patient to exhale slowly and hold the exhalation phase momentarily as directions of motion are carefully combined in a smooth torsion arc of movement to promote a release and return to a central resting position
5. Retest shoulder/trunk motions in the seated position

Procedure No. 2: Concurrent Diagnosis and Treatment: Through the Upper Extremity

1. The patient is in a left lateral recumbent position. Stand in front of the patient. With the left forearm, support and introduce motion through the patient's right arm, having it relaxed and folded at the elbow as seen in Figure 52D.13B
2. The right fingers overlie the tissue tension/restriction identified at the rib angle and monitor response to respiratory tests to confirm continuing resistance to inhalation
3. Palpate for response to motion tests introduced through the patient's right arm. Typical findings include resistance to internal

Figure 52D-13 Example 2: Right rib 3 resists inhalation. **A.** In seated position. **B.** In left side-lying position.

rotation (about the long axis of the humerus), adduction, and caudad movements

4. In the treatment procedure, monitor increasing ease to external rotation, abduction, and cephalad movements, during a directed slow exhalation phase of the patient
5. Following release, retest arm motion components in the side-lying position and retest inhalation and exhalation throughout right ribs 2, 3, and 4

Although the description of these two examples of rib technique (exhalation restriction and inhalation restriction) begins with the seated phase followed by the side lying, the order is not necessarily important and can be optional.

The physician's approach in functional technique is important. Evaluate immediately as each direction of motion is introduced. Combine these minor ranges in each direction, as described, to produce a smooth torsion arc of motion during the appropriate final respiratory phase. This complements the continually monitored

response of increasing ease. The palpable tension decreases to a sense of release, and the patient is returned to a resting state. Although these aspects of rib technique are presented as specific directions patterned to inhalation or exhalation restrictions, they should not be applied as if to copy a technique procedure. Rather, test each direction to promote appropriate summation of increasing ease, and monitor decreasing tension throughout each manipulation.

Thoracic Cage: Differentiating Somatic and Visceral Inputs

The spinal cord provides communication pathways that conduct impulses from sensory receptors in both musculoskeletal and visceral tissues. When noxious stimuli are persistent, the afferent bombardment contributes to palpable somatic manifestations of spinal dysfunction. Segmental motion asymmetries develop individuality in their dysfunctional behavior depending on the afferent source, somatic or visceral.

From functional methods in descriptive research, Figure 52D.3 illustrates a three-segment configuration of vertebral motion asymmetries that characterizes somato-somatic reflex activity. The primary dysfunction at the central segment demonstrates a complete asymmetric behavior in response to motion tests introduced through the shoulders and trunk in the seated position; the secondary dysfunctions at adjacent segments display mirror-image (opposing) motion asymmetries. The reflex basis for these secondary mirror images becomes apparent when all three segments return to motion symmetry following successful response to a functional manipulative procedure that addresses only the central (primary) dysfunctional segment.

In Figure 52D.4, the mirror-image phenomenon is still evident. However, this time it accompanies central segments that present a different primary orientation. The primacy relates to a vertebra and one adjacent rib at the same spinal level presenting *identical* motor asymmetries, rather than opposing. The term *linkage* applies to this phenomenon, because both vertebra and rib respond to motion tests in identical fashion, as if they were now linked together as a single mobile unit. This dysfunctional unit's motion asymmetry is typically complete in rotary, translatory, and respiratory tests; secondary mirror images exist at the adjacent coupled segments, as indicated.

Clinical data from interexaminer (31) and longitudinal (32,33) studies with hypertensive subjects, as well as a controlled clinical trial with renal, hypertensive, and normotensive subjects (21) have supported the presence of linkage as a somatic manifestation of visceral disease. The characteristic motion asymmetries at several linkage sites are reproducible and have been reported (20).

Manipulative treatment at a linkage site requires attention to two aspects of the motion behavior disturbed at such a dysfunctional costovertebral level. The segmental locus demonstrates not only asymmetry to spinal motion tests in the seated position induced through the shoulders/trunk, but also in recumbent positions to motion tests introduced through the lower extremities. A manipulative approach to address the former behavior has been detailed for both diagnostic and treatment procedures, seated, in the preceding thoracic section of "Examples of Functional Technique." However, maximum response at a linkage site also demands attention to motion behaviors related to the lower extremities (34). An example of diagnostic and treatment procedures follows.

Findings

Examined in the seated position, the patient has segmental dysfunction at spinal level T5, with linkage to left rib 5, and

resistance to inhalation locally (and to exhalation at adjacent segments above and below). There is also resistance to anterior translation, monitored at tissues overlying the transverse processes at T5 and the angle of left rib 5. Under these circumstances, positioning the patient prone (rather than supine) enhances posterior translation and begins to decrease the palpable tension locally, as a first step in a functional procedure (35). The physician now stands at the left of the prone patient, as illustrated in Figure 52D.14. With both legs initially resting on the table, begin with the right leg resting semiflexed. With plantar contacts of your right hand at the patient's right heel, control for the introduction of inversion and eversion motion tests of the whole right limb. Monitoring responses with the left hand in contact at the T5 left linkage site will reveal immediately increasing resistance to *both* directions initiated. Similar testing with the left leg will reveal *asymmetric* behavior; for example, with eversion there is once again resistance, while with inversion there is increasing compliance.

Note: For linked segments in the thoracic region, this characteristic behavior during lower extremity tests is typical, in that responses are asymmetric to tests with the leg ipsilateral to the linked costal component, while resistance is present in both responses to tests with the contralateral leg.

Procedure: Concurrent Diagnosis and Treatment of Costovertebral Linkage

Engage support at the knee for control of the patient's left leg semiflexed as illustrated in Figure 52D.14. Maintaining slight inversion freedom, monitor responses at the T5 linkage site to compare inversion with eversion, flexion with extension and cephalad with caudad directions of the limb. Select and combine initial aspects

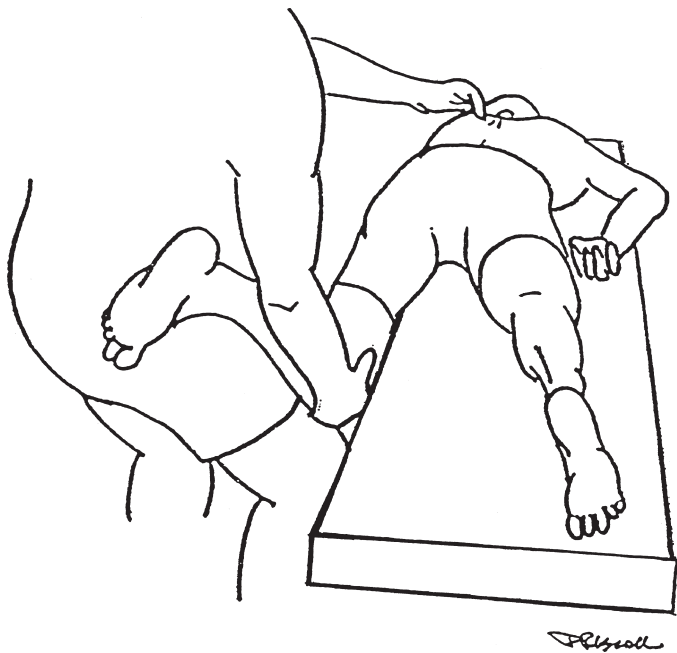

Figure 52D-14 Examination of linkage left site at T5 spinal level leads to treatment, prone, involving specific motion directions introduced through the ipsilateral lower extremity. With appropriate control by right hand support at the left knee, the operator monitors response at the left hand contacting the linked costovertebral segments. (From Johnston WL. Segmental definition, part IV. Updating the differential for somatic and visceral inputs. *JAOA* 2001;5:278–283, with permission.)

of these other elementary directions of increasing ease. In Figure 52D-14, abduction of the limb laterally from the table, flexion, and caudad directions are combined. With the finding of resistance to inhalation, the final decrease in palpable tension is maximized during a slow exhalation phase to release, followed by return of the leg to natural positioning on the table. When successful, repeating the diagnostic tests involved with each leg will reveal a return to symmetry in these aspects of the dysfunctional behavior at T5.

Note: Apart from the linkage phenomenon, as recognized in the costovertebral region, an additional distinctive characteristic of visceral input is now applicable for those spinal levels lacking costal components, that is, in cervical, lumbar, and sacral regions. Our continuing interest in examination of viscerosomatic linkage sites has led to a descriptive study. The following excerpt details that characteristic:

For example, consider any non-linked dysfunctional vertebral or costal segment that shows increased resistance to the seated test for sidebending right as compared with left, introduced through the shoulders/trunk. In such an instance, an expectation also exists for increased resistance to sidebending right compared with left when introduced through the head/neck. However, segments involved in linkage do not show accord in response to these two apparently similar sidebending tests. Instead, segmental resistance to sidebending *right* through the shoulders/trunk will accompany resistance to sidebending *left* introduced through the head/neck. *This lack of accord serves as a convenient tool for use in differential diagnosis of active visceral influence in any spinal region dysfunction* (34).

Comment: Regarding Somatic Manifestations of Visceral Input

When spinal analysis identifies a site with palpable signs positive for visceral input, the search for the source of the visceral input narrows somewhat, based on the known distribution of visceral afferent pathways via dorsal routes (36,37). Further, the palpable characteristics of the spinal tissue changes presented at a site of visceral input bear directly on the time element involved. When historically connecting possibly relevant incidents of illness, recent/current paravertebral soft tissue changes trend toward aspects of local prominence and congestion. On the contrary, when related illness is longstanding/recurrent, there is a depressed area of the spinal musculature overlying the transverse processes at the vertebral site central to the visceral input. This sparse, deep, horizontal band of markedly increased tissue tension reflects the hypoxia associated with tissues that are subjected to prolonged, concentrated reflex action. In time, this action will be both primary visceral and secondary somatic, since the spinal dysfunction once initiated continues as a focus for motion stress and becomes self-maintaining within continuing demands of the motor system.

Innominate

The patient has an elementary kind of pelvic dysfunction, one with palpatory findings localized to one side of the pelvis, with asymmetric response to motion tests introduced through only the ipsilateral lower extremity (and no resistance encountered with tests introduced through the contralateral limb).

Findings

There is a tissue texture abnormality (TTA) and limited mobility at the left ilium/gluteal region (at the level of S2). There is palpable resistance at the left innominate to external rotation (eversion) of the left lower limb.

Diagnostic Procedure

1. The patient is supine, with the left knee semiflexed and the foot resting on the table; the physician stands at the patient's left
2. Locate with the right hand the area of TTA and limited mobility at the left ilium/gluteal region, at the S2 level, and maintain contact throughout the procedure
3. With the left hand at the patient's left knee, initiate internal and external rotation (moving knee toward right, then left), revealing resistance palpated at the right hand to the initiation of external rotation (eversion)
4. Introduce similar comparison of internal and external rotation tests through the right semiflexed limb, but monitor it at the right hand, revealing left innominate compliance to both directions of the test

Treatment Procedure

1. Position the patient right lateral recumbent. Stand in front, with left hand contact at the innominate, TTA at level S2 (Fig. 52D.15). Direct the patient to shift the pelvis slightly in anterior translation relative to the shoulders. Maintain this positional shift if this direction decreases tension at the S2 level, compared with posterior translation
2. With your right hand supporting the patient's knees, introduce flexion through both legs together to localize action at the S2 sacral level monitored by the left hand
3. Now alter your support to the left leg only (Fig. 52D.15), with the right hand/forearm to monitor (in this example) the increasing ease at your left hand in response to abduction of the limb (vs. adduction), backward bending (vs. flexion), and caudal traction (vs. cephalad). Each of these components is combined during introduction of internal rotation (external rotation is resisted)
4. Direct the patient in inhalation (the direction of ease of the TTA)
5. During the final component of directed inhalation ease, combine these directional elements appropriately to achieve a palpable sense of decreasing tension and then a release by the holding forces. Return the limb to its resting position with the patient in lateral recumbency
6. Reexamining the motion tests supine indicates a return to symmetry of response at the left innominate, with reduced tissue tension of the left gluteal musculature

Variations in the findings from those described for this example simply require application of elementary motion testing procedures

Figure 52D-15 Right lateral recumbent position for left innominate technique.

at a diagnosed focus of TTA, and restricted mobility, wherever these are evident on pelvic structural examination (35). Specific directions of positioning and motion are then applied in a controlled manner to the pelvic location diagnosed, to ease increasingly the holding forces of restricted motor function.

Appendicular Regions

Note: There is a continuing application of principle here as the physician maintains use of the six elementary motions and respiration as functional tools for testing and reducing specific dysfunction in an appendage.

Findings

In this example, the left knee fails to hyperextend. On examination in the supine position with the physician standing at the left side, the left knee lies slightly raised from the table surface when compared with the right. In this uncomfortable, slightly flexed position, it is tenser to palpation than the right and resists further passively introduced extension. A prominence is palpable at the anteromedial border of the joint interspace (tibiofemoral), indicating the edge of the medial semilunar cartilage.

Position

The patient is supine and the left knee is flexed; stand by the left side of the table.

Procedures: Concurrent Diagnosis and Treatment

1. The right palm spans the patellar area with the thumb following the lateral aspect of the joint interspace. The third finger follows the medial aspect, as indicated in Figure 52D.16. This hand is keyed sharply to the distorted sense of rigid binding resistance where it is most apparent. Keep the contact light enough to appreciate this palpable marker, yet firm enough in grasp to assist in the manipulative procedure
2. The left hand firmly grasps above the left ankle to assist in slowly bringing the knee up into the freer direction of flexion

Figure 52D-16 Appendicular example at the left knee. Right hand monitors and supports. Left hand introduces major motions in testing and treatment.

3. Explore additional directions of motion test for the limb while it is supported in freedom from the table by both hands: these motions address the other rotary aspects, which are found to be freer in medial rotation and abduction. Begin the introduction of these motions with the left hand and monitor response with the right
4. Maintain the initial introduction of rotary components
5. While still monitoring response at the knee, the tests using translatory directions for the limb indicate increasing ease anterior, above the table (binding posterior), increasing ease to the left (compared with right), and cephalad (with binding in caudal traction). The respiratory test indicates easier response to inhalation
6. In the final maneuver, the right-hand contact at the knee guides the lifting support anteriorly to the left, while the left hand controls the amount of each rotary motion in a cephalad direction via the distal tibiofibular contact. There is a proportionately larger amount of flexion introduced, guided by the sense of continuing increasing ease. (This aspect of the knee's template of motion has the greatest range.)
7. Direct the patient to slowly exhale to promote the final release of holding forces. Mobility then allows an easier return into improved extension range as the leg is guided back down onto the table

SUMMARY

The term *functional technique* applies to an indirect method of osteopathic manipulation in which the treatment procedure is organized around palpatory information gained from tests for motor function. By paying attention to the feedback constantly monitored by the fingertips, the physician will experience improved psychomotor skill and proficiency in the use of this treatment method, and in many other clinical procedures as well.

52E

Visceral Manipulation

KENNETH LOSSING

KEY CONCEPT

In this section, emphasis is placed on direct palpation, evaluation, diagnosis, and treatment of viscera. Impaired or altered mobility/motility of the visceral system is reflected in abnormal motion tests showing change in distensibility of attachments or change in normal viscoelasticity. The concomitant consideration is to recognize that visceral and pelvic pathologic processes have spinal effects.

CASE STUDY

A 78-year-old female presented to the office with a history of bronchitis for the last week. She has continued coughing and feeling sick in spite of medical therapy.

Physical Examination:

Vital signs were normal. Pulmonary exam revealed diffuse rhonchi. Structural exam revealed restriction of ribs 1 and 2 on the left and rib 12 bilaterally. The left occipitomastoid suture was restricted. Decreased compliance of the lungs, increased tension in the trachea and bronchus, and congested lymphatics of the lungs, airways, and the thoracic cage were noted.

Diagnosis:

1. Acute bronchitis
2. Somatic dysfunction—thoracic, rib, cranium.

Plan:

The lymphatics of the airways were treated first. The ribs were then treated with balanced ligamentous tension technique. By then, the thoracic compliance had improved a lot and the patient was breathing easier. The lungs were directly treated last, as it was now possible to more accurately palpate their compliance. The lungs were treated by compression and decompression, which resulted in markedly improved compliance and again improved the respiration. The coughing was reduced by significantly within an hour.

INTRODUCTION AND DEFINITION

Direct palpation, evaluation, diagnosis, and treatment of the viscera have existed since the time of Dr. Still. This valuable approach opens the doors to being able to help a wide range of functional disorders. A visceral dysfunction is defined as “impaired or altered mobility or motility of the visceral system and related fascial, neurological, vascular, skeletal, and lymphatic elements.” This is reflected in abnormal motion tests, showing a change in the distensibility of the attachments, or a change in their normal viscoelasticity, among other physical findings.

This means we have different aspects/models of a dysfunction, each equally valid:

- Fascial model—tested with motion testing and fascial pull (listening technique)
- Fluid model—arterial and venous blood, interstitial fluids, and lymphatics can be tested with palpation, Doppler ultrasound, or perfusion studies as necessary

- Respiratory model—excursion of tissue with respiration can be tested with palpation, fluoroscopy, or real-time MRI
- Neurological model—tested with palpation and motion testing, or EMG
- Inherent motions model—tested with palpation/sensing
- Temperature changes/energy/emotions—tested with palpation, or thermography

In this chapter, we look at all of these models in connection with the respiratory system, but first a look at history.

HISTORY

Dr. Still developed osteopathy in the late 19th century. He had been trained as a medical doctor, but found that he could treat most diseases by palpating dysfunctional areas, and treating them with his hands. He called this new science Osteopathy, meaning to “begin with the bones.” By finding where the bones were not properly aligned and where they were not moving properly, it can guide the physician to the area of the body that needs to be treated, as they reflect where the forces of life are not moving properly. Notice that he “began with the bones,” but did not end there. In his writing, he constantly talked about joints, fascia, blood supply, nerves, internal organs, and lymphatic flow. Dr. Still, and his students, treated all of the known medical diseases of the day.

Osteopathic manipulation of the viscera began with Dr. Still. He described treating many different digestive, respiratory, and urogenital complaints (1). For Dr. Still, almost all medical conditions had an osteopathic treatment, in some cases curative, in some cases supportive. Dr. Still left few descriptions of techniques of any kind, but some of his early students, McConnell (2), and Barber (3) did. Dr. Still described few techniques in his writings; the most specific information was in his last book, *Research and Practice*, published in 1911.

There are many principles that we can learn from Dr. Still. For instance, when treating appendicitis, he would treat the colon first, then the spine. In treating colic, he treated the spine first, then the colon. Although he never spoke of his rationale, we can at least assume that there are times to start with the viscera, and times to start with the spine.

A little-known fact is that Dr. Still palpated temperature changes when looking for the dysfunctional areas. In *The lengthening Shadow of Andrew Taylor Still*, (4) Hildreth states that he often observed Dr. Still running his hand along the patients spine, throat, thorax, abdomen and pelvis, looking for areas of heat or a variation in temperature.

One of Dr. Still's earliest students was Carl McConnell. Dr. McConnell graduated from the American School of Osteopathy in

1901 and stayed on as an instructor for some years. Dr. McConnell was very prolific, writing 6 books and over 250 articles. Among this body of literature, he described direct treatment of all of the viscera, except the lungs and the heart. Dr. McConnell wrote over 10 different articles describing various visceral technique principles.

“Those who overlook ventral (visceral) technique are practicing a greatly limited osteopathy. In fact, confining osteopathic adjustment to the posterior plane (no matter how fundamental spinal therapy is) means the neglect of essential factors that even enter into vertebral and pelvic pathology. Structural lesions of the chest, abdomen, and pelvis frequently originate primarily within these cavities. Of course these structural changes present concomitant affects in the spine, and vice versa.”

“There is no organ of the abdomen and pelvis that cannot be influenced by improving the structural and physiological balance through direct adjustment methods.”

Relatedness, 1939. *“One of Dr. Still’s most enlightening statements, embryologically, physiologically, biologically, and technically, in my opinion, is as follows; It is only the perfection of the organism and the connected oneness that is the keynote to osteopathic practice. Every part has a duty to perform not only for its own maintenance, but also for the health and harmony of the interrelated whole. This is part of the law of supply and demand, which is absolute through all of nature. It is important to know the exact place that each organ and tissue occupies in its normal position. It is only by knowing the normal we are able to detect the abnormal. Each organ seems to be a creator of its own fluid substances. We must know the nerve and blood supply and the drainage.”*

One of Dr. Still’s other early students, Sutherland, credited him with the original idea of the cranial concept. Dr. Still often told his students that D.O. stands for “Dig On,” encouraging them to expand their view of osteopathy (7). While Dr. Sutherland is most known for his work in the cranial area, he never implied that it should be the only area diagnosed or treated. He gave multiple references to treating the viscera.

“When you want to observe the abdominal viscera that may be in ptosis, with the patient supine gently place one hand over or just below the area of interest. This hand is passive; it does nothing. Then place your other hand over it. You use the upper hand for gentle lifts and observation. That gentle application will tell you a great deal about where you are so that you can feel what the tissues can reveal. The lower hand can be permitted to sink into the tissues below, but the upper hand does the lifting in cooperation with the exhalation excursion of the diaphragm.”

Jacques Weischenck, D.O., wrote one of the first textbooks on visceral technique *Traite d’osteopathie Viscerale* in 1982. He described the normal exchange of pressure in the abdomen, visceral dysfunction chains, normal and dysfunctional axis of motion of the organs during respiration, palpatory diagnosis, and manipulative treatment for all of the abdominal viscera. His concept of organs having a normal axis of motion during respiration, which becomes perturbed in a dysfunction, was later tested and proved by two of his students, Georges Finet, D.O., and Christian Williamae, D.O.

The most prolific author, innovator, and teacher of visceral manipulation has been Jean-Pierre Barral. He graduated from the European School of Osteopathy in Maidstone, England, at a time when British Osteopathy consisted of spinal diagnosis and treatment. At the time, most of the early American literature was not easily available. Barral applied the concepts he had learned for the spine in developing visceral approaches. In addition, he came up with the concepts of “general and local listening” to the tissues, manual thermal diagnosis, visceral emotional connections, and visceral motility.

Barral’s books (8), energy, enthusiasm, and love of teaching have resulted in visceral manipulation spreading across the world.

THEORETICAL CONSIDERATIONS

“Virtually all forms of organ injury start with molecular or structural alterations in cells, a concept first put forth in the nineteenth century by Rudolf Virchow, known as the father of modern pathology. We therefore begin our consideration of pathology with the study of the origins, molecular mechanisms, and structural changes of cell injury. Yet different cells in tissues constantly interact with each other, and an elaborate system of extracellular matrix is necessary for the integrity of organs. Cell-cell and cell-matrix interactions contribute significantly to the response to injury, leading to collectively to tissue and organ injury, which are as important as cell injury in defining the morphologic and clinical patterns of disease.”

Robbins *Pathological Basis of Disease* (9).

In order to understand visceral approaches in osteopathy, we will need to do a short review/update of some basic sciences. Advances in biology, embryology, physics, and physiology over the last 30 years have dramatically changed how we look at the mechanical forces generated, utilized, and distributed during human life.

In the past, it was thought that genetics determined everything. During the 1960s, the German embryologist Blechschmidt (10) questioned this idea. Based on the microscopic dissection of very young embryos, he concluded that mechanical forces generated during embryologic cellular growth interact with the environment to change the way the cell functions and what it develops into. Cellular circulation, metabolism, and waste removal start as soon as there are cells. Differential growth patterns, between the central nervous system, vascular system, the various organ systems, and the musculoskeletal system, cause tension and compression forces to affect the shape and function of the cells.

“It is now known that many cell types express different genes (i.e. perform different functions) in response to even small changes in their mechanical environment.” Humphrey and Delance (11).

Until recently, the organelles inside of cells were thought to be floating in the intercellular fluid, as a sort of soup. It turns out that this is not the case. The organelles, cellular membrane, and nucleus are all interconnected by microtubules that act like a cellular skeleton, and microfilaments that give elastic support to the cell (12).

With the recent discovery of integral proteins (intergrins) in the cellular membrane, we now know more about the mechanical links between the cell, the extracellular matrix, and all tissue systems (13). Intergrins mechanically connect the cell membrane with microfilaments, microtubules, the cell nucleus and DNA, with the extracellular matrix, transmitting mechanical forces of tension and compression throughout the whole organism.

Visceral ligaments are viscoelastic (14), that is, they act both like a fluid and like a solid.

Visceral ligaments can respond to a “strain” (compression or tension) biomechanically speaking, with both elastic and plastic properties, depending on the amount of force and the amount of time over which the strain is applied. In an elastic deformation, the tissue returns to its original shape and configuration after the straining force is removed. In a plastic deformation, the original shape and distensibility is altered, with a resulting storage of force. In a visceral dysfunction, the stress in the ligament has a certain amount of force stored (as potential energy or “potency”), in a certain direction, and that tissue has a certain speed that it will

respond to. This results in an altered viscoelasticity curve for that ligament. (The viscosity is more, the elasticity is less).

When that force is exactly matched, in force, direction, and speed, the tissue will change, returning to a more normal distensibility. In the process, there is a dissipation of heat, movement of fluid, and a restructuring of the elasticity curve. A dysfunction can be caused by any of or a combination of: trauma, mechanical stress, emotions, chemical imbalances, circulation problems, imbalances in the nervous system, imbalances in circulation of life forces, and hormonal imbalances.

The arteries, veins, nerves, and lymphatic channels to the internal organs all go through the visceral attachments (ligaments). If there is increased mechanical tension in the visceral ligaments, the first fluid vessels to get compressed (compromised) will be the lowest pressure, the lymphatic vessels and veins, leading to a relative edema, with retention of metabolic byproducts. With further increased tension, the artery can become compressed, leading to decreased nutrition, oxygen, and eventual death.

“Any occlusion of lymphatic vessels is followed by the abnormal accumulation of interstitial fluid in the affected part, referred to as obstructive lymphedema.”

Robbins Pathologic Basis of Disease (9).

Tension and compression forces are always in relationship with each other. Buckminster Fuller (15) coined the term tensegrity to describe architectural buildings/structures invented in 1948 by Kenneth Snelson. Tension occurs when something is stretched. Integrity is a state of wholeness. So, tensegrity is the balancing of tension and compression forces, attractive and repulsive forces, in a whole structure. When these forces are balanced and relatively evenly distributed, the whole structure is stronger and able to withstand more stress. When the forces are unequally distributed, weakness and strain result. In the human body, we know bones take compressive forces, the connective tissues distribute tension forces, but the viscera also interact with both of these forces. Besides the static forces generated in architecture of buildings, the human frame also has the constantly changing forces of respiration, circulation, physical movement, gravity, digestion, and other factors. Visceral and somatic dysfunctions cause an imbalance in the distribution of tension and compressive forces, weakening the whole structure.

Let us look at what happens during respiration and pulmonary ventilation. The movement of air into and out of the lungs depends on a few basic things: (1) the pressure and volume inverse relationship: as volume increases, the pressure falls and the volume depends on the movement of the diaphragm and ribs, (2) internal and external air pressure, and (3) the compliance of the lungs.

As the ribcage expands during inhalation, the anterior ribcage moves superior (pump handle rib motion), the lateral ribcage moves laterally (bucket handle rib motion), and the respiratory diaphragm descends. The excursion of the diaphragm during normal volume respiration is 1.5 to 4 cm, as measured by CT scan (16), but can go as far as 7 cm. At the same time venous blood flow in the superior vena cava increases, and in the portal vein decreases. This shows a clear respiratory effect on blood circulation. At the same time, the pericardium swings around the attachments for the great vessels, with its inferior border moving 1.5 cm medial and inferior (17). The thoracic contents mechanically are stretched, so the tension increases in the pericardium, pulmonary ligaments, and lung parenchyma, as the negative pressure inside the lungs becomes more negative (8), and the negative pleural pressure becomes more negative. The negative pleural pressure keeps the visceral and

parietal pleura in contact, which also increases the mechanical tension to the lung parenchyma. Normal tidal volume is about 500 mL air.

As the thoracic contents expand, along with diaphragmatic contraction, it compresses the abdominal contents. The splenic flexure of the colon descends an average of 1.43 cm and the sigmoid colon descends less, about 0.25 cm. Using fluoroscopy and ultrasound, all of the abdominal viscera have been proved to move in the sagittal, coronal, and frontal planes in specific reproducible motions (7). These movements become perturbed in a visceral dysfunction and can be normalized with treatment.

The lymphatic system of the lungs plays many roles, immune response, disease resistance, and fluid drainage. The lymphatics may become congested due to infection, inflammation, inhalational allergies, and mechanical tension in the surrounding tissues. If the fluid drainage is impaired, the mechanical tension increases, leading to less compliance in the lungs. Only recently has it been discovered that the lymphatic vessels between the valves, called lymphangions, contract. These movements are biphasic and palpable (18).

During rest and exercise, the tidal volume changes, depending on demand, but also depending on the functional capacity of the overall structure. For instance, it is easy to understand that if a rib is in dysfunction, it will not move as well, the thorax will not be able to expand as well, and less intrathoracic volume translates into less air inhaled and exhaled. What may not be as immediately evident is the fact that the compliance of the lungs can be impaired by mechanical factors, also reducing tidal volume. A visceral dysfunction of a lung will reflect itself in reduced compliance.

Stretch receptors of the lungs connect via the vagus nerve to the ventral respiratory group of the medulla. Visceral afferent receptors send information to the spine, and also the brain. They are chemosensitive, mechanosensitive, and thermosensitive. The sensory system can be overstimulated leading to a decreased threshold required for stimulation. Osteopathic literature has called this facilitation, very similar to the current medical terminology of peripheral and central sensitization. Whatever the mechanism, and whatever the current terms, the functional result is an associated mechanical tension. In the case of the sympathetics to the lung, facilitation will result in a restricted upper thoracic segment, or segments, between T1 and T6, or rib restrictions in those areas. The parasympathetics can also be irritated. Cranial dysfunction near the jugular foramen can compress the vagus nerve, and there is some reason to think that the parasympathetic nerves can become facilitated also.

Since the time of Hippocrates, there have been clinical associations between problem areas of the body and an increased output of heat in the same area. Hippocrates is said to have put wet mud on a person, to see where it dried first, in an attempt to localize the problem. We know, of course, that often in ankle sprains, the area of the ligament is warmer. What has been less clear is why there are so many small temperature variations in a person's body. Clinical research using temperature recording devices over the 10 years has led to the conclusion that somatic and visceral dysfunctions (functional problems) project heat imbalances, generally warmer, but sometimes cooler, relative to the surrounding area.

To summarize, a visceral dysfunction of the lungs and airways will have related spinal and rib dysfunctions, cranial dysfunctions, neurological dysfunctions, lymphatic other fluid dysfunctions, and temperature imbalances. The art of practice is to find out the most efficient treatment order and the most effective treatment that the body can accept.

INDICATIONS, CONTRAINDICATIONS, AND COMPLICATIONS

The indications for visceral technique can be categorized into the following:

1. Visceral dysfunctions associated with known medical diagnosis. Almost all medical diagnosis of the viscera have a component that is functional, in other words, can be changed. Since the functional component cannot be recognized with lab or radiological test, the only way to find out is to treat it. Generally one to three treatments will reveal if an osteopathic approach is helpful and cost effective
2. Visceral dysfunctions mechanically connected to somatic dysfunction. The viscera are connected to the musculoskeletal system by connective tissue forming functional chains that connect from head to toe, all of the anatomical structures

Contraindications to visceral treatment are abdominal aneurysm, internal bleeding, infections uncontrolled by antibiotics, severe pain induced by palpation or manipulation, and medical indications for emergent medical workup.

PALPATION AND DIAGNOSIS

Palpation of the viscera starts with being able to identify the individual organs. The liver, for instance, is easy to identify and palpate for texture, outline, and size. The lungs, however, present some challenges. How is it possible to palpate through the ribcage to feel a lung? Perhaps not as difficult as one might expect, if one remembers Newton's second law: "For each action, there is a reaction." In this case, doing layer palpation on the thorax will reveal skin, superficial fascia, muscles, ribs, endothoracic fascia, pleura, and finally the lungs. As one compresses deeper, each layer will press back into the hand. At each layer, one can palpate for fascial pulling in the direction of tension, a dysfunction, and motion test for directions of ease and directions of increased tension, a barrier.

EXAMPLES OF TECHNIQUE

When considering any organ, of course it is needed to appreciate all of the functional connections. Here is a brief look at a few of the viscera themselves.

THE MAINSTEM BRONCHUS AND AIRWAYS

The main stem bronchus can be appreciated by tractioning the trachea superiorly to tension, and while maintaining the tension, translate it to the left and the right, noting distance and end feel. If there is no abnormal tension, one should be able to feel the airway distend all the way to the inferior lobes of both lungs. If there is a dysfunction, the distensibility will be less and the "end feel" harder. For instance, if the right airway is in dysfunction, there will be a shorter tracheal translation to the left, and the end feel will be harder. To mobilize the right airway, traction the trachea superiorly to tension while palpating the second and third rib interspace about 2 to 3 cm from the midline. A slight inward tug will be noted. Using the right thenar eminence at that place, compress posteriorly until a slight feeling of tension is appreciated. Have the patient inhale and exhale, drawing the area inferiorly during each exhale, and maintaining tension during the inhale. Typically within about three breaths a release will be felt. Recheck the motion testing parameters.

The Lungs

To evaluate and treat the right lung, place the patient in the left lateral recumbent position. Place the left hand over the lateral chest wall at the level of ribs 3 to 6. Place the right hand over the left hand. Use the right hand to compress and the left hand to palpate. Pay attention to each layer, skin, adipose, superficial fascia, external muscles, ribs, intercostal muscles, endothoracic fascia, parietal pleura, visceral pleura, and the lung. Feel if the lung is being tractioned superior/inferior, anterior/posterior, or medially/laterally. Motion test in these same directions to reconfirm the findings (Figs. 52E.1 and 52E.2). In the plane of the largest restriction, find the direction of ease. Find the midpoint between the restrictive barrier and the physiological barrier in the direction of ease. Stack the middle point of all three planes, and add a slight compression. A change in the viscoelasticity will be felt as the dysfunction resolves. Recheck fascial pull and motion testing. If these are not fully balanced, take the tissues to the largest remaining barrier, and stack the remaining two planes at their

Figure 52E-1 Diagnosis and treatment of bronchi—superior.

Figure 52E-2 Diagnosis and treatment of bronchi—anterior/posterior.

restrictive barriers. Add a slight compression, and wait for the release. When the motion testing is normalized, compress the lung, and release, noting the ease and speed of the return. Assume this speed, compressing and releasing, until a viscoelasticity shift in the tissue is felt.

CASE STUDIES

Case Study 2

A 45-year-old female presented to the office with a 2-year history of right flank pain subsequent to a motor vehicle accident. During the accident, her trunk was rotated to the right. Her car was struck from behind. Using general and local listening, it was found that the right kidney was in a second degree ptosis (dropped inferior more than a centimeter and externally rotated). The kidney was mobilized. On a follow-up visit one month later, the patient reported all flank pain to be resolved.

Case Study 3

A 7-year-old female presented to the office with a 6-month history of tummy aches and a sensation of acid in her mouth. No other symptoms were present, and her medical history was otherwise normal. Physical exam revealed somatic dysfunction of the left occipitomastoid suture, T6 on the left, and a visceral dysfunction of the gastroesophageal junction. These areas were treated. On a follow-up visit one month later, she reported no tummy arches and no instances of acid taste.

52F

Still Technique

RICHARD L. VAN BUSKIRK

KEY CONCEPT

In this section, emphasis is placed on introduction of a force vector resulting in a smooth arc carried toward the position of tissue compliance. The position is altered while maintaining this force, carrying it toward and through the position of restricted position and motion. Historically, this is described as a redevelopment of a manipulative method developed and used by Andrew Taylor Still.

CASE STUDY

A 47-year-old male presents with a complaint of pain, numbness, and tingling in his right hand and forearm that developed rather suddenly after a fall about 3 months ago. He states that his right hand appears much weaker than it used to be. He is right handed. He also admits that he has some pain in his right neck and dorsal shoulder since the fall. His symptoms have affected his ability to work (he is an accountant and uses computers daily), and over the past week, his sleep is disturbed.

X-rays of his shoulder were unremarkable but those of his neck showed mild C6-7 disc space narrowing and mild spondylotic changes involving C4-6. An electrophysiological study

of his brachial plexus demonstrated no abnormalities, including specifically no evidence of conduction slowing across the wrist, eliminating carpal tunnel syndrome. An MRI of the cervical spine demonstrated mild degenerative discs in the lower cervical spine, spondylotic changes, but only a mild stenosis involving the left C5 and C6 foramen.

Past medical history includes being slightly overweight and asthma as a child. He denies any history of diabetes, thyroid disease, peripheral vascular disease, or neurological disease. He does not smoke and limits himself to one glass of wine whenever he and his wife have dinner at a restaurant. Review of systems reveals that he admits to occasional heartburn but only after eating spicy foods.

Physical Examination:

HEENT, GI, GU, Neuro—noncontributory. CV—positive Adson's right. The musculoskeletal examination reveals no tenderness or restriction of motion of the wrist (i.e., scaphoid and lunate bones), the elbow (radial head, medial, and lateral elbow condyles), and the anterior shoulder and clavicle. No joint restrictions are noted in the right arm although there is some tenderness over the coracoid process and proximal medial humerus with restrictions in shoulder anterior and anterior-lateral flexion indicating tightness in the pectoralis minor and major.

Examination of the cervical spine and first ribs identifies the following restrictions: AA is rotated right; C5 ERS right, C6 FRS left, C7 ERS and the right first rib head is superior, tender, noncompliant to compression, and immobile during exhalation. The left first rib head is relatively inferior at rest, tender, noncompliant to compression but immobile during inhalation. Thus, both first ribs are restricted, even though the only nerve compression symptoms are on the right. Spasm and tenderness are noted in the trapezius muscles and rectus capitus posterior superior bilaterally, and the right posterior and medial scalene muscles.

Other spinal segmental restrictions are T1 N SR RL, T3 FRS right, T4 ERS right, T6 ERS right, T10 ERS right, T11 FRS left, L2 FRS right, L3 ERS left, and L4 FRS right. The right innominate is anteriorly rotated and the sacrum shows fascial restrictions at the sacral sulcus and ILA on the left.

ASSESSMENT

1. Acute brachial plexopathy
2. Somatic dysfunction—OA, cervical thoracic, lumbar, sacrum, pelvis, and rib

PLAN

1. OMT to the above areas using Still technique

The restrictions producing the acute brachial plexopathy are most likely due to dysfunctions of the cervical spine or first rib. The possibility that this could represent a carpal tunnel syndrome related to his repetitive computer use has been eliminated as has the remote possibility of it representing a Pancoast's tumor in the lung apex.

HISTORY

The Still technique is a redevelopment of a manipulative method originally developed and used by the founder of osteopathic medicine, Dr. Andrew Taylor Still. The methodology was abstracted from a few quotes by one of Dr. Still's students and colleagues at the American School of Osteopathy, Hazzard, D.O. (4). The first modern statement of this recovered method was published in the *Journal of the American Osteopathic Association* in 1996 (18). Subsequently, a more up-to-date and complete description of the Still Technique and its many applications has been published (19). The attribution of the technique to Dr. Still has been repeatedly confirmed by applying Dr. Still's own quoted applications (ref) as well as being validated by the use of descriptive writings by other students of Dr. Still's students and colleagues (2,4,8,15,16).

The abstracted method of the Still technique had been described by Carl Phillip McConnell, D.O., Ph.D., and later by the author's

friend and mentor, Herb Yates, D.O., F.A.A.O., as "indirect and then direct." Currently, the method includes the following steps:

1. Evaluate the affected tissue and place it in its position of ease
2. Introduce a force vector to the affected tissue from another part of the body. This compression or traction should be less than 5 lb (2 kg)
3. Use the force vector to move the affected tissue initially into a smooth path to its position of ease and then alter the position while maintaining this force toward and through to the position of the restriction of position and movement
4. As the tissue moves through its restriction, a "bump" and/or a click may be felt or heard. Neither is necessary for correction of the somatic dysfunction
5. The region is passively moved back to neutral and retested

It is apparent that the Still technique shares components with a number of other manipulative methods in use in osteopathic medicine today. Its position of ease is comparable to the treatment position of Counterstrain (5). The restricted position through which the tissue is carried is identical to the positioning for muscle energy (3,9,10) and HVLA (3,20).

Still technique has even more in common with Facilitated Positional Release developed by Schiowitz, D.O., F.A.A.O. (11,12), although there are notable differences:

1. Still technique's position of ease is more exaggerated than FPR's "easy neutral."
2. Still technique requires movement of the affected tissue from its ease through the restriction. FPR does not require such movement although frequently its practitioners include a finishing movement into the range of the initial restriction

Among the manipulative techniques that Sutherland, D.O., taught besides cranial osteopathy are those "for the rest of the body." Although there is a range of different methods currently being taught as derived from Sutherland under the term ligamentous articular strain (refs), some are quite similar to the Still technique. Starting with the tissue placed at ease, compressions introduced into the tissue, and then that compressive force and myofascial unwinding are utilized to carry the tissue from ease past restriction. Sutherland himself commented that Dr. Still tended to use a rather more direct approach than what he was accustomed to using since Sutherland felt the tissue's own vitality should carry the tissue into release (ref). As with this and some of the other techniques (i.e., FPR, counterstrain, HVLA), the operating forces are all applied by the physician and the patient remains passive throughout.

Finally, there is the Still-Laughlin technique preserved and taught in the modern era by Edward Stiles, D.O., F.A.A.O. (personal communication; see also Ref. [19]). It is hypothesized that this advanced method was a development by Dr. Still toward the end of his life. It uses much of the same technique as the Still technique, but requires additional identification of the Key dysfunctions or areas of greatest restriction. These are addressed by subsequent stacking of each identified dysfunction into its position of ease on top of those lower in the body and then sequentially using the force vector to unwind the body through each dysfunction. It is an incredibly efficient method but requires a high degree of anatomical knowledge, diagnostic ability, kinesthetic appreciation, and intense concentration. As such, it is not considered a technique that is easily mastered.

The physiological and anatomical mechanisms thought to underlie the Still technique have been extensively discussed elsewhere (17,19). Basically, they are based on the concept that a

somatic dysfunction develops and is maintained by a complex interaction of neural elements, particularly the nociceptor and central nervous system reprogramming (memory), myofascial repair mechanisms and elastic memory, and immunological, inflammatory, and vascular changes. The Still technique starts at ease, disarming the neurological protective mechanisms and relaxing the myofascial components. The force vector allows reprogramming of the neurofascial-vascular complex in the same fashion that trauma originally triggered the somatic dysfunction but in a normalizing direction, freeing the tissue from its restriction.

The Still technique is used successfully to treat virtually all tissues of the body, including the cranium, spine, sacrum, pelvis, limbs, muscles, tendons, ligaments, and viscera. Its efficacy is only limited by the practitioner's knowledge of functional anatomy. As with most manipulative techniques, it is not advisable to use Still technique across recent wounds (surgical or otherwise) or fractures less than 6 weeks old. Since it utilizes minimal force, it is safe to use for patients of all ages.

Diagnostic methods used for the Still technique are similar to those used in determining muscle energy or HVLA diagnoses, although the *Still Technique Manual* (19) does give a number of practical shortcuts. The definitions of rib and sacral dysfunctions used in Still technique are different from those commonly in use (19).

In the case of an acute brachial plexopathy, such as is seen in the aforementioned case study, the primary focus is on the sites of possible restriction to the brachial plexus and as well to the areas of pain. Logically, one would also address and treat the lumbosacral somatic dysfunctions present since failure to do so could result in a recurrence of the cervical, thoracic, rib, and shoulder dysfunctions. However, space constraints preclude further discussion of treatment for the sacrum and pelvic bones.

TECHNIQUES

739.8: Rib Somatic Dysfunction

The superior right first rib dysfunction results in the position of the head of the first rib at ease in a superior position, while the costomanubrial connection will be relatively inferior. Positioning the neck into a flexed and side bent away position from the side of the superior first rib head will place that rib at ease. Its restriction will be with the neck extended and side bent to the same side as the affected first rib:

1. The patient is seated
2. The physician stands either facing or behind the patient
3. Place the monitoring hand so that the index finger is on the affected first rib head
4. Place the operating hand on the top of the patient's head
5. The head and neck are side bent and flexed toward the side opposite the affected first rib (left in this case). This position produces tissue relaxation over the rib head (Fig. 52F.1)
6. Introduce compression through the head in a vector toward the affected rib head
7. While maintaining the compression vector from the top of the patient's head, the patient's head and neck are moved into side bending toward the affected rib. Finally, extension is introduced. Alternately, one can start by carrying the head and neck into extension first and then into side bending toward the side of the elevated first rib. Either sequence may be effective (Fig. 52F.2)

Figure 52F-1 Superior first rib, right, initial position.

Figure 52F-2 Superior first rib, final position.

8. After release is noted, the head and neck are returned to neutral
9. The dysfunction is reassessed

If a first rib head is inferior, the position of ease will be with the neck side bent toward the side of the inferior rib head and extended down to the rib head. Treatment will carry the neck (and first rib head) into flexion and side bending away from the side of the inferior first rib.

739.2: Thoracic Somatic Dysfunction

Thoracic segmental dysfunctions seen in this case study include vertebrae below T1 or T2. Treatment can be performed in various positions. An example is T3 F RL SL:

1. The patient is seated on a table
2. The physician stands behind the patient
3. The pad of the index finger of the monitoring hand that of the same side as the somatic dysfunction is placed over the prominent transverse process of the affected segment
4. The physician's other arm is placed over the patient's opposite (right) shoulder around the superior chest wall and that hand is placed on the shoulder on the side of the somatic dysfunction (ease). This gives the physician adequate leverage to introduce the necessary flexion or extension, compression, side bending, and rotation

Figure 52F-3 T3 flexed, side bent, and rotated left. Initial position.

Figure 52F-4 T3 flexed, side bent, and rotated left. Final position.

5. The patient's thorax and spine are then flexed (in this case) and rotated toward the side of the somatic dysfunction (left) and compression introduced (Fig. 52F.3)
6. Once the tissues and transverse process have palpably relaxed, the operating arm simultaneously reduces flexion and rotates the spine through neutral and then into the previously restricted range (right side bending and rotation with extension) (Fig. 52F.4)
7. Compression is reduced and the patient is passively returned to neutral
8. The somatic dysfunction is reassessed

Extended thoracic somatic dysfunctions can be treated with the same method except that the spine is brought to an extended, side bent and rotated toward the side of ease position, the compression force vector is introduced, and the spine and the segment are carried into flexion, side bending and rotation toward the opposite side (restriction). It should be noted that this same method can be used throughout the lumbar spine as well.

52G

Chapman's Approach

CHRISTIAN FOSSUM, MICHAEL L. KUCHERA, WILLIAM H. DEVINE, AND KENDALL WILSON

KEY CONCEPT

In this section, emphasis is placed on identification of gangliform contractions believed to be fascial congestions resulting from lymph stasis secondary to visceral dysfunction. These contractions are generally deep to the skin and subcutaneous tissue, most often lying on the deep fascia or periosteum. Generally described as neurolymphatic points, vibratory stimulation is utilized for reduction/elimination of the points.

CASE STUDY

A 34-year-old female presented to the office with complaints of gastrointestinal (GI) upset, nausea, and vomiting. The nausea and vomiting started suddenly 7 days ago and has continued "on and off." She was seen in the ED 3 days ago and a diagnosis of early viral gastroenteritis was made. The medicine prescribed had helped the nausea, but the patient continued to have vomiting, fatigue, and weakness. She complained of abdominal pain that was diffuse, sharp, and cramping with eating. She denied fever or chills.

Physical examination revealed a lethargic female with vital signs of $T = 98.0$, $P = 112$, $R = 20$, $B/P = 110/80$ (normal for the patient was $80+/60$). Abdominal examination revealed suprapubic tenderness to palpation. There was no hepatomegaly. Structural exam revealed a tender Chapman's reflex (CR) on the *anterior sternum* consistent with pylorus. The blood sugar was normal at 73 mg/dL. The urine dipstick revealed a high specific gravity of greater than 1.030. The pH was 6.0. There were moderate-large ketones along with 2+ urobilogen and a trace of bilirubin.

Diagnosis:

Vomiting with Dehydration

Plan:

The patient was admitted to the hospital for further workup and rehydration. The patient had a complete workup that included abdominal and pelvic ultrasounds and an upper GI. Other than dehydration, all findings were normal except for "mild swelling of the duodenum" on the UGI, which was reported as a "nonspecific finding." She was treated with IV fluid replacement. The patient was discharged on the third hospital day. Her discharge diagnosis was gastroenteritis with fluid depletion and dehydration.

Her physician continued to treat the patient weekly for headaches using cranial osteopathy. At each of these weekly visits, the patient would report that her GI problem was "getting better." Each time, the CRs on the sternum remained tender—indicating pyloric stenosis (although not always at the same intensity of discomfort as originally noted).

After 11 weeks, the physician performed another regional screen for CR. Again, there was a positive reflex for pyloric stenosis, but also positive reflexes for stomach peristalsis and stomach acidity. The patient finally admitted that she really had not been able to keep much food down since leaving the hospital.

The patient was referred to an osteopathic internist for reevaluation. Endoscopy revealed pyloric valve swelling and constriction necessitating the use of a pediatric endoscope to examine the duodenum. A new diagnosis of prepyloric antral ulcer was made.

In this case, CRs identified the problem almost 3 months *before* the definitive diagnosis was made by endoscopic evaluation. Although the original diagnostic workup was negative, only the CRs consistently pointed to the correct diagnosis 2 months prior to reevaluation. CRs correlate well with her final diagnosis.

DEFINING CRs

The palpable tissue texture phenomenon known as a *Chapman's reflex* has a rich history, appreciating the historical evolution of its definition and integration by different practitioners, and provides a better understanding of how today we locate, interpret, and clinically use this somatic finding. The current definition used by the osteopathic profession defines CRs as "a system of reflex points that present as predictable anterior and posterior fascial tissue texture abnormalities (plaque-like changes or stringiness of the involved tissues) assumed to be reflections of visceral dysfunction or pathology" (ECOP, 2006). This definition encompasses the lymphatic, neuroendocrine, and autonomic response to injury, illness, and disease as palpable and predictable viscerosomatic tissue reflexes found on the anterior and posterior body surface. Historically, definitions of the CR point reflect its structural feel linked to an evolving speculation as to the underlying dysfunction causing it (Table 52G.1).

Several mechanisms for the CR points have been proposed by those who value their use empirically. These include lymphatic abnormalities, fibrositis deposits, inflamed lymph vessels passing over ribs and bones, inflamed nerve endings, and inflamed sympathetic nerve filaments around terminal arterioles (Ketchum, 1943). Thus, it can be seen that lymphatic, neuroendocrine, and autonomic interactions were considered to be a part of CRs from early on.

HISTORICAL BACKGROUND

Early osteopathic medicine emphasized the role of the nervous system and body fluids in health and disease. Somatic dysfunctions of the musculoskeletal system were considered to be anatomical abnormalities obstructing these physiological processes, and through these structure and function considerations, osteopathic manipulation was employed to assist the body's recovery from injuries, illnesses, and disease (Deason, 1940; Hulett, 1922; Still, 1899, 1902, 1910). This was the prevailing philosophy when Frank Chapman (1871 to 1931) enrolled at the American School

TABLE 52G.1

Historical Definitions of CR

Definition	Author
The original description of <i>Ganglion-formed</i> became <i>Gangliform contracted lymphoid tissue nodules</i>	Frank Chapman, D.O. 1928
"It seemed to me that the lymphatic system had much more profound influence on bodily functions than it had been given credit for ... my special plea is on behalf of the lymphatic aspects of disease, which I regard of paramount importance whether they originated in bony lesions, infections, toxins, or other cause."	Frank Chapman, D.O. 1937
"A Chapman lesion is the result of a lymph stasis in the viscus. This lymph stasis is responsible for the dysfunction of the organ. Both the lymph stasis and the resultant dysfunction are reflexly responsible for the Chapman lesion, due, in part, to nerve impulse and also to a chemical reaction of the lymphoid tissue in which the lesion is found"	Charles Owens, D.O. 1944
"I believe that it is an autonomic nerve reflex, and that the lesion or nodule is a granulation tissue reaction"	H.L. Samblanet, D.O. 1944

of Osteopathy in Kirksville, Missouri. After graduating in 1899, he returned to Galesburg, Illinois, where he practiced until his death (Samblanet, 1944). In 1901, Chapman had a patient with severe adenitis whose response to osteopathic treatment directed to the spine was slow. He noticed that the groin glands and those on the medial side of the thighs were indurated and painful, and he decided to gently manipulate these glands and nothing else. When the patient returned, his improvement was such that he confined the treatment solely to the manipulation of these indurated areas. This observation led Chapman to a more detailed study of the lymphatic system and its role in health and disease (Lippincott, 1946). Building on his osteopathic knowledge, which at that time lacked a detailed discourse on the lymphatic system, Chapman came across *Mechanical Vibratory Stimulation* published by Maurice F. Pilgrim, M.D., in 1901. This seminal text emphasized the capacity for mechanical stimulation of reflex centers to influence body fluids and lymphatic drainage, thereby affecting a variety of physiological functions such as respiration, digestion, secretion, excretion, and muscular metabolism (Pilgrim, 1903; Lippincott, 1946). Though Pilgrim's method of treatment differed from Chapman's, it was likely to have provided him with the inspiration that eventually led to the conception of *lymphatic* or *CRs*.

Encouraged by positive clinical outcomes, Chapman diligently began making observations and case records. He mapped the congested lymphatic areas that he found in consistent locations close to the body surface and, believing that they bore a physiological relation to the lymphatic and nervous system, referred to them as *neurolymphatic points*. By the late 1920s, Chapman located over 200 centers on the body surface and established their association with the visceral and endocrine glands (Lippincott, 1946). He published his observations and the first chart in his 1929 text *Lymphatic reflexes: a specific method of osteopathic diagnosis and treatment* (Chapman, 1929).

Charles Owens, D.O., was Chapman's brother-in-law and classmate at the American School of Osteopathy. He had little involvement in the development of the CR system until close to Chapman's death. Owens asked Chapman's clinical opinion on an encumbering dizziness that was troubling him. He was intrigued by the manner in which Chapman diagnosed and relieved the ailment. Owens encouraged Chapman to chart the specific reflex lesion areas for the wider use by the osteopathic profession, a task completed shortly before Chapman's death (Samblanet, 1944). The

concept of the CRs was introduced to the osteopathic community in an article penned by Owens (1930):

"In this connection, I am glad to draw attention to the conclusions of an osteopathic physician, Dr. Frank Chapman of Galesburg, IL. As a result of years of research and study, Dr. Chapman advances the idea that in addition to the well-known spinal and sympathetic nervous system, with its controlling nerve centers, there lies within this same system an independent group of gangliform centers which control the activities of the lymphatic system in its relation to the viscera of the body, the knowledge of which enables the practitioner to determine with the utmost precision and accuracy the exact state of the various organs of the body... That this information will be received with profound interest by that portion of the profession who have given much attention to the spleen and lymph flow in their practices, goes without saying... That the ability to be able to tell his patient, for example, by the condition of one of these lymphatic centers, that he has a markedly disturbed condition of the hydrochloric secretions of the stomach; or, that the muscular action of the stomach is retarded by the state of another of these same centers, or, that he has a highly acid condition of the blood, due to a stenosis of the pyloric orifice holding the contents of the stomach against normal ejection until, by the continued accumulation of hydrochloric acid, the pylorus is compelled to open and permit some of the stomach content to pass, and do all this by these centers in place of having to resort to test meals, x-rays, etc., is hard to believe."

After Chapman's death, Owens continued developing the system and organized several postgraduate teaching seminars. Owens recognized CRs as viscerosomatic tissue reflexes and believed them to be a result of a lymph stasis in the viscus, which he hypothesized was the cause of the organ dysfunction. He proposed the causative factor to be pelvic girdle somatic dysfunctions interfering with the blood and nerve supply to the gonads, triggering a cascade of endocrine responses. Owens named this cascade the *pelvic-thyroid* (with adrenals) *syndrome* (Owens, 1937, 1943)—later renamed the *pelvic-thyroid-adrenal*, or *PTA syndrome* (Arbuckle, 1947). The thyroid was central to this syndrome and its involvement was considered to result in a widespread metabolic disturbance causing incomplete oxidation in cells, body fluids to move slowly, and lymphatic engorgement leading to retention of toxins. The area of least resistance in the body would develop a local lymph stasis

through nerve impulses and chemical reactions of the lymphoid tissue (Owens believed acetylcholine to be involved), and would result in a positive corresponding CR point on the body surface (Owens, 1940). As a treatment approach, addressing CRs was proposed to deal directly with the disturbed body metabolism through the autonomic nervous system, the lymphatic system and the endocrine glands, and the treatment would help normalize endocrine secretions, augment flow of body fluids, and release inhibited trophic (nutritional) centers.

Paul E. Kimberly, D.O., F.A.A.O., first organized CRs into a course for the profession, but it was never offered. In the late 1970s, Kimberly integrated CRs into osteopathic physical examination teachings during his tenure at the Kirksville College of Osteopathic Medicine. Based on the apparent correlation with the tissue texture changes occurring at the anatomic sites where the cutaneous vascular-lymphatic bundle exited together with the anterior and lateral cutaneous nerves (Figs. 52G.1 and 52G.2), and like Chapman and Owens, he used the term *neurolymphatic points* to describe them but presented them to his students as viscerosomatic reflexes related to the facilitated segment concept work of faculty colleagues, Korr and Denslow.

Figure 52G-1 Anterior CR points.

Subsequently, other osteopathic educators tended to describe the reflexes as more highly correlated with the sympathetic nervous system rather than the lymphatic system, indicating that this treatment influences visceral function by acting on some part of a reflex arc (Patriquin, 1992). In the previous edition of the *Foundations* text, Patriquin expresses some discomfort with his earlier attempt at defining these points as being sympathetically mediated findings in and of themselves (Patriquin, 2003). Other authors have classified CRs as part of the palpatory findings in a viscerosomatic reflex level involvement, pointing to the consistency in both the location of the CRs and of the sympathetic innervation of the dysfunctional organ (Kuchera and Kuchera, 1994). In the opinion of one of the authors (MLK), defining a tissue texture abnormality as a CR without the evidence of other concomitant visceral or viscerosomatic findings may be less reliable.

LOCATING AND PALPATING CRs

CRs are manifested by gangliform contractions, which are believed to be congestions within fascia due to lymph stasis secondary to visceral dysfunction (Capobianco, 2004). The types of visceral dysfunction believed to cause positive CRs are inflammation, spasm, or distention of the viscera (Wilson, 2006). The reflexes are located deep to the skin and subcutaneous areolar tissue, most often lying on the deep fascia or periosteum (Patriquin, 1997, 2003). It is mostly found in specific locations with a size varying from a “BB” pellet to a pea, or from a pinhead to an almond, and have certain recognizable palpatory characteristics (Capobianco, 2004; Patriquin, 2003; Samblanet, 1944). Owens described them as follows (Owens, 1943):

- Gangliform
- Edematous
- Ridge-like or ropy
- Fibrospongy
- Shotty

The technique best used for palpation might depend on the location of the CR points (e.g., see Table 52G.2). For instance, in cases where the points are located on the transverse processes of vertebrae, there might be contracted muscles overlying the Chapman’s point. Remember that its location in many cases is in the deep fascia or periosteum, and it may be necessary to first relax the overlying muscle to effectively treat the CR point (Hinckley-Chapman and Owens, 1932; Owens, 1943). The patient usually feels tenderness ranging from slightly painful to almost unbearably painful. There may however be a few patients who show no tenderness response to even firm digital pressure, although the CR point is palpable (Owens, 1943). It is unknown if this is related to the visceral dysfunction being in early or chronic stages, if the patient’s pain threshold is very high, or if it is just a coincidental finding with no bearing at all. Historically, it has been proposed that the intensity of pain denotes the relative amount of involvement of the related organ, and the complete lack of pain denotes a process of long duration and very marked involvement (Brown, 1949). It has also been suggested that the absence of tenderness in the point might indicate abnormal hypofunction of the associated organ (Mitchell, 1974). For a CR point to be positive, both the anterior and the posterior CR should be present (Lippincott, 1946). It is generally recommended to initially use the anterior CR for diagnostic purposes as their consistency in location and the fact that they are more widespread than the posterior CR points. This eliminates the confusion as to which organ is involved (Brown, 1949). Once a positive anterior CR has been established,

Figure 52G-2 Posterior Chapman points.

its diagnosis is confirmed through the presence of a posterior CR (Lippincott, 1946).

When examining for CRs, the use of the chart to know the specified location of each CR point together with well-developed tactile skills to discriminate the findings from either normal or other abnormalities, combined with the patient’s presenting complaint and medical history, will typically yield best results.

SIMILARITIES AND DIFFERENCES BETWEEN OTHER PALPABLY SIMILAR POINTS

Palpable tissue texture changes appearing in the myofascial tissues have long been described and mapped—in the case of acupuncture points, for thousands of years. Their clinical use, interpretation, and even their names are often dependent upon the perspective of the health care provider who finds and groups them together based on the perception of a commonality. Yet between grouping systems (and even within some systems), there are significant differences that distinguish that set of somatic body points from the others.

Osteopathic physicians should attempt to differentiate between various tissue texture abnormalities, including CRs, myofascial

trigger points (MTrP), tender points as first described by Jones in the counterstrain system, those considered by the American College of Rheumatology to be present in fibromyalgia syndrome, and possibly even acupuncture points. Based on the possible relationship among these different somatic or body point systems, the view has been expressed that these seemingly diverse observations are but different views of the same phenomena (DiGiovanna et al., 2005; Northup, 1941). Though it is difficult to argue a certain overlap between these discrete clinical findings, the involved pathophysiology, pattern of associated signs and symptoms, and clinical implication are often very different (Table 52G.3).

One study argued a topographical congruency of 68% (when they were found within 1.5 cm of each other) between CR points and counterstrain tender points (Johns, 2003), and another study alludes to a possible overlap between CR points and acupuncture points (Riley et al., 1981). When looking at the pathological association (e.g., both point systems used for similar conditions) or congruency of a CR point to spatially related acupuncture point, there was a 20.6% congruency of the anterior points and 44.2% congruency of the posterior points (Kim, 2008). The correlation between MTrP and acupuncture points has also been investigated.

TABLE 52G.2

Examples of Palpatory Techniques for Various CR Points

CR Point	Palpatory Technique
Broad ligament (female) and prostate (male)	Deep kneading pressure with lift (should be longitudinal), fingers flexed toward palm of hand
Colon	Deep pressure with longitudinal rotary movement
Ovarian	Gentle rotary movement
Kidneys	Deep firm rotary movement
Adrenals	Deep firm rotary movement
Duodenum	Gentle but firm rotary movement
Stomach	Firm rotary movement
Spleen	Firm rotary movement
Small intestine	Gentle but firm rotary movement
Eye	Gentle but firm rotary movement
Ear	Gentle rotary movement
Throat, nasal, bronchial, pharynx, larynx, Esophagus, tongue	Firm rotary movement
Upper and lower lung	Deep firm rotary movement
Arms	Deep firm rotary movement (sometimes steady pressure)
Neuritis of the upper limb	Firm but gently rotary movement
Cerebellar	Gentle rotary movement
Cerebral	Firm gentle rotary movement
Heart	Firm deep rotary movement
Neurasthenia	Deep firm rotary movement
Atonic constipation	Gentle rotary movement
Appendix	Deep but gentle rotary movement
Urethral	Deep but gentle rotary movement
Cystitis	Firm and deep rotary movement
Sciatic–neuritis	Firm rotary movement
Wry neck	Deep rotary movement
Thyroid	Firm but gentle rotary movement
Gallbladder and liver	

Source: Adapted from Owens (1943)

Palpation should be directed and titrated to reach the tissue depth and location where the tissue texture change resides. Examples using the more diagnostically suited anterior points are as follows:

- Intercostal Sites (including sinus, bronchus, stomach): finger pad directed posterosuperiorly along undersurface of the rib searching with a deep, firm rotatory movement (examine adjacent sites using a little longitudinal glide along the undersurface of the rib rather than a poking or prodding motion)
- Anterior Point Chart: Tip of floating rib (example appendix): Deep but gentle rotator stimulation at tip of rib using finger pad
- Anterior Point Chart: Abdominal wall (including kidney, bladder): Compress with finger pad through subcutaneous fat and tissues until reaching the deepest layer of the abdominal wall and there use a deep, firm, rotatory motion
- Anterior Point Chart: Pelvis (including ovary and uterus): Use deep, firm, rotatory movement approximating the periosteal level of the pelvic bone
- Anterior Point Chart: Iliotibial band region (including colon and prostate): Deep kneading pressure with lift (should be longitudinal), fingers flexed toward palm of hand; finger pads should compress medially approximating the periosteal level of the lateral femur
- Posterior Point Chart (Paraspinal): Deep firm rotatory pressure midway between transverse processes of the vertebral segment involved and the segment below; lateral distance from the spinous process is about halfway to the tip of the transverse process ipsilateral to the side of the involved organ. Tissue characteristics will involve more bogginess than the anterior points.

TABLE 52G.3

CR Points, MTrP and Tender Points

	Location	Palpatory Quality	Pain Characteristics	Association	Classic Treatment
Chapman reflex	Located in soft-tissue structures: subcutaneous tissue, fascia, muscle, ligament, and perichondral or periosteal tissue. Mostly in deep fascia or periosteum.	Granular feel of tissues overlying the CR. The CR itself is gangliaform, contracted, edematous, ridge-like or ropy, fibrospongy, or shotty. Varying in size from a pinhead to that of an almond	Tenderness ranging from slightly painful to almost unbearable. It is well localized under the finger and has an almost sharp quality. No pain radiation.	Viscerosomatic tissue reflex with definite relationship to viscus or gland; pattern of associated somatic dysfunction includes somatic dysfunction in related collateral ganglion, paraspinal tissues (same facilitated segment) and perhaps cranial or sacral referral site of viscus	Rotary stimulation for 20–60 s
MTrP	Central MTrP in fibers in the midportion of muscle. Attachment MTrP in the myotendinous junction. Depth varies with muscles	Distinct nodules (contraction knots) at the MTrP felt in the muscle and a rope-like induration (taut band)	Localized pain in taut band of muscle with referred pain to a characteristic distant region based on myofascial referral maps	Local pathophysiology in the muscle exhibiting the MTrP. May cause motion restriction in associated joints; often stimulation of point causes taut band twitch	Injection, dry needling, ischemic compression, postisometric relaxation (MET), spray and stretch, counterstrain
Tender point	Typically located in tendinous attachments, in the belly of a muscle, or in the ligaments associated with a joint dysfunction	Discrete, small, tense, and edematous, about the size of a fingertip	Exquisitely tender, very localized with no pain radiation. Typically at least four times as tender as the adjacent tissues	Specific muscle or joint somatic dysfunction	Counterstrain

One study looked at the overlap (positive correlation was when the points were found within 3 cm of each other) between MTrP and acupuncture pain points (Ah Shu), showing a 71% correlation based on spatial orientation of points and pain patterns (Melzack et al., 1977). The results of these studies should be interpreted with caution as the definition of correlation or congruency differs between the authors (e.g., 1.5 to 3 cm).

It should be noted that MTrP have the ability to create altered neural, autonomic, vascular, and lymphatic changes as well, and a number of MTrP with viscerosomatic and somatovisceral reflex activity have been reported in the literature (McPartland, 2004; Travell and Simons, 1999). Several MTrP linked to GI, cardiac, and genitourinary dysfunctions are identical to or in close proximity to the sites of CRs from these organs. Treatment of MTrP now embraces use of multiple interventions from dry needling to osteopathic treatment modalities such as muscle energy and counterstrain. Travell and Simons reported treatment of an MTrP located in the lower anterior chest wall (diagrammatically consistent with the pattern of palpatory findings that might be recorded by an osteopathic physician who found celiac ganglion and stomach CR dysfunction). In treating this point, the following was reported: “Pain, which previously had responded to medical therapy for a duodenal ulcer, became unresponsive and persisted until MTrP in the abdominal musculature were found and inactivated” (Travell and Simons, 1999).

The system now called *Applied Kinesiology* was developed in the 1960s by chiropractor George Goodheart who initially based his system upon applying the muscle testing of physical therapists Kendall and Kendall to the location of Chapman’s “neurolymphatic” points. Later, this system added Bennett’s points for vascular function and has since expanded to include acupuncture meridians (Kendall and Kendall, 1971; Walther et al., 1988).

A given point in a given system does not need to “read a book” to know where it should or could be; it simply exists. This means that a number of these existing points end up in multiple systems. Their clinical use and interpretation—along with their names—are often dependent upon the perspective of their discoverer. The evolution of CRs is no different. The points were grouped by an osteopathic practitioner reasoning from anatomy and physiology to see their somatic relationship to underlying visceral or systemic dysfunction. Their clinical diagnostic and therapeutic use is still based upon physicians applying them within the major osteopathic models of care and weighing the risk to benefit ratio of doing so.

DIAGNOSTIC UTILITY

Many osteopathic physicians use CRs as part of a screening or comprehensive osteopathic physical examination, contributing to the differential diagnosis and implying dysfunction of an organ system rather than as a therapeutic intervention (Patriquin, 2003). This said, because many modalities can be used to directly treat these points, it is important to perform a complete or focused diagnostic screen prior to any use of physical therapy or preparatory OMT (such as soft-tissue massage) that might temporarily reduce their sensitivity or tissue texture characteristics. One of the authors (KW) has formulated two principles when it comes to using CRs as a diagnostic tool: (1) a nontender CR, *by itself*, indicates nothing. *Never* make a diagnosis based solely on a nontender CR, and (2) *Never* ignore or trivialize a tender CR unless you have a good explanation for the findings. (This is especially true of a persistently tender reflex.)

From a diagnostic perspective and particularly in the hospital, they are more likely to be used selectively, as in the 30- or 45-seconds CR screening examinations (Figs. 52G.3 and 52G.4),

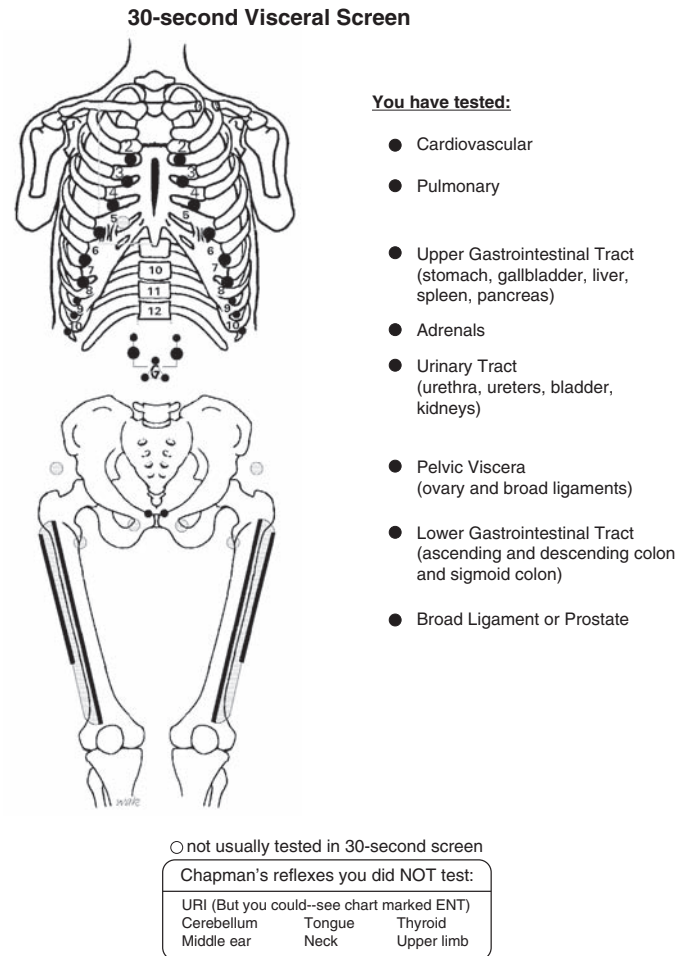

Figure 52G-3 30 second visceral screen.

which is a time-effective screen that focuses on selected organ systems and in conjunction with other findings in the history and physical examination of the patient. The following case study illustrates the use of CRs in establishing a diagnosis.

Case Study

A 13-year-old female is admitted to the pediatric floor of an osteopathic teaching hospital for complaints of severe lower abdominal/pelvic pain. She is examined and is found to be tender in the RLQ and midline pelvis. Urinalysis is normal. In this age group, the three most likely diagnoses to consider (in no particular order) are as follows: (1) Appendicitis, (2) Cystitis, and (3) Ovarian cysts.

CRs showed bilateral tender reflexes on the anterior/medial pubic bones near the pubic symphysis and unilateral posterior CRs at T9-10 on the right side only. No other positive CRs were found in that region of the body (particularly those associated with the right kidney, urinary bladder, or appendix):

- Preoperative diagnosis (without the use of CRs): Appendicitis versus right ovarian cyst (50/50 probability)
- Preoperative diagnosis (with the use of CRs): Problem with right ovary involving the entire ovary—both the medial and the lateral halves
- Postoperative diagnosis: Massive right ovarian cyst obliterating the entire right ovary

45-second Visceral Screen

Figure 52G-4 45 second visceral screen.

The operation performed was a right oophorectomy and right salpingectomy. This case also serves to illustrate the *high degree of specificity* that can be obtained in diagnosing visceral pathology in certain internal organs. It also illustrates the most common use of CRs by osteopathic physicians in the present day—as a *differentiator* when the physician has narrowed the differential diagnosis to two or three possible conditions.

The preoperative prediction of right ovarian involvement was based on the fact that all of the patient's discomfort and tenderness to palpation was to the right of midline in the lower abdominal/pelvic region. As mentioned above, there were bilateral tender Chapman's points on the anterior medial pubis although unilateral posterior CRs on the right. With paired organs where only one organ is dysfunctional, but the dysfunctional organ is associated with a marked degree of pathology, the physician may occasionally encounter a bilateral Chapman response (especially with the anterior points).

Additional palpatory information to help in the differential diagnosis would include tight, tender superior mesenteric ganglion site (not present when the pubic ramus point is secondary to AL5 counterstrain point) and somatic dysfunction (especially ERS_R at T10 or T11).

The use of CRs has also been used to augment other forms of osteopathic patient evaluation. Visceral dysfunctions in terms of *mobility* and *motility* are usually detected through the careful palpatory evaluation of the body cavities. Because of the depth and partial inaccessibility of some structures, it is not uncommon to have an approximate diagnosis where the presence (and relative severity grading of >1) of CRs can help to specifically determine the structure with dysfunction, or differentiate in terms of relevance between two or more diagnosed dysfunctions.

Example

The spinal region of T5-9 had increased sudomotor activity. There was increased tension in the paravertebral muscles and motion restrictions indicating a single type II (extended, rotated, and side bent right) segment within the otherwise type I (side bent left and rotated right) group curve in this region. These findings led to the conclusion that the somatic dysfunction was secondary to viscerosomatic reflex activity. With the patient supine and doing a local listening technique to the abdominal tissue, the palpating hand was drawn toward the upper right abdominal quadrant. Palpation into the quadrant below the border of the ribs revealed tension and tenderness around the liver, gallbladder, lesser omentum, and the hepatic flexure of the colon. Testing the elasticity of the fascial-ligamentous structures as well as the movement of the structures on their sliding surfaces indicated visceral dysfunctions involving the lesser omentum, liver, and gallbladder. Proceeding to using CRs, the physician found positive points for both the liver and the gallbladder, and the CR point to the gallbladder was significantly more positive than the liver CR, leading the physician to conclude that the visceral dysfunction responsible for the viscerosomatic reflex activity was the gallbladder.

INTEGRATING CRs IN THE CLINICAL SETTING

Incorporation of CRs does not constitute a stand-alone approach. Its diagnostic and therapeutic usefulness depends on its integration with a more comprehensive osteopathic management strategy. The lymphatic system should be addressed by removing obstructions to lymph return and techniques to augment lymph flow. Somatic dysfunctions of the thorax and the pelvis should be treated to reduce autonomic interference caused by segmental facilitation. Respiratory efficiency should be restored by addressing rib cage mechanics and muscles of respiration. The patient's overall energy expenditure should be reduced by improving overall biomechanical and postural function. Addressing these factors together with CRs is a useful tool in improving musculoskeletal and systemic function as well as reducing the patient's overall allostatic load.

In the original teachings of CRs, the following points were emphasized when using this system for diagnosis and treatment (Owens, 1943):

- Know the exact anatomical location of each CR and its clinical significance
- Do not overtreat the CR: 15 to 30 or 30 to 60 seconds is enough time for each center
- Sequence your treatment
 - Address biomechanical dysfunctions of the pelvic girdle first
 - Treat the CR comprising the pelvic-thyroid-adrenal syndrome (PTA syndrome)

- Treat the CR corresponding with organs of elimination to reduce load placed on the body from the overall osteopathic treatment of the case at hand
- Treat the specifically involved CR
- Do not forget assessment and treatment of the lymphatic system, especially involved regions of impaired lymphatic drainage
- Articular treatment to the axial spine and ribs to reduce normalize sympathetic activity
- After reestablishing the “endocrine” balance through CR, other somatic dysfunctions can be treated

It is important to keep in mind that this recommendation was made in the 1930s and 1940s, and even though the general principles might still be applicable today, the evolution of osteopathic treatment models has allowed for its reinterpretation. Excessive manipulative intervention is recognized as a potential body stressor: procedures employed prior to the use of CR treatment should be administered judiciously, specifically and with restraint (Mitchell, 1974). The algorithm in Figure 52G.5 serves to illustrate how CRs could be integrated in a clinical setting.

SPECIFIC TREATMENT USING CRs

There are several possible approaches commonly employed to treat patients using the CRs (Table 52G.4):

1. The original recommendation by Chapman was to start with the anterior points and then proceed to the posterior ones. He stated that treating the anterior points first would greatly aid in the treatment of the posterior points. Chapman’s original protocol warned against excessive pressure and he wrote that gentler means rather than forceful pressure would result in quicker relaxation (Chapman, 1928)
2. If the points are too sensitive to be palpated and treated, myofascial release of the tissue around the gangliform area can help drainage be more comfortably established, which in turn can make it possible to treat the point directly (Lippincott, 1946)
3. If the anterior points were too sensitive to treat, OMT to the soft tissues posteriorly often decreases or even totally dissipates the related anterior points; the residual change then only needing minimal treatment. For this reason, however, use of preparatory soft-tissue methods that temporally negate the presence of the anterior points for diagnosis should be avoided (Kuchera, 1994)

PATTERNS OF CRs IN CLINICAL CONDITIONS

After having completed the osteopathic evaluation of the patient, the physician will typically sequence their osteopathic manipulative treatment based on the pattern of dysfunctions present in the

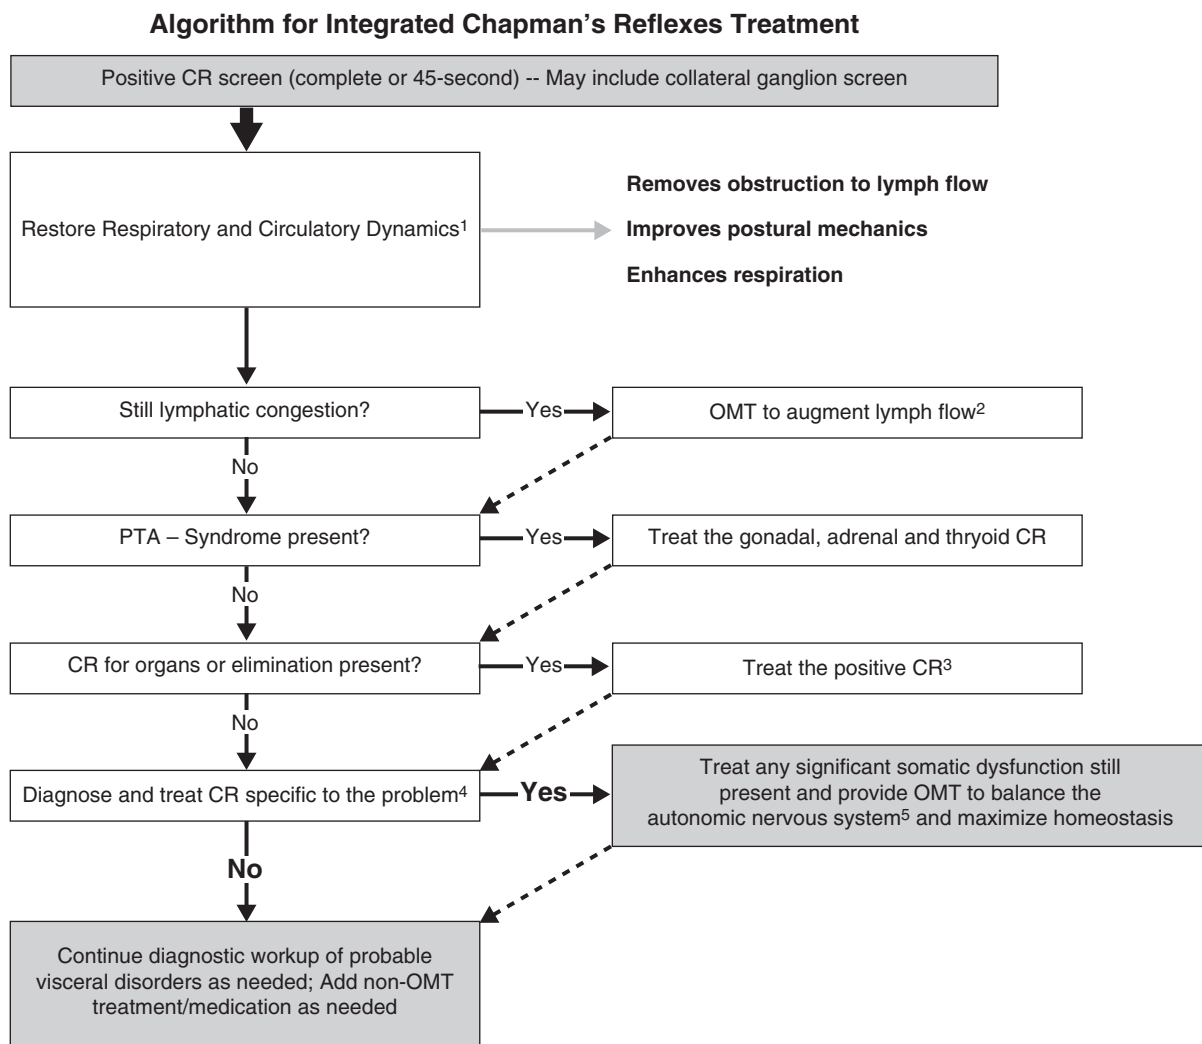

TABLE 52G.4

Troubleshooting with CRs

Problem	Possible Solution
The CR is too painful to treat.	Treat the myofascial tissues overlying and surrounding the CR with gentle direct or indirect myofascial release. This may help the local drainage of the tissues reducing the sensitivity of the CR. Somatic dysfunctions if present, in segmentally related areas may also be treated to influence the reflex arc involved in the CR and thereby the sensitivity of the CR this includes considering treating the related CR on the other side of the body).
There is minimal change in the CR in response to its treatment.	Verify that the tissue texture change is a clinically significant CR and not a different type of somatic change. Both the anterior and the posterior for any given structure along with other clues of visceral and viscerosomatic reflex activity should be present for it to be a positive CR. If they are both present, but still little response in the CR to treatment, evaluate for contributing factors, such as somatic dysfunctions in areas segmentally related to the CR, impaired lymphatic drainage of the area or region where the CR is found.
The effect of the CR treatment is short lived.	When treating CR, the sequencing of the treatment can be important. The overall biomechanical and postural pattern of somatic dysfunction should ideally be treated first, together with OMT strategies to improve respiratory and circulatory dynamics. Then the PTA syndrome may have to be addressed specifically with CR before attending to the CR correlated with the presenting complaint. Recall that in viscerosomatic reflexes, the pathophysiology lies in the visceral component. Treatment of the somatic end of the reflex may not alone be either adequate or, in some cases, appropriate. Repeated recurrence of a CR warrants further diagnostic or therapeutic action with respect to the underlying visceral cause.
The patient with the CR is extremely ill (also a consideration in certain hospitalized patients).	When treating hospitalized patients, the primary objective is to support the body's physiology through the process of illness and disease. Extensive OTM may not be advisable so as to minimize the energy expenditure of the patient. Treat the CR related to the areas of chief complaint and possibly those that impede the normal homeostatic processes.

patient. Interaction between dysfunctions and how they might influence each other through various biomechanical, postural, neurological (autonomic and somatosensory), and circulatory mechanisms is also of major importance. Understanding these interactions typically helps the physician establish the priority and sequence of the treatment. Similarly, when evaluating and treating pain patterns from MTrP, it is important to understand that active trigger points can be maintained by distant satellite MTrP.

A historical look at the patterns of positive reflex points palpated and treated in some commonly seen conditions illustrates how the early use of CRs was not focused on a single target organ (Owens, 1943) and how in many cases the hormonal-metabolic model was integrated (Table 52.5).

These and similar patterns of CRs should be integrated in the overall osteopathic management of the patient rather than used as a stand-alone method of treatment.

RESEARCH RELATED TO CRs AND THE OSTEOPATHIC CONCEPT

Palpable change in the absence of other objective findings had rendered MTrP and tender points in fibromyalgia patients difficult to instantiate; such is the case with osteopathic points in the CR and counterstrain systems. Nonetheless, there is a growing body of evidence demonstrating a possible basis for such identifiable tissue

texture abnormalities. There is little research currently investigating the specific physiological or chemical characteristics of these very specific clinical osteopathic findings. There are a number of related studies, however, that might be considered in way of interpretation:

- In patients with fibromyalgia, researchers had demonstrated highly ordered collagen cuffs around terminal nerve fibers in skin biopsies that were not found in healthy controls (Spratt et al., 1997). They termed them *microscars* and concluded that this collagen crosslink, as evident by a decreased collagen metabolism, was needed to maintain the collagen cuffs around the nerves in the skin (Spratt, 2003). One of the proposed reasons for this collagen formation was neurogenic inflammation, which has been demonstrated in the skin in patients with fibromyalgia (Salemi et al., 2003)
- Investigating the biochemical milieu of MTrP, microdialysis was performed on MTrP collecting small volume of fluids, at sub-nanogram levels of solutes, from the muscle tissue (Shah, 2008). Subjects with active MTrP had lower pH levels in the vicinity of their MTrP, and significantly higher concentrations of substance P, calcitonin gene-related peptide, bradykinin, serotonin, norepinephrine, tumor necrosis factor- α , and Interleukin-1 β (Shah et al., 2005). Furthermore, continuous nociceptive input from MTrP can increase excitability of dorsal horn neurons, linking the peripheral nociceptive events to central sensitization (Mense, 2008)

TABLE 52G.5

Examples of Patterns of CRs in Clinical Conditions

Condition	CRs Involved
Asthma, hay fever and sinusitis	In hay fever and sinusitis, the sinus CR will be positive. In asthma, the bronchial CR will be positive. The duodenal CR is also invariably present in cases of sinusitis, asthma, common colds, influenza, sore throat, and tonsillitis.. Treat gonadal and thyroid CR for endocrine balance. Treatment may place a load on organs of elimination: diagnose and treat CR of spleen, liver, and kidney in preparation for this; CR for colon and small intestines are therefore also relevant.
Allergy	Treat the whole PTA syndrome. Invariably, the adrenal CR will be involved. For food allergies, check the pancreas CR. In cases where patient regurgitates food, the pyloric CR will be involved.
Diabetes	PTA syndrome, adrenals, pancreas, and duodenum CR are consistently involved. In addition, look for stomach, colon, and kidney CR.
Eyes	In all eye affections, the sinus CR will be involved. In eye strain and conjunctivitis, consider additional examination of liver, small intestines, stomach, and bladder CR.
Digestive disturbances	If present, CR of the gonads, thyroid, and adrenals should be treated first. Then, special attention is given to the entire digestive tract, CR of the stomach, duodenum, pancreas, small intestines, colon, and liver as well as to organs of elimination, kidneys, spleen, and colon. Mesenteric releases may support treatment.
Inflammatory arthitides	Address the PTA syndrome that is invariably present. CR of the pancreas and duodenum are often present, as well as other digestive and eliminative organs. Reestablishing proper lymphatic drainage in conjunction with CR is very important in these cases.
Headaches	If caused by menstrual or menopausal symptoms, treatment to the uterine and ovarian CR may give relief. In blinding, dizzy headache, treatment of the duodenal CR may support the treatment. Often in cases of vertigo, steady pressure to the cerebellar CR may give relief.

- Local tissue findings such as tenderness, edema, and vasodilatation in areas seemingly unrelated to the primary site of dysfunction or injury may be due to neurogenic inflammation where neuropeptides are released from the peripheral terminals of nerves following repeated depolarization. This is referred to as the *axon reflex*. The stimulation of a C-fiber branch due to tissue injury and inflammation can result in depolarization and antidromic activity in other branches unrelated to site of injury or inflammation, releasing neuropeptides into noninflamed or injured tissue (Van Griensven, 2005, Willard, 2008). This may help to explain why tissue texture abnormalities and tenderness can be found in areas that are seemingly unrelated to the actual problem
- Other anatomically localizable, noninflammatory changes in the soft tissues that are thought to be reflexly associated with somatic dysfunctions in the axial spine have also been described. Such tissue texture phenomena are referred to as *irritation zones* and represent small (0.5 to 1.0 cm), painful soft-tissue functional abnormalities that are painful to palpation (Dvorak et al., 2008)

Even though each of the findings abovemight not be able to be universally linked to CRs, MTrP, counterstrain tender points or other such groupings, these and other studies provide a rationale to better understand the relationship between peripheral tissue events, the nervous system, and dysfunction. Reliability when pal-

pating the counterstrain, CRs, and MTrP have in a few studies been found to be moderate to good (Hsieh et al., 2000; McPartland and Goodridge, 1997; Washington et al., 2003), and using palpation of tissue texture abnormalities coupled with pain provocation and the patient's medical history could be considered reliable in detecting the presence of such abnormalities.

Research demonstrating the effectiveness of using CRs on clinical conditions is limited. One study of hypertensive subjects investigated the effect of treating the posterior CRs for the adrenals. This group of subjects demonstrated a decrease in serum aldosterone levels lasting 36 hours after treatment (Mannino, 1979). Another study reported that combining CR treatment and soft-tissue techniques resulted in a significant improvement in forced vital capacity from first pretreatment to last posttreatment in a group of 30 asymptomatic subjects, 5 of which reported a past history of asthma or bronchitis (Lines et al., 1990).

In order to hypothesize how CRs work, it is necessary to consider its potential for modulating autonomic nervous system activity (and its integrated action with the somatomotor and neuroendocrine immune system) and augmenting lymph flow. Though it is not direct evidence for the clinical benefits of CR, it has been proposed that manual techniques stimulating fluid flow can assist repair processes and homeostatic controls in different tissues, which partly explains some of the various effects of manual approaches (Lederman, 2005). In a rat model, using a fluorescent probe placed

in the lower extremity, intermittent pressure to the ventral thorax of the animal increased the uptake of lymph in the tissues peripheral to area in which the technique was applied (Dery et al., 2000). Using dogs, it was possible to establish that the thoracic and abdominal lymphatic pump techniques produced net increases in the thoracic duct flow (Knott et al., 2005). Other studies also using a dog model confirmed the net increases in the thoracic duct flow in response to lymphatic pump techniques (Downey et al., 2008; Hodges et al., 2007) and in addition, one of those studies reported a significant increase in the leukocyte count in samples taken from the catheterized thoracic duct, supporting the notion that such techniques can enhance an individual's immune response (Hodges et al., 2007).

The stimulation of somatic structures has been shown to influence autonomic function in many experimental studies using a variety of animal models (Sato et al., 1997). Though caution should be exercised when extrapolating such results to humans and clinical conditions, these observations from animal experiments are an indication of somatosympathetic or somatoautonomic interaction. There are studies in the manual medicine literature providing evidence for sympathetic responses from techniques addressing the spinal zygapophysial joints. Specific sympathetic nervous system changes reported after articular techniques had been applied to the cervical and the lumbar spine include alterations in sudomotor function, cutaneous vasomotor changes, and changes in cardiac and respiratory functions (Chiu and Wright, 1996; McGuinness et al., 1997; Perry and Green, 2008; Petersen et al., 1993; Slater et al., 1994; Sterling et al., 2001; Vicenzino et al., 1994, 1998; Wright and Vicenzino, 1995). Sympathoexcitatory effects following manual spinal therapy have also been reported with the mechanical hypoalgesic effect of such intervention in both asymptomatic and symptomatic human subjects, indicating an activation of the descending pain inhibitory systems from the periaqueductal gray region (Hoeger Bement and Sluka, 2008; Perry and Green, 2008), effects that also has been reported in animal studies (Skyba et al., 2003). Using suboccipital inhibition, a soft-tissue technique applied to the myofascial tissues of the upper cervical spine, and digital strain plethysmography recording changes in the pulse contour, it was concluded that the OMT resulted in favorable autonomic changes in the form of sympathetic dampening (Purdy, et al., 1996). A recent study demonstrated the ability of OMT to influence sympathovagal balance in asymptomatic subjects, reporting that it shifted from the sympathetic to the parasympathetic nervous system in response to myofascial release in the cervical region (Henley et al., 2008).

Even though this is not direct evidence for either the mechanisms of action or the clinical effects of CRs, this information illustrates the potential of OMT to influence the lymphatic system as well as the sympathetic and the parasympathetic nervous system. Much more research is needed to confirm the potential role of CRs in modulating such activity as well as the clinical benefits of the treatment for patients with a variety of conditions.

SUMMARY

CRs have a long tradition in the osteopathic profession as a diagnostic and therapeutic tool. The evidence base for their use as a valuable diagnostic tool has grown considerably from their original empirical and anecdotal descriptions and is currently the focus of numerous interexaminer and correlative studies. Nonetheless, despite being linked to specific visceral or systemic conditions,

there is a lack of research as to what they precisely represent as a tissue texture abnormality. Their somatotopic organization is very predictable and consistent, and it is hypothesized that the lymphatic, the autonomic, and the neuroendocrine immune systems are involved in the mediation of the reflexes and the therapeutic action from treating these reflexes. Their use should be integrated in the overall osteopathic evaluation and management of the patient, which is integral to the success of applying these reflexes in treatment.

52H

Fulford Percussion

RAJIV L. YADAVA

KEY CONCEPT

In this section, emphasis is placed on synchronization of palpatory diagnostic interpretation with the application of an external percussion device. This device, the percussion vibrator, amplifies what is normally done through the hands alone and thus can increase the amount of energy delivered to the tissues. The energy state in the dysfunction field must be matched to properly release it. Intrinsic to this approach is the incorporation of thought derived from Andrew Taylor Still's expression of "mind, matter, motion."

CASE STUDY

A 21 y/o F presents to the office with a complaint of right leg discomfort for the past month. She has an "achiness" of her right leg that radiates into her lateral ankle. She remembers standing on the rung of a ladder for some time to clean her windows. There is no other history of trauma. Past medical/surgical history is negative. She has been using Arnica Montana for relief, but the discomfort returns.

Physical Examination:

T-98.8, P-72, R-12, B/P 110/70, Ht-64," Wt-120#; HEENT/CV/Pulmonary/Abdomen/GU-noncontributory. Neurological exam is intact. Structural exam reveals level landmarks, normal AP curves, no lateral curves. There is tenderness to palpation along the lateral aspect of the right calf. Lateral malleolar motion appears sluggish. There is tension in the interosseous membrane.

Diagnosis:

Somatic dysfunction of the lower extremity—ankle, calf.

Plan:

Treatment of the subtle motion restriction with the percussion hammer (see Example 1 at the end of the chapter).

Definition

It is an osteopathic manipulative technique developed by Robert C. Fulford, D.O., involving the use of an instrument referred to as a percussor. The percussor utilizes a specific application of a mechanical vibratory percussive force to treat somatic dysfunction. This modality is distinct from other massage, vibration, or oscillatory approaches. The use of the percussor is coupled with the operator's palpatory feedback before and during the treatment.

When other physicians used the percussor in a modified way Dr. Fulford would quietly disapprove of it. Although he never addressed these individuals directly or publicly, he felt that they never really understood the philosophy and principles he was teaching and so they would change the way it was used to accommodate their lack of understanding.

History and Philosophy

To understand the philosophy of Dr. Fulford's percussion, it is helpful to have an understanding of the history behind his development of it. Dr. Fulford faced many obstacles in his life, but what he

Dr. Robert C. Fulford at the 1985 A.A.O. Convention Colorado Springs, Colorado. Courtesy of Dr. E. Sara Saxton D.O.

learned from the difficulties shaped his understanding and future. He could not attend medical school in 1929 due to the depression. This forced him to work at Union Carbide where he developed an appreciation for subtle motion and the impact it could have on the purity of oxygen produced. There he found that a slight mechanical turn of a dial would be the difference between getting impure oxygen or pure oxygen. In 1936, he was denied admission to medical school. In 1937, he had an injury that awakened an old desire

for becoming a physician. He obtained admission to Kansas City College of Osteopathic Medicine and became fascinated with Dr. A.T. Still's Philosophy of Osteopathy. He developed an interest in metaphysics, spirituality of all religious philosophies, astrology, yoga, esoteric teachings, and many natural healing arts of the world. He was well read and knowledgeable in these areas. This broad-mindedness, grounded in medical science and an understanding of osteopathic anatomy, allowed him to "read between the lines," so to speak, as he studied the Osteopathy of Dr. A.T. Still.

In his junior year at Kansas City College, he became interested in Dr. Harold Saxson Burr's energy work. Dr. Burr, an anatomist at Yale School of Medicine, published over 90 papers and raised interest among his colleagues many of whom became leaders in science. Through his readings of Dr. Burr's experiments of measuring energy fields, Dr. Fulford believed that these fields provided a blueprint for all living things. Dr. Fulford considered these fields diagnostic for mental as well as physical conditions.

In 1941, WWII resulted in increased hours of work due to a number of physicians having to leave the area for the war efforts. In addition to this, Dr. Fulford noticed that there was considerably more tension among the patient population after the war began. Patients were more challenging to treat. A thought from the past occurred to him when he worked for Union Carbide. His superintendent would say that where possible let a motor do the work for you. After he experimented with various vibrators without acceptable results, the Foredom Vibrator Flyer arrived in the mail in the 1940s by chance and was found to fulfill his needs allowing the manipulative procedures to be performed more easily and effectively after its use. He would say that many instances in his life he found that what he needed was provided to him spontaneously as it were.

Dr. Fulford originally met Dr. Sutherland in 1939 as a student. His first course with Dr. Sutherland was in 1942 as his interest again turned to the energy field. He describes the impact Dr. Sutherland had on his thinking at Des Moines College in 1949. "It was a most important day of my life when I had an opportunity to sit in the classroom of Des Moines College back in 1949. Dr. Sutherland was teaching his cranial concept. His ideas were heavily charged with energy and they soon began to work in me like some powerful force."

Dr. Fulford was convinced Dr. Sutherland was aware of the energy fields.

According to Dr. Fulford, his understanding of cranial osteopathy as taught to him by Dr. Sutherland was different than what was taught after Dr. Sutherland's death. He stated the first week of cranial osteopathy was about anatomy. The second week was taught by Dr. Sutherland himself where Dr. Sutherland would draw a house on the board with all the windows out and floating in the ocean. According to Dr. Fulford, this house symbolized the human body and the ocean with its many waves representing the primary respiratory mechanism (PRM) (universal energy). Dr. Fulford further states this does not correspond with the commentaries of Dr. Sutherland's recordings. In regard to PRM, primary is the universal life force expressed as mind, energy, and breath, the breath being the first principal in the cerebral spinal fluid (CSF). Respiratory is a rhythmic motion of mind energy, fine energies of the CSF, as they motivate and manifest life. Mechanism is a process, conscious or unconscious where a result of accomplishment is produced, in this case, where the sensory motor energies relate sensation, experiences and expression in the world of matter.

Dr. Fulford appreciated two other basic principals from Dr. Sutherland in addition to the ones he drew on the blackboard (the house with wavy lines). One was that as osteopathic physicians

we should stay close to our maker and the other is the importance of breath in life and healing. Dr. Fulford was spiritual. He mentioned the use of meditation or "running the energies through the body," and breathing exercises. He credited a breathing exercise with keeping his body alive for as long as he did.

He would say there are many people who are claiming to do cranial work with little or no knowledge of the theory behind the PRM. "They know the mechanics of how (PRM) works but little about how consciousness is part of a successful treatment." His description of Dr. Sutherland treating is as follows, "It was of interest to watch Dr. Sutherland treat. He sat on a stool, his back straight as a rod and his shoulders level and balanced. The arms extended and appeared as though they were weightless. His eyes were closed; whether he was in a meditative or contemplative state no one will ever know. Then after a few minutes his hands and arms would fly out into space as though they were suddenly given a push outward."

It was confusing for some to hear Dr. Fulford downplay the cranial rhythmic impulse (CRI). He did acknowledge rhythms but did not focus on any particular rate. To him, a still point or a fulcrum was not a particular place but a state of being in which everything is centered.

Additionally regarding Dr. Sutherland's writings, Dr. Fulford has stated, "In Dr. Sutherland's writings he stresses the mechanics as part of the cranial concept, as an engineer would and thus he could be understood. But he himself went beyond that in his findings and touch. That was his secret that he could not teach. He tried to leave us his secret when he gave us the phrase, "thinking and knowing fingers...."

Quoting Dr. Sutherland, "seeing, feeling, thinking finger... fingers that endeavor to get away from the sensation of physical touch wherein you have knowing touch....by knowing I mean not information gained by the physical sense but a knowledge that comes from getting as far as one can from the physical sense" (27).

Just as Dr. Fulford says of Dr. Sutherland that he could not teach directly of what he knew of osteopathy, Dr. Sutherland states the same of Dr. Still. "Dr. Still could not speak of all the things he understood about the living human body. We were not ready to hear him. If you read between the lines in his 'Philosophy of Osteopathy' you will see that this is so."

Around 1949 to 1950, Dr. Fulford along with a number of other DOs left to study with Dr. Beryl E. Arbuckle, D.O. The reason being was the impressive results she was obtaining. Dr. Fulford said that her treatment of children would cause an autonomic response in just a few minutes resulting in perspiration. She would then move to the next child lying on an adjacent table and do the same through several tables in a row. She originally met Dr. Sutherland in 1942 and was one of Dr. Sutherland's early trainers for osteopathy in the cranial field. Also, she was one of the few physicians who Dr. Sutherland allowed to treat him. Having done well over 250 dissections of fetal cadavers at the Philadelphia College of Osteopathy, she felt that the dural stress bands and bony buttresses should be given more importance before moving on to nonbony and nonmembranous aspects of cranial osteopathy that Dr. Sutherland was evolving toward at the time. It was not that she did not appreciate the fluid anatomy, but she felt that we must understand what could be verified physically with anatomy before moving on to fluid, potency, and the breath of life aspects of cranial osteopathy Dr. Sutherland was teaching.

Dr. Arbuckle's influence on Dr. Fulford could be seen by the way he firmly put his hands on the cranium. One could also see the use of Dr. Arbuckle's craniometric points in Dr. Fulford's percussion work as well. Dr. Sutherland's communications of the nonphysical aspect of osteopathy, with its mental, emotional, and

spiritual implications could be observed and felt on the patients Dr. Fulford would treat as the fluid forces would move with great vigor under his hands, a phenomenon unique among his peers. Dr. Koss states, "Many osteopaths do not realize the power that this humble, feeble-looking man had....the power he generated was, to say the least, incredible."

It is interesting to note that according to Dr. Fulford, the CRI with its rates, and amplitude was not a focus with Dr. Arbuckle or, for that matter, with Dr. Sutherland while he was living. These individuals were more focused on the source of the phenomena manifesting as the rate, rhythm, and amplitude.

After 1950, Dr. Fulford met Randolph Stone, D.O. He said, "Dr. Stone and I were good friends." Both these men had great interest in matters of spirituality beyond the boundaries of any particular religion. Dr. Stone developed Polarity Therapy from his influences of the ancient Ayurvedic Medicine of India. Dr. Fulford knew it to be more involved than those who utilize it today. Many believe Dr. Fulford's understanding and appreciation of polarity with regard to diagnosis and treatment was from Dr. Stone, but Dr. Fulford, himself, credits Baron Karl von Riechenbach (1778 to 1869) with that.

Riechenbach was a chemist, naturalist, geologist, metallurgist, and industrialist known for his discoveries of chemical products extracted from tar. He spent his last years researching the energy field, which he called the odic force.

The number of influences and contacts Dr. Fulford had would be too numerous to name and describe in this short essay. It would be safe to say that he had an almost childlike enthusiasm for knowledge of truth in all matters concerning the understanding osteopathic medicine and healing. Nothing would be overlooked until it was examined by him and then accepted or discarded.

Diagnosis

Dr. Fulford would say that it takes the mind of a physician to understand osteopathy. He felt that without the osteopathic understanding of the interrelationship between structure and function, an accurate diagnosis could not be forthcoming.

Both the history and the examination were important for Dr. Fulford's diagnosis. In fact, diagnosis was considered to be a more important subject than treatment. It was a holistic view of diagnosis and treatment that included the physical as well as the mental and emotional levels of the patient. Another unique feature of Dr. Fulford's diagnosis on the physical level was how much importance was given to the extremities, abdomen, and anterior chest wall as opposed to being primarily restricted, at least by habit of mind, to the spine and cranium for any particular complaint. The breath was also important in diagnosis and not just the breath of the thorax but of the whole body from head to toe. Physical as well as subtle breath was important to him.

Dr. Fulford considered trauma to be an important part of the history intake. First would be birth trauma, which would be reflected in the breath of the individual and greatly influenced by the first breath the individual took as an infant. Second would be physical trauma, especially early in life, and third would be psychological trauma especially early in life. Most of his diagnosis was complete in his mind after getting the history from the patient. As a result, the physical exam served to reassure the patient that he acknowledged their area of complaint.

During the physical examination, the dysfunction was understood to be the area where the "life force is not flowing." The examination would begin in the foot and ankles and continue to the knees, hips and pelvis, abdomen, diaphragm, rib cage, upper extremity,

shoulder joint, lumbar, thoracic, cervical vertebrae, and the cranium. The exam would consist of finding restrictions of motion within the joints. One's attention was directed to the subtle motions of the area being examined and looking for the lack of motion there. This is different than gross motion where light touch is not an important factor. Here, we are using a light touch to appreciate the presence or absence of a "life force" or underlying motion.

Mechanism of Action

There are probably multiple explanations of the mechanism of action using the percussion vibrator as Dr. Fulford has instructed. Note that the percussion vibrator simply acts as an amplifying device for what the operator initiates with his hands.

Dr. Fulford added and changed many techniques of treatment over the years as he evolved. Many of these techniques would "just come to him," like a gift, out of nowhere. The diagnosis and treatment of Dr. Fulford relies on the bioelectric properties of fascia and bone. When mechanical energy is absorbed into the body, there is a distortion within this bioelectrical matrix creating a higher energetic state within the fascia and bone. This distortion can be palpated as a subtle motion restriction, a depression, or elevation along the tissues of the body. These restrictions can be very subtle and so the physician's level of skill will determine how much they will appreciate under their palpating hands. Dr. Fulford would say that "When you can feel the placement of a single hair under 18 sheets of paper you are ready to do the cranial work." This higher energy state within the tissue needs to be matched with an equal quantum of energy in order to release to a more normal state of structure and function. This may take time as the cells within the tissues take time to redeposit themselves after partial or full release of their potential energy. Tissues are always being turned over and their chemical components redeposited. The epithelial cells of the gut last about 5 days, but those of the main body of the gut last about 120 days. The epidermis of the skin is recycled every 2 weeks. The liver has a turnover time of 300 to 500 days. The entire human skeleton is replaced every 10 years. The manner in which the tissues are redeposited could be influenced at least in part by the bioelectric field present.

It is also believed that mental/emotional trauma can be absorbed into the memory of the tissue through this bioelectric phenomena described. Thoughts and emotions are known to influence the health and well being of individuals.

The percussion vibrator amplifies what is normally done through the hands alone and thus can increase the amount of energy delivered to the tissues. As mentioned the energy state in the dysfunction field must be matched to properly release it. High-impact physical trauma, great psychological trauma and stress can produce and maintain these dysfunction fields with high-energy states. As a practical matter, if 100 ft-lb of force is absorbed into the tissues, the operator cannot apply that much physical force to release it. One must rely on the bioelectric mechanism of the tissues to address this situation. The operator's intention and attention is amplified with the percussion vibrator and will assist in the release. Dr. Fulford would say empathically that "Thoughts are things," and "Energy follows thought." Following the release of these high energetic states, the body areas can return to having a more normal rhythm, or fluctuation of fluids, through the area and thus, healing can begin.

A cursory description of a practical demonstration would be as follows: The percussion vibrator is placed on one side of the body part being treated. The other side is monitored by the other hand usually on the opposite side of that body part. With the skillful

application of the percussor hand and the monitoring hand, there will be a resonant wave of energy created between the two. This force will resonate with the dysfunction field between the hands. In order to get this resonating wave, the speed, direction, pressure, and placement of the percussing hand will vary depending on the area being addressed and the dysfunctional field present. The resonating force will be present until there is a release, relaxation, and flow of the life force through the area. It is believed that the energy within the resonant wave will match the energy within the dysfunctional field before a release occurs. One's thought and intention for the patient's well being will be key in releasing the most difficult of dysfunctional areas. Dr. Fulford states, "The work of healing will be greatly assisted by tremendous stimulation of the love nature.... We must be sure to pursue genuine healing. Far too often, healing is thought of as relieving stressful symptoms, so we are not bothered by them. As a result, the effort to heal frequently becomes little more than an attack on what is wrong or painful. The healing potential is tapped primarily by learning to identify with the health and using the resources of health to enrich the consciousness and heal the distress as we build up greater health while that which is unhealthy fades away."

A true understanding of this can be gained when one has a background in osteopathic medical training, experience, and help from a qualified, experienced instructor.

Use and Response of Fulford Percussion

When used with discrimination, the Fulford percussion vibrator can be used on almost all patients. The Fulford percussor can be utilized for any osteopathic dysfunction, but it is with resistant dysfunctions that its usefulness can be most appreciated. Difficult dysfunctions will respond with less treatment time. Because of the enhanced tissue response and release, there is a greater chance of rebound symptoms to occur. Treatment frequency may need to be reduced. This, of course, will depend on the skill of the operator using the percussor. Contraindications would include an area where one would choose to release less tissue such as postsurgical cardiac, abdominal, or orthopedic patients within the last 6 months, prosthetic devices such as heart valves and hip replacements. The use of Fulford's percussion vibrator is generally not advised in the lumbar, sacral, and lower abdomen areas of pregnant patients. Acutely painful areas should never be addressed directly with the percussor.

Technique

Example One

Subtle motion restriction is found in the right ankle joint involving the talus, distal fibula, and tibia (Fig. 52H.1). Percussor speed is adjusted to the lower end because of the areas relative decrease in soft tissue mass. The placement of the percussor is over the lateral malleolus. Pressure and aim is adjusted for maximum response between the percussing hand and the monitoring hand on the opposite side (over the medial malleolus). The response one is looking for is a process of interchange of the life force between the hands. This response will continue until there is a release and the tissue is relaxed. One will be able to experience the life force flow through the area again.

Example Two

A restriction in the subtle motion of the left femoral head was found (Fig. 52H.2). The percussor will be placed over the right greater trochanter and the monitoring hand over the left greater

Figure 52H-1 Treatment of ankle.

Figure 52H-2 Treatment of femoral head.

trochanter. This is due to concept of polarity that Dr. Fulford used in diagnosis and treatment. In regard to the pelvis, percussion on the right side clinically allows more efficient release even if the restriction is on the opposite side, as in this case, at the left femoral head. This is particularly true when release of the entire pelvis is desired. Percussion speed would be relatively high due to the relative increase in soft tissue in the area. Again, once the release is achieved, one should be able to appreciate the flow of energy through the pelvis at the end of the treatment.

SUMMARY

This chapter offers a glimpse of Dr. Fulford's percussion. It is not intended to provide a substitute for appropriate training, both didactic and practical under credible guidance, and is meant for those with a complete osteopathic education and not for any other purpose.

As a profession, there is much to be gained from those with great clinical results regardless of whether we have theoretical model to support it at that time or ever. The clinical experience shapes and develops the art over time. The osteopathic profession

can choose to divide itself among differences or inherit the richness of diversity brought to the table from great minds. The proof is in the consistency of their clinical results as observed by many who witnessed those events repeatedly.

Dr. Still states, "...we should treat with respect and reverence all truths, great and small....each truth or division as we see it, can only be made known to us by the self-evident fact, which this truth is able to demonstrate by its action."

No description of Dr. Fulford's work would be complete without mention of the love he would say was required to properly carry out diagnosis and treatment. The care and love he had for the patient's welfare came across in every encounter with his patients. It was reflected in his behavior with friends, as well as those from which he would prefer to distance himself. His professional and personal life was living testimony to that embracing principle of love seldom experienced in a life.

Dr. Eschtruth said of him, "Medicine in general, and the osteopathic profession in particular is immeasurably better because this selfless, humble man from southern Ohio who spent his life teaching others his unique way to reach the still point in his patients. Some of Bob Fulford's patients crossed oceans to seek his unique treatment. Bob Fulford gave himself as few others have in the medical profession. He will be sorely missed, but his presence will continue to be felt and his teachings will live on and grow forever."

The late William E. Wyatt, DO, FFAO was a popular presenter at the Annual Convocation Program of the American Academy of Osteopathy. In a striking moment, he stopped in the middle of a presentation to speak directly to Dr. Fulford. He asked "Do you know what kind of effect you are having on the Academy?"

The influence Dr. Fulford has had on the medical profession is undeniable and being enjoyed by us all. The late and great baseball player Jackie Robinson said it simply, "A life is not important except in the impact it has on other lives."

IV

Approach to
Osteopathic
Patient
Management

This page intentionally left blank.

KEY CONCEPTS

- Nonreversible causes of dementia can be classified into four basic categories: (1) degenerative, (2) vascular—previously referred to a multi-infarct, (3) trauma, and (4) infections.
- Standard medical evaluation tends to miss some of the most prevalent health issues experienced by older adults; these tend to include the five I's of geriatrics: (1) impaired homeostasis, (2) incompetence or intellectual impairment, (3) iatrogenesis, (4) immobility, and (5) incontinence.
- Dementia is difficult to diagnose due to the quandary of a potential multifactorial cause.
- There are no pharmacologic agents that can cure dementia; however, medications may be helpful in slowing the progression of the disease.
- The overall goal in older adult patient care is to maximize the patient's residual functional capacity to meet patient-centered goals for care for an optimal quality of life.
- The field of geriatrics and the care of older adult patients are well suited to incorporating the osteopathic approach to patient care.

CASE VIGNETTE

CHIEF COMPLAINT

Mr. S, a 77-year-old white male, is brought to the office by his daughter for a second opinion due to her concerns regarding his walking and his mood and behavior changes.

History of Present Illness:

The daughter, who usually lives out of state, notes that Mr. S has had a gradual progression of difficulty walking and he is getting “just mean.” The daughter is concerned that he will really hurt himself some day if he falls. He is using a cane at her request, but he is adamant that he doesn't need it.

She is unsure of the onset of his instability since she lives out of state, but relates that he has had memory difficulties for years and was on donepezil for this. His wife had cared for him until her recent passing due to a stroke. The daughter admits that her father had trouble walking for some time and maybe for years, but it has been particularly worrisome to her since he was placed on Carbidopa/Levodopa for Parkinson disease a few months ago. He has declined since then without the stabilizing influence of his wife.

The patient denies any difficulty and states that he uses the cane only because the daughter insists. Mr. S stated that he is forced to use a cane by “those people who are trying to put me away” and wishes “they would stop their incessant talking because they just confuse me.” He is unable to identify who “they” are but claims he sees them “when they want to be seen.” The daughter states that this pattern has been progressive over the last 3 to 4 months. Mr. S has not actually fallen but admits that he is slowed down by what he feels is arthritis. The daughter is also concerned about his driving due to slow reaction times from apparent stiffness. Mr. S refuses to give up the car keys and states “they want to take my car away, how am I suppose to get around?” He has been increasingly frustrated, short tempered, and easily agitated, which he attributed to

daughter's nagging, but the daughter believes his agitation and “weird thoughts” are due to the passing of his wife. She notes that he makes accusations about people taking things from him and talks to people who are not there. He no longer enjoys walking or caring for the dog. He now bathes infrequently and won't accept assistance to clean the house.

Mr. S feels he is being slowed up by stiffness, which he believes could be arthritis from his early life of physical labor. He believes his children want him out of the way and want him in a nursing home.

Past Medical History:

Hypertension at age 45, dyslipidemia at age 45, osteoarthritis at age 70, Alzheimer dementia at age 75, Parkinson disease at age 76.

Past Surgical History:

Appendectomy at age 22; left total knee replacement, osteoarthritis at age 68.

Social History:

He is an ex-smoker (quit 20 years ago) but smoked a pack a day from age 15 until then a 42 pack-yr history; alcohol consumption—couple of beers on the weekend while watching sports; no illicit drugs; married 50 years; two adult children—living and well. Daughter lives in another state 4 hours away, the son lives overseas and is estranged from the family. Mr. S has been relatively socially isolated due to his illness and his wife's illness. He has not resumed previous activities (no longer does maple sugaring or read books) or previous involvement (Rotary Club).

Family History:

He is the youngest of four siblings. A sister is deceased from renal failure and diabetes at age 84. Still living are a brother aged 83 and a sister aged 80. Both have high blood pressure and live independently. His father died at age 90 in a car accident and his mother died at age 87 from a cause unknown to him.

Current Medications:

Metoprolol: 50 mg PO BID
 Simvastatin: 40 mg PO qhs
 OTC: Naproxyn sodium 222 mg PO once or twice a day for knee or back pain (average 5 pills/wk)
 Chondroitin sulfate from the health food store—dose unknown
 Donnezpizil: 10 mg PO qhs
 Carbidopa/Levodopa: 10/100 PO TID

Immunizations:

Flu vaccine last fall. Pneumococcal vaccine 2 years ago. Last PPD or tetanus unknown.

REVIEW OF SYSTEMS

Head:

Denies headaches, no change in vision, hearing, smell, or taste. He wears bifocals with a new prescription nearly a year ago. He denies syncope, near syncope, or dizziness.

Heart:

Denies chest pain or palpitations. He has no cardiac history except as noted in past history without claudication, angina, or history of MI.

Lungs:

He denies shortness of breath, wheezing, coughing, dyspnea on exertion or orthopnea. No history of occupational exposure or TB.

GI:

Denies food intolerance, dysphasia, odynophagia, acid reflux, appetite changes, nausea, vomiting, diarrhea, constipation,

changes in character of bowel movements or weight loss; although the daughter believes he looks thinner (Box 53.1).

GU:

Denies frequency of urination, hematuria, or dysuria. He admits to nocturia 1 to 2 per night. He states his stiffness makes him unable to get to the bathroom when he needs to, which causes him to wet himself at times.

Musculoskeletal:

He admits to a general stiffness usually without pain. He takes Naproxen occasionally for what he says is arthritis in his back and left knee. He believes this has caused a slowness of ambulation with gait changes. He denies tics, twitches, convulsions, paresthesias, or paralysis.

Psychiatric History:

He has had no psychiatric evaluations or hospitalizations. He claims to be satisfied with his life if people would just leave him alone. He denies feeling sad hopeless or worthless. He denies suicidal or homicidal ideation but jokes that he might change his mind if they keep pushing him. Despite reporting seeing people who are not there, he denies delusions, hallucinations, anxiety, or depression. The daughter reports social withdrawal, a short temper, and accusatory language and notes her father gets easily agitated and has difficulty with daily routines. He is not compliant with usual daily routines or medications since his wife died.

Activities of Daily Life:

The daughter reports that he dresses himself but would put on the same clothes day after day if she did not lay out the clothes for him. Likewise he feeds himself but only after she prepares the

Nutritional Health Checklist

Perform the following Nutritional Health Risk Questionnaire. Circle the score for “yes” responses and add up the total of circled scores at the bottom.

	Yes
Do you have an illness or condition that makes you change the kind and/or amount of food you eat?	2
Do you eat fewer than two meals per day?	3
Do you eat few fruits, vegetables or milk products?	2
Do you have three or more drinks of beer, liquor, or wine almost every day?	2
Do you have tooth or mouth problems that make it hard for you to eat?	2
Are there times when you cannot afford to buy the food you need?	4
Do you eat alone most of the time?	1
Do you take three or more different prescribed or over-the-counter drugs per day?	1
Have lost or gained 10 or more pounds in the last six months without wanting to?	2
Are there times when you are physically unable to shop, cook, and/or feed yourself?	2

Total score

Score interpretation

- 0–2: Low nutritional risk
- 3–5: Moderate nutritional risk
- 6 or more: High nutritional risk

Additional nutritional questions:

How would you describe your current appetite? _____ Good _____ Poor _____ Variable
 For how long? _____ Details:

meals and sets them up. He ambulates with a cane as previously noted. He toilets himself, but the daughter notes occasional urinary incontinence and his underwear is sometimes soiled as if he does not clean himself well. He frequently has to be reminded to shower and at those times the daughter is afraid he will fall but he refuses her help or to use the shower chair.

Instrumental Activities of Daily Life:

Mr. S is able to answer a phone but does not dial it or look up numbers. He does no shopping or housework. The daughter shops, prepares meals, and handles his finances for him which her mother had done for the past 2 or 3 years. Mr. S needs assistance with travel and is unable to plan a trip or describe how to get from his house to places with which he was previously familiar yet he insists he can drive.

PHYSICAL EXAM

Vital signs:

BP: 119/72; pulse: 64; respiration: 14; O₂ Sat: 95%.

General:

Mr. S is alert, well hydrated, and well nourished although there are signs of recent weight loss as his clothes are ill fitting. He looks his stated age. He is in no acute distress, but he is obviously displeased at being at the doctor's office.

HEENT:

Head is atraumatic and normocephalic. Facies have a paucity of expression. Pupils are equal and reactive to light. Fundoscopic exam reveals no papilledema, AV nicking, exudates, or hemorrhages. Pharynx is without erythema or masses. There is no evidence of cervical or submandibular lymphadenopathy. The thyroid is palpated without tenderness masses or nodularity.

Heart:

The heart is regular without murmur, gallop, or rub. The point of maximum impulse is in the left fifth intercostals space. No jugular venous distention or carotid bruit is appreciated.

Lungs:

The lungs are clear to auscultation and percussion with good respiratory excursion.

Abdomen:

The abdomen is flat and soft without hepatosplenomegaly, masses, tenderness rigidity, or rebound. Bowel sounds are auscultated. A lower right quadrant scar is present compatible with his history of appendectomy.

Extremities:

There is no evidence of digital clubbing, ulceration, or cyanosis. The left knee has a well-healed scar consistent with previous arthroplasty. Degenerative changes of both knees are evident. Dorsalis pedis and tibialis posterior pulses are present. The knees are slightly flexed at rest, as are the hips. He sits comfortably on the exam table, uses his arms to rise to the standing position, and sways slightly upon rising. He uses a cane to walk and has a slight hesitation upon initiation of walking and steps are unequal. He prefers to stand with a widened stance. His attempts to turn are noted to be irregular and discontinuous and he plops into the chair when asked to sit down.

Neurologic:

Deep tendon reflexes are +2/4 at knee, elbow, and forearm but 0/4 at the Achilles bilaterally. Strength is 5/5 proximal and

distal in upper and lower extremities. Cranial nerves II to XII are intact. Facies are flat without droop. Speech is articulate but slow. No tremor or cog wheeling is noted, but joint stiffness is noted on range of motion testing and handwriting is particularly small. No clonus is noted and Babinski Reflex Test (Adams, 2000, pp. 19–23) is physiologic.

Psychiatric:

He is oriented to place and person but believes it is 10 years ago and that it is Fall when it is actually Winter. He is able to spell "WORLD" forward but not backward. He recalls 3/3 objects immediately but only 1 of 3 after 5 minutes despite cues. He follows a two-step command but has trouble with a three-step command. He refuses to draw a clock. He writes a three-word sentence that is difficult to read due to its small size. Patient is cordial and responds to questions although he is not happy about being in the physician's office. He believes his daughter wants him declared incompetent to prevent his driving and to place him in a nursing home. He relates that he has heard voices telling him she wants him "put away."

Structural Exam:

There is slight flexion posturing of the knees and hips with a generalized increase in paraspinal muscle tone in the thoracic and lumbar areas. There is flattening of the lumbar lordosis and a mild accentuation of the dorsal kyphosis. Periarticular changes of the knees and fingers are present.

DIFFERENTIAL DIAGNOSIS

The medical evaluation of older adults differs from standard medical evaluation in three general ways: "(1) it focuses on older individuals with complex issues; (2) it emphasizes functional status and quality of life; and (3) it frequently takes advantage of an interdisciplinary team of providers." Quite often standard medical evaluation will tend to miss some of the most prevalent health issues experienced by older adults. These include the *five I's of geriatrics*: (1) *impaired homeostasis*—otherwise referred to as *homeostenosis*; (2) *incompetence or intellectual impairment*; (3) *iatrogenesis*; (4) *immobility*; and (5) *incontinence* (Wagner et al., 1996). Unfortunately, these conditions are often considered to be the "giants" in geriatrics because they consume much of the physician's time. The geriatric assessment effectively addresses these as well as other areas of older adult care in order to prevent disease and disability while successfully providing care interventions.

It is fitting to review these "giants" in relation to Mr. S and within the context of the osteopathic approach. Questions that may come to mind for the physician as the geriatric assessment is taking place and the geriatric giants are being considered include.

Impaired Homeostasis

Does he have evidence that his situation is due to *homeostenosis*? Has there been a change that has interfered with the body's inherent capacity to self-regulate? Is the loss of his caregiver support evidence that a social homeostasis has been lost?

Incompetence or Intellectual Impairment

Does his mental status exam suggest that he may have *intellectual impairment*? If so, it is important to determine in what realms and to what degree. Is the impairment quantifiable? Is it from a

Competency Evaluation

Due to psychiatric illness, mental retardation, delirium, or dementia, older adult patients may in some situations be incapable of making decisions that safeguard their own self-interests. Although the MMSE provides useful information regarding a patient's global cognitive function, it is important to assess, by way of an interview, his or her competency in at least two areas: medical and financial decision-making. Following are questions to consider in the evaluation of a person's competency to make decisions directly affecting their health and financial security:

- Is the patient aware they have a mental illness (as listed above)?
- Does the patient understand the nature of the proposed treatment?
- Does the patient understand the need for treatment and the implications of refusing treatment?
- Does the mental illness interfere with judgment and reasoning so much that it accounts for refusal of treatment?
- Does the patient have knowledge of their current assets?
- Does the patient have knowledge of their monthly expenses and bills?
- Does the patient know where their assets are located and being managed?
- Can the patient complete simple calculations?
- Is the person's judgment so affected that his or her finances would be in jeopardy?

metabolic, vascular, psychiatric or other source, or perhaps a combination? Physicians may determine capacity to function, use cognition, perform activities of daily living (ADLs), or meet executive abilities such as planning insight and judgment, but it is the courts that decide competence. Therefore, physicians need to be aware of how the courts referred to and define *incompetence*. Box 53.2 presents questions to consider in the evaluation of a person's competency to make decisions directly affecting their health and financial security.

Iatrogenesis

Is there a possibility of *iatrogenesis*? Has a previous diagnosis been in error? Has a treatment been instituted or not instituted that has created or exacerbated the current situation? Has treatment been started that is based on a symptom and rather than a cause? Is there a possibility of polypharmacy with drug/drug interactions?

Immobility

Is Mr. S's apparent *immobility* his central and most important problem? Does this put him at risk for a cascade of disasters as his daughter fears? Although it is the chief complaint, is immobility the root cause or the symptom of something significant?

Incontinence

Finally, Mr. S has an *incontinence* problem. Is it a physical problem (is his bodily system intact), is it caused by decreased cognitive function, or is it a physical function issue (he has difficulty moving to the bathroom)? Perhaps it is not an intrinsic problem unto itself but rather it is the manifestation of another problem.

This patient's history and physical exam are strongly suggestive of dementia, and although it was not the presenting complaint,

TABLE 53.1

DSM-IV Diagnostic Criteria for Dementia

A	The development of multiple cognitive deficits manifested by both: <ol style="list-style-type: none"> 1. Memory impairment (impaired ability to learn new information or to recall previously learned information) 2. One (or more) of the following cognitive disturbances: <ol style="list-style-type: none"> a. Aphasia (Language disturbances) b. Apraxia (impaired ability to carry out motor abilities despite intact motor function) c. Agnosia (failure to recognize or identify objects despite intact sensory function) d. Disturbance in executive function (i.e., planning, organization, sequencing, abstracting)
B	The sequencing deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning
C	The course is characterized by a gradual onset and continuing cognitive decline

Source: Ward RC, Hruby RJ, Jerome JA, et al. *Foundations for Osteopathic Medicine*. Philadelphia, PA: American Osteopathic Association, Lippincott Williams & Wilkins, 2002. Adapted from the Diagnostic and Statistical Manual of Mental Disorders—DSM IV. 4th Ed. American Psychiatric Association: Washington DC, 1994.

his cognitive function has the greatest clinical implication for his long-term health. The physician must determine if there are diagnostic criteria for dementia. The DSM-IV R lists criteria for the diagnosis of dementia (Table 53.1). Concerning Mr. S, one need to only apply the findings of short-term and long-term memory, with the patient's functional capacity in ADLs to recognize that our patient has a cognitive loss that meets the diagnostic criteria for dementia.

The differential diagnosis of dementia can be divided into two broad classifications—those that are reversible (Box 53.3) and

Potential Reversible Causes for the Dementia

- Neoplasm
- Autoimmune (lupus, arthritis, multiple sclerosis)
- Metabolic disorders
- Drugs/medications
- Toxins (ETOH, heavy metals, organic poisons)
- Nutritional disorders
- Infections
- Psychiatric disorders (depression, delirium, psychosis)
- Other
- Normal pressure hydrocephalus

those that are not. The first responsibility for the physician is to distinguish between these two categories, and much of the workup is aimed at precisely this distinction. Failure to find reversible causes, if they exist, results in unnecessary treatment and stresses for the patient and the family.

The initial workup for reversible dementias always begins with a thorough history and physical examination. As with many conditions the history is central to the diagnosis and as osteopathic physicians, it is the functional consequences of the disturbance that should be investigated and documented for its impacts on the patient and the patient's support system. The physical exam should emphasize the neurologic and cardiovascular systems. Because the definitive diagnosis of dementia can only be proven by tissue sample from a brain biopsy, the diagnosis is one of exclusion. One must evaluate the patient for other reasonable causes of the diagnosis and when that fails, the physician is left with the likely diagnosis of dementia. Likewise, it is the constellation of signs and symptoms of the whole person that steers the physician to the conclusion of the type of dementia once the determination that a dementia exists is made.

The laboratory and imaging evaluations may include:

A. Blood studies

- Complete blood count (CBC)
- Comprehensive metabolic profile
 - Glucose
 - Renal functions—BUN, creatinine
 - Electrolytes—sodium, potassium, chloride
 - Liver functions—AST, ALT
 - Calcium and phosphorus
- Thyroid-stimulating hormone (TSH)
- Vitamin B₁₂ and folate
- Serologic test for syphilis

B. Radiographic studies

- Computerized tomography (CT) or magnetic resonance imaging (MRI) of the brain
- Selected patients may need autoimmune studies and neuropsychological testing.

It is also important to quantify the degree of the dementia to assist with the diagnosis and to provide a baseline for future assessments to determine the effectiveness of interventions. This could include a test for cognition such as the SLUMS, the Folstein Mini Mental Status Exam, or the Clox test. It could include a test for depression such as the Geriatric Depression Scale. A functional assessment of his ADLs is also useful and can be accomplished with such tests as the ADLs Scale or the Instrumental ADL (IADL) Scale. Many of these tests are easy to administer and can be done in the office by trained paramedical personnel.

Nonreversible causes of dementia can be classified in a number of different ways. The Agency for Health Care Policy and Research lists four basic categories: (1) degenerative, (2) vascular—previously referred to a multi-infarct, (3) trauma, and (4) infections (Costa et al., 1996). There is considerable overlap and some patients may have a mixture.

AD is known to account for approximately 50% of the dementias, vascular (previously called multi-infarct) dementia accounts for another 25%. Fifteen percent of dementias are caused by irreversible central nervous system (CNS) disorders such as Pick disease, Huntington chorea, inoperable brain tumors, and Parkinson disease. The remaining 10% result from treatable causes such as the effects of various drugs, brain tumors, vitamin B₁₂ or folate deficiencies, depression, thyroid disturbances, and CNS infection.

Dementia with Lewy bodies accounts for up to 20% to 25% of dementia cases listed above. Age at onset is typically greater than 60 (Galvin et al., 2008).

In some cases, causes of dementia may overlap. That is the case for Alzheimer dementia and Parkinson disease. When the patient has dementia with detailed hallucination, Parkinsonian signs, and alterations in alertness and attention, one might suspect dementia with Lewy bodies (Table 53.2).

Vascular dementias are predominately caused by circulatory interruption to the brain. Often they are related to infarcts (strokes). They can be progressive as the patient experiences recurrent infarcts and hence were previously referred to as multi-infarct dementias. Many of these strokes happen at the subcortical level and are too small to cause permanent residual neurologic deficits in the motor or sensory systems. The key characteristic that distinguishes a classic vascular dementia is the typical stepwise decline. Unlike Alzheimer disease (AD) that usually shows a steady downward course, vascular dementias show a new decline with each new vascular insult followed by a period of stability and then another decline with the next event.

Mr. S presents with a past history of Parkinson disease and Alzheimer dementia with a recent decline in cognition that is slowly getting worse over the previous few months and has been exacerbated since the death of his wife. In treating the whole person, consideration must be given to his previous diagnosis of AD, the recent initiation of anti-Parkinson drugs, and the loss of his primary caregiver whose support may have masked the true seriousness of his cognitive loss.

The physician is left with the quandary of a potential multifactorial cause for his current presentation. This is especially true when one remembers that the body is an integrated sum of its parts and that care of the presenting disease must include considerations by the physician for not only the patient's physical body, but also his emotional, social, and spiritual health. The challenge is that there are no algorithms for such considerations, which calls upon the skill of the physician to consider these factors at every stage of the diagnostic and treatment process. The differential diagnosis of subacute, progressive cognitive decline, and gait and behavioral changes in a 77-year-old man with a history of hypertension, dyslipidemia, AD, and Parkinson disease can be viewed in Table 53.3.

In considering the whole context of Mr. S presentation, the Parkinson disease diagnosis can be confirmed as illustrated by his handwriting, his gait, and his paucity of facial expressions among other characteristics. However, the fact that his dementia was exacerbated by the initiation of anti-Parkinson medication and the presence of delusions and psychotic overlay suggests a Lewy body dementia. Lewy bodies are rounded eosinophilic intracytoplasmic neuronal inclusions that contain the protein α -synuclein; they are characteristic of dementia with Lewy bodies and of Parkinson disease. In dementia with Lewy bodies, Lewy bodies occur in the cerebral cortex and other areas of the brain. In Parkinson disease, Lewy bodies occur in selected subcortical structures, most notably the substantia nigra. Dementia with Lewy bodies, Parkinson disease, and AD overlap considerably. For example, patients who have Parkinson disease may develop dementia with Lewy bodies; patients who have AD may have a modest number of Lewy bodies, and patients who have dementia with Lewy bodies may have neuritic plaques and neurofibrillary tangles. Further research is needed to clarify the relationships among these disorders (Aarsland et al., 2004; Hurtig et al., 2000; Merdes et al., 2003; Tsuboi and Dickson, 2005).

However, in the case of Mr. S, AD is unlikely to be accompanied by the level of psychotic symptoms displayed by Mr. S. Pseudodementia in the form of depression may also be considered,

but his presentation is not convincing for depression based on the DSM criteria for depression or his depression test score. Vascular dementia usually has a more abrupt onset with a gradual stepwise decline as more vascular events occur and impact brain function.

OSTEOPATHIC PATIENT MANAGEMENT

The osteopathic approach to patient care, first described in the 19th century, dovetails well with the much newer field of geriatric medicine that stresses the care of the individual as much as the care of the disease state. This symbiotic relationship is paramount in older adult healthcare. The physician is tasked with helping the patient achieve maximal residual functions. It cannot be stressed enough that the majority of older adults age successfully; they are survivors. Nationally, approximately 5% require institutional care (AHCA, 2007), leaving 95% of older adults to be cared for in the community with an increasingly limited number of physicians trained in geriatrics. Unfortunately, it is the 5% who consume much of the health

care dollars and physicians' time and limited resources (Flowers et al., AARP, 2003). Despite this, it is the physician's responsibility to work with older adult patients and their caregivers to facilitate successful aging well before the onset of a health crisis. Implementing preventive activities at younger ages includes primary and secondary disease prevention and health promotion activities such as proper nutrition, physical exercises, cognitive exercises, and the careful exploration of psychosocial dimensions. These activities can be implemented with patients of all ages and health conditions. Suffice to say, it is never too late to make changes to augment health.

The overall goal is to maximize the patient's residual functional capacity to meet patient-centered goals for care for an optimal quality of life. A variety of measures are useful for the well being of patients with dementia and their families. These interventions range from the assessment and potential alteration of the physical living environment, to education on the use of specific strategies of care to providing information and counseling services or referrals. It is important to remember that this can only be done with the

involvement of a multiprofessional team and it is the physician's duty to recognize the need and to provide avenues to the appropriate resources when possible. The management of patients is best done in the least restrictive environment possible. The preparation for changes in level of care must always be anticipated, as dementia is a progressive disease. The support for the family and caregivers is crucial to this effort. Guilt, feelings of being overwhelmed and underprepared are common. The physician should proactively assess the family for signs of physical, emotional, and financial stresses that will impact the care of the patient and thus advocate for strategies that minimize those stresses. Services, such as those from Area Agencies on Aging, the Alzheimer's Association or Lewy Body Dementia Association may be of value (Box 53.4). Local agency and chapters can be found via a web search or in local phonebooks.

Biomechanical Model

While there are no biomechanical changes specific to the diagnosis of dementia, we are aware of certain prevailing tendencies for the older adult population. It should also be emphasized that many healthy older adults often practiced good health habits in their younger years. If the osteopathic physician is to see the results of healthy aging, then the interventions such as immunizations, smoking cessation, lipid management, calcium and vitamin D supplementation, and exercising the mind and body must begin well in advance of the diagnosis of disease. A good health foundation gives older adults a stronger base to call upon.

Regardless of past health practices, older adults tend to experience alterations in biomechanical functions such as an increased incidence of protein crosslinking in the soft tissues and a loss of elastin that leads to a generalized stiffening and slowness of reaction. There is a loss of subcutaneous fat and subcutaneous tissues making the patient vulnerable to trauma and ecchymoses, Bony joints are subject to the development of degenerative conditions such as arthritis due to longevity and wear and tear. Thus, TART—tissue texture abnormality, asymmetry, restriction of motion,

tenderness—(Mosier and Kohara, 2007) findings must be interpreted in the context of usual aging. We can expect that the older adult will have tissue texture abnormalities based on elastin loss and changes in tone and turgor. We will find there is usually asymmetry and motion restrictions in the absence of trauma. Tenderness can be a useful guide to the onset of new conditions for considerations. The older adult patient loses height while preserving span due to the loss of hydration in the intervertebral discs and the prevalence of osteoporosis. The *typical* older adult will demonstrate a "flexion posture." Thus, the knees and hips may not extend as far and forward bending at the lumbar spine may be restricted. There is typically flattening of the usual lumbar lordosis and accenting of the dorsal kyphosis and or cervical lordosis. Cranial sutures calcify with age and cranial motion abnormalities and their interpretation can be difficult to detect in older adults.

Osteopathic manipulative treatment (OMT) can be applied in cases where there is degenerative neurologic disease especially in which dopaminergic synapses in the corpus stratum deteriorate leading to tremor, bradykinesia, and muscular rigidity. Muscle energy techniques are thought to be especially helpful in treating these patients. The author usually avoids thrust and impulse techniques because of the risk of osteopenia in many geriatric patients. A combination of manipulation, physical therapy, and strength training, especially in the earlier phases of dementia of the Lewy bodies type, may improve head and neck posture, increase stride length, increase hip, knee and ankle flexion, increase foot lift from floor, decrease incidence of falls, decrease depression, thereby improving quality of life (DiGiovanna and Rowante, 2005).

Respiratory Circulatory Model

Vascular dementia may be caused by macrotrauma such as in a stroke, but it can also be caused by the changes in blood flow brought on by aging. Arteries may narrow, slowing capillary flow. This may affect the intrinsic function of the brain; the failure to clear the waste also may assist in the accumulation

of waste products, and toxic β -amyloid creating a chemical imbalance of the neuronal ability to function (Center for Dementia Research, NIH Report, 2001).

Many clinicians and researchers have observed lifestyle factors in the onset and progression of dementia. We know that exercise and nutrition play a large role in healthy aging in general, and this seems to be true for dementia prevention as well. The activities reduce concomitant risk factors such as obesity, elevated lipid levels, and high blood pressure. Pursuing intellectual activities (exercise for the mind) and active social contacts are contributors to healthy aging (Snowdon, 2003). Epidemiologic studies show that higher level of physical activities reduces cognitive decline. Animal studies show that activity increases capillary formation in the brain. Although a fair amount of research has been conducted, more trials are needed to expand our knowledge.

Neurological Model

Dementia results from a confluence of numerous influences. Some such as Parkinsonian dementia and Alzheimer dementia are rooted in genetic, environmental, and systemic factors that then lead to the accumulation of abnormal proteins or reduced oxygen flow to tissues and resulting toxic processes. These toxic processes then lead to the manifestations that we can observe. These early symptoms depend on the area of the brain affected but can include tremor, memory loss, executive functions losses of planning insight and judgment, gait and movement disorders, hallucinations, delusions, and rigidity.

Alzheimer researchers have uncovered the apoE gene on chromosome 19 that is believed responsible for some cases of familial AD as it produces a protein referred to as apolipoprotein E. But this connection is incomplete and does not account for all cases. The two hallmarks for AD are the plaques and neurofibrillary tangles found in brain tissue. Plaque formation involves the production and deposition of β -amyloid plaques. Tau is the protein that is the chief component of the tangles. These tangles are commonly found in the frontotemporal dementias such as those associated with Parkinson disease and may be a cause of dementia. These hypotheses warrant aggressive ongoing research.

Scientists do not yet fully understand what causes AD or other dementias. Age is the most important known risk factor. For example, the number of people with AD doubles every 5 years beyond age 65 (Launer et al., 1999). Some researchers have implicated a low-grade chronic inflammation as an inciting factor. Others have targeted the metabolic processes that produce free radicals that cause oxidative damage on cellular mitochondria. These damaged mitochondria then cause malfunctions of the cellular functions including neurotransmitter production and receptivity. Since the brain has a high rate of metabolism, it may be especially susceptible to this oxidative damage.

A strong component of the care of patients with dementia is pharmacological therapy that addresses the neurological pathology and sequelae of the condition. The pharmacotherapeutics fall into three broad categories: drugs that (1) enhance cognition and function, (2) treat coexisting depression, and (3) treat complications of dementia. None of the medications in these categories cure the disease but may slow the progression of the disease thereby adding functional months to the patient's quality of life. They may also be useful in managing comorbid conditions associated with the dementia. For medications that enhance cognition, currently available medications include the cholinesterase inhibitors such as Donepezil (Aricept), Rivastigmine (Exelon), and Galantamine (Razadyne). These drugs work by slowing down the action of acetylcholinesterase to maintain higher levels of the acetylcholine neurotransmitter in the brain.

The newest agent is Memantine (Nemenda) that affects another neurotransmitter, glutamine. Like the cholinesterase inhibitors, this agent will not stop or reverse the dementia. It may be necessary to use these agents in combination (Qaseem et al., 2008).

As with all medications, there are risks and benefits, and drug treatment should be instituted with the mantra of "start low, go slow, but go." Low dosages are instituted and gradually adjusted upward, slowly but deliberately. Consequently, repeated assessments and adjustments of medication over time are needed. The astute physician must recognize and counsel the patient and family on these risks and benefits. For many patients and their families, an ethical struggle may eventually ensue around the discontinuation of medications when they no longer serve to meet a patient-centered goal related to the quality of life.

In considering which pharmacologic agents to institute, one must also consider which agents the patient may already be taking that can exacerbate the symptoms or are incompatible with those planned to be instituted. Reversible causes of dementia may include iatrogenically prescribed medications and other treatments. Mr. S should stop his anti-Parkinson medication as it can exacerbate the psychoses of dementia with Lewy bodies. Antipsychotic medications may be instituted with caution. He probably should continue on donepezil.

Behavioral Model

In a society with fewer extended families, the psychosocial aspects of the dementias can be paramount in care management. In terms of the whole patient, the cultural and spiritual foundations of the patient and the family of caregivers will influence the care decisions and the context in which they are suggested by the physician and the manner in which they are accepted by the patient and caregivers. Autonomy is prized as an ethical precept and should be honored when possible in the patient with capacity. As dementias progress, practitioners must increasingly rely on secondary sources of information to determine values and wishes of the patient. It is therefore important to try to determine these preferences as early in the disease process as possible.

The psychosocial elements of dementia range from the emotional response to the diagnosis to stressors from coping with the ongoing management of the individual, to honoring the individual's beliefs and values. Honoring the patient's previous stated wishes may cause dissonance among caregivers who want to honor those wishes but find it difficult to do so. Role reversal as offspring assumes care for their parents is stressful. Practical matters of advanced directives, aggressiveness of interventions, preferences for religious support, and guardianships or power of attorney should be discussed early on in the management. Since the "mind is robbed before the body," patients and their families may experience a divide between the apparent abilities of the older adult and the actual abilities. Issues of alone time, driving, and financial management may become obstacles and create a dynamic tension in the patient and in intrafamily relationships (Family Caregiver Alliance, 2009).

The osteopathic philosophy makes very clear the distinction between treating disease in patients and treating patients who have disease (Still, 1892). It is the latter that must dominate our osteopathic approach. Clarity of goals of care, honoring the culture and belief systems of families and individuals, providing support systems for patients and families must all be sought. Care must be tailored to the needs of the individual and families, not institutions. For the physician, the issue involves more than just managing the dementia; it is imperative to help the patient make the most of their remaining years (Rabin, 2000).

Most patients with dementia express the desire to remain in their homes. Caregivers often have considerable guilt and feelings

of inadequacies when this is no longer possible. Geriatric practitioners would support the home environment as the best place for ongoing care. As the patient loses ADL skills, the concerns about safety, provision of care, and the need for continual supervision may become overwhelming. Home health agencies can be of assistance but are often limited as to length and depth of service availability. To further compound care for older adults with dementia, financial outlay for care can be considerable, regardless of the skill and availability of such care, it is often difficult to secure even for those with the means to pay out of pocket.

A study conducted in 2006 (Buhr et al., 2006) cited the caregiver reasons for placement of older adult loved ones in nursing homes. These included (a) the need for skilled care (65%), (b) the caregiver's health (49%), (c) dementia-related behaviors (46%), and (4) the need for more assistance (23%). Behaviors are often the last straw for decision makers. These include socially inappropriate behaviors, agitation, delusions, wandering, and incontinence. In an earlier study (Magaziner et al., 2007), the prevalence of dementia in Maryland nursing homes—a state with similar admissions to nursing homes elsewhere in the United States—was 48.2% with an upper bound estimate at 54.5%. Prevalence was highest in smaller (<50 beds) facilities (65.5%) as compared with those with a higher number (200+) of beds (39.6%). Percentages were also higher in urban versus rural areas (50.0% vs. 39.1%). Of note is that dementia-related admissions represent high percentages of all nursing home admissions.

Metabolic Energy Model

The single most identifying characteristic of the aging process is a narrowing of the homeostatic window. As we age, processes come into play that impact the individual's response to physical, biologic, or psychologic insults. This has been called homeostenosis. The ability of the body to self-regulate and to marshal resources to heal is challenged in older adults. For example, the cardiac reserves are lessened as cardiac output diminishes and the heart is less responsive to a catecholamine stimulus. Similarly, the endocrine system is less responsive to the stimulating hormones. There may be reduced receptor responsiveness to endogenous and exogenous stimuli, the immune response may be blunted, and osmoreceptors are less sensitive to changes in fluid and electrolytes. With less ability for older adults to tolerate physiologic stress, the line between health and wellness narrows. Further, a person with dementia may find it difficult to marshal the psychological and social resources to cope with illness. This homeostenosis makes older adults prone to a cascade of disasters. An example of this could be: dementia leads to less mobility, the immobility leads to instability, the instability leads to a fall, the fall leads to a fracture, the fracture leads to more immobility that leads to respiratory stasis and atelectasis, which leads to pneumonia, and so forth. However, it must be stressed that this characteristic of aging does not apply universally. Individuals age individually; meaning that aging itself is not a disease and individuals must be approached individually.

Diet has been an area of interesting research as well with attention to antioxidants and folate. Individual studies have been promising but inconclusive when reviewed as a whole. Mega doses of vitamin B and the use of herbal medications and antioxidants have been proposed. Ginkgo biloba has been the leading herbal promoted for memory improvement. Vitamin E has been likewise had its advocates. Anti-inflammatory medications such as ibuprofen have been recommended for their anti-inflammatory abilities. Despite the fervor of some, none of these has proven more effective than a balanced diet and exercise of the mind and body (Engelhart et al., 2002; Gray et al., 2008; Heyn et al., 2004; Mazza et al., 2006).

Additional resources on dementia of the Lewy body type may be found in Box 53.5: Lewy body dementia resources for physicians.

The key principles of managing dementia can be found in Box 53.6.

Principles in Managing Dementia

- I. Optimize function
 - Investigate and treat reversible and comorbid medical conditions
 - Avoid unnecessary medications especially anticholinergic and sedating medications
 - Provide appropriate assistive devices such as walkers, hearing aids, eyeglasses
 - Modify the environment such as widening doors, the addition of grab bars, ramps, elevated toilet seats and the removal of scatter rugs
 - Prepare patient and family for changes in location and time to adapt to new placements
 - Emphasize nutrition and exercise
- II. Identify and manage complications
 - Behavioral disorders
 - Depression
 - Loss of insight and judgment (wandering, driving, planning)
 - Psychoses
 - Incontinence
 - Team based care with nursing, occupational and physical therapists, social work, home health agencies and others
- III. Information management for patient and family
 - Nature of disease with regular updates of progression and prognosis
 - Social service agency resources such as the Alzheimer's Association
 - Advanced directives
 - Respite service options
- IV. Family/caregiver counseling
 - Identify supportive services
 - Identify and resolve family conflicts
 - Handle feelings of guilt anger and despair
 - Legal concerns
 - Financial concerns
 - Ethical concerns
 - End of life care

SUMMARY

The treatment of an older adult with dementia begins with a history and physical to determine the degree of progression of the condition. Applying the osteopathic practices and principles including evaluating for predisposing dysfunction of the entire body is a part of the physical examination. The diagnosis includes considerations of two broad classifications of dementia—those that are reversible and those that are not. The physician must distinguish between these two categories, which is accomplished by and large by the history, physical, and lab results. Treatment is directed to the identified dementia and must include considerations of the patient as a whole person. OMT may be utilized when appropriate to improve head-and-neck posture, increase stride length, increase hip, knee and ankle flexion, increase foot lift from floor, decrease incidence of falls, decrease depression, thereby improving quality of life. The environment must also be considered in the case of dementia diagnosis and a determination of ways of modifying the environment to improve the overall health or at least quality of life is essential.

KEY CONCEPTS

- Asthma is an obstructive pulmonary disease with an inflammatory component.
- The dynamic balance between sympathetic and parasympathetic influences in the lung is distorted in asthma.
- Aspects of anatomical and physiological immaturity in young children with asthma result in vulnerability for respiratory muscle fatigue, inefficiency of diaphragmatic mechanics, and ineffectiveness of tissue recoil.
- There are biomechanical, respiratory-circulatory, metabolic, and neurological influences that need to be considered in the management of the child with asthma.
- Osteopathic manipulative medicine used in conjunction with standard care may improve the severity of asthma symptoms and decrease the need for pharmaceutical management.

CASE VIGNETTE

CHIEF COMPLAINT

A 10-year-old female patient with a history of asthma was brought from school to the clinic by her mother. This patient was well known to the clinic, as she has been seen two to three times per week for her symptoms. She has often been sent to the clinic during school hours.

History of Present Illness:

The patient has been noted to be noncompliant with her medications. On this particular visit, the patient ran out of her albuterol measured dose inhaler (MDI) and was having an asthma attack. The clinic staff approached the patient in a somewhat dismissive manner, stating that the patient was only trying to get out of school.

Past Medical History:

Positive for recurrent upper respiratory tract infections with exacerbation of wheezing and cough. The patient has been hospitalized four times in her lifetime because of asthma exacerbations, but she has never been ventilated. Her last hospitalization was 2 years ago. She has also had numerous emergency room visits because of her asthma. As an infant, she had reflux and recurrent ear infections.

Past Surgical History:

Positive for tympanoplasty and ventilation tubes at 8 months of age and 2 years.

Family History:

Father is 36 with anxiety/depressive disorder and hypertension. Mother is 34 with irritable bowel syndrome. Both parents smoked until 2 years ago. One elder sister with scoliosis, two younger sisters in good health except for ear infections as infants.

Social History:

The patient lives at home with her parents and three sisters. The family is economically challenged and there is some concern about regarding her and her family's ability to comprehend and comply with medical instructions regarding her asthma therapy.

Medications

Albuterol MDI—two puffs q.i.d.
Beclomethasone inhaler—two puffs q4-6h as needed

Immunizations

Up-to-date

REVIEW OF SYSTEMS

General:

She admits to fatigue but denies fever, chills, and sweats.

HEENT:

She denies headache, visual changes, she admits to nasal congestion but denies sneezing and sore throat.

Lungs:

She admits to “trouble breathing” and feeling “chest tightness” and “out of breath.” She admits to cough, which is nonproductive. She admits to wheezing.

Cardiovascular:

She denies weakness.

GI:

She denies nausea, vomiting, stomach pain, diarrhea, burning chest pain

Orthopedic:

She denies myalgias and arthralgias

PHYSICAL EXAM

Vital signs:

HR: 98 beats/min, RR: 24 breaths/min, BP: 180/90 mm Hg, and pulse oximetry O₂ saturation: 93% while breathing room air. The patient was afebrile and blood pressure was 120/88.

General:

She appears mildly ill and has occasional paroxysm of coughing.

HEENT:

Normal.

Heart:

Heart rate is regular. No murmur or gallop is auscultated.

Lungs:

Diffuse bilateral expiratory wheezing with full breath sounds. Moderate accessory respiratory muscle use with respiration without paradoxical thoracoabdominal breathing was noted.

Abdomen:

Soft and nontender without hepatosplenomegaly. Bowel sounds are normal.

Orthopedic/Structural Exam:

There is a mild right thoracic scoliosis present with forward bending, which is 50% reducible with passive sidebending. The pelvis is rotated right. The lumbosacral junction is sidebent right. The thoracolumbar junction is sidebent right and rotated left. Expiratory motion of the upper ribs on the right is decreased and overall there is decreased rib compliance and reduced excursion during the exhalation phase of respiration especially involving ribs three to five with bilateral paraspinous muscle spasm at these levels. C7-T1 is sidebent and rotated to the left. There is compression of the cranial base and occipitomastoid area on the right.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of diffuse expiratory wheezes, moderate accessory respiratory muscle use, increased pulse rate, and decreased oxygen saturation level in a patient with known asthma supports the working diagnosis of an acute exacerbation of asthma. The staff was immediately notified to begin a nebulized albuterol treatment.

Asthma is the most common chronic disease of children and adolescents. The most common symptoms include wheezing, shortness of breath, chest tightness, and cough (Barrios, 2006; Colice, 2004). Asthma symptoms may be exacerbated by cold, exercise, infection, medications such as aspirin and NSAIDs, and allergens. Although the precise etiology is still unclear, asthma involves hypersensitivity of the bronchi and lower airways to allergens, cold, or other irritants including pollution. The resulting inflammation, bronchospasm, and mucous plugging lead to intermittent airway obstruction and difficulties in breathing. In severe cases, death may result (Barrios, 2006; Eder, 2006). The severity of asthma should never be underestimated.

Asthma can be thought of as an obstructive respiratory process. In addition to high-pitched diffuse wheezes, it may present with night time cough or prolonged expiratory phase of respiration.

Asthma is classified by severity of symptoms and management is based upon this classification. Mild intermittent asthma occurs when symptoms present 2 or fewer days per week or 2 nights per month; mild persistent asthma presents more than 2 days per week or more than 2 nights per month but less than once daily; moderate persistent asthma presents daily nightly; and severe persistent asthma occurs continually during the day and frequently at night.

Exploring the natural history of asthma has raised awareness of the variability within the disease continuum (Barrios, 2006). Asthma commonly begins in infancy; as one study found, 5% of infants had at least one physician encounter for reported wheezing within the first year of life (Reed, 2006). During the age range from infancy into adolescence, intrinsic asthma appears to be associated with exposure to respiratory infections, such as Respiratory Syncytial Virus. Asthma, which is termed “allergic or extrinsic,”

has been found to develop most often during the second decade of life with some persistence into adulthood (Barrios, 2006). Persistent symptoms of asthma more often occur in children with atopy (Carroll, 2008; Reed, 1999; Sears, 2008; Singh, 2006). Although different criteria have been used to diagnosis asthma over the past thirty years, the incidence of asthma appears to have increased over the last two decades (CDC, 2008), and external factors such as environmental pollutants may have contributed. There is a greater incidence of asthma in children who are minorities, of low socioeconomic status, or live with people who smoke.

A number of factors may precipitate an asthma attack, including:

- Emotional stress including anxiety, fear, anger, and suppressed feelings
- Exercise
- Gastroesophageal reflux
- Inhaled and ingested allergens (e.g., animal dander, food allergies, house dust, mold, pollens, spores, chemicals, food additives)
- Inhaled irritants (e.g., tobacco, smoke, air pollution, aerosol sprays, strong odors)
- Medication (e.g., aspirin, NSAIDs, beta-blockers)
- Poor diet and mucogenic foods (e.g., dairy products)
- Viral respiratory infections especially sinusitis
- Weather changes (including wind and changes in temperature and humidity)

Anecdotally, some osteopathic physicians suspect that mechanical injuries can precipitate an asthma attack. One group has found that injuries to the head or sacral regions may precipitate an asthma attack (Frymann et al., *personal communication*, 2009).

Asthma as a disease has been characterized by intermittent airway obstruction, also termed reversible airway obstruction. It is proposed to consist primarily of two major components, bronchospasm and inflammation. Bronchial smooth muscle is innervated by the vagus nerve (CNX) and vasovagal reflexes can cause bronchoconstriction. This may be the mechanism involved in the reported association between gastroesophageal reflux and asthma (Kase, 2009; Yoshida, 2009). In asthma, bronchial spasm and increased bronchial secretions can be caused by overactivity of the bronchial branches of the vagus nerve. Actions of the sympathetic nerves innervating the bronchi are diminished and the normal equilibrium with the vagus nerve is disturbed. On a cellular level, many changes can take place. The first component is bronchospasm or hyperresponsive bronchial smooth muscle, which is mediated through β -adrenergic receptors and interleukin-13 that act directly on bronchial smooth muscle and epithelium to elicit hyperreactivity. The second component is the inflammatory mechanism leading to edema of the airways. Two principal immune mechanisms linked to the inflammatory process involve the T helper cells, of which secrete multiple cytokines and interleukins, and the hypersensitivity pathway as mediated by IgE produced by the B cells, which leads to activation and degranulation of mast cells, basophils, eosinophils, and other airway cells (Colice, 2004). This in turn leads to the well-known process of histamine release and the subsequent inflammatory response.

Gross pathologic features consist of overinflation of the lung through a process known as “air trapping,” especially in individuals who expire in status asthmaticus. Other features are the mucus plugs, composed of mucus, serum proteins, inflammatory cells and debris, occluding the medium and small-sized bronchi and bronchioles. In fact, bronchiectasis has been described as a complication in 15% to 20% of asthmatic patients. Microscopic pathologic features include both goblet cell hyperplasia and submucosal gland hypertrophy. One study reported that there may be up to a three-fold

TABLE 54.1

Asthma Management Recommendations National Asthma Education and Prevention Program

	<5 Years Age	>5 Years Age
Mild intermittent asthma: 2 or less days per week and 2 or less nights per month	Treat as needed only, not daily	Treat as needed only
Mild-persistent asthma: for >2 d/wk but less than once daily, and >2 nights per month	Daily low-dose inhaled corticosteroid, OR cromolyn or leukotriene receptor antagonist	Daily low-dose inhaled corticosteroid, OR nedocromil and sustained release theophylline.
Moderate-persistent asthma: daily and 1 night per week	<5 years age; low-dose inhaled corticosteroid + long-acting inhaled beta-2 agonist; OR medium-dose inhaled corticosteroid only; medium-dose inhaled corticosteroid + long-acting inhaled beta-2 agonist in recurring severe exacerbations	>5 years: low-to-medium-dose inhaled corticosteroid + long-acting inhaled beta-2 agonist; increase corticosteroid and add long-acting inhaled beta-2 agonist in recurring severe exacerbations
Severe-persistent asthma: continuous or repeatedly during the day and frequent at night	High-dose inhaled corticosteroid + long-acting inhaled beta-2 agonist; oral corticosteroid PRN	High-dose inhaled corticosteroid + long-acting inhaled beta-2 agonist; oral corticosteroid PRN

Source: Adopted from Key clinical activities for quality asthma care: recommendations of the National Asthma Education and Prevention Program. *MMWR Recomm Rep* 2003;52(RR-6):1-8.

increase of both goblet and mucin cells in asthmatic patients versus controls (Ordenez, 2001).

Repetitive episodes of inflammation lead to a production of matrix proteins and growth factors that in turn can potentially cause airway remodeling. This may include the theory that frequent damage to the epithelium and subsequent repair also contribute to remodeling. It is also thought that remodeling, with increased muscle mass, mucosal edema and reduced elasticity, may lead to decreased efficacy of bronchodilators (Barrios, 2006).

Although wheezing is a characteristic breath sound in asthma, it may not be heard in the most severe cases in which all breath sounds will be markedly reduced. In a patient with suspected asthma exacerbation, look for the following signs and symptoms when examining the patient: use of accessory muscles of respiration, posturing to enhance respiratory muscle mechanics, flaring of the nostrils, a prolonged exhalation phase of breathing, increased heart rate, or acrocyanosis. In addition to the auscultated wheezes, this patient shows moderate accessory muscle use and a slightly increased heart rate.

Based upon this patient's history and physical examination, she appears to have mild persistent asthma; her symptoms are reportedly occurring greater than two times per week but she does not appear to have night-time symptoms. The guidelines for asthma management and prevention from the National Asthma Education and Prevention Program recommend pharmaceutical treatment specific for the severity of the asthma. According to these guidelines, this child is probably not receiving optimal medical therapy and her medication regimen should be adjusted. (Table 54.1.) There is evidence that chronic use of short-acting beta-2 agonists such as albuterol does not provide clinical benefit and may in fact worsen symptoms in patients with mild asthma. Short-acting beta-2 agonists should be reserved for rescue therapy during symptom exacerbation rather than regular control (Walters, 2003). Corticosteroids are effective in controlling asthma in children although there is some evidence that chronic inhaled corticosteroid use may impair growth rate (Pauwels, 2003; Sharek, 1999).

OSTEOPATHIC PATIENT MANAGEMENT

Biomechanical Model

There are key anatomic considerations (Allen and D'Alonzo, 1993) when utilizing osteopathic manipulative treatment (OMT) in asthmatic patients (Box 54.1). Depending upon the degree of accessory muscle involvement needed during labored breathing, the muscles engaged in respiration can extend from the cranial base to the pelvis. The thoracic cage is the center of all this activity. It houses some of the most important organs in the human body, namely, the heart, lungs, and great vessels. The thorax is one of the most intricate and dynamic regions of the body, with an orchestrated movement of over 146 joints (Kuchera and Kuchera, 1994; Moore and Dally, 1999).

Factors That Affect Breathing Difficulties

From an osteopathic perspective, the following areas may contribute to or exacerbate the patient's breathing difficulties.

1. Upper thoracic vertebrae, ribs, sternum
2. T1-6 because of sympathetic innervation to the lungs
3. Occipitoatlantal junction and the course of the vagus nerve that supplies parasympathetic input to the pulmonary tree
4. Accessory muscles of respiration
5. Anterior cervical fascia
6. Thoracic diaphragm (The diaphragm is enervated by the phrenic nerve from the cervical plexus (C3-5), and its mobility is influenced by the lower six ribs, L1-2 and the sternum.)
7. Chapman's reflexes for the lungs, sinuses, and adrenal glands
8. The cranial-sacral mechanism
9. T10-L2 and the lower ribs

Figure 54-1 Dissection of term infant, right lateral view. The ribs 1 through 9 have been removed as has the right lateral abdominal wall to reveal the dome of the diaphragm draping the superior surface of the liver. The zone of apposition lies between the dome of the diaphragm and its inferior attachment and represents the length of inferior excursion possible during inhalation. (Used with permission from Willard & Carreiro Collection.)

The child with asthma suffers from an obstructive respiratory disease. The amount of effort needed to maintain normal air movement through the bronchioles is increased, as is the work of breathing. This can have significant consequences in the pediatric population. First, infants are at risk for muscle fatigue and respiratory failure due to immaturity of acetylcholinesterase and increased contraction and relaxation times of muscles (Panitch, 1993). There is also evidence that the immature innervation patterns in respiratory muscles of children more than 3 years old result in uncoordinated and random contraction sequences that become exacerbated during times of increased demand (Haddad and Perez Fontain, 1996).

Second, when compared with adults, the mechanical effectiveness of the diaphragm and rib cage is compromised in children less than ten years old. This is because the rib cage is more flexible and laterally splayed, and the dome of the diaphragm is flatter than in an adult (Figs. 54.1 and 54.2). As a result, diaphragm excursion is shallower, intrathoracic respiratory pressures are less negative, and there is less tissue recoil during exhalation (Oppenshaw et al., 1984). During times of increased demand, children will compensate by increasing the rate and decreasing the depth of respiration.

In all children, the increased workload of breathing increases oxygen demand and cellular waste production, which alter pH and change the cellular milieu. This may be a contributing stress on the cardiopulmonary system. Optimizing mechanical function of the structures involved with breathing may help to decrease the overall workload placed on the child's cardiopulmonary system.

Figure 54-2 Schematic diagram comparing zone of apposition in the infant with that of the adult. The flattened diaphragm and widened thoracic cage contribute to the decreased zone.

Breathing is the only subconscious vital function that can be raised to a conscious level. Proper breathing helps the nervous system relax, while shallow, spasmodic breathing signals alarm. In the older child, breathing exercises may help strengthen peripheral and accessory muscles that aid breathing. Since asthma is an air-trapping disease, exercises that facilitate exhalation may be useful. In older children yoga, tai chi, and noncontact martial arts that integrate breathing with movement can be fun and health promoting. Exercise has been shown to improve breathing function.

RESPIRATORY-CIRCULATORY MODEL

The primary muscle of respiration is the diaphragm. With the average respiratory rate between 10 to 18 breaths/min, the diaphragm will move approximately 14,400 times in a day. The role of the diaphragm goes beyond mere movement as it is intimately connected to the cardiac and pulmonary pleura above and the hepatic and gastric pleura below. The movement of the diaphragm not only changes the intrathoracic and intra-abdominal pressures but also alters the circulation and lymphatic flow in these respective cavities (Moore and Dalley, 1999). Fluid movement through the vena caval system is dependent upon effective diaphragmatic excursion. Lymphatic fluids and deoxygenated blood reenter the cardiac system through the pressure changes generated by the diaphragm and respiratory muscles. Extravascular fluids in the abdominal compartment are absorbed by lymphatic lacunae situated on the abdominal surface of the diaphragm in response to mechanical changes in the diaphragmatic fascia (Schmid-Schonbein, 1990; Shinohara et al., 2003). To some extent, the removal of cellular waste products, the maintenance of tissue pH, and the reentry of fluids into the circulatory cycle are influenced by diaphragmatic function.

Neurologic Model

An important consideration in children with asthma is the perpetually dynamic interplay between the autonomic (sympathetic and parasympathetic) nervous system. The sympathetic nerve fibers of the lungs arise from the sympathetic chain ganglion at the level of T1-6.

The parasympathetic fibers travel within the vagus nerve as it exits the jugular foramen of the cranial vault and makes its way down the cervical region and through the thoracic inlet where it then splays onto the lungs. Smooth muscle fibers traveling from the intrapulmonary bronchial tree to the alveolar duct are innervated by sympathetic, parasympathetic, and primary afferent fibers. Parasympathetic input maintains dynamic tone during quiet breathing. Changes in autonomic activity or inflammation will alter the tone of the smooth muscle.

Somatovisceral reflexes associated with asthma have been found in the paraspinal muscles between T1 and T6 in adults (Beal and Morlock, 1984). The osteopathic physician may attempt to influence sympathetic activity by treating the upper thoracic area, and parasympathetic activity by addressing somatic dysfunction in the cervical region, including the craniocervical junction and cranial base. Dr. A.T. Still reportedly had great success relieving asthma and hay fever. He attributed his success to correcting spinal somatic dysfunctions, especially of the third and fourth thoracic vertebrae, that may represent a viscera-somatic reflex as well as being two of the spinal segments, which provide sympathetic innervation to the lungs.

Many authors have described the role of afferent drive on the neuroendocrine immune system and inflammatory diseases (Ganong, 1988; Gold and Goodwin, 1988; Ricci, 1989; Seeman et al., 1997; Willard et al., 1997). Arguably, somatic dysfunction increases afferent drive. Asthma, which has a strong inflammatory component, appears to be exacerbated by stress, endocrine changes, and immunity. The bronchodilators, corticosteroids, and anticholinergics used to treat asthma do so by influencing neuronal control and inflammatory mechanisms in the lower airways. Medications such as leukotriene inhibitors and mast cell stabilizers are used to control related allergy symptoms. OMT used in conjunction with these medications may help to reduce the necessary dosage of medication required to control symptoms.

Behavioral Model

Focusing on the patient as a “whole” is a simplified view of the principles and philosophy of osteopathic medicine. Still M.D., D.O., founded osteopathic medicine in 1874 and during this time established the tenets of the body’s own inherent capacity for health and well being, the importance and interrelationship between structure and function, the removal of impediments to the optimal flow of the body’s fluids and nerve function, and the concept that the body is an integrated unit (Seffinger, 2003). To achieve this, one must look at a patient collectively and evaluate their physical, mental, emotional, and spiritual state. Additionally, in today’s world, the clinician must also consider psychosocioeconomic implications that patients face. In fact, numerous studies have mentioned the significant impact of emotional triggers and poor outcomes in asthmatic individuals with inadequate support systems and insufficient self-care. Two systematic reviews reported improvements in some asthma parameters after self-management education and family therapy (Panton and Barley, 2005; Wolf et al., 2002). The national and global difficulty in providing accessible health care for impoverished patients is a concern of all health care providers. Even if patients were able to receive the necessary medications, their response to these medications is dependent on multifactorial elements ranging from genetics to the environment. In short, one has to approach the patient as an individual and treat the person, not the disease.

Metabolic Energy Model

The importance of a fresh, whole food diet cannot be overemphasized. Just as structure is foundational, so is the food that builds our

structure. It is important to avoid processed, devalitized food. Many food colorings, sulfites, preservatives, and other food modifiers cause asthma and allergic reactions. For instance, “modified wheat starch,” a thickener used in many processed foods, is “modified” by six different chemicals all of which can trigger asthma and allergic reactions in susceptible individuals. Empirically, some physicians find that asthmatic children benefit from the avoidance of foods such as milk, ice cream, excess cheese and processed flour, sugar, and corn syrup sweeteners. There is some evidence that asthmatics are more likely to have antioxidant imbalances (Nadeem et al., 2008), so adequate vitamin C with bioflavonoid and a B vitamins may be beneficial. Intravenous magnesium has been shown to have a positive effect on respiratory function and hospital stays in children with asthma (Mohammad and Goodacre, 2007). Patients with asthma with a high dietary intake of magnesium have better lung function and a reduction in wheezing (Bede et al., 2008). Encouraging breastfeeding exclusively in the first 3 months of life decreases the incidence of developing reactive airway disease (Scholtens et al., 2009).

Although inhaled corticosteroids are far safer than systemic steroids, some of the inhaled steroid is swallowed and passes through the gastrointestinal (GI) tract. Esophageal candidiasis is most commonly reported (Aun, 2009; Nielsen, 2007), but swallowed steroids may also adversely affect the normal flora of the intestine. Some physicians believe these types of medications can play a role in “leaky gut” syndrome, which in turn may contribute to allergic issues that are already present.

Patient Outcome

OMT may provide some benefit to an asthmatic patient. First, by using myofascial release and balanced ligamentous tension to address thoracic cage and diaphragm impediments, one can restore optimal diaphragmatic motion for that patient. Rib raising techniques may help to mobilize the thoracic cage as well as stimulate the sympathetic chain ganglion and alter sympathetic outflow to the visceral organs. Soft tissue techniques such as paraspinal inhibition of the cervical region and a suboccipital release may influence parasympathetic input to the lungs. Osteopathy in the cranial field may be effective in patients who have suffered a hard fall with mechanical injuries to the head or sacrum that have triggered an asthma attack (Centers et al., 2003). The goal of using OMT in the treatment of a child with asthma is to optimize the dynamic balance between parasympathetic and sympathetic input to the pulmonary system, remove mechanical restrictions that adversely affect respiratory mechanics, decrease the workload of breathing, and facilitate the child’s ability to function normally.

SUMMARY

Given its multifactorial nature, asthma is difficult to treat and requires a comprehensive evaluation on the part of the clinician. A multifaceted approach, including diet, allergen prevention, medication, and alternative modalities such as OMT, may work synergistically to control the symptoms of an asthmatic patient and potentially modify the severity (Hondras et al., 2006; NAEPP, 1997; NIH, 2005; Rowane and Rowane, 1999). In a randomized controlled trial, Guiney et al. (2005) reported a statistically significant improvement in peak expiratory flow measures in asthmatic children after treatment with OMT. Bockenbauer et al. (2002) compared OMT to sham treatment in a pilot study of adults with chronic asthma using a crossover design. Upper thoracic and lower thoracic forced respiratory excursion was statistically increased after osteopathic manipulative procedures compared with sham procedures although there were no significant changes in peak expiratory flow rates.

It has been the experience of this author that osteopathic modalities applied to asthmatic patients prior to and during the administration of medication contribute to an improvement in symptoms.

KEY CONCEPTS

- Heart failure is a clinical syndrome characterized by fluid overload.
- Fatigue and dyspnea are characteristic symptoms of heart failure.
- Heart failure can be both acute and chronic.
- Patients with both acute and chronic heart failure exhibit changes in the musculoskeletal system.
- These musculoskeletal changes can be divided into five distinct pathophysiologic models, which provide an osteopathic interpretation of heart failure.
- The osteopathic physician can utilize these models to plan a rationale for treatment of patients with heart failure that includes both pharmacologic and osteopathic manipulation.
- There are biologic and physiologic data to support this approach.

CASE VIGNETTE

CHIEF COMPLAINT

A 79-year-old female comes to the office complaining of shortness of breath and worsening fatigue for 1 week.

History of Present Illness:

W.S. has a complicated medical history, which is significant for known coronary artery disease (CAD), ischemic cardiomyopathy with an ejection fraction of 45%, previous episodes of congestive heart failure (CHF), hypertension, hypercholesterolemia, diabetes mellitus (DM) type 2, and osteoporosis.

The patient reports that over the last week she's had increasing fatigue and worsening shortness of breath from some baseline symptoms which have exacerbated in the last 24 hours and she is now having shortness of breath at rest. The patient reports a nonproductive cough and wheezing and has noticed increased lower extremity swelling over the past week. She reports that last night she slept in a recliner in order to breathe and experienced episodes of chest pressure last night which improved transiently with nitroglycerin.

Prior to this recent episode, the patient has been feeling depressed due the recent loss of her husband. The patient also admits that she has recently been eating some very salty foods and also admits that she has recently missed some dosages of her medications.

Past Medical History:

CAD diagnosed in 1998 after non-ST elevation myocardial infarction (MI). Mild mitral regurgitation and mild aortic stenosis by echocardiogram (ECHO) done last year. Ejection fraction 45% with moderate diastolic dysfunction. CHF. DM type 2. Hyperlipidemia.

Past Surgical History:

Appendectomy in 1960. Total abdominal hysterectomy with bilateral Salpingo oophorectomy in 1980. Coronary artery bypass graft (CABG) in 1998 with left leg vein harvesting. Left knee arthroscopy in 2002.

Allergies:

No known drug allergies. ACE inhibitor caused cough.

Medications:

Carvedilol: 12.5 mg twice daily. Valsartan: 320 mg daily. Aspirin: 81 mg daily. Furosemide: 40 mg daily. Amlodipine: 10 mg daily. Atorvastatin: 10 mg daily. Calcium: 600 mg and Vitamin: D 600 IU taken twice daily. Metformin: 1,000 mg twice daily.

Social History:

Patient is a retired schoolteacher. Patient lives alone in an assisted living complex. Patient's husband is recently deceased. Patient has two grown children nearby who are active in her life.

Family History:

Father deceased at age 57 of MI. Mother deceased at age 80 of old age. Two siblings with cardiac disease. No family history of diabetes, cancer, or blood disorders.

REVIEW OF SYSTEMS

General:

No constitutional symptoms of fever, chills, night sweats. Admits to fatigue and approximately 12-lb weight gain over the last 2 weeks.

Head:

Denies headache.

Eyes:

Denies diplopia, change in vision, eye pain.

ENT:

Denies change in hearing, earache or tinnitus. No sinus tenderness or nasal discharge. No voice changes, hoarseness, or sore throat.

Neck:

No neck stiffness, tenderness, swelling, or masses.

Cardiovascular:

Admits to chest pressure, shortness of breath, and dyspnea on exertion. Three pillow orthopnea. Denies palpitations.

Respiratory:

Admits to nonproductive cough and wheeze. Denies hemoptysis or pleuritic chest pain.

GI:

Admits to decreased appetite, some abdominal fullness. Denies heartburn, abdominal pain, nausea, vomiting, diarrhea, rectal bleeding, change in bowel habits. No change in stool color or caliber.

GU:

No dysuria, polyuria, urinary retention or incontinence. No increased frequency. No blood in urine.

CNS:

No disturbance of smell, dizziness, vertigo, weakness, convulsions, gait disturbance, or involuntary movement.

Extremity:

Admits to recent worsening lower extremity swelling. Denies cyanosis.

Vascular:

No history of claudication but recent complaints of exertional leg pains.

Integument:

No rashes, change in moles, pigmentation, or pruritus noted by the patient.

Endocrine:

No increased hunger, thirst, urination. No hot or cold intolerance.

Hematology:

No history of bleeding or clotting disorders. No active bleeding.

Musculoskeletal:

No significant joint pains, muscle aches, deformities.

Psychiatric:

No mood swings or crying spells, No changes in sleep, personality or memory, No suicidal or homicidal ideation.

PHYSICAL EXAM**Vital Signs:**

Temp: 99°F, BP: 150/88 in right arm, pulse: 104 bpm, RR: 22 and shallow. Height: 63 in, Weight: 149 lb.

General:

Patient was alert, attentive, and oriented. She appeared extremely deconditioned.

Head:

Normocephalic and atraumatic.

Eyes:

PERLLA, EOMI, sclera was anicteric, and no xanthelasma was appreciated.

ENT:

Bilateral tympanic membranes were normal. Pharynx was clear without erythema or exudate.

Neck:

Neck was supple, trachea was midline, no carotid bruit was appreciated, and neck veins were slightly distended at 45 degrees.

Cardiovascular:

Faint S1 and prominent S2, rhythm was regular, rate was 104, 2/6 systolic ejection murmur at the RUSB without radiation is appreciated, S3 gallop is appreciated.

Pulmonary:

Decreased air entry bilaterally with normal quality of breath sounds and bilateral crackles midway up lower lung fields and wheezes throughout.

Abdomen:

Abdomen slightly distended but soft, nontender, without guarding or rigidity. Positive Hepatojugular reflux was elicited.

Extremities:

Extremities revealed muscle atrophy and 2 + pitting edema on right, 3+ on left. Bilateral cyanotic appearing feet

Osteopathic/Musculoskeletal:**Cranial:**

OA Extended rotated left and sidebent right. Suboccipital tissues were boggy.

Cervical:

C2 is rotated right, C5 is extended rotated and sidebent to the left.

Thoracic:

Increased kyphosis. T1 is in a neutral position rotated to the right and sidebent to the left, T3 and T4 are both extended, rotated and sidebent to the left. Skin was warm and boggy, yet with a ropey texture underneath in this region. T12 is flexed, rotated, and sidebent to the right. Sternum inferiorly distracted. Decreased diaphragmatic excursion bilaterally.

Ribs:

Bilateral ribs 10 to 12 have an inhalation dysfunction.

Lumbar:

Psoas hypertonicity on right. Slightly increased lumbar lordosis. Sacrum: Increased nutation

Pelvis:

Right anteriorly rotated innominate.

UE:

left elevated clavicle, internally rotated humerus.

LE:

Right internally rotated femur. Right femoral triangle congestion. Left externally rotated femur with femoral triangle congestion.

DIFFERENTIAL DIAGNOSIS

W.S. is a 79-year-old patient with multiple chronic medical problems presenting with acute or chronic dyspnea, cough,

The American College of Cardiology/ American Heart Association College of Cardiology Guidelines for Initial Evaluation of Heart Failure

- History and physical
- CBC
- Chemistry profile
- Calcium
- Magnesium
- Lipid profile
- LFT
- TSH
- UA
- Cardiac enzymes and BNP
- Oxygen saturation level and ABG if needed
- EKG
- CXR
- ECHO, if indicated

wheezing, lower extremity edema, and worsening fatigue. She also admits to several episodes of chest pressure. Although this is a complicated case, the patient's complaints can be categorized into those that are potentially life threatening and those related to her chronic disease. This constellation of symptoms suggests the following possible diagnoses: exacerbation of CHF, first episode of exacerbation of chronic obstructive pulmonary disease, acute bronchitis with exacerbation of chronic CHF, pneumonia, and acute ischemic heart disease.

To help narrow our differential and arrive at an accurate diagnosis, it is reasonable to check basic laboratory studies. The American College of Cardiology/American Heart Association College of Cardiology guidelines for initial evaluation of heart failure (Box 55.1) recommend a thorough history and physical examination, including assessment of volume status (Hunt, 2005). Recommended labs include complete blood count (CBC), chemistry profile including calcium and magnesium, lipid profile, liver function test (LFT), thyroid-stimulating hormone (TSH), and urinalysis (UA). Other tests include cardiac enzymes to evaluate cardiac ischemia, and a beta natriuretic peptide (BNP) level to corroborate suspicions of CHF. Liver function studies (LFT) should be considered in this patient, given her abdominal complaints.

In terms of diagnostic imaging and functional testing, a hemoglobin oxygen saturation level is used to evaluate the patient's oxygenation status and if this is abnormal, arterial blood gas (ABG) analysis is a reasonable next step. An electrocardiogram (EKG) is included to evaluate for acute changes consistent with cardiac ischemia. If possible, the EKG should be compared with a previous EKG to evaluate for changes. A chest x-ray (CXR) (Fig. 55.1) can provide evidence of lung infiltrates or findings suggestive of CHF such as vascular prominence, Kerley B lines, bilateral alveolar infiltrates, or bilateral pleural effusions.

Once we have decided on the most likely diagnosis, corroborative tests that are not in the current ACC/AHA guidelines may be used to confirm it such as impedance cardiography, which can be used to evaluate increased thoracic fluid in CHF. The ACC/AHA guidelines do recommend an ECHO to assess left ventricular (LV) function and look for the presence of critical valvular disease.

Figure 55-1 Typical heart failure CXR.

Ultimately making an accurate diagnosis is a combination of pattern recognition, test results, and clinical judgment.

In this case, the following laboratory and diagnostic test results were obtained:

- Na[±]: 130 mmol/L
- K[±]: 3.0 mmol/L
- Bun/Cr: 66/2.4mg/dL
- Magnesium: 1.9 mg/dL
- Troponin: I 1.5 ng/mL
- BNP: 10,000 pg/mL
- AST/ALT: 90/120u/L
- TSH: 1.25 mIU/L
- UA: specific gravity of 1.030, PH of 5.5, no cells or casts seen.
- Oxygen saturation: 87% on room air
- EKG: Sinus rhythm at 105 bpm. Left bundle branch block pattern. No changes compared with previous EKG from 1 year ago
- CXR: Cardiomegaly noted. Cephalization of vessels noted. Bilateral infiltrates. Small bilateral pleural effusions
- ECHO: Ejection fraction 45%. Moderate diastolic dysfunction. No critical valvular disease
- Impedance cardiogram: Increased thoracic fluid content. Decreased cardiac index. Increased systemic vascular resistance

In summary, we have a 79-year-old female with previous history of CAD, ischemic heart disease with ischemic cardiomyopathy, moderate diastolic dysfunction, previous episodes of CHF who complains of progressive dyspnea, fatigue, chest pressure, increased nitrate use, and a recent history of dietary indiscretion and depression.

Physical examination revealed findings consistent with CHF exacerbation, including:

- Past medical history—CAD, CHF, ischemic cardiomyopathy, and diastolic dysfunction
- Review of systems—progressive dyspnea, fatigue, chest pressure, increased nitrate use, dietary indiscretion, and depression
- Physical exam—tachypnea, shallow breathing, increased jugular venous distension, S3 gallop, pulmonary crackles and wheezes,

positive hepatojugular reflex, LE edema, somatic dysfunction at T3/4, decreased diaphragmatic excursion and thoracic compliance, hyperkyphosis, and femoral triangle congestion

These findings are consistent with the increased respiratory rate and shallow breathing. There was jugular vein distension which is evidence of right heart failure. There was an S3 gallop present on cardiac exam, and crackles and wheezes appreciated on pulmonary exam. Abdomen revealed some minimal distension but more significant was the positive hepatojugular reflux which is consistent with right heart failure. There was significant lower extremity edema which is also consistent with heart failure although could also be a side effect of Amlodipine (1).

There are no musculoskeletal findings specific to heart failure; however, this patient had somatic dysfunctions that have been associated with cardiovascular disease (108,109,110) such as the changes at occipital atlantal joint, C2, and the thoracic area (warm, boggy region at T3/4 region). Additionally, the changes in thoracic compliance, decreased diaphragmatic excursion, changes at the lumbar, sacrum, and pelvis while not specific for either heart disease or cardiac disease are common in patients with pulmonary and cardiovascular disease and could have been impacting W.S.'s presentation. Congestion in the femoral triangle could be seen in any condition of increased lower extremity edema as is this case.

Our patient's troponin and BNP are both elevated, which is evidence of acute cardiac ischemia. This is consistent with the patient's complaints of chest pressure that responded to nitrate use. It should be noted, however, that often in cases such as this, it may initially be unclear whether an acute ischemic event has triggered an exacerbation of heart failure or an exacerbation of heart failure has triggered acute cardiac ischemia. Furthermore, this patient has significantly decreased renal function and the elevated troponin level may a decrease in clearance of troponins from the blood, rather than cardiac ischemia.

The hyponatremia (sodium 130) seen in this patient may be from diuretic use, pulmonary pathology, or pain. It could also result from increased ADH secretion and the absorption of free water (2). Her UA showed a specific gravity of 1.030, which indicates increased ADH secretion. This could be from intravascular depletion (dehydration) or decreased effective circulating volume (fluid overload states). Given the other presenting complaints, historical features, physical examination findings, laboratory and radiological features of this case the latter scenario is more likely.

This patient has renal failure. This patient's baseline creatinine was 1.1 and baseline creatinine clearance was approximately 45 mL/min. When she arrived at the hospital, her creatinine clearance had decreased to approximately 20 mL/min. Although this is a complicated topic on its own, we can explain this by a combination of factors.

In heart failure, there is a decrease in effective circulating volume. This is due to decreased cardiac output. This causes a decrease in renal blood flow. In addition, this patient is on a diuretic agent (furosemide) which may have contributed to intravascular depletion and decreased renal blood flow. She is also taking an Angiotensin 2 receptor blocker. Angiotensin 2 constricts the efferent arteriole in the kidney and acts to increase filtration by raising intraglomerular pressure. Angiotensin 2 receptor blockers remove the ability to constrict the efferent arteriole and effectively reduce intraglomerular pressure and glomerular filtration. Although there may be other factors to

account for the renal findings, there is sufficient evidence that these factors are all prerenal and would act to reduce renal blood flows. The rise in serum creatinine indicates a decrease in glomerular filtration rate. (2). Hyponatremia, renal failure, increased specific gravity in UA, and elevated BNP in a patient who appears to be clinically volume overloaded helps support the diagnosis of heart failure. The diagnosis is further supported by the patient's CXR and echocardiographic findings both of which are consistent with the cardiomyopathy and impedance cardiography results.

HOSPITAL COURSE

The patient was admitted to the hospital and placed on a telemetry unit. The Heart Failure Society of America and the European Society of Cardiology have published guidelines on managing acute decompensated heart failure as well as other topics related to heart failure management (3,4). Our patient was started on nitrates to decrease preload and help decrease pulmonary pressures. Intravenous diuretic treatment was instituted to remove fluid from this patient. We used supplemental oxygen, which was effective at raising oxygen saturation levels. If this had not helped, we could have used noninvasive ventilation methods (CPAP and BiPAP), which is sometimes useful in heart failure exacerbations (5). The patient underwent musculoskeletal and osteopathic evaluation. Osteopathic diagnosis and treatment was instituted as an adjunct to medical treatment (6). Patient underwent serial cardiac enzyme testing, which showed a trend of decreasing enzyme levels. Fluid inputs and outputs were tracked and patient underwent daily weight testing. Patient had an excellent diuresis and over the course of 3 days she lost 5 lb of weight. Patient showed good improvement in oxygen levels and symptoms. She was able to be removed from supplemental oxygen. Because of patient's renal failure, her angiotensin receptor blocker was held. Additionally, because of renal failure, her metformin was also held during her hospitalization (7). Over the next 3 days, patient had normalization of her renal function, sodium level, and the remainder of her electrolytes. Serial electrocardiograms showed no changes. W.S. underwent repeat ECHO and results were obtained as earlier (8). The patient was eventually restarted on her regular medications. In addition, she received counseling from social work while in the hospital and was started on an antidepressant. This patient was discharged to her home at the assisted living with outpatient follow up arranged with her primary care physician. Visiting nurse was arranged to monitor patient at home and do serial weight and vital sign checks (9,10). The patient was referred to a supervised cardiac rehabilitation center to begin a comprehensive rehabilitation course (8). As an outpatient, W.S. continued to receive osteopathic evaluation and manipulative treatment as an adjunct to her medical management.

OSTEOPATHIC PATIENT MANAGEMENT

The case described above is primarily a case on CHF, but the principles that underlie the models of musculoskeletal medicine can apply to many different cardiovascular patients. For the purposes of illustration and brevity, we will focus on this patient and the topic of heart failure for the remainder of the chapter. This is not meant to be an in-depth discussion and review of the topic of heart

failure for there are many excellent articles and texts which cover this topic, but the purpose of this chapter is to view this topic through the osteopathic lens. The attempt was to focus in on those aspects of heart failure which relate to musculoskeletal medicine and the osteopathic perspective.

The five pathophysiologic models for musculoskeletal medicine are as follows:

1. Biomechanical model
2. Respiratory—circulatory model
3. Neurologic model
4. Metabolic—energy model
5. Behavioral model

Throughout the remainder of this chapter, we will look at the principles illustrated by this case in each of these pathophysiologic models. By understanding these principles, we can not only understand the role of musculoskeletal medicine in this patient but also construct a rationale for the role of osteopathic treatment to assist in the restoration of homeostasis in this and other patients with cardiovascular disease. At all times, attempts will be made to cite biological, physiologic, pathophysiologic, and clinical data to support an osteopathic approach; however, it should be noted that there are few randomized clinical trials that have examined this subject and fewer that meet the rigor of the current practices of evidenced based medicine. Because of this, most times we must rely on biological and pathophysiologic plausibility to support our approach.

BIOMECHANICAL MODEL

When there is a change in structure, functional changes follow. This is one of the basic osteopathic tenets. Structural changes can lead to changes in physiology and lead to pathology (11).

The heart and associated vascular system are essential for life. The heart is a muscular structure that resides in the mediastinum. It is encased in the pericardium that is anchored to the thoracic diaphragm below and that blends and encases the great vessels above. The left ventricle pumps blood into the systemic circulation via the aorta, which in turn transmits blood into branching vessels. The arterial system accepts blood via the aorta and distributes it throughout the body (Fig. 55.2). The circulatory system provides nourishment and oxygen for the cells and via the venous system provides a waste removal and blood return system (12). The structural model would view those elements that provide support and stability to our system. Structural elements are those of bone, muscle, fascia, and all connective tissues. Alterations in these can affect cardiovascular function. An extreme example is the effect of a pronounced kyphoscoliosis on cardiopulmonary function (13). Less obvious examples are the effect of small alterations in posture affecting the efficiency of the body's ability to regulate venous return to the heart and lymphatic flow to return into the systemic circulation (14). Yet another example is the development of compartment syndrome in an extremity after a trauma (15).

The heart undergoes remodeling and structural changes after MI and heart failure. These occur through neurohumoral activation as well as other processes. Besides the biochemical and biological changes that occur, there are structural alterations in the geometry and architecture that are deleterious. Dilation of the LV, thinning of its wall, change in shape of the left ventricle from an elliptical to a more spherical shape, and mitral valve incompetence can all occur. These changes create mechanical factors which worsen function. The change to a more spherical configuration creates an increase in end diastolic wall stress and dilation will result in

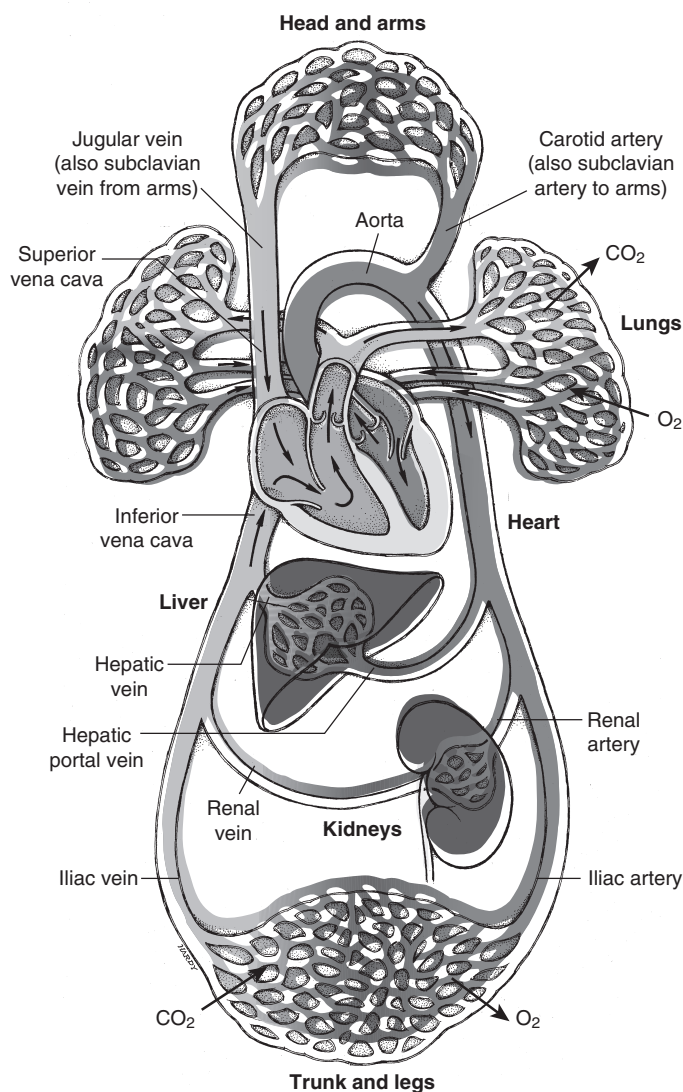

Figure 55-2 Schematic diagram of heart and vascular system and pressure changes with portal circulation.

increased LV work and oxygen usage. There is a cascade of events which result in biochemical and other biophysical changes in the myocardium (16).

The venous and lymphatic systems are low pressure systems and as such are much more susceptible to structural changes (17). The venous system is assisted by muscular contractions to assist in the return blood from the periphery into the abdomen. Once in the abdomen, diaphragmatic contractions and pressure differentials created by diaphragmatic contractions help return venous blood to the right atrium where it is then propelled by cardiac contraction to the lungs (18).

The lymphatic system is also a low pressure system and depends on several factors for return into the systemic circulation. The lymphatics have an intrinsic contraction that occurs at a rate of approximately every 6 seconds (19). The walls of the lymphatic vessels are anchored firmly by filaments (19). Motion of the extremity or structural deformity of the vessel will create pressure changes in the lymph vessel and help draw extravascular proteins and fluids into the lymphatic system and help propulsion. Muscular contraction also assists in propulsion away from the extremities. Valves

help prevent back flow. Once in the abdomen, pressure changes generated by the diaphragm will draw lymph into the cisterna chyli and eventually into the systemic circulation (18).

The changes in skeletal muscle tone and volume found in a deconditioned state, combined with decreased physical activity and immobility, can compromise musculoskeletal forces needed to assist in venous and lymphatic return from the periphery. Thoracic mechanics and diaphragmatic action will also greatly influence fluid movement, and if altered can lead to stasis and edema formation (20).

In this patient's surgical history, we note that she has had a CABG which required a midline sternotomy and rib retraction. This can alter the motion of the ribs post sternotomy (21). Recent research suggests that fascia has active contractile properties (22). CABG requires cutting through the pericardium which may change the fascial relations in the mediastinum and fascial attachments both superiorly (investing fascia of the great vessels up into the neck as the pretracheal fascia and eventually to the cranial base [23]) and inferiorly (connection to the central tendon of the diaphragm), although I know of no studies demonstrating this.

The patient's bypass vessels were harvested from her left lower leg. This often predisposes patients to the development of lower extremity edema. Our patient had worse pitting edema on the left and this is a likely contributing factor (24).

The somatic dysfunction in this patient's pelvis and lower extremities is also impacting venous and lymphatic drainage (20). This is evidenced by the increased congestion in the femoral triangle which serves as a drainage point for the lower extremities into the pelvis (25). As we work our way into the systemic circulation, drainage is further hampered by decreased diaphragmatic excursion and decreased rib motion. This decreases the range of the pressure differentials generated with each breath. Adding to this there is somatic dysfunction at the thoracic-lumbar junction and an increased kyphosis which also can decrease pressure changes and pumping action of the thoracoabdominal cylinder. Lastly, there is somatic dysfunction at the T1-rib 1/manubrium complex (14).

The thoracic duct, or left lymphatic duct, is a vascular structure which transmits lymph from the cisterna chyli and returns it into the systemic circulation. The thoracic duct must exit and then reenter this ring as it pierces sison fascia twice to join at the union of the left Internal jugular and Subclavian veins at which point the lymph reenters the systemic circulation (26,27). Drainage from the right half of the thorax and right upper extremity occurs through the right lymphatic duct, which reenters the circulation at the junction of the right subclavian vein and internal jugular vein (27,28). In the setting of a fluid overload state, these factors will further impede efficient return of lymph into the systemic circulation.

After informed consent was discussed and signed, this patient underwent osteopathic treatment at the hospital bedside. Gentle osteopathic technique was utilized throughout her treatment course. This was a combination of balanced ligamentous tension technique, myofascial release, and some articular techniques.

Our goals were to improve range of motion of joints, tissue texture and help improve musculoskeletal structural relationships to assist the body in restoring homeostasis.

RESPIRATORY-CIRCULATORY MODEL

The respiratory-circulatory model is a way of viewing the movement of fluids throughout the body and the maintenance of the intracellular and extracellular environments. From the macroscopic perspective, we look at the movement of blood and lymph

throughout the body. From a microscopic view, we can focus on the exchange of oxygen and nutrients and removal of metabolic waste products at a cellular level. There are many scenarios where macrocirculation appears intact, yet at the microscopic level the needs of the end tissues and cells are not met (29). If there is inadequate end tissue oxygen levels, the cells shift from aerobic to anaerobic metabolism (30). This causes the production of lactic acid. If there is inadequate drainage from these regions, there is accumulation of lactic acid. In some cases this is a local phenomenon, but in severe cases can be systemic. These severe cases can occur in heart failure, acute cardiac ischemia as well as other pathophysiologic states such as sepsis (31). Proper tissue functioning depends on adequate supply and removal. As already stated, efficient venous and lymphatic drainage from the extremities requires musculoskeletal assistance. Muscle tone, immobility, and fascial relationships influence this. Neurologic tone influences vascular smooth muscle diameter which influences both arterial inflow and venous and lymphatic outflow from tissues. Increased sympathetic tone raises blood pressure which can promote movement of fluids into the third spaces and inhibits drainage. It can also increase heart rate, contractility, and respiratory rate, which is an adaptive response to restore homeostasis by providing more flow through the system.

Thoracic cage mechanics and diaphragmatic action is important in moving lymph and venous blood from the abdomen and thorax back into circulation (18). The thoracic diaphragm acts as the "heart" of the lymphatic and venous system and as such contributes to preload. It anchors the heart within the pericardium and flattens the spinal curves with each contraction. Estimating 12 breaths per minute yields 17,280 breaths per day. Each healthy diaphragmatic contraction causes a profound change in pressure differentials in our bodies. This contributes to preload, draws air into our lungs, assists in lymphatic flow, flattens the spinal curves, and may contribute to passive diffusion processes throughout the body (18).

Heart failure is characterized by fluid overload. Fluid overload states are characterized by the movement of body fluids from the intravascular space to the extravascular space. Pulmonary edema is a frequent and potentially life-threatening consequence of decompensated heart failure. This occurs when there is an acute rise in the pulmonary capillary pressure, which overwhelms the ability of the pulmonary lymphatic system to drain the excess fluid (32).

The lymphatic system removes the products of inflammation and relieves congestion. Lymphatic system is under autonomic nervous system control, specifically the sympathetic system which produces vasoconstriction and impairs lymph drainage. The Peripheral Lymphatic Ducts contain valves which help move the lymph in one direction (Fig. 55.3). The Lymphatic system utilizes mechanical advantage as much as possible and as such lymphatic vessels travel with the arteries and are usually contained in a sheath. With each pulse bringing arterial blood to the extremities, the lymphatics get a mechanical boost back to the central circulation. Once in the central circulation, lymphatic flow is assisted by the diaphragm creating both pressure differentials and directly influencing the cisterna chyli (18).

Our patient had pleural effusions documented by CXR and peripheral edema. She also had some mild abdominal complaints and some abdominal distension on examination and elevated liver function enzymes in her blood testing. This pattern is consistent with abdominal third spacing and passive hepatic congestion although we did not confirm this with any studies.

In viewing our patient from this respiratory—circulatory perspective, we can see evidence of many of the above concepts.

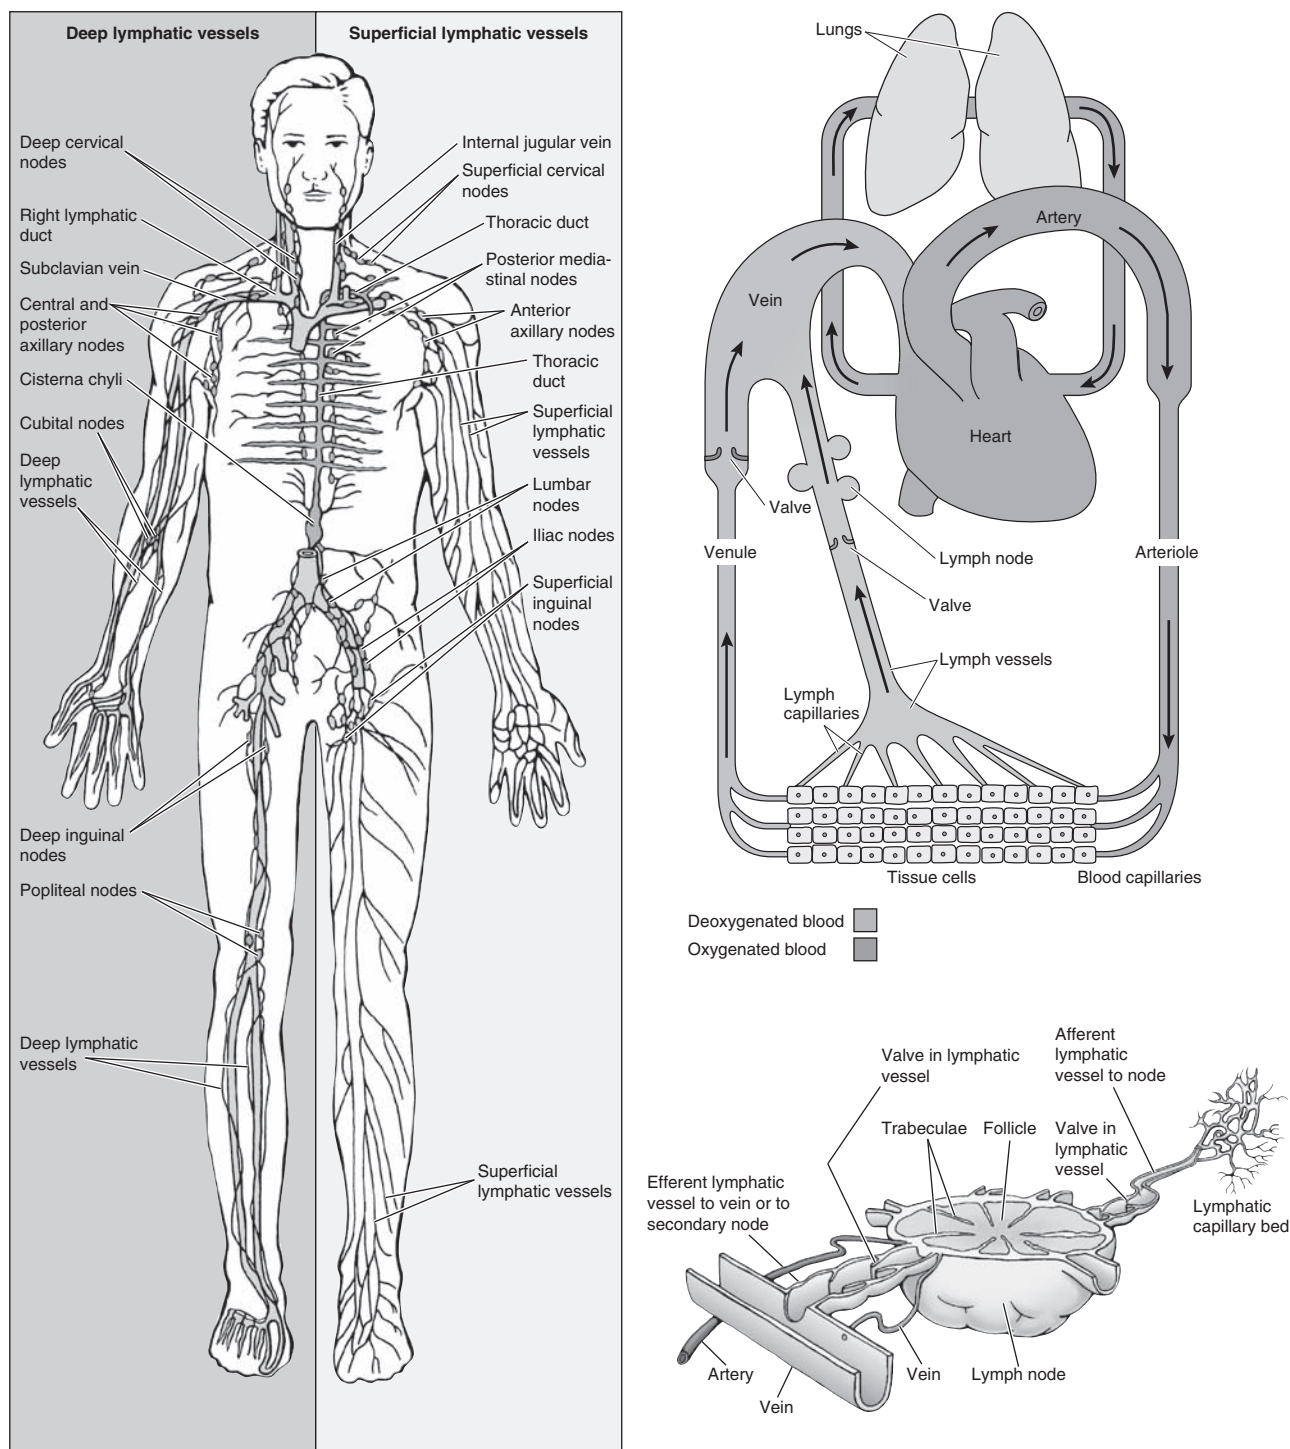

Figure 55-3 Lymphatics.

This patient had a cardiomyopathy with depressed ejection fraction and diastolic dysfunction which makes her more susceptible to fluid balance disturbances. This patient was taking rapid shallow breaths with poor diaphragmatic and thoracic excursion. Additionally, her thoracic mechanics were compromised by poor compliance and an increased kyphosis. This resulted in decreased thoracoabdominal pressure changes. She was quite deconditioned and along with increased lumbar lordosis and sacral nutation had limited musculoskeletal efficiency. She had increased sympathetic activity as evidenced by increased blood pressure, heart

rate, respiratory rate, and cyanotic appearing feet. This is also evidence of vasoconstriction that would affect fluid flow throughout the body.

One of the principles of osteopathic medicine is the ability of the body to self-regulate (11). It is the osteopathic physician's job to assist the body in this capacity. There are no adequate randomized controlled trials (RCT) addressing heart failure with OMT; however, by appreciating the factors that influenced this patient's clinical state, we used plausible ways to improve this patient's physiology using an osteopathic approach.

In terms of the respiratory-circulatory model, we looked to augment the pharmacologic and respiratory treatments that were initiated. Our goals were to augment venous and lymphatic drainage to assist in the ability to reabsorb fluids that had been third spaced. This improves the removal of metabolic wastes and as end tissue pressures are decreased, helps improve oxygen delivery and may improve delivery of medications.

Once the patient had stabilized, we addressed peripheral drainage by using myofascial release to improve the mechanics at the T1/rib 1/manubrium. This was done to optimize thoracic duct drainage. We then used a gentle lymph pump to induce drainage (14,33). We used balanced ligamentous tension (BLT) and rib raising to the rib cage, thorax, and lumbar spine to improve compliance, pliability, and decrease the spinal curvature (18). We redomed the diaphragm to improve efficiency of the thoracoabdominal-pelvic cylinder in order to improve flow through the central circulation (14). The goal of this was to increase pressure changes throughout the thoracoabdominal-pelvic cylinder. Lastly, lymphatic pump techniques were employed to assist drainage from the peripheral tissues. As we were mobilizing fluids from extravascular spaces and augmenting return into the systemic circulation, we were careful not to overload the patient at any point and paid careful attention to physiologic parameters (18).

In summary, the respiratory-circulatory model deals with fluid movement. Our patient had fluid overload. We used a combination of diuretics (furosemide), preload reduction (nitrates), and OMT to help restore more physiologic somatic relationships to facilitate venous and lymphatic drainage and help the body mobilize and ultimately remove excess fluids.

NEUROLOGIC MODEL

The cardiovascular system is under constant influence from the nervous system. The autonomic nervous system regulates heart rate, force of cardiac contraction, vascular tone, and blood pressure. The preferred homeostatic state of the cardiovascular system is under parasympathetic dominance. In decompensated heart failure and many chronic cases of heart failure, there are increased levels of catecholamines and hypersympathetatonia (34).

Under states of increased sympathetic tone, the body experiences increased heart rate (chronotropy), increased force of contraction (ionotropy), vasoconstriction, and elevated blood pressure. This in turn leads to increased myocardial oxygen demand. This is coupled with decreased coronary blood flow (CBF) from vasoconstriction and decreased time of diastole and this can lead to cardiac ischemia. Sympathetic and parasympathetic considerations are outlined in Table 55.1.

Under conditions of increased sympathetic tone, the myocardium undergoes a remodeling process (35). There is a prolonged healing time and decreased angiogenesis (36). This has been well recognized after both cardiac ischemia and in the setting of heart failure. This is the heart's attempt to restore homeostasis and occurs through several mechanisms including genetic transduction and protein synthesis. Unfortunately, under the influence of a hypersympathetic state and other neurohumoral influences, the body produces changes that are ineffective and inefficient (35). There are other pathologic structural changes that occur in the myocardium under these conditions which were discussed in the preceding section. This is part of the basis of providing beta blockade and has been shown to modify the remodeling process and improve survival (37–41). Also, adding ACE inhibitors or Angiotensin receptor blockers has also been found to prevent and reverse some of the pathologic remodeling that occurs and also improves mortality (42–46).

TABLE 55.1

Neurologic Model Considerations

Sympathetic	<ul style="list-style-type: none"> • Increased catecholamines • increased chronotropy/ionotropy • increased BP • Increased oxygen demand • Decreased CBF • Decreased time for diastole • Cardiac remodeling • Impaired Lymph drainage • Typical VSR
Parasympathetic	<ul style="list-style-type: none"> • Vagal • Decreased ionotropy (in some cases increased) • decreased chronotropy • Decreased BP • Increased CBF • Improved lymph drainage • Myocardial stabilizing • C1/2 segments No typical musculoskeletal reflex activity

Our patient had LV dysfunction/cardiomyopathy from her ischemic heart disease and resultant heart failure. This is a common remodeling pattern. On presentation, she had signs of hyper-sympathetic tone with elevated heart rate, blood pressure, and vasoconstriction (cool extremities).

The sympathetic outflow to the heart is from spinal levels T1–6 (47). The outflow nerves relay through the middle cervical ganglia and the stellate ganglion. They then join up with the cardiac plexus and ultimately synapse on and innervate the myocardium. Nerves carrying nociceptive information are called Nociceptors and travel with the sympathetic nerves. Cardiac nociceptors are very sensitive to ischemia and inflammation (36). Afferent nerves from both visceral and somatic structures synapse in the spinal cord onto the same lamina and facilitate viscerosomatic reflex somatic dysfunctions (48,49).

Viscerosomatic reflexes or segmental facilitation is characterized by warmth, muscle spasm, tenderness, and moisture. These are explained by the physiologic processes of vasodilation, reflex stimulation of alpha motoneurons in the deep back musculature, activation of the inflammatory cascade and inflammatory mediators such as substance P. These are the basic findings that characterize somatic dysfunctions. Several studies have been performed that demonstrate this and that has bearing in our patient (50,51).

In 1983, Cox et al. published a paper entitled “Palpable musculoskeletal findings in CAD: results of a double-blind study.” During this study, 97 patients who were having cardiac symptoms had a blinded musculoskeletal assessment for somatic dysfunction. All patients went on for cardiac catheterization. The authors concluded that there was a high correlation of changes at T4 in patients with significant cardiac disease in the men and women (52).

Nicholas published a similar study in the *British Medical Journal* in 1985 entitled “A somatic component to myocardial infarction.” The authors concluded there was a significantly higher incidence

of somatic dysfunction confined almost entirely to the upper for thoracic levels in patients experiencing MI. The authors then went on to conduct a 3-year follow-up published in the *British Medical Journal* in 1991 whereby they reassessed patients who had had MI in the previous study after 3 years post-MI. They found a significant decrease in palpable somatic dysfunctions in these patients who had survived and were treated (53,54).

A study whereby dogs were subjected to induced myocardial ischemia demonstrated increased muscle tension and texture from T2-5 on the left and increased amplitude on EMG on T4 and T5 during myocardial ischemia. This again demonstrates this well-known phenomenon of this viscerosomatic interaction. Interestingly, the same experiment conducted after sympathectomy failed to demonstrate these somatic changes reinforcing the pathway of viscerosomatic reflexes propagating through the sympathetic nervous system (55).

Although it has been written about in the osteopathic literature, and there are experimental data examining somatovisceral reflex activity, there are no studies that have investigated the impact of somatic dysfunction and in particular somatovisceral reflexes on the development or worsening of visceral dysfunction. This is, however, an intriguing concept that bears further study (56,57).

Our patient had changes in her upper thoracic region that correlate with cardiovascular viscerosomatic reflexes. In addition to the findings of acute viscerosomatic reflexes, such as the warmth and boggy tissue texture, she was found to have had an underlying ropey texture associated with more chronic somatic reflexes. Perhaps these findings may be contributing to her pathology by acting as a somatovisceral stimulus. Treatment was directed to this area; however, any acute viscerosomatic reflexes were treated with extreme care because of the potential to induce somatovisceral input on an already pathologic area (18). During outpatient follow-up, we focused on this region to reduce the long-term potential of somatovisceral reflexes to influence her cardiac physiology.

Parasympathetic outflow occurs through the right and left vagus nerves. The vagus nerve exits through the jugular foramen at the occipitomastoid suture and enters the cardiac plexus (58). Parasympathetic activity slows the heart rate and lowers the blood pressure and has a myocardial stabilizing effect that is antiarrhythmic. In the decompensated heart, such as a patient with heart failure, increased parasympathetic activity can increase ionotropy by moving the cardiac physiology to a more favorable portion of the Frank-Starling curve (59).

There are well-described “vagal reflexes” in the osteopathic literature that tend to involve the C2 segment. These have been described by osteopaths in both cardiac and pulmonary conditions (18,50). Along with the C2 segment, the occipital atlantal junction and occipitomastoid are areas that have been written about in osteopathic literature that tend to influence autonomic tone (60). Some experimental animal data have shown that vagal afferent activity is mediated through the C1 and C2 spinal segments (61,62). There is evidence that vagal cardiac afferent activity is inhibitory and decreased muscular spasms and affected response to cardiac sympathetic generated by introducing noxious cardiac stimulation (63–65).

Our patient did have changes at C2, which may indicate that there are changes in vagal tone. If treating C2 and the other areas of vagal outflow (jugular foramen, occipital mastoid suture, occipital atlantal joints) could change the autonomic balance toward a parasympathetic predominating state, then this could have a positive influence on our patient.

In addition to the above changes that take place, there are endocrine changes in the decompensated heart failure patient. There is a cascade of events that lead to heart failure. Our patient admits to eating salty foods and skipping some of her medications. This is quite common for heart failure patients (66). With increased salt load, there is increased retention of fluids. With increased fluids, there is increased pressure in the vasculature. There is a decrease in the effective circulating volume sensed by the kidneys. This leads to activation of the renin-angiotensin-aldosterone system, which attempts to preserve fluid volume by salt and fluid reabsorption. ADH secretion from the hypothalamus acts to reabsorb free water and can contribute to the development of hyponatremia. These changes can lead to heart failure, peripheral edema, and lymphatic stasis.

In summary, along with appropriate medical treatment (beta-blockade and ACE inhibition) to improve neurohumoral balance and prevent or reverse cardiac remodeling, we also utilize osteopathic treatment. Our osteopathic treatment goals were to identify somatic dysfunction that may have contributed to our patient's pathology and defacilitate viscerosomatic reflexes to assist her body help restore parasympathetic dominance to the autonomic nervous system.

METABOLIC ENERGY MODEL

Fatigue and dyspnea are common complaints in heart failure patients. These were our patient's presenting complaints. Exercise capacity is the ability to perform activity or endurance of an individual. Exercise intolerance is when an individual is not able to exercise to the expected level and is a concomitant feature of heart failure (67).

Exercise capacity depends on the ability of the cardiovascular system to deliver oxygen to exercising skeletal muscle and the ability of that muscle to extract oxygen from the blood and is based on cardiovascular dynamics, the ability of pulmonary gas exchange, and skeletal muscle metabolism (68). Peak exercise capacity is defined as the maximum of this capacity and maximal oxygen uptake (VO_{2max}) has a strong linear correlation with cardiac output and skeletal muscle blood flow (67).

Heart failure patients have a reduced capacity to increase cardiac output with even mild exertion (67). Several factors may contribute to the inability of heart failure patients to have sufficient response to exercise (Box 55.2). There is downregulation of beta receptors in the setting of chronically elevated catecholamine levels, and this results in a reduced ionotropic and chronotropic response (69,70). There is an increase in diastolic dysfunction that may impair cardiac output. There is a demonstrated, abnormal increase

Changes Occurring in Heart Failure

- Downregulation of beta receptors
- Increased diastolic dysfunction
- Increased wedge pressure
- Impaired pulmonary diffusion
- Muscle changes
- Myocyte apoptosis
- Reduced capillary density
- change from fatigue resistant to fatiguable
- change to anaerobic activity and increased lactic acid
- enhanced ergoreceptors and mechanoreceptors
- Diaphragm change from type 2 to type 1 fibers

in pulmonary wedge pressure that can exacerbate pulmonary congestion causing dyspnea and limiting exercise capacity. There can be impaired pulmonary diffusion even in the absence of pulmonary congestion.

Previously, it was thought that poor exercise capacity was due to depressed cardiac output and decreased oxygen delivery and that treatment with positive inotropes would improve symptoms and exercise capacity. Several studies investigated the impact of inotropes and vasodilators on exercise tolerance and found that although there were measurable increases in both cardiac output and peripheral blood flow, which would also increase oxygen delivery to exercising muscles, there were no significant increases in exercise capacity (71). The researchers were able to demonstrate that these interventions had limited impact on maximal oxygen consumption (VO_{2max}) and concluded that this may have been from decreased oxygen extraction by the muscle. Subsequently, it became recognized that there were intrinsic skeletal muscle changes, which were present in heart failure patients that had a substantial role in exercise tolerance. This became known as the muscle hypothesis (72).

There are several contributing factors in the development of skeletal muscle abnormalities. Physical deconditioning and inactivity is thought to be one factor. Another factor may be chronic hypoperfusion of skeletal muscle secondary to an inadequate response to exercise and a shift from aerobic to anaerobic metabolism (73).

There are several abnormalities that have been found in skeletal muscle of heart failure patients. Myocyte apoptosis has been identified and correlates with the degree of limitation in exercise capacity (74). Capillary density is reduced in heart failure patients compared with controls and has an inverse relationship with oxygen consumption (75). Biochemical abnormalities have been found that include changes in the types of muscle fibers from fatigue resistant to more fatigue able types of fibers (76). Other studies have found lower intracellular pH, indicating increased lactic acid buildup secondary to anaerobic metabolism, evidence of more rapid depletion and, less efficient utilization of high-energy phosphates both in the presence of preserved blood flow (77).

Functional abnormalities have been found in patient with heart failure. There has been demonstrated enhancement of ergoreceptors and metaboreceptors which may partially explain the increased ventilatory response and dyspnea in heart failure (78–80). Respiratory muscles undergo the above changes in heart failure patients and may also be contributing to the symptom complex by early fatigue (81). The diaphragm undergoes change from type 2 (fast twitch, glycolytic, fatigue susceptible) fibers to type 1 (slow twitch, oxidative, fatigue resistant) fibers, which is thought to be from the increased work of breathing and are similar to changes that occur with endurance training (82).

Exercise training and cardiac rehabilitation have been studied and have been shown to have many benefits: Improved peak VO_2 , improved muscle energetics, more efficient oxygen utilization, and improved symptoms of fatigue and dyspnea (83,84). Reduced sympathetic tone and increased vagal tone at rest, decreased systemic vascular resistance, reduced neurohumoral activity, and decreased levels of angiotensin, aldosterone, and BNP have also been demonstrated (85–88). Reversal of skeletal muscle abnormalities such as mitochondrial density and a shift from type 2 to type 1 muscle fibers are seen (89).

Improvements in VO_{2peak} can be seen and this translates to improved symptoms, exercise capacity, ability to perform activities of daily living and maintain independence. Also, improvement in NYHA class and 6-minute walk distance as well as reduction in hospitalization rates has been shown (90–93).

One meta-analysis concluded there was reduced mortality and rate of hospitalization in patients who participated in a supervised program for 8 weeks at 2 years of follow up (94).

Exercise training has a class 1 recommendation from the ACC/AHA for heart failure patients with reduced systolic function (8).

W.S. had a stiffened thorax to palpation. She was also very deconditioned and we could reasonably assume that her respiratory muscles were weakened. Because of these changes, the work of breathing and oxygen utilization would be expected to be increased.

One of the tenets of osteopathic medicine is the reciprocal nature of structure and function (11). Many of the above changes in cardiac and skeletal muscle function show this relationship. This is illustrated clearly by the diaphragm which changes structure on the microscopic level to accommodate functional changes on a macroscopic level.

There are no studies looking at the impact of osteopathic manipulation on energy utilization or documenting changes in the structure of skeletal, respiratory, or diaphragmatic muscle or the types of biophysical and biochemical changes listed previously in heart failure patients; however, by evaluating and treating somatic dysfunctions we addressed our patients structure in the expectation there would be a positive change in her function and functional status.

Our patient had complaints of both dyspnea and fatigue at baseline that were exacerbated at presentation. Once her acute symptoms were treated and she had clinical improvement, she was appropriately referred for a supervised cardiac rehabilitation program. She continued to undergo outpatient osteopathic diagnosis and treatment with a goal of reducing the work of breathing by improved pulmonary and chest wall compliance and improving her overall functional status by improved musculoskeletal relationships and decreased somatic dysfunction severity.

BEHAVIORAL MODEL

In osteopathic medicine, we are trained to look at the person as a whole. One of the basic tenets of osteopathic medicine is that the person is a unity of body, mind, and spirit (11). When we review the history of this patient, it is important to note some of the behavioral aspects that have a direct impact on this patient's life and well-being. She has recently lost her spouse of many years. Our patient reports that she has been feeling depressed because of a recent change in her living arrangement after the death of her husband. She had gone from living independently with her spouse to living interdependently alone in an assisted living apartment. She has been grieving these losses. This could be having a large impact in her immediate and long-term health. She admits to eating foods that she knows are deleterious for her. Additionally, she is skipping her medications at times. These two factors alone could precipitate her present condition and are in a large part resulting not from medical but more behavioral factors. This underscores the importance of addressing these concerns.

It has long been suspected that there is an increase in the incidence of depression in patients with heart failure (95,96). There have been several studies looking at this relationship. And it is becoming clear that not only is depression common in heart failure patients but that it is associated with increased mortality and rehospitalization (97,98). The findings of depression and social isolation worsen mortality (99). Anxiety, although also common in this population, has had conflicting data in regard to whether it is associated with increased mortality (99).

A recently published trial looked at treating heart failure patients with Sertraline for a period of 12 weeks. All patients in the

trial received nursing intervention and one arm of the trial received Sertraline (100,101). The trial showed no significant difference in patients treated with the antidepressant versus patients who had just nursing intervention. Although the study was not powered to look at hospitalization rates, there was a trend toward decreased hospitalization rates in the treatment group (101). Another interesting observation was that most of the patients benefited from nursing intervention. The author notes that this was a powerful intervention for these patients and may have blunted the response to medication (100). This may indicate that nursing intervention could be a preferred treatment for these patients. Additionally, the author believes that part of the reason antidepressants may help in heart failure is the restoration of normal autonomic function which may improve immune and inflammatory factors (100).

There are not many controlled trials looking at the treatment of mood disorders with manipulation. The studies that have been performed do not readily translate to the typical heart failure patients.

One small trial looked at treating premenopausal women with depression with osteopathic manipulation. The patients were randomized to either a control group, which received a structural examination; or a treatment group, which received OMT. Both groups received Paxil and psychotherapy weekly for 8 weeks. At the end of the study, there was a significant difference in favor of the treatment group. This was a small pilot study and it is unclear whether the results of this would translate to a larger population group (102). Additionally, this was a study done in pre-menopausal women, few of whom are typical heart failure patients.

Patients with fibromyalgia frequently have concomitant depression. A small study looked at treating patients with fibromyalgia with osteopathic treatment alone or in combination with medication. There was a noted improvement in depression in the patients treated with manipulation and medicine (103). Again, this does not easily translate to our patient's population.

Neither of the above studies found any somatic dysfunction pattern that was "typical" for the patient with depression. Despite the lack of applicable randomized control trials, these studies do offer some evidence in favor of osteopathic manipulation as an intervention for patients with depression. The etiology of this benefit is less clear.

One possible explanation may be found in the concept of Allostatic load. The term Allostatic load was coined by Dr. Bruce McEwen and refers to the physiological costs of chronic exposure to neuroendocrine immune stress responses. It is used to explain how frequent activation of the body's stress response, an essential tool

for managing acute threats, can in fact damage the body in the long run through activation of the hypothalamic-pituitary axis (104). The nervous system integrates information from the somatic, visceral, and psychological sources, and these can summate to achieve a stress response (Fig. 55.4). It is possible that by treating underlying somatic dysfunction we might decrease the overall allostatic load to our patients (105–107).

In our patient's case, it was important to discuss her living arrangement. It is important that this patient realize the implications of her actions on both her short-term and long-term health. W.S. received social work evaluation during her hospitalization and then outpatient follow-up from visiting nurse services and social work after she returned home. Additionally, as she believed that she was depressed and still grieving her losses, she was given the option of pharmacologic treatment, which she chose to begin. An antidepressant was started during her hospitalization and followed as an outpatient.

W.S. was receiving osteopathic treatment in hospital as part of a comprehensive plan of acute management for heart failure, and this was also continued after her hospitalization. Over time, this patient's mood did improve and she demonstrated a renewed interest in her health and well-being.

In osteopathic medicine, we are trained to look at the person as a whole. One of the basic tenets of osteopathic medicine is that the person is a unity of body, mind, and spirit (11). This is demonstrated in the connection between depression, anxiety, social isolation, and outcomes in heart failure referenced above. One intervention we can offer as physicians is to recognize the connection between heart failure and depression and take corrective steps in order to address this. Frequent outpatient physician visits, visiting nurse services, counseling, or mobilization of support services may provide improved care. Another intervention may be to include osteopathic diagnosis and treatment in our approach to these patients. Our goals would be to treat the somatic dysfunction we find with the possible goals of decreasing any somatic contribution to the overall allostatic load.

To summarize, there is an established connection between heart failure and depression. This has been demonstrated in several studies and should be in our minds when evaluating patients with either acute or chronic heart failure. It is reasonable to institute appropriate interventions in the belief that these will positively impact our patients' health and although no large RCTs demonstrate this, we have some cursory evidence and pathophysiologic rationale to include osteopathic treatment as a possible intervention in this patient population.

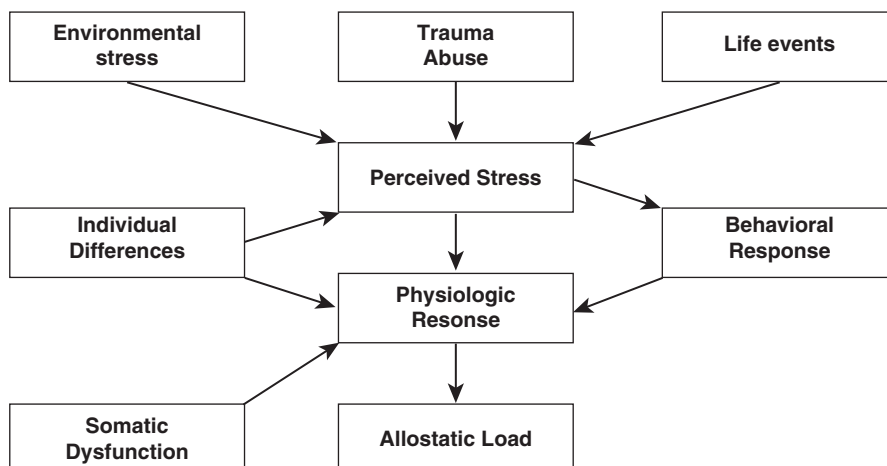

Figure 55-4 Allostatic load.

SUMMARY

Heart failure is a complicated diagnosis, which has many causes that can lead to changes in the structure of the heart and vasculature (remodeling), neurohumoral changes, and endocrinologic changes throughout the body. There are changes in the skeletal muscle that have a large contribution to two of the hallmark symptoms of heart failure: dyspnea and fatigue. There are medications that have been shown to improve mortality and morbidity and decrease hospitalization rates (8). Despite the available medical treatments, there are patients who will remain symptomatic and we must look at other impacting factors. There is a recognized correlation with depression, which should be recognized, evaluated, and will need to be treated in some patients. Lastly, although no sufficient RCTs have been conducted to examine the role of osteopathic medicine in heart failure, there are supporting data in the form of physiologic and pathophysiologic plausibility for the use of adjunctive osteopathic diagnosis and treatments.

W.S. showed many classic findings and complaints consistent with heart failure and has served to illustrate the principles in the evaluation and treatment of heart failure patients.

Adult with Chronic Pain and Depression

MICHAEL L. KUCHERA AND JOHN JEROME

KEY CONCEPTS

- Chronic pain and depression are intimately linked, physiologically and psychologically, and can become part of a vicious interdependent cycle.
- Osteopathic philosophy provides several perspectives within which to view this chronic pain–depression cycle.
- Helping a patient to cope with his or her pain can break that cycle and influence his or her life in many ways.

CASE VIGNETTE

Chuck, a 45-year-old farmhand, was seen in the clinic with back pain.

Chief Complaint:

Chronic back pain for 3 years. This discomfort, present on his right side, was described as deep, nagging, and constant, with periods of acute exacerbation into the right hip, groin, and down the back of the leg to just above the knee. Full symptoms would occur with prolonged walking or standing and would persist for several weeks. The patient was unable to lift more than 25 pounds (11 kg) without aggravating his symptoms. His back took several hours to fully relax after lying down, even on “good” days.

History of Present Illness:

Pain onset had first occurred while the patient carried a small bale of hay in front of his body. He had stepped in an unseen pot-hole, stumbled, and fell. The next day, he noticed full symptoms, which persisted as recurring episodes for several months. Between and during episodes, he achieved only partial relief with ibuprofen (800 mg/d). Physical therapy reportedly aggravated his pain.

During the next 3 years, the patient visited several physicians, visits that were prompted by three to four substantial recurrences of pain radiation per year. Negative results from electromyographic, magnetic resonance imaging, and radiographic studies—coupled with negative results from tests of reflex changes and nonspecific, nonradicular patterns of muscle weakness—during these 3 years left the patient with no specific diagnosis beyond “low back pain with recurrent lumbosacral sprain.” He was unable to work on the farm and said that he had the impression that physicians believed he was “malingering,” or “lazy.” He was depressed because he thought his family also shared these beliefs, and he became concerned about his marriage.

PHYSICAL EXAMINATION

Clinical findings revealed a slim white man who denied smoking or illicit drug use. Review of his nonmusculoskeletal systems was noncontributory. Results of deep tendon reflexes, pathologic reflexes, straight leg-raising testing, Chapman’s viscerosomatic reflex screen, and Lloyd test were all negative. The result for a Trendelenburg test (a test to determine any weakness of hip abductors) of the right leg was questionable. Somatic dysfunction included reduced lumbar lordosis, left iliacus tender point, right sacral shear, and tenderness over the right iliolumbar ligament and posterior sacroiliac ligament,

as well as tenderness and hypertonicity in the right piriformis muscle. Flexion tests and measurements of iliac crest height along with very mild scoliotic spinal curves suggested a possible “short leg syndrome.” The common compensatory pattern noted by Zink and Lawson was violated by the lumbopelvic junction, and the pelvic floor was tight.

The patient was informed that this constellation of somatic dysfunction could cause chronic low back pain (LBP) that often responded favorably to osteopathic manipulative treatment (OMT).

DIFFERENTIAL DIAGNOSIS

Depression

Depression occurs in roughly 50% of chronic pain patients (56–58). Pain severity is strongly associated with depressed mood (59, 60). Depression worsens suffering (54) (55) by interfering with social and occupational functioning (29, 30) and decreases activity levels (31, 32). Finally, depression predicts negative treatment outcome, disability (33), and increased use of medical services (34). Early treatment of depression avoids excessive diagnostic procedures and multiple surgeries (35).

Chuck depression appears more situational (i.e., dysthymic disorder) and secondary to his pain as there is irritability, sadness, lack of interest in enjoyed activities, fear of movement and reinjury by heavy farm work. In contrast, more severe clinical depression (i.e., major depressive disorder) would occur most of the day, every day with weight change of more than 5% of body weight in a month, insomnia or hypersomnia, fatigue, irritability, difficulties with concentration, and reoccurrent suicidal ideation (39). Remember, pain alone is not usually a sufficient condition for the development of depression (40, 41). Specific perpetuating factors that predict depression secondary to pain are (41–44):

1. Reduction in activity
2. Interference with life activities
3. Decreased sense of quality of life
4. Work interference

All these factors appear present in Chuck case.

Family and Spouse Response

Research has consistently shown that the spouse of the chronic pain patient can exert powerful effects on the way the patient copes

with their pain (15). Much of the research focuses on the spouse reactions to their partners in pain.

Chronic LBP drastically changes the roles and relationships in families. The impact is particularly great for the spouses (45, 46) leading to more negative interactions (47–49) which we see in this case. Actually, the spouses are themselves also at greater risk of depression (50), loneliness (49), distress (50, 51), and marital discord (52, 53). Marital discord means less communicating, commitment, sexual frequency (50, 51), and more negative interactions (47). Spouse perceptions that appear critical (i.e., “lazy”) and that are hostile or punishing further add to negative thinking and depression on the patients part (52, 53). On the flip side, when pain patients are satisfied with the response of their spouse, then pain and depression are less likely. Spousal support may help to mitigate negative thinking.

Chronic Pain

Persistent nonmalignant pain is not a single entity. It has many different causes and manifestations, each with varied characteristics and names. In an osteopathic approach, a complete patient history and physical examination are used to reveal any previously unidentified pain generator or underlying cause for persistent pain. In addition, osteopathic physicians need to understand the individual’s unique response to pain and will therefore screen patients for signs of depression or other significant nonsomatic links contributing to pain. Based on such patient histories and examinations, osteopathic practitioners can develop individualized osteopathic prescriptions to address their findings, with the mutually beneficial goals of decreasing biomechanical, biochemical, and psychological stressors, removing barriers to self-healing, self-regulating mechanisms, and empowering patients themselves to reduce the impact of persistent pain on quality of life.

Figure 56.1 shows an osteopathic algorithm for management of patients with chronic or recurrent pain. An OMM approach that integrates palpatory diagnosis and OMT provides balance for patients with persistent nonmalignant pain seeking both state-of-the-art interventions and individualized patient-centered care. The various osteopathic models offer strategies to both decrease pain and to enhance physiologic function. In this fashion, the osteopathic perspective offers two major recognized advantages: an expanded differential of potentially treatable etiologies and an individualized, patient-centered pain prescription based on the application of osteopathic principles.

Osteopathic Patient Management

In addition to providing appropriate strategies for management of pain, an osteopathic management algorithm (such as the one shown in Fig 56.1) incorporates the five common osteopathic models of care to identify and address a variety of host factors directed toward the underlying cause, secondary signs and symptoms, and the tangible and persistent impact of both in patients. These models also provide a framework for the patient education needed to foster compliance built on an understanding of complex interrelationships among many different factors. Each osteopathic prescription seeks to discover and incorporate those factors needed to address a patient’s unique response to pain. The emphasis in treating patients who have persistent nonmalignant pain should be on improving function, decreasing peripheral nociception and central facilitation, and empowering individuals to move forward in resuming their normal activities of daily living.

The five most commonly applied osteopathic models include:

1. Biomechanical
2. Respiratory-circulatory

3. Neurologic
4. Metabolic-energy
5. Behavioral

Each was considered in this case history and two models in particular, biopsychosocial and postural/biomechanical, were found to be most specifically involved in this case. The other three models could easily have been involved as well and are therefore also discussed below.

Biomechanical Model

Significant and distinctive contributions to the evidence base surrounding LBP management commonly stem from application of the postural/biomechanical model. One such contribution lies in the identification of six somatic diagnoses commonly found in chronic back pain patients—the so-called dirty half-dozen. Using a structure-function approach, Greenman examined 183 patients who had persistent LBP for an average of 31 months. With osteopathic palpation, he identified three or more of six common diagnoses of somatic dysfunction in 50% of this cohort. Treatment with OMT to eliminate the identified somatic dysfunctions resulted in nearly 75% of the dysfunctional group returning to work or to their other activities of daily living (37).

Chuck benefited from the osteopathic clinician’s recognition of both the mechanism of injury and its potential relationship to at least three of this dirty half-dozen nonphysiological (traumatic) somatic dysfunctions documented in the literature. He also benefited from the capability of the DO to deliver effective OMT to return function to the region itself and to prepare the rest of the body to accept the associated postural and biomechanical change that would inevitably follow.

The beneficial role for manual modes of therapy, including OMT, in removing somatic dysfunction (the “manipulable lesion”) has been documented for patients with acute, subacute, and chronic LBP (33–36). In patients with LBP, spinal manipulations generally—and OMT specifically—produce physiologic effects similar to efficacious prescription nonsteroidal anti-inflammatory drugs, and has the potential to create effects more beneficial than either physical therapy or home back exercises (13, 36). Beneficial long-term functional outcomes for manual therapy have also been demonstrated in patients with chronic LBP (38). In fact, based on a review of the literature, Mein postulated that patient populations with subacute (secondary) and chronic (tertiary) LBP would benefit most from manipulative care, rather than from more costly behavioral modification, functional restoration, and chronic pain management programs. Why live with and learn to cope with pain if it is possible to remove somatic dysfunction?

In the postural/biomechanical model, OMT is applied primarily to remove somatic dysfunctions and their objective manifestations of tenderness, asymmetry, ROM alteration, and tissue texture change. That said, identifying and addressing the “key lesions” (or primary somatic dysfunctions) becomes the goal of the model. For example, postural imbalance and compensatory somatic dysfunction above the sacral shear was a real, albeit secondary, consequence in Chuck case. Even in the absence of significant LBP, it would therefore not have been uncommon for other patients like Chuck to be seen repetitively for other somatic symptoms (such as headache, midthoracic back ache, and knee pain) or even somato-visceral symptoms (such as irritable bowel syndrome) that would benefit transiently from the more limited use of the postural/biomechanical model.

Obviously, without specific palpatory examination for sacral, innominate, and pubic shears, they will be overlooked; pubic

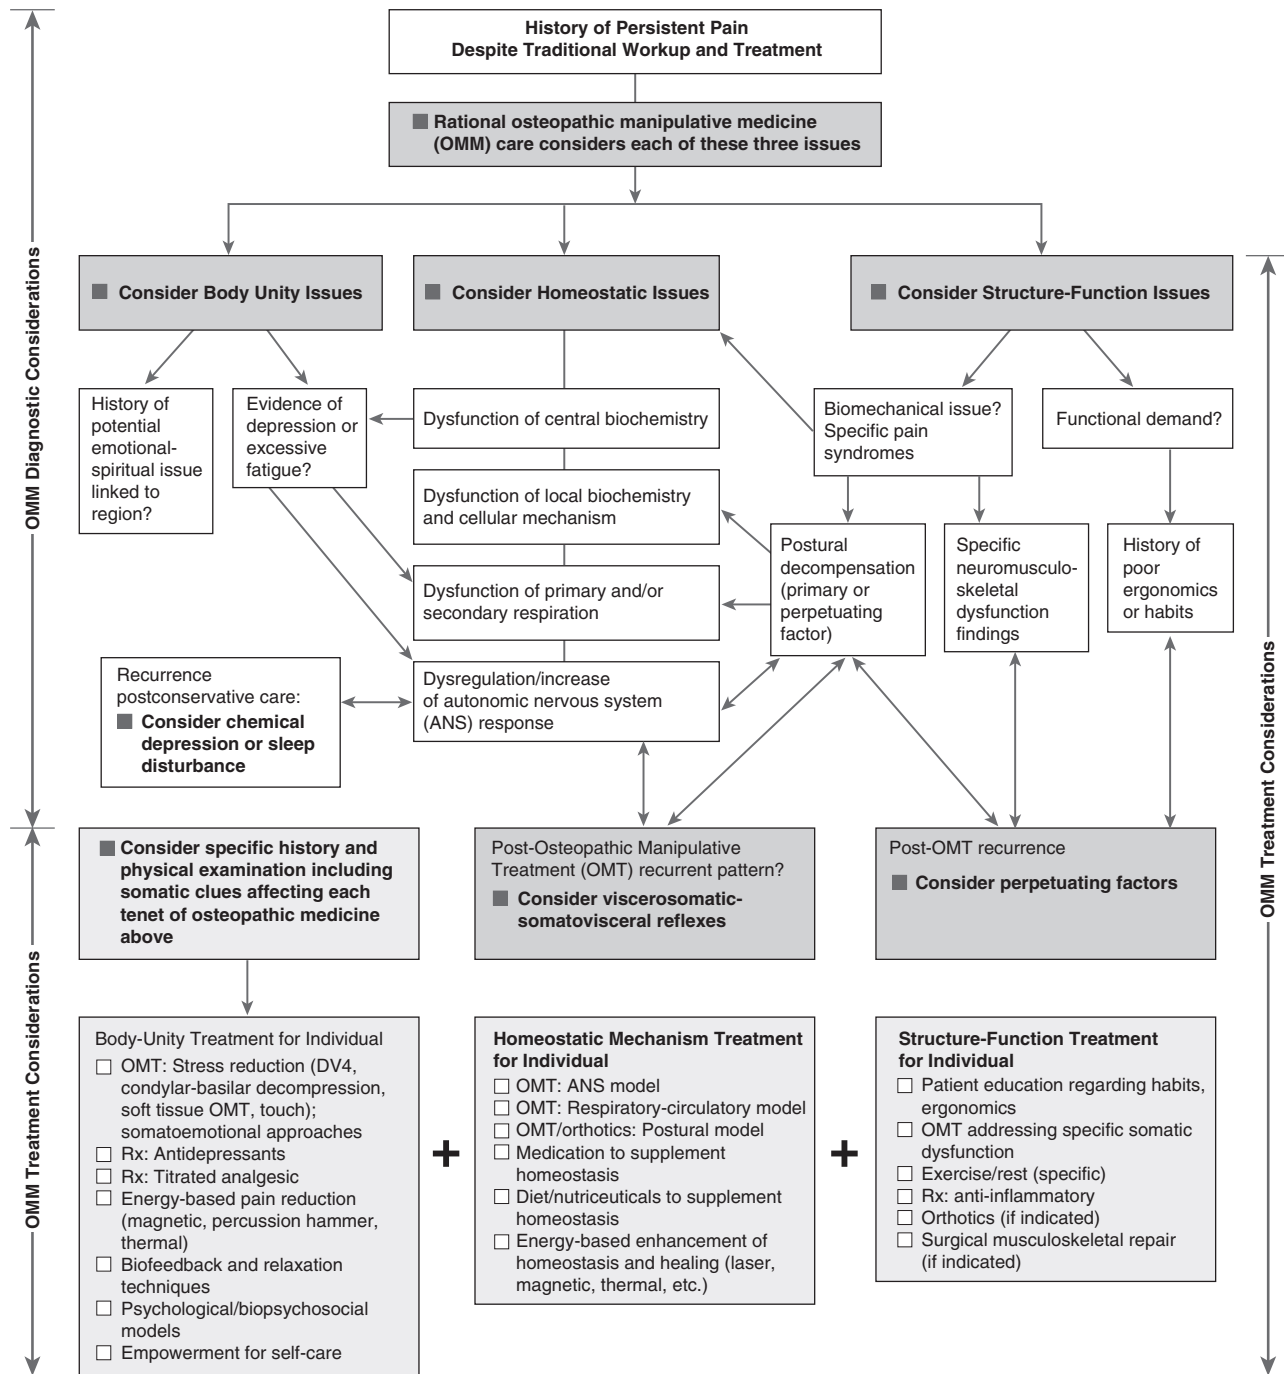

Figure 56-1 Osteopathic algorithm for management of patients with chronic or recurrent pain.

dysfunction (in the front of the pelvis) was present in 76% of Greenman dirty half-dozen causes of chronic LBP! Shears or compression at the pubic symphysis are common dysfunctions that can happen in the peripartum period, after a fall, and after a missed step (40); pubic dysfunction restricting pelvic motion anteriorly causes the two sacroiliac joints to overwork and therefore be painful. Likewise, dysfunction of one sacroiliac joint due to nonphysiologic pelvic shear forces greatly increases functional demand on the other sacroiliac joint and its stabilizing ligaments (40). In this frequently encountered scenario, a unilateral sacral dysfunction is overlooked because the associated pain is located in the overused sacroiliac joint rather than the dysfunctional one.

Failing to make a diagnosis of the key somatic dysfunctions or being misled by pain to concentrate treatment on secondary or compensatory sites constitute two significant elements in the postural/biomechanical model that the physician can rectify. Undiagnosed, key somatic dysfunctions—particularly “nonphysiologic dysfunctions” (e.g., traumatically induced pelvic shears)—might inadvertently result in several years of persistent pain (either locally or at distant sites linked through compensatory mechanisms) or the development of latent myofascial trigger points (MTrPs) that recur whenever they are stressed. If the sacral shear had been overlooked in Chuck case, his apparent “short leg syndrome” might have been recognized as another of the “dirty half-dozen” and treated with

a heel or shoe lift on the short leg side to level his sacral base. Unfortunately for Chuck, regardless of the impact initially on restoring balance, alignment, and function above with a lift, the long-term effect of such a strategy would be to increase the shear forces on the sacroiliac joints thereby increasing the patient's symptoms. The diagnosis of "short leg syndrome" (or more properly that of sacral base unleveling requiring lift therapy) should be reserved until—at a minimum—lumbopelvic and lower extremity somatic dysfunctions are addressed.

Reduction or alleviation of pain is one of the greatest benefits of applying the postural/biomechanical model, as was demonstrated in Chuck case. Furthermore, the close link between this somatic model and the biopsychosocial model has already been discussed. The remainder of this chapter will discuss the three other models that were considered or that were secondarily involved.

Respiratory-Circulatory Model

Note that mentally or emotionally stressed patients with chronic pain often breathe more shallowly and rapidly. As pain and stress are relieved, often the patient will be seen and heard to sigh deeply and switch their respiration over to a slower, deeper, and more effective respiration. This, in turn, helps to maintain that pain reduction. To this end, the respiratory-circulatory model has been applied by osteopathic physicians in managing chronic pain patient. One goal is to reduce pain and edema by removing local metabolic waste products such as substance P, histamine, kinins, and certain interleukins that add to the allostatic load. This and the link between the postural-biomechanical and respiratory-circulatory models have already been discussed in the chapters of this text associated with each topic.

In western medicine, focusing on the breath (as in Lamaze) has been an effective method for pain and stress reduction. The ancient Chinese used their own version of a respiratory-circulatory model—the combination of deep breathing and meditation—to help control arthritis pain. With inhalation, all spinal curves straighten; with exhalation all exaggerate; respiration creates motion down to the cellular level. This mental-spiritual focus can be linked with the act of breathing to create motion or to link it with other motions as in Tai Chi. In the first example, the key is motion; in the second, motion is key.

Maximizing the respiratory system to act as a suction pump to reduce local pain is accomplished not only through mechanical intervention by the osteopathic physician using OMT and postural strategies but also by teaching the patient how to link mind, spirit, and emotion (elements in the biopsychosocial model) to the structures most commonly thought of as being part of the respiratory-circulatory model. Again, regardless of the underlying mechanisms involved, the respiratory-circulatory model goals can be effectively applied in the chronic pain patient.

Neurological Model

Although there were only weak neurological signs in Chuck case, those objective findings present—and others—could certainly have been several more prominent. In similar cases possessing stronger neurological symptoms, either patient or physician might become fixated upon a pathologically linked neurological diagnosis such as radiculopathy; even when diagnostic tests or treatment trials fail to confirm the link between the anatomical site and the pain. In this same fashion—and even in the absence of neurological findings—often the concomitant finding of degenerative changes in the lumbar spine or that of an incidental bulging disc eventually prove to be only incidental; in the meantime, their diagnosis and ineffective treatment consume tremendous fiscal, emotional, and temporal resources.

A common example of this is seen in the constellation of pain in the back and lower extremity coupled with weakness of a number of muscles that happen to share the L5 nerve root as the source of their innervation. Travell and Simons have given the moniker "failed laminectomy syndrome" to the practice of surgical intervention for the constellation of back pain with lower extremity referral that is also associated with a positive Trendelenburg test due to pelvic stabilizer muscle weakness arising from MTrPs in the glutei muscles and the pain pattern produced by these MTrPs and stress on overworked posterior sacroiliac ligaments. Missing such a biomechanical cause can lead to unnecessary surgery while also magnifying the risk-to-benefit ratio of that procedure, which is, in fact, indicated in a small percentage of neurological cases with pathology.

Another true neurological finding such as sciatica secondary to Chuck sacral shear somatic dysfunction could easily have been present and would have further complicated the case presentation. Pelvic shears often disrupt muscle balance both related to their pelvic attachments and to the body's compensation for these disruptive somatic dysfunctions. Piriformis hypertonicity is commonly with sacral shears because of its sacral attachments. Such piriformis dysfunction can manifest with posterior pelvis and thigh pain, rarely moving below the knee, secondary to MTrPs or mechanical pressure upon—or even entrapment of—a portion of the sciatic nerve. In the 11% (Caucasian) to 33% (Asian) individuals with the anatomic variation in which the peroneal portion of the sciatic nerve passes through the body of the muscle, weakness of ankle dorsiflexion might be seen due to entrapment. Counterstrain or even procaine injection of the piriformis muscle may provide temporary relief from sciatica, referred pain, or even a mild footdrop, but will recur until the pelvic shear is corrected. One of the authors (MLK) has seen multiple injections and even transaction of the piriformis muscle in attempts to employ the neurological model where final resolution was only obtained using the postural/biomechanical approach.

Lastly, it was interesting in Chuck case to note that his irritable bowel symptoms resolved with the correction of the somatic dysfunctions associated with his traumatic and compensatory somatic dysfunctions. Patients like Chuck will often withhold information that they do not feel is relevant to their chronic pain only to remark about the coincidence of symptom resolution. This common occurrence might be explained through the interaction between somatic dysfunction and the autonomic nervous system. In applying this model to Chuck case, sacral or innominate shears and nociception from the piriformis might all be expected to increase sacral afferent load; overlapping with parasympathetic innervation to the left half of his colon. Unleveling of the sacral base in sacral shear cases typically leads to compensatory scoliotic curves often with a compensatory postural crossover at the thoracolumbar junction, segmental facilitation affecting the sympathetic innervation of the colon. Irritable bowel syndrome is considered as a functional manifestation of dysautonomia or autonomic imbalance between the parasympathetic and the sympathetic systems—leading to alternating diarrhea and constipation. This is further magnified by segmental facilitation that acts like a "neurological lens" for both biopsychosocial model stressors and increased nociceptive afferent load from biomechanical pain generators.

This case may have benefited from the palpation of collateral ganglia and Chapman's points associated with the area of the postural crossover (T11-L2). Such a rapid screening examination could have revealed tissue texture changes and tenderness consistent with colon dysfunction; this is empirically noted in perhaps 80% of irritable bowel cases. After a careful history, such additional somatic

clues discovered during the osteopathic structural examination and interpreted through an application of the neurological/autonomic model often prompts the DO to ask additional and more pointed questions. While in Chuck case, the condition appeared to be somatovisceral in nature, but one of the authors (MLK) has seen frequent instances where somatic dysfunction, even in the piriformis, has been perpetuated by visceral pathology through a viscerosomatic reflex.

The neuroendocrine/immune connection is another important component of the neurological model. Stress from pain, inability to accomplish desired tasks, marital discord, and depression all are capable of creating effects beyond central nervous system facilitation, in fact. The hypothalamic-pituitary adrenal axis is affected by the chronic pain state. The resultant increases in cortisol influence interleukin and other components of the immune system. This may impact overall health. Seeman and McEwan have described these relations in terms of allostatic load (61).

Behavioral Model

Over 80% of all physician visits are for complaints of pain. Pain patients are five times more likely to utilize health care services (54–56). Chuck, a 45-year-old farm hand, with chronic LBP represents what is recognized today as the major cause of absenteeism and disability in every industrialized society (59). Like Chuck, those who develop chronic pain will use more than 80% of all health care dollars for back pain.

The behavioral model of chronic pain emphasizes pain as a multidimensional (i.e., mind, body, spirit) phenomenon expressed as interactions among somatosensory inputs, cognitive and behavioral processes, emotions, and various adaptive/maladaptive coping strategies (57, 58). Chronic pain is punctuated by high incidence, high relapse, and low rate of recovery (Kuchera M.).

Osteopathic physicians treating chronic back pain often encounter returning symptoms. Sometimes, these patients are thought to be exaggerating, “lazy,” or malingering when they fail to make expected progress following initial treatments (27) (28). Patients like Chuck who has had pain for 3 years are particularly frustrating to health care providers trying to identify pain generators, somatic dysfunction, and a return to optimal function and health.

“Secondary gain,” “malingering,” “psychogenic pain,” “lazy,” “nonorganic,” etc. concepts are often invoked as possible explanations for relapse particularly when it is clear that the pain is now adding attention, possible injury compensation, avoidance of work, decreased physical activity/responsibility (16–19).

When all the psychosocial factors are examined, secondary gains are rare (20–22) and the secondary costs (20) are great. In Chuck’s case, loss of job, probable financial instability, and the family and physician questioning his intent create tremendous chronic stress affecting immune, neurologic, endocrine, and musculoskeletal systems. Couple this with shame or guilt for not being able to work and not living up to family expectations, perhaps anger for not being believed, and the sheer burden of persistent nociception, and it is clear that secondary losses outweigh any value added by pain. Given any chance of hope, Chuck, like most chronic pain patients, will strive to regain health and function. The art of managing the doctor/patient relationship is essential to success in this case.

Negative attitudes and beliefs by the family physician toward Chuck can greatly expand fear of pain and avoidance of movement and activity (9–12). Osteopathic practitioners know motion is the basic function of life (ECOP). There is strong evidence for chronic back pain that staying active, continuing normal activities, and

returning to work as soon as possible leads to faster recovery and lowers rates of disability. In fact, a belief by the physician that there is psychogenic pain (“lazy” or “malingering”) leads to no practical diagnosis, is dualistic (i.e., mind vs. body) and counterproductive. Counterproductive means we have challenged Chuck integrity and truthfulness (1,2); contributed to family disruption (7); set the stage for social isolation and withdrawal (13) and; encouraged hypervigilance, negative thinking, and fear (3,4) resulting in avoidance of activity and movement (5,6) as seen in this case. Depression would be the likely result.

CASE CONTINUED

OMT given to the patient consisted of applying the springing, direct method articular technique to the right sacral shear, counterstrain to the iliacus and piriformis tender points, and indirect balanced ligamentous tension to the thoracolumbar and sacral regions. Fascial patterns were treated with high-velocity low-amplitude techniques aimed toward symmetry, and abdominal and pelvic diaphragms were treated with indirect and direct myofascial release, respectively.

Post-OMT iliac crest heights and flexion measurements were normal. The patient left with instructions to drink lots of fluid, switch to acetaminophen as needed, avoid jumping or lifting until his next visit, and return in 1 week for follow-up examination.

At 1-week follow-up, the patient noted that both his acute and nagging pains had been relieved for nearly 4 days, but mild nagging pain had since recurred. A recurrence of sacral shear (approximately 40% of original) and piriformis muscle dysfunction were also noted and re-treated with OMT. Two weeks later, the patient returned with no symptoms and no recurrence of pain. He also noted in passing that what had been diagnosed as irritable bowel syndrome had “coincidentally” disappeared. He was instructed to make an appointment for 1 month later, but to cancel the appointment if he remained symptom-free. He phoned 1 month later, reporting that he was without pain and able to function normally at home.

FOLLOW-UP

Depression must be considered a comorbid condition if Chuck’s pain returns, without appreciable presence of somatic dysfunction or reinjury, and in association with continued tension in his marriage, sadness, fear of movement; or failure to return to work. In this case, the osteopathic physician must reassure Chuck and his wife that depression is common and it is normal to feel depressed under the stress of chronic pain and all the trouble it causes. The old saying, “Pain sets in a still joint and depression sets in a still person” applies here.

Remember, a patient’s depression does not invalidate somatic dysfunction, pain, or suffering, nor does it imply the pain is “not real,” or that being depressed is a personal weakness. Concepts such as sensitization, neuroplasticity, neuromodulation, kindling, wind-up, supersystem, dysregulation, etc. provide cogent hypothesis to explain the clinical spectrum of chronic LBP.

The simple message to Chuck is, “I believe you... I know that you have pain... the pain is real. The pain occurs in your body and for that we will do ..., etc.” “You also have a reaction to the pain that has affected your function, family and quality of life. For that we will do..., etc.”

CHRONIC PAIN CAN REQUIRE CHRONIC CARE

Expect relapse. Effectively managing the biopsychosocial component (25–28) for Chuck and his spouse requires the following:

- Establishing trust and rapport. Address fears. Rule out malin-gering and communicate this clearly to the patient and family. Define pain generators, mechanisms, and rationale for targeted individualized treatment
- Expect something back. Expect compliance in treatment and recognize specific goals and endpoints to treatment
- Provide logistic and psychosocial support. Advocate, document, and reinforce Chuck pain self-management strategies and active problem-solving efforts
- Confront secondary gain. Lay out clearly the cost to benefit to risk of secondary gain. Dispel illusions. “No ‘pot of gold’ at the end of a disabling rainbow... Cut your losses and live a meaningful life in spite of pain, if necessary”
- Ignore “exaggeration” and “pain talk” without being judgmental or condescending. Reinforce positive, ignore negative.
- Set goals of decreasing pain, restoring a functional role in the family and return to normal work activities as soon as possible.
- If relapse, discuss and address patient’s fears, gather more biopsychosocial information, and recommit to self-management goals of pain control (i.e., not cure) and functional improvement (i.e., not 100% recovery)
- Educate the family. Chuck family also needs education and support to help him and the treatment team achieve specific goals, rather than being an unintended obstacle to rehabilitation. Chuck spouse may be depressed and need treatment. Routinely evaluate the family every few visits and actively engage them in planning treatment. Therapy groups for patients and spouses have also proven very helpful in reducing depression and interpersonal sensitivity

SUMMARY

When osteopathic models are actively integrated and applied to create a treatment plan for a patient with chronic pain, the result is a personalized, effective care plan typically combining nonpharmacological treatment strategies with appropriate types and levels of pharmacotherapy. Placing the patient at the center of the program and including patient education in a comprehensive treatment plan helps to improve quality of life and to break the vicious cycle resulting from pathophysiological mechanisms of persistent pain.

Dizziness

HARRIET H. SHAW AND MICHAEL B. SHAW

KEY CONCEPTS

- Balance depends on the intricate interaction of **sensory input** (vestibular, visual, and proprioceptive), **central processing** (vestibular nuclear complex and cerebellum), and **motor response** (eyes and postural muscles).
- Disturbance in the cervical proprioceptive input to the vestibular nuclear complex and cerebellum is suggested as a cause for dizziness without hearing loss (cervicogenic vertigo), following neck injury.
- Benign paroxysmal positional vertigo, a common and well-described form of vertigo, is most effectively treated with particle repositioning maneuvers, aimed at the return of displaced otoconia to the vestibule.
- Looking for the root cause is paramount, since dizziness is a symptom that can be associated with a multitude of conditions and diseases.
- Vestibular sedating drugs such as meclizine and diazepam impair the process of central compensation by decreasing sensory input. These drugs should be avoided in most cases of dizziness, or limited to a short course.
- Because of its effect on proprioceptive input and its ability to help patients stay more active, osteopathic manipulative treatment has an important role in the treatment of many forms of dizziness.

CASE VIGNETTE

CC:

HH is a 72-year-old male who presents to an outpatient clinic complaining of dizziness.

HPI:

The patient reports a sensation of whirling and unsteadiness, which occurs daily, lasting several seconds to 2 hours. It began 1 month ago shortly following a motor vehicle accident in which he was driving, stopped at a red light, and struck from behind by a car going 35 miles/h. Even though he was wearing a seat belt, he experienced rapid flexion and extension of his neck, with subsequent neck pain that was diagnosed as cervical strain. Head and neck movement can bring on or aggravate the dizziness.

Current Medications:

Chlorothiazide 500 mg daily for control of hypertension; ibuprofen 200 mg b.i.d. to t.i.d. when needed for joint pain and stiffness.

Allergies:

None known to medications, inhalants, or food.

Past Medical/Surgical History:

The patient had right medial meniscectomy 20 years ago. Currently, he has Type II diabetes controlled with diet and exercise, mild osteoarthritis of the knees, and hypertension controlled with medication, diet, and exercise.

Environmental and Social History:

The patient denies smoking, admits to drinking four to five beers a week, and denies use of recreational drugs. He is a retired engineer, married with grown children.

Family History:

Two younger siblings are living with no apparent health problems. Mother had hypertension and died at age 92 of a myocardial infarction. Father died of colon cancer at age 80. There is no family history of vertigo or neurologic diseases.

Review of Systems:

Eyes—The patient's vision is corrected with glasses. He reports no blurred vision, double vision, or eye pain. **ENT**—He has dizziness as noted in chief complaint, but denies hearing loss, tinnitus, earaches, sore throat, rhinorrhea, and epistaxis. **Cardiovascular**—The patient was diagnosed with hypertension 5 years ago. He denies chest pain, fainting, shortness of breath, irregular heartbeats, and palpitations; reports no extremity edema. **Respiratory**—He denies difficulty breathing, wheezing, and cough. **Gastrointestinal**—He also denies nausea and vomiting, abdominal pain, diarrhea, and constipation. The patient had a normal colonoscopy 1 year ago. **Genitourinary**—The patient has no complaint of dysuria, hesitancy, or frequency. His last prostate exam, 6 months ago, revealed mild hypertrophy with no masses. **Musculoskeletal**—The patient complains of neck pain and stiffness worse on the right side in the upper neck. Ibuprofen offers some relief. He has bilateral knee pain with prolonged standing, also helped by ibuprofen. He denies muscle weakness. **Neurological**—The patient has vertigo as noted, but denies tremors, seizures, headaches, numbness, or tingling in the extremities. He has had no difficulty with gait other than the unsteadiness associated with his dizziness. He denies memory loss, difficulty with speech or coordination. **Psychological**—The patient denies anxiety, unwarranted sense of panic or depression. He reports no disturbance of sleep. **Endocrine**—He denies fatigue, skin and hair changes, and intolerance to heat or cold. **Hematologic/lymphatic**—He reports no abnormal swelling, bruising or bleeding; denies fatigue and feeling faint.

Vital Signs:

Temperature, 98.6°F; pulse, 74; respirations, 14/min; BP, 130/74 with no significant change from supine to upright; height, 6'1"; weight, 204 lb.

Physical Exam:

The patient is well nourished, appearing stated age, and is alert and communicative. He walks with a normal gait.

Head:

Head is normocephalic without signs of trauma. Pupils are equal and reactive to light and accommodation; conjunctiva is clear. Fundoscopic exam is normal. With the patient looking straight ahead (seated on a swivel stool), nystagmus is noted during rotation of the body.

ENT:

ENT exam is within normal limits. Mild, high frequency, bilateral hearing loss, appropriate to patient age, is identified. There are no bruits ausculted over the carotids and no lymphadenopathy or masses are noted in the neck.

Heart:

Heart has a regular rate and rhythm with no murmurs ausculted.

Lungs:

Lungs are clear to auscultation.

Abdomen:

Bowel sounds are heard in all four quadrants and the abdomen is soft and nontender with no masses palpated. Liver edge is not palpated or percussed below the costal margin.

Neurologic:

Neurologic exam reveals cranial nerves II to XII to be intact, deep tendon reflexes to be equally responsive bilaterally in upper and lower extremities. No atrophy, spasticity, clonus or tremors are noted. The patient is able to perform finger-to-nose, heel-to-shin, and Romberg tests. Sensation and two-point discrimination are intact.

Musculoskeletal/Structural:

Findings include tenderness and hypertonicity in the suboccipital area and right upper cervical muscles; left temporal internally rotated, right sphenobasilar side-bending rotation, OA is flexed sidebent left and rotated right, C3 is flexed sidebent and rotated to the left, the right scapula is superior when compared with the left, there is tenderness at the insertion of the right levator scapula, the lumbar paraspinal muscles are hypertonic on the right, and the talus is biomechanically anterior to the tibia on the right.

DISCUSSION

Dizziness is used by patients to describe a variety of symptoms including lightheadedness, feeling faint, weak or unsteady, as well as the sensation that the room is spinning. Giddiness is described as the feeling that one's head is spinning. Vertigo is the sensation of movement, usually spinning, rotating, or whirling, associated with dysfunction in the vestibular system. Disequilibrium, imbalance or unsteadiness, only occurs when walking or standing and may or may not be accompanied by vertigo.

The complaint of dizziness is a common one in the primary care and emergency department settings. It may be due to disease in almost any of the body systems and often presents a perplexing challenge for diagnosis and treatment. Severe dizziness can be disabling, but seldom represents a life-threatening condition. Accurate history and physical will often differentiate dizziness-like symptoms that are related to anemia, cardiac irregularities, orthostatic hypotension, transient ischemic attacks, and stroke. The association with vascular headaches may identify dizziness as a component of migraine. Neurologic signs could suggest a central nervous system lesion and require imagining for further diagnosis. Dizziness is identified in the *Physicians' Desk Reference* as a side effect to numerous prescription drugs, so an accurate drug history in relation to the patient's symptoms may indicate a pharmacologic cause. Lightheadedness, giddiness, faintness can be associated with hyperventilation, anxiety, and panic disorder, making a history of phobias, apprehension, worry, and insomnia helpful in diagnosis.

The assessment of vertigo depends on an understanding of the body's systems of balance. Dysfunction in any of the components can cause a patient to complain of dizziness or vertigo. Certain conditions or dysfunctions have warranted specific names and are associated with distinct presentations. Of these, labyrinthitis, BPPV, Meniere disease, acoustic neuroma, and cervicogenic vertigo will be discussed. Familiarity with the pertinent anatomy and physiology is important in interpreting any presentation of dizziness.

RELEVANT FUNCTIONAL ANATOMY AND PHYSIOLOGY

Balance is a whole-body experience that depends on the interaction of and processing of information from multiple sources. There are three primary sensory inputs to the balance system—vestibular (inner ear), visual, and proprioceptive. Central processing of balance-related information takes place in the vestibular nuclear complex and cerebellum. Motor output, primarily to the eyes and postural muscle, helps the body react to balance issues. (Fig. 57.1)

Vestibular System

The vestibular system consists of the bony and membranous labyrinth, including its blood and nerve supply. The complex, which is housed in the temporal bones bilaterally, consists of the cochlea (responsible for hearing), the semicircular canals, and a central chamber or vestibule. (Fig. 57.2) The bony portion contains perilymphatic fluid (somewhat like cerebral spinal fluid), in which the membranous structures are suspended. The membranous labyrinth contains endolymphatic fluid (similar to intracellular fluid) and specialized sensory hair cells, responsible for the neural firing of the labyrinth. (Fig. 57.3)

The semicircular canals are three in number, each having a widened end called the "ampulla." The sensory hair cells are located in the ampullae and are sensitive to rotational movement of the head. The semicircular canals are oriented perpendicular to each other, similar to the floor and two adjacent walls of a rectangular room. Pairing of the bilateral structures, in mirror image fashion, allows detection of motion in any direction. Their arrangement corresponds closely to the pulling directions of the extraocular muscles. Information from the semicircular canals helps the eyes remain still in space as the head moves, making clear vision possible.

Figure 57-1 Sensorimotor integration for balance—sensory input, central processing, and motor output.

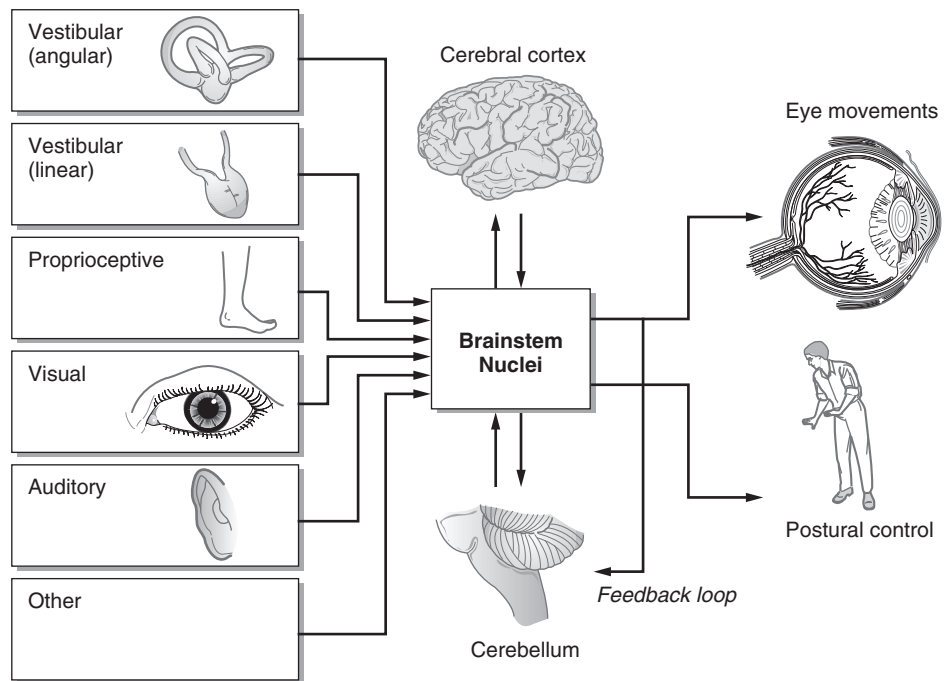

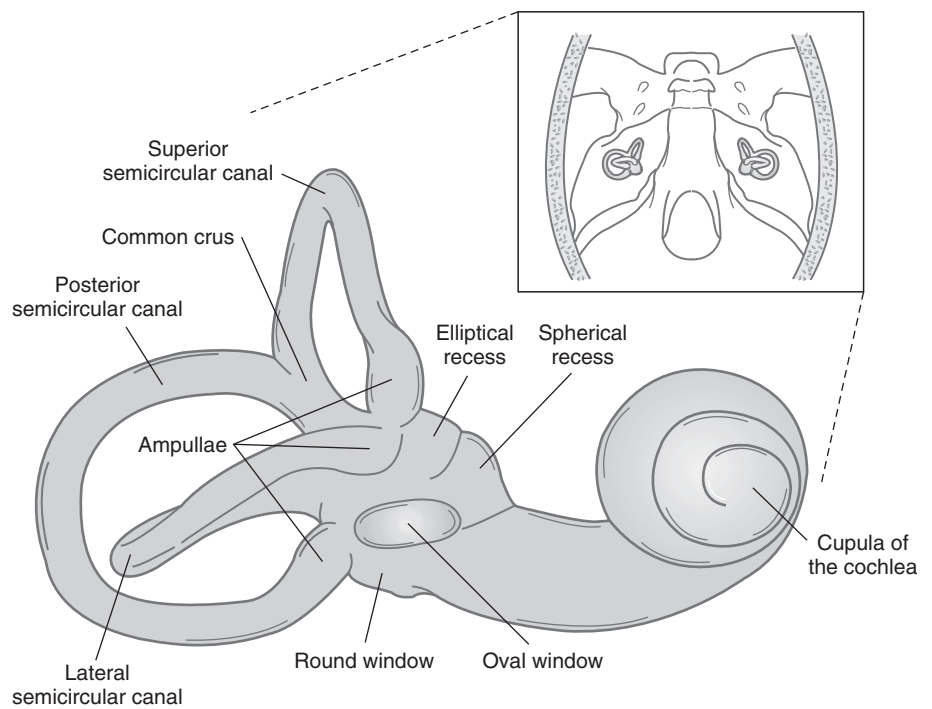

Figure 57-2 Vestibular complex housed in temporal bones.

The utricle and saccule are sensory organs of the membranous labyrinth. They are located in the vestibule and contain calcium carbonate crystals called otoconia, in addition to sensory hair cells. Their arrangement (the saccule is vertical while the utricle is horizontal) along with the mass of the otoconia make these otolith organs sensitive to gravity and linear acceleration (Fig. 57.4).

Afferent signals from the labyrinth are carried by the vestibular nerve, which courses along with the cochlear nerve, facial nerve, and labyrinthine artery, through the internal auditory canal of the petrous portion of the temporal bone. The vestibular nerve enters the brain stem at the pontomedullary junction, and its information goes to the cerebellum and vestibular nuclear complex.

Arterial blood supply to the labyrinth is from the vertebral basilar system. The labyrinthine artery usually is a branch of the anterior inferior cerebellar artery, but may be a direct branch from the basilar. Its branches supply the cochlea, semicircular canals, utricle, saccule, ampulla, and vestibular nerve. There is no collateral circulation, making the labyrinth very susceptible to ischemia and disruption of blood flow.

Visual and Proprioceptive Systems

Visual information is processed along with that from the vestibular system and all the proprioceptors of the body to determine position

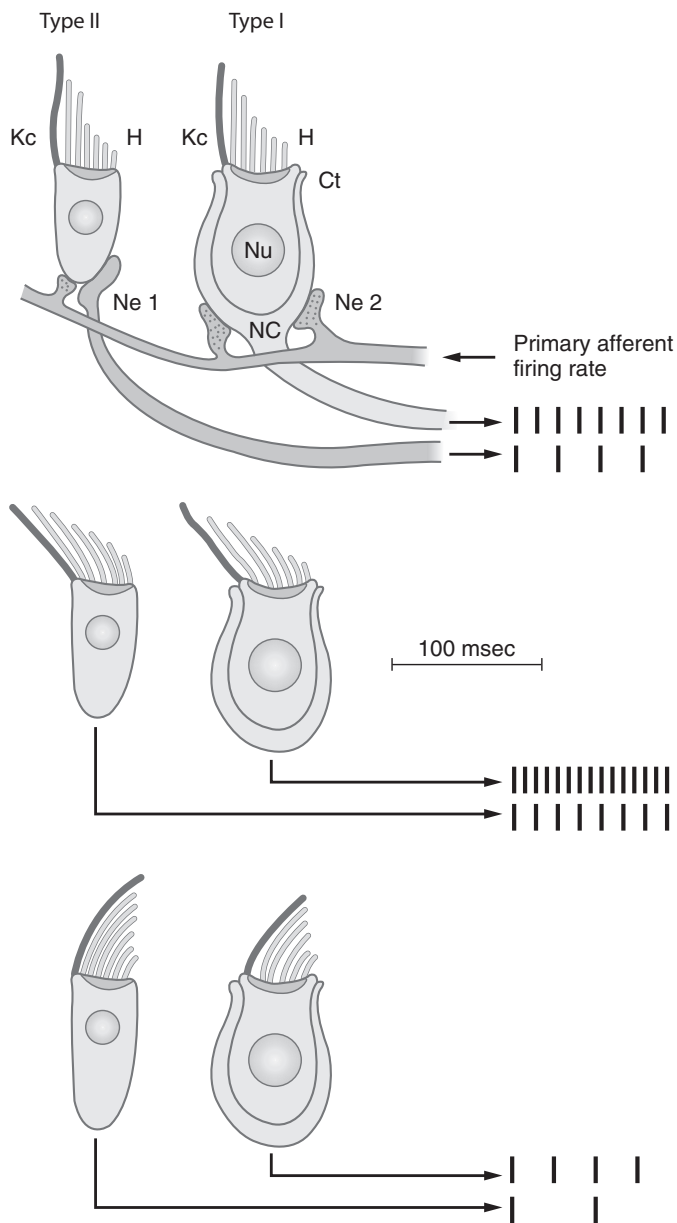

Figure 57-3 Specialized, sensory hair cells of the membranous labyrinth are deflected during head movement.

in space. Proprioceptive input from postural muscles, related fascia, joints, and ligaments is all interpreted, but information from the ankles and neck is especially important in balance control.

Central Processing

The vestibular nuclear complex (four major and seven minor nuclei) in the pons and medulla is the primary processor of the information from the above sources. It provides fast and direct connection between incoming information and motor output response. The cerebellum is the adaptive processor, acting as a modulator and monitor. Fine tuning and adjustments to the system are done in the cerebellum. Regulation of the various reflexes responsible for balance occurs due to interaction between the vestibular nuclear complex and the cerebellum. The balance function of the

brain stem and cerebellum depends on symmetrical, accurate, and consistent information from its sensory sources. It can, however, compensate for some missing information by using information from the other sources. Generally, compensation is possible if two of the three sources are functioning properly, even though this may require some adaptation over time.

Vestibuloocular Reflex

Using information from the semicircular canals and otoliths (sacculle and utricle), the vestibuloocular reflex (VOR) provides clear vision during head motion. Motor impulses to the extraocular eye muscles generate eye movement compensatory to head movement.

Vestibulospinal Reflex

Functioning to stabilize the body and prevent falling, the vestibulospinal reflex (VSR) is more complex than the VOR. Motor impulses are sent to skeletal muscles, in response to information reaching the vestibular nuclear complex and cerebellum. This information is then used to carry out strategies to maintain upright posture. These may include a number of complex interactions such as stepping forward, flexing the ankles, grabbing a stable object.

Vestibulocollic Reflex

Vestibulocollic reflex (VCR) acts to stabilize the neck in response to vestibular output. This reflex could explain the neck pain sometimes experienced with diseases of the inner ear—viscerosomatic reflex.

Cervico-ocular Reflex

Stimuli from neck ligaments, muscles, and joints cause a responsive movement of the eyes. This cervico-ocular reflex (COR) interacts with the VOR. Normally, the gain of the COR is very low.

Differential Diagnosis

Cervicogenic Vertigo

Many people have reported symptoms of dizziness, unsteadiness, and imbalance following neck injury, especially with whiplash-associated disorder (WAD). The symptoms are concurrent with neck pain and stiffness, and made worse by neck movement. There is no accompanying hearing loss or tinnitus, but nausea may occur. Disturbance in the cervical proprioceptive input to the vestibular nuclear complex and cerebellum has been suggested as the probable cause. De Jong and De Jong (1) produced ataxia and nystagmus by injection of local anesthetic into the neck. Studies based on posturography data showed patients with cervicobrachial pain had poorer postural control than normal subjects (2). Prolonged contraction of the posterior cervical muscles, bilaterally, can alter balance control (3). Montfoort et al. (4) observed increased COR gain in patients with WAD, seemingly linked to reduced neck mobility, and offering a possible explanation for the vertigo reported by these patients.

Various studies have shown different types of manual manipulation to be successful in improving symptoms of dizziness (5–7). In addition, numerous case reports over the years in the osteopathic literature discuss the success osteopathic manipulation in treating dizziness and vertigo. Still, controversy remains as to whether cervicogenic vertigo is a distinct diagnosis. Brandt and Bronstein (9)

Figure 57-4 Otolithic membrane in the utricle and saccule is embedded with calcium carbonate crystals. Linear acceleration or change with respect to gravity causes the membrane to shift and trigger underlying hair cells.

in their summary article on cervical vertigo note that vertigo can be accompanied by cervical pain, associated with head injury, whiplash injury or cervical spinal disease, and be dramatically improved with physiotherapy. Still the mechanism is yet to be proved. They conclude, “If cervical vertigo exists, appropriate management is the same as that for the cervical pain syndrome and that management should not be denied any patient.”

Acute Labyrinthitis

Inflammation or infection of the inner ear may occur alone or in combination with a viral, or less commonly, a bacterial infection. In acute labyrinthitis, the patient complains of sudden onset of severe vertigo. It is accompanied by hearing loss, tinnitus, nausea, and vomiting. Nystagmus is present. The acute episode lasts 24 to 48 hours. The condition slowly resolves with several days of disequilibrium and motion-induced vertigo, followed by slow improvement over several weeks.

Benign Paroxysmal Positional Vertigo

Thought to be caused by debris in the endolymph of the posterior semicircular canal, BPPV presents with episodic vertigo brought on by changes in head position. Commonly, patients report rolling over in bed or rapid neck extension precipitates symptoms. The episodes last 30 seconds to 2 minutes, and will subside even if the offending position is maintained. There is no associated hearing loss or tinnitus, but rotatory nystagmus accompanies the vertigo. Performing the Dix-Hallpike positioning test—a rapid change from sitting to lying, with head hanging turned toward affected side—brings on vertigo and nystagmus, which then subsides after

holding the position for 10 to 40 seconds. (Fig. 57.5) BPPV is self-limiting and responds to vestibular exercises and particle repositioning maneuver (Fig. 57.6).

Meniere Disease (Endolymphatic Hydrops)

A disorder of the inner ear with increased endolymphatic pressure, Meniere disease can cause devastating vestibular symptoms and hearing loss. Patients initially experience pressure in the ear, reduced hearing, and tinnitus. This is followed by severe vertigo with nausea and vomiting. Severe symptoms can last 30 minutes to 24 hours. Intensity of symptoms diminishes over several days time. Unsteadiness may persist for weeks. Hearing loss and tinnitus may gradually improve, or sensorineural loss may be permanent. As the disease progresses, attacks continue with continuation of hearing loss, but the severity of vertigo may decrease. Although salt restriction and diuretics have been used as treatment, there is no indication of their effectiveness. Betahistatin has been used with some effectiveness (10). Other vestibular suppressants should only be used during the acute attack, not on a chronic basis. Many patients require psychological support in coping with the ramifications of the disease.

Acoustic Neuroma (Vestibular Schwannoma)

Schwannoma of the eighth cranial nerve causes unilateral sensorineural hearing loss and tinnitus. Vertigo, when it occurs, is not an early symptom and is usually short lived, replaced by a sense of imbalance or disequilibrium. Suspicion of acoustic neuroma should be followed up with an MRI of the internal auditory canal with gadolinium contrast.

Figure 57-5 Dix-Hallpike maneuver for detecting BPPV.

Osteopathic Patient Management

As dizziness is a symptom that can be associated with a multitude of conditions and diseases, looking for the root cause is paramount. Somatic dysfunction may be present in any of these cases as an associated finding or, as some suggest, a significant etiologic factor. Somatic manifestations of vestibular disease could appear in the cervical area by way of shared neural reflex pathways (VSR, VCR).

Certainly, any identified underlying cause of dizziness needs to be treated. Often, a cause is not identified or available treatment is only symptomatic. Addressing the management from a multifaceted approach is usually the most successful.

Biomechanical Model

Trauma seems to play a role in some types of dizziness. Patients with WAD frequently complain of dizziness (11). Lockhart (12) reported on two cases of Meniere syndrome resulting from multiple traumatic brain injury. Treleaven et al. (13) showed WAD patients with dizziness showed significant error in returning their head to natural posture (joint position error), compared to controls and WAD patients without dizziness.

OMT to normalize proprioceptive input, improve range of motion, promote venous and lymphatic circulation, and balance neurologic reflexes makes sense in the management of patients with balance disorders.

Figure 57-6 Particle repositioning treatment for BPPV may be performed by physician and taught to patients.

Proprioceptors in the neck supply important information to the balance system of the central nervous system. Inappropriate signals due to cervical somatic dysfunction may be responsible for some forms of dizziness or exacerbation of dizziness due to other causes. Recent studies demonstrate decreased range of motion in the cervical spine causes increased activity in the CVR (4) and may partially explain the improvement in dizziness reported with manual manipulation (5–8,14).

Other areas of the body also provide proprioceptive input to help regulate balance and must respond when postural adjustments need to be made. Somatic dysfunction in any of these areas, particularly the feet and ankles, may impact balance and the individual's ability to compensate for imbalance. Range of motion in the extremities is important for balance rehabilitation training. OMT to improve extremity motion can be beneficial in rehabilitation for those patients suffering from dizziness.

Magoun (15) states, “vertigo often follows trauma to the ear or the neck.” Considering the location of the paired labyrinth organs on the petrous portions of the temporal bones bilaterally, and the importance of coordinated input from the two sides, dysfunction of the temporal bone may be responsible for disturbance of equilibrium. For those skilled in the cranial approach, gently realigning the temporal bones to their proper orientation and motion will normalize the inner ear mechanisms.

BPPV is a common and well-described form of vertigo, most effectively treated with particle repositioning maneuvers (16). The goal of the maneuvers is the return of displaced otoconia to the vestibule. Vestibular sedating drugs such as meclizine and diazepam are not effective and usually not recommended for these patients. Lower extremity strength, range of motion, and coordination have important roles in the rehabilitation of vertiginous conditions. Good structural diagnosis can help direct appropriate musculoskeletal treatment and home exercises. OMT for somatic dysfunction in the neck, cranium, and extremities can offer relief to many patients suffering from dizziness. For those with cervicogenic vertigo, resolution of involved somatic dysfunction is the treatment of choice.

Respiratory-Circulatory Model

Congestion in the middle and inner ear, while not a major recognized cause of vertigo, is a component to some diseases (e.g., Meniere’s) and may be associated with lightheadedness and imbalance. OMT aimed at improving venous and lymphatic circulation from the head and neck may offer symptomatic relief in those cases.

The vestibular system is particularly susceptible to vascular compromise. Awareness of postures and maneuvers that may impede blood flow through the vertebrobasilar system is important in patient education and when applying any type of manipulation. Avoidance of hyperextended positions of the upper cervical spine is recommended. If venous or lymphatic congestion is believed to be involved in the symptomatology, osteopathic techniques that promote venous and lymphatic drainage from the head may offer relief. Diuretics and salt restriction diets have been used with varying success in the treatment of Meniere’s in an attempt to decrease the inner ear fluid volume. Although the endolymphatic space of the labyrinth does not directly communicate with the subarachnoid space, fluid movement in the inner ear may be augmented by cranial movement. Cranial treatment to improve cranial bone motion has been used with some success to reduce the symptoms of Meniere disease.

Neurologic Model

When one aspect of the sensory input to the brain stem and cerebellum balance system is absent or dysfunctioning, the brain compensates by using information from the other systems. The more disinformation or lack of information, the more difficult is the compensation process. Rehabilitating patients with vertigo and balance disorders includes retraining the coordination of eye movement with head, neck, and body movements through exercises. Enhancing the intact sensory inputs may entail sharpening proprioceptive input from the neck or extremities through exercises, encouraging activities and OMT. Manipulative techniques contributing to a decrease in afferent load (e.g., counterstrain, indirect myofascial) could help balance the involved neural reflexes. Corrective lens, when needed, can improve the accuracy of sensory input from the eyes. Dural tension around the internal auditory meatus has been suggested to impair proper function of the nerves coursing there (vestibular, cochlear, and facial). Osteopathy in the

cranial field addresses bony relationships and dural tensions in the head, thereby impacting function of the vestibular nerve. Relieving tension in the upper cervical spine and around the jugular foramen (occipitomastoid suture) may reduce symptoms of nausea and vomiting by effecting vagal tone. Medication use must be carefully considered, as vestibular sedatives, such as meclizine, impair the process of central compensation by decreasing the sensory input. If needed to control severe dizziness, these drugs should be limited to a short course (usually two to three doses.) Anticholinergic (e.g., scopolamine) and antidopaminergic (e.g., prochlorperazine) drugs may also offer some relief. Combination therapy can be beneficial when a single drug regimen fails. Again, the sedating effects can be counterproductive to rehabilitation.

Metabolic-Energy Model

Postural considerations are especially important in the management of dizziness and balance disorders. Evaluation and treatment of postural imbalance from the standpoint of sacral base unlevelness, muscle tone problems, or postural strains can play an integral part in the resolution of dizziness and unsteadiness.

Drugs with potential for ototoxicity must be considered as a cause of vertigo. A few drugs such as the aminoglycoside antibiotics and some antineoplastic drugs cause irreversible damage. Others such as aspirin, when stopped, will result in resolution of symptoms.

Behavioral Model

Patients with dizziness who succumb to a sedentary life style have much worse outcomes. Encouraging activity, in spite of symptoms, is very important. Persistent vertigo can be very disruptive to a patient’s life, and many patients become frustrated, even depressed. Psychological support may be critical. Some antidepressant medications have dizziness as a side effect, so pharmacologic treatment must be carefully monitored. Psychological disorders may also manifest symptoms of dizziness. It is the second most common symptom reported by people with panic disorder.

Discussion

Since dizziness is used to describe a variety of sensations and may result from a variety of problems, approach to a patient complaining of dizziness must start with an in-depth history. Description of the patient’s sensation must be specific as to whether it is disorientation, a sense of moving, being off-balance, difficulty walking, impending faint, lightheadedness, motion sickness, panic, trouble focusing, or spinning. History of present illness should include the timing and nature of the first episode and subsequent episodes. What are the frequency and duration of the spells and when was the last spell? Precipitating factors and associated symptoms need to be considered. Other contributory information is found in medication history, allergic history, family history, social history, and review of systems.

Appreciation of the sensorineural integration involved in balance helps in diagnosis and treatment of dizziness. Always consider the three major components in achieving good balance—sensing the environment, central processing of information, and musculoskeletal response. Also consider the three dominant sensory inputs to this system—vestibular (inner ear), visual, somatosensory (joint proprioception). Comprehensive history and understanding of the involved anatomy and physiology will make the evaluation and treatment of patients with dizziness much more satisfying.

Patient Education: Self-treatment of Dizziness

- These exercises can be best done with the help of an assistant
- If on initial attempt of these exercises the response is too severe to continue, the prescribed medication may be used
- Refer to the diagrams below while reading these instructions

Identification of Problem Ear

The first step in the self treatment of dizziness is to identify the side of the poorly functioning ear. This is done as follows:

1. Identify the position on a firm bed where you can lie back without hitting anything.
2. Identify where your shoulders will lie when you lie back in the bed.
3. Place a midsized pillow on the bed where your shoulders will land when you lie back in the bed.
4. Position yourself in the bed as above.
5. Lower yourself with your shoulders contacting the pillow and your head contacting the bed and your head turned to the left.
6. Remain in that position for 2 minutes, and record your feelings.
7. Repeat the above maneuver; however, this time turn your head to the right.
8. Again remain in that position for 2 minutes and record your feelings.
9. Identify the side your head is turned to, which produced the most uncomfortable feelings whether they be dizziness, anxiety, or fear.
10. Record this side that produced the most uncomfortable feelings.

Treatment of the dizziness

1. Sit on the bed positioned as above and with the pillow positioned as above.
2. Turn your head 45 degrees.
 - a. If your head turned to the right produced the most uncomfortable feelings, turn to the right in No. 3.
 - b. If your head turned to the left produced the most uncomfortable feelings, turn to the left in No. 3.
3. Rapidly lie down in the bed turning your head to the above position, with your shoulders positioned on the pillow and your head touching the bed.
4. Remain in that position for 1 minute.
5. Turn your head 90 degrees toward the opposite side (45 degree angle but to the other side) without raising your head.
6. Remain in that position for 1 minute.
7. Turn your head 90 degrees further in the direction you are presently turned (so you will be looking down at an angle), and move your body as necessary.
8. Hold this position for 1 minute.
9. Sit up in this manner:
 - a. keep facing the direction your head was turned
 - b. hang feet off the bed
 - c. place your chin on your chest throughout the sitting up motion
10. Remain in that sitting position for 1 minute.
11. Do not lie flat for 24 hours. A semirecumbent position is best (recliner position).
12. Assume normal activity after 24 hours.

KEY CONCEPTS

- Pediatric ear pain can be caused by diseases and processes both within the ear structure, and referred to the ear from distant structures.
- Structural, environmental, genetic, ethnic, and other factors predispose some children to be “otitis-prone.”
- Osteopathic manipulative treatment (OMT) has been shown clinically to be complementary to routine medical care of pediatric ear pain, including acute otitis media.
- Suggested OMT protocols include the treatment of biomechanical, respiratory-circulatory, neurological, biopsychosocial, and metabolic aspects of the pediatric patient.
- The OMT of children differs from that of the adult.

CASE VIGNETTE

DW is a 2-year-old Native American female with a history of three prior ear infections in the last 12 months, who presents with irritability, pulling at her right ear and fever to 102°F for the past day. Her appetite and usual activity level are decreased. She had a mild upper respiratory infection the previous week, which was getting better until these symptoms presented. Her most recent ear infection, which responded to azithromycin, was 2 months prior, and was followed by documented normal tympanograms.

Past Medical History:

Her first ear infection was at 6 months of age, soon after she began attending day care. She has had no other serious illnesses or hospitalizations.

Birth History:

She was delivered via assisted suction extraction to a primigravida mother. She breast fed only for a week, due to poor suck, and required several formula changes during her first few months because of frequent vomiting. Also during her first few months, she had episodes of unexplained irritability lasting up to three hours, usually in the evening, which resolved by four months of age.

Developmental History:

Her development has been appropriate for age. Immunizations are up to date.

Allergies:

She has no known allergies to medications or food.

Social History:

She lives at home with her mother who is single and works at the day care center where the child attends. Mother smokes, but states she doesn't smoke around the child.

Family History:

There are no contributory inherited diseases, except that the mother has a history of frequent ear infections as a child, requiring placement of ventilation tubes.

REVIEW OF SYSTEMS

General:

The child's mother states that “she just hasn't been herself.” She is more irritable than usual and having trouble sleeping.

Respiratory:

She has been congested for about a week with alternating stuffy and runny nose. There has been no coughing, wheezing, or blueness about the lips or fingers.

Gastrointestinal:

Her appetite has been decreased since she became congested although she is taking fluids appropriately. There has been no diarrhea.

PHYSICAL EXAMINATION

Vital Signs:

Temperature 102°F, respirations 30, pulse 105

General:

The child is well hydrated but seems in obvious pain.

HEENT:

There is no evidence of tenderness with movement of her pinna or palpation over her jaw or face. Her right tympanic membrane (TM) is dull and inflamed, with a fluid level of yellow pus visualized behind the TM. The left TM is retracted but pearly, and neither TM moves. There is minimal white-yellow nasal drainage, and her throat shows mild redness, but no exudates. Her 2-year molars are erupting. Neck is supple, with mild anterior cervical lymphadenopathy.

Lungs:

Chest is clear to auscultation, and breathing is unlabored.

Heart:

Heart is normal sinus rhythm without murmur or gallop.

Abdomen:

Abdomen is soft and without organomegaly or masses.

Musculoskeletal:

Extremities show no cyanosis, clubbing, or edema, and pulses are normal.

Neurological:

Neurological exam is intact for cranial nerves (CN), strength, reflexes, and sensation.

Osteopathic Structural Examination:

There is compression of the cranial base with right temporal bone internally rotated and compression of the occipitomas-toid suture on the right. There is suboccipital muscular tension and the occipitoatlantal joint is extended. The thoracic inlet is rotated right and the abdominal diaphragm is rotated left, with lower ribs held in exhalation. The pelvis shows compression of the right sacroiliac area.

Laboratory

Rapid strep test is negative.

DIFFERENTIAL DIAGNOSIS

The causes of ear pain in children are more numerous than many would imagine. Ear pain can arise from the ear structures themselves (*primary etiology*), including the external, middle, or inner components, or from a nonotogenic origin (*secondary, or referred otalgia*), usually resulting from the complex sensory afferent innervation of the ear, which also provides innervation to a wide variety of other structures, many noncontiguous to the ear. While otitis media is reported to be one of the most common reasons that children visit their physicians (Wetmore, 2007), the actual frequency of this diagnosis as a cause of otalgia may range from as low as 11% (Ijaduola, 1985) to 46% (Ingvarsson, 1982). Secondary causes of otalgia are seen in 22% (Ijaduola) to 44% (Ingvarsson) of children and in as many as 50% of adults (Shah and Blevins, 2003).

Primary Ootalgia

Primary otalgia can arise from the external ear (otitis externa or mastoiditis) or middle ear (otitis media). Inner ear disease usually does not result in otalgia, due to the nature of its innervation. (See discussion of neurological model in pediatric ear pain.)

Otitis Externa

External ear pain is usually from one of two causes: otitis externa or a foreign body in the ear. Otitis externa can be subdivided into six distinct subgroups: (1) acute diffuse bacterial (swimmer's ear), (2) acute localized (furunculosis), (3) chronic, (4) eczematous, (5) necrotizing, and (6) fungal (Bruderly and Bojrab, 1996). All of these causes can give rise to exquisite ear pain, and treatment is based on the underlying cause. The primary cause of swimmer's ear is a rise in the normal acidic pH of the external auditory canal (EAC), which allows for overgrowth of pathogenic bacteria. Furunculosis is usually secondary to trauma of pilosebaceous units in the superior posterior EAC with bacterial overgrowth. Chronic otitis externa is a thickening of the skin of the EAC from chronic low-grade inflammation, leading to narrowing of the EAC with dryness, itching, cracking, and pain of the skin of the EAC. Eczematous otitis externa encompasses those dermatological conditions that predispose the EAC to inflammation. Necrotizing otitis externa is potentially life threatening, and consists of an invasive bacterial infection of components of the external ear and adjacent structures, usually in an immune-compromised patient. Funtally, fungal otitis externa, which is from

a fungal infection of the skin of the external ear, accounts for approximately 10% of otitis externa in the United States.

Foreign bodies in the EAC in children are commonly seen in the primary care clinic and emergency department. Most can be removed under direct visualization and without general anesthesia (Ologe et al., 2007). Impacted cerumen has also been associated with pediatric ear pain. Impacted cerumen may need a few days of softening with an over-the-counter agent prior to in-office removal with a curette. While there is no osteopathic manipulative treatment (OMT) generally indicated in the treatment of otitis externa and foreign bodies in the middle ear, the reader may be interested in a dissertation by Andrew Taylor Still in his *Philosophy of Osteopathy* (1899) regarding the significance of ear wax in diseases of the head and neck. In it, Dr. Still hypothesizes how ear wax production may be influenced by blood flow to the external ear canal, which is regulated by autonomic innervation, and how impairment of blood or lymph flow to and from the canal could be related to underlying somatic dysfunction.

Mastoiditis

Mastoiditis is a rare, but serious, complication of bacterial acute otitis media (AOM). Since the mastoid air space is continuous with the middle ear through the aditus ad antrum mastoideum, infection in the middle ear can spread to the mastoid air cells. Likewise, medical treatment of the AOM generally also treats any infection in the mastoid air space. The incidence of mastoiditis and other intracranial complications of AOM has been approximately 0.24% since the advent of routine antibiotic use in the 1960s. Recently, however, the incidence has been increasing due to emergence of resistant bacterial strains (Wetmore, 2007). Optimum treatment of mastoiditis requires early detection and prompt antimicrobial treatment. Complications of acute mastoiditis include periosteitis, acute mastoid osteitis, and intracranial infection.

The addition of OMT in the treatment of mastoiditis should be limited to treatment designed to improve functioning of the lymphatic system, and no direct treatment of the head and neck should be performed until the mastoid infection is under control. Such a treatment could include myofascial release of the thoracic inlet and abdominal diaphragm, and rib raising (respiratory-circulatory model).

Barotrauma

Barotrauma is due to rapidly changing pressures against the TM that cannot be adequately accommodated, leading to ear pain (Bluestone and Klein, 2001; Buchanan et al., 1999). This is most commonly seen in descent when flying in airplanes, when the dysfunctional eustachian tube (ET) is not able to open spontaneously or with yawning or swallowing, to equilibrate the relative negative middle ear pressure. Crying commonly opens the ET, via pull of the tensor veli palatini muscle. Persistent barotitis may result in high negative middle ear pressures and development of effusion. Interestingly, when middle ear effusion (MEE) is present, barotitis is less likely (Bluestone and Klein). Pretreatment before flying with decongestants has been recommended, although some literature indicates its usefulness is limited (Buchanan et al., 1999).

If the parent has been trained in the Galbreath mandibular drainage, doing this procedure during descent when flying in an airplane may assist the child in equilibrating the middle ear pressure, and hence reduce the pain. Treatment of the underlying ET dysfunction is the recommended means of preventing barotitis. Anatomical and functional changes during maturation of the cranial base and ET make barotitis less likely as the child ages. (For a discussion of

the rationale for osteopathic treatment to improve ET functioning, please see “The Cranial Base and the Eustachian Tube.”)

Otitis Media

Of all of the causes of pain originating from the middle ear, otitis media is by far the most common. AOM is the inflammation or infection of the air-filled middle ear space. It is a significant worldwide problem commonly affecting children between six and 18 months, and is the most frequent reason for childhood illness visits to a physician in the United States (Bluestone and Klein, 2001). The middle ear is an air-filled space that transmits sound vibrations from the TM to the inner ear, where sound is recognized. AOM is usually accompanied by development of fluid (effusion) in the middle ear during the inflammatory process. When the middle ear space is filled with fluid, the ability of the TM to vibrate and transmit sound is impaired. In 70% of children, this fluid persists for 2 weeks after the onset of middle ear infection, and in 40% of children, fluid is still present at 1 month (Bluestone and Klein). Persistent MEE is the sequela of AOM for which there is as yet no widely accepted medical treatment supported by the literature.

The cost of providing care for this prevalent disease is staggering. The annual medical and surgical cost for the treatment of otitis media was estimated to be \$5.3 billion in 1998 (Bondy et al., 2000). This estimate did not include social costs, such as lost workdays of caregivers and the costs for speech therapists and learning assistance. A 2001 report in the *Journal of Managed Care Pharmacy* estimated the cost of one episode of AOM to be \$483 and the cost for treatment of recurrent AOM including treatment with antibiotics and the eventual insertion of tympanostomy tubes to be \$3,683 (Pill, 2005). This cost is borne not only by families of the child, but also society.

Certain children have been described as more “otitis prone.” This is thought to be related to age (<3 years old), male gender, family history of ear infections, presence of older siblings or smokers in the home, not being breast fed, and attendance in day care (Bluestone and Klein, 2001; Wetmore, 2007). Children who have their first ear infection before 6 months old tend to have recurrent infections. Racial differences in incidence of otitis may be related to variations in cranial base morphology (see Biomechanical considerations; cranial base). Children in developing countries, children with poor nutrition, and those in lower socioeconomic groups also have more severe and persistent episodes (Lasisi 2007). Pacifier use has been documented to be associated with more episodes of otitis, as well as prone sleep position (Rovers et al., 2008; Sexton, 2008; Tully et al., 1995). The seasonal incidence of otitis follows the increased frequency of upper respiratory infections in general.

The diagnosis and management of uncomplicated AOM in children from two months through 12 years of age was clarified in 2004 by the publication of a Clinical Practice Guideline from the American Academy of Pediatrics (AAP) and the American Academy of Family Physicians (American Academy of Pediatrics Subcommittee on Management of Acute Otitis Media). This guideline states that diagnosis of AOM requires: (1) a history of acute onset of signs and symptoms (e.g., fever, irritability, ear pulling), (2) the presence of middle-ear effusion (confirmed by decreased mobility of the TM), and (3) signs and symptoms of middle-ear inflammation. These three requirements are further defined in that document. The usual treatment for AOM is antimicrobial, although it is recognized that some portion of these infections are viral in origin. Criteria for initial antibacterial treatment versus observation are stratified by age (<6 months, 6 months to 2 years, and >2 years), diagnostic certainty, illness severity, and assurance of follow-up. These protocols give a structured approach to antibiotic

use, with recommendations for “wait and see prescription” or “safety net antibiotic prescription” for children who are not acutely ill. This protocol has substantially reduced the unnecessary use of antibiotics in children (Spiro et al., 2006). The management recommendations in this Clinical Practice Guideline are not to be applied to children with recurrent AOM within 30 days of antibiotic treatment or otitis media with effusion (OME), or children with any underlying condition that may alter the natural course of AOM, such as cleft palate, genetic conditions, immunodeficiencies, and presence of cochlear implants. In cases of chronic MEE, which is often associated with recurrent AOM, there are similar guidelines suggesting when to consider a surgical approach and when not (AAP Clinical Practice Guideline: Otitis Media With Effusion, 2004; Maw et al., 1999). Antibiotic treatment has been shown to be more beneficial in children aged less than 2 years with bilateral AOM, and in those with both AOM and otorrhea (Rovers et al., 2006).

AOM becomes recurrent in about one third of children (Prellner et al., 1991). Consequently, one third of children are receiving frequent treatments with antimicrobials, leading to drug sensitivities and reactions and antimicrobial resistance, as well as significant cost. When recurrent infection leads to persistent middle ear fluid of 3 months or more duration, and hearing loss is documented, surgery is recommended to drain the middle ear of the fluid (American Academy of Pediatrics Clinical Practice Guideline: Otitis Media With Effusion, 2004). The recommended surgery performed for this reason is tympanostomy with tube placement, which has become the most common surgery performed in children in the United States beyond the newborn period, second only to newborn circumcision (Paradise et al., 2001). Evaluation of long-term benefits and sequelae of this procedure on children younger than age three with asymptomatic MEE is calling to question whether three months wait for spontaneous resolution of documented MEE before surgery is sufficient (Paradise et al., 2007).

It is known that the greatest risk of developing AOM is after a viral upper respiratory infection. Therefore, prevention of the initial viral infection is one means of preventing a secondary bacterial AOM. Clinical trials have generally shown improvement in recurrence rates of AOM in children immunized for influenza (Belshe et al., 1998; Clements et al., 1995; Hoberman et al., 2003), and the Centers for Disease Control now recommends immunization of healthy children at age six months for influenza and annually thereafter. Also recommended are immunizations for *Haemophilus influenzae* type b and pneumococcal vaccine beginning at age two months. (Center for Disease Control, 2008) Prolonged antibiotic prophylaxis was once a common practice, but its effect is small and the practice is now discouraged because of the risk of developing antibiotic-resistant bacteria (Wetmore, 2007).

While there are no recommendations for any complementary or alternative treatments for AOM in the 2004 Guidelines “based on limited or controversial data” (American Academy of Pediatrics Subcommittee on Management of Acute Otitis Media, 2004), osteopathic physicians have long reported favorable clinical outcomes in children treated with OMT in addition to standard medical care. In 1928, Galbreath reported on application of manipulation to the jaw for the treatment of “catarrh” (congestion) of the ear in the *Journal of the American Osteopathic Association*. Various case reports and practice guidelines advocating the use of OMT for the treatment of otitis media have been published in the osteopathic literature since that time (Bezilla, 1997; Carreiro, 2003; Centers et al., 2003; Frymann, 1998; Heatherington, 1995; Magoun 1996; Pital and Kurtz, 1989). There are two clinical studies in the literature, which were published after the period of review of articles utilized for the 2004 Clinical Practice Guidelines and

which demonstrate improved outcomes in children with recurrent AOM who receive OMT in addition to standard medical care (Degenhardt and Kuchera, 2006; Mills et al., 2003).

Miriam Mills, M.D., and others published a clinical trial in 2003 on 57 subjects, reporting on the efficacy of OMT as adjunctive treatment in recurrent AOM. This was a prospective, randomized, blinded, controlled, multicenter clinical trial with two study groups: standard care plus OMT and standard care alone. Those subjects who received standard care plus OMT for otitis media demonstrated the following significant findings in comparison to standard medical care alone at 6-month follow-up:

1. Fewer episodes of AOM ($p = 0.04$)
2. Fewer ENT surgeries ($p = 0.03$)
3. More surgery-free months ($p = 0.01$)
4. More normal tympanograms over 6 months ($p = 0.02$)

The Mills study demonstrated a significant improvement in clinical outcomes in children with recurrent AOM and persistent MEE who were treated with OMT in addition to their standard medical care, as compared to children receiving standard care only for treatment of recurrent AOM.

Degenhardt and Kuchera (2006) administered OMT weekly for 3 weeks to eight children, ages 7 to 35 months, with a history of recurrent otitis media, and then followed these subjects for 1 year. Their results showed that five subjects (62.5%) had no recurrence of symptoms during the year follow-up, one had a bulging TM, one had four episodes of otitis media, and one had surgery after AOM recurrence at 6 weeks post treatment. In addition to reduction of recurrence of otitis media, OMT has also been observed to provide immediate improvement in middle ear functioning in children as measured by tympanograms before and immediately after OMT (Carreiro, 2003).

OMT in children with AOM is directed toward structural impediments to optimum functioning (biomechanical model); improvement of middle ear drainage (respiratory-circulatory model); reduction of compression neuropathies affecting functioning of the oropharynx and upper gastrointestinal system and causing pain (neurological model); improvement of the environment in which the child lives (biopsychosocial model); and reducing the stress of infection and hearing impairment so the child can exist in his or her environment with greater functionality and contentment (bioenergetic model). (For a discussion of specific osteopathic techniques for each of these goals, please see the discussion of each model below.)

Secondary Otalgia

Ijaduaola (1985) describes the most common causes of secondary otalgia in children as tonsillitis (21% of all otalgia), foreign body in the pharynx (5%), and foreign body in the nose (2%). Ingvarsson (1982) describes that in children, ear pain not specifically involving infection of the ear is still often associated with upper respiratory congestion, and may be related to the discomfort of swallowing, nasal obstruction, fever, teething, or moderate hearing loss. The aphorism that “more things are missed by not looking than by not knowing” rightly applies in the evaluation of otalgia (Leung et al., 2000). The myriad of pathologies that can present with pain in the ear are complex and occasionally sublime, ranging from ectopic facial hair in the oropharynx (Papay et al., 1989) to fibromyalgia (Goldenberg, 1987; LeLiever, 1990) from ascariasis (LaGrone, 1977) to thyroiditis (Slatosky et al., 2000), and from eccrine spiradenoma (Nadig et al., 2004) to subdural hematoma (Zaidat and Ubogu, 2002). Even Munchausen syndrome in a 13-year-old boy has been reported to present as ear pain (Leung et al., 2000). When

a child with ear pain has a normal exam of the TM, the practitioner must take into consideration the neuroanatomy of the extensive sensory innervation of the ear arising from six nerve roots, which share common neuronal pathways with many other structures in the head, neck, and thorax.

Ingvarsson (1982) emphasizes that otitis media is both overlooked and overdiagnosed. In general, young children may not verbalize or localize pain very accurately, and will frequently point to the ear when experiencing teething pain, if they have experienced ear pain in the past. If a complete examination of the external and middle ear structures, and careful history relating to hearing and balance functions do not point to an etiology relating to the ear structures themselves, it is important to consider the more common etiologies of referred pain, with particular attention to the more rare but insidious presentations of malignancy. A complete head and neck exam should include the nose and nasal cavities, oral cavity, pharynx (particularly teeth and tonsils), the temporomandibular joint, and the nasopharynx and larynx, which may require fiberoptic endoscopy. Dental appliances should be removed if possible to allow for a complete examination, keeping in mind that the appliances themselves may be causing nerve irritation resulting in referred pain. Radiologic imaging may be necessary to rule out abscess or tumor (Teitelbaum et al., 2004).

Relevant features of the history and physical findings will be highlighted in each descriptive section of the following more common etiologies. The following discussion will focus more on children, but the relative frequency of similar presentations in adults will be mentioned.

Sinusitis

Acute sinusitis is the fifth most common diagnosis for which antibiotics are prescribed (Fagnan, 1998). The diagnosis is based in the patient’s history of a biphasic illness (“double sickening”), purulent rhinorrhea often associated with fever which first clears and then returns, maxillary toothache, pain on leaning forward, and pain with a unilateral prominence. The symptoms overlap with simple upper respiratory infections, of which young children have an average of six to eight a year. The duration of the illness is a helpful clue. Foreign bodies should be ruled out with examination of the anterior nasopharynx, and adenoid hypertrophy can be excluded with a lateral neck radiograph. Otherwise, radiologic imaging is not considered necessary for diagnosis and can be misleading in children, as they commonly have asymmetric sinus development. A basic evaluation of ocular and neurologic function is necessary to rule out potential complications. OMT is often helpful in relieving the symptoms and enhancing recovery by balancing the autonomic stimulation to the area (neurologic model), stimulating lymph drainage (respiratory-circulatory model), and alleviating the underlying predisposing structural components (biomechanical model).

Pharyngitis and Infections of Other Proximal Structures

Pharyngitis, aphthous ulcers, stomatitis, gingivitis, glossitis, and sialadenitis (inflammation of a salivary gland, which may be associated with obstruction of the duct or infection), including parotiditis (particularly mumps) may also present as otalgia. Older children and adults may also present with abdominal pain or headache. Chronic tonsillitis may be associated with debris within the tonsillar crypts called tonsillitis. Children account for one third of all episodes of peritonsillar abscesses, and it is usually due to group A β -hemolytic *streptococcus*, and is associated with fever, dysphagia, and voice

change. Although it is not likely to present with otalgia as an isolated symptom, it must be suspected to be found, especially in a nonverbal child, and may require surgical drainage. It must be differentiated from neoplasia, which will more likely present with fleshy, granular, or pale tissue (Wetmore, 2007). OMT for infections of the pharynx is used to improve lymphatic circulation and respiratory chest wall excursion (respiratory-circulatory model); reduce pain by relieving compression on CNs exiting the cranial base, especially the Vagus nerve (neurologic model); and reduce the muscle spasm of the upper cervical area that exacerbates pain and reduces mobility (biomechanical model). However, direct treatment to the infected areas of the head and upper neck area should not be performed until the infection is under control with medical management.

Viral infections of the mouth include rhinovirus, coxsackievirus, mononucleosis, herpangina, herpes simplex gingivostomatitis, herpes zoster, measles, mumps, and aphthous ulcers. Human papillomavirus may present as painless papillomatous lesions on the soft palate or uvula, and occasionally may undergo malignant transformation. Given the venereal component of this virus, its presence in a child might suggest sexual abuse. Herpes zoster may be accompanied by vesicles on the auricle, but intense otalgia may present weeks before they erupt. When this is associated with facial nerve palsy, it is called Ramsay Hunt syndrome, and may also involve hearing loss and vertigo. The ear pain may persist for weeks after the vesicles resolve. When facial paralysis is associated with vesicle eruption, the facial palsy is more likely to persist (Bluestone et al., 2003; Leung et al., 2000; Shah and Blevins, 2003; Wetmore, 1997). While viral upper respiratory infections are usually self-limited, OMT is useful to reduce inflammation of the tissues that may contribute to pain by promoting lymph and venous sinus drainage (respiratory-circulatory model) and relieving pressure on the associated nerves and ganglia (neurologic model).

Bacterial infections of the mouth such as gingivitis are sometimes associated with poor hygiene, poor nutrition, or immunosuppression. Ludwig angina refers to an acute bacterial infection of the floor of the mouth, associated with submandibular fullness, drooling, and voice change, and may progress without treatment to airway compromise. Parotiditis can be bacterial, as can infection of the submandibular glands, but are also associated with systemic symptoms rather than solely otalgia, and frank pus may be expressed from the associated salivary duct. *Streptococcus pneumoniae* and *Staphylococcus aureus* are usually implicated. Recurrent parotiditis may indicate an underlying collagen vascular disease (Charlett and Coatesworth, 2007; Wetmore, 1997).

Yeast infections in the mouth are common in infants and may be related to recent antibiotics in the child or mother of a nursing baby. It is obvious by inspection of the mouth and cheeks for whitish patches. Medical treatment is simple, and response is usually rapid.

Dental Problems, Including Temporomandibular Joint Dysfunction

Pain from tooth eruption, caries, impacted teeth, gingivitis, and periapical infections may all be referred to the ear, and can usually be diagnosed by thorough visual inspection of the mouth. Carious teeth may be associated with sensitivity to hot or cold temperatures, which may persist after the evoking stimulus is removed. Caries are initially seen as a white spot of the tooth, which changes to a brown color as cavitation progresses. Abscess presents with more systemic symptoms and swelling. Trauma to the mouth and teeth is common in children, who tend to run with things in their mouths and fall down, often unnoticed by a parent. Tooth eruption as an etiology of otalgia is more common in children than is temporomandibular

joint dysfunction (TMD), but the latter is not uncommon, and should be considered in children who have intermittent unilateral otalgia of three or four days' duration and whose exam and ear functioning are normal. Shah and Blevins (2003) noted that as many as 48% of patients with TMD presented with otalgia.

TMD is characterized by temporomandibular joint (TMJ) tenderness on palpation, restricted motion of the jaw, which is frequently accompanied by "clicking," and is often unilateral, more pronounced in the morning, and aggravated by chewing or biting. The ear pain may be related to nerve irritation, muscle spasm, or degenerative changes in the joint. The pain can be elicited by palpating preauricularly, intraotically (with fingers pushing forward), or orally, palpating along the last molar, where the pterygoids connect the maxilla to the mandible. It may be exacerbated by a pillow that is too high (Zenian, 2001). In children, the pain is usually due to muscle spasm and is often seen with a history of recent orthodontic treatment. Other causes of TMD include bruxism, dental malocclusion, jaw clenching, excessive gum chewing, and trauma, Lyme disease, and connective tissue disorders such as juvenile rheumatoid arthritis (Pertes, 1998).

Menner (2003) suggests that TMD is underdiagnosed because it may present with a somewhat abnormal-looking TM. Furthermore, chronic dislocation, ankylosis related to connective tissue diseases, and neoplasia must be considered in refractory cases and require more aggressive intervention (Kramer and Kramer, 1985; Leung et al., 2000; Shah and Blevins, 2003).

TMD often responds to OMT, especially when it relates to orthodontic treatment. In a child with a clear-cut recent history of minor head trauma involving the temporal bone such as a whiplash or fall on the chin, a brief trial of OMT might be warranted and may clear the symptoms completely. The OMT for TMD secondary to dental intervention or head trauma is specific for the somatic dysfunction found and commonly requires treatment of the head using osteopathy in the cranial field (OCF) techniques. Examination and treatment of the child's entire body is necessary following trauma in order to remove somatic dysfunction in areas distant to the head that are causing strain and impaired functioning of the TMD (biomechanical model).

Gastroesophageal Reflux

Children presenting with otalgia secondary to gastroesophageal reflux may be fretful and irritable. Irritation of the respiratory epithelium of the larynx and pharynx by gastric acid stimulates CN IX and X. Other symptoms may include hoarseness, dysphagia, a sensation of a lump in the throat, chronic cough, or overt intermittent wheezing. It can occur in the absence of typical symptoms of gastroesophageal reflux such as heartburn and regurgitation. Direct irritation of the opening of the ET can cause swelling and contribute to middle ear pathology, and an association between recurrent AOM and GER has been suggested (Wetmore, 2007). Endoscopy may demonstrate evidence of inflammation, and pH monitoring is considered the gold standard for diagnosis. It has been shown that in 60% to 90% of children with OME, gastric pepsin can be found in middle ear fluid (Crapko et al., 2007; Tasker et al., 2002). This in itself may be a cause of ear pain (Gibson and Cochran, 1994) as well as a contributor to recurrent middle ear infection.

Compression of the cranial base is a common osteopathic finding seen in children with GERD. From the osteopathic perspective, this compression leads to impingement of the Vagus nerve resulting in ineffective closure of the lower esophageal sphincter and reflux of stomach contents (Sergueef, 2007). OMT is often helpful in reducing the severity of the reflux, using the whole-body approach. Impaired gastric emptying may occur from spasm of

the abdominal diaphragm, and can be treated with indirect and direct myofascial techniques (biomechanical model). Soft tissue techniques to the upper cervical area reduce impingement of cervical nerves 3 to 5 innervating the diaphragm, and occipital decompression techniques reduce compression on the Vagus nerve as it exits the jugular foramen, resulting in improved lower esophageal sphincter functioning and reduction of pain mediated via the Vagus nerve (neurologic model).

Headaches and Other Cervicofacial Pain Syndromes

Migraine headaches, which are considered to be related to neurogenic inflammation with secondary cerebrovascular changes (Pertes, 1998), are usually characterized by a throbbing or pounding, often unilateral headache, accompanied by nausea, vomiting, and photophobia, with an aura frequently preceding the headache. Otolgia may be a nondominant symptom (Leung et al., 2001). Tension headaches may be either episodic or chronic, and may trigger migraine-type symptoms. Boes et al. (1998) describe two cases of paroxysmal hemicrania manifested solely by otalgia with a sensation of external acoustic meatus obstruction. Trigeminal neuralgia and glossopharyngeal neuralgia may refer primarily to the ear, and has been found on occasion to be associated with multiple sclerosis and Charcot-Marie-Tooth neuropathy (Manzoni and Torelli, 2005). OMT of migraine headaches is commonly provided between headache episodes and is designed to reduce the intracranial strains that contribute to the frequency and intensity of the headaches. Relief of pressure on the involved intracranial ganglia with OCF is often helpful (Magoun, 1996). (neurologic model).

Yount (2004) reviews atypical earaches and otomandibular symptoms, with reference to Travell's trigger points (Simons et al., 1999) and emphasizes how central sensitization incorporates several different sources of pain (undiagnosed pain, "piggy-back" pains, frequent recurrent pains, and chronic pains) to induce anatomical, neurochemical, and physiological changes in the nervous system that may confound accurate diagnosis. Forward head posture, especially when accompanied by forward shoulder position, has been associated with development of trigger points, or with occipital neuralgia (Pertes, 1998). The areas that frequently refer pain to the ear include the lateral pterygoid, the deep masseter, the clavicular sternocleidomastoid, the medial pterygoid, and the suboccipital muscles. OMT targeted to dysfunctions of the head and neck area, and postural treatment and education are commonly helpful (biomechanical model). OMT without postural realignment and reeducation will generally not provide long-term relief.

Thyroiditis

Thyroiditis, including chronic lymphocytic thyroiditis (also known as Hashimoto thyroiditis), may present with ear pain before a goiter is noticed. Symptoms of hyper- or hypothyroidism may not predominate initially. It is seen more commonly in adults, but is the most common cause of sporadic goiter in children, and its incidence is rising. Subacute granulomatous thyroiditis is more commonly associated with pain, which may be referred (Slatoksy et al., 2000).

Regarding benign space occupying lesions, one series of patients with acoustic neuromas found that 4.2% presented with ear pain (Charlett and Coatesworth, 2007). Branchial cleft cysts, dermoid cysts, and thyroglossal duct cysts may present with ear pain, and usually make their presence known in the first decade of life. A case report of cervical spine meningioma presenting as otalgia, but was associated with progressive neurological deficits over a prolonged time, has also been described, though not in children (Danish and Zager, 2005). Stretching of the dura by a nonneoplastic

lesions, such as a subdural hematoma, may also trigger otalgia (Zaidat and Ubogu, 2002; Charlett and Coatesworth, 2007), and a case of heparin-induced thrombocytopenia involving near total occlusion of the internal jugular and subclavian veins, secondary to placement of a hemodialysis catheter, has also been described (Marinella, 2007). Determining the exact location of the pain may give an indication to the site of the disease (see neurological model considerations in pediatric ear pain).

Diagnosis

The diagnosis in this case is AOM, either from a viral or bacterial etiology. This child demonstrates an increased susceptibility to ear infections due to numerous factors:

1. Age and ethnicity-related anatomical and physiological functioning of the middle ear and auditory or ET (biomechanical model)
2. A history of stress on the fetal head during delivery (biomechanical model)
3. Exposure to other children at day care and exposure to passive cigarette smoke at home (biopsychosocial model)
4. Presence of somatic dysfunction of the head, neck, and torso impairing clearing of the middle ear (respiratory-circulatory model)
5. Presence of somatic dysfunction of the cranial base, causing pain in the head area, and compression of CNs controlling the feeding process leading to autonomic dysfunction (neurological model)

Osteopathic Patient Management

DW has a history of feeding difficulties and presumed colic, which would lead the osteopathic physician to conclude that the somatic dysfunction diagnosed today has been present since birth, and has contributed to feeding disorders and a longstanding impairment of middle ear functioning. In addition to standard medical care of this child, the addition of OMT to her care is provided with the goal of hastening recovery and reducing the chance of recurrence of middle ear infection

Dr. Viola Frymann (1998) wisely notes that "...the identification of otitis media ... is only the beginning. A comprehensive diagnosis of the child who suffers from the disease is essential if the etiologic factors... are to be recognized and addressed." The following discussion will review the biomechanical factors affecting middle ear function and dysfunction, and the appropriate use of OMT in the treatment of middle ear disease in children.

Biomechanical model

The Cranial Base and the Eustachian Tube

Middle ear disease has long been considered to be related to ET dysfunction (Bluestone et al., 2003). Under normal conditions, the ET fluctuates between a patent and closed position. Middle ear pressure is equilibrated with atmospheric pressure through the periodic openings of the ET that occur with swallowing and other activities. In children, middle ear pressures are slightly negative compared to adults (Bluestone and Klein 1996), and most children, even those without middle ear disease, have difficulty in maintaining appropriate pressures. The ability to maintain appropriate pressures appears to be related to the stiffness of the ET. The fact that the tube is relatively pliable in children is thought to be responsible for the increased incidence of middle ear disease in this age group (Bylander, 1980; Bylander and Tjernstrom, 1983). Deficits in ET function impede normal drainage to the nasopharynx (Takahashi et al., 1989) and create a negative

pressure within the middle ear as compared to atmospheric pressure. The resulting negative pressure may promote insufflation, aspiration, or reflux of nasopharyngeal secretions into the middle ear.

Within the biomechanical model, ET dysfunction is thought to be influenced by mechanical dysfunctions of the cranial base and the surrounding tissues. The child's cranial base and ET differ anatomically and physiologically from those of the adult in ways that make them more vulnerable to otitis media. At birth, the temporal bone is in three parts: the squamous portion, the petrous portion, and the tympanic ring, joined by cartilage (Carreiro, 2003). The ET travels through the petrous portion of the temporal bone, emerging into a cartilaginous sheath, closely adherent to the base of the skull, nestled between the greater wing of the sphenoid and the petrous portion of the temporal bone, emerging into the posterior pharynx at the posterior edge of the medial pterygoid plate of the sphenoid. The juncture, between the osseous and the cartilaginous portions, resembles two "truncated cones," narrower than both portions of the adjacent tube. The tube is lined with pseudostratified columnar epithelium of the ciliated type, continuous with the lining of the tympanic cavity and nasopharynx at each end. It is also tethered at each end by fibrous attachments, at the posterior end extending into the osseous portion by approximately 3 mm, and at the anteromedial end, the cartilage protrudes into the nasopharynx with fibrous bands attaching it to a tubercle on the posterior edge of the medial pterygoid plate (Bluestone et al., 2003).

It is noteworthy that the timing of the decline in frequency of ear infections, about 6 years of age, seems to coincide with the maturation of the cranial base and adjacent structures (Carreiro, 2003). The relationship of the tube to other contiguous structures, particularly the tensor veli palatini, the levator veli palatini, and the saphingopharyngeous muscles, and the difference between the characteristics of the cartilage between children and adults, may contribute to biomechanical forces acting upon the ET in young children (Carreiro, 2003). The medial bundle of the tensor veli palatini muscle lies immediately adjacent to the lateral membranous wall of the ET, and when contracted, opens the tube. This muscle curves around the hamulus of the medial pterygoid plate of the sphenoid and attaches to the posterior margin of the hard palate. In children with cleft palate, its function is less than optimal. In infants, the angle of this muscle to the tube is more acute placing it closer to the middle ear. When contracted, the tensor veli palatini may actually distort the ET rather than effectively open it (Bluestone et al., 2003). Spasm of this muscle, which is comparatively large compared to the tube in infants, may conversely cause the tube to be patulous, leaving it vulnerable to influx of pharyngeal organisms. Carreiro (2003) also suggests a possible contribution of the medial pterygoid muscle, which is comparatively bulkier in the infant, to extrinsic compression on the ET in contraction. Figures 58.1 to 58.3 demonstrate the relationship of these structures.

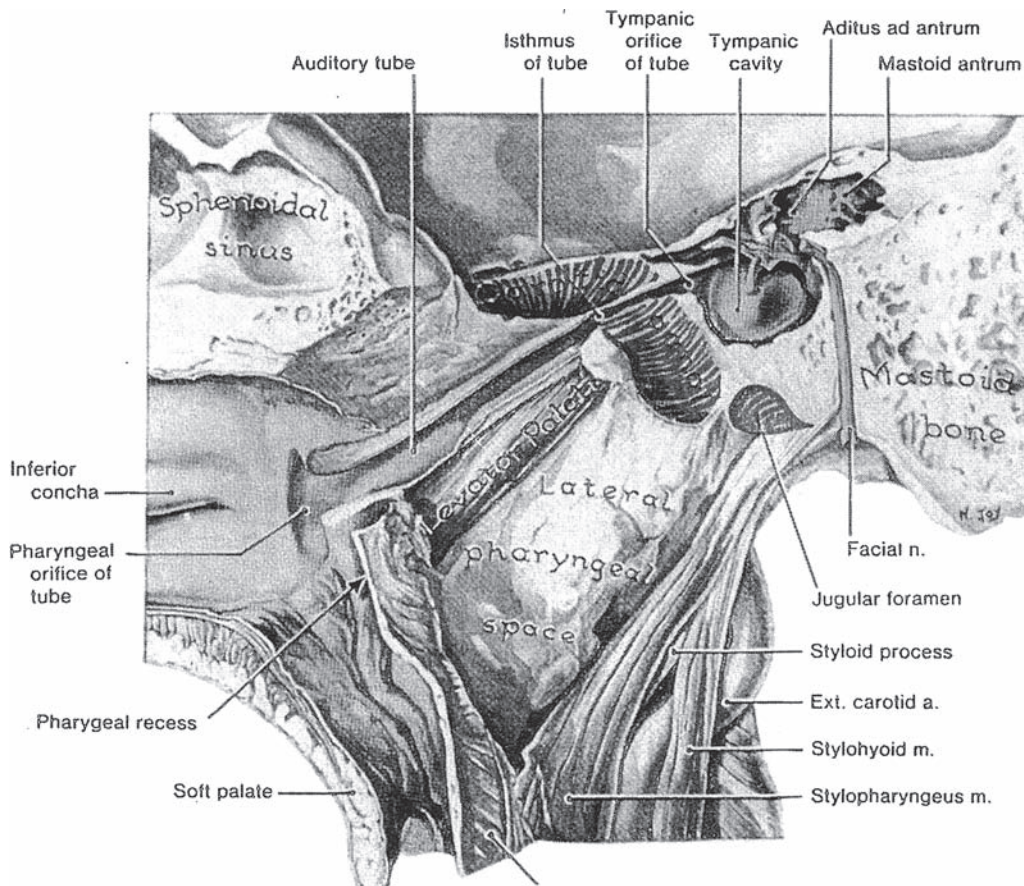

Figure 58-2 Interior view of relationship of ET to adjacent structures in the adult. (Used by permission, Ward RC, Ed. *Foundations for Osteopathic Medicine*. 2nd Ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2003.)

A

B

Figure 58-3 **A.** Lateral view of neonatal dissection. The mandible and zygoma bones have been cut and the muscles of mastication removed. The TM has collapsed, revealing the middle ear (ME) and malleus. The styloglossus (StG) and stylohyoid (StH), orbicularis oculii (ORB Oc), mandibular branch of the trigeminal (V3) and greater wing of the sphenoid (GWSph) are labeled. (Used with permission, Willard & Carreiro Collection.) **B.** Close-up of area indicated by the arrow in **(A)**. The lateral aspect of the temporal bone has been drilled away to reveal the ET surrounded by the tensor veli palatine (TVP) and levator veli palatini (LVP) muscles. Note the relative size of the muscles as compared to the ET. The middle ear (ME), styloglossus (StG), stylohyoid (StH), greater wing of the sphenoid (GWSph), and ophthalmic branch of the trigeminal nerve (V3) are labeled. (Used with permission, Willard & Carreiro Collection.)

Other differences between the adult and the pediatric ET include the fact that the infant's tube is more compliant (and therefore more floppy), smaller in diameter, and shorter in length. There is also a difference in the relationship of the ET as it enters the posterior

pharyngeal wall. In the infant, the cartilaginous tube lies at a 10 to 30 degree angle from the horizontal in relation to the osseous portion, although in adults, it is increased to 45 to 50 degrees (Bluestone and Klein, 2001; Carreiro, 2003). At the same time,

the posterior pharyngeal tissues are relatively more anterior and superior in the child. These differences are due to changes in the shape of the cranial base and the growth of the lower facial bones. The smaller angulation may act to narrow the junction between the two components of the ET, while the position of the posterior pharynx may narrow the orifice of the tube.

The articulation between the temporal and sphenoid changes angle at the point that the ET emerges from the temporal bone. The biomechanical model suggests that via its myofascial structures, neck and jaw movements may contribute to passive pumping actions on the ET, “milking” it and helping clear it of secretions.

Twin studies suggest a genetic component to ET dysfunction, which may be related to anatomy as well as physiology (Caselbrandt et al., 1999). Skull base configuration is also implicated in explaining the clustering of otitis in certain families (Bluestone et al., 2003) and in individuals with skull base malformations such as Down Syndrome, Apert syndrome, Crouzon syndrome, Treacher Collins syndrome, Hurler-Hunter syndrome, and Turner syndrome (Bluestone et al. 2003; Wetmore, 2007). There is a difference in frequency of ear infections racially, with decreased incidence described by some in African Americans and Chinese, and increased in Native American, Canadian, and Alaskan Native children. Doyle (1977) suggested that significant differences among various racial groups in the length, width, and angle of the tube may affect a predilection to otitis. Bluestone (2003) suggests that the relative size of the nasopharynx at the proximal end of the ET may also play a role in a predilection to otitis, in that it has been reported that children with a relatively small nasopharynx, measured radiographically, had a higher incidence of otitis than children with larger dimensions.

According to Sutherland’s model, the base of the cranium undergoes rhythmic changes that can be palpated (Magoun, 1996). This phasic change is basic to the concept of OCF. Understanding this model allows the osteopathic practitioner to predict the potential effects of palpated strains on middle ear functioning. According to this model, the cranial base and temporal bone are vulnerable to both compressive and tensile mechanical stress. Furthermore, tissue strains of the cranial base and the contiguous soft tissue may influence ET function, as well as potentially all structures above, below, or penetrating the cranial base (Magoun, 1996). For most children, the process of birth is the most profound force their head experiences (Fig. 58.4).

Carreiro has hypothesized that mechanical strains may contribute to edema of the tissues surrounding the ET (Carreiro, 2003). This in turn may influence intravascular fluid exchange in

Figure 58-4 Child receiving osteopathic manipulative treatment for AOM with parent nearby, utilizing OCF technique.

the middle ear, drainage of the tube, and fluid flow through its lymphatic and venous channels. In the newborn, the structures of the cranial base are somewhat malleable, allowing for passage through the birth canal and for the rapid growth (doubling in size) of the head in the first year of life. This same malleability makes the cranial base vulnerable to compression or distortion during delivery.

Pilot studies suggest that osteopathic manipulative medicine, and specifically OCF, may be relevant in treating patients with otitis media and serous otitis media (Degenhardt, 2006; Mills, 2003). Figure 58.2 shows a child receiving OMT in the form of OCF, for treatment of AOM, with the parent nearby.

Using chart analysis, Carreiro (2003) describes somatic dysfunction of the vault often associated with biomechanical strains in the cranial base and venous sinus system. She hypothesizes that the vault findings are probably secondary and recommends normalizing the base mechanics first. Magoun (1996) describes a number of techniques that may be used in infants and children to facilitate function of the ET and the surrounding tissues. These techniques are used to promote more physiologic functioning of lymph, blood, and nerves in the head. While there have been rare reports of serious adverse events in children treated with high-velocity thrust chiropractic spinal manipulation (Ernst, 2003), the gentle techniques recommended for OMT in children (Bezilla, 1997) have been shown to be well tolerated by children, with few side effects and no serious adverse events reported (Hayes and Bezilla, 2006).

Respiratory-circulatory Model

“It is important to have perfect drainage, for without it, the good results from a treatment cannot be expected to follow your efforts to relieve diseases above the neck” (Still, 1899).

The middle ear is continuous with the posterior pharynx via the ET, and with the mastoid air cells via the narrow aditus and antrum. Ideally, it is filled only with air and serves to transmit sound waves from the TM to the fenestra vestibuli and the eighth CN. Because of various factors, primarily associated with ET dysfunction, the middle ear may become filled with fluid. If the fluid is not drained naturally, surgery may be considered. OMT may provide a means of facilitating the natural drainage of the middle ear, thereby potentially averting recurrence of infection, antimicrobial resistance, and even surgery (Mills, 2003).

The body has many natural mechanisms to ensure drainage of the middle ear, so that an air-filled space can be maintained. These include a dense lymphatic and venous network, and the natural pumping mechanisms associated with sucking and swallowing. William Sutherland, D.O. (Magoun, 1996), described another mechanism, a rhythmic motion in the tissues of the cranium occurring 10 to 14 times/min. He hypothesized that this rhythmic motion in the cranial tissues acted to facilitate ET functioning. Some osteopaths have reported an association between impairments in this “cranial rhythmic motion” and otitis media (Degenhardt and Kuchera, 1994; Frymann, 1966; Mills, 2003). Within the respiratory-circulatory model, chewing, crying, and sucking influence venous and lymphatic structures in the head and neck facilitating tissue perfusion and drainage. In addition, neck movements are thought to provide intermittent tensile forces on the ET and surrounding structures influencing fluid movement through the low pressure circulatory system.

The respiratory circulatory model recognizes that breathing and crying alter intrathoracic pressures and contribute to fluid drainage from the head and neck. Within the concept of this model, crawling and walking may affect the circulatory system by generating intermittent tensions on the abdominal diaphragm and

Figure 58-5 Child receiving OMT of the pelvis to assist with function of middle ear drainage.

lower ribs via the myofascial attachments of the iliocostalis and the crura of the diaphragm. Figure 58.3 demonstrates a child receiving OMT for treatment of pelvic somatic dysfunction, with the goal of improving function of the respiratory-circulatory system and indirectly influencing middle ear drainage (Fig. 58.5).

Neurological Model

An appreciation of the complex sensory innervations of the structures surrounding the ear, and the interaction of these same nerves with other, sometimes more distant structures, may facilitate understanding of the many potentially confusing possible etiologies of otalgia. The ear structures are provided sensory innervation by CNs V, VII, IX, and X, and by cervical nerves 2 and 3.

It is important to keep in mind that there is considerable variability among individuals. Though here is no role of the CN VIII in carrying pain fibers from the inner ear, resulting in the observation that significant inner ear pathology can develop without otalgia, sensation mediated by this nerve can be felt by the patient as a “fullness” in the ear, such as is seen in Meniere disease (Shah and Blevins, 2003). Clinically, areas innervated by CN IX may refer an intense pain deep in the ear. There is no evidence of referral of pain from ear pathology to the distal structures (Scarborough et al. 2003).

These complex interrelationships are the result of embryologic development, stemming from the otic vesicle coming to lie between the branchial arches 1, 2, 3, and 4, giving rise to CN V, VII, IX, and X, respectively (Scarborough et al., 2003). The autonomic nerve supply to the upper respiratory tract including the middle ear and sinuses consists of parasympathetic stimulation via the CN VII and sympathetic stimulation via T1-4. Figure 58.4 graphically displays the autonomic nerve supply to the upper respiratory tract.

It is useful to be aware of the location and pathways of these nerves and their ganglia, as somatic dysfunction along the way may contribute to otalgia, and relief of those strain patterns might benefit the patient, even if no underlying cause is found for the ear pain.

There are complex immunohistochemical changes associated with ear pain that may contribute to the pathophysiology of otitis media. Nagaraj and Linthicum (1998) described the presence of

catecholaminergic nerve fibers in the human middle ear mucus membrane that may play an important role in the pathogenesis of MEE. Animal studies of the role of substance P in osteoclastogenesis, a common finding in otitis media, and the effect of capsaicin pretreatment on the neurogenic inflammatory component of otitis media offer a tantalizing suggestion into further applications of this area of research in humans (Basak et al., 2005; Sohn, 2005). Caye-Thomasen (2004) describes depletion of mucosal substance P in AOM in rats. In humans, Teodorczyk-Ineyan (2006) has shown that spinal manipulation may reduce inflammatory cytokines but not substance P production in normal subjects. This finding suggests a potential objective marker for monitoring the downregulation of inflammatory responses to manipulation. Whether these findings can explain the improvement of pain in patients receiving manual medicine techniques remains to be determined.

The fact that our case child had a difficult delivery and problems sucking does not surprise the osteopathically oriented physician. The history of colic and spitting up may be related to the patient’s somatic dysfunction. Frymann’s classic study of 1,250 newborns correlated specific areas of somatic dysfunction on osteopathic examination with distinct symptomatology in the newborn nursery (Frymann, 1966). Carreiro (2003) postulates that babies with compression dysfunction at the cranial base may also develop symptoms as they start to develop head control, adding more muscle tension to an area already irritated, thereby exacerbating preexisting somatic dysfunction.

It is the experience of osteopathic practitioners worldwide, and over many years’ observation, that there is an association between recurrent AOM and a difficult or rapid delivery (Carreiro, 2003; Sergueef, 2007; Sorrel, 2004; Woods, 1976). These same authors also report that children with recurrent AOM are often firstborn and frequently have a concomitant history of colic, dacryostenosis, feeding difficulties, or gastroesophageal reflux in the newborn period. As with our patient, there is an association between otitis media and gastroesophageal reflux (Caruso, 2006), which is thought to be either a vagal-vagal reflex or have an inflammatory component. From an osteopathic perspective, gastrointestinal motility and function of the gastroesophageal junction may be influenced by somatic dysfunction in the cranial base via vagal input or thoracolumbar somatic dysfunction influencing the diaphragmatic contribution to the gastroesophageal sphincter. Bluestone (2003) reports that children who are “otitis-prone” also have more episodes of bronchopulmonary, gastrointestinal, and urinary tract infections, as well as more visits to the orthopedic clinic than control subjects. This might lead one to suggest that somatic dysfunction may be a common denominator of these problems.

Metabolic Energy Model

Good nutrition is a staple of good health. Children, who are undernourished or poorly nourished, may be at greater risk for infectious diseases such as otitis media and less able to respond to therapy. Nutritional supplements have gained favor in some communities, as has an emphasis on eating organic and locally grown foods. For example, “glyconutrients,” which are reported to have some benefit on immune function (Axford, 1997; Murray, 2006), have enjoyed increased usage in recent years.

Treatment and Outcome

Following the current guidelines for treatment of AOM (American Academy of Pediatrics Subcommittee on Management of Acute

Otitis Media, 2004), DW was treated with ibuprofen to achieve pain control and given a prescription for amoxicillin-clavulanate, to be filled if DW's symptoms were not resolved in 48 hours. She was also treated with OMT, consisting of Galbreath mandibular drainage, temporal decompression, occipitomastoid decompression, myofascial release of the upper cervical musculature, thoracic outlet and abdominal diaphragm, and rib-raising techniques. DW tolerated the procedure very well. Mother was advised to quit smoking, and was taught to do the Galbreath mandibular drainage, rib raising, and lymphatic pump techniques and advised to do them twice daily until recheck. At recheck two weeks later, the ear examination was normal and tympanograms were normal.

Behavioral Model

Environmental and Complementary Measures for Middle Ear Disease

As previously discussed, socioeconomic and environmental factors have been shown to influence the occurrence of otitis media. For children who are unable to control their surroundings, it falls to the physician to encourage healthy habits in the family that might reduce the risk of recurrence. Taking into account the particulars of the patient and his or her home situation, the physician needs to consider breast feeding, discouraging pacifier use and bottle feeding when supine, avoidance of exposure to smoke and other environmental toxins and allergens, avoiding crowded settings and early child care (Bluestone et al., 2003), and teaching hand washing, and avoidance of sharing drinks. The physician also needs to consider the role of comorbidities such as gastroesophageal reflux, which predispose to recurrent otitis media. It is helpful to educate the parent to not mix bottles of milk for prolonged room-temperature storage (as in a diaper bag), not store pacifiers in airtight containers, or bottles with nipples attached in the refrigerator, and not reuse unconsumed formula after a particular feeding, not only because of possible yeast infection, but also bacterial contamination. Parents should also be informed that the Center for Disease Control (CDC) now recommends administration of pneumococcal, *Haemophilus influenzae* type b, and influenza vaccines in infants and children, which have been shown to reduce the incidence and transmission of respiratory disease, and its secondary AOM (CDC, 2008).

Considering that at least 10% of patients have tried at least one or more forms of alternative/complementary medicine before presenting for consultation, it is useful for physicians to inquire regarding their use (Eisenberg et al., 1993; Kemper, 1996). Physicians should be aware of preventative strategies that may have limited benefit such as the use of the xylitol gum or syrup, and probiotic bacterial replacement (Wetmore, 2007). Various herbal and homeopathic remedies and nutritional supplements have been suggested as alternative or complementary to traditional medical approaches (Bluestone and Kline, 2001). A double-blind study comparing naturopathic herbal extract ear drops to anesthetic ear drops, with or without amoxicillin (Sarrell et al., 2003) showed a mild but statistically significant benefit with ear drops, particularly the naturopathic remedy. (Need to add detail re: what study was comparing.) Kemper (1996) has also reported, but does not specifically recommend, herbal teas including those containing Echinacea, goldenseal, and licorice root. Chamomile, hops, and passion flower are sometimes used because of their sedation effect. Homeopathy has been shown to reduce otalgia associated with AOM at 2.4 times faster than placebo, and without complications (Frei and Thurneysen, 2001). Common homeopathic remedies used for children with ear pain include Aconite, Belladonna,

Chamomilla, Ferrum phosphoricum, and Pulsatilla (Kemper, *The Holistic Pediatrician*, 1996; Morgan, 1992; Schmidt, 1990). A combination remedy called "ABC," contains Aconite, Belladonna, and Chamomilla, and is commonly recommended for children. Physicians need to be aware that some parents may choose to treat their children without prior examination by a health care professional. For the sake of the child, it is very important that the physician maintain a relationship with these parents and not alienate them. Physicians should educate parents as to the warning signs of worsening infection, sepsis, meningitis, and other serious complications of untreated infection. The practitioner should also be aware that a systematic review of serious adverse effects of unconventional therapies for children and adolescents revealed the greatest number of adverse events to occur secondary to herbal medicines (Ernst, 2003).

Parents often feel helpless when their child is ill. This can exacerbate their anxiety and influence their response to the sick child and perhaps even the child's perception of their own illness. Interventions that empower the parent without risk to the child may prove beneficial to both on many levels. It is sometimes comforting to apply mild heat to the outer ear, in the form of warm washcloth, heating pad, or hair dryer. A common folk remedy for otalgia is warmed sweet oil, garlic oil, mineral oil, or olive oil instilled in the ear canal. There is no evidence of efficacy but these pose no threat to the child as long as the ear drum is intact.

In addition, parents may also be taught simple osteopathic techniques such as lymphatic pump, rib raising, or the Galbreath mandibular drainage technique, which can be administered at the first signs of an upper respiratory tract infection. Schmidt's classic study of 100 patients with upper, middle, and pararespiratory illnesses, in which 63%, who were treated within day 1 of their illness, compared with 34%, who received OMT >2 days after onset of symptoms, showed more rapid resolution of symptoms, fewer complications, and fewer recurrences in the early-treated group (1990). Given that busy medical practices (and busy parent schedules) may not accommodate same-day appointments for patients with very early respiratory symptoms, the possibility of involving parents early in the child's illness may prove beneficial.

Notes on Treating Children with OMT

Treating children with OMT presents some unique challenges, but the practitioner should not be daunted, as the benefits can be enormously rewarding. Children are not just small adults. Their bodies are more flexible, more resilient, and less complex than adults. Their somatic dysfunction is easier to fix, and doing so can be life changing. Parents can be taught many activities of daily living that can improve somatic dysfunction in children. The normal squirming of a child, though it may be distracting to the practitioner, may actually help in the treatment. Treating children takes flexibility and time to develop trust, using positions familiar to the child, face-on first, such as with changing a diaper, or allowing the child to sit in the parent's lap. Toys, books, and frequent changes in position are often necessary to keep the child engaged. In some children, particularly two-year olds, brief gentle restraint may be necessary during the treatment.

CONCLUSION

The treatment of a child with ear pain begins with a history and physical to determine the cause of the pain. Working within the osteopathic paradigm, an evaluation for predisposing dysfunction of the entire body is a part of the physical examination. The

diagnosis includes consideration of the anatomical and functional differences in the child's head and neck, as compared to the adult. Treatment is directed to the identified cause of the pain, as well as removing predisposing factors in the child's body with the use of OMT, when appropriate. Factors in the environment that are modifiable are addressed to improve the overall health of the child.

Difficulty Breathing

WILLIAM FOLEY, HUGH ETTLINGER, GILBERT D'ALONZO, AND JANE CARREIRO

KEY CONCEPTS

- Most acute exacerbations of chronic obstructive pulmonary disease (COPD) are preceded by an infection, either viral or bacterial. The patient typically reports worsening cough and chest congestion, increased sputum production, and dyspnea.
- Obstructive diseases such as COPD require the patients to alter their mechanics of breathing by engaging accessory muscles causing hypertrophy, which alters biomechanics this creates somatic dysfunction.
- Patients with obstructive diseases such as asthma and COPD have restricted movement of the thoracic tissues during the exhalation phase of respiration, potentially reducing local drainage of lymph from the small airways and central lymph drainage through the thoracic duct.
- Bronchospasm and mucous production, the two main pathophysiologic events of asthma and COPD, are mediated through the vagus nerve.
- Smoking cessation is essential for respiratory health.
- Regular osteopathic manipulative treatment visits focused on facilitating normal posture and function may assist in reducing metabolic energy requirements.

CASE VIGNETTE

Chief Complaint:

A 71-year-old man presents to your office with a 3-day history of shortness of breath, fever, wheezing, chest congestion, and a nonproductive cough, requiring more than usual inhaled albuterol to help his breathing.

History of Present Illness:

He inhales tiotropium every morning and fluticasone and salmeterol every 12 hours each day and usually is comfortable from a pulmonary standpoint. He has never required home oxygen therapy. However, over the last few days, his symptoms have worsened and he currently feels out of breath while doing routine activities. He denies chest pain and diaphoresis. Just 3 months ago, he was admitted to the hospital for an exacerbation of his chronic obstructive pulmonary disease (COPD).

Past Medical/Surgical History:

stable angina pectoris, gastroesophageal reflux disease, essential hypertension and a left inguinal herniorrhaphy 20 years ago.

Medications:

tiotropium 1 inhalation daily, salmeterol/fluticasone 250/50 1 inhalation every 12 hours, omeprazole 20 mg daily, amlodipine 10 mg daily, and lisinopril 10 mg daily.

Allergies:

none.

Social History:

100 pack-year history of tobacco use, presently ½ pack of cigarettes each day. He admits to rarely drinking alcohol and he has never used illicit drugs.

Physical Exam:

Vital Signs:

HR: 100 beats/min, RR: 24 breaths/min, BP: 180/90 mm Hg, and pulse oximetry O₂ saturation: 89% while breathing room air

General:

Mildly ill and has frequent paroxysm of coughing. He does not have lower extremity edema.

HEENT:

Normal. There is no thrush.

Heart:

Heart rate tachycardic and cardiac rhythm is regular. No murmur or gallop is auscultated. Jugular vein distension was not found.

Lungs:

Diffuse bilateral expiratory wheezing, decreased breath sounds, and poor air movement. Significant accessory muscle use with respiration without paradoxical thoracoabdominal breathing was noted. Mild lower intercostals space muscle retractions were seen.

Abdomen:

Soft and nontender without hepatosplenomegaly. Bowel sounds are normal.

Structural Exam:

Reveals left ilium posterior, left SI restriction, general decrease in side bending, and rotation throughout lumbar with L1-3 flattening of normal lordosis. The thoracic spine has a significantly reduced range of motion during sidebending and rotation especially between T5-10. T10 is in a flexed position, sidebent, and rotated to the right. T5 is in an extended position,

sidebent, and rotated to the right. T2 is also extended but sidebent and rotated to the left. There is decreased rib compliance throughout the rib cage with reduced excursion during the exhalation phase of respiration. Chest is barrel shaped. C7 is flexed, sidebent, and rotated to the left. C2 is extended, sidebent, and rotated to the right. The right occipitoatlantal articulation has restricted motion mechanics. The sternocleidomastoid and scalene muscles are tense and hypertrophied bilaterally. Diaphragm excursion is decreased during inhalation by percussion, and there is decreased motion in the lower ribs.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of dyspnea with hypoxemia for this patient (Box 59.1) includes COPD, bronchiectasis, pulmonary embolism, pneumonia, and congestive heart failure, and it is possible that more than one condition is present.

Any patient presenting with dyspnea must be stabilized from both a respiratory and hemodynamic standpoint before a more thorough history and examination are conducted. This patient uses accessory respiratory muscles at rest, clearly demonstrating that he is working very hard to breathe. The patient was immediately placed on nasal cannula O₂, and pulse oximetry was used to carefully monitor an improvement in oxygenation. The use of O₂ in a patient with COPD should be monitored closely because of the risk of CO₂ retention or hypercapnea. An office electrocardiogram (EKG) was done, which showed sinus tachycardia. The EKG showed low voltage but no ischemic abnormalities. At this point, the patient was transferred by ambulance to the closest emergency department where he was placed on telemetry. The supplemental O₂ via nasal cannula was continued and nebulized bronchodilator therapy was initiated.

The initial work-up for the complaint of dyspnea should include a chest x-ray (posterior-anterior and lateral views), EKG, and several blood studies (arterial blood gas, complete blood count and differential, serum electrolytes, creatinine, and blood urea nitrogen). This initial work-up will determine if the cause is cardiac, pulmonary, metabolic, or due to anemia. With these data, a more focused, in depth work-up can be pursued (Box 59.2).

The patient's chest x-ray revealed hyperinflated lungs without a lung infiltrate (Fig. 59.1). His hemoglobin and hematocrit are

normal, but there was leukocytosis (14,000) without band forms. No metabolic derangement was identified. Arterial blood gas results showed normal acid base balance and moderate hypoxemia, without hypercapnia (Fig. 59.2). These results were used to reduce the initial differential diagnosis to the most likely diagnosis of COPD exacerbation.

Figure 59-1 COPD. Frontal (A) and lateral radiographs show hyperinflation with flattening of the diaphragm (B). In A, note the vertical appearance of the heart, which is compressed by the over-inflated lungs.

Differential Diagnosis for Dyspnea with Hypoxemia in an Elderly Male with a History of COPD and Cardiovascular Disease

- Exacerbation of COPD
- Bronchiectasis
- Pulmonary embolism
- Pneumonia
- Congestive heart failure

Initial Work-up for Patient with Dyspnea and Hypoxemia, Once They are Stabilized

- Chest x-ray (posterior-anterior and lateral views)
- EKG
- Arterial blood gas
- Complete blood count with differential
- Serum electrolytes
- Creatinine
- Blood urea nitrogen

Arterial Blood Gas Interpretation Reference			
Normal range: pH 7.35 - 7.45, PaCO ₂ 35 - 45 mm Hg, PaO ₂ 80 - 100 mm HG, HCO ₃ 22 - 26 mEq/L			
Disorder	pH	Primary disturbance	Compensation
Respiratory acidosis	↓	↑PCO ₂	↑HCO ₃
Respiratory alkalosis	↑	↓PCO ₂	↓HCO ₃
Metabolic acidosis	↓	↓HCO ₃	↓PCO ₂
Metabolic alkalosis	↑	↑HCO ₃	↑PCO ₂

Figure 59-2 Arterial blood gas interpretation.

Medications were begun and included ceftriaxone 1 gm i.v. daily, nebulized ipratropium 0.5 mg, and albuterol 2.5 mg every 6 hours, and methylprednisolone 40 mg i.v. every 6 hours. Supplemental oxygen was continued and an additional albuterol treatment could be given every 2 hours for breathing distress.

Most acute exacerbations of COPD are preceded by an infection, either viral or bacterial. The patient typically reports worsening cough and chest congestion, increased sputum production, and dyspnea. Tachypnea and hypoxemia are common findings. The chest radiograph may show signs of infiltrate (concomitant community-acquired pneumonia or bronchiectasis), and often there are findings consistent with lung hyperinflation (flat diaphragm, hyperlucent lungs, and increased retrosternal air space). Sputum cultures and CT of the chest may be necessary if the clinical picture remains unclear.

COPD patients often have substantial musculoskeletal findings on examination, and they can benefit from a carefully planned osteopathic treatment program that involves both pharmacologic and nonpharmacologic interventions.

OSTEOPATHIC PATIENT MANAGEMENT

Biomechanical Model

Breathing is in large part a mechanical process. Changes in intrathoracic pressures involve contraction and relaxation of skeletal musculature that are attached to the spine and bony thorax. These motions, during inspiration and expiration, produce pressure gradients within the thorax and between the thoracic and abdominal cavities. This process is critical for respiration and the movement of fluids throughout the body. A detailed review of these mechanics will offer insight as to how osteopathic treatment may improve the efficiency and effectiveness of breathing for patients that are experiencing an acute exacerbation of COPD. A recent pilot study (Noll et al., 2008) suggests there is a role for osteopathic manipulative treatment (OMT) in the management of COPD patients.

The physical action of producing a negative intrathoracic pressure requires a definable amount of energy, referred to as the work of breathing. Although difficult to quantify, increased work of breathing is clinically relevant, since many pulmonary diseases dramatically alter the work of breathing. An increase in the work of breathing is an important factor in the pathophysiology of all lung diseases (West, 1992). In the pathophysiology of asthma and COPD, patients can progress to respiratory failure due to an inability to maintain adequate ventilation and oxygenation because of respiratory muscle fatigue and eventual exhaustion. Failure of the thoracic pump may be due to severe airflow obstruction and thoracic hyperinflation, both of which develop as a result of obstructive air trapping within the lung. Thoracic hyperinflation places the entire pump at a mechanical disadvantage increasing muscle workload and the potential for muscle fatigue. Any intervention that can improve airflow and reduce hyperinflation will delay the onset of muscle fatigue and respiratory failure.

The mechanical process of breathing involves tissue compliance and recoil. Compliance is the ease with which tissues are stretched during inhalation. Recoil involves the elastic ability of the lung parenchyma to passively contract during exhalation. Respiratory system compliance has at least two components, lung tissue and chest wall, that make up the total thoracic compliance. Lung tissue compliance is reduced in disease processes that are infiltrative or restrictive such as pneumonias or effusions. Lung recoil is affected by the structure of the lung parenchyma. Conditions that destroy or alter the structure of the parenchyma can affect recoil and interfere

with the ability of the lung tissue to expel air. In COPD, the ability of the lung to expel air is compromised. The increased residual volume and decreased O_2 levels damage the delicate alveoli wall. Adjacent alveoli sacs coalesce forming larger tertiary spaces, as a result the surface area of the lung is decreased and there is less area available for gas exchange. This condition is called emphysema (Fig. 59.3). The damage to the parenchyma increases the compliance but decreases the elastic recoil properties of the lung. The subsequent tendency for air trapping increases the workload of both expiratory and inspiratory muscles; expiratory muscles are engaged in an attempt to decrease residual lung volumes, while inspiratory muscles must now work against the increased residual alveoli volume. Consequently, there is an overall increase in the work of breathing.

Obstructive diseases such as COPD require patients to alter their mechanics of breathing by engaging accessory muscles that are not continuously used in a healthy person. The respiratory muscles hypertrophy in response to the increased workload. Muscle hypertrophy alters biomechanics and creates somatic dysfunction. Somatic dysfunction can reduce the compliance of the bony thorax, alter respiratory biomechanics, and further increase the work of breathing. Thus, a vicious cycle is created whereby patients with COPD are compromised in their ability to meet their respiratory demands.

Somatic dysfunction of the thoracic spine and ribs is often found in patients with lung disease (Beal and Morlock, 1984). The shape of the thorax in patients with COPD who have emphysema with hyperinflation (barrel chest) can produce dramatic changes in

Figure 59-3 Schematic diagram depicting normal alveoli and alveoli in COPD.

chest wall compliance, which are obvious on osteopathic structural exam. In addition to the specific dysfunctions noted in association with pulmonary disease, this altered chest wall compliance may contribute to patients' respiratory dysfunction. General osteopathic manipulative techniques may be used to address these thoracic compliance issues, in combination with more specific techniques for individual somatic dysfunctions. Osteopathic treatment to improve the compliance of the thorax may not necessarily directly alter the parenchymal pathology, especially in those with chronic lung disease. However, it should improve the comfort and work of breathing and perhaps exercise tolerance, providing patients with the ability to enhance their functional capacity. Reducing the work of breathing during exercise has been shown to improve exercise tolerance of the chronic lung patient (West, 1995).

As noted, in addition to general changes in compliance of the bony thorax, specific somatic dysfunctions may have an effect on the function of the respiratory mechanism that goes beyond the changes in compliance they invariably produce. The movement of a typical rib during breathing operates in conjunction with the orientation of its costotransverse and costovertebral joints. Rotation of the thoracic vertebrae with somatic dysfunction will not only create resistance to movement but also change the orientation of the costotransverse and costovertebral articulations, further impairing the ability of the muscles for inhalation to move the rib. With rotation of thoracic vertebral units involved in somatic dysfunction, a rib with a predominantly bucket-handle movement might become oriented to move more like a pump-handle movement. Lumbar somatic dysfunction, particularly in the upper lumbar spine, likely alters the length and orientation of the diaphragm crura and could impair their function and the contraction of the diaphragm.

Angus Cathie (1974) has described the movement of the entire spine with respiration. During inhalation all spinal curves straighten, including counternutation of the sacrum with the base moving posteriorly. Reverse movements occur with exhalation. Somatic dysfunction anywhere in the body may adversely affect breathing.

Increases in work of breathing contribute to respiratory muscle fatigue. Respiratory muscle fatigue has been implicated in the pathophysiology of respiratory failure (McKenzie and Bellemare, 1995; Rossi et al., 2002). Obstructive diseases like COPD may produce respiratory muscle fatigue because of the effects of lung hyperinflation (Roussos and Macklem, 1986). Muscular fatigue may be one of the factors contributing to the demise of the patient with respiratory failure. For example, during a severe asthma attack, the muscles of inspiration fatigue and the patient has difficulty hyperventilating to maintain adequate pulmonary gas exchange. As a result, progressive hypercapnia and hypoxemia may occur both of which lead to cardiovascular instability, arrhythmia, and death. Respiratory muscle fatigue may also play a role in COPD and has led to the identification of the potential role of chronic respiratory muscle fatigue in the pathophysiology of lung disease (Grassino et al., 1984). Respiratory muscle fatigue has also been implicated in diverse problems such as pulmonary edema and difficulties weaning patients off mechanical ventilation (Cohen, 1982; Grassino et al., 1984). Improving thoracic compliance will reduce respiratory muscle workload and may decrease the likelihood of fatigue in both acute and chronic lung disease conditions. Osteopathic treatment may also be used to improve the function and efficiency of the respiratory musculature. OMT should be used in conjunction with the general medical management of the patient. Improvements in mechanical function and thoracic compliance may decrease the need for bronchodilators and steroids. As the patient's respiratory function improves, the ability to clear mucous by coughing may also improve, eliminating the need for expectorants and potentially decreasing airway resistance. Incorporating manipulative

treatment into the care of a patient with COPD may allow the physician to decrease the need for pharmaceutical interventions, and the risks and complications associated with the use of these agents.

Respiratory muscles, like all skeletal muscle, operate on the principle of their length-tension relationship. In this relationship, muscles will develop a far stronger contraction at a longer resting tone. Physical changes associated with exacerbations of obstructive lung disease such as a flattened diaphragm (as visualized on x-ray) and hypertonicity of accessory muscles, such as the sternocleidomastoid, represent shortened musculature that have reduced contractile force during increased workload. In the case of chronic obstructive lung disease, the barrel-type changes in the thorax actually prevent respiratory muscles during inspiration from returning to their full resting length during exhalation. Likewise, increased muscle tonicity may prevent the thorax from achieving a position of complete exhalation, contributing to the overall shape change of the thorax. In addition to altering muscle length-tension relationships, increasing the resting tone of the respiratory musculature will alter its blood supply and oxygen delivery/consumption ratio. Muscles receive most of their blood supply during their resting or diastolic phase. The increased tone during contraction increases the pressure within the muscle and shunts blood away via nonnutritive arterioles. This has been demonstrated to occur in the diaphragm (Grassino et al., 1984). It has also been shown that increased demand in an otherwise normal diaphragm will produce oxygen consumption that is in excess of its supply (Grassino et al., 1984). Increasing the resting tone of a muscle will increase its pressure and reduce incoming blood supply, while simultaneously increasing its oxygen demand, further stressing the oxygen delivery/consumption ratio. Muscles that are forced to function anaerobically are as much as 15 times less efficient than those utilizing aerobic metabolism (West, 1991). Fatigued diaphragms have been found to have high levels of lactic acid, indicating a high degree of anaerobic metabolism (Grassino et al., 1984). Increased resting tone of the respiratory musculature during inspiration can be identified during the osteopathic structural exam as increased muscle tone, generalized tenderness, or tissue bogginess. Osteopathic treatment directed toward increasing the length and decreasing the resting tone of respiratory musculature is indicated in the treatment of acute and chronic lung disease. The diaphragm in particular is prone to increases in tone and associated flattening in acute and chronic obstructive disease. If severe enough, the flattening of the diaphragm may reverse the movement of the lower ribs during inspiration, producing paradoxical rib motion. This reduces the transverse diameter of the chest and greatly decreases the efficiency of the entire respiratory mechanism. In osteopathic literature, restoration of the length and vertical orientation of the diaphragm is called doming of the diaphragm. Doming of a flattened diaphragmatic muscle will increase the pressure gradients that are able to be produced between the thoracic and abdominal regions and can help reverse paradoxical rib motion and improve the function of the diaphragm as well as the respiratory mechanism as a whole. Addressing the mechanics of breathing, including the work of breathing, the compliance of the thorax and spine, both specifically and generally, and the function and efficiency of the respiratory musculature will have far-reaching applications in the treatment of acute and chronic respiratory diseases.

Respiratory/Circulatory Model

Traditionally, the osteopathic concept has viewed the cervicothoracic, thoracolumbar, and pelvic diaphragms as working together to maintain pressure gradients in the pelvis, abdomen, and thorax

(Frymann, 1968, Johnson, 1991, 1992; Zink and Lawson, 1979). These gradients aid in fluid movement through the venous and lymphatic systems, often referred to as the low pressure circulatory system. The actions of the diaphragm, and thorax in particular, have a major influence on the function of the lymphatic and venous systems. This is the basis of the "respiratory/circulatory" model. Zink's original model (Zink, 1977) describes the role of respiration, with its action on central venous flow and pressure, as they influence the emptying of the thoracic duct into the junction of the internal jugular and brachiocephalic veins. Studies that have measured the role of respiration on thoracic duct lymph flow demonstrate that 35% to 60% of the total thoracic duct drainage is in response to respiratory movements (Aukland and Reed, 1993; Browse et al., 1971; Dumont, 1975). Thorax motion during respiration has also been shown to be involved in the actual formation of lymph in a variety of areas, including the lungs and abdomen. Lymph formation is a critical step in the overall mechanics of lymphatic circulation, as a small but significant uphill hydrostatic gradient exists that must be overcome in order for fluid to move from the interstitium into the initial lymphatic, a blind, open-ended vessel (Aukland and Reed, 1993). The excursion of the thorax has been shown to be the primary force moving fluid from the pulmonary interstitium into the initial pulmonary lymphatics. The expansion of the pulmonary interstitial tissue, to which the initial lymphatics are tethered by anchoring filaments, increases the volume of the initial lymphatic flow and produces a temporary pressure gradient for filling these small lymphatics. Exhalation then closes the vessel and moves the lymph forward, past the first valve and into the contractile part of the vessel. The respiratory cycle, then, acts as a pump that initiates the process of lymph formation. All initial lymphatics have anchoring filaments and will therefore respond to respiratory movements to the degree which they occur in the area. The initial lymphatics in the abdomen and pelvis, in particular, respond significantly to respiratory excursions. Lymphatic stomata located in the subperitoneal space of the diaphragm are also involved in the absorption of intra-abdominal fluids. Respiratory movements in the diaphragm act to open and close the mesothelial and endothelial cells assisting lymph flow into the collecting lymph vessels (Bettendorf, 1978).

The clinical significance of the respiratory-circulatory concept in pulmonary disease is likely very important and underestimated. Obstructive lung diseases are associated with inflammation of various pulmonary tissues (Fig. 59.4). Asthma and COPD patients have an overall restriction of thoracic movement during the exhalation phase of respiration, reducing both local drainage of lymph from the small airways and central lymph drainage through the thoracic duct. During an obstructive exacerbation, perhaps initiated by lobar pneumonia or acute bronchitis, there is an intrapulmonary inflammatory process produced that will produce an increased demand on the regional lymphatic circulation. The excursion of the thorax, however, is consistently and significantly reduced by the exacerbation. This restriction in movement leads to a reduction in local drainage of exudates, a decrease in the delivery of antigen to regional lymph nodes, and perhaps impairment in both the cellular immunological response and the transport of antibiotics to the affected areas since lung interstitial pressure rises and shunts blood away from the area. Restoring a greater excursion of the thorax will improve the body's ability to move lymph in this situation; specific lymph pump techniques are also indicated.

Neurologic Model

Autonomic nervous system influences are important in a variety of lung diseases. Vagal activity is involved in the bronchospasm and

Figure 59-4 The relationship between emphysema and chronic bronchitis. Most patients with COPD have a mixture of bronchial inflammation and alveolar destruction.

mucous production in the pathophysiology of asthma and COPD. C2 somatic dysfunction has been consistently noted in diagnostic studies of pulmonary disease (Beal, 1985). Ipsilateral cranial base dysfunction, in particular the occipitomastoid articulation, is usually involved in reflexes involving the vagus nerve. The sensory ganglion of the vagus nerve lies within the jugular foramen, adjacent to the occipitomastoid suture. Though the cervical findings are reported less frequently than upper thoracic, this may be because the vagus and other parasympathetic nerves will not vasodilate or stimulate sweat glands, producing the associated temperature and skin moisture changes that are among the most common recognizable signs of acute segmental facilitation. It is therefore possible that segments facilitated in areas of parasympathetic innervation are under-recognized. Upper cervical findings in pulmonary disease, especially asthma and COPD, may be the most significant structural findings, due to the pathological effects of segmental facilitation of the vagus nerve in this disease. Perrin Wilson (1946) also notes a consistent finding of right T4-5 and right 4th or 5th rib somatic dysfunctions, another common finding in asthmatic patients. He reported significant improvement in acute asthmatic attacks with OMT of these dysfunctions.

Enhanced vagal tone plays a role in producing bronchospasm and airway secretions (Paggiaro et al., 1989; Szekeley and Pataki, 2009). Sensitization or facilitation of the vagus as a result of somatic dysfunction at C2, the occipitomastoid suture or the cranial base may contribute to vagal tone and increase the degree of bronchospasm and secretion. Reducing segmental facilitation may decrease vagal tone and influence bronchospasm. This in turn has the potential to decrease bronchial sensitivity, reduce the need for bronchodilators, and help reduce the severity of an acute attack. Vagal reflex somatic dysfunction should be identified and treated in patients with pulmonary diseases.

A different type of somatic dysfunction is present when pneumonia coexists with the obstructive lung disease. Pneumonia is often accompanied by a local reduction in rib excursion. This dysfunction pattern is described as “barrel chest” in standard physical diagnosis textbooks as well as the osteopathic literature. This phenomenon may be a viscerosomatic reflex carried through visceral afferents, although the dysfunction levels in lower lobe pneumonia are outside the levels of the sympathetic innervation of the lung classically described as T1-5 (Beal and Morlock, 1984; Richardson, 1979; Sato, 1995; Widdicombe, 1991; Wojtarowicz et al., 2003) It is more likely they are produced through the parietal pleura, which carries a local, intercostal innervation. These reflex changes may be involved in the pleuritic chest pain, which often accompanies pneumonia. Treatment of these reflex changes is thought to be important in the overall treatment plan of patients with pneumonia.

Upper thoracic findings associated with pulmonary disease (T1-5, and occasionally T6) are commonly found in patients with acute and chronic bronchitis (Beal and Morlock, 1984). This is consistent with the notion that the primary afferent sensory innervation of the large airways travels via visceral afferent fibers associated with the sympathetic nerves (Cervero, 1985), while the sensory innervation of the small airways (asthma, COPD, lobar pneumonia) travels predominantly via the vagus. While sympathetic outflow may not be as detrimental to pulmonary function as

vagal influence, sympathetic firing may increase the production of the thick, tenacious secretions associated with bronchitis that are difficult to expectorate (Bleecker, 1986). The associated thoracic segmental dysfunction will result in further restriction of the upper thorax and ribs further reducing the ability of the patient to expectorate secretions and should be treated when found.

Costochondritis as well as pectoralis tenderpoints can develop from chronic cough. Osteopathic manipulation to ribs, sternum, thoracic vertebrae, and chest musculature can resolve myofascial and ligamentous articular strains thereby decreasing pain.

Metabolic Energy Model

For COPD patients, physicians need to be acquainted with the metabolic challenges the patient may face. For example, protein-calorie malnutrition is common in severe COPD. High caloric supplements or appetite stimulants can be considered but have not shown long-term benefits. In addition, altered or restricted gait has been shown to increase oxygen demand. Regular OMT visits focused on facilitating normal posture and function may assist in reducing metabolic energy requirements. Once the patient is stable, comprehensive pulmonary rehabilitation should be considered to improve quality of life and exercise capacity. There is a large body of data on the benefits of pulmonary rehabilitation for patients with COPD and other respiratory diseases that you may wish to discuss.

Behavioral Model

Shortness of breath caused by lung disease is a major source of anxiety (Fig. 59.5). Increased sympathetic tone may exacerbate vasoconstriction and bronchial constriction. Stress and anxiety may be higher in patients of lower socioeconomic status. Physicians should have appropriate knowledge of their patients’ ability to pay for their medications and meet other financial obligations that impact their health status. Smoking cessation is essential for

Figure 59-5 The cycle of anxiety and COPD symptoms.

Figure 59-6 Effect of risk factors from smoking on loss of lung function (forced expiratory volume in the first second [FEV₁]). Upper curves are derived from subjects who do not smoke or are not susceptible to the effects of smoking. They lose lung function gradually throughout adult life (15 to 30 mL/y). Lower curves show accelerated loss of lung function in subjects who are susceptible to the effects of cigarette smoke. At age 65 years there is respiratory disability because FEV₁ has decreased to 25% to 30% of predicted (1 to 1.2 L), and further functional deterioration eventually will cause death because of complications of respiratory insufficiency. If the subject stops smoking, life may be prolonged but a respiratory death still eventually will result. If intervention is initiated earlier in life (age: 40 to 50 years) when COPD is mild, accelerated loss of lung function is reversible and a respiratory death will be prevented. Although this figure illustrates theoretical loss of FEV₁ for an adult cigarette smoker, susceptible smokers will lose lung function at different rates, thereby becoming disabled at different ages. (Modified from Fletcher C, Peto R. The natural history of chronic airflow obstruction. *BMJ* 1977;1:1645, with permission.)

all patients and paramount for patients with COPD (Fig. 59.6). The best results are seen when counseling and medication therapy are combined (Sadr et al., 2009). Prevention of infection with the proper use of vaccines, such as the pneumococcal and influenza vaccines, should be discussed with the patient annually.

PATIENT OUTCOME

The next day the patient had improved. He was now hemodynamically stable. Systemic steroid therapy and nebulized bronchodilator treatments were tapered over a 2-week period. Long-acting anticholinergic and beta-adrenergic inhalers and inhaled corticosteroid therapy was continued and pulmonary rehabilitation was recommended. Rib-raising and diaphragm- doming techniques were continued daily throughout his hospital stay. As he progressed, more focus was given to the cervical and lumbar areas using indirect,

balancing, and soft tissue techniques. The thoracic outlet was also treated to improve lymphatic flow through the thoracic duct. Both thoracic and pedal pumps were initiated and performed two to three times daily. After discharge from the hospital, the patient followed up for monthly OMT to maintain compliance of his thorax.

Suggested protocol for using OMT in the acute stage of a COPD exacerbation: focus the OMT on the ribs, thoracic spine, and diaphragm to reduce mechanical restrictions. Next, incorporate treatments that target the autonomic nervous system (Box 59.3). Start with indirect treatments such as myofascial release, balanced ligamentous tension, osteopathy in the cranial field, and FPR. As the exacerbation improves, more direct techniques such as HVLA and muscle energy are appropriate if no contraindications. A patient with a chronic condition such as COPD may benefit from OMT to prevent further acute exacerbations. The time interval for OMT is individualized and will depend on the patient, but generally speaking follow-up is usually every 1 to 4 months.

Suggested OMT Protocol for Treating Patients with COPD

Cervicogenic Headache

RAYMOND J. HRUBY, MARCEL P. FRAIX, AND REBECCA E. GIUSTI

KEY CONCEPTS

- Cervicogenic headache (CGH) has a precise clinical definition and a typical presentation.
- The pathophysiology of CGH has been elucidated.
- There is some evidence base for the use of osteopathic manipulative treatment in CGH using the five-model approach.
- Patients with CGH should receive thorough somatic evaluation.

CASE VIGNETTE

A 32-year-old right hand dominant Caucasian female presents to your clinic complaining of episodic headache type pain for the past 2 months. The pain has a pressure-like quality and is located in the bilateral occipital and frontal regions of the head. It lasts for approximately 30 minutes and primarily occurs in the morning. The headaches occur two to three times per week and appear to be more frequent when the patient experiences increased stress at work or lack of sleep. The patient was involved in a motor vehicle accident 3 years prior as a restrained passenger and did sustain a whiplash type of injury. She does not have a history of head trauma and currently denies experiencing photophobia, visual changes, or nausea.

Past Medical History:

Seasonal allergies

Past Surgical History:

Tonsillectomy at age 5 years, wisdom teeth extracted at age 26 years

Family History:

Her mother is 58 years old, and her father is 59 years old with a history of asthma. She has no siblings. There is no family history of migraine headaches.

Social History:

She is single, sexually active in a monogamous relationship for 3 years. She is employed as an administrative assistant. She does not use tobacco and uses coffee and alcohol only occasionally.

Medications:

She takes acetaminophen, two tablets every 2 to 4 hours as needed for pain, uses an antihistamine as needed for seasonal allergies, and takes oral contraceptive pills for birth control.

Allergies:

No history of drug or food allergies

REVIEW OF SYSTEMS

General:

She is in good health, exercises two times per week, and reports no recent change in appetite or weight, no fever or night sweats.

HEENT:

No sore throat or dysphagia, no sinusitis, no auditory changes, tinnitus or vertigo, seasonal allergies

Respiratory:

No cough or dyspnea

Cardiovascular:

No chest pain or palpitations

Nervous:

No sensory changes or motor weakness, no ataxia

Musculoskeletal:

Intermittent neck and upper back pain that occurs with prolonged sitting at work. No joint pain or swelling

PHYSICAL EXAM

Vital Signs:

Temperature 37°C, pulse 82/min and regular, respirations 12/min, blood pressure 128/84

General:

Well-nourished female in no acute distress, alert and oriented to person, place, and time

HEENT:

No signs of trauma, sclera clear, fundoscopic examination demonstrates sharp disc margins without papilledema, visual acuity is 20/20, auditory canals are clear, and tympanic membranes are intact. No nasal drainage is noted and the nasal septum is midline. The oropharynx reveals no exudates or erythema.

Respiratory:

No wheezes, rhonchi, or rales

Cardiovascular:

Regular and without murmurs

Neurological:

Cranial nerves II to XII are grossly intact, motor strength is 5/5, and reflexes are 2+/4+ bilaterally in upper and lower limbs. Sensation is intact to light touch and pinprick, and coordination is intact.

Osteopathic Structural Exam:

Cranial examination reveals restricted movement of the right occipitotemporal suture. The cervical spine demonstrates decreased active and passive ranges of motion in all planes, somewhat worse with right sidebending and rotation. The cervical paravertebral and upper trapezius musculature demonstrate increased tone with mild tenderness to palpation. Specific joint motion restrictions include: OA R_RS_L, AA R_R, C2-C3 ER_LS_L, T1-3 R_RS_L, T4-5 ER_LS_L, and a left sacral torsion around the left oblique sacral axis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of headache includes the following:

- Cervicogenic headache (CGH)
- Occipital neuralgia
- Migraine and tension-type headache

A particularly difficult diagnostic challenge is distinguishing CGH from migraine without aura and tension-type headache. CGH must also be distinguished from other causes of headache that are more serious and potentially life threatening. These include the following:

- Arteriovenous malformation
- Cerebral aneurysm
- Chiari malformation
- Glaucoma
- Meningitis
- Posterior fossa tumors
- Pseudotumor cerebri
- Epidural, subdural, or subarachnoid hemorrhage
- Vasculitis, such as temporal arteritis
- Vertebral artery dissection

The absence of systemic signs such as fever, chills, etc. rules out infection pathology. Normal vital signs and the absence of neurological signs make tumor, pseudotumor, vertebral artery dissection, arteriovenous malformation, vasculitis, and cerebral aneurysm less likely. There are no visual changes but intraocular pressures can be assessed to rule out glaucoma. There are also other causes of head pain that come from cervical pathology, although these are unlikely in this patient because of her age and presentation (Box 60.1).

The most likely differential diagnosis in this patient includes cervicogenic, migraine, or tension-type headache. These three entities are differentiated primarily by patient history. As described below; the most likely diagnosis for this patient is CGH.

Cervical Causes of Headache

A-V malformation
 Cervical spondylosis
 Greater occipital nerve compression or inflammation
 Herniated cervical disc
 Rheumatoid arthritis
 Trauma
 Tumors
 Vasculitis
 Vertebral artery dissection

OVERVIEW OF CERVICOGENIC HEADACHE

CGH may be defined as pain referred to the head region, typically unilaterally, from cervical musculoskeletal dysfunction. It is characterized by the presence of cervical somatic dysfunction as exhibited by muscle spasm, decreased range of motion, and pain upon digital provocation. It is usually worse with movement and better with rest. It can be associated with tendonitis in any of the cervical muscles, trigger points or tender points in the cervical or head region, and/or inflammation of the cervical spinal joints (1,2).

EPIDEMIOLOGY

Patients of all ages can be affected by this problem, with the mean age being 42.9 years (3). CGH is four times more common in females than males (4) and accounts for 14% to 18% of all chronic and recurrent headaches (5,6). It is a common symptom following neck trauma (54% to 66% of patients with whiplash associated disorder complain of headache). It should be noted that 54.8% of patients seen by pain specialists have CGH or CGH in combination with other types of headache (7). The prevalence of CGH in the general population is estimated to be 0.4% to 2.5% (3).

CGHs often lack a regular pattern. They are often episodic, recurrent, lasting hours to days per episode, and can seriously affect the patient's quality of life (8). Some patients develop CGH after trauma, such as a whiplash injury (9). These headaches often resolve within a year. However, previous traumas or preexisting headache and neck pain may lead to chronic CGH after whiplash injury (10).

The effect of CGH on society is also significant. In a United States survey totaling 13,343 respondents, 9.4% reported missing work more than rarely because of headache, 31% reported that their work level was reduced more than rarely by headache, and 9.2% reported that their work level was reduced more than 50% by headaches during work (11). On average, individuals lost the equivalent of 4.2 d/y because of headache. Subjects with migraine headache were much more likely (57%) to report actual lost work-days because of headache, whereas tension-type and other headache types accounted for a large proportion (64%) of decreased work effectiveness because of headache. Headache type, headache severity, and education level were each independent predictors of workplace impact of headache.

In a 2001 to 2002 random sample telephone survey of over 28,900 American workers, 13% of the total workforce experienced a loss in productive time during a 2-week period due to a common pain condition (12). Headache was the most common pain condition resulting in lost productive time, accounting for a mean loss of 3.5 hours in productive time per week. Among active workers, lost productive time from common pain conditions (i.e., headache, back pain, arthritis) costs an estimated \$61.2 billion per year, with \$20 billion due to headache. The majority (76.6%) of the lost productive time was not due to an absence from work but was explained by reduced performance while at work.

Risk factors for developing CGH include the following:

- Head or neck traumatic injuries can predispose a patient to CGH symptoms
- Sustained neck postures or movements may precipitate CGH
- Primary or significant compensatory cervical somatic dysfunctions

PATHOPHYSIOLOGY

Cervical somatic dysfunction refers pain to the head and face via the trigeminal nerve (CN V). This same nerve innervates cranial

and facial structures, including the cerebral blood vessels and dura mater, and sends its sensory information to the pons in the mid-brain and then to the thalamus and somatosensory cortex. The trigeminal nerve also has tracts that descend into the spine. For example, the upper cervical spinal cord contains the Trigeminal Nucleus Caudalis (TNC). The TNC descends as low as C4 and is contiguous with the spinal gray matter in the substantia gelatinosa in lamina II of the dorsal horn.

The first three cervical spinal nerves innervate the zygapophyseal joints, uncovertebral joints, intervertebral discs, cervical muscles and ligaments, the vertebral artery, the cervical spinal dura, the posterior scalp, and even the lower layer of the tentorium cerebelli. Afferent fibers from these structures converge with the TNC within the spinal cord. As a result, pain signals from the neck can be referred to the same receptive field in the thalamus as that of the head and face, giving the patient the sensation that the pain is emanating from the head or face when in fact it is coming from the cervical spine.

Nociceptive stimuli from the C5-7 nerves can also refer pain to the head and face through the TNC since afferent nociceptive information can ascend between 1 and 3 levels before entering the dorsal horn and interacting with interneurons that connect with the TNC.

Nociceptive input originating from cervical structures can therefore be perceived as head pain in the regions innervated by the trigeminal nerve (16,17).

The superior and inferior vagal ganglia lie superior and inferior to the jugular foramina, respectively. The vagus (CN X) is a mixed nerve with motor, sensory, and parasympathetic components. Of interest in CGH is the fact that nociceptive or inflammatory stimuli from the larynx and pharynx, as well as the thoracic and abdominal viscera, are transmitted by the vagus and converge with upper cervical afferents (18). The increased afferent activity converging in the upper cervical region is thought to increase the efferent discharge of cervical spinal motor neurons accounting for the palpable increase in myofascial tissue tension in the upper cervical spine, thus constituting a viscerosomatic reflex. In addition, primary sensory axons from the superior vagal ganglia terminate in the TNC and convey general sensation from the external auditory meatus, external surface of the tympanic membrane and skin of the ear to the trigeminal receptive field in the thalamus. The spinal accessory nerve (CN XI), which sends motor efferents to the trapezius and sternocleidomastoid muscles, also has some sensory afferents that may converge with the TNC (16,17).

With respect to the sympathetic nervous system, sympathetic nerve fibers are dense in the basal region of the occipital dura mater and alongside as well as independent from blood vessels (19). The superior cervical ganglia are positioned anterior to the articular pillars of C2. They have postganglionic fibers that innervate the vasculature, mucous membranes of the head region, including the middle ear, the lacrimal glands, and pupils of the eyes. Their preganglionic cell bodies emanate from the spinal cord at levels T1-4.

Within the peripheral nervous system, a number of structures may be involved with CGH. The greater and lesser occipital nerves originate from roots at C1-3; the medial branches of the dorsal rami of C2 and C3 form the greater occipital nerve and the third occipital nerve. The greater and lesser occipital nerves innervate the posterior scalp. Occipital neuralgia may arise from entrapment or trauma to these nerves, the upper cervical zygapophyseal joints or the C2 spinal root. The suboccipital (C1) nerve innervates the occipitoatlantal joint and may be involved with somatic dysfunction that can refer pain to the occipital region. The AA joint and C2-3 are innervated by the C2 spinal nerve. Neuralgia arising from

C2 can result in a deep or dull pain that usually radiates from the occipital to the parietal, temporal, frontal, and periorbital regions. A paroxysmal sharp pain may be superimposed over the constant pain. Lacrimation and conjunctival injection of the eye on the affected side are common associated signs. The third occipital nerve, arising from the dorsal ramus of C3, innervates the joints at C2 and C3. Somatic dysfunction of these joints may be involved in referring pain to the frontotemporal and periorbital regions (17).

TYPICAL PATIENT PRESENTATION

Patients may describe the pain of CGH as moderate to severe in intensity, deep, nonthrobbing, and nonlancinating. Certain precipitating factors may be involved, such as certain neck movements or particular sustained head positions. There may be a history of whiplash or other head or neck injury prior to onset of symptoms. It should be noted, however, that patients frequently have difficulty in identifying factors that precipitate, aggravate, or alleviate their headaches.

In CGH, the location of the head pain may be in the frontal, posterior, or lateral part of the head, at the vertex, or behind the orbit. The pain is typically unilateral, although it may occasionally be bilateral (1). The pain may radiate along the ipsilateral side of the head, to the neck and/or shoulder, and occasionally into the arm (1). There may also be scalp paresthesias or dysesthesia. Other characteristics include headache episodes of varying duration, and lack of response to medications that are usually helpful in alleviating other types of headache. Associated symptoms may include nausea, phonophobia, photophobia, dizziness, ipsilateral blurred vision, difficulties with swallowing, and ipsilateral periorbital edema. Coughing or sneezing may also trigger the pain.

PHYSICAL EXAMINATION OF THE PATIENT WITH HEADACHE

The physical examination of the patient with headache should include vital signs, a screening cardiovascular, neurological and musculoskeletal examination, and a regional evaluation of the head and neck. Normal vital signs help to rule out endocrine, cardiovascular, and infectious processes. The screening neurological examination is used to rule out focal deficits suggesting intracranial mass or event, and peripheral etiology such as peripheral nerve impingement with radiculopathy or spinal cord impingement from a herniated cervical disc.

The screening musculoskeletal exam evaluates large and small joints for systemic inflammatory conditions such as rheumatoid arthritis, which may present with headache. The head and neck areas should be examined for pharyngeal and tonsillar inflammation, glandular hypertrophy and/or tenderness, or lymphadenopathy that would alert the practitioner to internal organic problems that can also be an underlying cause of headache. The carotid arteries should be auscultated for any bruits.

The osteopathic physician should perform a general osteopathic screening exam of the musculoskeletal system, followed by a regional exam and then a segmental exam. The main areas of focus will likely be the head and cervical spine, but as noted above, other body regions may reveal somatic dysfunction deemed to be associated with the patient's CGH symptoms. The reader is referred to Chapters 56, 57, and 58 for further information.

Asymmetry of musculoskeletal structural landmarks, altered quantity or quality of active or passive neck motion, tissue texture abnormalities, and tenderness, lead the practitioner to consider mechanical neck disorder, or somatic dysfunction diagnosis.

It is also possible that somatic dysfunction of more distant body regions, such as the lumbar spine and pelvis, may be contributing factors in the patient with CGH. Restriction of motion of the AA (C1-2) joint is a very common finding in patients with CGH (29). There may be asymmetrical neck and head position in relation to the shoulders. Head pain can often be reproduced by digital pressure over the upper cervical or occipital region on the symptomatic side. Restriction of active and passive neck range of motion, particularly in the upper three cervical joints, is a common finding. There may be neck muscle stiffness and trigger points in the lower cervical or shoulder muscles that refer pain to the ipsilateral head region. Identification of clinically significant somatic dysfunction provides the indication for the use of osteopathic manipulative treatment.

LABORATORY AND RADIOLOGIC FINDINGS

These evaluations are not typically necessary if the history and physical examination is consistent with mild sprain or strain of the neck musculoskeletal tissues. In acute whiplash or other trauma, however, it may be necessary to obtain cervical radiographs to rule out vertebral fracture or dislocation. Patients with chronic mechanical neck pain refractory to osteopathic manipulative treatments and exercise may require further diagnostic imaging to rule out less common causes underlying persistent neck pain. Blood tests for systemic pathology are typically negative, and any cervical disc bulging seen on MRI or CT scan is usually nonspecific (30).

FIVE MODELS FOR APPLYING OMT FOR CGH

The osteopathic physician may organize osteopathic philosophy and principles according to a conceptual framework developed by the Educational Council on Osteopathic Principles (ECOP) (36). ECOP delineated five models for consideration. These models are mechanical, neurologic, respiratory-circulatory, metabolic-nutritional, and biopsychosocial. In the case of CGH, each model allows the osteopathic physician to consider:

- How the elements of the particular model are affecting, or being affected by, the patient's condition by contributing to the overall allostatic load on the patient
- Treatment options applicable to the particular model, including osteopathic manipulative treatment (OMT)
- Preventive measures relative to the specific model

BIOMECHANICAL MODEL

This model deals with factors that alter posture, motion, and gait. This approach includes evaluating altered joint relationships, muscle imbalances, and abnormal fascial tensions. These somatic dysfunctions can cause or contribute to adverse neurologic and circulatory functions. This process, along with the energy demands of the body's attempt to cope with abnormal mechanical stresses, can be part of the allostatic load contributing to CGH. The goal of treatment within this model is the restoration of free motion within the body's musculoskeletal system elements. A wide range of OMT techniques can assist in alleviating these stressors. These OMT techniques include high velocity-low amplitude, muscle energy, and articular and functional techniques, among others.

RESPIRATORY-CIRCULATORY MODEL

This model addresses altered respiratory mechanics that may predispose to congestive changes, decreased lymphatic flow, venous

return, and edema formation. These adverse changes can lead to insufficient oxygen and nutrient distribution to tissues, reduced venous and lymphatic return, impaired immune system function, and insufficient removal of metabolic waste products from the body. The treatment goal within this model is to restore the body's ability to adequately move air and fluids throughout its systems. Somatic dysfunctions relative to this model include altered rib cage mechanics and restricted motion of the thoracic diaphragm and other functional diaphragms of the body. Commonly used OMT modalities for this model include osteopathy in the cranial field, myofascial release, and lymphatic pump techniques.

NEUROLOGIC MODEL

The neurologic model deals with the effects of facilitated spinal cord segments and sustained sympatheticotonia, resulting in viscerosomatic and somatovisceral reflex phenomena, including the signs and symptoms of CGH. Goals of treatment within this model include restoration of autonomic balance, alleviation of segmental facilitation, decrease in or elimination of abnormal afferent signaling, and relief of pain. Various OMT techniques can be used here, but some modalities that are thought to be especially effective within the neurological model include counterstrain and the treatment of Chapman reflex points.

METABOLIC-ENERGY MODEL

The metabolic-nutritional model takes into consideration such things as dietary deficiencies and excesses, food allergies, the effect of toxins, and any other factors that may affect the self-regulatory and self-healing mechanisms of the body. Treatment goals for this model include promoting energy conservation by balancing the body's energy expenditure and exchange, and enhancing immune system function. In this model, a major emphasis is on such things as nutritional counseling, dietary advice, avoiding obesity, and encouraging exercise.

BEHAVIORAL MODEL

In this model, we consider the psychological and social components of the patient's health status. Some of these components include the patient's spiritual outlook, social support system, ability to cope with stress, and ability to make healthy lifestyle choices. In particular, stress is a well-known cause or contributor to headache, including CGH. Thus, reduction of stress factors can contribute to the ultimate control of CGH in some patients. The treatment goals for this model include optimizing the psychological and social components of the patient's overall health. This might include teaching the patient strategies for stress reduction, helping the patient improve his or her abilities for social interaction, and helping the patient improve his or her spiritual outlook. OMT is not commonly a part of the treatment approach in this model, although some osteopathic physicians advocate the use of OMT to improve autonomic balance for these patients, thus secondarily helping to relieve stress on the body.

BIOLOGICAL BASIS FOR THE USE OF OMT—BEST EVIDENCE

CGH may be related to somatic dysfunction of the OA and AA joints and neck pain most often related to C2-7 somatic dysfunction. Up to 50% of whiplash patients with chronic neck pain and dominant headache symptoms have C2-3 zygapophyseal joint pain

that can be abolished with nerve blocks (22,23). Nerve blocks of the greater occipital nerve and lower cervical segments have also abolished headache symptoms, implying that these structures may become sensitized and thus involved in producing CGH (24,25).

Cervical somatic dysfunction has been thought to involve the trigeminal and spinal accessory cranial nerves, which innervate structures in both cervical and head regions. It is theorized that the TNC in the upper cervical spinal cord interacts with upper cervical peripheral afferents and the spinal accessory nerve (CN XI) to account for the bidirectional referral of painful sensations between the neck and the trigeminal receptive sensory fields of the face and head (17).

Muscle hypertonicity in the upper cervical and occipital regions may induce tension transmitted through the myodural connective tissue and elicit head pain. The facet joints between C1 and C2 produce pain in the posterior auricular area in the distribution of the greater occipital nerve. Diseases of the structures innervated by the vagus nerve may produce sensitization of upper cervical spinal segments and predispose the patient to upper cervical somatic dysfunction, leading to CGH (26). Cervicogenic pain has also been abolished with cervical myofascial trigger point and botulinum toxin injections, indicating peripheral sensitization in the soft tissues plays a role in CGH genesis as well. It has also been shown that increased levels of proinflammatory cytokines and nitric oxide are higher in patients with CGH compared with patients with migraine headaches and likely promote hyperalgesia (27). However, the lack of calcitonin gene-related peptide in symptomatic CGH patients indicates that the trigeminovascular system is not activated by this condition as it is in migraine patients (28).

Osteopathic physicians theorize that cervical mobilization and manipulation procedures decrease the afferent stimulus into the spinal cord from cervical joint receptors by relaxing the paraspinal muscles and releasing strain on the connective tissues and joints, thus relieving the pain of CGH. OMT and physical conditioning exercises for moderate to severe pain of any duration are effective for patients of all ages or gender (31–34). Ongoing exercise and physical conditioning programs can be beneficial for long-term prevention and control of symptoms (35).

Although OMT is a highly safe procedure, there are potential risks associated with its use. The primary risk identified in the literature is hyperextension coupled with rotation of the upper cervical spine due to concern regarding potential occlusion of the vertebral artery. Caution should also be exercised with patients with primary or secondary bone, neural or muscular disease as is true in any body region. Commonly accepted contraindications to manual medical treatment of mechanical cervical spine disorders include the following:

- Vertebral or carotid artery dissection
- Acute fracture of cervical vertebra or vertebrae
- Metabolic or neoplastic bone disease in the cervical spine
- Acute trauma to the head or neck without established diagnosis
- Certain primary muscle or joint diseases
- Patient refusal of treatment

Certain clinical conditions do not necessarily contraindicate the use of OMT but do require caution on the part of the osteopathic physician. For example, patients with congenital anomalies, such as those with Down Syndrome, may have deformities of the upper cervical spine that will alter the biomechanics in that region. Caution is also warranted in treating patients with rheumatoid arthritis as there may be laxity of the odontoid ligament and hypermobility of the AA joint.

The benefits of OMT for CGH include decreased pain frequency, intensity, and duration (31); improved ability to perform activities of daily living and work activities; and decreased reliance on analgesic and other medications that can have unwanted side effects and complications. The consensus among most practitioners is that CGH should be treated with a combination of manual treatment, exercise, locally injected and oral medications, stress reduction counseling, and education. Surgery is reserved for refractory conditions.

PHYSICAL MEDICINE AND REHABILITATION PERSPECTIVE

In spite of additional knowledge and experience in managing cervical spine disorders, the physician spine specialist oftentimes still finds the diagnosis of CGH to be quite challenging. Although various anatomical structures, including the cervical spine musculature, nerves, discs, and zygapophyseal joints, have been implicated in the pathophysiology of CGH, there is limited evidence that supports any of these structures as clearly causing CGH. Most research regarding this issue has focused on examining patient symptomology in response to structure-directed treatment, including facet and trigger point injection and cervical discectomy and fusion. Diagnosing the cause of CHG is also made more challenging by the fact that it is oftentimes difficult to differentiate between cervicogenic, migraine, and tension-type headaches. Given these challenges, it is helpful to use an approach, such as the five conceptual models, that addresses the various structures and pathological processes that may be concomitantly causing CGH.

One reason why it may be difficult to diagnose and define the cause of CHG is that the upper cervical nerve roots innervate many of the structures typically suspected of causing CHG. These nerve roots converge with trigeminal nerve fibers in the upper cervical spinal cord, potentially explaining why nociceptive input from cervical spine structures may cause pain in the head and face. Diagnosis is also difficult due to the fact that there is no diagnostic or clinical finding that is specific for CGH. Historically, radiological abnormalities of the cervical spine have been used as diagnostic criteria for CGH (37). Even though radiographic abnormalities such as cervical spondylosis may be present when evaluating a patient with CGH, there is limited evidence demonstrating that these abnormalities are specific to CGH (38). Additionally, studies examining the cervical MRI studies of patients with CGH failed to demonstrate a difference between control subjects and those with CGH when evaluating for MRI abnormalities such as cervical disc bulging (30). While laboratory results may be abnormal in the presence of systemic disease, such as rheumatoid arthritis, there is also no laboratory marker that is specific for patients with CGH. Some research, however, has demonstrated that proinflammatory mediators may be higher in patients with mechanically induced CGH than those patients with migraine headache (39). Due to the equivocal nature of these diagnostic findings, it is important that the spine specialist perform a detailed history and physical examination when evaluating a patient for CGH. This is helpful in identifying cervical spine disease, including cervical spondylosis and nerve root compression, as well as excluding more serious conditions such as tumor or infection (40). Important components of the clinical evaluation include cervical range of motion, motor and sensory testing, and provocative testing for nerve root compression. Clinical evaluation can also be helpful in differentiating CGH from migraine headache. These are often difficult to discern from one another due to the overlap in diagnostic criteria, including photophobia and nausea. It appears that the most significant

criterion in distinguishing CGH from migraine headache is the precipitation of headaches with movement of the neck or application of pressure to the neck (41). Given the fact that the etiology of CGH may be multifaceted and that its diagnosis requires assessment of multiple structures and physiological processes, it again may be useful to use the five conceptual models when evaluating a patient with CGH.

Because of its multifaceted nature, management of CGH often entails a combination of treatments, including osteopathic manipulative medicine (OMM), medication, injections, and surgery. As an expert in spinal disorders, the spine specialist is interested in better understanding the potential pain generating source of CGH, so as to potentially render more effective treatment. One way in which this is accomplished is through the use of cervical injection techniques, which can be helpful in both diagnosing and treating the pain-generating structures causing CGH. These include cervical zygapophyseal joint and medial branch blockade for facet disease, epidural for degenerative disc disease and nerve root compression, and occipital and cervical nerve blockade, and trigger point or botulinum toxin injection for muscle spasm. Although there is limited evidence supporting the efficacy of these techniques, it does appear that patients may experience some degree of pain relief if their CGH is secondary to a well-defined disease process. The idea that CGH may be due to abnormal muscle tension is potentially supported by a study, which found that injection of botulinum toxin into the cervical paraspinal muscles significantly reduced pain and increased cervical range of motion (42). Surgical techniques such as anterior discectomy and fusion are typically reserved for refractory cases that demonstrate clear cervical spine pathology, including cervical radiculopathy and degenerative disc disease. Some studies have suggested that such surgical techniques are effective in treating CGH when it is associated with specific cervical spine pathology (43). Like much of the research examining the efficacy of injection techniques, however, they are of limited value given their small sample sizes and suboptimal outcome measures. Interestingly, it appears that cervical manipulation is the means of treatment most supported by a reasonable body of literature (44). This includes a randomized controlled trial demonstrating that cervical manipulation utilizing high velocity amplitude technique resulted in reduced CGH intensity and frequency and analgesic use when compared to deep friction massage (45). This is an important point to consider when integrating osteopathic manual medicine into the treatment plan, whether that entails the physician performing OMM or referring a patient to a Neuromusculoskeletal Medicine/OMM specialist.

SUMMARY

CGH is a common medical problem affecting a significant percentage of the population. A holistic, patient-centered approach, consistent with osteopathic philosophy, principles, and practice, provides a strategy for optimal control of this condition in patients. Osteopathic physicians can use the tenets and organizing principles of osteopathic medicine, a five-model approach to patient care, and their distinctive OMT modalities to achieve a high degree of success in helping patients with this condition.

Large Joint Injury in an Athlete

KURT HEINKING, PER GUNNAR BROLINSON, AND THOMAS A. GOODWIN

KEY CONCEPTS

- Rotator cuff strains can develop as a result of repetitive overuse.
- The kinetic chain associated with shoulder movements extends from the head to the pelvis.
- Somatic dysfunction in any of the tissues associated with the kinetic chain can exacerbate and contribute to shoulder disorders.
- An integrated approach to shoulder pain, including the use of manual medicine, can be effective in decreasing pain, reducing functional disability, and returning the patient to normal activities.

CASE VIGNETTE

Ms. Jones is a 52-year-old Caucasian right-hand dominant high-level recreational tennis player who seeks medical care following an injury to her right shoulder.

CHIEF COMPLAINT

Acute exacerbation of chronic aching pain in her anterior/lateral right shoulder for the past 6 weeks, after participating in the Regional United States Tennis Association (USTA) event.

HISTORY OF PRESENT ILLNESS

The pain has been present for the past 6 weeks. The pain began after participating in the USTA regional event where her team qualified for the State tournament. She noted that the pain began while playing in a doubles match during which she hit multiple overhead strokes in addition to normal serving in the closely contested match. Just prior to the regional event, she purchased a new racquet with all of the “latest technology.” She states that the pain has not improved despite taking one week off from playing, and now she is developing stiffness of the right shoulder. The pain is affecting her in daily activities. She is concerned about the ongoing discomfort as she wants to begin to prepare for the State tournament with her team. She describes her pain as being a constant 5/10 in intensity and having a burning/aching quality. When she attempts to reach overhead, the pain increases to a 7/10 in intensity. The pain radiates to the right medial scapular border and also down the biceps muscle anteriorly. She has difficulty sleeping on her right side night as she develops pain in the region of the deltoid insertion. She notes that she cannot hook her bra or put a sweater on overhead without significant discomfort. She denies having significant neck pain, but does have some stiffness in turning left and right. She denies having numbness or weakness involving her right hand. She denies chest pain, fever, shortness of breath, cough, or stomach upset. She has had shoulder pain on the right side in the past that resolved with home treatment. She has taken naproxen sodium 220 mg twice daily without improvement. She used ice on the shoulder for the first two days, but has not used any ice or heat since then. She has not had any other workup or imaging performed as of this time.

Past Medical History:

Positive for gastroesophageal reflux disease, Hyperlipidemia, and menopause

Past Surgical History:

Appendectomy at age 18, Tonsils and adenoids at age 6

Past Trauma History:

Motor vehicle accident 1982 during which she sustained a minor concussion and whiplash

Family Medical History:

Mother alive (age 75 HTN); type II diabetes; father deceased (cirrhosis of the liver at age 58); siblings, one brother (age 49), healthy

Gynecologic History:

G2 P, 2002; LMP, 2 years ago; last mammogram, 1 year ago—normal; last pap and pelvic, rectal exam 1 year ago—normal

Social History:

Married; husband: Roger, 22 years; 2 children: Mary—21, healthy and Grace—19, healthy; Denies tobacco use, illicit drug use, occasional alcohol (holidays). Patient is an office manager for a large medical group. She normally plays tennis four to five times weekly during the competitive season and one to two times weekly during the off-season.

Childhood Illnesses:

Chicken pox, possible measles, Mononucleosis at age 18

REVIEW OF SYSTEMS

General:

She denies fever, chills, and malaise

HEENT:

She admits to occasional tension headaches, which have not changed since the onset of the shoulder pain. She denies dizziness.

Cardiovascular:

She denies chest pain, shortness of breath, fatigue.

Pulmonary:

She denies cough, wheeze, and pain with breathing.

Gastrointestinal:

She denies abdominal pain, nausea, vomiting, intolerance to fatty foods, excessive alcohol use, change in stools, and change in appetite.

Musculoskeletal:

She denies pain, swelling and stiffness in other joints, although she does admit to episodes of mid and upper back pain.

Neurological:

She denies weakness, numbness.

Endocrine:

She denies weight change; she admits to occasional hot flashes. She is menopausal.

PHYSICAL EXAMINATION**Vital Signs:**

T 97.6, P 78, R 16, BP 140/ 82, height 5' 6", weight 148 lb

General:

Alert, oriented, cooperative, neatly groomed, and an excellent historian. She appears younger than her stated age.

Skin:

No rashes, no abnormal-appearing moles, normal hair and nails

HEENT:

PERLA EOMI, Pharynx without erythema, No adenopathy, TM's good cone of light without erythema, no nasal erythema, no sinus tenderness

Cardiovascular:

RRR without S3 S4 murmur, no clubbing, cyanosis, or peripheral edema. Equal pulses bilaterally

Lungs:

CTA without rales, rhonchi, wheezes

Breast:

No breast masses, nipples everted, no discharge, no axillary adenopathy

Abdomen:

BS × 4 quadrants without rigidity, rebound, guarding, Neg CVA pain, No masses appreciated. No RUQ discomfort on palpation, Negative Murphy sign.

Neurological:

CN's 2 to 12 intact, DTR's 2/4 bilateral, No sensory deficits, 5/5 motor strength bilateral

MUSCULOSKELETAL**Upper Extremities:**

Right shoulder: Active abduction full, but with painful arc from 50 degrees to full abduction. Active external rotation limited to 20 degrees secondary to pain. Active and passive adduction, flexion, extension and internal rotation full and pain free. Positive Jobe test (empty/full can), Positive Hawkins sign, Neg Speed's test, Neg Drop arm test, Positive Neer test, Positive

A/C tenderness, Neg subscapularis test (lift-off/Napoleon's), Neg labral tests (O'Brien's, Zaslav, Biceps load, Crank etc.), No gross scapular winging although observation of active scapular motion reveals right scapula dyskinetic in early abduction coupled with flexion. Neg Roos test, No cyanosis, clubbing or edema, Pulses equal bilaterally, brisk capillary refill.

Lower Extremities:

Full Hip, Knee, Ankle AROM PROM, Neg Lachman test, Neg joint line pain, Neg Mc Murray's and Apley's; Negative Patellar grind, Neg Hip comp. No cyanosis, clubbing or edema, Pulses equal bilateral, good capillary refill

OSTEOPATHIC STRUCTURAL EXAM

C5 is flexed rotated and sidebent right, T4 is extended sidebent and rotated right, there is an exhalation dysfunction involving rib 10 on right, L1 is flexed rotated and sidebent right, right anterior innominate, left on left sacral torsion, right psoas hypertonic and tight, superior right sternoclavicular joint.

DIFFERENTIAL DIAGNOSIS

Table 61.1 outlines the differential diagnoses for shoulder pain.

WORKUP AND INTERPRETATION

Shoulder x-rays were obtained. These included an AP view, axillary view, scapular y view, and outlet view. The x-rays demonstrated a type II acromion with cystic change at the acromioclavicular joint. The humeral head was without osteoarthritis, fracture, or subluxation. The remainder of the osseous anatomy was normal. An arthrogram of the shoulder was obtained. Again demonstrated is a type II acromion with cystic change at the acromioclavicular joint. Findings also included a full-thickness tear of the supraspinatus tendon with retraction. A small amount of fluid was seen in the subacromial bursa. The humeral head was without osteoarthritis, fracture, or subluxation. The glenoid labrum appeared intact.

Diagnosis

The patient's diagnosis based on the clinical history, examination, and diagnostic imaging was as follows: (1) full-thickness rotator cuff tear with retraction of supraspinatus tendon; (2) type II acromion osteoarthrosis of the acromioclavicular joint; (3) somatic dysfunction: cervical, thoracic, rib, lumbar, sacrum, pelvis, and upper extremity; (4) scapular dyskinesis; (5) kinetic chain dysfunction; and (6) GERD (acid reflux disease)—controlled currently.

Relevant Functional Anatomy

The shoulder complex is a loosely constructed highly mobile complex of bones, muscles, and ligaments. It is designed for increased mobility to the upper extremity with only sufficient stability to provide a proper foundation for muscular function that is vital for the performance of sports or activities of daily living. The shoulder complex includes both static and dynamic stabilizers. The static stabilizers are Glenoid, glenoid labrum, capsule, ligaments (superior glenohumeral, middle glenohumeral, and inferior glenohumeral), joint cohesion, and intra-articular negative pressure.

The dynamic stabilizers are the rotator cuff muscles along with the long head of the biceps. The scapulothoracic stabilizers are the

TABLE 61.1

Differential Diagnosis

Muscular/Tendinous	Osseous	Capsular	Biomechanical	Neurovascular	Referred Pain Pattern
Rotator cuff tendonitis	Osteoarthritis	Shoulder laxity/instability	Impingement syndrome	Thoracic outlet syndrome	Diaphragm, liver, gallbladder
Rotator cuff tear	Humeral stress fracture	Adhesive capsulitis	Scapular dyskinesis	Cervical radiculopathy	Pancoast tumor or pulmonary pathology
Subacromial bursitis		Labral tear	Acromio-clavicular dysfunction		
Biceps brachii (long head) tendonitis		Pigmented villonodular synovitis	Somatic dysfunction		
Deltoid muscle strain			Neuromuscular inhibition with abnormal muscle firing patterns		
Trapezius muscle strain					
Rhomboid muscle strain					

rhomboids, trapezius, serratus anterior, and the pectoralis minor muscles (7).

The glenohumeral joint is multiaxial ball and socket synovial joint enclosed by a strong ligamentous capsule. This anatomic design allows for the joint's tremendous mobility, but the unique bony structures sacrifice stability. The capsule is weak anteriorly and inferiorly (inferior glenohumeral ligament complex), allowing for instability or dislocation to commonly occur in that direction. The posterior capsule is commonly tight, which causes anterior translation and elevation of the humeral head. This situation can cause secondary impingement of the rotator cuff (as well as micro-instability perhaps leading to gross instability) (1). Movement of the shoulder requires coordinated movement of the three joints (SC, AC, and GH) and the scapulothoracic articulation. All four of these components work together in a synchronous fashion to allow the extensive range of motion (circumduction). In any given arm position, the scapula aligns itself to allow the glenoid cavity to be in the best position to receive the head of the humerus.

The rotator cuff is critical to the dynamic stability of the glenohumeral joint. The cuff is formed by the confluent tendon of the supraspinatus, infraspinatus, teres minor, and subscapularis. The supraspinatus, infraspinatus, and teres minor insert on the greater tuberosity, whereas the subscapularis inserts on the lesser tuberosity of the humerus. Historically, the supraspinatus has been described as initiating abduction; however, recent evidence suggests that it is functionally more of a glenohumeral joint stabilizer (1). Because of its angle of insertion (70 degrees from the glenoid), the supraspinatus acts as a tensioner, applying a compressive force through the glenohumeral joint. Its synergistic action with the deltoid results in abduction. Without a properly functioning supraspinatus, impingement of the cuff between the humeral head and under surface of the acromion occurs. Over time, this allows the humeral head to glide anteriorly in the glenoid placing strain on the anterior capsule

and ligamentous structures. This microinstability may eventually lead to frank subluxation and/or dislocation.

The teres minor and infraspinatus work synergistically to depress and externally rotate the humeral head. The subscapularis internally rotates and depresses the humeral head. During throwing, the subscapularis and infraspinatus muscles are two of the most important dynamic stabilizers of the glenohumeral joint (1). The teres major functions along with the latissimus to extend internally rotate and adduct the humerus (2).

The majority of the vascular supply to the shoulder is supplied by the axillary artery. The axillary artery passes posterior to the pectoralis minor muscle and becomes the brachial artery at the inferior border of the teres major muscle. Branches from the axillary and brachial arteries supply the structures of the shoulder, arm, forearm, and hand. Some investigators feel that there is a "critical zone" of potentially deficient blood supply to the rotator cuff muscles secondary to the intrinsic vascular anastomotic properties. It is in this critical zone that rotator cuff tears can begin due to the relative avascularity of this region (1). One such example is in the supraspinatus tendon immediately proximal to its insertion on the greater tuberosity of the humerus (1).

Vascular tone and lymphatic flow are determined by the sympathetic nervous system. The sympathetic innervation to the upper extremities arises from the upper thoracic spinal cord (T1-4). The sympathetic ganglia lie anterior to the rib head, in the fascia common to both structures. Nerve roots C5-8 and T1 form the brachial plexus. These nerve roots pass through the intervertebral foramen of the cervical vertebrae and pass between the anterior and the middle scalene muscles. The roots unite to form successive trunks, divisions, cords, and branches. The anterior and the middle scalenes can spasm, applying pressure to the brachial plexus. The thoracic inlet can be considered in both anatomical and functional terms. The anatomic boundaries include the manubrium of the

sternum anteriorly, the first thoracic vertebrae posteriorly, and the first rib laterally.

Physiology

Injury to a large joint sets up an inflammatory cascade in the structures involved. The severity, intensity, and location of the inflammation depend upon the mechanism of injury and the structures involved. For the shoulder, many times, the issue is repetitive overuse. Tendonitis and subacromial bursitis occur commonly, as does tendonitis of the long head of the biceps. Because most shoulder problems are soft tissue in nature, pain, tightness, and stiffness with impaired mobility is a concern. Pain is usually due to impingement of the soft tissue structures under the coracoacromial arch. Stiffness and decreased range of motion are multifactorial and can be mediated anatomically, biomechanically, and/or neurologically. Loss of strength may indicate rotator cuff tear but may also be related to the factors described above (5).

Osteopathic Patient Management

Any patient presenting with pain in the shoulder joint complex should receive a thorough osteopathic examination. Osteopathic techniques can be applied to the areas of somatic dysfunction in patients presenting with rotator cuff tear pathology. The models described below of structure–function relationships guide the osteopathic practitioner’s approach to diagnosis and treatment. The five structure function models provide a framework for integrating objective and subjective clinical findings with osteopathic structural exam findings.

Biomechanical Model

A kinetic chain is described as a sequencing of individual body segments and joints to accomplish a task. It generally functions from a base of support proximally and then proceeds distally, but this is entirely dependent on the task at hand. Because of the tremendous demands that overhead sporting activities place on the spine and the shoulder joint complex, the ability to recognize kinetic chain disorders related to the upper extremity and their interactions with related components of the musculoskeletal system is important for athletic medical practitioners. Due to the complexity of the anatomic and biomechanical interactions as well as neuromuscular control issues, evaluation and accurate diagnosis are clinically challenging. Disruption of the kinetic chain, if left unidentified, may lead to altered muscle firing patterns resulting in overload to connective tissues (capsular laxity and instability, labral tears), or the joint itself (osteoarthritis, etc.). While the patient may complain of pain due to one traumatic event, the majority of shoulder problems result from repetitive overuse of the osteoarticular system and related neural, soft tissue, and muscular elements. This is especially true in overhead athletes, as they try to transmit the ground reactive force from their pelvis and trunk through their upper extremity. Weakness of the abdominals, gluteus, and scapular stabilizers, with subsequent tightness of the psoas, hamstrings, latissimus dorsi, and upper trapezius, produces the substitution patterns that begin at the myofascial level, which may result in outlet obstruction at the coracoacromial arch. This situation is known as “impingement” (1). Impingement syndrome results in part from suboptimal biomechanical position manifesting grossly as protracted shoulders, weak lower trapezius, and tight upper trapezius. As a result, the glenoid fossa’s abnormal position places stress on the anterior stabilizers (both static and dynamic) of the shoulder. Over time,

this abnormal stress leads to loosening of the anterior capsule with subsequent tightening of the posterior capsule. This places stress on not only the joint capsule, but also the glenoid labrum. If left untreated, the asymmetric positioning causes abnormal load on the dynamic stabilizers (the rotator cuff muscles) that may eventually manifest as frank rotator cuff pathology. This situation can be secondary to internal pathology as just discussed or may result from external causes. In the case of scapular dyskinesis of primary origin, abnormal stabilization of the scapula again places the shoulder at a biomechanical disadvantage. This leads to abnormal scapular positioning as discussed above, which may lead to the same pathologic conditions.

Failure to assess the functional biomechanical factors related to the shoulder joint complex may lead to less-than-optimal results. For example, after a patient undergoes surgery for a torn rotator cuff, the mainstay of postoperative care is physical therapy. If the therapist and/or clinician fails to recognize dysfunction in the kinetic chain (scapular dyskinesis, altered muscle firing patterns, etc.) the patient’s altered biomechanics will place the shoulder and newly repaired cuff under the same abnormal forces as before and result in a suboptimal outcome.

Impingement is caused by a decrease in the subacromial space and compression of the rotator cuff tendons under the subacromial arch. Tension in the latissimus dorsi causes internal rotation and adduction of the humerus, further causing the greater tuberosity of the humerus to impinge upon the acromion. Weak abdominals cause an increase in the lumbar lordosis, an increase in the thoracic kyphosis, a slumped posture and forward head. The forward head position causes tightness of the scalenes and myofascial strain of the thoracic inlet, clavicles, and shoulders. The clinical biomechanical summation of the above results in a “functional thoracic kyphosis” characterized by rotator cuff impingement resulting from scapular dyskinesis (protracted scapula) and may ultimately lead to rotator cuff muscle fiber failure.

Form follows function. Given enough time, the biomechanical and neuromuscular dysfunctions described above can result in bony and soft tissue changes leading to a painful shoulder syndrome for which the patient seeks medical attention. Functional evaluation of this patient’s complaint often reveals that the inciting event is part of a longstanding underlying process of kinetic chain dysfunction.

The key in any patient with somatic dysfunction is the restore normal structural alignment to allow the kinetic chain to function properly (form follows function). In this patient, when considering the biomechanical model, the physician needs to address the flexed lumbar dysfunction and the psoas tension. By treating these, the normal sacral motion should be restored, which will allow the ground reactive force to be efficiently transmitted up the kinetic chain. Osteopathic treatment will also restore functional mobility to the thoracolumbar junction. This will improve diaphragm motion and decrease latissimus tension. Treatment of the upper thoracic dysfunction should correct scapular dyskinesis. The result will be restoration of normal postural alignment and kinetic chain function.

Respiratory/Circulatory Model

Osteopathic manipulation may be used to improve blood flow to the area of injury and remove edema, which may assist in pain reduction and improve mobility. The axillary vein receives tributaries that correspond to the branches of the axillary artery and receives venae comitantes of the brachial artery. The subclavian vein passes over the first rib and below the clavicle, crossing over the anterior scalene muscles insertion on the first rib (3). The left brachiocephalic

vein passes posterior to the left sternoclavicular joint then crosses the midline. The right subclavian lymphatic trunk drains into the right lymphatic duct. The left subclavian lymphatic trunk drains into the thoracic duct. Somatic dysfunction affecting the venous system may also affect lymphatic drainage, thereby producing congestion in the upper extremity (4). Fascial restriction of the thoracic inlet and pectoral fascia can also cause lymphatic stasis of the upper extremity.

Improving motion in the lower thoracic region will help the function of the diaphragm from a mechanical perspective. Improving motion in the cervical region will help the function of the diaphragm from a neurologic perspective. Both restore normal diaphragmatic motion, which is the primary driving force to move lymph. This treatment should follow thoracic inlet release, which removes any proximal restrictions to lymphatic flow. In this patient, treatment of the right sternoclavicular restriction will further aid in this process by normalizing fascial tensions of the thoracic inlet. Then, attention is moved distally to remove pectoral and axillary restrictions. Originally, Spencer's technique was described as a lymphatic technique for the upper extremity. Over the years, its clinical utility has broadened and it is often modified to address other musculoskeletal dysfunctions of the upper extremity. It may be used in this case as an adjunctive treatment. Treatment of the distal arm and hand may be necessary as well if indicated.

Additionally, somatic dysfunction involving any of the following structures may affect arterial supply and venous return (4): anterior and middle scalenes, upper thoracic vertebrae, upper ribs, clavicles, and the fascia of the upper extremity.

Neurological Model

Another objective is to normalize neurologic input to the upper extremity. Sympathetic innervation to the shoulder joint complex is mediated through treatment of the T4 dysfunction and the associated ribs. Increased sympathetic tone to the upper extremity can cause vasoconstriction, edema, sensitivity of the nerves, irritability of the muscles, and sweat gland overactivity. OMT in this region can improve those related pathophysiological findings.

Also peripheral fascial restrictions are removed to limit compression of nerves supplying the region. Tension in the anterior scalenes and the thoracic inlet can compress the neurovascular bundle, impairing nerve transmission and vascular supply to the rotator cuff and scapular stabilizing muscles. Removal of the fascial restrictions and resultant compression to the neurovascular bundle will facilitate axoplasmic flow, enhancing the nerves trophic function.

Metabolic-Energy Model

Efficient transfer of energy in the overhead athlete is vital to performance. While the biomechanical implications of this have been discussed, metabolic processes are also responsible. These manifest grossly in the cardiac, respiratory, neurological, and psychological systems. One analogy is to envision the body as a large machine. The cardiovascular system is the engine that drives the metabolic system. This diverse system has the ability to adapt quickly to changing needs. When needed, the system shifts from the homeostatic life-sustaining mode to supercharged state for athletic activity. This is mediated at the cellular level as cell depolarization that results in measurable changes in cardiac output that enable the athlete to meet the demands placed upon him or her by athletic activity. The "fuel" that drives this system is supplied by the pulmonary system via the gas exchange that occurs at the level of the pulmonary

capillaries. This oxygen-rich blood is transported through the larger pulmonary veins and eventually to the left atrium. This fuel is then supplied to the neuromusculoskeletal system and throughout the rest of the body. Occasionally, these systems function together with perfect harmony and precision. The integration of these processes combined with the influence of psychological factors leads to an efficiently functioning machine that some have referred to as the "quantum athlete." Some believe this balance is responsible for an athlete's "court sense" or "being in the zone." Under these ideal circumstances, there is optimal balance between energy expenditure and energy intake. Disruption in any of these metabolic processes, as in an injured athlete, shifts the balance and leads to an inefficient system (8).

Behavioral Model

An athlete's mood is affected whenever he or she is restricted from practice and competition. Often an athlete's perception of himself or herself is intimately tied to their athletic performance. The effects of an athlete's injury can manifest in many different ways and can impact psychosocial, cultural, behavioral, and spiritual elements. In an affected athlete, this can influence interpersonal relationships, social interactions, school, and/or work performance.

Cognitive learning theory and skills that apply to the athletic setting include self-efficacy, arousal regulation, attentional focus, and mental imagery. During periods of injury, the athlete's ability to access this system is altered, which can have significant psychosocial and emotional impact. For the athlete, this is directly evident by the missed practice and playing time that affects their individual season as well as their teammates. The athlete often feels isolated from the team during treatments and can suffer from a "confidence crisis."

Self-efficacy allows the athlete to actively participate in the rehabilitative process and regain confidence in their ability to get better and return to competitive athletics. Enhanced self-efficacy predicts psychological well-being, adherence to prescribed treatments, and pain-coping mechanisms. Poor self-efficacy produces mood fluctuations, reduction in functional ability, and a feeling of helplessness that frustrates both the patient and the clinician if not understood (9). Enhancing self-efficacy promotes decision-making skills and problem-solving ability through practice and role playing to deal with disease-related issues (10).

INTEGRATIVE TREATMENT APPROACH

As osteopathic physicians, we can use OMT as a powerful treatment tool for musculoskeletal complaints. Application of osteopathic principles is an important component in the treatment of musculoskeletal complaints. As has been discussed previously, restoration of proper function of the shoulder requires reestablishment of normal structure. Barring contraindications, OMT should be performed in all patients with shoulder complaints, as indicated, for this reason. The type of treatment is based on the physician's ability, the patient's response and presentation, the type of dysfunction found, and time limitations of the practice.

While the body has the innate ability to self-heal, adjunctive therapies may be required, most patients will require a comprehensive approach including the appropriate use of other treatment modalities such as medications, injections, physical/occupational therapy, activity modification, dietary changes, occupational changes, and counseling (or emotional support as discussed above) if necessary. In the patient with a full-thickness rotator cuff tear and pain in the shoulder joint complex, the decision between a surgical or conservative approach may not always be straightforward.

Each case should be individualized based on patient desire, activity level, and long-term goals. A patient who wished for nothing more than pain relief would be treated differently than a patient who desired high-level physical activity. A detailed discussion of surgical options is beyond the scope of this chapter. If a surgical approach is elected, the specifics of the procedure should be considered. However, for the patients who undergo surgery, osteopathic treatment is a powerful adjunctive therapy postoperatively.

If conservative treatment is chosen, what should be the chronological sequence of rehabilitation? Typically, inflammation is reduced with simultaneous improvement in range of motion. Then proprioception, flexibility, and strengthening occur. During these stages of rehabilitation, are different manipulative techniques required?

If conservative treatment is chosen, do the areas of somatic dysfunction need to be removed first, or should exercises be prescribed initially to help alleviate the somatic dysfunction? Where should treatment start? In the involved extremity, at the area of greatest restriction, or at a site distant from the injury?

A major goal in the treatment of acute shoulder pain is to control inflammation. In addition to cryotherapy (icing), systemic therapy with nonsteroidal anti-inflammatory drugs will help resolve swelling and decrease pain. Local anti-inflammatory measures (with corticosteroid medication or NSAIDs) can also be employed. Steroids or NSAIDs may be used topically by iontophoresis and phonophoresis during physical therapy, while subacromial bursal steroid injections may be performed as well. Additionally, some patients may require narcotic analgesic for short-term use. Muscle spasticity may need to be treated with muscle relaxers or benzodiazepines.

Activity modification, work restrictions, and lifestyle change are important aspects of the rehabilitative process. For shoulder injuries, the physician needs to stress relative rest vs. absolute rest. If the patient begins to restrict certain ranges of motion secondary to pain, eventually the shoulder capsule will adapt to this decreased range of motion and a fibrous adhesive capsulitis will result. Many times, Codman pendulum exercises and wall walking exercises are prescribed to maintain mobility. Overhead movements should be modified as they can exacerbate impingement. In the case of fractures, dislocations, and surgeries, shoulder immobilizers are sometimes required for short periods of time.

Outcome Studies for Manual Treatment of the Shoulder

Described below are three randomized, controlled trials that showed promising results for the application of manipulation and physiotherapy in the management of shoulder pain.

The first randomized clinical trial evaluating the effectiveness of shoulder manipulation as an addition to standard care (i.e., nonsteroidal medication) compared with physiotherapy and corticosteroid injection was reported in the *British Medical Journal* by Winter and colleagues 1997 (6). A total of 172 subjects were randomized to receive one of the adjunct therapies after a standard 1-week treatment with anti-inflammatory medication. Results showed that the shoulder girdle dysfunction group that received manipulation had a shorter duration of complaints and fewer reports of treatment failure than those that received physiotherapy.⁶

Berman and coworkers recruited 150 patients with shoulder symptoms and dysfunction of the shoulder girdle from general practices in the Netherlands. The patients were randomly assigned into usual care versus usual care plus manipulative therapy (up to six treatment sessions). At the end of the study period of 12 weeks, 21% of the usual care group and 43% of the intervention group reported full recovery. This significant difference in improvement was also observed at 52 weeks of follow-up.⁶

In a trial by Hay and associates, 207 patients with shoulder pain recruited from primary care clinics in the United Kingdom were randomly divided into a physiotherapy group and a corticosteroid injection group. At 6 months, 60% in the physiotherapy group and 53% in the injection group reported a minimum 50% drop in their disability scores.⁶

Risks and Benefits of Manipulative Treatment for the Shoulder

Complications or adverse events occurring after manipulation of the shoulder have not been reported in the literature (6). None of the clinical trials evaluating this modality have reported any complications or adverse events in patients with shoulder somatic dysfunction.

Risks of increasing shoulder pain, dislocation, and disability may occur if proper diagnosis is not made. For example, if the practitioner manipulates a hypermobile shoulder that is already unstable due to loss of integrity (i.e., tear) of the rotator cuff, labrum, or other primary shoulder structure, a poor outcome may result.

Manual medicine can be used to treat shoulder pain related to somatic dysfunction. Manual procedures can increase motion, strengthen weak muscles, lyse adhesions, and decrease pain. As described above, manipulative therapy for the shoulder girdle in addition to usual care by a general practitioner can accelerate recovery from shoulder symptoms and reduce their severity (6).

Multiple Small Joint Diseases in an Elderly Patient

KURT HEINKING, JAMES LIPTON, AND BETH VALASHINAS

KEY CONCEPTS

- Hand pain and stiffness is a common complaint in the elderly patient, and thorough history and physical exam need to be done to rule out an inflammatory condition.
- Chronic hand pain and stiffness can adversely affect daily living activities and contribute to depression and a loss of personal motivation in an otherwise healthy individual.
- An integrated approach to the management of the patient with hand pain and stiffness, including pharmacotherapeutics, osteopathic manipulation, and behavioral modification, can provide relief and improved function.

CASE VIGNETTE

Ms. Anderson is a 62-year-old Caucasian female who seeks medical care for chronic severe worsening hand stiffness and pain.

CHIEF COMPLAINT

A 3-month history of chronic aching pain in bilateral hands with associated morning stiffness lasting over 1 hour, as well as chronic daily headaches for the past year

HISTORY OF PRESENT ILLNESS

The patient denies any recent traumas. The pain has been affecting her in daily activities as well as in employment. Over the past 3 months, Ms. Anderson missed a significant amount of time at work and she lost her job. She worked at a health food store and had a difficult time stocking the shelves. She is concerned about the ongoing discomfort in her hands, as well as having daily headaches. She attributes both of these to a multi-level cervical fusion 6 years ago. Her hand pain is approximately a 7/10 in. intensity with attempting to open jars, or perform repetitive tasks. She describes symmetrical joint stiffness in her hands, worse in the morning upon awakening, often lasting over 1 hour. She further relates difficulty sleeping at night secondary to pain, predominantly in her neck. She notes that she cannot hook her bra, undo buttons, or knit a sweater without significant discomfort. She has taken naproxen sodium 220 mg twice daily with minimal improvement. She used a heating pad for her neck, and “arthritis cream” for her hands, but has not used any ice as therapy. She has not had any other work-up or imaging performed as of this time. She denies having numbness, weakness, or paresthesias involving her hands. She denies chest pain, fever, shortness of breath, cough, or stomach upset.

Past Medical History:

Osteopenia, osteoarthritis cervical spine, knees, hips; GERD (acid reflux disease), chronic daily tension headaches, hyperlipidemia, postmenopausal, last colonoscopy 1-year ago normal.

Past Surgical History:

Cervical fusion C5-7 at age 52, cervical fusion C2-5 at age 54, right knee replacement at age 59, appendectomy at age 18, tonsillectomy and adenoidectomy at age 6, C-section at age 29.

PAST TRAUMA HISTORY: MOTOR VEHICLE ACCIDENT 1982, MINOR CONCUSSION, WHIPLASH INJURY

Family Medical History:

Father deceased secondary to alcohol-induced cirrhosis at age 58, siblings: one brother aged 59, healthy, no family history of rheumatologic disorders other than OA

Gynecologic History:

G2 P 1011, LMP 12 years ago, last mammogram 2 years ago—normal, last pap and pelvic, rectal exam 2 years ago—normal, last DEXA scan 2 years ago osteopenia

Social History:

Widowed—husband John passed 10 years ago, 1 son—Marty 29 healthy, positive tobacco use (1 pk day intermittent for 35 years), denies illicit drug use, occasional alcohol (holidays). Patient was an employee for a large nutrition store. She does not exercise regularly.

CHILDHOOD ILLNESSES: CHICKEN POX AND POSSIBLE MEASLES

Medications:

Alendronate Sodium: 70 mg wk, Atorvastatin Calcium: 40 mg daily, Esomeprazole Magnesium: 40 mg daily, Naproxen Sodium: 220 mg twice daily, Acetaminophen: 500 mg four times daily prn, conjugated estrogens/medroxyprogesterone acetate tablets: 0.625 mg daily

REVIEW OF SYSTEMS

General:

She complains of fatigue and daily tension headaches. She denies fever, chills, change in appetite, or weight change.

Cardiopulmonary:

She denies chest pain, palpitations, and shortness of breath.

Neurological:

She denies numbness, weakness, and paresthesias of the extremities. She further denies any visual changes.

Musculoskeletal:

She admits to neck stiffness, bilateral hand pain and stiffness, daily tension headaches in the suboccipital and frontal region

described as a tight sensation. She denies shoulder and hip discomfort and jaw claudication.

PHYSICAL EXAMINATION

Vital Signs:

T: 97.6, P: 78, R: 16, BP: 150/82, height: 5'4", weight: 138 lb.

General:

Alert, oriented, cooperative, affect somewhat flat, and a good historian. She appears her stated age.

HEENT:

PERLA EOMI, normal visual acuity. No xerophthalmia or xerostomia. Pharynx without erythema, no adenopathy, no thyromegaly, TMs good cone of light without erythema, no nasal erythema, no sinus tenderness, no tenderness over the temporal arteries or scalp

Neck:

Supple, no JVD or bruits. Some discomfort noted with full ROM

Skin:

No rashes, no abnormal appearing moles, multiple seborrheic keratoses (back), dry hair and nails. No petechiae, purpura, livedo reticularis, telangiectasias, or evidence of Raynaud phenomenon

Breast:

No breast masses, nipples everted, no discharge, no axillary adenopathy

Cardiovascular:

RRR without S3 S4 murmur, no clubbing, cyanosis, or peripheral edema. Equal pulses bilaterally

Lungs:

CTA without rales, rhonchi, wheezes

Abdomen:

BS × 4 quadrants without rigidity, rebound, guarding, Neg CVA pain, no masses appreciated. No RUQ discomfort on palpation, negative Murphy sign

Neurological:

CNs 2 to 12 intact, DTRs 2/4 bilateral, no sensory deficits, 5/5 motor strength bilateral

Musculoskeletal:

Upper extremities: Active and passive adduction, flexion, extension and internal rotation of the shoulders full and pain free. Slightly decreased full extension of both elbows, but no nodules palpated or frank contractures noted. Tenderness over both lateral and medial epicondyles bilaterally. Tenderness and synovitis noted over the second and third metacarpal phalangeal joints and proximal interphalangeal joints (PIPs) bilaterally, with evidence of underlying bony swelling consistent with Bouchard nodes on multiple PIPs. Several Heberden nodes also noted. No ulnar deviation appreciated. Nails appear brittle with ridges, but no pitting is observed. No cyanosis, clubbing, or edema. Pulses equal bilaterally, brisk capillary refill noted. Negative Tinel and Phalen sign. No thenar atrophy. Normal nail fold capillaroscopy

Lower extremities: Full hip, knee, ankle AROM PROM, negative Lachman test, negative joint line pain, negative Mc Murray and Apley; negative Patellar grind, mild crepitus noted in left knee. Negative hip compression test. Positive Bunion deformity of both great toes with tenderness of the metatarsal phalangeal joints bilaterally, without synovitis. No cyanosis, clubbing, or edema. Mild onychomycosis of the toenails. Pulses equal bilateral, good capillary refill

Osteopathic Structural Exam:

Sphenobasilar compression with a right lateral strain, bilateral occipitomastoid compression. C2 rotated left, occiput rotated right, and sidebent right, T4 ERS right, increased paraspinal muscle tension bilaterally at T10-12 and T12-L3 sidebent left and rotated right, sacrum has a left on left forward torsion, right sternoclavicular joint is superior with fascial restriction bilaterally in the upper extremities, short right leg, ribs 4 and 5 on the right have an inhalation dysfunction, and first rib on the right is elevated.

DIFFERENTIAL DIAGNOSIS

The most common pathophysiological processes that need to be considered in the differentiate diagnosis of bilateral hand pain and stiffness are mechanical, inflammatory, and neurological (Table 62.1).

TABLE 62.1

Differential Diagnosis for Symmetric Hand Stiffness and Pain in an Elderly Patient

Mechanical	<ul style="list-style-type: none"> a. Extensor tendonitis b. Repetitive overuse c. Thoracic outlet syndrome d. Compartment syndrome e. Osteoarthritis of the hands f. Cervical Spondylosis Hemochromatosis
Inflammatory	<ul style="list-style-type: none"> g. Rheumatoid arthritis h. Psoriatic arthritis i. Calcium Pyrophosphate Dihydrate Deposition Disease (CPPD or Pseudogout) j. Systemic Lupus Erythematosus k. Seronegative Spondyloarthropathies l. Scleroderma m. Polymyalgia rheumatica n. Polyarticular gout o. Bechet syndrome p. Reactive arthritis Infectious arthritis
Neurologic	<ul style="list-style-type: none"> q. Peripheral neuropathy r. Bilateral carpal tunnel syndrome s. Cervical stenosis/radiculopathy t. Syringomyelia/myelopathy

WORKUP AND INTERPRETATION

Cervical spine and bilateral hand x-rays were obtained. The cervical spine films showed A-P, lateral, oblique, and open mouth views were obtained. There is a reversal of the normal cervical lordosis. There is no fracture or subluxation. There is a stable appearing cervical fusion from C2 to C7. Diffuse degenerative changes are seen from C4 to C7. Facet hypertrophy is seen at the C5 to C7 levels. Degenerative changes are seen from C0 to C2 suggesting an arthritic process. No evidence of atlantoaxial instability, but full cervical spine series with flexion and extension views needed to adequately evaluate. Clinical correlation advised.

A-P and lateral views of the hands were obtained. There are no fractures or subluxations appreciated. Periarticular soft-tissue swelling with a fusiform appearance and juxta-articular osteopenia noted in interphalangeal joints. Suggestion of small marginal erosions along second and third metacarpophalangeal joints. Some diffuse joint space narrowing noted. Sclerosis and osteophyte formation predominantly involving distal interphalangeal joints bilaterally, with limited PIP involvement.

DIAGNOSIS

The patient's diagnosis based on the clinical history, examination, and diagnostic imaging was as follows:

1. Rheumatoid arthritis
2. Osteoarthritis of the cervical spine, knees, and hands
3. Somatic dysfunction: cervical, thoracic, rib, lumbar, sacrum, pelvis, and upper extremity, lower extremity
4. Osteopenia
5. Multilevel cervical fusion $\times 2$
6. GERD (acid reflux disease)-controlled currently
7. Hyperlipidemia
8. Tobacco abuse

Relevant Functional Anatomy

In a patient with a bilateral upper extremity complaint, a functional anatomy review should cover the thoracic spine and ribs, the cervical spine, the thoracic inlet, and finally the forearm wrist and hand. This is because from a biomechanical standpoint, each of these areas can produce, intensify, or be related to the symptoms in this patient. Osteopathic manipulative treatment of these anatomic areas may also improve the patient's symptoms; therefore, a prior knowledge of the anatomy is necessary in order to carry out these procedures.

The upper thoracic spine neurologically influences the upper extremity via the sympathetic nervous system. The sympathetic innervation to the upper extremities arises from the upper thoracic spinal cord (segments T1–4). The sympathetic ganglia lie anterior to the rib head, in the fascia common to both structures. Dysfunction in the upper thoracic spine and ribs may increase sympathetic tone to the upper extremity and produce altered motion, nerve dysfunction, and lymphatic and venous congestion (1). Increased sympathetic tone is accompanied by palpatory findings in the upper thoracic/rib area and increased sensitivity to painful stimulus. Restricted motion or position of the ribs, and abnormal position of the costovertebral joints can apply fascial tension to the sympathetic chain ganglia. The upper thoracic spine and ribs are the origin for the scapular stabilizing muscles. These muscles include the rhomboids, serratus anterior, trapezius, and pectoralis minor.

Dysfunction in these muscles alters the position of the scapula, which in turn alters the position of the upper extremity. Trigger points in these muscles can refer pain into the upper extremity.

The cervical spine supplies neurologic innervation to the upper extremities. From an anatomic perspective, a smooth cervical lordosis, adequate intervertebral disc height, and patent neuroforamina are desirable. However, with degeneration due to aging, genetic factors, trauma, postural effects and repetitive overuse, the anatomy of the cervical spine may be far from optimal. The cervical vertebrae from C2 to C7 are saddle shaped and contain a specialized set of synovial joints on the lateral surface of the vertebral bodies. These are known as uncovertebral joints (uncinate) or joints of Luschka, and provide stability to the cervical spine. They may also decrease the likelihood of herniated nucleus pulposus in the cervical region. The joints of Luschka are not synovial in nature; thus, inflammatory arthropathies would spare these areas. However, the facet joints and atlantal-axial joint have synovial membrane that could be involved in inflammatory arthropathies. At the base of the skull, the tectoral membrane (occipital-axial ligament) is a strong continuation of the posterior longitudinal ligament that lies immediately behind the body of the axis. The alar ligaments are short, strong bundles of fibrous tissue directed obliquely upward and laterally from either side of the upper part of the odontoid process to the medial aspect of the occipital condyles (2). They are often referred to as the "check" ligaments. The transverse ligament of the atlas is a broad strong triangular ligament arching across the ring of the atlas and firmly anchored on each side to a tubercle in the medial surface of the lateral masses of the atlas. The transverse ligament has two fascicles layered in a crosswise fashion, which gives it a cruciate configuration. The transverse ligament portion of the cruciate ligament complex supports the atlas in rotating about the dens. The anterior surface of the spinal cord lies immediately posterior to the transverse ligament. Rupture of this ligament (or laxity, which may occur with rheumatoid arthritis) creates the possibility of the dens contacting the spinal cord and causing catastrophic neurologic damage. The cervical spinal canal is wider at the atlantoaxial level and narrows maximally at the C6 level. The cervical cord itself is wider from C3 to T2, corresponding to the increase in nerves supplying the upper extremities (2).

In the cervical spine, the discs are thicker anteriorly than posteriorly and are entirely responsible for the normal cervical lordosis. Each disc is situated between the cartilaginous endplates of two vertebrae. Successive layers of these fibers slant in alternate directions so that they cross each other at different angles depending on the intradiscal pressure of the nucleus pulposus. Positions of the cervical spine affect intradiscal pressure. Intradiscal pressure is least in the supine position, and extension of the cervical spine results in the greatest intradiscal pressure (3). After 50 years of age, the nucleus pulposus becomes a fibrocartilaginous mass that has characteristics similar to those of the inner zone of the annulus fibrosis (3).

The thoracic inlet is anatomically defined as the area above the clavicles; between the sternum, the first thoracic segment (T1), and the first rib. The brachial plexus and the subclavian artery travel through this area. The subclavian artery traverses between the first rib and clavicle (a potential site of compression) and then between the anterior and middle scalene muscles. The brachial plexus also travels between the anterior and middle scalene muscles. The thoracic outlet is the area where the neurovascular bundle travels between the clavicle and first rib, exiting between the anterior and middle scalene muscles. The subclavian vein passes over the first rib anterior to the anterior scalene muscle, so it is not involved in compression (2). Moving toward the arm, the subclavian artery

becomes the axillary artery at the lateral border of the first rib. The axillary artery passes posterior to the pectoralis minor muscle and becomes the brachial artery at the inferior border of the teres major muscle. Branches from the axillary and brachial arteries supply the structures of the shoulder, arm, forearm, and hand.

Lymphatic compression can also occur, usually due to myofascial restrictions. The major lymph nodes of the upper extremities are found in the fibrofatty connective tissue of the axilla. They are arranged in five groups, four of which lie inferior to the pectoralis minor tendon and one lies superior to it. The thoracic duct is on the left and drains into the brachiocephalic trunk.

The three main peripheral nerves of the upper extremity include the median nerve, the ulnar nerve, and the radial nerve. Understanding the innervation of each and site of potential compression is important. Compression of the median nerve in the carpal tunnel (carpal tunnel syndrome) typically causes sensory symptoms such as night pain, paresthesias, and numbness in the hand in the radial three and one half digits. Symptoms may be referred proximally from the hand toward the forearm and even the elbow and may be reproduced or elicited by Phalen maneuver or Tinel sign. Thenar muscle weakness and atrophy represent advanced disease. Moving down into the hand, the *scaphoid*, *lunate*, and the *triquetral* bones articulate with the greater and lesser multangular, the capitate, and hamate where motion between these rows of bones is freer in flexion. If bony point tenderness is present in the face of hand trauma, always x-ray the hand, and in particular with respect to the anatomic snuff-box to make sure a navicular fracture is initially evaluated. The first carpometacarpal articulation is cavoconvex, and classified as a saddle-shaped joint. It is freely movable in two planes and rarely subject to dysfunction. The second to fifth carpometacarpal joints are gliding joints. The fifth is the most mobile, then the fourth. The second and third are fairly restricted in motion (4). Patients with arthritis of the wrists and hands can develop bony encroachment or irritation of tendons, blood vessels, and nerves. This may lead to comorbid conditions such as carpal tunnel syndrome in a patient with wrist osteoarthritis, or a de Quervain tenosynovitis in a patient with thumb arthritis and instability of the first carpometacarpal joint.

Motion, Posture, and Biomechanics

The cervical spine is better suited for mobility and is not required to transmit heavy loads. Precise control of head position and unrestricted movement is essential for normal functioning of the special senses. The saddle shape of each cervical vertebra provides mobility and stability. The anterior column composed of the vertebral body, longitudinal ligaments, and intervertebral disc provides some weight-bearing capacity, shock absorption, and a flexible structure. The posterior elements composed of the osseous canal, the zygapophyseal joints, and the erector spinae muscles protect the neural elements, and act as a fulcrum, to guide movement for the functional unit.

Alterations in the degree of curvature in one area of the spine result in reciprocal alterations in curvature in other areas of the spinal column to preserve the orientation of the body over the center of gravity. For example, an increase in lumbar lordosis results in increased cervical lordosis.

Physiology

Small joints, in particular those of the hand, are made up of a number of structures that allow for smooth motion, specificity of function, and strength of purpose. The small joint structure includes

articular cartilage, and subchondral bone forming articulating surfaces in an attempt to work in concert with the musculoskeletal system making demands upon joint structure and function as a whole. Normally, articular cartilage is produced, and functioning bone is maintained, through cellular metabolism, circulation, respiration, synthesis, and remodeling. Homeostasis is a physiologic process by the organism to preserve form and function, an effort that declines in effectiveness as the organism ages.

Manifestations of Joint Disease

Joint disease in general can be monoarticular or polyarticular in nature. Monoarticular joint symptoms may be caused by many diseases, including infectious, traumatic, and crystal deposition diseases as well as noninflammatory conditions, such as osteoarthritis or avascular necrosis. Some inflammatory polyarticular diseases may occasionally present with monoarticular symptoms as well, such as early rheumatoid arthritis, psoriatic arthritis, viral arthritis, or reactive arthritis. Monoarticular joint disease by chronology can be transient (intermittent hydrarthrosis), acute (septic arthritis, trauma, gout), or subacute/chronic (pseudogout, neuropathic Charcot, tumor, infectious granuloma, TB, or osteoarthritis) in nature. Polyarticular joint disease in inflammatory arthritis often presents with symmetric, small joint involvement in diseases such as rheumatoid arthritis, SLE, psoriatic arthritis, and viral hepatitis. Polyarticular diseases with acute presentations include infectious arthritides, such as gonococcal, meningococcal, viral, Lyme disease, acute rheumatic fever, and bacterial endocarditis. Inflammatory polyarthritis that may be either acute or chronic in nature includes diseases such as rheumatoid arthritis, juvenile idiopathic arthritis, systemic lupus erythematosus, reactive arthritis, polyarticular gout, psoriatic arthritis, and arthritis associated with sarcoidosis. Noninflammatory polyarticular symptoms commonly arise from osteoarthritis, calcium pyrophosphate deposition disease (CPPD), fibromyalgia, benign hypermobility syndrome, and hemochromatosis (5). In this case, we will focus on both osteoarthritis and rheumatoid arthritis.

Pathophysiology

Osteoarthritis

Osteoarthritis (OA) is a disease process that characteristically includes degeneration of articular cartilage, subchondral sclerosis, hypertrophy of bone at joint margins (osteophytes), and multiple alterations in the synovial membrane as well as the joint capsule itself. There are multifactorial considerations germane to a discussion of the pathogenesis of OA, including biomechanical influences (isolated macrotrauma or repeated microtrauma), genetic alterations, and the relationship to aging, particularly with regard to morphologic changes in cartilage matrix composition and structure.

While aging is considered the most significant risk factor for the development of OA, obesity, mineral deposition, and systemic hormones all impart a higher risk for OA.

Morphologic, biochemical, and metabolic changes occur in OA. In early OA, irregularity of the surface of articular cartilage and changes in proteoglycan distribution occurs, followed by eventual ulceration of cartilage with exposure of bone, resulting in attempts at self-repair. Local repair involves increased chondrocyte concentration, and new bone formation in the form of osteophytes. Biochemical changes vary during the stages of OA, with increased water content of articular cartilage in early OA, and increased collagen and diminished proteoglycan concentrations later in the

disease. Early degeneration of cartilage is likely related to matrix metalloproteinases whose enzymes degrade both collagen and proteoglycans (6). The initial stages of OA are thus marked by a complex interplay of multiple factors, including increased cell proliferation and synthesis of matrix proteins, proteinases, growth factors, cytokines, and other inflammatory mediators by chondrocytes. The disease process ultimately affects the joint structure in its entirety, including cartilage, synovium, ligaments, and subchondral bone.

One central problem with osteoarthritis is that an adult articular chondrocyte has limited capacity to regenerate damaged original cartilage matrix architecture. Indeed, an age-related reduction in chondrocyte function has been shown with the end result of morphologic and structural changes in aging articular cartilage, such as thinning of the articular surface, decreased size of matrix proteoglycans, and diminished strength and stiffness of the matrix (6). The chondrocyte may attempt to regenerate the matrix by mimicking early stages of cartilage development, but original cartilage cannot be replicated. Current pharmacological interventions do not include a proven structure-modifying approach. Cartilage tissue engineering (with or without replacement) or gene therapy is a possible approach in the future. Animal models of OA have yet to reproduce the human condition, perhaps in part because they often represent secondary rather than primary OA (7).

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic systemic inflammatory disease characterized predominantly by persistent, symmetric inflammation of multiple joints, although extra-articular manifestations may also occur. It is the most common inflammatory arthritis, affecting approximately 1% of the population. The primary target in RA is the synovium, in which infiltration of mononuclear cells, such as T cells and macrophages, synovial intimal lining hyperplasia and angiogenesis occur. A complex interplay between synoviocytes, T cells, B cells, and inflammatory mediators eventually leads to aggressive cartilage destruction and progressive bony erosions. Untreated, rheumatoid arthritis often leads to progressive joint destruction, disability, and premature death.

Although extensive research has been conducted with regard to the pathogenesis of RA, the exact etiology remains elusive. Roles of multiple inflammatory mediators, including cytokines, chemokines, growth factors, adhesion molecules, and matrix metalloproteinases, have been defined thus far. It is known that these mediators are responsible for both attracting and activating cells in the peripheral blood, in addition to local activation and proliferation of synoviocytes (8). Susceptibility to RA is likely resultant from a combination of environmental and genetic factors. One of the most significant genetic risk factors uncovered thus far involves the class II MCH haplotype of an individual. Certain HLA-DR molecules are more commonly found in patients with RA (e.g., HLA-DR4), and consistency in a particular amino acid sequence in the third hypervariable region of the beta chain of MHC-susceptible alleles has led to the "shared-epitope" hypothesis. This hypothesis postulates that presumed antigen(s) bind to this particular site, resulting in the cascade of inflammation in RA (9).

Rheumatoid arthritis is also closely mimicked by transient arthritic conditions provoked by several microbial pathogens, leading to the consideration of infectious etiologies in the pathogenesis of RA. A role for infection in the development of rheumatoid arthritis has long been postulated, including potential bacterial and viral pathogens, but it has not yet been proven. Other potential antigens include heat-shock proteins, MHC molecules themselves, and certain epitopes within type II collagen (9).

A complex array of constituents in the immune system interact to cause the initiation and perpetuation of inflammation found in RA. Memory T cells, B cells, plasma cells, cytokines, macrophages, vascular endothelium, and rheumatoid factor all play important roles. Just a few of the memory T cells functions include enhanced T cell, macrophage, and antigen-presenting cell activation, while macrophages act as effectors, producing multiple proinflammatory cytokines, such as IL-1, IL-6, TNF, among others. Rheumatoid factors of multiple isotypes form immune complexes that not only fix complement but also activate neutrophils. B cells are also found within the rheumatoid synovium, and although the exact mechanisms involved in pathogenesis are yet unknown, the therapeutic use of rituximab, and a chimeric anti-CD20 (B cell) monoclonal antibody, has produced significant responses in patients with RA. Multiple cytokines exist within the rheumatoid synovium, exhibiting complex roles, including mononuclear cell migration, cell activation, and direct damage to articular cartilage and bone. Tumor necrosis factor- α (TNF- α) is an important proinflammatory cytokine, and TNF-blocking therapies (adalimumab, etanercept, and infliximab) have been successful in the treatment of RA. Newer therapies focused on cytokines currently under investigation or soon to be released include inhibitors for IL-15 and IL-17, and IL-6 blockade, respectively (10).

Osteopathic Patient Management

For any patient presenting with pain in the hands, a thorough osteopathic examination, using the five-point structure function model, is essential. Osteopathic techniques can be applied to the areas of somatic dysfunction in patients presenting with arthritic-type pathology. The models of structure-function relationships described below guide the osteopathic practitioner's approach to diagnosis and treatment. These models provide a framework for integrating objective and subjective clinical findings with osteopathic structural exam findings.

Biomechanical Model

Short leg mechanics can lead to a worsening of a patient's arthritic upper extremity symptoms by adding postural stress to the upper extremity with resultant aches and pains. Vleeming's work can be used to understand the anatomical relationship between sacral base unleveling from short leg mechanics, subsequent iliac crest unleveling, and the postural tension created in the shoulders through the latissimus dorsi muscle via the thoracolumbar fascia. Altered shoulder biomechanics can strain muscles and increase intrinsic pressure on the intra-articular tissues, both of which may exacerbate joint pain.

Another biomechanical consequence of postural imbalance is concomitant changes in the A-P curves. With a forward head position and protracted shoulders, the rotator cuff muscles, levator scapulae, and serratus posterior superior become tight and develop myofascial triggerpoints. Triggerpoints in these muscles refer to the upper extremity (14). Scalene tension can cause neurovascular compression as can elevation of the first rib, narrowing the space between itself and the clavicle. All these factors can biomechanically be related to painful syndromes in the upper extremity, including the hands.

Respiratory/Circulatory Model

Another objective of osteopathic treatment is improvement of local blood flow to the area of arthritis in the hands as well as removal

of edema to assist in pain reduction and improve mobility. This is done by addressing the areas of somatic dysfunction that may influence arterial, venous, or lymphatic flow. Our patient has dysfunction in the lower thoracic and thoracolumbar areas, both of which may influence diaphragm function. Improving motion in the lower thoracic region will help the function of the diaphragm from a mechanical perspective. Improving motion in the cervical region may help the function of the diaphragm from a neurologic perspective. Treating both regions will aid in restoring normal diaphragmatic motion, which is the primary driving force to move lymph and venous blood. This treatment should follow thoracic inlet release, which removes any proximal restrictions to lymphatic flow coming from the upper extremities. In the patient described in the case, treatment of the right sternoclavicular restriction will further aid in this process by normalizing fascial tensions of the thoracic inlet. Then, attention can be moved distally to remove pectoral and axillary restrictions, and then on to the elbow, wrist, and hand for the same purpose. Abnormal interosseous membrane tension of the forearm may contribute to lymphatic and venous stasis by altering the mechanics of radius and ulnar and their role in generating intracompartmental pressures. This is especially true in patients who repetitively use their forearms, as their muscles and fascias become tight. Peripheral fascial restrictions in the distal arms may affect the vascular structures traveling through them. Restrictions in the scalene muscles, first rib or thoracic inlet may impede fluid movement through the vascular bundle supplying the upper extremity. Treatment of these areas may improve lymphatic and venous drainage and arterial flow.

Neurological Model

The sacrum is the base of support of the spinal column; unleveling of the sacrum results in adaptive or compensatory curves in the vertebral column. No matter if there is an “S”-shaped or a “C”-shaped adaptive group curve, there will be crossover points of the curve. A crossover point is where the curve changes direction. This vertebral unit is commonly found to have type II dysfunction. These segments can become facilitated and act as an “irritable focus” of neuronal activity (11). If the crossover point is between T1 and T4, as it is in this patient, the upper extremities may be affected. Increased activity in somatic fibers between T1 and T4 can be referred to the upper extremity via a somato-somatic reflex. Dorsal root reflexes may activate primary afferent fibers in the peripheral area served by the upper thorax resulting in the secretion of proinflammatory substances that may exacerbate arthritic symptoms. Increased nociceptive activity at the level of T1–4 has the potential to activate fibers in the adjacent lateral horn. As the sympathetic neurons become facilitated (12), the abnormal sympathetic drive affects vascular tone and peristalsis resulting in venous and lymphatic stasis in the upper extremities. Increased vascular tone can also make muscles stiff and noncompliant. Sympathetic overactivity will alter the secretory activity of sweat glands, and sensitize nociceptors and mechanoreceptors (13).

One objective of osteopathic management is to normalize neurologic input to the upper extremity. Sympathetic innervation to the upper extremity may be influenced through treatment of the upper thoracic and the associated rib dysfunctions. As stated above, increased sympathetic tone to the upper extremity can cause vasoconstriction, edema, sensitivity of the nerves, irritability of the muscles, and sweat gland overactivity. OMT in this region may improve those related pathophysiologic findings.

Peripheral fascial restrictions may affect somatic nerves, in addition to the aforementioned vascular structures. Tension in the anterior

scalenes and the thoracic inlet can compress the neurovascular bundle, impairing nerve transmission and vascular supply to the rotator cuff and scapular stabilizing muscles. Removal of the fascial restrictions and resultant compression to the neurovascular bundle will facilitate axoplasmic flow, enhancing the nerves' trophic function. Tension of the pronator teres muscle in the forearm can compress the median nerve (pronator syndrome) producing hand symptoms as well (15). Stiffness of the joints of the hands and elbows can cause overuse of the forearm muscles to make up the motion lost. Stiffness, swelling, enlargement, and ulnar deviation of the digits can affect the small nerves in the hands. If these nerves are already sensitized from spinal facilitation, they will report increased levels of pain.

Metabolic Energy Model

Patients who have painful musculoskeletal conditions can require increased energy expenditure to function when compared to a healthy patient of the same age. Increased oxygen demand can cause fatigue if they have to ambulate a long distance with arthritic knees, hips, ankles, or feet. For those who repetitively use their hands, as in typing, upper extremity stiffness and pain can be problematic. They can become fatigued, make errors, and become frustrated. Both the working environment and the recreational environment may become affected, changing the patient's ability to cope in comparison to their premorbid condition. Osteopathic patient management must address the factors that may contribute to energy demand and production.

If the clinician's objective is to improve the patient's energy flow and metabolic activity, then removing barriers to the proper function of physiological mechanisms is important. Osteopathy in the cranial field recognizes the primary respiratory mechanism as a fundamental component of health (1990). According to Sutherland model (1998), patients who have a significant sphenobasilar synchondrosis compression do not have optimal function of the primary respiratory mechanism and therefore suboptimal recuperative capacity. Compression of the fourth ventricle, a cranial technique, has been hypothesized to assist in the normalization of cerebrospinal fluid flow and other components of the primary respiratory mechanism (16).

Behavioral Model

Small joint disease presents a challenge in accomplishing these tasks subsumed under the concept of activities of daily living (ADLs). For those patients with small joint disease, simple tasks such as opening a jar of pickles can present a constant reminder of declining capabilities. The challenge in caring for these patients is to provide alternative coping skills for the maintenance of spirit. When met with challenges, many people turn to prayer or spirituality to guide and strengthen their efforts to lead meaningful lives in the larger sense and to accomplish ADLs on a much smaller scale. Support groups may be of value, especially if the patient has expressed feelings of isolation with regard to his or her disease. Patient education can assist in the preservation of self-worth, and educational materials for patients with RA may be obtained from the Arthritis Foundation, American College of Rheumatology, and the National Institutes of Health. Encouragement along with the revelation of the many ways in which the patient can rise above the pain and diminished function that can accompany small joint disease can help them to achieve or maintain spiritual and behavioral satisfaction. The goal is to achieve or maintain function at a premorbid level though this may not be possible in the long run. In this fashion, patients with small joint disease with proper treatment can

maintain their own self-image in addition to the way they are perceived by society to be functioning as a whole. The osteopathic physician is well placed to provide not only physical and pharmacologic medicine, but also education and emotional support to assist the patient in achievement of shared goals.

Outcomes Studies and Best Evidence for Manual Treatment

Both osteoarthritis and rheumatoid arthritis are common problems and can be chronic disabling conditions. For many patients, conventional therapies are not completely effective and are limited by side effects. This can lead to ongoing pain and frustration. Complementary and alternative medical therapies (CAM) therapies are defined as being outside scientific mainstream medicine. These nonpharmaceutical treatments are generally unproven in efficacy but perceived as safe. The American College of Rheumatology (ACR) believes practitioners should be informed about cam therapies and be able to discuss them knowledgeably with patients. Meanwhile, scientific studies are underway to test the efficacy of these modalities. OMT may be considered a CAM therapy by some clinicians, while others feel it is an integral part of osteopathic patient care.

Conservative treatment for patients with hand arthritis (both RA and OA) may include (but is not limited to) the following: medications, diet, heat or cold therapy, physical or occupational therapy, modalities, tens, braces and splints, injections, osteopathic manipulation, chiropractic manipulation, massage therapy, and acupuncture.

Manipulative techniques for upper extremity complaints have been taught in the osteopathic schools' curriculum since its inception. OMT has been shown to be beneficial to decrease pain and increase patient's function in a variety of clinical situations. Manipulative techniques have been employed and studied in the treatment of injuries and osteoarthritis of the fingers and hand (17). Yet, there none or few randomized controlled studies to show that OMT is beneficial for patients with RA or OA of the hands.

There have been a number of studies in the literature reporting that acupuncture is effective in treating rheumatoid arthritis. One such study evaluated acupuncture in the treatment of rheumatic knee pain. As compared to sham treatment, the acupuncture group had improved pain scores for as long as 3 months after treatment (18). More studies assessing the effectiveness of acupuncture for rheumatoid arthritis are needed. There is moderately strong evidence from the above studies to support the use of acupuncture as an adjunctive therapy for osteoarthritis.

A recent meta-analysis (19) of seven studies concluded that chondroitin sulfate may be useful in decreasing pain and improving function in osteoarthritis. Chondroitin sulfate may be useful in the treatment of osteoarthritis. Larger studies are needed to further examine the usefulness of chondroitin sulfate in osteoarthritis.

The application of pulsed electric device (PEMF) stimulation for osteoarthritis is a relatively new area. In two different studies (20,21), chronic knee osteoarthritis was treated with PEMF by way of skin surface electrodes. The treatment was superior to placebo in symptom reduction. The treatment also seemed to be cost effective. PEMF therapy is considered safe but should be avoided in those who are pregnant, with permanent pacemakers, and patients with known cancer.

Integrative Treatment Approach

Osteopathic Manipulation

As Osteopathic physicians, we often make use of Osteopathic Manipulative Treatment (OMT) as a powerful treatment tool

for musculoskeletal complaints. OMT is part of the Osteopathic physician's overall treatment armamentarium and the use should follow from the careful consideration of Osteopathic principles and practice used in the evaluation of every patient. The use of OMT is frequently based on the physician's ability, the patient's presentation and responses, and the type of dysfunction found. OMT can be tailored to fit almost any practice model. There are many benefits to osteopathic manipulation. Some of the primary benefits include increased range of motion, decreased pain, improved ADLs, and shortened disability time (quicker return to work). Some secondary benefits include reduced reliance on medications (especially narcotics) and improved postural efficiency (22). In patients with rheumatoid arthritis of the occipitoatlantal and atlantal-axial articulations, caution must be applied to the choice of technique used to treat the somatic dysfunction present. Rheumatoid arthritis of the upper cervical spine is a contradiction to thrust (HVLA)-type manipulation. This is thought to be due to the relative laxity and instability in this region due to the inflammatory process (23). However, it is also to be remembered that for subacute and chronic neck pain, spinal manipulation is more effective when compared with muscle relaxants or the usual medical care. Efficacy was enhanced when combined with other modalities, such as exercise (24).

Pharmacologic Treatment

While the body has the innate ability to self-heal, therapies with pharmacological treatments are often essential in the treatment of an inflammatory arthritis such as RA. Disease-modifying antirheumatic drugs (DMARDs), either alone or in combination, as well as biologic therapies (e.g., TNF- α blockers), and nonsteroidal anti-inflammatory drugs (NSAIDs) are often the cornerstone of treatment therapies. Early and aggressive interventions may result in lower morbidity and mortality, as evidenced by slower radiographic progression, less disability, and fewer surgical interventions (25). In fact, recent studies have suggested that patients on methotrexate combination therapy or TNF inhibitors have less morbidity and mortality from cardiovascular events as well due to diminished systemic inflammation (26,27). Thus, even in the most skilled hands, most patients require a combined approach with the appropriate use of other treatment modalities including medications or local injections of corticosteroids to reduce inflammation.

Physical and Occupational Therapy

The role of physical and occupational therapy is also of great importance, especially in the early treatment of an inflammatory arthritis such as RA, but may also be beneficial in OA as well. Physical therapy is usually considered for issues related to ambulation or predominantly lower extremity dysfunction, while occupational therapy encompasses the upper extremity, focusing on the assessment of functional abilities within home/work environments. Patients should be evaluated for ability to engage in ADLs, ability to ambulate, level of fitness, etc. Treatment modalities may then be fashioned to ensure joint function as well as joint protection, and steps may be taken to potentially prevent contractures or deformities (28). Joint protection interventions have been studied in patients with RA, and home hand exercises have resulted in improved grip strength as well as diminished morning stiffness (29–33). Another study evaluating joint protection and home hand exercises for patients with hand osteoarthritis also showed increased hand strength and global hand function, underscoring the importance of nonpharmacologic interventions in the treatment of both RA and OA (34). Whole-body strength training and gripper exercises have

also been shown to improve dynamic and static grip strength while decreasing pain in older patients with hand OA (35). These therapeutic modalities have no side effects, are generally readily acceptable, and can be performed easily, making them useful adjunctive treatments in both of these chronic diseases. Other useful non-pharmacologic interventions include adaptive devices that may be customized to improve independence in daily activities, such as opening jars and car doors, self-care, grooming, and dressing.

Multiple lines of evidence support the case for early intervention in rheumatoid arthritis, as functional health status tends to decline early in the disease, mortality rates rise over the course of the disease, and radiographic changes occur much earlier in the disease process than previously thought. Work disability increases from approximately 25% at 6.4 years to 50% at 20.9 years after onset of disease (36). Mortality rates also rise over the course of the disease, with rates as high as 35% by 20 years (37).

All of these factors have to be taken into consideration, coupled with the need to individualize each case based on patient desire, functional status, and long-term goals. Additionally, due to patient desire, medical conditions and/or other factors, the patient may not be a candidate for certain treatment modalities, such as surgical joint replacement, forcing a conservative approach. More than 70% of patients with RA have some form of hand disability, often crippling hand deformities if the disease has been longstanding (38).

Surgical Intervention

The role of surgical intervention in the treatment of RA remains somewhat controversial, and it should be determined by both the level of pain and the functional status of the individual. Many practitioners will not recommend surgical intervention unless pain disrupts sleep, and true functional gain has to be rigorously assessed as well. Likewise, nonoperative treatments for osteoarthritis should be employed, such as medications, intra-articular steroid injections, hand therapies, and splinting prior to consideration of surgical interventions (39). If a surgical approach is required, the specifics of the procedure should be considered. If two different procedures are being considered, how would each of these different procedures change the duration of healing and required physical therapy postoperatively? How would any or each of these procedures affect the presence of somatic dysfunction in the cervical, thoracic or lumbar spine? Osteopathic treatment can be a helpful adjunctive therapy postoperatively. Postoperative patients who develop cervical spasm, rib restrictions, atelectasis, or sacral malpositioning, for example, may benefit from OMT for relief of cervical, thoracic, lumbar, or sacral somatic dysfunction. Postoperatively, activity modification, work restrictions, and lifestyle change are important aspects to consider to assist patients in their recovery and to enhance the healing process.

Treatment Sequence

A good rule of thumb for the practitioner is to assess how acute the area to be treated actually has become. There are many reflexes active in the body and generally the more normal relationships that can be established distant from an acute area the easier it will be to address that remaining acute area for a response. For example, suppose a patient has an elevated first rib that is causing distal arm pain, but the patient's main complaint is radial head dysfunction felt at the elbow. Advantage can be gained in relaxing to as normal a state the facilitated irritation being generated by the elevated first rib, which can reasonably be expected to increase tone in distal musculature. By following this approach, when it comes time to

move the radial head, there may be that much less resistance to movement encountered from muscles attached to the radius. Similarly, with small joint disease, working to release the carpal tunnel from undue pressure via the opponens roll technique may decrease pain perceived distally in the small joints of the fingers (40).

The emotional component to the patient's condition needs to be evaluated and addressed. For example, the patient may not be compliant with therapy due to financial constraints, personal reasons, or other factors. This may result in delayed progress/healing and perhaps a sense of guilt that they are not doing everything they could for their condition.

SUMMARY

In conclusion, it is through the use of multiple modalities that we as osteopathic physicians can provide the most comprehensive and therapeutic treatment strategies for patients with both rheumatoid arthritis and osteoarthritis as it involves small joints of the hands. The combination of state-of-the-art pharmacologic interventions, physical and occupational therapies, and osteopathic principles and practice enable osteopathic physicians to uniquely enhance the lives of individuals affected by these debilitating and potentially devastating diseases.

Lower Extremity Swelling in Pregnancy

MELICIEN TETTAMBEL

KEY CONCEPTS

- Swollen legs are a common condition of pregnancy and are often related to the physiologic hypervolemia of pregnancy.
- A woman's body undergoes many biomechanical adaptations as her pregnancy progresses; these may adversely impact the low-pressure systems of the body resulting in passive venous congestion.
- While passive venous congestion is often a contributing factor in swollen legs during pregnancy, other causes must be ruled out.
- Addressing tissue strains and compensatory postural adaptations to pregnancy may help alleviate passive tissue congestion and improve symptoms associated with peripheral edema.

CASE VIGNETTE

Diane, a 26-year-old primigravid female, is seen for her prenatal care visit, complaining of swelling of both lower extremities. She is 29 weeks pregnant, and to date, has not had any other problems in her prenatal course.

Chief Complaint:

Swelling of lower extremities

History of Present Illness:

She reports that the swelling in her legs usually resolves by morning; but gradually increases throughout the day. Shoes become tight and uncomfortable as well. She denies trauma to the lower extremities or pelvis.

Past Medical History:

Noncontributory

Past Surgical History:

Negative

REVIEW OF SYSTEMS

She denies headache, dizziness, and nausea. She denies blurred and double vision. She denies high blood pressure. She admits to occasional acid reflux. She denies diarrhea and constipation. She denies change in tolerance to temperature. She admits to mild fatigue. She denies pain, burning, weakness, and paresthesias.

PHYSICAL EXAMINATION

Vital Signs:

Blood pressure: 116/62, heart rate: 68 and regular, weight: 146 lb (increased by 3 lb from last month's visit). Urine dipstick indicates absence of glucose, protein, and nitrite.

Cardiovascular:

Heart has a regular rhythm without murmur or gallop; all pulses are intact.

Lungs:

Clear to auscultation and percussion

Abdomen:

Gravid abdomen, no tenderness to palpation, no venous distention

OB/GYN:

Fundal height consistent with gestational age, fetal heart tones located in lower right quadrant with rate of 146

Extremities:

No tenderness on palpation of lower extremities. Mild, nonpitting edema appreciated in both lower extremities, no edema in the upper extremities, and pulses are regular and intact. There is no venous distension and no signs of trauma are noted.

Neurological:

Deep tendon reflexes +2/4 bilaterally symmetrical and equal in all extremities, sensory and motor are grossly intact.

Musculoskeletal:

Gait and posture are unremarkable for this stage of pregnancy. There is a slight increase of lumbar lordosis and anterior pelvic tilt, but there is no tenderness to palpation of muscles of lumbar spine and pelvis.

Osteopathic Structural Exam:

Lumbosacral junction is rotated to the left, and thoracolumbar junction is also rotated to the left. The right innominate is rotated anteriorly and the right pubic tubercle is inferior and tender to light palpation. The left quadratus lumborum is hypertonic and ribs 10 to 12 on the left are inferior compared with those on the right. There is restricted movement in exhalation of the lower ribs 6 to 12 bilaterally. The thoracic kyphosis is somewhat flattened, and there is tension in the cervical muscles bilaterally extending from the cervicothoracic junction to the suboccipital area. The cervicothoracic junction is rotated right, the occiput is sidebent right and rotated left, and C2 is rotated right. There is mild restriction at the left occipitomas-toid area.

DIFFERENTIAL DIAGNOSIS OF LOWER EXTREMITY EDEMA

Complaints of swelling of the face, hands and, especially, the legs and feet are common in pregnancy. This chapter describes the causes of lower extremity swelling in pregnancy from osteopathic and obstetric points of view. There are standard recommended guidelines for “routine” prenatal visits that are utilized by most obstetrical care providers (1–5). These guidelines identify potential problems of fetal growth and development, as well as maternal well-being. Baseline information such as maternal age, first day of last normal menstrual period, number of pregnancies and their outcomes, maternal weight, employment activity, past and present family and medical history is recorded. At each prenatal care visit, the following information is recorded: gestational age, weight, blood pressure, fundal height, fetal heart tones, and urine dipstick detection of glucose, protein, and maternal urine nitrites. Patient concerns are recorded with related care plans or screening tests. Next follow-up visit is also documented.

In the second and third trimesters of pregnancy, women are concerned about weight gain, fetal activity, fatigue, and edema. During this time, swelling may be the result of salt and fluid retention, hormonal changes, alteration of cardiovascular, lymphatic and renal dynamics; and/or musculoskeletal changes to accommodate an enlarging uterus.

Eighty percent of pregnant women report swelling of the legs and feet in pregnancy (6). There are a variety of causes from benign physiologic changes to serious medical problems. Box 63.1 lists some of the most usual differential diagnoses. Each of these potential causes will be discussed within the framework of the case presented at the beginning of this chapter.

Varicosities

Varicose veins, also known as varicosities, occur when a valve in the blood vessel wall weakens, causing stagnation of blood flow. Venous circulation slows as the venous walls dilate and distend. Just below the skin, the vein may swell into a small balloon-like structure. Leg veins are most commonly affected as they are working against gravity especially with prolonged standing. Pregnancy is a major contributing factor in the development of varicose veins as the enlarging uterus puts additional valvular pressure on veins of the pelvis resulting in hemorrhoids and varicosities of the vulva. The increasing weight of the expanding uterus also puts pressure on the inferior vena cava. Veins in the legs are most commonly affected by additional gravitational challenges to supply circulation to the lower half of the body.

Varicose veins are most commonly seen in women in North America and Western Europe where people may have more sedentary

lives and utilize modes of transportation rather than walking long distances. Varicose veins are less common in the Mediterranean, South America, and India; and even more uncommon in the Far East and Africa, where obesity is not prevalent (7,8). The development of varicose veins may also be due to a history of phlebitis, type of physical activity, or genetics (familial dominant, x-linked) (9). Parous women have a higher incidence of varicose veins compared with nulliparous women and multiparous women have the highest risk (10). Previous pregnancy with resultant weight gain, and fascial and ligamentous laxity may have further tilted the pelvic bowl with its contents in a more anterior position. Tissue changes, postural changes, and maternal age, in conjunction with weight changes, all may contribute to varicosities. Though varicosities often manifest in pregnancy, they may regress until the next pregnancy. Furthermore, there is no direct correlation between the severity of varicosities and the severity of the patient’s symptoms.

The development of varicose veins during pregnancy may be influenced by the combination of high cardiac output and an increase in the hormone progesterone that relaxes the muscular walls of the blood vessel. It is hypothesized that estrogen and progesterone receptors on saphenous veins may provoke venous dilation and valve failure in pregnancy (11).

The most common symptoms of varicose veins are swelling, pain, night cramps, numbness, tingling, and heavy aching legs. The skin around visible venous distention may itch, throb, or feel like it is burning. Legs appear unsightly. Symptoms tend to worsen after long periods of standing and with each subsequent pregnancy. For some women, however, varicose veins and swelling may cause little or no discomfort.

On physical exam, pulses are intact, and neurological exam is unremarkable, and there may or may not be tenderness to palpation of the area of venous distention.

PASSIVE VENOUS CONGESTION

The same process responsible for varicose veins in the lower extremities can in turn lead to venous insufficiency. Impeded circulation causes blood to pool in the legs, forcing fluid from the intravascular space into the extravascular tissues of the feet and ankles. Leg edema affects up to 80% of pregnant women and should not be considered a sign of pregnancy-induced hypertension or preeclampsia (12). Chronic venous insufficiency may lead to varicose eczema, with brown or purplish discoloration of the skin. Over time, skin ulcers may develop (13).

Preeclampsia

Preeclampsia is a condition specific to pregnancy. Pregnant women with a blood pressure of 140/90 after the 20th week of pregnancy should be evaluated for preeclampsia (14). The obstetrical literature defines preeclampsia as an elevation in blood pressure of 140/90 mm Hg after 20 weeks of pregnancy, with or without proteinuria or edema (15). There is reduced organ perfusion secondary to vasospasm and vascular endothelial activation resulting in elevated blood pressure and proteinuria of greater than 300 mg per 24 hours. Urine dipstick testing may register +1 proteinuria (30 mL/dL). Patients may have gradual or rapid onset of edema of the extremities. They may also complain of rapid weight gain of up to 2 lb on a prenatal care visit. On clinical exam, the edema may be mild or pitting. There is no cyanosis of the lower extremities. Pulses are equal and intact.

Differential Diagnoses of Swelling of Lower Extremity in Pregnancy

- Varicosities
- Passive vascular congestion
- Preeclampsia
- Lymphedema
- Thrombophlebitis
- Deep vein thrombosis
- Cellulitis
- Urinary tract changes in pregnancy
- Somatic dysfunction

Lymphedema

Lymphedema may be a lifelong condition that results from disruption of the lymphatic system. It can be classified as either primary or secondary. Primary lymphedema is an inherited disorder from prenatal developmental abnormalities of the lymph vessels. In females, it may first present during their late teens or early twenties, and become worse with pregnancy. Symptoms usually persist postpartum (16). The secondary form is acquired and may be the result of prolonged venous insufficiency, increased weight, obesity, and/or trauma to the lymphatic capillaries. In addition to biomechanical injury, burns and cicatrix formation may cause chronic edema and subcutaneous fibrosis. On clinical exam, often only one extremity is swollen although both legs may be affected. The patient does not complain of pain, and while neither tenderness nor pitting edema is elicited on examination, the leg feels rubbery to palpation. Ulceration and stasis dermatitis are absent (17).

Thrombophlebitis and Deep Vein Thrombosis

Potential complications associated with varicose veins and resultant edema are thrombophlebitis and venous thrombosis. Thrombophlebitis is inflammation of the vein, due to trauma (10,13,18). The patient may complain of throbbing of her legs with weight bearing although she is able to ambulate independently. On examination, the traumatized area is warm, mild erythematous and tender to light palpation. Sometimes, there is a bruise over the traumatized area. The pulses of the leg are intact.

A venous thrombus is a clot in the vein. The clot may occur in a superficial vein or in a deeper vein. If there is obstruction in a deep vein, a clot may migrate to the lung and cause a pulmonary embolism, which could be fatal. On physical exam, there is tenderness to manual compression of the vein or the muscles of the calf with pitting edema. In advanced cases, with deep vein involvement, the patient may have difficulty walking or bearing weight. On inspection of the leg, the calf circumference may be three or more centimeters greater than the unaffected leg. There may be low-grade fever. If pain is elicited with dorsiflexion of the foot, the extremity feels cold and pulseless or appears cyanotic; duplex sonography and D-dimer studies should be obtained to confirm a diagnosis of deep venous thrombosis. Treatment with anticoagulants should be initiated as soon as possible (13).

Cellulitis

Cellulitis usually occurs as a result of lower extremity trauma with secondary acute superficial staphylococcal or streptococcal skin infection. Common causes of cellulitis include cuts from shaving legs or abrasions that may develop into inflammation or pustules. Pregnant diabetic patients are at increased risk of developing cellulites. Patients complain of mild edema and erythema with tenderness on palpation. There is no difficulty with weight bearing or ambulation. Fever may or may not be present. On clinical examination, red streaks on the legs along the path of trauma, laceration, or abrasion may be present (9).

Urinary Tract Infection

Hypervolemia occurs in pregnancy to protect the mother, as well as the fetus, against negative effects of compromised venous return in the supine and erect positions. However, as the circulatory system delivers nourishment to the expanding uterus, pressure is placed upon the renal system. The renal calyces, ureters, and bladder all

experience changes in shape and function. Glomerular filtration rate increases in pregnancy. The calyces and ureters become dilated, usually the right ureter more than the left (19). The left ureter may be cushioned by the sigmoid colon. The uterus also undergoes dextrorotation as it enlarges. Additional pressure is placed upon the right ovarian vein complex near the ureter. Ureteral dilation causes urinary stasis, which may lead to urinary tract infection. The bladder also becomes compressed by the uterus. Complete emptying during urination may be prohibited. Urinary stasis with some retention may also result. Urinary tract infection is one of the most common bacterial infections in pregnancy. In addition to complaints of changes in frequency, amount, pressure, or pain with urination, pregnant women may also report a puffiness of the lower extremities. Urinalysis, with urine culture, confirms the diagnosis of infection, which influenced the mild edema of the legs.

Somatic Dysfunction

During the course of pregnancy, maternal posture and gait change to accommodate the shifting center of gravity. Gait is steadied by increased separation the feet and legs while in standing position. As lumbar lordosis increases, the pelvic bowl tilts forward, and weight is put on areas of the posterior leg and pubic region. As previously mentioned, the expanding uterus puts pressure on the bony skeleton and structures contained within the pelvis. Vascular congestion of the organs and lower extremities results to cause edema constipation, bladder pressure, varicosities, and hemorrhoids. There is also concomitant drag on muscles fascias and ligaments. Weight gain, gravitational, pressure of the uterus, and increasing anterior-posterior spinal curves all present challenges to comfortable respiration in the pregnant patient.

OSTEOPATHIC PATIENT MANAGEMENT

Biomechanical Model

It is understood that the body may have a variety of areas of somatic dysfunction that may impact edema, such as the cervical spine and the thoracic outlet. Weight and postural strain of pregnancy may be addressed through the osteopathic biomechanical treatment model. Abnormalities of gait, unlevel sacral base, accentuated spinal curvature in either the lateral or anterior-posterior planes should be addressed to reduce musculoskeletal fatigue and circulatory congestion. Bony and ligamentous restrictions of the hips and lower extremities are reduced to remove circulatory impediments within the pelvic floor. The patient may also experience greater ease in ambulation to help with venous return of the lower extremities. Reduction of lumbar lordosis and anterior pelvic bowl tilt may assist in lifting the uterus off the veins of the lower extremities. Diuresis may also ensue when the uterus and related ligamentous-visceral strains are reduced in the area around the bladder.

Attention to body regions below the respiratory diaphragm will be given through utilization of the respiratory/circulatory model. Osteopathic manipulative treatment may attempt to resolve restrictions of the respiratory and pelvic diaphragms to improve respiration. Circulation of fluids within the abdominal-pelvic cavity may become more efficient with improved respiratory effort. Myofascial treatment of the anterior abdominal-pelvic wall addresses strains of the subcutaneous and deeper fascias that also contain lymphatic tissue. Edema of the legs due to lymphatic congestion may respond to osteopathic techniques to increase lymphatic drainage after somatic dysfunction of the pelvis has been addressed. Diuresis may also ensue when the uterus and related ligamentous-visceral strains

are reduced in the area around the bladder. Visceral treatment of the uterus is applied to “center” the uterus and to reduce congestion and compression of other pelvic organs and related vasculature.

Respiratory/Circulatory Model

Within the respiratory-circulatory model of structure and function the inability to breathe deeply due to restriction of motion of the respiratory diaphragm, rib cage, and cervical fascias increases fatigue and vascular congestion; both which may aggravate edema. The enlarging uterus may also compress the vena cava when the patient lies in a supine position for a period of time. In this position, there is edema due to delay of venous return of the lower body. When the patient lies on her left side, the uterus is displaced, facilitating diuresis and decreasing swelling of the lower extremities.

On palpatory musculoskeletal examination, the following should be evaluated: respiratory diaphragm motion restrictions, leg length discrepancy, compression of lumbosacral junction, physiologic motion of the sacrum; strains of the pubic symphysis, pelvic diaphragm, hip joints, fibular heads, ankles, feet; and tissue texture changes of anterior abdominal wall, groin, and lower extremities. Scars on abdomen, pelvis, and lower extremities may constitute fascial restrictions or tissue texture changes. Note any lymphatic congestion or circulatory compromise resulting in edema. Palpate temperature changes with tissue texture changes locally and regionally throughout the musculoskeletal system which may suggest autonomic imbalance that could influence body fluid dynamics of cardiovascular circulation or renal function (Box 63.2).

Incorporation of adjunctive integrative treatment may be beneficial within the bioenergetic treatment model as well. Compression stockings have been used to control edema; however, the result is also temporary and transient. Bamigboye and Smyth reviewed the 2006 updated Cochrane database regarding treatment of edema in pregnant women and found that compression stockings often were no more effective than elevation of the feet for 30 minutes (20).

Neurological Model

The neurological model of osteopathic treatment recognizes the dynamic balance between the parasympathetic and sympathetic nervous systems and the potentially disruptive influences of nociception and biomechanical strain on those systems.

Osteopathic manipulative treatment of the thoracolumbar junction is performed to correct diaphragm and lower rib dysfunction that may interfere with balanced autonomic nerve activity to the kidneys and urine output. Treatment of the sacrum may

influence parasympathetic activity to the vascular and structures of the renal and urinary systems.

Metabolic Energy Model

Consideration of the metabolic energy model of osteopathic care entails evaluation of the patient’s ability to maintain balance between energy production and expenditure during pregnancy to reduce edema of her lower extremities. Discussion about avoidance of tight or restrictive clothing about the waist that may reduce venous return from the lower half of the body should occur. The patient should be advised to wear comfortable shoes that would not challenge her gait or aggravate her already increased lumbar lordosis.

Behavioral Model

The biopsychosocial social model of osteopathic treatment considerations of pregnant patients with swelling of the lower extremity may include evaluation of patient environment and work activities. Prolonged sitting or standing may aggravate edema. Low-impact exercises and frequent walks throughout the day will help the patient to improve vascular and lymphatic circulation. Intake of water, rather than caffeine or carbonated beverages, may increase hydration and elimination of metabolic waste that may contribute to edema. Additionally, an exercise program may help the patient to avoid gaining large amounts of weight that may further tax her musculoskeletal system, and changing posture during her pregnancy. Physical activity provides beneficial stressors such as improved respiration and circulation to accommodate visceral and other structural changes from both anatomical and physiological perspectives.

CONTRAINDICATIONS TO OSTEOPATHIC MANIPULATIVE TREATMENT

There are some contraindications to osteopathic manipulative treatment of edema in pregnancy. Patients with unstable blood pressure and deep vein thrombosis should be evaluated, treated, and stabilized. Fetal health should be established. Assessment of risk factors for preterm labor should also be performed.

INTEGRATIVE TREATMENT CONSIDERATIONS

In addition to osteopathic treatment, other recommendations may be offered to the pregnant patient to relieve swelling of the lower extremities.

Advice pertaining to rest or exercise depends upon a medical condition related to the pregnancy. If the patient has preeclampsia or venous insufficiency, rest or elevation of the legs is recommended. When the patient rests on her left side, the uterus is displaced from the aorta and inferior vena cava to facilitate venous return and diuresis. “Water weight” is also reduced. Varicosities are also temporarily reduced. Exercise, especially walking, may enhance circulation of blood and lymph to relieve dependent edema. Exercise in moderation also controls weight gain in pregnancy. Ladies with lymph edema have additional challenge of increased pregnancy weight on their extremities. Those who cannot exercise have derived benefit from hydrotherapy, or water aerobics (21,22).

Studies of manual massage-reflexology treatments addressing the lymph glands around the feet and ankles did not result in significant reduction of edema in third trimester patients; however, in

Areas of Somatic Dysfunction in Patients with Lower Extremity Edema

- Cervical spine
- Thoracic outlet
- Lumbar spine
- Sacrum
- Boney pelvis
- Ligaments of pelvis
- Uterus
- Pubic symphysis
- Abdominal and pelvic fascias
- Hip joints
- Lower extremity

these small study group populations, there seemed to be a pattern of symptom relief from the patients' view points (21–23).

Some women have requested diuretics to relieve edema or abdominal bloating associated with their menstrual periods. During the course of their pregnancies, they may again request diuretics to reduce edema of their extremities. However, diuretics are not indicated as they do not mobilize extracellular fluids that have extravasated into the legs. These extrarenal fluid factors can override the kidneys' usual function. The "pregnant" kidney continues to retain sodium and water despite expanded blood, plasma, and extracellular fluid volumes. The kidney's modulation of total body sodium and water during pregnancy is not completely understood. Cardiac output cannot provide the major influence on the ability of the kidney to regulate sodium and water balance (24). Pregnancy is a hypercoagulable state. Diuretic-induced acute or chronic depletion of the plasma volume can lead to placental hypoperfusion and preeclampsia (25). Fluid restriction has not been found to reduce edema as the "normal" kidney can retain excessive amounts of sodium and water when cardiac output is low or high. Therefore, the integrity of arterial circulation is an important factor in body fluid composition and volume regulation.

OPPORTUNITIES FOR RESEARCH

For clinical research, pregnancy constitutes a "special population" because of risk of adverse reaction to the mother or to the unborn fetus. Presently, there are studies being conducted on the effects of osteopathic treatment on pregnant women at the University of North Texas Health Science Center–Osteopathic Research Center (26). There are no recent published studies regarding osteopathic treatment of lower extremity swelling in pregnancy. However, the aim of osteopathic treatment principles is to reduce edema through application of basic scientific principles pertaining to the understanding and attempted management of changes of body fluid volume in pregnancy. Combination of increased fluid intake and retention causes elevation in total body water content during high estrogen states (i.e. pregnancy). Some of this excess water resides in plasma, leading to plasma volume expansion. Regulatory mechanisms to maintain optimal body fluid volume involve reflexes within blood vessels and the brain that act to modify rates of fluid intake and output (27). Osteopathic treatment effectiveness incorporating fluid and fascial techniques to reduce edema could be investigated to understand arterial and venous function within the musculoskeletal system and to pelvic viscera (28,29).

CASE VIGNETTE (CONTINUED)

Diane was diagnosed with mild passive venous congestion. She was evaluated for somatic dysfunction in the above-mentioned areas and treated with a variety of manual osteopathic techniques. She was advised to continue walking and to wear comfortable clothing. Evaluation of complaints of edema was performed at each prenatal visit, along with her weight, blood pressure, and urine dipstick testing for proteinuria. During the third trimester of pregnancy, Diane was also advised to rest frequently, on her left side, with her legs elevated for at least 30 minutes. Her blood pressure remained stable. She reported that she felt less "puffy" after her osteopathic treatments, which were coordinated with her prenatal visits. She also continued to take short walks in the afternoon, and sometimes in the early evening. At 39 weeks of gestation, she delivered a healthy

baby girl without complication. During her postpartum visit 6 weeks later, she had no complaint of swelling of her legs. On exam, no edema was detected. She returned to her usual duties as wife and mother. She also continued to walk outside and lost 15 lb. An osteopathic treatment was performed to mobilize the pelvis and related structures, as well as the lower extremities so that Diane could comfortably maintain her busy schedule. She was advised to monitor herself for any signs of edema or bloating that might be associated with return of her menstrual periods, and to return as needed for further osteopathic care.

Low Back Pain in Pregnancy

MELICIEN TETTAMBEL

KEY CONCEPTS

- Low back pain is a common condition of pregnancy and may be related to hormonal changes associated with pregnancy; however, other causes should be ruled out.
- A woman's body undergoes many physiologic changes and adaptations as her pregnancy progresses; these may adversely impact her postural stability mechanisms resulting in biomechanical instability and pain.
- Passive venous congestion in the vertebral vessels may contribute to low back pain during pregnancy.
- Addressing tissue strains and compensatory postural adaptations to pregnancy may help improve postural stability mechanisms and back pain.

CASE VIGNETTE

Barbara is a 26-year-old pregnant patient at 35 weeks' gestation.

Chief Complaint:

Low back pain that sometimes radiates into her posterior legs, just above her knees.

History of Present Illness:

She has had this pain since the fourth month of her pregnancy, and it is gradually getting worse. She is considering taking early maternity leave. Her back pain is aggravated by lifting children and, sometimes, by rising from a chair. Relief is obtained by resting in bed, sitting with her feet propped up in a recliner-chair, or with a prolonged warm shower.

Past Medical History:

She has a history of endometriosis, which was confirmed with laparoscopy a few years ago.

Past Obstetrical History:

Her first baby was delivered by cesarean section, after an arduous labor, 3 years ago.

Past Surgical History:

Cesarean section as described above.

Family History:

Noncontributory.

Social History:

She is employed as a child care attendant for 3 year olds at a day care center.

REVIEW OF SYSTEMS

General:

She is well hydrated, alert, and uncomfortable.

Obstetrical:

To date, there have been no complications during this pregnancy. She has gained 20 lb, which is similar to her previous pregnancy.

Gastrointestinal:

Denies nausea, vomiting, and changes in bowel.

Neurological:

Denies weakness and tingling in the arms and legs. The pain does not radiate. There have been no changes in bladder function.

Musculoskeletal:

There is joint swelling. She admits to feeling stiff in her back but denies other joint stiffness or pain.

PHYSICAL EXAMINATION

Vital Signs:

Temperature: 37°C, Pulse: 88/min and regular, respirations: 20/min, blood pressure: 124/80

General:

Well hydrated in no acute distress

Obstetrical:

Obstetrical exam reveals no abnormalities; active fetus in vertex position, no contractions, mild swelling of all extremities.

Neurovascular:

Unremarkable, DTRs are intact and symmetrical. There is no weakness. Negative straight leg raise.

Musculoskeletal:

No joint swelling, erythema, or tenderness is noted. There is no tenderness to percussion of the vertebral spinous processes.

Osteopathic Structural Exam:

There is an increased lumbar lordosis with anterior pelvic tilt and unlevel sacral base. The psoas muscles are hypertonic bilaterally. There are no lateral spinal curves. Tissue texture of the lumbar spine is congested but also mildly taut. There is tenderness to palpation of the lumbosacral junction and right sacroiliac joint. Patient has a waddling gait due to change in center of gravity to accommodate enlarging uterus. On examination of anterior pelvis, a small infraumbilical scar and a transverse scar above the pubes are noted. Increased fascial tension is noted about the lower scar.

DIFFERENTIAL DIAGNOSIS OF BACK PAIN IN PREGNANCY

Approximately, two thirds of pregnant women complain of low back pain during pregnancy (1,2). Pain may start as early as the first trimester, when levels of the hormone relaxin are most elevated, or worsen during the course of pregnancy, causing fatigue, sleep changes, and interference with work or activities of daily living (3,4). Cause of the back pain may be anatomical, biomechanical, traumatic, or psychoemotional. Contributing factors, osteopathic diagnosis and treatment, as well as other methods of treatment will be presented and discussed within the context of a case presentation.

Overview of Low Back Pain in Pregnancy

Low back pain rates have been found to increase in young gravidas: women with advanced maternal age (1,5), woman with a history of back pain during previous pregnancy, and woman with an increasing number of previous births (either vaginally or operatively). There is no consistent relationship reported regarding height, weight, maternal weight gain, or weight of the fetus (6). Low back pain may also occur postpartum. However, back pain beyond pregnancy will be further discussed in another chapter about pelvic pain.

In addition to changes in maternal weight and posture in pregnancy, there can be a variety of factors contributing to low back pain in pregnancy (Table 64.1). Biomechanical instability is the most prevalent cause, as the enlarging gravid uterus and accompanying compensatory lordosis of the lumbar spine contribute to musculoskeletal strain. The psoas muscles may become shortened with lordosis, aggravating back pain (7). It is interesting to note that there is much discussion about lumbar lordosis and low back pain in pregnancy, but there is little discussion about low back pain in pregnant women who have scoliosis. Two hundred sixty seven women with adolescent idiopathic scoliosis, treated either surgically or with bracing, did not appear to have more or worse low back pain in pregnancy than matched control subjects who did not have scoliosis (8). It was also observed that the scoliotic curve did not seem to increase as a result of childbearing.

Pelvic rotation about a fulcrum at the second sacral segment increases as the lordosis increases. Center of gravity is shifted anteriorly, producing additional strain on lumbar spine and sacroiliac joints. As the sacroiliac joints become increasingly lax under the hormonal influence of relaxin during pregnancy, even more strain is placed on the low back and pelvis (9). It has been reported that pregnant women who were most incapacitated by low back pain had highest levels of relaxin (10–12). Not all were obese or had multifetal gestations. Weight gain during pregnancy is usual; however, in combination with ligamentous laxity, a 20% weight increase may increase force on a joint by as much as 100% (3,7,8).

The additional hormonal influences of estrogen and relaxin cause the pubic symphysis to widen. This widening normally is less than 10 mm (13,14) and begins during the 10th to 12th week of pregnancy. Relaxin levels begin to decline again until the 17th week (11). Palpation of the pubic symphysis may refer pain to the low back. Osteitis pubis is characterized by resorption of the pubic bones, followed by spontaneous reossification. In later pregnancy, there is a gradual onset of pubic symphysis pain; however, there can be rapid progression over the course of a few days to excruciating pain radiating down the medial aspect of the thighs. Walking or lower leg motion aggravates the pain. Because of pain due to weight bearing with altered gait, the muscles and ligaments become involved in the pain mechanism (15).

TABLE 64.1

Causes of Low Back Pain in Pregnancy

Cause	Examples
Mechanical	Spinal facet Spondylolisthesis Leg-length inequality Congenital disorders (e.g., scoliosis, anatomical structural variants) Increased weight Multifetal gestation Trauma Discogenic Spinal curves Ligamentous laxity Somatic dysfunction
Nonmechanical— Viscerogenic	Urinary tract changes Bowel function changes Endometriosis Pelvic infection Labor
Nonmechanical—Vascular	Compression of great vessels Venous plexopathy Thrombosis Placental location
Metabolic	Osteoporosis Osteonecrosis
Psychoemotional	Seeking disability Depression

Neuropathies of Pregnancy

Peripheral nerves are susceptible to injury in the pregnant woman by compression, traction, and ischemia. Soft tissue edema is common during pregnancy, and also contributes to the weight-bearing factor on biomechanics of prolonged standing or sitting. Additionally, the uterus puts pressure on neighboring pelvic organs, ligaments, lumbosacral plexus, and lower limb peripheral nerves. Compression neuropathy is most common in anatomic locations where excessive pressure can occur. An example is meralgia paresthetica, or compression of the lateral femoral cutaneous nerve. The lateral femoral cutaneous nerve is a sensory nerve supplying sensation to the waist band area and down into the anterolateral thigh. It arises at the level of the third lumbar vertebra and travels toward the pelvis to pass slightly medial and inferior to the anterior superior iliac spine; then exiting the pelvis beneath the inguinal ligament. Injury to this nerve can result in burning, pain, or numbness along the course of innervation, causing what is known as meralgia paresthetica syndrome (16). Pregnancy along, with obesity, diabetes mellitus, trauma, belt pressure, and anatomic variations are risk factors for this syndrome (17). An anatomical variation is bisection of the inguinal ligament by the lateral femoral cutaneous nerve. Augmented lumbar lordosis of pregnancy may also contribute compressive forces on this nerve. Cesarean delivery may also lead to meralgia paresthetica from a wide incision, stretching of

tissues around the incision, or surgical retractor equipment; although the prevalence does not substantially vary with method of delivery (18,19). In subsequent pregnancies, nerve irritation may recur with physiologic and postural changes.

Lumbosacral Plexopathies

Lumbosacral plexopathies may result from prolonged standing, sitting, or squatting. Proximal or distal lower limb weakness can occur. Plexus-associated foot drop can be the result of compression of the peroneal division of the sciatic nerve in the pelvis. The common peroneal nerve can also become compressed at the fibular head (20).

Unlike the above anatomical changes discussed as predisposing factors for low back pain, true lumbar disc herniation is rare. LaBan has written extensively about this problem and reported that about 1 in 10,000 cases of lumbosacral pain in pregnancy are herniated lumbar discs (21–23). Previous sciatica may become aggravated in subsequent pregnancy. Surgery for low back pain is generally contraindicated unless a herniated disk fails to respond to conservative treatment or produces bowel or bladder incontinence. Most patients will respond to conservative treatment until the baby is born. At times, cesarean section delivery may be offered to avoid increased pressure on the nerve root during delivery.

There are additional sites and causes of nerve compression; however, many occur in the labor and delivery process. Therefore, they will not be discussed in this chapter.

Spondylolisthesis

Spondylolisthesis is a condition where one vertebral body (usually in the lumbar spine) appears anteriorly displaced to the one just below. This most commonly occurs from L5 slipped forward from S1. This may be secondary to a defect in the pars interarticularis (24). Degenerative spondylolisthesis is most common at the L4-5 level. This condition is more prevalent in females than males in general. It has not been determined why this condition most commonly occurs at L4-5 level. Sanderson and Fraser (25) reported that women who had children had a significantly higher incidence of spondylolisthesis at this level than nulliparous women. In women with previous spondylosis, it has been thought that this slip may progress; however, there may be no increase in back symptoms or an increase in segmental slip in subsequently pregnant patients.

There are additional sites and causes of nerve compression; however, many occur in the labor and delivery process. Therefore, they will not be discussed in this chapter.

Hip Pain of Pregnancy

Pregnancy-related hip pain can present with progressive symptoms and lead to disability. Conditions of the low back and pelvic girdle can present with pain in the hip. Likewise, intra-articular hip pathology can refer pain to the back and pelvis, and can be misdiagnosed as pelvic instability. With the pelvis and lower spine maintained in a stable position, to differentiate intra-articular hip pathology from referred pain, hip range of motion must be assessed to rule out referred pain (14). Antalgic gait in a pregnant woman should raise the question of the possibility of transient osteoporosis of the hip or osteonecrosis of the femoral head.

A rare condition, usually occurring with weight bearing in the third trimester of pregnancy, is transient osteoporosis of the hip (26,27). Etiology of this condition is unknown. It is characterized by pain and limitation of hip motion. The pain may be of sudden or insidious onset. Weightbearing exaggerates the pain, causing the patient to require a wheelchair or bed rest. This diagnosis is

made by x-ray, MRI, or pelvic sonogram, not by palpatory physical exam (28). X-ray, with appropriate shielding, is helpful to establish that the osteoporosis is associated with the current pregnancy and not related to osteoporosis antecedent to the pregnancy. Failure to diagnose this condition can result in fracture (29). Surgical intervention then becomes necessary.

Avascular necrosis of the femoral head has been reported in pregnant women without any previous or additional risk factors (30). Proposed theories of pathogenesis include higher adrenocorticoid metabolism combined with weight gain as well as elevated levels of estrogen and progesterone in conjunction with increased joint pressure and strain (31). Symptoms typically occur in the third trimester, with increased weightbearing in the hip, pelvis, or groin. Symptoms of osteonecrosis usually begin in the third trimester with pain deep in the groin. Pain radiates to the knee, thigh, or back. Pain with range-of-motion testing of the hip may differentiate this from pain felt in the pubic symphysis or sacroiliac joint. Treatment consists of decreased weightbearing by using a walker or crutches to allow revascularization of the femoral head (32).

Vascular Causes of Low Back Pain in Pregnancy

Abnormalities or changes of the lumbar epidural venous plexus may give rise to symptoms mimicking nerve root compression. Gormus, Paksoy, et al. (33,34), noted that epidural veins were enlarged in patients with inferior vena caval thrombosis or obstruction just below the renal vein orifices in pregnant women. They presented with radicular syndromes or back pain. Vascular studies confirmed deep vein thrombosis. Pain resolved with medical treatment or delivery.

Posterior location of the placenta has been noted on pelvic obstetrical sonography in nonlaboring women who have complained of low back pain during pregnancy. Musculoskeletal exam usually is unremarkable. Fetal activity does not influence the pain. Possible explanation for this pain may be that pain insidiously occurs as the enlarging uterus strains the vascular bed to which the placenta is attached (35). If the patient has sustained some kind of physical trauma, such as a fall or motor vehicle accident, she may experience low back pain in conjunction with uterine activity that may be associated with placental abruption (36). Vaginal bleeding may also occur. She and her fetus should be evaluated as soon as possible to prepare her for an emergent operative delivery, which will resolve the back pain.

Organic Causes of Back Pain in Pregnancy

In women with upper urinary tract infections, pyelonephritis may present as lumbar pain in pregnancy (37). The pain may be dull and persistent. Fever or chills may also accompany the pain. Urinalysis indicates the possibility of infection; urine culture identifies the offending organism (usually *Escherichia coli*). If the back pain is colicky in nature, and there is tenderness of the costovertebral angle on palpation, nephrolithiasis may be present. Urinary tract infection may or may not accompany the process of attempting to pass the stone (38). Most stones are calcium oxalate (39). Ninety percent of gravidas with nephrolithiasis present with back pain. The possibility of preterm labor must also be considered as complication of infection, or result of irritation of the sympathetic nervous system on uterine activity.

Other obstetrical conditions can present as low back pain. Ectopic pregnancy (in the first trimester) with bleeding or impending rupture causes peritoneal irritation as blood may collect in the cul de sac. Threatened or impending spontaneous abortion may manifest as back pain if the uterus is retroverted. Ovarian cyst or concomitant pelvic infection may cause back pain due to pressure

within the pelvic cavity, stretching of previously formed adhesions, or collection of fluid in the cul de sac. A posterior uterine fibroid may put pressure on the pelvis and hypogastric plexus as the pregnant uterus is growing out of the pelvis and into the abdomen. Some patients experience low back pain as a sign of labor. As labor progresses, pain may become more intense as the fetal head enters the pelvic outlet, or if the maternal pelvis is trying to accommodate a fetal presenting part that is putting excessive pressure on maternal pelvis and soft tissues during the labor or delivery process.

Evaluation and Treatment Plans

The pregnant patient who develops low back pain will usually also describe low anterior or posterior pelvic pain. Pain can be aggravated by activity and most often relieved by lying down, sitting, or using a supportive device. Occasionally, the pain may radiate down to one or both buttocks and into the posterior thighs to the knees. Sciatica has pain distribution all the way down the posterior leg to the heel, along the distribution of the nerve root. Meralgia paresthetica, likewise, causes burning and numbness along the course of the lateral femoral cutaneous nerve. She does not correlate this type of pain with fetal activity (1,3,9).

Further questioning may reveal what factors improve or aggravate pain. These factors may be physical or psychological, and affect the patient's ability to perform her usual activities of daily living. Inquiries about stress, or changes in sleep, diet, or working conditions may provide opportunities to explore what remedies, if any, the patient may have tried in her pursuit to obtain relief.

The physical examination of the pregnant woman should begin with an obstetrical evaluation to evaluate maternal and fetal health. Regarding maternal well-being, the physician should ascertain whether complaints of low back pain are related to urinary dysfunction, colon dysfunction, or "early warning" signs of uterine dysfunction that may precipitate labor.

The neuromusculoskeletal examination should include observation, palpation, range of motion, muscle imbalances, leg-length inequality, deep tendon reflexes, posture, station, gait, and degree of lumbar lordosis. There may be spasms of the paraspinal muscles. Tenderness may be elicited over the sacroiliac joints. Sacroiliac compression tests, bimanual compression over the iliac crests; FABER and Patrick tests all may elicit sacroiliac pain. The hip joint and pubic symphysis should also be evaluated. Segmental motion of the lumbar spine should be noted. Lumbosacral mechanics can be evaluated according to the various motion tests discussed elsewhere in this book, regarding diagnosis of somatic dysfunction of this area of the spine. It would be interesting to note whether osteopathic physicians diagnosed a greater frequency of sacral torsion or unilateral sacral flexion (shear) somatic dysfunction in pregnant patients.

Osteopathic Patient Management

Biomechanical Model

As previously described, biomechanical instability is the most prevalent cause of back pain in pregnant women. Our patient had an anterior pelvic tilt, unlevelled sacral base, dysfunction at the sacroiliac and lumbosacral areas, hypertonic psoas muscles, and signs of somatic dysfunction in the paralumbar tissues. Any and all of these findings could be causing or contributing to her chief complaint. While many of these areas of somatic dysfunction probably represent postural adaptations to pregnancy, the resulting biomechanical changes will stress and potentially strain the involved joints and myofascial structures. This produces tissue irritation, inflammation, and pain that may present as back or pelvic pain (62).

Respiratory/Circulatory Model

The gravid uterus tends to put pressure on neighboring organs in the abdomen and pelvis, altering function. Decreased fluid intake, in conjunction with altered, usually slowed, bowel function may lead to constipation. Back pain can occur as result of colonic distention and pressure, or from straining efforts of the patient to empty the bowels. Our patient has somatic dysfunction involving the sacrum and pelvis, which affect the pelvic diaphragm. Within the respiratory/circulatory model of structure function, the pelvic diaphragm is thought to play an important role in venous and lymphatic drainage from the pelvic organs including the gravid uterus. In this patient, we would be concerned that her pelvic and sacral dysfunction may contribute to venous stasis and congestion in the pelvic tissues and uterus. Distension of the uterine veins and pelvic tissues has been shown to produce pelvic and back pain (59–61).

Neurological Model

Several studies have described an association between a history of trauma or previous pain presentation and the occurrence of low back pain during pregnancy (5,6,43,44). In one study, women with pelvic girdle pain revealed a history of previous low back pain or trauma of the back or pelvis. Women who complained of double-sided sacroiliac pain had previous low back pain or trauma to the back and pelvis. Most of the women who reported low back pain also had history of hypermobility before and during pregnancy. These findings suggest the presence of sensitization or low-level spinal facilitation that may predispose a patient to developing pain as the pregnancy progresses. Our patient has a history of endometriosis, a painful pelvic condition that may have sensitized neurons in the lower lumbar cord.

Low back pain as a predictor of depression in pregnancy has also been studied. Gutke investigated the possible association of lumbopelvic pain, pelvic girdle pain, and postpartum depression (40). Pregnant women were given a musculoskeletal exam of the lumbar spine and pelvis, completed a pain drawing, and were evaluated according to the Edinburgh Postnatal Depression Scale. Postpartum depressive symptoms were three times more prevalent in women having lumbopelvic pain than those without. Field attempted to correlate low back pain with mood states and biochemistry in pregnancy. Relationships were noted between back pain and urinary cortisol and epinephrine. Pain and increased levels of cortisol and epinephrine measured in second and third trimester pregnancy were present in women who were angry or depressed (41). In a study of 412 primigravidas, patients recorded low back pain or pelvic girdle pain early in pregnancy and again at 36 weeks' gestation. They were followed at 3 months and again at 1 year after delivery. Those reporting pelvic girdle pain in pregnancy were less mobile and often required ambulatory assistance. They also required treatment for depression. No association was found between obstetric factors and pelvic girdle pain (42). The association between pain and depression is a chicken and egg conundrum. On one hand, pain has been shown to alter the hypothalamic-pituitary-adrenal axis resulting in increased cortisol and symptoms of depression. Alternatively, clinical depression is associated with lowered tolerance for nociception, a heightened perception of pain, and increased risk for developing chronic pain.

Metabolic-Energy Model

There is great physiologic stress associated with pregnancy, and while the female body has developed to meet these demands, they extract a cost. The overall metabolic energy needed for daily activities increases significantly during pregnancy. Nutritional intake is being used for both mother and child. The metabolic building

blocks for strong bones, brain, and muscles come from maternal food intake and maternal stores. Pregnant women should be counseled in dietary and nutritional matters to best meet their own metabolic needs and those of their growing child. Normal physical demands and activities may be more difficult and fatiguing for the pregnant woman. Many pregnant women complain of increased fatigue during the latter stages of pregnancy and physicians need to make appropriate recommendations regarding workload, sleep requirements, and other activities.

Behavioral Model

Osteopathy also encompasses the behavioral approach to patient care. History, reviewed from perspective of the interrelationship of structure and function, also aids in development of a treatment plan. Wang et al. (1) reported that 95% of 640 patients informed their prenatal care providers about loss of sleep and inability to perform routine activities because of low back pain. However, 25% of the care providers recommended adjunctive care for biomechanical problems. Other investigators linked patient complaints with physical examination and devised a classification of back in pregnancy (6,43,44). In addition to a history of previous pain patterns, the aforementioned studies also reported an association between various biopsychosocial factors and back pain in pregnancy. In one study, women with pelvic girdle syndrome were more likely to report multiparity higher weight, higher level of self-reported stress, and lower job satisfaction. They also had higher postpregnancy weight and body mass index. Women with pubic pain, or symphysiolysis, were more likely to be multiparous, overweight, and smokers. Women with one-sided sacroiliac pain had a prior negative obstetrical delivery experience. This group also had vocational training or professional education that contributed to stress levels. Women who complained of double-sided sacroiliac pain were also multiparous, and had poorer spousal relationships and less job satisfaction than the previously mentioned groups. In all four groups, there was no correlation with menarche or use of oral contraceptives (estrogen).

Osteopathic Manipulative Treatment

A variety of osteopathic manipulative treatment approaches to low back pain in pregnant patients can address the many factors that cause pain. Muscle energy techniques focus on addressing muscle imbalances. High-velocity low-amplitude approaches have been utilized to relieve joint restrictions. Although there is only a single case report published concerning complications of direct manipulation in the pregnant patient (63), osteopathic practitioners have expressed their reasons for avoiding certain kinds of techniques in pregnant women. Some prefer to treat soft tissues and balance ligaments because they are mildly edematous from hormonal influences, have increased laxity; both influences that tend to contribute to the pain of neurovascular entrapment. Others prefer to relieve joint restrictions with more direct approaches other than thrust by incorporating patient's weight or posture to mobilize skeletal dysfunctions. Pregnant patients present interesting challenges to those who perform osteopathic treatment while positioning the patient comfortably without compromising her fetus. An enlarged uterus may preclude the patient from being treated in a prone position or lying supine for a prolonged period of time. Technique selection often depends upon the patient's ability to lie or sit comfortably for a period of time while being treated.

It is important to establish the etiology of low back pain in order to develop and execute a treatment plan that may consist of medication or manipulation or both. Box 64.1 lists contraindications

Contraindications to Osteopathic Manipulative Treatment of Low Back Pain in Pregnancy

- Undiagnosed vaginal bleeding
- Ectopic pregnancy
- Placental abruption
- Untreated deep vein thrombosis
- Elevated maternal blood pressure
- Preterm labor
- Unstable maternal vital signs
- Fetal distress

to manipulative treatment in pregnant patients. From an obstetrical perspective, manipulative treatment should not be performed on pregnant patients with low back pain who have undiagnosed vaginal bleeding, ectopic pregnancy, placental abruption, uncontrolled elevated blood pressure, untreated deep vein thrombosis, unstable vital signs after sustaining physical trauma, preterm labor. These conditions may require aggressive medical or surgical treatment. Maternal health and fetal health are assessed before somatic dysfunction is to be addressed.

Additional Treatment Considerations

Currently, there are no studies to determine whether low back pain can be prevented in pregnancy. Risk factors have been previously discussed. Exercise and weight control before pregnancy have been recommended, but they do not prevent or determine who will have low back pain in pregnancy. Some investigators report that prenatal care providers are aware of back pain, but do not consistently offer treatment or have specific recommendations for relief, other than rest (1). This may be due to the fact that some back pain is expected to occur during the course of pregnancy and that it almost always resolves in the postpartum period. Most commonly, activity modification with periods of rest with feet elevation is advised. Elevated feet with flexed hips reduce lumbar lordosis and ease muscle spasm in acute pain. An exercise program, following a period of rest, may increase muscle strength and abdominal tone to reduce low back pain symptoms. There are a variety of published American and Canadian guidelines pertaining to exercising before and after pregnancy (45–48). Both the American and the Canadian guidelines caution against activities with high risk of falling or abdominal trauma. The guidelines also include specific warning signs to discontinue exercising, such as incompetent cervix, vaginal bleeding, history of preterm labor, or extreme shortness of breath. Exercise in normal temperature pool water has been shown to reduce back pain in pregnant women due to buoyancy unloading joint pressure (2). However, immersion in a warm whirlpool or hot tub can produce maternal hyperthermia. Elevated maternal body temperature can cause deleterious fetal effects in the first trimester of pregnancy, the time of fetal neural tube closure and organogenesis.

Orthoses may be able to temporarily relieve back pain. A trochanteric belt, if comfortable for the patient with lumbar lordosis, may reduce anterior pelvic tilt while stretching psoas muscles (2). A belt that supports the sacroiliac joints may reduce pelvic joint laxity (49). A pilot study evaluating the use of maternity back supports found a reduction in pain scores in a small population (50). In addition to osteopathic treatment to reduce sacral base unleveling, a heel lift may help maintain lumbosacral stability or reduce lumbar lordosis (51). Acetaminophen can be added for pain relief since antiprostaglandins such as aspirin and NSAIDs are

relatively contraindicated in pregnancy. Narcotics are not indicated as first-line pharmacotherapy.

Physical therapy modalities may be limited or contraindicated when the energy produced by the modality may adversely affect the developing fetus. In a recent review by Batavia (52), pregnancy has been cited as a contraindication to therapeutic ultrasound and superficial heat. Heat may produce maternal hyperthermia; therefore, precaution should be taken with application of hot packs to the low back and abdomen. Diathermy is also contraindicated due to the effect of deep heat and exposure to electromagnetic fields (53).

There are no recent data available in the medical literature regarding the use of lumbar traction during pregnancy. However, lumbar traction belts may cause excessive pressure on the abdomen and aggravate pelvic ligament laxity (54).

Because electrical current effects on the fetus are not yet fully understood, electrical stimulation should not be applied to the low back, abdomen, or pelvis. On the other hand, the electrical current of transcutaneous nerve stimulation (TNS) has been used safely during pregnancy, labor, and delivery for pain control. In a meta-analysis of six randomized placebo controlled trials, TNS provided some relief of back pain (55).

Acupuncture for pain relief has been studied in the last trimester of pregnancy. No maternal or fetal adverse effects have been reported in three studies (56–58). In all three studies, women receiving acupuncture completed either questionnaires or visual analog scales to report decrease in pain at rest, increased energy, and positive emotions to complete activities of daily living. The study by Guerreiro (57) indicated that those who received acupuncture also utilized less acetaminophen for pain

CASE VIGNETTE (CONTINUED)

Barbara's low back pain is a result of normal biomechanical changes of pregnancy: increased lumbar lordosis, weight gain, and ligamentous laxity due to hormonal influence. Bending and lifting aggravate the pain, as well as uterine pressure on scar tissue from endometriosis and previous surgery. Rest, exercise, and osteopathic treatment to stabilize musculoskeletal imbalance, joint laxity, and postural changes would be helpful to relieve pain during pregnancy. Hydrotherapy, acupuncture, possibly orthotics, and acetaminophen may provide additional relief before delivery. Barbara would also appreciate family and social support as she prepares to welcome a new baby into the family.

KEY CONCEPTS

- The differential diagnosis of myalgia can be extensive, encompassing common, easily diagnosed, and less well recognized clinical conditions.
- The chief complaint in fibromyalgia is a condition encompassing chronic, relapsing, diffuse aching pain, and tenderness, which can be intermittent and nondermatomal.
- Other features of fibromyalgia include hyperesthesia, allodynia, severe fatigue, insomnia, depression, anxiety, cognitive difficulty (specifically, issues with motivation, concentration, and organization), exercise intolerance, and nonrestorative sleep.
- Approximately 2% of United States and Canadian citizens have fibromyalgia.
- Current theories include atypical sensory processing in the central nervous system (i.e., central sensitization), dysfunction of skeletal muscle nociception, and dysfunction of the hypothalamic-pituitary-adrenal axis.
- Treatment for fibromyalgia should include OMT, patient education, and aerobic exercise.

CASE VIGNETTE

A 31-year-old woman reports muscle pain “all over my body” with the most intense pain in the neck, back, shoulders, and thighs. The pain started 2 years ago in her low back after a minor car accident. The back pain at that time was mild and plain x-rays were negative. Since then, the pain has gradually spread to her entire body and has become a constant ache that waxes and wanes in intensity. Over-the-counter medications such as ibuprofen and acetaminophen have been somewhat helpful but only on a temporary basis. She has not used narcotics since they made her nauseated when she took them after a previous surgery.

She describes her pain as a 6/10 currently but that it can range from 4 to 8 on a scale of 1 to 10. About a year ago, she completed 6 weeks of physical therapy that she feels was beneficial, but she did not keep up with her prescribed home exercises due to excessive pain. She reports no known tick or other insect exposure or bite. Her biggest complaint is that she can no longer work due to the pain and that she is having a hard time caring for her two small children. She feels like “a prisoner to her pain.” Six months after the car accident, she began experiencing new fatigue, insomnia, and abdominal bloating; she denies abdominal pain, diarrhea, or constipation. Her fatigue is now most pronounced after increased or sustained activity. She can feel exhausted after simple events such as going to the mall or cleaning the house. At night, she falls asleep easily but awakens two to three times per night and finds it difficult to fall back asleep.

Past Medical History:

Her past medical history is significant only for seasonal allergies.

Past Surgical History:

Positive for uncomplicated Cesarean sections x 2

Medications:

She is currently taking loratadine 10 mg as need for her allergies and a daily multivitamin.

Allergies:

She has no known drug allergies.

Social History:

She does not smoke or use illicit drugs. She drinks one glass of wine daily. She reports that she is happily married for 6 years.

REVIEW OF SYSTEMS

She reports no fevers or recent weight loss.

HEENT:

Her vision and hearing are normal.

Cardiovascular:

She has no chest pain, palpitations, or shortness of breath.

Lungs:

She denies shortness of breath, wheezing, and cough.

Gastrointestinal:

She denies stomach pain, nausea, vomiting, diarrhea, and change in stools. She admits to bloating.

Skin:

She has no skin rash.

Musculoskeletal:

She denies joint swelling and joint pain although she admits to muscle pain as described above.

Neurological:

She denies paresthesias, weakness, loss of consciousness, tics, twitches, and seizures.

Psychiatric:

She complains of difficulty with concentration, organization of tasks, motivation, and a shortened attention span. She has progressively had more depression as a result of her condition and reports feeling hopeless at times.

Endocrine:

She denies chills, fever, and weight change. She admits to fatigue and sleeping difficulties as previously described.

PHYSICAL EXAMINATION**Vital Signs:**

In the office, her heart rate is 68 beats per minute, respiratory rate is 16 beats per minute, blood pressure is 112/70, and she is afebrile.

General:

She appears in no acute distress.

Eyes:

Extraocular muscles are intact and pupils are equally round and reactive to light.

ENT:

Her oral mucosa is moist. Her neck is supple with no lymphadenopathy or thyromegaly.

Cardiovascular:

Her heart has a regular rate and rhythm without murmurs and the lungs are bilaterally clear to auscultation.

Lungs:

Breath sounds are full and clear to auscultation.

Abdomen:

The abdomen is soft and nontender.

Skin:

She has no rash.

Neurological:

Reflexes are +2 and equal in both the upper and lower extremities. Sensation is intact to light touch and pin prick. Muscle strength is 5/5 globally.

Musculoskeletal/Structural:

She has no muscle atrophy or spinous process tenderness. There are no joint effusions or tenderness. No synovitis is palpable. Multiple tender points are present in the anterior neck at the C5–7 intertransverse spaces, at the insertions of the suboccipital muscles, in the upper midtrapezius bilaterally, in the supraspinatus above the medial scapular spine, just distal to the lateral epicondyles, at the upper outer quadrant of the buttocks, and posterior to the greater trochanter prominences. The cervical, thoracic, and lumbar paraspinal muscles are tender and hypertonic. The occipital-atlantal junction is extended sidebent right and rotated left. There is a sphenobasilar synchondrosis compression, the atlantal-axial junction is rotated right, the thoracolumbar junction is sidebent left and rotated right and the lumbosacral junction is sidebent right and rotated left, the right innominate is rotated posteriorly, and there is bilateral sacroiliac restriction. Both shoulders are protracted.

DIFFERENTIAL DIAGNOSIS

Diffuse myalgia associated with fatigue is a common complaint in the primary care setting. The differential diagnosis of myalgia can be extensive, encompassing common easily diagnosed and less well recognized clinical conditions, some of which can present with similar

manifestations and can coexist with fibromyalgia. Careful history taking and methodical physical examination assist in narrowing down the possibilities. The differential (Table 65.1) includes most commonly, bursitis, tendonitis or synovitis, hypothyroidism. Somewhat less common but deserving of consideration are infectious conditions such as Lyme disease and hepatitis C and inflammatory conditions such as polymyalgia rheumatica, polymyositis, dermatomyositis, rheumatoid arthritis, systemic lupus erythematosus, and scleroderma.

Degenerative/structural problems such as cervical stenosis may present as myalgias, but the patient will also typically have neck pain associated with dysesthesia, numbness, and, if involving the central canal, myelopathic symptoms of extremity spasm, bowel and bladder dysfunction, unsteady gait, lower limb weakness and numbness, abnormal reflexes, muscle atrophy, and decreased muscle tone. Certain metabolic processes can be associated with myalgias, the most common being thyroid disease and vitamin B₁₂ deficiency and, rarely, as well as toxicities or side effects of some lipid-lowering agents, and antiviral medications. Frequent concomitant conditions that need to be considered are depression, chronic fatigue, fibromyalgia, and myofascial pain.

The presence of fatigue, insomnia, or other constitutional symptoms in a patient with diffuse myalgia tends to focus the differential on systemic or chronic conditions. Often, lab work (such as complete blood count [CBC], liver and kidney functions, creatinine phosphokinase [CPK], erythrocyte sedimentation rate [ESR], C-reactive protein [CRP], and thyroid functions) may be needed to rule out diffuse or systemic pathology.

In this case, the patient's pain and constitutional symptoms seem to be temporally related to a motor vehicle accident suggesting myofascial pain as a result of trauma rather than a systemic condition. However, some inflammatory diseases such as rheumatoid arthritis and systemic lupus erythematosus can initially present in similar fashion with myalgia as the initial complaint followed by fatigue and other systemic signs. Consequently, a careful review of all systems and laboratory studies is necessary to determine the diagnosis. Also, myofascial disease can coexist with other disorders of defined structural pathology, such as rheumatoid arthritis, fibromyalgia, and chronic fatigue syndrome, which are considered diagnoses of exclusion, necessitating that other causes of diffuse muscle pain be first ruled out.

Workup and Interpretation

This patient's chronic and diffuse clinical temporal profile helps to rule out most infectious processes; however, an elevated white blood cell count could indicate chronic infection or an inflammatory disease. Elevated CRP and/or an ESR are also indicators of inflammation. If either is elevated, further studies would be necessary to identify the etiology of the inflammation. Elevated CPK levels suggest an inflammation of muscle. Liver and renal function tests can be elevated in hepatitis C, myositis, lupus, rheumatoid arthritis, and other autoimmune diseases. Thyroid disease can present with muscle pain or weakness, depression, fatigue, and insomnia; a thyroid-stimulating hormone (TSH) level is usually sufficient to rule out this as a cause.

Other tests that could be considered in the workup of diffuse myalgia include vitamin B₁₂ level, hepatitis C screen, and a Lyme titer. Vitamin B₁₂ deficiency would be high on the differential if the patient had undergone small bowel resection, was malnourished, had a history of excessive alcohol intake, or followed a diet low in B vitamins. Generally, this information can be obtained from the history and, unless there is suspicion, lab testing is not necessary. In the same way, a hepatitis C screen should be performed if hepatitis C is suspected or there is a history of blood transfusion, multiple sexual contacts, intravenous drug use, or a prior accidental needle stick. Screening for

TABLE 65.1

Differential Diagnosis of Myalgias**Mechanical/Degenerative Conditions**

Bursitis	Involves Only One Joint or Limb
Tendonitis or synovitis	Usually has a single focus and is associated with tendon motion
Cervical stenosis	Neck pain associated with dysesthesia, numbness, and, if involving the central canal, myelopathic symptoms of extremity spasm, bowel and bladder dysfunction, unsteady gait, lower limb weakness and numbness, abnormal reflexes, muscle atrophy, and decreased muscle tone

Infectious Conditions

Lyme disease	A characteristic erythema migrans, usually only one to two joints are involved, one of which is often the knee and associated neuropathy and nephropathy and frequent facial nerve involvement
Hepatitis C	Need characteristic lab findings

Inflammatory Conditions

Polymyalgia rheumatica	Features symmetric, proximal weakness, normal CPK, neuropathic pain, and hyperesthesia
Polymyositis and dermatomyositis	Present with severe, symmetric proximal weakness, and high CPK
Rheumatoid arthritis:	Morning stiffness that may last for several hours, joint swelling and pain, symmetric polyarthritis, joint warmth and effusion, multiple elevated serum immune complexes, and complement consumption
Systemic lupus erythematosus	Characteristic malar or discoid rash, vasculitis, lymphadenopathy, thrombocytopenia, and nephritis associated dark urine and peripheral edema along with elevated ANA
Scleroderma	Features skin and multiorgan fibrosis

Metabolic Processes

Hypothyroidism	Can be assessed via a TSH level
Thyroid disease	Can be assessed with imaging
Vitamin B ₁₂ deficiency	A simple blood test can measure B ₁₂
Toxicities or side effects of some lipid-lowering agents	This is a diagnosis based upon clinical presentation and exclusion of other etiologies
Toxicities or side effects antiviral medications	This is a diagnosis based upon clinical presentation and exclusion of other etiologies

Lyme disease should be performed if the patient has a history of tick bite, a characteristic rash, or reported migratory joint pains. There was no objective muscle weakness found in this patient; however, if weakness of unknown etiology were present after initial workup or if there were concern for possible radiculopathy, myopathy, or nerve entrapment, an electrodiagnostic study should be performed. If any of these tests are abnormal, then a muscle biopsy or further testing for immunologic or other systemic disorders may be warranted.

CASE VIGNETTE (CONTINUED)

Labs performed during the initial visit with this patient included a CBC, renal and liver functions, CRP, ESR, CPK, and TSH levels. The initial lab work was negative. This patient was diagnosed with fibromyalgia. The history and physical exam, in conjunction with lab results, indicate her pain is likely myofascial in origin.

Diagnosis

The three most common causes for myofascial pain are myofascial pain syndrome, chronic fatigue syndrome, and fibromyalgia. Fibromyalgia is differentiated from myofascial pain syndrome in that it usually has multiple tender points in predictable bilateral locations, chronic widespread pain, a 10:1 ratio prevalence in females, fatigue, and sleep disturbance while myofascial pain syndrome has trigger points, more regionalized pain, a 1:1 ratio of males and females, and rarely has systemic features.

Fibromyalgia may be distinguished from chronic fatigue syndrome by virtue of the fact that chronic fatigue syndrome is usually preceded by a viral illness, which is not the case with fibromyalgia. Fatigue, a characteristic of both diseases, is usually of more than 6 months' duration but is, in chronic fatigue syndrome, also associated with at least 4 of the following: decreased memory or concentration, sore throat, tender cervical or axillary nodes, multijoint pain, new headache, postexertion malaise, nonrestorative sleep, and

muscle pain. Fibromyalgia is a chronic syndrome, predominantly in women, that is marked by generalized chronic pain, multiple well-defined tender points, fatigue, and sleep disturbance.

The chief complaint in fibromyalgia is a condition encompassing chronic, relapsing, diffuse aching pain, not just tenderness, that can be intermittent and nondermatomal. Patients may complain of hyperesthesia and allodynia. The pain presents, often bilaterally, in muscles and muscle tendon junctions especially in the neck, shoulders, second ribs, elbows, hips, buttocks, and knees. Other features of fibromyalgia include severe fatigue, insomnia, depression, anxiety, cognitive difficulty (specifically, issues with motivation, concentration, and organization), exercise intolerance and nonrestorative sleep. Fibromyalgia patients may have concomitant migraine headaches, temporomandibular joint disorder, urinary frequency, paresthesias in the hands and feet, or irritable bowel syndrome.

Approximately 2% of United States and Canadian citizens have fibromyalgia. On a typical day, a primary care physician may see several patients with this diagnosis. The etiology of fibromyalgia is unknown. To date, no pathology has been found in the muscles of fibromyalgia patients. Current theories include atypical sensory processing in the central nervous system (i.e., central sensitization) and dysfunction of skeletal muscle nociception and the hypothalamic-pituitary-adrenal axis. Psychosocial factors seem to play a large role in the development of the disease; in fact, disability is most common in persons with jobs involving physical labor, who have poor coping strategies, who feel helpless, and who are involved in litigation (Winfield, 2006).

Osteopathic Patient Management Biomechanical Model

This patient has a large number of somatic dysfunctions that likely contribute to biomechanical stress and increased nociception. Since 2 years have passed after the proposed inciting insult, treating the original somatic dysfunction in the low back will likely not be sufficient due to local and central sensitization. It is important to treat all areas of somatic dysfunction initially in this patient, concentrating on the areas of greatest functional compromise. Decreasing biomechanical stress is key in avoiding continued local and central sensitization. Aerobic exercise should focus on stretching and strengthening the musculature and combating deconditioning. Core strengthening is beneficial in treating deconditioned abdominal and paraspinal muscles that are either weak or inordinately tight.

Respiratory/Circulatory Model

Somatic dysfunction can alter the musculoskeletal system's contribution to tissue perfusion. The venous and lymphatic systems are low-pressure circulatory systems dependent upon external forces for proper function. Pain may result in muscle splinting and altered movement mechanics in the thoracic tissues and respiratory muscles. Altered tissue tone and restrictions can directly impede tissue perfusion. Resolution of somatic dysfunction may improve circulation to injured or damaged muscles and nerves.

Neurological Model

Recent clinical investigations have suggested that fibromyalgia is a central sensitivity syndrome and that it has a neurophysiologic base. Many researchers now feel that risk factors for developing fibromyalgia include vulnerability issues (such as being female, low self-efficacy, history of adverse experiences) occurring while the brain was developing and persistent stress or distress, in terms of anxiety, poor coping skills, and personality disorders, all of which

may negatively impact long-term prognosis. It is felt that patients with fibromyalgia have a generalized decreased pain perception threshold, excess excitatory (nociceptive) neurotransmitters (as examples, substance P and glutamate, which concentrate in the insula of the brain), low levels of inhibitory neurotransmitters (such as serotonin and norepinephrine), enhanced temporal summation of pain, altered endogenous opioid analgesic activity, and dopamine dysregulation. (Winfield, JB. "Fibromyalgia" eMedicine, 2009)

In treating fibromyalgia, it is important to remember that this is not a localized condition. Treating myofascial trigger points may help in the short term but have not been shown to be effective in long-term treatment of fibromyalgia. An osteopathic treatment approach should address the whole patient. Empathetic listening and acknowledgment of the legitimacy of the patient's pain, assessing possible perpetuating or concomitant factors, relaxation training, activity pacing, and exercise are useful initial strategies that can be supplemented with other approaches as needed. In this patient, pain started locally in the back and then spread. If the original injury to the back does not resolve, it may continue to send acute nociceptive signals to the spinal cord, which in turn sends signals to the brain. Chronically sustained insults to a nerve can lead to local sensitization and phenomena known as "facilitation" and "wind-up," where short-term potentiation of pain signals occurs that is associated with repeated C-fiber stimulation (Gary, 2002). Afferent pain signals from hypersensitive spinal nerves can affect related muscles and joints. Hyperesthesia, allodynia, and pain may then result in innervated structures. Hypersensitive proprioceptors can also cause structural alterations that lead to somatic dysfunctions, such as ligamentous articular strains, muscle spasm, fascial strains, and myofascial trigger points, all of which may lead to increased or sustained pain. The central nervous system's response to prolonged painful stimulation is known as central sensitization, a long-term potentiation of pain signals associated with NMDA receptor activation and with the induction of specific genes. Chronic nerve impingement can lead to dorsal horn sensitization of its nerve roots. When central sensitization occurs, it can affect two segments above and below the innervating site. Therefore, multiple spinal levels can become painful and dysfunctional, as is seen in this patient. As a result, pain from a local injury can appear to spread to other regions of the body. Nociceptive signals from the spinal cord can be consolidated in the brain causing further sensitization in the central nervous system. In this patient, central sensitization may account for her depression, fatigue, insomnia, and cognitive impairment.

The patient was treated pharmacologically with duloxetine and later pregabalin. Duloxetine, a serotonin and norepinephrine-reuptake inhibitor and antidepressant, has shown encouraging results in fibromyalgia studies (Arnold et al., 2007). Pregabalin, an anticonvulsant, is the only FDA-approved drug for fibromyalgia. Recent studies show statistically greater improvement in pain, fatigue, sleep, and quality of life (Crofford et al., 2005). Both act on the central nervous system and are likely able to lessen fibromyalgia symptoms by modulating neurotransmitters and affecting central sensitization. The literature does not support the effectiveness of nonsteroid anti-inflammatory drugs or steroids for the disease, but they can be useful in management of coexisting inflammatory processes. Beta blockers, increased fluid intake, NMDA receptor antagonists under supervision, analgesics, anxiolytics and hypnotics, muscle relaxants, and the selective estrogen receptor modulator raloxifene are desirable, to name a few. Tricyclic antidepressants have shown benefit with pain and sleep. When using this class of medication, it should be remembered that nortryptilene has a lesser side effect profile (i.e., dry mouth, constipation, fluid retention,

weight gain, and decreased concentration). Botulinum neurotoxin, produced by the anaerobic bacterium *Clostridium botulinum*, is one of several neurotoxins with similar effects on human tissue—it has been shown to inhibit release of neurotransmitters involved in pain transmission (such as substance P and glutamate) in animal studies; it also reduces signs of pain, local edema, and appears to act only upon motor nerve endings, thereby sparing sensory nerve fibers. Botulinum toxin also secondarily appears to affect improved blood flow and to release nerve fibers under compression by abnormally contracting muscle via its presynaptic inhibition of release of acetylcholine.

Metabolic Energy Model

Finally, it is important to consider the metabolic energy model when planning long-term treatment for a patient with fibromyalgia. Diet (especially addressing potential 25-hydroxyvitamin D deficiency), graded aerobic exercise, lifestyle modifications, and decreased somatic dysfunction load are all important in decreasing or eliminating future exacerbations of fibromyalgia.

Behavioral Model

Psychological components are often prominent in fibromyalgia. Not only does the patient report depression but also the worry and anxiety about her family and work. While this may be partially emotional, somatic dysfunctions may contribute to the sensitization of the brain's emotional center, that is, the limbic system. Gold and Goodwin (1988a,b) first reported depression and other “psychological” symptoms in patients with chronic pain. Since that time, the association between depression and pain has become widespread (Robinson et al., 2009). Recent evidence suggests in patients with fibromyalgia, pain may also adversely affect overall health via its contribution to allostatic load (Martinez-Lavin and Vargas, 2009).

CASE VIGNETTE (CONTINUED)

PATIENT OUTCOME

Information about fibromyalgia was provided to the patient through patient-physician discussion and patient handouts from the American Pain Society. OMT was performed starting on the first visit. Initially, gentle techniques including myofascial release, balanced ligamentous tension, and cranial osteopathy were performed due to the patient's sensitivity even to light touch. As she progressed with treatments, other techniques were added. She was also started on an exercise program that consisted of gradually increasing aerobic workouts to reach a goal of 30 minutes of daily exercise. Most authorities agree on the value of patient education and aerobic exercise. Education should be centered on reassurance that the illness is real and that fibromyalgia is neither progressive nor life threatening.

The patient returned every 4 weeks for reevaluation and OMT. At each visit, continued aerobic exercise was encouraged and medications were titrated as needed. Counseling to improve diet and decrease stress was provided at each visit.

From the osteopathic perspective, it is important for the patient to be as healthy as possible in order to heal. This would include modifications in diet, habits, exercise, and stress. In the case of this patient, diet was not an issue but she did start a weekly meditation and yoga class. In other patients, discussion of whole foods, proper water intake, and smoking cessation may need to be addressed. For some patients, referral to a nutritionist or psychologist may be helpful.

By the fifth treatment, the patient was 75% improved. Follow-up visits were increased to every 3 months where she has been stable for 3 years. While her fibromyalgia has not completely resolved, she is now able to do work, take care of her family, and is not restricted by her disease.

SUMMARY

Using the osteopathic models of patient management, the physician can approach the patient with fibromyalgia from a whole person perspective, addressing all the various factors that may contribute to this multifaceted condition.

KEY CONCEPTS

- The osteopathic approach to patients with neck pain begins with a thorough history and physical exam, including an osteopathic palpatory exam of the neuromusculoskeletal system.
- Differential diagnosis utilizes a structure-function approach in determining whether the pain is due to local pathology, spinal somatic dysfunction of the cervical or upper thoracic region, localized manifestation of a systemic pathophysiologic process, or referred pain from intern organ disease.
- Osteopathic treatment plan includes judicious application of osteopathic manipulative treatment to alleviate somatic dysfunction and improve biomechanical, neurological, metabolic, respiratory/circulatory, and behavioral functions.
- Neck pain due to whiplash-associated disorder is a common cause of neck pain in middle-age adults and is considered to involve the whole person, not just the cervical spine.

CASE STUDY

Chief Complaint: Neck Pain

HPI:

A 45-year-old female presents to the ambulatory clinic with a complaint of acute neck pain that began after a motor vehicle accident (MVA) 3 days ago; she requests a note to stay off work. Three days ago, she was sitting in her car at a stoplight in her compact car when it was hit from behind by a pickup truck going about 35 mph. She was wearing her seat belt, hit her head against the headrest, but had no loss of consciousness; however, she did complain of neck pain after she stepped out of her car. She was looking up to the right into her rear view mirror at the time of impact. She was seen in an emergency room (ER) later that day where a cervical spine x-ray series showed no fractures or dislocations, but loss of cervical lordosis was noted. She was discharged home the same day with a soft cervical collar and given a prescription for an analgesic for pain, a narcotic for severe pain, and a muscle relaxant for muscle spasms.

She still has neck stiffness and pain, 8/10, better laying supine, worse when sitting up. It lasts throughout the day and is dulled a little by the analgesics. The neck collar gives her some relief. She has no other medical problems. Currently, she is taking the medications given to her at the ER, which provide some relief, although they make her drowsy and she has been sleeping several times throughout the day. The pain radiates to her shoulders and head. It is constant with intermittent sharp and shooting radiating pain to her shoulders and head.

PMH:

She has no major medical problems, no hospitalizations.

PSHx:

None to date.

MEDS:

Ibuprofen 800 mg tid prn pain; hydrocodone/acetaminophen 500 mg one every 4 hours prn severe pain; carsiprodol one every 6 hours prn muscle spasms.

ALL:

She has no allergies to medications.

SOC Hx:

She works as a secretary at a business office, types, files and answers phones 8 hours a day, 5 days a week. She is divorced, is sole caregiver for her elderly and frail mother, has two grown children and one grandchild. She denies smoking, drinks a glass of wine with dinner nightly, and denies illicit drug use.

REVIEW OF SYSTEMS

General:

She denies recent weight loss or gain, fevers, night sweats, or travel.

Cardiovascular:

She denies chest pain, shortness of breath, orthopnea, dyspnea on exertion.

Respiratory:

She denies history of tuberculosis, asthma, cough, phlegm, difficulty breathing.

HEENT:

She denies visual, hearing, smell, taste, or phonation problems; no drainage or infections.

GI:

She has nausea but no emesis; decreased appetite; constipation; no hematochezia, melana, or hematemesis. She has no history of abdominal pain or distention. No history of ulcers, hepatitis, gallstones, pancreatitis, or colitis.

Neurological:

She gets intermittent dizziness that resolves spontaneously; no history of seizures, stroke or weakness; she does have chronic low back pain.

OB/GYN:

She is G2P2. Her last menstrual period was 2 weeks ago, normal flow and regular. She has not been sexually active in the

past 2 years. She states that her last pap and breast exams were normal 6 months ago.

Psychiatric:

She denies fatigue, but has had nightmares since the accident. She is anxious, fearing she will not be able to continue her job or take care of her mother. However, she denies a history of anxiety or psychiatric illness or hospitalization. She denies bipolar disease, depression, or schizophrenia. She is frustrated that the narcotics and muscle relaxers make her unable to function. She would like to have another alternative to help her deal with the pain that will allow her to still carry out her responsibilities at home and at work.

Hematological:

She denies history of anemia or bleeding dyscrasias. She sustained a bruise from the seat belt across her neck, but has no history of easy bruising.

Endocrine:

She denies heat or cold intolerance; no polydipsia, polyphagia, polyuria.

MSK:

She denies skin lesions or rashes; no swollen joints, hands, or feet; constant bilateral frontal vice-like headaches and low back pain since the accident, with radiation to the left buttocks. She has a history of low back pain treated by a series of visits to chiropractors, osteopathic physicians, and physical therapists off and on for over 10 years since she fell skiing when she was 18. She was told she had scoliosis and a short left leg for which she wore a ¼ in. lift for 10 years, but stopped using it for the past 17 years. She has not had disabling back or neck pain since then, though on occasion gets a headache or low back pain that resolves with a nonsteroidal anti-inflammatory medication, some stretching exercises for the neck and low back, and a couple of days of rest from strenuous activities.

PHYSICAL EXAM

Vital signs:

Height: 5'6", weight: 150, BP: 150/88 mm Hg, R: 18 breaths/minute, P: 86 beats/minute, T: 98.6F.

General:

Although somewhat low energy and anxious in appearance, she is well nourished, well developed, and in obvious pain and discomfort in the seated position with a soft cervical collar around her neck.

Integument:

There is a mild abrasion over the left upper shoulder where the seatbelt was with slight ecchymosis. No ecchymosis in the other extremities, chest, or abdomen.

HEENT:

There are no contusions, lacerations, erythema, discharge, or swelling. Pupils are equal, round, reactive to light and accommodation, and external ocular muscles are intact (PERRLA, EOMI). There is no thyromegaly or tenderness. No lymphadenopathy.

Heart:

Has a regular rhythm without murmurs; no carotid or vertebral bruits.

Lungs:

Are clear to auscultation with equal breath sounds bilaterally.

Abdomen:

The abdomen is flat; there are bowel sounds present in all four quadrants, nondistended, tympanic, no masses, no hepatosplenomegaly or tenderness. No suprapubic tenderness.

Extremities:

No swelling, full ROM of the joints, pulses full and capillary refill less than 2 seconds in upper and lower extremities.

Neurologic exam:

Alert and oriented to person, place, and time. Gait is normal. Muscle strength is 5+/5+ in all muscles in upper and lower extremities. CN II to XII are grossly intact. Deep tendon reflexes are 2+/4+ bilaterally, symmetric in the upper and lower extremities. Babinski's test elicits bilateral downward going toes. There are no cerebellar or sensory deficits. Straight leg raise is negative bilaterally to 90 degrees. Cognitive exam (mini mental status exam) is negative. Spurling's maneuver for the cervical spine is negative for eliciting radiating pain.

Osteopathic/musculoskeletal exam:

Static tests for symmetry of anatomical landmarks: In the standing postural assessment, her head is held anterior to the gravitational line, with loss of cervical lordosis, decreased thoracic kyphosis and lumbar lordosis; the left shoulder is elevated; the left tip of scapula is superior; there is a thoracic scoliosis T5-11 convex right, apex at T8; there is a lumbar scoliosis L1-5, convex left with apex at L3; the left PSIS landmark is lower than the right; the left iliac crest is about 1 cm lower than the right; there is a short left leg approximately ¼ inch; and the left ASIS is inferior.

Motion tests reveal:

Positive standing and seated flexion tests on the left; the sacrum has decreased motion in both flexion and extension and feels compressed into L5; inherent sacral motion is diminished; L1-5 are rotated left sidebent right in neutral and the sacrum is also rotating to the left; T5-11 are neutral rotated right sidebent left; T3 is extended, rotated, and sidebent right with boggy, edematous, and tender paraspinal soft tissues at that level; T1 and T2 are extended rotated left sidebent left; there are myofascial restrictions of the thoracic inlet; the left first rib is restricted during exhalation; right ribs 3 to 6 are restricted during inhalation; left ribs 6 to 12 are restricted in exhalation; the left diaphragm is restricted during exhalation; there is decreased cervical range of motion bilaterally, especially flexion, extension, and sidebending; the occipitoatlantal (OA) articulation is extended sidebent left rotated right; the atlantoaxial (AA) articulation is rotated right; cranial motion is diminished in amplitude bilaterally with little movement palpable.

Palpation reveals:

Tender anterior cervical muscles; there are bilateral cervical spasms from C3 to C7 making it difficult to assess segmental restrictions; trigger points are present in the trapezius and pectoralis muscles bilaterally; there is a tender L5-S1 interspinous ligament; and Jones' tenderpoints are found at the left LPL5, right LC1, right AC1, and right PC2.

ASSESSMENT

1. Neck Pain ICD-9: 723.1
2. Whiplash-Associated Disorder (WAD) ICD-9: 847.1

3. Somatic Dysfunction ICD-9: cranium (739.0), cervical (739.1), thoracic (739.2), lumbar (739.3), sacrum (739.4), pelvis (739.5), lower extremity(739.6), and ribs (739.8)
4. Abrasion ICD-9: 911
5. Anxiety ICD-9: 300.4
6. Contusion ICD-9: 923.0
7. Dizziness ICD-9: 780.4
8. Muscle spasms ICD-9: 729.1
9. Nausea ICD-9: 787.02
10. Scoliosis, idiopathic ICD-9: 737.30
11. Short leg ICD-9: 755.32

DIFFERENTIAL DIAGNOSIS

Differential diagnosis utilizes a structure-function approach in determining whether the pain is due to local pathology, spinal somatic dysfunction of the cervical or upper thoracic region, localized manifestation of a systemic pathophysiologic process, or referred pain from intern organ disease. Since local neck pain generators may be located in the muscles, fascia, ligaments and joint capsules, periosteum, intervertebral discs, arteries, glands, organs, esophagus, trachea, lung and dura, all pathologic processes affecting these structures should be considered as possible causes of her pain. These include degenerative, infectious, inflammatory, neoplastic, congenital diseases, fractures, dislocations, spinal cord and peripheral nerve injuries, and vascular diseases, including arterial dissection. Differential diagnoses of acute neck pain from local pathology are listed in Table 66.1 along with characteristics and diagnostic tests used to confirm each.

In the patient above, gross fracture and dislocation are not likely, but possible, even in light of a negative initial cervical

spine x-ray series (1). The upper cervical somatic dysfunction is symptomatic and likely related to her recent accident, but she has underlying dysfunction in all body regions related to her short leg and scoliosis. Her neck pain could be an exacerbation of her already dysfunctional back and spine.

It is unlikely she has a disease process radiating pain to the neck as her history and physical do not support this theory, so a myocardial infarction, pancoast lung tumor, esophageal or tracheal tumor or inflammation, thyroiditis or tumor, pulmonary embolus, collapsed lung, pleurisy, vertebral artery dissection, carotid artery dissection, tuberculosis, cancer of the mediastinum or neck or cervical lymphadenopathy are less likely and can be removed from the differential at this time; however, if her course of recovery does not follow a pattern consistent with a primary musculoskeletal injury, these occult sources of pain might be investigated further.

An underlying metabolic disease, such as osteoarthritis, rheumatoid arthritis, rheumatoid-related conditions, like dermatomyositis, temporal arteritis, Lyme's disease and fibromyalgia, goiter or thyroiditis, infection of the soft tissues, that is, cellulitis, the cervical discs or lymph channels (lymphangitis), or diet-related calcium or potassium deficits are not likely as there is no support for these conditions in the history and physical.

Neurological conditions that cause neck pain need to be considered, such as cervical radiculitis, atypical facial pain, trigeminal and glossopharyngeal neuralgia, reflex sympathetic dystrophy, neurogenic inflammation, but these are less common causes and are unlikely given the history of a recent whiplash injury just before the onset of her pain.

Neck pain from somatic dysfunction that is mechanical in origin is typically amenable to osteopathic manipulative treatment (OMT) and not only involves the cervical region but also is accompanied by dysfunction in the upper back, ribs, head, and upper extremities (2). It is characterized by the presence of muscle

TABLE 66.1

Differential Diagnosis of Neck Pain from Local Pathology

Diagnosis	Characteristics	Tests
Acute pharyngitis	Erythematous pharynx; exudates	Strep screen
Carotid aneurysm dissection	Tender carotid, bruit on auscultation	Carotid US, angiogram
Carotidynia	Tender carotid	Carotid US
Cervical fracture	Muscle splinting, history of trauma	Cervical spine x-rays
Dental disease	Teeth and/or gingival pain, tenderness, swelling	Dental x-rays
Lymphadenitis	Enlarged, tender lymph nodes	CBC, ESR
Meningitis	Nuchal ligament rigidity, fever, malaise	Spinal tap
Myositis	Very tender muscles	CBC, ESR
Peritonsillar abscess	Tonsil protruding anteriorly and/or medially	Aspiration
Spinal cord injury	Neurologic deficits below neck; if C3-5: diaphragm paralysis	MRI C-spine
Submandibular gland disease	Tender, mass palpable	US, CT
Temporomandibular joint syndrome	Tender TMJ, deviation of jaw upon opening, decreased movement	CT
Thyroiditis	Palpable thyroid, may be tender	TSH, T4, T3
Torticollis	Contracture of SCM muscle	Cervical x-rays
Tumor of tongue	Palpable mass	MRI
Vertebral artery dissection	Ophthalmologic and neurologic deficits	US, MRI angiogram

spasm, decreased range of motion, as well as a reduction in the quality of motion; there is pain with movement that improves with rest; and there is no organic pathology that could radiate pain to the region or cause viscerosomatic reflexes (2).

The incidence of motor vehicle collisions and WAD has increased in western nations over the past 30 years (3). Neck pain is the most frequently reported complaint in connection with whiplash (acceleration/deceleration); however, as is the case with low back pain, neck pain in general runs an episodic course and the most significant risk factor predictive of future episodes of neck pain is a previous history of neck pain (3). The Quebec Task Force on WAD defined whiplash as “an acceleration-deceleration mechanism of energy transferred to the neck that results in soft tissue injury that may lead to a variety of clinical manifestations including neck pain and its associated symptoms” (4). That task force also coined the term “WAD” to describe the clinical entities related to the injury, and to distinguish them from the injury mechanism. Though people mostly associate whiplash injury with neck symptoms, osteopathic physicians have long advocated for the perspective of whiplash as a total body, or total person, injury (5–10). Indeed, along with neck pain, patients also complain of a variety of WAD, including headache, cognitive disturbances, vertigo, visual disturbances, jaw pain, low back pain, and/or interscapular pain (11,12).

Cervical spine “whiplash” or acceleration/deceleration injury is a mechanism of injury, not a type or extent of injury. There are conflicting theories of the mechanism of the cervical spine component of the injury:

- One is that the body propels forward with the head relatively stationary, followed by hyperextension, which then is followed by hyperflexion of the neck while the head recoils forward (after hitting the headrest), the damage being rapid tissue stretch secondary to traction, hyperextension, and hyperflexion
- Another theory proposes that compression and concomitant torques at the level of C1 and C7, with a flexion torque at C1 and an extension torque at C7, cause ligamentous and myofascial sprain (13)

Probably both occur, with hyperextension causing the greatest insult. With hyperextension, if there is no head rest support for the head, the motion far exceeds the physiologic barrier and anterior neck soft tissues can be stretched, strained, and ruptured. However, cervical response is not so simple; it is modified by impact force, awareness and direction (14):

- The greater the weight and speed (force) of the impacting vehicle, the more force is transmitted to the people in the car being hit
- If the person is aware of the impact, muscles will contract in preparation for the collision, stabilizing the spine and diminishing the strain and stretch on the myofascial tissues; an unaware person’s muscles and connective tissue would stretch before contracting, likely causing more damage
- Direction of impact affects the muscles that will be activated in response to the force, and those that will likely be injured by stretch and strain forces (14)

The patient described above has WAD and somatic dysfunction in several body regions. The dizziness and nausea are likely secondary to the cervical somatic dysfunction as it affects equilibrium and neural afferents involved in the sensation of nausea (CN X). Muscle spasms and tenderpoints are also related to the WAD and associated somatic dysfunctions. The contusion and abrasion is most likely caused by the seat belt restraint. The underlying short

leg and scoliosis are chronic problems and, although not directly related to her complaint of neck pain, likely have a significant role in the decreased resilience of the cervical spine to the whiplash motion effect.

OSTEOPATHIC PATIENT MANAGEMENT

Biomechanical Model

The entire postural mechanism needs to be considered even though the patient’s primary complaints are in the neck and upper body regions (5–9). The motion present in the cervical spine is determined by the unique cervical spine articular anatomy (see Chapter on Cervical Region Anatomy) and dynamic interaction of the various muscles attached to the cervical spine that are coordinated in function during head, neck, thoracic, rib and upper extremity movements (14). The thoracic spine anchors the origins of muscles that stabilize and extend the cervical spine, such as the splenius cervicis and semispinalis capitus. These are not the muscles often injured in WAD; rather, the muscles most commonly injured, hypertonic, or tender upon palpation include the sternocleidomastoid, splenius capitus, and trapezius (14).

Assessing the mechanics of any injury is helpful in making a diagnosis and developing a management plan. Mechanical aspects of a whiplash-associated injury affect the degree of injury, treatment options, and prognosis. For example:

- Bracing the hands against the steering wheel reduces anterior translation of the body, thereby reducing cervical injury but increasing the probability of soft tissue injury to the shoulders, ribs, and thoracic region
- The presence of a headrest on top of the driver’s seat reduces the chance of hyperextension and reduces the chance of cervical injury (15)

The body is a unit mechanism and all parts are deranged in a whiplash injury (7–9). The prevertebral fascia of the anterior neck is continuous with the mediastinum, which is continuous with the crura of the diaphragm surrounding the psoas major muscle. Thus, hyperextension can lead to strains in fascial patterns and dysfunctions in the thorax, abdomen, pelvis, and even the lower extremities (9). Comorbidities, in this case, scoliosis and short leg, will decrease the patient’s adaptability to the sprained and strained upper body myofascial and ligamentous structures; osteoarthritis, rheumatoid arthritis, and similar soft tissue or joint inflammatory diseases can alter the tissue responses to the acceleration/deceleration injury. In many cases, sacral dysfunctions may prevent the patient from recovering in spite of OMT provided to the cervical and thoracic regions (5).

Pelvic somatic dysfunction occurs most commonly associated with the driver planting the foot on the brake in anticipation of, or in attempt to avoid, the accident, causing ilial rotations and superior pubic shears. The paravertebral muscles of the spine and the latissimus dorsi attach to the iliac crests. Movements of the spine and shoulder girdle operate against the resistance of the stabilized ileum. Patients may exhibit pain and decreased range of motion secondary to sacral and ilial dysfunction. Look for iliopsoas strains, strain or sprain of the hip, knee, foot, and ankle. Hip and pelvic fractures are quite common if the patient’s foot was planted at the time of impact. Sacral dysfunction disturbs the body’s balance and homeostatic mechanism—thus hindering the healing process (5). During cervical hyperextension and hyperflexion, the continuity of various muscular, ligamentous, and dural attachments causes the sacrum to be forcibly lifted and dislodged from its floating position

between the ilia (5). Craniosacral restriction may be accompanied by gross lumbosacral and sacroiliac dysfunctions. Becker recommends diagnosing and restoring the primary respiratory (i.e., craniosacral) mechanism before addressing the interaction between the pelvis and the sacrum (5).

Whiplash injury occurs simultaneously in the cervical and thoracic regions (6). The continuity of the cervical, thoracic, and lumbar spine that is provided by the ligamentous attachments and paravertebral musculature, along with somatosomatic reflexes, transmits the acute cervical strain to the thoracic and lumbar regions. A significant thoracic extended dysfunction is produced in taller patients, often in the region of the top of the seat. Also, rotation and lateral forces are introduced into the spine. Lastly, the intimate relationship of the thoracic and cervical spine with the shoulder girdle makes it especially susceptible to injury. Usually, the occiput and the sacrum have the same dysfunctions. Asymmetric traction by muscles that attach to the cranium can result in torsions and sidebending or rotary dysfunctions; the temporal bones are especially vulnerable to these forces (7). Strain patterns are usually present if the patient has struck any object (7). The patient described above has decreased palpable cranial and sacral motion likely because of sphenobasilar compression as well as lumbosacral compression.

An osteopathic approach to this patient would entail helping her to improve her posture, short leg and scoliosis, as well as to evaluate and improve joint motion with OMT and exercises.

For patients with WAD, even in the 1960s and 1970s, osteopathic physicians advocated for adjunctive therapies in addition to OMT for somatic dysfunctions of the thoracic, lumbar, and sacral areas, and any obvious dysfunctions of the cranial and cervical spine (6–8):

- Acupuncture
- Adequate nutritional support
- Appropriate exercise
- Cervical traction
- Gentler forms of manipulation such as myofascial release and muscle energy (i.e., isometric resistance) techniques
- Heat and cold applications
- Help the patient to effectively address emotional difficulties such as anxiety and depression often associated with WAD
- Muscle relaxants
- Preventative measures including public education regarding whiplash injury, and the use of seatbelts and appropriately adjusted head restraints while driving
- Treatment of myofascial trigger points with ice massage or ethyl chloride spray and stretch
- Ultrasound
- Various types of neck collars in the acute phase
- Vitamin therapy.

Current evidence-based recommendations emphasize OMT to relieve somatic dysfunction and individualized exercises for rehabilitation (2,16); cervical collars are still used in the first few days up to a couple of weeks, but evidence has shown that patients who use a soft or firm cervical collar have no measurable benefit in improvement when compared to patients who receive general medical care only (17).

Respiratory/Circulatory Model

In the respiratory/circulatory model, evaluating and treating patients with neck pain considers the possible respiratory and circulatory relationships involved in the cause as well as in the treatment.

As is common with patients suffering from neck pain, the above described patient exhibits not only cervical, but also thoracic, lumbar, and sacral spinal somatic dysfunctions as well; costal and diaphragmatic dysfunctions are also present. Respiratory movements are compromised not only at the level of the diaphragm, but also in the costal cage and spine. Proper respiratory motion and optimal function relies on normal spinal and costal cage mechanics. The diaphragm attaches to ribs 6 to 10, and to the upper three lumbar vertebrae. Dysfunctions in these joints render the diaphragm less effective. The phrenic nerve, which emanates from cervical spinal nerves C3–5, controls diaphragm contraction. Optimal lymph drainage also requires normal costal cage mobility that enables alternating intrathoracic pressure differentials with each breath so that the passive lymphatic channels return lymph from below the diaphragm to the heart via the thoracic duct. Cervical and cranial lymphatics drain into the subclavian veins en route to return to the central circulation via the heart. Cervical somatic dysfunction involving the scalene muscles and anterior cervical fascia can compromise the supraclavicular fascia surrounding the thoracic inlet and thoracic duct and right lymphatic duct as they empty their contents into the subclavian veins. The fascial tension can interfere with free flow of the lymphatic drainage, so OMT using, for example, myofascial release, will help restore normal motion mechanics to that vital region. Therefore, in addressing the cervical, costal, upper extremity, thoracic, lumbar, and sacral somatic dysfunctions of the patient, consider the goal of restoring normal lymphatic and venous drainage through improved respiratory mechanics. Relieve tense myofascial components of the supraclavicular, thoracic inlet and outlet, the ribs, and the diaphragm. Maximize cervical lymphatic drainage with soft tissue and lymphatic OMT. Relieve somatic dysfunction along the entire spine, including the sacrum and pelvis. The patient may benefit from a shoe lift to relieve strain at the lumbosacral junction due to the unlevel sacral base. Improving sacral motion improves the primary respiratory mechanism function through the core link to the occiput via the spinal dura.

The vertebral artery traverses the cervical spine within a foramen in each vertebra but makes three 90-degree turns at the C1-occipital joint before entering the foramen magnum to provide blood to the base of the brain and cerebellum via the basilar arteries. Due to the vulnerability of this artery to dissection and occlusion resulting in stroke (cerebral vascular accident and subsequent central nervous system deficits), cervical spine HVLA procedures, especially those that require extension and rotation at the upper cervical spine to correct somatic dysfunctions, need to be performed with great caution and skill. It is impossible to predict whether a manual procedure will cause vertebral artery compromise; however, if prior to manipulation of the upper cervical spine, the patient complains of vertigo, has nystagmus, or syncope upon rotation of the head, these could be signs of vertebral artery compromise. If these symptoms or signs are present, performing the HVLA procedure is not recommended. Rather, place the patient's head back on the treatment table and reassess for vertebral artery compromise (auscultate for bruit, and obtain imaging with ultrasound and/or magnetic resonance or computerized axial angiograms to rule out dissection or occlusion). The American Osteopathic Association supports the use of HVLA for cervical somatic dysfunction. This position paper reviews the literature related to this topic as well and is highly recommended reading.

Somatic dysfunction in the upper thoracic spine and cervical spine is thought to affect blood flow to the cranium as the sympathetic cervical chain ganglia are situated just anterior to the cervical vertebra bodies. Louisa Burns, D.O., demonstrated the effects on cranial blood flow and ears, nose, and throat diseases from

Comorbid Conditions that are Found Associated Most Commonly in Patients with Neck Pain Include

- Autonomic failure (49)
- Cardiovascular disease (35,36)
- Concentration problems (50)
- Digestive system disease (36,41)
- Dizziness (50)
- Headaches (39,41)
- Low back pain (36,39,41)
- Nausea (50)
- Occipitoatlantal osteoarthritis (51)
- Orthostatic hypotension (49)
- Shoulder pain (36–40, 45, 52–55)
- TMJ syndrome (56)
- Trapezius muscle ischemia (57)

experimentally induced thoracic and cervical somatic dysfunction in animal models (31). Johnston and Kelso later documented a somatic dysfunction pattern of C6, T2, T6 in patients with hypertension (32). In a large retrospective chart review from osteopathic physicians across America in the 1950s, the most common somatic dysfunction related to cardiac symptomatology was OA dysfunction (33). More recently, much other comorbidity have been found in association with neck pain (Box 66.1).

Neurological Model

The patient has dizziness from her WAD and somatic dysfunctions. Understanding the upper cervical spine anatomy provides clues to the relationship of the somatic dysfunction found on physical exam and her symptoms. Dizziness is a symptom that occurs when there is disequilibrium. Equilibrium depends on normal vestibular function. The eyes and neck movement are coordinated via the tectospinal tract to maintain balance and equilibrium. The temporal bones house the vestibular apparatus that consists of three semicircular canals in three different planes with endolymphatic fluid and cilia that enable us to maintain a sense of where we are in relation to our environment. The posterior suboccipital muscles level the head to the horizon and keep the temporal bones level so we feel balanced. Thus, cervical somatic dysfunction interferes with head position, temporal bone levels, and eye-neck coordination, disturbing equilibrium function. Correcting the cervical somatic dysfunction with OMT should relieve the sense of dizziness if indeed this is the cause of the troublesome symptom. Dizziness could also be a symptom of vertebral artery dissection or occlusion, so the astute osteopathic physician should be aware of this possibility, especially if there are other central neurologic signs of deficit or dysfunction.

The patient also has nausea. Peripherally induced nausea sensation is transmitted to the brain most commonly via the vagus nerve afferents. The inferior nodosal (vagal) ganglia is situated immediately outside the cranial cavity as the vagus nerve exits the jugular foramen between the occiput and temporal bones, before the nerve enters the carotid sheath along with the jugular vein and carotid artery. Osteopathic clinicians believe the vagus nerve is vulnerable to the effects of somatic dysfunction in that vicinity and vice versa; if there is increased vagus nerve activity, that is, from thoracic or abdominal visceral inflammation, the surrounding somatic structures are affected and show signs of somatic dysfunction in the upper cervical spinal joints and surrounding soft tissues. Treatment

of the cervical somatic dysfunction with OMT is also intended to restore normal vagal activity and function, including relieving sensation of nausea that is caused by the cervical somatic dysfunction.

The relationship between cervical somatic dysfunction and symptoms of dizziness and nausea, and their abolishment by OMT, are anecdotal (expert clinical experience) and await animal or human laboratory studies and prospective randomized clinical trials to prove cause and effect. The current trend in osteopathic manual medicine practice, as exemplified by recent articles by osteopathic clinicians, favors treatment of somatic dysfunction not only in the cervical region, but throughout the body for patients with symptoms of dizziness and nausea (18,19).

The patient has pain and tenderpoints in the cervical as well as pelvic regions. They are likely due to the WAD. However, WAD is not the only cause of acute neck pain. In the United States, almost 85% of neck pain may be attributed to chronic stresses and strains or acute or repetitive neck injuries (20). In general, somatic dysfunction involving the OA and AA joints usually causes head pain primarily with neck pain secondarily, and somatic dysfunction of C2-7 joints causes neck pain primarily with head pain and/or shoulder pain secondarily (21,22). Cervical facet pain is typically a unilateral, dull aching pain with occasional referral into the occipital or trapezial region, depending on the facet joint involved. C1 and C2 zygapophyseal joints refer pain to the cranium, whereas C3-7 refer pain to the trapezium and interscapular regions (20). The pain referral zones for facet pain overlap both myofascial and disc pain patterns making it difficult to ascertain the exact level of the pain generator. In some patients, neck and head pain are associated with trigeminal nerve activity, either from dental-facial problems, activation of the cervical branches of the trigeminal nerve or influence of the trigeminal nerve on the thalamic pain receptor field in the brain (23).

With WAD, myofascial tenderpoints are commonly found in the trapezius, scalene, semispinalis cervicis, semispinalis capitis, and multifidus (10); the semispinalis capitis muscle seems to be most likely to develop a painful trigger point (24). In some patients, neck and head pain are associated with trigeminal nerve activity, either from dental-facial problems, activation of the cervical branches of the trigeminal nerve, or influence of the trigeminal nerve on the thalamic pain receptor field in the brain (23).

The most reliable physical examination tests for patients complaining of neck pain are the patient's response to digital pressure on bone or muscle, as is used with assessing for strain/counter-strain tenderpoints; tests for regional range of motion; and Spurling's maneuver for cervical radiculopathy (extension, sidebending, and rotation at the cervical spinal level of suspected spinal nerve root compression, combined with axial compression to limit the size of the intervertebral foramen, to see if pain radiates to the arm in a dermatomal distribution related to the spinal nerve being assessed) (25).

Systematic reviews of randomized clinical trials have shown that manipulation plus exercise is beneficial for acute and chronic mechanical neck disorders with or without accompanying pain radiation to the head (16). In a multisite randomized clinical trial comparing the effectiveness of OMT with intramuscular non-steroidal anti-inflammatory medication (ketorolac tromethamine) for patients with acute neck pain seen in the emergency department, the OMT group had significantly reduced pain intensity and equivalent efficacy at relieving pain assessed at 1 hour post treatment (26). All patients received an initial structural exam. Fifty-eight patients were enrolled and met inclusion criteria if they had somatic dysfunction with no history or evidence of underlying organic disease. More than half of the patients in each group

had neck pain as a result of a motor vehicle collision. Osteopathic physicians palpated the cervical region to assess patients for tissue texture changes, joint restrictions, and areas of tenderness. OMT performed at the discretion of each physician with no set protocol included isolated or a combination of HVLA thrust, muscle energy, and/or soft tissue techniques. Intervention with OMT lasted less than 5 minutes (26).

Autonomic effects can accompany cervical somatic dysfunction. Sympathetic innervation to the head and neck regions is derived from preganglionic fibers arising from the lateral horn of the spinal cord from T1 to T6. These fibers proceed cephalad to the sympathetic chain to enter the cervical ganglia and synapse with the postganglionic fibers. The inferior cervical ganglia lie at the superior border of the first ribs, anterior to C7. The inferior cervical ganglia send branches to the heart. The middle cervical ganglia are at the level of the transverse process of C6. The middle cervical ganglia send fibers to the thyroid gland and also to the heart. The superior cervical ganglia are at the level of the AA joint. The superior cervical ganglion postganglionic fibers accompany the internal carotid and ophthalmic arteries into the orbit, and to the glands of the head and face. Postganglionic fibers accompany the vertebral arteries and enter the skull to supply the vestibular portion of the ear, some cranial nerves, and the pharynx. Additionally, the cervical vertebra bodies and intervertebral discs are entirely surrounded by a network of interlacing nerve fibers (27). The anterior longitudinal ligament (ALL) receives bilateral contributions from the medioventral small branches of the sympathetic trunk forming a plexus of nerves throughout all levels. The posterior longitudinal ligament (PLL) likewise receives bilateral contributions from the sinuvertebral nerves that form a nerve plexus throughout all levels. There, nerve plexus of both the ALL and the PLL meet through the rami communicantes (27). Sympathetic symptoms can occur as a result of stimulation of the peripheral nerves as they pierce the soft tissue, stimulation of the sensory elements of C1 and C2, simultaneous compression of the nerve route in its foraminal passage or compression of the vertebral artery. Sympathetic symptoms include the following:

- Aural: tinnitus, deafness
- Ocular: blurred vision, retrobulbar pain, and a pupil that dilates when the head is turned and returns to a neutral midline position
- Vestibular: postural dizziness or vertigo

This patient exhibits signs of central and peripheral sensitization, or facilitation. OMT would be helpful in decreasing the irritability of the nervous system. It has been demonstrated that cervical spine manipulation alters cortical somatosensory processing and sensorimotor integration; the primary muscle afferents (probably Ia) are the most likely mediators of these effects (28). Resetting of the muscle spindle afferents with muscle energy OMT increases range of motion in cervical spinal joints (29). In randomized clinical trials, cervical spine manipulation and mobilization provide at least short-term benefits for patients with acute neck pain and headaches (17).

For this patient, OMT was directed at removing any impingement upon peripheral or central nervous structures, with cervical traction and indirect OMT procedures in the acute phase of recovery; tenderpoints were treated with strain/counterstrain; medications or other adjunct therapies may be needed to modulate neurological function depending on the patient's response to OMT. Thoracic manipulation has an analgesic effect in patients with mechanical neck pain (30). OMT for somatic dysfunction in other body regions, especially the thoracic spine and upper ribs, will help relieve the pain and dysfunction of the cervical spine.

Relieving somatic dysfunction with OMT to the rest of the body will decrease the somatic burden, relieve pain, and reduce the allopathic load. This will contribute significantly to the restoration of normal neurological function.

Metabolic Energy Model

The physiologic and metabolic mechanisms, set into motion due to internal or external factors, that are interpreted by the human body as pain are very complex and have yet to be completely elucidated. What is known is that irritation of the tissues through trauma, repetitive/overuse injury patterns, structural abnormalities, infection, degenerative and systemic disease can lead to the process of nociception and eventually a facilitated spinal cord segment. The inflammatory cascade can lead to a relentless positive-feedback cycle where inflammation can increase the pain that then potentiates the inflammation further (34). As inflammation and harmful metabolites begin to accumulate, structural changes in the affected tissue begin to occur and can ultimately lead to ischemia of the tissue (34). If the metabolic and physiologic alternations are not modified and persist for an extended period of time, long-term structural changes occur in the muscles, tendons, or joints and lead to limited functionality and eventual disability. The goal of soft tissue OMT is in part to relieve muscle spasms and assist the lymphatic system in clearing local toxic metabolites.

Some patients present with acute neck pain related to pharyngitis or peritonsillar abscess. Thus, even though there is evidence of somatic dysfunction on palpatory exam, the osteopathic physician should also assess the status of the internal organs capable of causing pain in the cervical region. OMT for somatic dysfunction related to infection or inflammation is directed at improving venous and lymphatic drainage, as in the respiratory-circulatory model. Using antibiotics as an adjunctive therapy is warranted when a bacterial pathogen is identified or highly likely based on the physical exam and course of the signs and symptoms over time.

There are patients with acute neck pain from thyroiditis who need further management with radiation, medication and/or surgery. In these patients, OMT was employed in the earlier part of the 20th century when no other treatment was available, and may be adjunctive in helping to improve lymphatic drainage even today, but in America OMT is not the standard treatment for this condition in the 21st century. Similarly, neck pain from metastatic cancer in the lymph glands or cervical structures, or primary carcinomas in the cervical region, are not treated directly with OMT. Patients may benefit from OMT to other body regions with the goal of reducing somatic dysfunction burden and relaxing the nervous system during and after definitive diagnosis and treatment with biopsy, radiation, chemotherapy and/or surgery.

For this patient, addressing metabolic-energy expenditure goals entails applying OMT to relieve muscle spasm and restore normal and efficient spinal motion to decrease the burden of poor posture and motion mechanics on energy expenditure. Additionally, ensure proper nutrition using wholesome foods and eliminate fast and fried foods, help the patient to restore normal sleep cycles, and encourage regular exercise. Remove infectious agents and decrease inflammation if present. Restore normal endocrine function if needed.

Behavioral Model

The patient typifies the most common scenario seen in osteopathic primary care practice. Patients with neck pain range in age from the first through the tenth decades (35–38). However,

most patients with neck pain related to motor vehicle collisions are between the ages of 20–40 (15). Although neck pain occurs in children and adults of all ages and genders, neck pain is most commonly reported by middle-age females, especially those who experience WAD (37). In the general population, peak incidence of neck pain is between ages 30 and 59 (35,39). Age and gender standardized annual incidence is 14.6%; however, only less than 1% develop disabling neck pain, so most patients continue to work (35). The point prevalence of neck pain is 8% to 24%. The life-time prevalence is 71% (35–37,40). Fifty-four percent of a general population surveyed have experienced neck pain within a 6 month period (41,42).

Neck pain is a chronic, episodic condition characterized by persistent, recurrent, or fluctuating pain and disability (35). Only about one third of patients with neck pain experience complete resolution (35). About one half of patients with an acute episode have persistent neck pain at 12 months (39). After whiplash injury, neck pain along with headache persists for up to 2 years in 29% to 90% of patients (depending on the study) and neck pain alone can persist at 10 years in 74% of patients (43). Drivers who have sustained a whiplash injury have a nearly three-fold risk of neck or shoulder pain 7 years after the collision (44). Even 17 years after a MVA, 55% still experience neck pain (11).

Neck pain is one of the most common complaints of patients seen by primary care practitioners worldwide (45). Mechanical neck disorder is the most common cause of neck pain (20). Second only to low back pain, neck pain is one of the most common reasons for which patients seek manual medical treatment. Neck pain is the most frequently reported symptom in connection with whiplash injury (43). Neck pain can result from 66% to 82% of rear end collisions and 56% of side impact collisions (43). Seventy percent of patients with neck pain after rear-end traffic collisions are female drivers (15). For female drivers involved in collisions, neck pain likelihood increases as head restraint height decreases below the head's center of gravity (15). Reported neck pain decreases for older female drivers, drivers in less severe crashes, and female drivers in heavier cars (15).

Neck pain accounts for substantial medical consumption, absenteeism from work, and disability (46). Medical disability can be temporary, but in about 10% of patients, permanent medical disability occurs. Permanent medical disability occurs in about 10% of patients involved in rear-end motor vehicle collisions (43). Although 79% may return to work within 1 month, 6% are unable to return to work at 1 year (43). A higher severity of pain at onset and a history of previous attacks seem to be associated with a worse prognosis; however, localization (radiation to the arms/neurologic signs) and radiographic findings (degenerative changes in the discs and joints) are not associated with a worse prognosis (47). Work-related risk factors for neck pain are listed in Box 66.2. (Compare with non-work-related risk factors in Box 66.3 and risk factors for radicular neck pain in Box 66.4.)

Based on data obtained from the Work Loss Data Institute's report on "Disorders of the neck and upper back," the 2008 edition of the National Guidelines Clearinghouse (http://www.ngc.gov/summary/summary.aspx?doc_id=12675&nbr=006563&string=neck+AND+pain) recommends up to 4 weeks of manual therapy, which includes OMT by osteopathic physicians, for workers with job-related acute neck pain not due to damaged tissue injury, that is, neck muscle strain, or whiplash as a mechanism of injury, with no radicular signs or symptoms (48). Initial management recommendations are for muscle relaxants for spasm for the first couple of days up to 1 week, with manual therapy beginning after day 3 at the earliest. After 2 weeks of manual therapy, the guideline

Work-Related Risk Factors for Neck Pain Include

- Hand-arm vibration (58)
- High and low skill (59)
- High quantitative job demands (59)
- Low job control (59)
- Low job satisfaction (59)
- Low social (coworker) support (59)
- Neck flexion (>20 degrees) (59)
- Sitting at work >95% of the time (59)
- Sustained arm postures (58)
- Twisting or bending of the trunk (58)
- Use of arm force (58)
- Workplace design not conducive to efficient cervical motion and function (58)

Non-Work-Related Risk Factors for Neck Pain Include

- Cycling (39)
- Poor ergonomics with driving (60)
- Female (39,60)
- History of motor vehicle collision (61)
- Older age (39)
- Previous low back pain (39)
- Previous neck injury (39,62)
- Psychological distress (39,55)
- Static postures (children) (63)
- Unemployed (39)
- Very slow or very rapid arm motion speed (64)

Characteristics of Patients with Radicular Neck Pain Include

- Dental-facial problems (65)
- Duration of work with a hand above shoulder level (66)
- Female (66)
- Mental stress (66)
- Middle age (66)
- Other musculoskeletal problems (66)
- Overweight (66)
- Smoking (66,67)

recommends switching from passive to active manual modalities. In the case of OMT, this would mean using more of the muscle energy-type procedures in which the patient is actively involved in the treatment. Contraindications and cautions regarding use of OMT for patients with acute neck pain are listed in Box 66.5.

Osteopathic primary care physicians are likely to see many patients with neck pain caused by somatic dysfunction and amenable to OMT. Neck pain from strain or sprain of the paraspinal soft tissues accounts for the greatest number of primary care visits to an outpatient clinic or ER of all musculoskeletal non-skin laceration soft tissue injuries (68). Neck somatic dysfunction was the most commonly reported somatic dysfunction in patients seen by 10 osteopathic practitioners board certified in neuromusculoskeletal medicine and osteopathic manipulative medicine over a 6-month period (69). Somatic dysfunction in the upper back, low back, and

Contraindications and Cautions Regarding OMT for Somatic Dysfunction in Patients with Acute Neck Pain

Care must be taken in the patient with an unstable cervical spine. Contraindications to HVLA OMT to the cervical spine include the following:

- A history of acute trauma before an assessment for any damage to the anatomy of the region and diagnosis of the origin of the pain
- Acute cervical herniated nucleus pulposus
- Acute cervical vertebra fracture or dislocation
- Carotid or vertebral artery dissection
- Ligamentous laxity
- Metabolic or neoplastic bone disease
- Patient refusal
- Primary muscle or joint disease in the cervical spine

shoulder can also predispose a person to develop cervical somatic dysfunction and pain. Thoracic somatic dysfunction is a significant predictor of neck-shoulder pain and hand weakness symptoms (30,70–72). This further supports the osteopathic approach to the patient with acute neck pain, which includes assessment and treatment of not only the cervical spine but also the entire musculoskeletal system as an integrated dynamic functional unit.

The human body functions as a unit and typically will respond to trauma, injury, or disease as a unit. This includes the psychological, behavioral, and social response that a person may have to pain and somatic dysfunction. Uncontrolled pain can lead to decreased functional capacity, which then increases the psychological burden of the patient and can lead to increased anxiety, stress, and depression. The increased psychological burden can impair the body's ability to heal and can further exacerbate the pain experienced by the patient. Therefore, it becomes vital for the osteopathic physician to evaluate the patient for comorbidities and mitigating factors that may impede a healthy recovery for the patient. Certainly, anxiety plays a role in this patient's neck pain, but she has no history of chronic anxiety or other psychiatric condition; her nightmares are related to her anxiety and probably disrupting her sleep patterns, which, along with the muscle spasms, increases her fatigue. She is not an active sports type person and has a sedentary lifestyle, so her muscles likely lack good tone. Her posture is normally not efficient and does not lend itself to compensation or adaptation to injuries such as she sustained recently.

Better psychological health and greater social support predicted a better outcome in primary care and general population samples with initial neck pain, whereas passive coping predicted a worse outcome (73). Economically, manual therapy (i.e., spinal mobilization) has been more effective and less costly for treating mechanical neck pain than physiotherapy modalities or care by a general practitioner who doesn't use manipulation (74).

For patients with neck pain, the osteopathic approach of treating the whole patient and not just the symptoms will help maximize the patient's restorative health potential. Applying the behavioral perspective to this patient, treat her anxiety, work with her to improve her sleep habits, dietary choices and habits, encourage nonsedentary lifestyle, improve posture and exercise habits, and encourage her to stop repetitive work behaviors that aggravate her condition. In patients who are athletes, help them to modify sports or other activities. If there is alcohol, tobacco and/or drug abuse as part of the clinical picture, encourage and help the patient to eliminate these addictions and abuses as part of the management plan.

Specialist Referral

The patient would be referred to the physician spine or pain management specialist for further evaluation and management if her neck pain did not improve or progressively worsened in spite of appropriate conservative treatments. If there is progressive or persistent loss of motor or sensory function, or altered sensorium or brain function, certainly neurological and surgical referrals are indicated. However, it is less clear if there is only limb paresthesias or radicular pain, which may be indicative of cervical nerve root compression. Nevertheless, it is helpful to utilize screening protocols, such as the Canadian C-spine rules, for patients with a low risk of cervical spine fracture and CT imaging for high risk patients with blunt trauma to the neck (75). In conjunction with the history and physical examination, electromyography (EMG) is relatively sensitive and specific for diagnosing cervical nerve root compression. Often, a neurologist or physiatrist is called upon to utilize the EMG to distinguish neck pain that is radicular versus nonradicular in nature. This distinction, along with an assessment for somatic dysfunction and relevant imaging studies, aids in more clearly identifying the cause of a patient's neck pain and instituting the appropriate treatment.

In general, it appears that the physical examination is more predictive of "ruling out" than "ruling in" a structural lesion, especially when assessing for neurological compression or significant pathology, such as cervical spine instability (75). Although MRI imaging is helpful in identifying cervical degenerative changes, these changes are common in asymptomatic subjects and research has failed to demonstrate a correlation between degenerative changes and neck pain symptoms. Similarly, there is no strong evidence supporting the validity of cervical discography or facet joint injections in diagnosing disc or facet pain, respectively, as the primary cause of neck pain (75). Evidence supports the use of provocative maneuvers, such as Spurling's test or contralateral rotation of the head with arm extension, when evaluating for cervical radiculopathy (76,77). Other physical examination components that should be incorporated include motor strength and sensory testing and cervical spine range-of-motion evaluation. There is some evidence suggesting that patients with chronic neck pain secondary to WAD have decreased cervical spine range of motion when compared to control subjects (78).

After completing the clinical and diagnostic evaluation and excluding significant pathology, including cervical spine instability or an infectious, neoplastic, or inflammatory process, the physician spine or pain management specialist utilizes a variety of modalities to treat neck pain, including medication, physical therapy, interventional procedures, manual medicine, and referral for surgical consultation. If a patient's neck pain is nonradicular and mechanical in nature, a multitherapeutic approach that incorporates medication, exercise therapy, and manual medicine is a reasonable approach. There is some evidence supporting exercise therapy, either alone or in combination with spinal manipulation, as being positively associated with short-term (6 to 13 weeks) reduction in chronic or recurrent neck pain when compared to spinal manipulation alone or usual care (17). Using one's skills as an osteopathic physician is sensible since the evidence supports the use of manual medicine in the treatment of neck pain. Cervical spine manipulation is more effective in reducing neck pain than muscle relaxants or usual care and at least provides short-term benefits for patients with acute neck pain. Furthermore, it appears that the benefits of manual medicine are enhanced when combined with exercise therapy and ergonomic adjustments (2). There is no evidence supporting the use of epidural or intra-articular corticosteroid injections in the

treatment of nonradicular neck pain (79). In contrast, patients with neck pain secondary to nerve root compression do have short-term improvement of cervical radicular symptoms with epidural or selective nerve root corticosteroid injections (79). This, however, has not been shown to decrease the overall rate of surgery in patients with significant cervical radiculopathy (79). The long-term outcomes of treating cervical radiculopathy surgically when compared to nonoperative treatment have not been studied. Regardless, both anterior cervical discectomy with fusion and cervical disc arthroplasty seem to offer rapid and substantial relief of pain and impairment in patients with true cervical radiculopathy (79). As with the clinical evaluation, it is imperative to make the distinction between radicular and nonradicular neck pain when implementing treatment. In doing so, the physician specialist improves the likelihood of successfully treating a patient's neck pain, whether that entails treating radicular pain with injections or mechanical pain with a multimodal approach, including of medication, exercise and physical therapy, and manual medicine.

SUMMARY

In summary, the osteopathic approach to the patient with acute neck pain begins with a thorough history and physical examination, including an osteopathic structural examination of the musculoskeletal system. The differential diagnosis considers potential etiologies from local pathology, somatic dysfunction in the cervical as well as other body regions, systemic pathophysiology with cervical manifestations, and referred pain from organs in the vicinity of the cervical region, that is, lungs and heart. Associated comorbidities are also assessed and treated as appropriate. One of the most common causes of neck pain is a history of whiplash-type injury. However, though this type of injury affects the cervical spine, its effects are not limited to the cervical region. Understanding the total body response to a traumatic event such as a motor vehicle collision helps to elucidate the application of osteopathic principles in practice. Osteopathic treatment utilizes a health-oriented, patient-centered approach, focusing on improving structure-function interrelationships. This entails applying OMT to alleviate somatic dysfunction and maximize biomechanical, neurological, metabolic, respiratory/circulatory, and behavioral functions. Patient education, individualized exercise prescription, and close follow-up are important components of the management plan. Referral to a spine or pain specialist is indicated if the patient's pain and/or dysfunction does not improve or progressively worsens with conservative measures.

KEY CONCEPTS

- Inflammation of the nasal and paranasal mucosa may be caused by bacterial or viral infection; fungal or allergic conditions. The most common bacterial pathogens involved in acute sinusitis in adults are *Streptococcus pneumoniae*, *Haemophilus Influenzae*, and *Moraxella catarrhalis*.
- Obstruction of the sinus drainage pathways and decreased mucociliary transport lead to stagnation of mucus in the sinuses, predisposing to sinusitis. Swelling and inflammation are common causes of obstruction.
- Osteopathic manipulative treatment, as a means to improve venous and lymphatic circulation, can play a major role in the treatment of sinusitis. Improving venous and lymphatic circulation from the head and neck to decrease the congestion and inflammation of the nasal mucosa would be expected to facilitate the sinus drainage pathways.
- Unopposed sympathetic stimulation leads to vasoconstriction and drying of the nasal mucosa. Sympathetic preganglionic fibers to the sinuses arise from T1-4 cord level, synapsing in the superior cervical ganglion (C2-3). Facilitation due to somatic dysfunction in the upper thoracic and cervical spine may, thereby, affect the health of the mucosa.
- Some over-the-counter antihistamines, often used for upper respiratory infections, can dry mucus and decrease ciliary effectiveness. Patients should be cautioned about their role in the development of acute sinusitis.
- Start nonantibiotic therapy initially for patients with low probability of bacterial infection.
- Consider antibiotic therapy in patients with high probability of bacterial sinusitis, severe symptoms, or when nonantibiotic therapy fails.

CASE VIGNETTE

CHIEF COMPLAINT

JP is a 42-year-old female accountant who presents to the family practice clinic complaining of headache, fever, and scratchy throat.

History of Present Illness

The last 4 days she has had a full feeling in her face, pressure behind her eyes, nasal congestion, sensitivity of her nose, pain in her upper teeth, and fatigue. At times, she is sensitive to light and sounds and has decreased sense of smell. A week earlier, she had a “cold” for which she took an over-the-counter “cold and sinus” preparation. She has a history of similar symptoms 2 to 3 years ago, treated with antibiotics with a prolonged recovery.

Current Medications

Over-the-counter cold and sinus preparation, but no other medications

Allergy

None known to medication, inhalants, or foods

Past Medical History

Patient was hospitalized for uncomplicated vaginal delivery at age 29. She had a tonsillectomy at age 5, for which she was not hospitalized. She has had no other surgery. Her most recent mammogram was 18 months ago and reported normal.

Environmental and Social History

She smokes ½ pack cigarettes per day and has an occasional glass of wine. She is married with one child. Two dogs also live in the house. She works part-time as dental hygienist.

Family History

Both parents are living. Father has hypertension. Mother is healthy. One female and one male sibling are both healthy. No family history of diabetes, asthma, stroke, or heart disease (other than father’s hypertension).

REVIEW OF SYSTEMS

Eyes:

No visual disturbance noted, but in the spring has watery, itchy eyes.

ENT:

As noted in chief complaint.

Cardiovascular:

Denies chest pain, syncope, shortness of breath, and extremity edema.

Respiratory:

Has occasional morning cough, gets “colds” several times a year, denies difficulty breathing.

Gastrointestinal:

Denies nausea, vomiting, food intolerance, diarrhea, constipation, or changes in bowel habits.

Genitourinary:

P1G1, denies hematuria, frequency, urgency, pelvic pain.

Musculoskeletal:

Complains of frequent neck and upper back stiffness and aching, denies weakness, muscle cramping, or other areas of back pain.

Neurological:

Denies vertigo, unsteadiness, numbness, or tingling or radiating pain.

Psychiatric:

Denies signs of depression, reports normal sleep, denies hallucinations or alterations in consciousness.

Endocrine:

Denies intolerance to heat and cold, rashes or changes in skin and hair.

Hematologic/Lymphatic:

Denies swelling and abnormal bruising.

VITAL SIGNS

Temperature: 101.6°F; pulse: 90; respirations: 14/min; BP: 134/80; height: 5'6" weight: 140 lb

PHYSICAL EXAM**General:**

Patient appears stated age and in no acute distress, but fatigued.

Skin:

Skin color is normal.

Eyes:

Conjunctiva appears clear. Pupils are equal and reactive to light and fundoscopic evaluation is normal.

ENT:

Examination reveals erythema and generalized congestion of the nasal mucosa. Pustular drainage is noted and there is a mild to moderate septal deviation caudally to the left. Posterior pharynx is inflamed with pustular drainage evident. Tympanic membranes are dull with questionable cone of light, but have adequate response to insufflation. Thyroid is not enlarged.

Musculoskeletal/Structural:

Tenderness is palpated in the upper cervical area, upper thoracic area, and in the right supraclavicular area. Motion changes are noted at T2, upper right ribs and C2, consistent with T2 FSR_L, rib 1 inhalation somatic dysfunction, and C2 FSR_R. Tenderness associated with slight nodularity is palpated anteriorly in the first intercostal space on the right and posteriorly between the spinous and the transverse process of C2 on the right. The suboccipital tissues are hypertonic and tender. There is decreased amplitude of the cranial rhythmic impulse, but the rate is normal. Tenderness is noted over the bridge of the nose and over the maxillae and zygomae. Percussion over the maxilla intensifies the tenderness.

Hematological:

There is no lymphadenopathy is palpated in the cervical or supraclavicular areas.

Respiratory:

Lungs are clear to auscultation.

Cardiovascular:

Heart has regular rhythm with rate of 90 bpm. There are no murmurs and no extremity edema is noted. Nail beds and digits appear normal.

Abdomen:

Bowel sounds are ausculted in all four quadrants. Abdomen is soft and nontender. No organomegaly is noted.

Neurological:

Patient is oriented in time and place and responds appropriately to questions. Cranial nerves II to XII are intact. Deep tendon reflexes of upper and lower extremities are equal and moderate bilaterally. Sensation is intact.

ANATOMICAL CONSIDERATIONS**Nose and Paranasal Sinuses Airflow**

The nose, being an organ of respiration and olfaction, functions to filter, humidify, and regulate the temperature of inspired air. The superior, middle, and inferior turbinates or conchae are elevations on the lateral nasal walls. Heavily endowed with blood vessels, they help in the temperature control of the inspired air. The nose also serves as a filter for particulate matter in the air. Much of the smoke, dust, pollens, bacteria, and viruses are trapped and removed before the air enters the lungs. The nasal septum and the turbinates create an air flow pattern in the nose that maximizes the air-conditioning function of the nose and paranasal sinuses. The paranasal sinuses in the maxillary, frontal, sphenoid, and ethmoid bones are air-filled cells and extensions of the nasal cavities. They serve similar functions to that of the nose. Regardless of the temperature of outside air, the temperature of inspired air is changed to approximate body temperature during its passage through the nose and sinuses. Similar changes are made in moisture content of inspired air so that it reaches the trachea at almost ambient humidity.

MUCOCILIARY TRANSPORT IN THE UPPER RESPIRATORY SYSTEM

The nasal cavity and paranasal sinuses are covered by pseudostratified, columnar, ciliated epithelium, as is the rest of the respiratory system, including the middle ear and auditory tube. Goblet cells and submucosal glands contribute a mucus blanket that covers and protects the epithelium. This mucus film has two layers. The cilia beat within the inner, serous (sol phase) layer. The outer, more viscous (gel phase) layer is moved by the synchronized ciliary action. (Fig. 67.1). The process is called mucociliary transport (or mucociliary clearance).

Secretions from the paranasal sinuses pass into the nasal cavity through the various ostia or openings in the sinuses. There are two basic drainage patterns for the sinuses. The anterior ethmoid, frontal and maxillary sinuses are part of the anterior pattern draining to the ostiomeatal unit under the middle turbinate. The posterior ethmoid and sphenoid sinuses are in the posterior pattern draining to the sphenoethmoid recess (Fig. 67.2). To appreciate the importance of efficient mucociliary transport, note that the ostiomeatal unit is located superior to much of the maxillary sinus, making it necessary to actively move the mucous blanket "uphill" for effective drainage. This nondependent drainage situation exists with the sphenoid and in some instances with the ethmoid sinuses, as well. The outer layer of mucous traps particulate matter, moving it through the sinus ostia into the nasal cavity, where mucus is transported into the nasopharynx and swallowed. Mucociliary transport actively collects and concentrates particulate matter, moving it out of the sinuses. Pathogens may be incorporated into the cells of the mucosa or destroyed by lysozymes and secretory immunoglobulin A within the mucus.

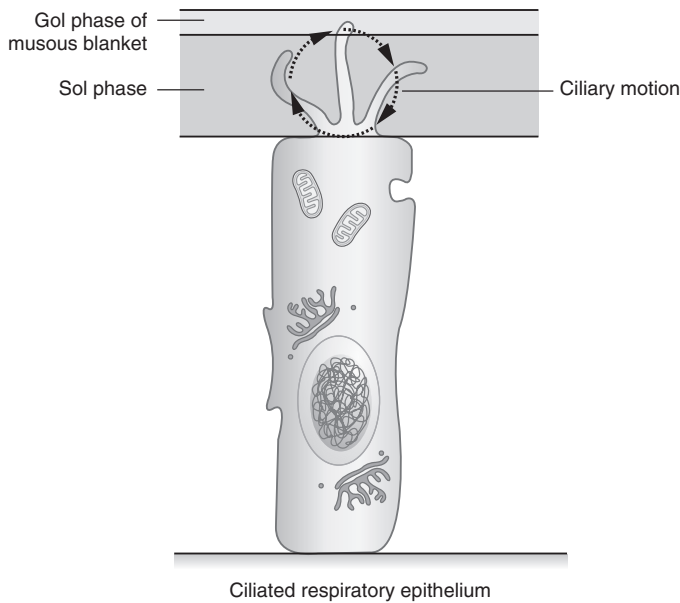

Figure 67-1 Ciliated respiratory epithelium.

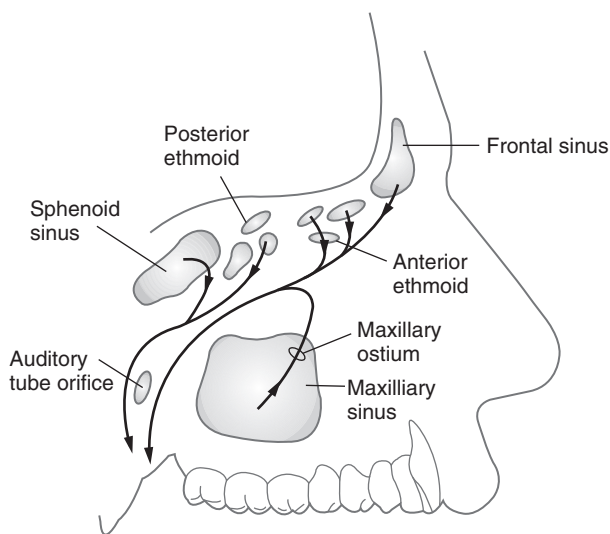

Figure 67-2 Sinus drainage patterns.

The viscosity of the mucus plays a role in the efficiency of the process. The architecture of the nose and the sinus ostia influence these mucus flow patterns. The way cilia are controlled and coordinated to power this process is only partly understood. Ciliary beat frequency may be influenced by primitive neurologic control, may be genetically determined, or may be an interactive phenomenon depending on the physical nature of the particulates. It is known that healthy functioning of this upper respiratory system depends on unimpaired nasal airflow and optimal mucociliary transport. Factors that disturb these body mechanisms lead to disease processes.

NERVOUS SYSTEM RELEVANT TO NOSE AND PARANASAL SINUSES

The autonomic nervous system (ANS) plays a crucial role in the physiologic function of the nose and paranasal sinuses (Loehrl,

2005; Sarin et al., 2006). Proper balance of the sympathetic and parasympathetic systems, and appropriate response of the sensory nerves are necessary for optimal function. It follows that disease of the nose and paranasal sinuses results when these factors are dysfunctional and poorly balanced. The nervous system of the nose also interfaces with the immune system especially in the face of inflammation (Lacroix, 2003).

Parasympathetic supply to the nose originates from the superior salivary nucleus. Its preganglionic fibers form part of the superficial greater petrosal nerve, which joins the deep petrosal nerve, forming the nerve of the pterygoid canal (vidian nerve). After passing through the pterygoid canal, the fibers synapse in the sphenopalatine ganglion (Fig. 67.3). The sphenopalatine ganglion is suspended in the pterygopalatine fossa, bordered by the pterygoid process, maxilla, palatine bone, and floor of the sphenoid. The parasympathetic postganglionic nerves modulate their effect by integrating inhibitory and stimulatory channels. Postganglionic fibers are distributed to the nasal mucosa from the sphenopalatine ganglion along with the sensory and sympathetic fibers.

The action of the parasympathetic nervous system on the upper respiratory mucosa is stimulation of the glandular epithelium with production of mucous, rich in glycoproteins, lactoferrin, lysozymes, secretory leukoprotease inhibitor, neural endopeptidase, and secretory IgA. There is a parasympathetic effect of vasodilation, although of much less significance than the glandular effect (Sarin et al., 2006). Several neuropeptides, including vasoactive intestinal peptide, neuropeptide Y, nitric oxide (NO), enkephalin and somatostatin, are associated with the nasal parasympathetic system (Lacroix, 2003). Nitric oxide is thought to be an activator of ciliary beat frequency, but its role is variable and still poorly understood (Landis, 2003).

Sympathetic fibers to the head arise from the upper thoracic segments of the cord (T1-3). Preganglionic fibers ascend from there to the superior cervical ganglion, located in the upper cervical area, where they synapse. Postganglionic fibers from the superior cervical ganglion join the internal carotid plexus, becoming part of the deep petrosal nerve and the nerve of the pterygoid canal (see Fig. 67.3). Sympathetic supply to the nose and paranasal sinuses passes (without synapsing) through the sphenopalatine ganglion in the pterygopalatine fossa. They continue with the parasympathetic fibers to the nose and sinuses.

The sympathetic nervous system acts in the nose to produce vasoconstriction and increased nasal airway patency. Norepinephrine is the primary neurotransmitter of the sympathetic system in the nose. Interaction and balance between these systems is complex, intricate, and only partially understood. It is quite clear, however, that the ANS plays a major role in regulating nasal airflow, and at least some role in mucociliary transport mechanisms (Sarin et al., 2006).

Afferent nerves, supplying the nose and derived from the olfactory nerve and ophthalmic and maxillary branches of cranial nerve V, provide protective reflexes. For example, exposing the nasal mucosa to mechanical irritation, allergens, or cold air elicits a response of sneezing, coughing, apnea, or avoidance behavior. This occurs through an axonal reflex. These afferent nerves also recruit systemic autonomic reflexes and mediate vascular, glandular, and inflammatory defenses. Stimulation of these afferent nerves also leads to the release of neuropeptides such as calcitonin gene-related peptide, gastrin-releasing peptide, substance P, and neurokinin A. Increase in these sensory neuropeptides along with reduction of their catabolism leads to the process of neurogenic inflammation (Lacroix, 2003). Symptoms resulting from nasal neurogenic inflammation are those common to rhinosinusitis—nasal

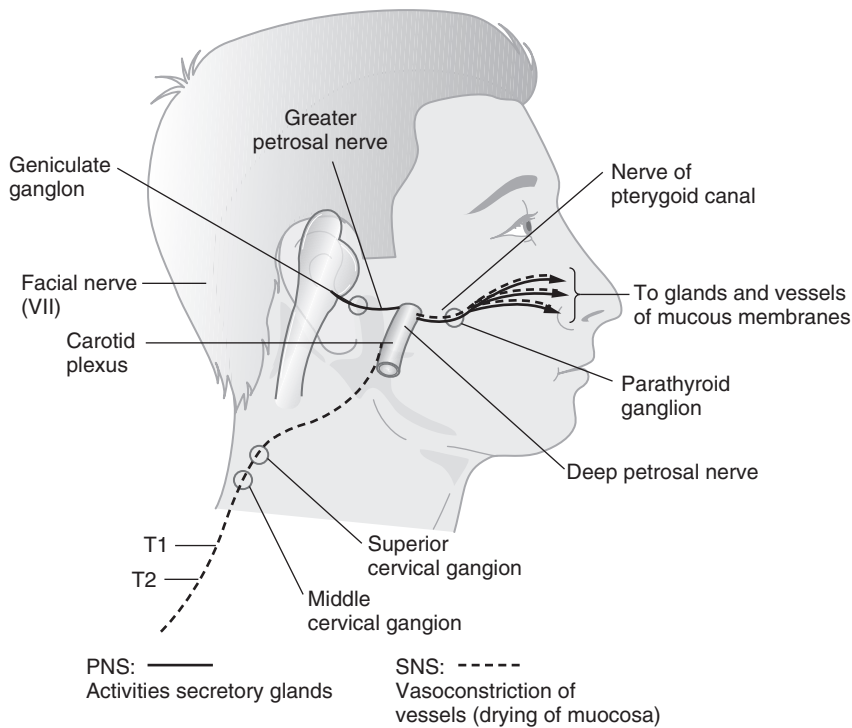

Figure 67-3 Autonomic nerve supply to upper respiratory tract.

obstruction, rhinorrhea, and headache. Interestingly, similar symptoms accompany migraine and may also implicate neuropeptides in the causal relationship (Bellamy et al., 2006).

LYMPHATIC SYSTEM RELEVANT TO THE HEAD AND NECK

The lymphatic system of the neck consists of numerous lymph nodes connected by lymphatic channels, eventually ending in the thoracic and right lymphatic ducts. The thoracic duct receives drainage from the left side of the head and neck, while the right lymphatic duct drains the right side. Each empties independently into the junction of the internal jugular and subclavian veins on

their respective side of the body (Fig. 67.4). Significant individual variability exists in these drainage sites.

Cervical lymph nodes are generally divided into the following groups—submandibular, submental, superficial cervical, deep cervical, and paratracheal. The submandibular and submental nodes are intimately connected with the superficial fascia covering the digastric and mylohyoid muscles. The superficial cervical nodes lie along the external jugular vein and on the external surface of the sternocleidomastoid muscle. The paratracheal nodes are irregularly located, and, as do all the aforementioned groups of nodes, drain into the deep cervical lymph nodes. These prominent, deep nodes form a chain embedded in the connective tissue of the carotid sheath around the internal jugular vein (Fig. 67.5).

Figure 67-4 Skeletal structures in relationship to thoracic duct termination.

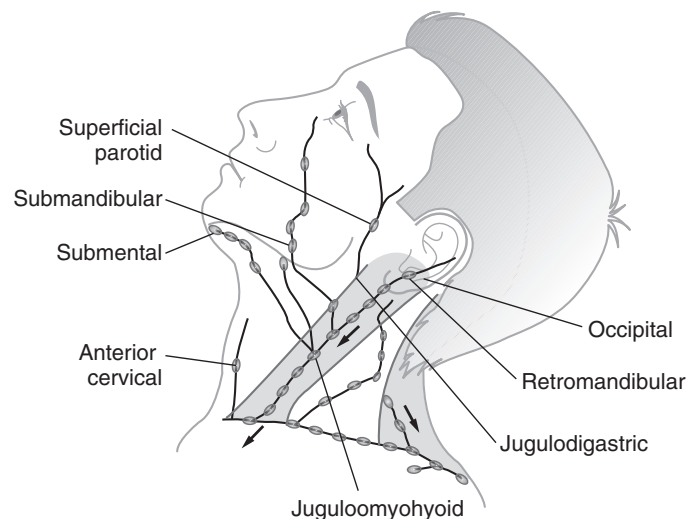

Figure 67-5 Superficial cervical lymph nodes. (From Moore, KL. *Clinically Oriented Anatomy*. 2nd Ed. Baltimore, MD: Williams & Wilkins, 1985; with permission.)

The intimate association of the lymphatic channels to the myofascial structures in the neck makes lymphatic flow particularly susceptible to changes in myofascial tone. Hypertonia in the cervical myofascial tissues can impede lymphatic flow. Muscle movement improves lymphatic circulation. Autonomic influence on lymphatic contractility suggests a role for osteopathic manipulative techniques to improve lymphatic circulation not only for its impact on muscle tone but also on autonomic tone (Degenhardt and Kuchera, 1996).

RHINOSINUSITIS

Acute rhinosinusitis is an inflammatory process involving the mucus membranes of the paranasal sinuses and nasal cavity lasting no longer than four weeks. Since rhinitis and sinusitis usually coexist, "rhinosinusitis" is the current preferred terminology (Fokkens et al., 2005). Chronic rhinosinusitis is diagnosed when the symptoms of sinusitis are present for 12 weeks or more. It differs in histopathology, prognosis, and management from acute rhinosinusitis. Rhinosinusitis lasting between four and twelve weeks is termed subacute. Some patients develop recurrent acute sinusitis with four or more acute episodes annually, interspersed with symptom-free intervals.

DIAGNOSIS

Patients who have had a recent upper respiratory infection and develop nasal obstruction, periorbital pain, and purulent rhinorrhea are suspect for acute rhinosinusitis. Other symptoms often present include olfactory disturbance, fever, maxillary toothache, fatigue, cough, and facial pressure made worse by bending over. The headache (or face pain) is usually described as pressure-like and dull. Engorgement of the nasal mucosa, which occurs during sleeping, causes sinus-related pain to be worse in the morning, improving after the patient is upright for a time.

Examination of the nose may reveal a deviated septum, inflamed nasal mucosa, and pus in the nasal cavity. Nasal polyps may be present especially if inflammation has been chronically present. The posterior oropharynx may demonstrate signs of postnasal drainage such as a lateral red streak, obvious drainage, or the cobblestone appearance of lymphoid hyperplasia. Although transillumination of the sinuses is a valuable diagnostic tool for some practitioners, it has been found to be unreliable for definitive diagnosis (Otten and Grote, 1989). Facial tenderness may be elicited with palpation.

Acute rhinosinusitis does not warrant radiographic diagnosis. Plain film radiographs, ultrasonography, computerized tomography (CT), and magnetic resonant imaging of the sinuses should be avoided in the diagnosis of acute rhinosinusitis and reserved for patients at risk for complications. Radiographs and CTs have high false-positive rates for acute rhinosinusitis, and radiography is not cost-effective compared to the use of clinical criteria with indicated treatment regimens (Fokkens et al., 2005).

Serious complications of acute bacterial sinusitis are rare, but patients who also present with ophthalmic or neurologic signs and symptoms need to be worked up in more depth and referred appropriately. Local extension of infection includes orbital or periorbital cellulitis and osteitis. Infectious spread beyond the paranasal sinuses may occur in the forms of meningitis, brain abscess, and infection of the venous sinuses. CT is appropriate if any of these complications are suspected.

Differentiating viral from bacterial rhinosinusitis is difficult except by way of sinus puncture, which is reserved for research use. Trigeminal neuralgia, migraine, dental abscess, and neoplasm may

also present with head and face pain and need to be considered as differential diagnoses. Many patients use the term "sinus headache" without specific diagnosis of sinus disease. It is the physician's responsibility, using clinical diagnostic skills, to differentiate the various causes of the patient's headache (Levine, 2006).

Inflammatory conditions in the nose and paranasal sinuses include allergic rhinitis and nonallergic rhinitis (vasomotor rhinitis). Both are characterized by nasal obstruction, increased secretions, and decreased olfaction. These inflammatory conditions exhibit hyper-reactive nasal mucosa, with exaggerated neural response to all stimuli. ANS dysfunction (hypoactive sympathetic relative to parasympathetic tone) has been demonstrated in nonallergic/vasomotor rhinitis (Jaradeh et al., 2000). In allergic rhinitis, IgE-sensitized mast cells release allergic mediators, including histamine and leukotrienes, leading to a type I hypersensitivity reaction. Patients with chronic rhinosinusitis have been shown to exhibit exaggerated humoral and cellular response to common airborne fungi, particularly *Alternaria*. (Shin) Lymphocytes, plasma cells, and eosinophils are present in the inflammatory infiltrate, similar to that of asthma.

Although still only a hypothesis that allergic disease predisposes to rhinosinusitis, it is prudent to address allergy as a contributing factor (Fokkens et al., 2005; Karlsson and Holmberg, 1994). Allergic signs and symptoms, such as sneezing, itchy, watery eyes, clear rhinorrhea, and nasal itching, should be noted, and their treatment considered as part of integrated patient care.

When evaluating a patient with rhinosinusitis, attention needs to be paid to the factors that decrease airway patency and limit air flow, and those that decrease the effectiveness of mucociliary transport. Treatment can then be directed toward the specific factors influencing each patient's problem.

FACTORS INFLUENCING AIRWAY PATENCY

Anatomic structures can compromise airway patency. Typically seen are deviated nasal septum, turbinate hypertrophy, and collapsed nasal valve. Various types of neural dysfunction are associated with upper airway disorders. Recent evidence suggests that hypoactive sympathetic influence leads to increased nasal airway resistance (Loehrl, 2007). Vasodilatation, due to increased activity of sensory neuropeptides, occurs in patients with hyperactive nasal mucosa characteristic of allergic and nonallergic rhinitis, as well as chronic rhinosinusitis (Lacroix, 2003). Nasal polyps, found either in the nose or paranasal sinuses, obstruct normal air flow. Infectious processes, especially viral upper respiratory infection, causes swelling and decreased airway patency. Overuse of topical nasal decongestants leads to *rhinitis medicamentosa*, described as a rebound phenomenon of nasal congestion, and loss of responsiveness to topical decongestants (Lin et al., 2004). Lymphatic congestion due to a variety of causes may add to swelling of the mucosa and poor nasal air flow.

FACTORS INFLUENCING MUCOCILIARY TRANSPORT

Ciliary beat frequency and the viscosity of mucus are main determinants in the quality of mucociliary clearance. Intrinsic ciliary defects occur with some diseases (primary ciliary dyskinesia), but are rare. Some antihistamines, poor hydration and, as some believe, dairy products thicken mucus. Mucociliary transport has been shown to be significantly reduced in cigarette smokers, probably due to decreased number of cilia or changes in the mucus (Cole et al., 1986; Mahakit and Pumhirun, 1995). Inflammatory conditions

of the nose, sinuses, and airways (allergic and nonallergic rhinitis, rhinosinusitis, and bronchiectasis) are also associated with decreased mucociliary clearance (Schuhl, 1995; Stanley et al., 1985). Cystic fibrosis, a hereditary disease that produces thick, abundant respiratory secretions, is accompanied by significant slowing of nasal mucociliary transport (Armengot et al., 1997). Slowed transport has been noted with chronic infection and in diabetics.

INTEGRATED TREATMENT APPROACH

Figure 67.6 presents a treatment algorithm for rhinosinusitis. Most patients with acute bacterial rhinosinusitis improve without antibiotics. For patients having symptoms more than seven days and those with more severe symptoms, consider antibiotic therapy with a narrow spectrum agent (Fokkens et al., 2005; Hickner et al., 2001). For those patients who require antibiotics for rhinosinusitis, amoxicillin or trimethoprim/sulfamethoxazole are considered first-line antibiotics for the common pathogens—*Streptococcus pneumoniae* and *Haemophilus influenzae*. Alternatives such as doxycycline and azithromycin should only be used for patients allergic to both first-line drugs. Initial course of antibiotic treatment should be 10 to 14 days (except if using azithromycin). In the case of partial resolution, extend antibiotic therapy to a total of three weeks.

Patient education regarding the incidence of antibiotic-resistant infections is important, whether or not prescribing antibiotic therapy. Patient information is available online at www.cdc.gov/drugresistance/community.

Since many cases of acute rhinosinusitis are due to viral infections and do not require antibiotics, treatment that is symptomatic and encourages inherent healing mechanisms should be considered. Of the nonpharmacologic therapies, none have been thoroughly studied and their effectiveness is unknown. Considering the underlying pathophysiologic process can direct decision making about recommending these therapies.

Promoting mucociliary clearance is essential to the overall treatment of rhinosinusitis and prevention of complications. Patients may be instructed to drink warm, clear fluids in order to hydrate the mucous membranes, and refrain from drinking milk. Saline nasal irrigation may relieve symptoms and is a low-cost option. Decreasing nasal inflammation improves airway patency. Identification of allergic symptoms in the patient history suggests the need to address allergy treatment of some kind. Perennial allergy symptoms may warrant allergy testing and immunotherapy. Avoidance of allergens or irritants can be difficult, but patient education is essential and often needs to be ongoing. Smoking cessation and avoidance of second-hand smoke and other chemical irritants are

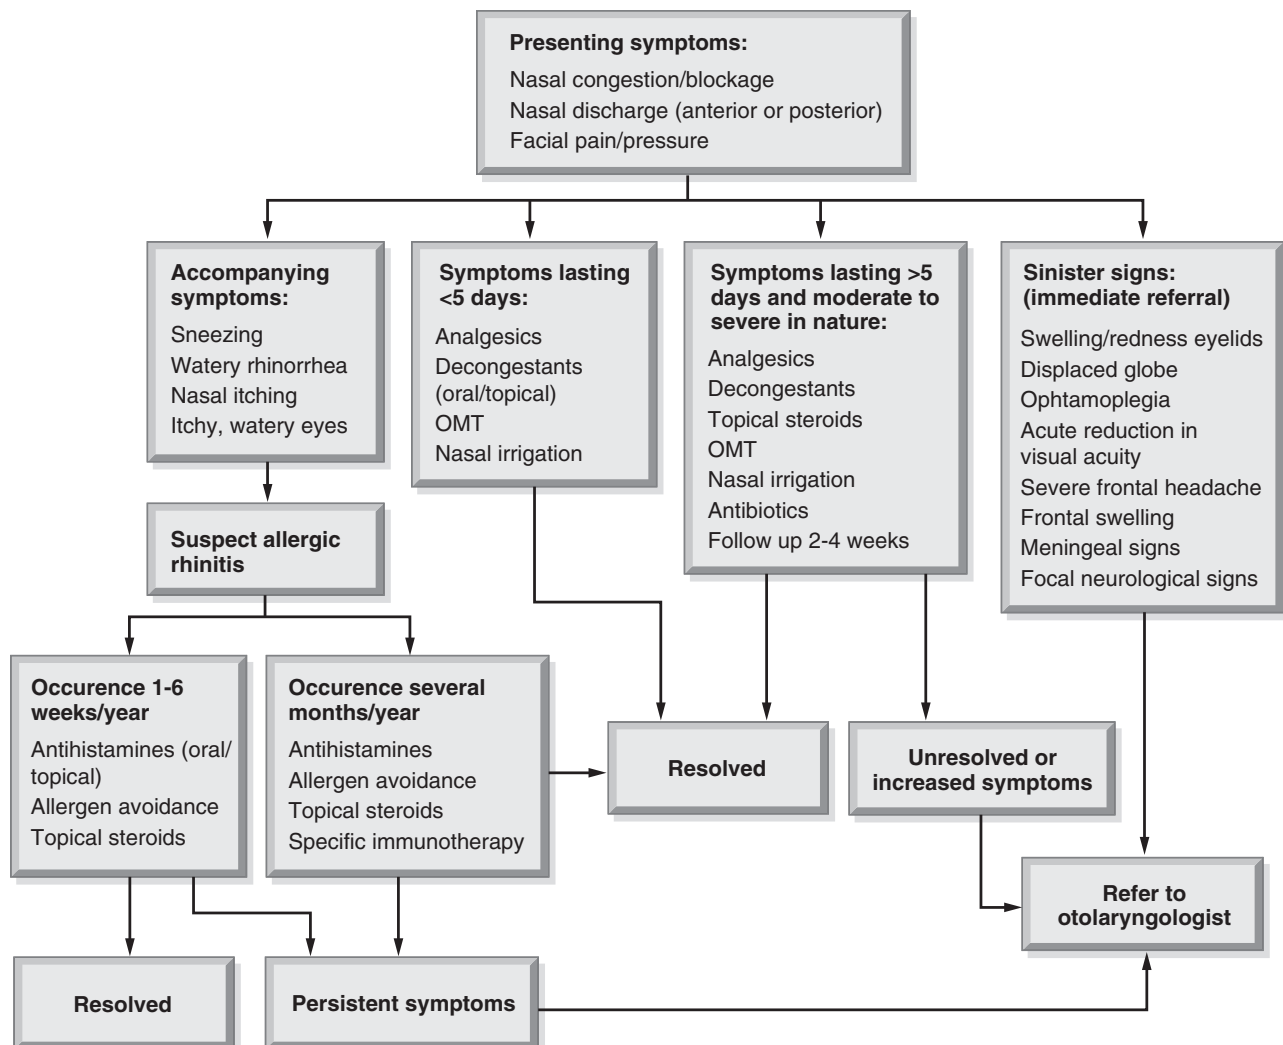

Figure 67-6 Sinusitis algorithm.

important for reducing inflammation and improving health of the mucus membranes. Osteopathic manipulative treatment (OMT) offers a nonpharmacologic approach to rhinosinusitis.

Many nonantibiotic pharmacologic agents are available and often used in the treatment of rhinosinusitis. Current knowledge indicating the role of sympathetic hypoactivity in nasal vasodilation would suggest the use of sympathomimetics (phenylephrine) and alpha-receptor agonists (oxymetazoline, naphazoline) as decongestants. Decongesting the nasal mucosa improves air flow and allows for better mucociliary transport and clearing of contaminants from the sinuses.

Nasal steroids, although more often used in chronic rhinosinusitis and in patients with polyps, are intended to decrease the inflammatory response thereby improving airway patency and mucociliary transport. They may be more effective if used after a nasal decongestant, so as to reach more of the nasal mucosal surface. Antihistamines make sense in the face of seasonal allergic rhinitis. Since many patients have already used over-the-counter antihistamines to treat the symptoms of an upper respiratory infection, overdrying of the mucosa and thickening of the mucus may have occurred. Most of the nonsedating antihistamines are not as apt to cause mucosal drying, but caution needs to be taken to assess whether antihistamines present a deterrent to good mucociliary transport. Guaifenesin has been associated with improvement of the symptoms of nasal congestion and thickened nasal secretions. Studies so far have been unable to demonstrate changes in mucociliary transport or ciliary beat frequency, so its mode of action is unclear (Sisson et al., 1995). Cysteinyl leukotriene blockers, such as montelukast and cromolyn, have been indicated in treatment of asthma and allergic rhinitis to decrease the inflammatory response. These agents are not recommended as first-line agents and are not efficacious when used alone. Patient follow-up in two weeks to assess the success of the treatment regimen is appropriate.

Consultation and referral to an otolaryngologist should be considered for patients who do not respond to treatment of acute rhinosinusitis, who have multiple recurrences, or who have polyps or other nasal structural problems contributing to chronic rhinosinusitis. Patients with chronic rhinosinusitis may require surgical intervention to remove polyps, correct a deviated septum, reduce the size of hypertrophied nasal turbinates, or address the patency of the sinus ostia. Of course, signs of potential complications such as periorbital edema, double vision, ophthalmoplegia, severe, unrelenting frontal headache, or focal neurologic signs require immediate referral (Fokkens et al., 2005).

OSTEOPATHIC PATIENT MANAGEMENT

The way an osteopathic physician proceeds in managing a patient's problem is influenced by how one thinks of influencing the biologic processes of healing. The five, classic treatment models suggest different ways of thinking about osteopathic management. One may focus on a single model or, as often happens, combine several models in a treatment plan. It is helpful to identify the contributions of each model to the particular problems of acute rhinosinusitis.

BIOMECHANICAL MODEL

Sutherland describes rhythmic movement of the facial bones (in particular zygomae, maxillae, palatines, and vomer) acting like a "plunger" on the sphenoid and maxillary sinuses to promote air exchange (Brooks, 1997; Sutherland, 1990). The vomer, forming part of the nasal septum, is important in directing air flow. The location of the sphenopalatine ganglion, as noted above, surrounded

by the palatine, sphenoid, and maxillary bones, puts it at risk for mechanical compromise if there is history of facial trauma. Many patients with nasal and sinus congestion have tenderness over the area of the ethmoid notch of the frontal bone, and respond to release of compression in that area (Cairro, 2003). Attention to the possibility of dysfunction in the cranial base and facial bones should be part of the evaluation of any patient with rhinosinusitis. Manipulative treatment specific to any identified cranial dysfunction is part of addressing the biomechanical issues of both acute and chronic rhinosinusitis. There are also mechanical considerations in the obstruction of venous and lymphatic flow from the head and neck.

RESPIRATORY/CIRCULATORY MODEL

Lymphatic and venous circulations are vital to reducing swelling in any part of the body and the tissues of the upper respiratory system are no exception. Removing metabolic waste products and inflammatory mediators that have accumulated in the tissues is another function of the lymphatic system. It has already been noted that the neuropeptides released from the sensory nerves, when stimulated, in the nasal and paranasal mucosa explain some of the symptoms of rhinosinusitis. OMT focused on removing impediments to venous and lymphatic circulation and stimulating flow when appropriate would aid in decreasing swelling and inflammation in the nasal region. Impediment to flow often presents in the form of myofascial tightness or constriction. Of particular interest is the anatomical area through which the lymph vessels, the thoracic duct, and right lymphatic duct must course to join the venous system. Working within the respiratory/circulatory model would include releasing myofascial tensions in the neck and upper thorax, particularly in the areas of the trapezius and sternocleidomastoid muscles, clavicle, and first rib. Superficial lymphatic drainage techniques such as effleurage to the face are directed at lymphatic flow as it leaves the nose and enters the lymphatics of the skin (Chikly, 2005; Moser, 1953; Schmidt, 1982).

Inhalation/exhalation motion of the ribs and diaphragm excursion also create a pump-like action for venous and lymphatic circulation with alternating negative and positive pressure in the thoracic cavity. Treating somatic dysfunction of the ribs, diaphragm, and their attachments helps promote good venous and lymphatic circulation *via* this mechanism (Stiles, 1977). There are also lymphatic pump and effleurage techniques intended to increase lymphatic circulation once the impediments to flow are removed. These include Galbraith technique for mandibular drainage, thoracic pump, and pedal pump (Chikly, 2005; Galbreath, 1925).

Arterial vasomotor tone is controlled by the sympathetic nervous system and is influenced somatically by dysfunction in the upper neck, where the superior cervical ganglion is located, and in the T1-3 area, the level of origin for sympathetic nerves supplying the head and neck. Lymphatic contractility in the head and neck is also mediated by these sympathetic nerves (Degenhardt and Kuchera, 1996).

NEUROLOGICAL MODEL

In light of current scientific information regarding the autonomic and sensory nervous system's influence on nasal mucosa, the neurologic model may be one of the most powerful ways to think about treating rhinosinusitis. Osteopathic manipulation's impact on somatovisceral and viscerosomatic reflexes offers a mechanism to improve autonomic balance to the upper respiratory mucosa. If, for instance, somatic dysfunction in the upper thoracic or upper

cervical area is inhibiting sympathetic tone or if parasympathetic tone is being facilitated by dysfunction in the sphenoid and palatine areas, the nasal mucosa would be congested and/or produce excessive mucus. Removing the somatic dysfunction allows better balance to be achieved in the autonomic system and nasal mucosa to function more normally. Irritation of the sensory nerves in the nose and sinuses clearly adds to neurogenic inflammation by way of antidromic stimulation and release of neuropeptides (Loehrl, 2005; Sarin et al., 2006). Addressing factors, such as pain and mechanical irritation, which excessively stimulate those reflexes in the nose, can offer an opportunity to reduce inflammation of the nasal mucosa (Lacroix, 2003).

METABOLIC ENERGY MODEL

Fatigue is a complaint that often accompanies rhinosinusitis. Working from a bioenergetic perspective, the physician would consider the impact of somatic dysfunction on body efficiency and energy expenditure. Though not totally explained, there seems to be therapeutic effect related to the energetic interaction of hands-on treatment of various kinds. An awareness of how osteopathic manipulation may impact the patient's feeling of well-being as well as their ability to function more efficiently is consistent with the bioenergetic model.

BEHAVIORAL MODEL

From an osteopathic point of view, educating patients as to behaviors that assist the body's innate healing can go hand in hand with OMT. Encouraging lifestyle modifications such as smoking cessation, allergen avoidance, adequate hydration, efficient breathing, and stress relief are important aspects in the treatment of rhinosinusitis. Informing patients relative to the appropriate use of all pharmacologic agents and symptomatic treatment options will improve patient compliance and satisfaction.

Palpation and identification of the structural and biomechanical dysfunctions associated with their problem can give patients confidence and trust in the treating physician. Patients with chronic rhinosinusitis often experience frustration and difficulty with treatment options. The ability to give them symptomatic relief with manipulative techniques relieves some of the anxiety and stress that accompanies any chronic disease.

DISCUSSION OF RELEVANT STUDIES

The osteopathic literature is replete with case reports and descriptions of the use of OMT to treat upper respiratory conditions including sinusitis. In the 1930s, articles in "The Osteopathic Profession" describe osteopathic manipulative approaches to address lymphatic drainage, normalize circulation, and balance viscerasomatic relationships for patients with sinusitis (Deason, 1935; Schoelles, 1937). L.M. Bush, D.O., at the 1942 American Osteopathic Association meeting in Chicago presented, "How the 'Old Doctor' treated nose and throat conditions," stressing "correction of spinal lesions and lesions of the clavicle" (Bush, 1942). In each of the following decades, case reports, promoting the use of OMT for sinusitis, appear in the literature. Shrum et al. (2001) describe the integration of pharmacologic agents and OMT (occipitoatlantal decompression, rib raising, lymphatic pump, myofascial release to the cervical, thoracic and lumbar areas, and mandibular drainage technique) into the treatment of sinusitis in children. Opinions expressed in letters to the editor of the *Journal of the American Osteopathic Association* in recent years have advocated the use of OMT in the treatment of sinusitis (Abend, 1999; Dudley, 1998).

The physiologic studies of Sato and Schmidt have shown that various types of mechanical, thermal, and chemical stimulation of the skin, muscles, and joints at various spinal levels produce reflex responses in visceral organs (Sato, 1989). That somatic afferent nerve stimulation can reflexively regulate various visceral functions, gives credence to the practice of relieving somatic dysfunction in the upper thoracic and cervical spine to improve function of the upper respiratory mucosa. Beal (1985), reviewed the specific somatic manifestations of visceral disease. Correlation of palpatory findings with visceral diagnoses suggests that an osteopathic structural examination makes a valuable contribution to clinical diagnosis.

Data gathered by the survey responses of 955 osteopathic physicians indicated that 2.49% of the respondents used OMT to treat sinusitis (Johnson and Krutz, 2002). When students were surveyed regarding which conditions they anticipated using OMT as part of their treatment plan, 20% included sinusitis (Chamberlain, 2003). A report on use of OMT in the emergency department suggests that symptoms of sinusitis (as well as several other complaints) could be ameliorated or eliminated with OMT (Paul, 1996).

Experience, coupled with anatomic and physiologic principles, strongly suggests that diagnosing and treating sinusitis, like so many other patient conditions, can be enhanced by the practice of osteopathic principles. This includes patient education and preventative care, musculoskeletal considerations for venous and lymphatic drainage and autonomic balance, use of other medical interventions that acknowledge the patient's self-healing mechanisms and respect their psychosocial milieu.

KEY CONCEPTS

- Osteopathic evaluation of the patient with abdominal pain considers five different domains that involve the musculoskeletal system: posture and motion, respiration and circulation, metabolic functions, neurological functions, and behavioral aspects.
- Differential diagnosis of abdominal pain entails consideration of possible etiologies based on the history and physical using an anatomical, pathophysiological approach.
- The osteopathic evaluation and treatment of abdominal pain considers the effects of somatovisceral and viscerosomatic reflexes, as well as somatosomatic and visceroviscero reflexes.
- Somatic dysfunction may be a primary cause or a secondary finding in patients with abdominal pain and gastrointestinal dysfunction
- Osteopathic management of patients with abdominal pain utilizes five models of osteopathic patient care
- Osteopathic manipulative treatment is used as an adjunct in the prevention and treatment of postoperative ileus and atelectasis which often occurs after abdominal surgery for treatment of acute abdominal pathology.

CASE VIGNETTE

PATIENT PRESENTATION

Chief Complaint:

Right lower quadrant (RLQ) abdominal pain.

History of Chief Complaint:

Janequa is a 28-year-old African American female who presents to the emergency department (ED) on a weekend with increasingly painful RLQ abdominal pain over the past 8 hours. It is accompanied by slight nausea, but no vomiting. The doctor on call for her primary care physician recommended she go to the ED for evaluation. She was brought by car from home. Onset was initially 3 weeks prior, with fluctuating pain daily since then, but usually tolerable. The pain intensity ranged from 2 to 5/10, but today it rose to an 8 on a scale of 10 (8/10) after lifting groceries out of the trunk of her car. The pain initially began after she traveled to Brazil for a week. She carried heavy luggage to and from the airport, and felt a pull in her right side when yanking it off the conveyer belt. The pain is constant now but had previously varied throughout the day depending on her activities. It is dull in nature, but does not have a cramping, off and on, quality. The pain has been in the RLQ without radiation since onset. Food does not make it worse. Medications such as aspirin, ibuprofen, and acetaminophen have not helped. It is worse with standing up after bending over while lifting over twenty pounds. The pain seems to be least when she is lying on her side in the fetal (knee to chest) position. There is no change in the pain with application of heat or cold. Her menstruation has been regular, normal in amount without clots, and neither exacerbates nor ameliorates the pain. Her pain is such that she cannot tolerate vacuuming, reaching into the cupboard over the kitchen counter, or sexual intercourse. She had right flank pain for 2 days 4 months ago when she passed a kidney stone.

Past Medical History:

No hospitalizations. She denies having any medical illnesses and takes no prescription medications, other than her oral contraceptives. No history of sickle cell disease, ulcer disease, gallstones, cholecystitis, gastritis, colitis, appendicitis, tuberculosis, diabetes, or lupus erythematosus.

Past Surgical History:

She reports no surgeries in the past.

Family History:

Her mother is 54, had cholelithiasis and cholecystectomy, multiple kidney stones through the years, but no renal failure. Father is 56 and has hypertension and diabetes. Two brothers, 34 and 32, and her sister, 26, are well.

Social History:

The patient is an executive secretary, newly married with no children, working long hours but enjoys her work. She does not smoke and denies any illicit drug use. She rarely drinks alcohol. She is not active in sports. She recently traveled to South America with her husband on her honeymoon.

Allergies:

She denies any allergies to known medications.

Medications:

No prescription medications; multivitamins, herbal products from a friend who sells them to her for weight maintenance, unknown contents.

REVIEW OF SYSTEMS

General:

She normally sleeps well but has been sleeping poorly due to this pain. She is very health conscious and has exercised

regularly before this pain started. She describes her nutrition as excellent. She denies fevers, chills, night sweats, recent weight loss or gain, although she feels not as hungry when the pain intensity increases.

Skin:

No history of rashes, moles, scaling.

HEENT:

No history of head trauma, changes in hearing, vision, smell, taste, or swallowing. No sore throat or swollen neck glands.

Cardiovascular:

No history of chest pain, shortness of breath, palpitations, congestive heart failure.

Respiratory:

No history of cough, phlegm, wheezing, or pneumonia.

Gastrointestinal:

She has had slight nausea, but no vomiting, diarrhea, constipation, hematemesis, melena, or hematochezia; no history of gastroesophageal reflux disease; no increased flatulence or bloating; she has normal daily bowel movements with no change in the color of her stool. No history of intolerance to fatty or fried foods.

Gynecological:

G0P0, she is sexually active, has unprotected intercourse with a single partner, has not missed any periods which have been regular and not heavier or lighter than normal; intercourse had not been painful for her prior to the onset of pain, but is now.

Genitourinary:

Has had a kidney stone, passed without sequelae 4 months ago, no recent hematuria, dysuria, or change in color of urine.

Neurological:

No history of seizures or stroke; no weakness, spasms, ticks, or problems with coordination.

Hematological:

No history of anemia, no sickle cell anemia or trait; any hemorrhage or abnormal bleeding diathesis.

Musculoskeletal:

No history of fractures, dislocations; had a sprained right ankle playing tennis 8 years ago; she gets occasional low back pain which resolves spontaneously with stretching. She denies joint pains or swelling.

PHYSICAL EXAM

Vital signs:

Pulse supine: 100/min; seated: 108. BP supine: 120/72 mm Hg; seated: 124/70. T: 37.5°C., R: 16/min, height: 5'8", weight: 145 lb.

General:

This is a well-developed, well-nourished female in moderate distress due to her abdominal pain, laying comfortably on her right side with knees flexed to chest.

HEENT:

Pupils are equal, round, and reactive to light and accommodation; external ocular muscles are intact; no skin lesions; mucous membranes slight dry otherwise oral exam normal; neck was supple; no bruits; no enlarged lymph nodes are present.

Heart:

Slight tachycardia, with regular rhythm; no extra sounds, murmurs, or rubs.

Lungs:

Clear to auscultation in all fields.

Abdomen:

No scars were present; no asymmetry to inspection; bowel sounds normal in all quadrants; moderate RLQ discomfort to palpation which is nonradiating; no masses or abnormal pulsations are palpated; no rebound tenderness is elicited. There is no guarding or costovertebral tenderness.

Pelvic exam:

Normal external and internal anatomy; no masses palpated; slight referral of pain to the RLQ on bimanual examination; no discharge or unusual odor noted, no cervical motion tenderness.

Breasts:

No masses, erythema, asymmetries, or discharge.

Rectal Exam:

tone is normal; no masses present; stool is brown, soft, no gross blood, and Guaiac test is negative for occult blood.

Extremities:

Normal range of motion all joints; no swelling is present; no pain is elicited on motion testing; no skin lesions are present; and pulses are present and normal to all extremities; capillary refill is less than 2 seconds in fingertips, nail polish occludes visualization of nail beds.

Neurological:

CN II to XII grossly intact; no sensory or motor abnormalities present; DTRs are 2+/4+ in biceps, triceps, brachioradialis, patellar, and Achilles tendons bilaterally. Babinski's tests elicit plantar flexion bilaterally.

Osteopathic Structural Exam:

Patient is examined in the standing, seated, prone, and supine positions for evidence of structural landmark asymmetries, altered range or quality of motion, tissue texture abnormalities, tenderness, or temperature variations.

Gait:

Gait is not antalgic but her left lower extremity is slightly externally rotated.

Postural Landmarks:

The right shoulder is inferior to the left; the head is held forward of the gravitational line; thoracic kyphosis is diminished as is the lumbar lordosis; the right anterior superior iliac spine is superior, right posterior superior iliac spine is inferior; the right leg appears shorter by 3 mm with the patient supine.

Active Motion:

Trunk sidebending left is restricted. There are positive right standing and seated flexion tests; in the prone position, with

the patient backward bending, there is a right rotated sacrum on a left oblique axis and L5 is flexed, rotated left, and sidebent left (L/R sacral torsion).

Passive and Inherent Motion:

There is an externally rotated right temporal bone; C2-3 is flexed, rotated left, sidebent left (FR_LS_L); T1 is extended, rotated right, sidebent right (ER_RS_R); T5 is extended, rotated right, sidebent right (ER_RS_R); T6 is extended, rotated left, sidebent left (ER_LS_L); L1 is flexed, rotated right, sidebent right (FR_RS_R); there is poor compliance of the sacrum to posterior-anterior pressure at L5-S1 (positive spring test); the right thoracic diaphragm is restricted in inhalation; her axial fascial pattern is rotated left in at the craniocervical junction, rotated right at the cervicothoracic junction, rotated right at the thoracolumbar junction and rotated left at the lumbosacral junction (L/R/R/L) there is restricted internal rotation of the left femur.

Soft Tissue Palpation:

There are no abnormal temperature variations over the abdomen or back regions; the superior mesenteric ganglion area is tender to palpation; the right psoas is hypertonic and shortened, and there is a positive right counterstrain tender point for the psoas muscle (see also Chapter 49); a positive left piriformis tender point (see also Chapter 49); there were no Chapman's points palpable at the stomach, liver, small intestine, large intestine, kidneys, and appendix sites. (see also Chapter 52G:)

DIFFERENTIAL DIAGNOSES

Regardless of the region of the abdomen in which the patient states she has pain, since the visceral afferents diverge several segments within the spinal cord, the pain is not always an accurate indicator of the precise location of a visceral pathology. The differential diagnosis of subacute RLQ abdominal pain without bowel changes in a female of child-bearing age includes infectious, inflammatory, metabolic, and mechanical pathology. As an Osteopathic Emergency Physician, the first priority is to rule out a life-threatening illness. For example, an ectopic pregnancy is a true medical/surgical emergency where the patient could bleed profusely from a ruptured fallopian tube and die within minutes, before definitive care can be delivered. The patient must be quickly evaluated and any necessary treatment measures begun immediately. Given this patient's presentation, several emergency conditions need to be ruled out. Ectopic pregnancy, appendicitis, infection, internal bleeding, hydronephrosis, hepatitis, pancreatitis, ruptured diverticula, perforated bowel and bowel obstruction are at the top of the list. Possible urgent conditions also include pregnancy, placenta previa if pregnant, salpingitis, ovarian cyst, endometriosis, tumor, kidney stone/infection, cystitis, and colonic inflammation.

OSTEOPATHIC PATIENT MANAGEMENT

Biomechanical Model

In the ED, whether there is or is not any signs of somatic dysfunction, it is imperative to first distinguish whether a patient with abdominal pain has pathophysiology requiring solely medical management or will require surgical management as well. If there is somatic dysfunction present, as in this patient's case, the osteopathic physician should determine if it is a primary musculoskeletal disorder or secondary to internal organ pathophysiology. If the somatic dysfunction is determined to NOT be primarily of

musculoskeletal origin, such as is found in the case of viscerosomatic dysfunction, osteopathic manipulative treatment (OMT) may not be the primary treatment for the patient. However, the osteopathic physician should consider whether osteopathic evaluation or treatment using OMT could help to diagnose or treat the condition better, as an adjunct to the primary treatment, which may be medical and/or surgical. If the patient has a surgical abdomen, meaning her abdomen would require life-saving surgery and is typically firm and tender, her soma should display signs of guarding and protecting an obstructed or inflamed internal organ. Related Chapman's reflex points should be positive. Another consideration is whether osteopathic principles or OMT could assist in making the patient a better operative candidate. Can osteopathic principles or OMT assist the patient to better handle the postoperative phase? Can osteopathic principles or OMT assist the patient in the recovery phase? Conversely, if the somatic dysfunction is determined to be primarily of musculoskeletal origin and there is no evidence of internal organ pathophysiology, as in this patient's case, then OMT would be the treatment of choice for her problem. Muscle energy treatment using isometric contraction against a controlled resistance, followed by relaxation and passive stretching to lengthen the psoas would be effective. Alleviation of the spinal somatic dysfunctions with high-velocity low-amplitude (HVLA), muscle energy, or other OMT procedures would also be beneficial.

The normal fascial patterns in a healthy patient are either L/R/L/R or R/L/R/L/ pattern at the transition zones. Her fascial pattern would indicate especially a loss of compensation and therefore a problem in the thoracolumbar region. The pattern of somatic dysfunctions of the ipsilateral respiratory diaphragm and psoas muscle with the contralateral piriformis muscle is a very common pattern with psoas syndrome.

The Thomas Test (7) involves flexing one hip joint at a time in the supine patient, whose legs from the midfemurs distally are off the end of the table, and comparing the distance of separation of the extended thigh from the table. For example, with a tight, hypertonic, and shortened psoas muscle on the right, the right leg will be pulled away from the table further upon flexion of the left hip joint compared to the contralateral test. This is seen as a screening test only and is not specific for the psoas, as other conditions (i.e., hip joint capsule restrictions) can influence this test as well. Sometimes with a very flexible patient the Thomas test will be normal despite a psoas dysfunction being present. However, in the patient with a normal hip joint, a positive test is a good indicator of psoas hypertonicity. The counterstrain tender points for the psoas and iliacus muscles provide further evidence of a primary psoas dysfunction/spasm. The points are palpated and the findings compared left with right. In the case of this patient, both the Thomas test and the counterstrain tender point for the right psoas muscle were positive, indicating a somatic dysfunction of the right psoas muscle.

The psoas muscles are attached to the vertebral bodies and the anterior surface of the transverse processes of the lumbar vertebra. They pass along the superior border of the true pelvis, are joined by the iliacus muscles, pass over the superior ramus of the pubes, and then turn posteriorly to insert on the lesser trochanter of each femur via common tendons.

Psoas syndrome is usually initiated when a person assumes any number of positions that shorten the origin and insertion of the psoas muscle for a significant length of time and then gets up quickly, suddenly lengthening the origin and insertion, and attempts to assume normal upright activity. The initial positions that might bring about this syndrome include sitting in a soft easy chair or recliner, bending over from the waist for a long period of time, working at a desk, or weeding in the garden. Psoas

syndrome can also be precipitated by overuse, such as doing sit-ups with the lower extremities fully extended. Apparently, each of these situations creates a neuromuscular imbalance that results in psoas muscle hypertonicity. The subsequent formation of somatic dysfunction then affects the psoas muscle and the lumbar spine. Once a patient realizes that he or she has been in one of these positions, the possibility of initiating a psoas syndrome can usually be avoided if he or she *slowly* returns to a neutral postural position.

The physician must be aware that there are organic causes for psoas tension or spasm, and if suspected, these must be ruled out by history and/or physical examination and special tests. These include:

- Femoral bursitis
- Arthritis of the hip
- Diverticulosis of the colon
- Ureteral calculi
- Prostatitis
- Cancer of the descending or sigmoid colon
- Salpingitis
- Psoas abscess

The key somatic dysfunction initiating or perpetuating psoas syndrome is believed to be a type II (nonneutral) somatic dysfunction (F Rx Sx) usually occurring in the L1 or L2 vertebral unit, where “x” is the side of side-bending of the somatic dysfunction. If this key somatic dysfunction remains, the patient’s symptoms may progress to full-blown psoas syndrome. Osteopathic structural exam findings indicative of this syndrome include:

- The key, nonneutral (type II) somatic dysfunction at L1 or L2
- Sacral somatic dysfunction on an oblique axis, usually to the side of lumbar side-bending
- Pelvic shift to the opposite side of the greatest psoas spasm
- Hypertonicity of the piriformis muscle contralateral to the side of greatest psoas spasm
- Sciatic nerve irritation on the side of the piriformis spasm
- Gluteal muscular and posterior thigh pain that does not go past the knee, on the side of the piriformis muscle spasm

Manipulative treatment is preceded by ruling out psoas involvement caused by one of the organic etiologies previously listed. Effective treatment of the “key” somatic dysfunction (usually found at L1 or L2) is essential for the patient’s comfort and for effective, long-lasting effects of manipulative treatment, regardless of the administration of other indicated medicines, chemotherapy, radiation, or surgery. Removing somatic dysfunction, wherever it occurs in the body, reduces afferent load to the spinal cord from secondary somatic sources and lessens the segmental activity of the primary facilitated spinal cord segments. This makes the patient more comfortable and supports the body’s homeostatic and defense mechanisms, thus hastening recovery.

An iliopsoas or psoas somatic dysfunction with hypertonicity and muscle shortening present for a long enough period of time can create a posterior position of the ipsilateral innominate. This is likely due presumably to the superior pull from the muscle leading to a compensatory shift of the innominate to ease tension within the muscle. This often leads to a functional (not anatomic) shortening of the ipsilateral leg, as is demonstrated by this patient.

The L5, sacrum, and innominate dysfunctions are likely compensatory to the initial psoas dysfunction (8).

The C-spine (C3-5) somatic dysfunction is likely related to her diaphragm somatic dysfunction via somatosomatic reflexes. (see also Chapter 13) The temporal bone somatic dysfunction is likely secondary to the cervical and sacral somatic dysfunctions. The “normal” Chapman’s points for the foregoing organs lend

further weight to the hypothesis that the internal organs are not primarily involved in her case but rather secondarily altered. (see also Chapter 52G)

Respiratory-Circulatory Model

This patient’s respiratory and circulatory functions seem to be intact. On exam, her resting pulse and respiratory rates are slightly elevated and her mucous membranes are slightly dry. This raises the possibility of her being volume depleted, but her blood pressure was within normal limits, and she was not dizzy upon standing. If she was volume depleted, that is, dehydrated, her blood pressure would drop more than 15 mm Hg, and/or pulse rate rise, more than 15 beats per minute, respectively, upon sitting from the supine position. But since her blood pressure is stable, her elevated heart and respiratory rates, and dry membranes, are therefore likely due to pain and anxiety as opposed to hemorrhage. She may have an ectopic pregnancy causing these signs, and the urine pregnancy test will help to rule that out.

An air embolism is typically discovered on plain upright abdominal x-ray under the diaphragm. Although causing some pain and bloating, the intensity of this pain is lancinating if the air transects fascial planes, that is, through the abdominal wall or fascia of the diaphragm, which is contiguous with the pericardium and fascia of the mediastinum. On occasion, air can enter the vaginal canal and find its way through the uterus, fallopian tubes, and into the abdominal cavity. A perforated intestine from ruptured diverticula, cancer, and inflammatory bowel disease can also cause air embolism, but there is no evidence in her history or physical exam to support this.

The color of the stool is another important finding when assessing a patient with abdominal pain. A finding of bright red blood makes us think of processes nearer to the anus, for example, hemorrhoids. While a finding of black tarry stool makes us think more of upper gastrointestinal (GI) processes, for example, a stomach or duodenal ulcer with bleeding. A normal color does not rule out GI bleeding. A Guaiac test is a test for occult blood in the stool. The test is done at the bedside following a rectal exam. If the stool is negative for gross blood and the Guaiac test is negative for occult blood, we can be fairly sure that there is no process present involving bleeding from the bowels. The normal vascular exam of the abdomen and lower extremities ruled out aortic aneurysm as well as other vascular problems or bleeding abnormalities in this patient.

An intravenous (IV) line was started with normal saline (NS) at 125 cc/h, as she was kept “n.p.o.” (*Latin*—nil per os—nothing by mouth); oxygen was started per nasal cannula at 2 L/min, which could have been titrated upward as needed in case of shortness of breath, and a heart monitor was attached to her chest to continually assess whether her heart maintained its normal sinus rhythm or required further interventions due to an arrhythmia, for example. Blood was drawn; urine was obtained and sent to the lab.

Recall that the patient’s resting pulse and respiratory rate are slightly elevated and her mucous membranes are somewhat dry, which is likely due to anxiety, given her negative lab and radiological studies. If this patient did have tachycardia due to blood loss or dehydration, she would need greater amounts of IV fluids, usually NS or lactated Ringers solution (5). Starting oxygen and attaching an EKG monitor are standard measures in the ED to support and monitor the patient (6).

Neurological Model

An appreciation of the neuroanatomy of nociception is helpful in discerning the cause of acute abdominal pain. Both somatic (peripheral nervous system) and visceral (autonomic nervous

system) innervations are involved. Visceral afferents transmit noxious stimuli, such as stretch, distention, inflammation, and ischemia, to the central nervous system (CNS). However, other tissue-destroying processes, such as is found with some intra-abdominal tumors or cancerous growths, or cutting and burning during surgery, cannot be perceived via these visceral afferent nerves and are thus not perceived as pain by the patient.

In the abdomen, the sympathetic component is contributed by the thoracic, lumbar, and pelvic splanchnic nerves, and the parasympathetic by the paired vagus nerves arising from the tenth cranial nuclei of the brainstem and the sacral splanchnic nerves arising from S2-S4 spinal segments (see also Chapter 10). The sympathetic cell bodies are in the intermediolateral cell columns of spinal segments T1-L2 with axons traversing through the ventral roots to the paravertebral ganglia. These paired chains of interconnected ganglia lie along each side of the spinal cord just anterior to the heads of the ribs like a string of pearls. The fibers from the paravertebral sympathetic chain ganglia converge anteriorly to form the sympathetic prevertebral or collateral ganglia: the greater splanchnic nerves from segments T5-9 form the celiac plexus; the lesser splanchnic nerves from segments T10-11 form the superior mesenteric plexus and the least splanchnic nerves from segments T12-L2 form the inferior mesenteric plexus. Postganglionic fibers innervate their target organs.

The parasympathetic innervation structure is more streamlined. Long, preganglionic axons from the vagus nerves extend through the prevertebral ganglia as they pass directly to the viscera. Their short, postganglionic fibers form part of the network in the visceral wall called the enteric nervous system. Both the sympathetic and the parasympathetic nerves exert their effects through the enteric nervous system. This network of fibers is composed of two layers. The outer myenteric (Auerbach) plexus controls GI motility. The inner plexus (Meissner) controls GI secretion and local blood flow. Perception of nociceptive stimuli results in alterations in gut function mediated at this level. For example, marked reduction in gut motility—ileus—commonly occurs in peritonitis via viscerovisceral reflexes.

Specific aspects of this anatomy explain why visceral pain is initially perceived as vague in location and quality. (see also Chapter 10) It is generally described as aching in nature, rather than sharp or intense, and is perceived as originating in the one of three midline regions versus a discrete unilateral location. This relates partly to the paucity of visceral afferents compared with the large number of somatic afferents originating in skin and musculoskeletal structures. Equally important is that the transmission of visceral pain occurs via slow nonmyelinated C fibers versus the fast-conducting A- δ fibers that transmit somatic pain.

Finally, the initial location of pain as regional versus specific relates to the embryologic development of abdominal viscera as midline structures with midline neurovascular supply. They divide into foregut (T5-9), midgut (T10-11), and hindgut (T11-L2) areas. Foregut structures include the distal esophagus, stomach, and the proximal duodenum, as well as the liver, biliary tree, and pancreas. Midgut structures include the small intestine, appendix, ascending colon, and proximal two third of the transverse colon. The hindgut includes the distal third of the transverse colon, the descending colon, and the rectosigmoid. They are loosely associated with the celiac, superior mesenteric, and inferior mesenteric ganglia, respectively. Thus, in general, pain from structures innervated at these levels will be perceived as occurring in the epigastric, periumbilical, or hypogastric midline areas, respectively.

The somatic component of acute abdominal pain is caused by the parietal peritonitis that occurs adjacent to the involved viscera as inflammation progresses. Also referred to as the “percutaneous

reflex of Morley,” it is conducted by A- δ fibers following the associated dermatome to unilateral spinal segments, which results in the localization and increasing intensity of acute abdominal pain, as well as the increased muscle tone of the abdominal wall associated with guarding and rebound tenderness.

The third component of acute abdominal pain, known as referred pain, is a clear example of how structure determines function. Referred pain is defined as discomfort occurring in a site distant from the diseased viscus. The explanation of referred pain lies in the intricacies of the neuroanatomy previously described. The spinothalamic tract is largely nondiscriminatory for visceral versus somatic pain. Because somatic nervous input far exceeds visceral, the CNS is “fooled” and perceives the pain as originating partly in the peripheral structures innervated by the same spinal segments as the diseased viscus. For example, the pain initiated by gallbladder inflammation (T7-8 visceral afferent innervation) is perceived as occurring in the right subscapular area (T7-8 somatic afferent innervation).

In a similar manner, visceral afferents synapse on interneurons in the spinal cord that stimulate somatic efferent neurons at the same level. This local reflex activity is referred to as a viscerosomatic reflex. It results in somatosensory changes palpable in a paraspinal location as tissue tenderness, asymmetry, range-of-motion restriction, and tissue texture changes. The finding of specific somatic dysfunction in a patient with acute abdominal pain can provide useful information as to the origin of the pain. The paraspinal location should direct one to consider organs known to have sympathetic innervation at the same level, resulting from the fact that visceral afferents that trigger viscerosomatic reflexes predictably follow the sympathetic efferent pathways. (see also Chapter 39)

With this discussion of nociceptive anatomy as a backdrop, consider the more clinical aspects of our patient with acute abdominal pain. The patient does not show signs of peritoneal inflammation or an acute abdomen and her vital signs are stable. The onset of the pain began shortly after strenuous physical activity and was associated with decreased ability to perform activities that required her to extend her hip and trunk. The pain intensity gradually increased over a period of weeks, as opposed to pain from an obstructed viscous or acute inflammatory process which typically has a more rapid progression of pain intensity.

With the patient supine, the sensitivity of the connective tissues surrounding the collateral sympathetic ganglia can be assessed gently palpating the abdomen overlying these areas. Assessment involves determining increased subjective sensitivity as well as tissue texture changes in these regions. Positive results will lead to further assessment of structures related to the altered ganglion. In this patient, a tender and noncompliant superior mesenteric ganglion area can be a sign of visceral pathology involving, for example, the small intestine or proximal half of the large intestine, or a kidney; or it can mean an increased afferent input to the segments T10-11 from another somatic structure, for example, the lower extremity or the respiratory diaphragm. In this patient, the decreased mobility of the right kidney compared to the left side (which can also be in part due to the respiratory diaphragm somatic dysfunction on the right) could be the explanation of the tissue texture changes felt around the superior mesenteric ganglion (3).

A common neurologic problem causing superficial abdominal pain is shingles (herpes zoster), which are vesicular, painful lesions along a cutaneous peripheral nerve, usually the intercostal nerve in the intercostal space, resulting from prior infection as a child (varicella zoster, aka “chicken pox”). However, her skin had no lesions so this possibility is highly unlikely.

Certainly, lower thoracic or upper lumbar spinal disease could cause nerve irritation, inflammation, and radiation of pain into the

lower abdomen. Although there was spinal somatic dysfunction, there was no history of trauma, cancer, or metastasis, and disc herniation is not common in this patient's age group, so these are least likely possibilities.

While the diagnostics to rule out emergent and urgent processes are ongoing, treatment involves primarily pain management, as well as OMT modalities. OMT to relieve pain is most efficacious when there are palpable signs of somatic dysfunction related to the pain, that is, muscle spasm, fascial restrictions, tissue congestion, or tenderness. Often, visceral OMT relieves pain related to tissue congestion, strain-counterstrain OMT relieves tenderpoints and myofascial, articular procedures or muscle energy OMT releases muscle spasms and connective tissue restrictions; HVLA may be used for restricted joint motion refractory to less forceful methods. For paraspinal muscle spasms and Chapman's reflex nodules, inhibition (sustained digital pressure with a slight circular motion) OMT is helpful.

An extremely important issue is whether or not to give analgesic (pain) medication to the patient pending lab and imaging studies as well as while awaiting consultations. Theoretically, if the patient receives a strong analgesic, they will no longer be able to respond appropriately to the assessment, and we will get confusing results from our examination. The patient is asking for medications for her pain. Current practice guidelines recommend using short-acting narcotic analgesics to control the patient's pain while undergoing laboratory and radiographic procedures and waiting for consultants to come to perform their evaluations (4).

Metabolic Energy Model

Four of the most common causes of acute abdominal pain that warrant surgical intervention include acute appendicitis, acute cholecystitis, diverticulitis, and small bowel obstruction. In each of these diseases, inflammation and infection are the result of obstruction of normal function of a hollow viscus or duct structure. The obstruction results in luminal distention, stasis of organ contents, which causes back pressure against the organ walls. Because venous and lymphatic drainage are passive, low-pressure networks, the increasing back pressure prevents proper drainage of these tissues, resulting in organ wall edema. This progresses to arterial obstruction and ischemia. Ischemia leads to wall gangrene, perforation, and peritonitis.

Because the GI tract is colonized with varying levels and types of bacteria, the stasis described above causes bacterial overgrowth. Transmural infection of the compromised viscus results and contributes to the peritonitis caused by gangrene and perforation. Bacterial liberation of endotoxins and the release of inflammatory mediators result in the systemic septic response. Inflammation and infection increase metabolic processes, elicit release of interleukins and other cytokines with subsequent generation of fever. Fatigue ensues. Left untreated, the systemic inflammatory response syndrome of multiple organ failure occurs with high levels of comorbidity and mortality.

In considering metabolic pathophysiology as the source of her abdominal pain, recall that she had nausea, but she did not have any other signs of GI or genitourinary system dysfunctions, including vomiting, oral or rectal bleeding, bloating, or fevers. She has a history of a kidney stone, and it is possible she has one again with associated muscle spasm related to a viscerosomatic reflex. An abdominal (kidney-urinary-bladder, or "KUB") x-ray would identify a calcium stone if present in a kidney or ureter; however, the absence of costo-vertebral tenderness argues against kidney stone or infection. A urine test is an inexpensive means by which hematuria could be detected if there is a ureteral stone, kidney or bladder inflammation, infection or hemorrhage. Although she has had regular menstruation

cycles and flow, a urine pregnancy test will help confirm she is not indeed pregnant and rule out ectopic pregnancy. If necessary an abdominal ultrasound would detect swelling, enlargement, cysts or masses in the liver, spleen, pancreas, intestines, kidneys, ovaries, fallopian tubes or uterus as would an abdominal or pelvic CT.

Although she is afebrile, this does not necessarily rule out an intra-abdominal infection and/or inflammation or other noninfectious pathology. Typically, intra-abdominal inflammation causes inflammation of the peritoneal lining of the intra-abdominal wall. As there was no rebound abdominal tenderness on physical exam, which is a fairly reliable sign of peritonitis, this possibility is unlikely. In this patient, the absence of rebound tenderness and palpable masses and the presence of normal bowel sounds make it less likely that she has a significant intra-abdominal pathology. A computerized tomography scan would help to rule out masses or abnormal anatomy from other pathophysiological processes.

The right ovary and/or fallopian tube could be inflamed, obstructed, or cystic and cause pain without causing a fever, so these pathologies are possible given her symptoms. The physical exam, including lack of Chapman's reflexes, did not localize a pathologic pelvic structure, though pain was felt in the RLQ during the pelvic bimanual exam.

The decision as to which lab tests to order is often a difficult one. Ideally, this is based upon having a solid differential diagnosis in mind. Lab test results should not be seen as a definitive "rule-out" but rather as another piece in the larger puzzle of the entire presentation of the patient. For example, with a normal complete blood count (CBC) and "normal" abdominal ultrasound studies, one might be inclined to rule out appendicitis in this case (1). That would be unwise as some cases of appendicitis have been found in spite of negative laboratory and radiographic tests. Similarly, with normal liver function studies and normal abdominal ultrasound exam, you might be inclined to rule out gall bladder disease. Keep in mind, however, that although the false-negative rate of abdominal ultrasound for detection of gallstones is less than 5%, sole reliance on this modality may miss a diagnosis of small stones or disease that could cause abdominal pain and require surgical treatment (2). A urine drug screen test is also helpful as the patient may not divulge use of illicit drugs during the history.

The results are back from the laboratory and radiology departments. Blood tests: CBC with differential is within normal limits, as are the electrolytes, amylase, lipase, liver function studies, and blood urea nitrogen: creatinine ratio; Urinalysis is negative for white blood cells, red blood cells, or nitrates. Drug screen is negative. Guaiac test is negative for occult blood. Urine and serum pregnancy tests are negative. Review of the abdominal x-ray series shows no free air, calcifications, or other pathology. Ultrasound study of the abdomen shows no pathology, and abdominopelvic CT study shows no free fluid, no masses, no abnormal visceral or vascular structures. Thus, a hemorrhagic problem, anemia, electrolyte abnormality, illicit drug use, pregnancy, urinary obstruction, renal failure, urinary tract infection, intra-abdominal, or intra-pelvic pathology were ruled out. If any of these test results are positive or equivocal (unable to discern positive vs. negative test), general surgical and/or gynecological consults would be ordered for opinions from their perspective as well as management beyond the ED in case the patient requires hospital admission or ambulatory care follow up with a surgical specialist.

Behavioral Model

Behavioral issues such as anxiety or depression, drug abuse, especially opiates, may all cause abdominal pain. A urine drug screen

would help determine if drug abuse is a potential cause of her pain. Anxiety and depression are possible in her situation, but less likely to cause such severe abdominal pain as she expresses. With somatic dysfunction in so many regions of the body, and constant pain, as well as being newly wed, anxiety is certainly part of the problem, and there may be underlying depression that was not admitted to in the history.

CASE VIGNETTE (CONTINUED)

The patient was treated with myofascial release (MFR) technique for the thorax and respiratory diaphragm; counterstrain, muscle energy technique (MET) and Still techniques for the right psoas; visceral techniques for the superior mesenteric ganglion and right kidney; counterstrain, MET for the left piriformis hypertonicity; MFR for the left pelvic floor; MFR, MET, and HVLA techniques for the right innominate; MFR, MET, and Still techniques for the sacrum. The patient tolerated the OMM treatment very well and reported a reduction of symptoms of about one-half, from 8/10 to about 4/10. She did not feel a need for medications at that point.

Final Diagnoses

The work-up for medical or surgical pathology was negative. The final diagnoses were as follows:

Somatic dysfunctions of the lower extremities, abdomen, costal cage, pelvis, lumbar spine, thoracic spine, cervical spine, and cranial regions. (ICD-9: 739.6, 739.9, 739.8, 739.5, 739.3, 739.2, 739.1, 739)

The primary source of her abdominal pain was attributed to a psoas spasm.

Disposition of the Patient

Based upon the negative work-up, negative consultation results, and excellent response of the patient to the OMM treatment, the decision was made to discharge the patient home

with follow-up with a local osteopathic physician specializing in NMM/OMM or skilled in using OMT. The patient was instructed to return to the ED or to her regular family doctor if the symptoms did not improve, worsen or, if they resolved from this treatment but returned again.

Further Treatment Modality Options

Treatment emphasizing self-help techniques for the patient will allow the patient to be an active part of her own return to homeostasis. Muscle-energy techniques for the psoas and piriformis muscles can be easily learned and applied several times daily for a faster and better result. (see also Chapter 46) MFR for the respiratory diaphragm and superior mesenteric ganglion can likewise be learned and applied regularly. (see also Chapter 47)

KEY CONCEPTS

- Osteopathic considerations for the patient with low back pain (LBP) entail assessing and treating biomechanical, respiratory-circulatory, metabolic-energy, neurologic, and behavioral aspects of the clinical condition.
- Differential diagnosis utilizes a structure-function approach in determining whether the pain is due to spinal or pelvic musculoskeletal somatic dysfunction, localized manifestation of a systemic pathophysiologic process, or referred from internal organ disease.
- Most causes of LBP are musculoskeletal and amenable to osteopathic manipulative treatment.
- Evidence-based literature and expert consensus guidelines support the utilization of OMT for patients with acute, subacute, and chronic back pain.
- The AOA House of Delegates passed a resolution accepting an evidence-based practice guideline recommending utilization of OMT for patients with LBP.

CASE VIGNETTE

Chief Complaint:

Low back pain (LBP)

History of Chief Complaint:

A 52-year-old male presents to the ambulatory clinic complaining of persistent LBP for the past 3 weeks. The pain started a few days after he hurt his left knee playing tennis. His knee pain has improved and he is no longer limping, but now he is experiencing dull, achy constant pain in the area of his low back, primarily on the right side. The pain is exacerbated with prolonged sitting and lifting more than 25 lb. It seems to get better with rest and lying down, although he does admit to having difficulty with finding a comfortable position when sleeping and prefers to lie on his side with his knees bent. The pain is sometimes sharp and radiates to the right posterior thigh, but not past the knee or into the foot. In the past, he had LBP that did radiate to the lateral foot, causing an intermittent numbness sensation, but it resolved after a week or so with decreased physical activity and stretching. He has also contended with dull and aching back pain periodically throughout the years that also resolved spontaneously after a couple of days. Over-the-counter nonsteroidal anti-inflammatory drugs (NSAIDs) offer some relief and reduce his current acute LBP from 8/10 to 4/10 in intensity. He is usually relatively active and enjoys playing tennis and golf on the weekends. He denies any problems with bowel or bladder function but has not been able to play for the past three weeks.

Past Medical History:

Hypercholesterolemia, seasonal allergies, left tibial stress fracture at age 35 while training to run a marathon; right rotator cuff tendonitis. No hospitalizations. Last physical was 10 months ago. He had a normal baseline prostate evaluation, PSA test, and colonoscopy at age 50. No history of rheumatoid arthritis, direct trauma to the low back, or motor vehicle accidents.

Past Surgical History:

Appendectomy at age 16

Social History:

Employed as a software engineer; nonsmoker; occasionally has a glass of wine or beer with dinner; lives at home with his wife and two children aged 16 and 14 who are all well.

Medications:

Atorvastatin 10 mg daily for hypercholesterolemia, loratidine 20 mg daily as needed for allergic rhinitis, naproxen 500 mg, 1 tablet every 12 hours as needed for pain.

Allergies:

Penicillin causes hives.

REVIEW OF SYSTEMS

General:

No fever or weight loss; mild fatigue

Skin:

No rashes or eczema.

HEENT:

No history of head trauma, recent changes in vision, smell, taste, hearing, or swallowing.

Cardiovascular:

No chest pain at rest or with exertion; no palpitations; no cyanosis or peripheral edema.

Respiratory:

No cough, shortness of breath, dyspnea; has history of exercise-induced and allergic asthma for which he used to use an inhaler as needed but has not needed it for several months; no history of pneumonia or tuberculosis.

Gastrointestinal:

No nausea or vomiting, loss of appetite or abdominal pain; no bloody stools; no diarrhea or constipation; no history of hepatitis, ulcer, diverticulosis, or gallstones.

Genitourinary:

No hematuria, dysuria, incontinence, but he does note that his urinary stream is not as strong as usual; no history of hernia;

sexual relations have diminished for past three weeks due to LBP.

Endocrine:

No polydipsia, polyphagia, polyuria. No heat or cold intolerance.

Musculoskeletal:

Mild left knee pain; sharp right-sided LBP; history of intermittent LBP that is usually dull and aching in nature; occasional right shoulder pain that is exacerbated with playing tennis.

Neurological:

No history of sciatica neuralgia; no muscle weakness in his upper or lower limbs; no muscle cramping or spasm; no persistent loss of sensation in his feet; occasional headaches characterized by a sensation of bilateral squeezing (tightness) which resolve with rest; no history of seizures or stroke.

Hematologic:

No history of anemia, blood dyscrasias, or bleeding tendencies.

Psychiatric:

No history of depression, anxiety, mania, hallucinations, or hospitalizations.

PHYSICAL EXAM

Vital signs:

Height: 5'10", weight: 170 lb, BP: 135/80, P: 86, R:14, T: 98.8°F

General:

Alert and in mild distress due to LBP; appearance is well kept, unable to get comfortable sitting on the treatment table; appears well dressed, clean and groomed.

Integument:

No erythema or increased warmth in lumbar region; no trophic changes in bilateral lower limbs; no malar or other rashes.

HEENT:

Head is atraumatic, normocephalic; pupils equal, round, reactive to light and accommodation; CN II to XII are grossly intact; external auditory canals are patent and tympanic membranes are intact with good cone of light; nasal mucosa is slightly erythematous and edematous; no sinus pressure tenderness to palpation or percussion; pharynx not injected, no tonsillar hypertrophy, no erythema or exudates.

Hematologic/Lymphatics:

No lymphadenopathy or peripheral edema.

Cardiovascular:

Heart has a regular rhythm; no murmurs; lower limbs nonedematous; dorsalis pedis and posterior tibial pulses are palpable bilaterally; no carotid bruits; no abdominal bruits or masses.

Respiratory:

Lungs are clear to auscultation bilaterally; no wheezes or rhonchi in the airways; no prolongation of exhalation.

Gastrointestinal:

Abdomen is nondistended and bowel sounds are auscultated in all four quadrants without bruits; abdomen is tympanic to percussion, soft, nontender to palpation without rebound tenderness or masses. Normal rectal sphincter tone on digital exam; guaiac stool test is negative for blood.

Genitourinary:

Prostate is firm, nontender, and small without nodules. No inguinal hernia.

Neurological:

Full motor strength present in bilateral upper and lower extremities; sensation diminished to light touch and pinprick over dorsal surface of right foot, with remainder of sensory exam normal in upper and lower limbs; muscle stretch reflexes: bilateral patellar and left Achilles 2+/4+; right Achilles 1+/4+; Babinski tests elicit down going toes bilaterally; straight leg raise tests elicit mild increase in LBP and tingling sensation but no pain in posterior legs or feet at 80 degrees; bilateral lower limb proprioception intact (negative Romberg test); normal heel and toe walking.

Musculoskeletal:

Mildly antalgic gait with decreased loading of left lower limb; increased right-sided lumbar paravertebral muscle tension with moderate tenderness lateral to L5 spinous process, decreased lumbar spine flexion (30 degree) and extension (10 degree), moderate pain with lumbar spine extension and left side-bending; limited range of motion of squat test; negative FABERE test bilateral hip joints; medial joint line tenderness of left knee with 5° deficit in extension, negative drawer test, and mild pain with McMurray's test; no effusion of left or right knee; right bicipital tendon tender to palpation, negative Yergason test; there is a right positive Thomas test for iliopsoas tension.

Osteopathic Structural Exam:

Patient is evaluated in the standing, seated, supine, and prone positions.

Cranial:

Normocephalic, atraumatic cranium, asymmetrical motion posterior quadrants, primary respiratory mechanism at 8 cycles per minute, restriction of the right occipitomastoid suture.

Cervical:

increased cervical lordosis with head anterior to gravitational line; OA extended, sidebent right, rotated left; C2 rotated right.

Thoracic:

Decreased thoracic kyphosis; T1 Extended Rotated right, Sidebent right; palpable deep right paraspinal muscle tension (intertransversarii, rotatores, multifidi) at T4-5 extending out to the 4th intercostal space laterally that binds even more with passive cervical right sidebending using the head as a lever in the seated position during exhalation; T8-10 Neutral Sidebent left, rotated right; T12-L2 Neutral Sidebent right, rotated left; tenderness of right 12th posterior thoracic counterstrain point.

Costal:

Exhalation restriction of right 1st rib, inhalation restriction of right 12th rib and thoracic diaphragm.

Lumbar:

Decreased lumbar lordosis; L5 Flexed rotated right, Sidebent right; tenderness of 5th posterior lumbar and right piriformis counterstrain points, and in the area overlying the right ilio-lumbar ligament;

Pelvis:

Positive left standing flexion test; ASIS, PSIS, and pubic tubercles are level;

Sacrum:

Positive left seated flexion test; left sacral torsion on a right oblique axis and positive (poor/decreased) lumbar spring test.

Lower Extremities:

No gross leg length discrepancy; tenderness of left medial meniscus counterstrain tenderpoint; ankle decreased quality and range in passive dorsiflexion.

Upper Extremity:

Right scapula inferior; full range of motion present in bilaterally upper extremities.

ASSESSMENT**LBP (lumbago)**

Somatic dysfunctions in the following regions: cranial (739.0); cervical (739.1), thoracic (739.2) with (viscerosomatic reflex at T4-5 related to asthma); lumbar (739.3); sacral (739.4); lower extremities (739.6); costal cage (739.8)

Left medial meniscus injury

History of hypercholesterolemia

Allergic rhinitis

Asthma

Right bicipital tendonitis

PLAN

This patient has acute LBP (<6 weeks' duration) due to somatic dysfunction that is amenable to osteopathic manipulative treatment (OMT). A review of the scientific literature supports this diagnosis and management plan (1–3). Osteopathic manipulative medicine (OMM) methods that can be used to address his somatic dysfunctions include soft tissue, articular, muscle energy, strain-counterstrain, high-velocity/low-amplitude (HVLA), osteopathy in the cranial field and myofascial release procedures. Lumbar spine range of motion and strengthening exercises, such as the commonly prescribed knee-to-chest and pelvic tilt exercises, 3 cycles of 10 repetitions, once or twice daily, often aid recovery and rehabilitation (1). Patient-specific exercise prescriptions based on the physical exam findings and goals of treatment are most beneficial (1,4,5). Physical therapy referral for abdominal, lumbar, and pelvic muscle stabilization exercises and training may be useful if progress is slow with self-directed home exercises (6).

The American Osteopathic Association recommended parameters for frequency of application of OMT for patients with acute somatic dysfunction are one to three times per week for 2 weeks, followed by two to three times per week for 2 weeks, then one to two times per week thereafter, up to 6 weeks (5). If symptoms and signs are continually improving, OMT should be continued. If symptoms and signs are not improving, or worsening, reassessment of the diagnosis and a new management plan should be initiated (5). However, this is only a guideline, for at each visit, the osteopathic physician should determine the frequency and duration of OMT based on the patient's response to previous treatments, prescribed exercises and ergonomics and current assessment of the clinical condition (5).

For patients with acute LBP who do not improve with self-care options, spinal manipulation is the best evidence recommendation (6). Patients should be educated to stay active and use proper ergonomics (6) (i.e., to pick up something to the side, do not bend over to the side, twisting the lumbar spine, with extended knees, which puts significant strain and stress on the low back; instead,

face the object, bend the knees, keep the back extended and lift the object close to the body). Both acetaminophen and NSAIDs have demonstrated benefit as first-line medications for short term pain relief (6).

National evidence-based practice recommendations for patients with subacute (6 to 12 weeks after onset) or chronic LBP (more than 3 months after onset) include spinal manipulation; intensive interdisciplinary rehabilitation; exercise therapy; acupuncture; massage therapy; yoga; cognitive-behavioral therapy; or progressive relaxation (6).

It is not recommended that physicians obtain radiological or laboratory evaluation routinely on patients with nonspecific (anatomical pathophysiology undefined) acute LBP (6). This includes patients with somatic dysfunction and no symptoms or signs of radiculopathy below the knee or evidence of organic or spinal pathology. It is recommended to obtain radiological evaluation (e.g., lumbar spine x-rays, A-P and lateral views, MRI, CT) if the LBP persists beyond 6 weeks, which is the average time frame of resolution of acute symptoms, or if there are signs of radiculopathy, or severe or progressive neurological deficits (6). Diagnostic imaging is also indicated when serious underlying conditions are suspected on the basis of the history and physical examination (6). Electromyograms and Nerve Conduction Studies (EMG/NCS) are useful if radiculopathy distal to the knee occurs. Refer patients with radiculopathy below the knee to a pain management specialist for epidural steroid injections or a surgeon for potential definitive intervention is appropriate (6). Assess for symptoms and signs of severe or progressive neurological deficits (i.e., bowel or bladder incontinence or change in lower limb muscle strength and sensation) at each office visit. Refer to a spine surgeon if there are signs of severe or progressive neurological deficits (6).

DIFFERENTIAL DIAGNOSIS

A patient's LBP can be defined as either acute or chronic. In general, acute LBP is self-limiting, and if it lasts longer than 3 months, it can be classified as chronic in nature (6). While this is a broad generalization, it can be a helpful one, since the diagnosis, prognosis, and treatment of acute versus chronic LBP differ from one another. It is important to keep in mind, however, that up to one third of patients presenting with LBP will have a recurrent, episodic clinical course over their lifetime (7).

This patient presents a clinical example of a patient with acute LBP, although he has had episodes of back pain with and without radiculopathy in the past. He currently has no symptoms of pain radiating past his knee, but the physical exam did find dermatome-specific signs of decreased sensation in his foot. This could be residual from previous injury or part of the current clinical picture. Since other neurological tests, including lower extremity motor, sensory and reflex exams, were within normal parameters, continued follow-up exams at each visit to document improvement, stability, or progression of this sensory deficit is indicated. EMG/NCS and diagnostic imaging would assist in the diagnosis if the deficit persists or progresses.

In developing a differential diagnosis, it is helpful to characterize the patient's LBP as localized or referred. Localized pathophysiology can be categorized as mechanical or nonmechanical. Even though it is often times not possible to define the exact etiology of LBP, up to 97% of LBP is mechanical in nature (8). Mechanical etiologies can cause pain in the low back region, or the pain may radiate to one or both legs or feet, that is, cause radiculopathy. LBP that is accompanied with radicular symptoms is usually indicative of nerve root irritation or compression. Patients who are experiencing

radicular symptoms typically report pain that is “burning” or “shooting” in nature and travels into the leg and below the knee. On the other hand, nonradicular mechanical LBP tends to be characterized as “aching” or throbbing” in nature and may radiate into the gluteal or upper thigh region, but not usually below the knee. There are also nonmechanical causes of LBP. These include infections, inflammation, and cancer. Psychological issues may also play a significant role (6). Lastly, LBP may be referred from another site. This type of pain can be visceral or retroperitoneal in origin

and although rare, it should not be missed, as it may be indicative of a serious disease process, such as gastrointestinal or renal disease or abdominal aortic aneurysm. Tables 69.1 and 69.2 categorize the differential diagnosis for LBP and provide a means by which the osteopathic physician can stratify it.

As can be discerned from Tables 69.1 and 69.2, the patient does not have history or physical findings of any of the pathological conditions listed; however, the history and physical do support the diagnosis of somatic dysfunction. Thus, the osteopathic physician

TABLE 69.1

Differential Diagnosis of LBP

	Characteristics	Labs/imaging
Localized LBP—Mechanical without Radiation Below the Knee		
Nonspecific—muscular and ligamentous injury	Localized to low back and buttocks Better with lying down and change of position Worse with activity Cyclic in nature Intact neurological function	Typically none
Somatic dysfunction	Asymmetry of structural position Altered range of motion Tissue texture abnormalities Tenderness Resolves with OMT	Typically none
Degenerative disc disease	Localized to low back and buttocks Better with lying down and change of position Worse with prolonged standing or sitting Chronic > acute	Lumbar films: A/P and lateral views MRI
Degenerative joint disease—facet arthropathy	Localized to low back and buttocks Better with lying down and change of position Worse with spinal extension Chronic > acute	Lumbar films: A/P and lateral views MRI
Fracture: Vertebral Spondylolysis	Acute > chronic Compression fracture: history of osteoporosis or trauma Pars interarticularis fracture: new-onset LBP in athletically active adolescent or history of trauma	Lumbar films: A/P, lateral and oblique views CT
Localized LBP-mechanical with pain radiation below the knee		
Radiculopathy	Leg pain that radiates below the knee Pain with dermatomal distribution Neurological function may be impaired: Lower extremity weakness Diminished reflexes	MRI
Spinal stenosis	Bilateral lower limb pain Neurogenic claudication Neurological function may be impaired: Lower extremity weakness Diminished reflexes	MRI
Cauda equina syndrome	Impaired neurological function: Saddle anesthesia Lower extremity weakness Diminished reflexes Urinary retention	MRI

(continued)

TABLE 69.1 (Continued)

Localized LBP—nonmechanical

<i>Infection:</i>	Pain at rest or night	CBC, Blood cultures MRI
Osteomyelitis	Fever	
Discitis	Recent skin infection or UTI or IVDA	
<i>Neoplasm:</i>	Pain at rest or night	MRI, CT, PSA, alkaline phosphatase
Primary: osteosarcoma, osteoid osteoma	Weight loss	
Metastatic: prostate, breast, lung, kidney		
Multiple myeloma		
<i>Inflammation:</i>	Significant morning stiffness	Lumbar and pelvic films
Spondyloarthropathy—ankylosing spondylitis reactive arthritis (Reiter disease)	Sacroiliac pain	CBC, ESR, CRP, HLA-B27, Rh factor
Rheumatoid arthritis	Uveitis Urethritis Joint pain and swelling	

Referred LBP

<i>Gastrointestinal disease:</i>	Abdominal pain, tenderness, distention	Abdominal films, US, CT
Inflammatory bowel disease		CBC, amylase/lipase
Diverticulitis	Hematochezia	
Pancreatitis		
<i>Renal Disease:</i>	Abdominal pain	US, CT
Nephrolithiasis Pyelonephritis	Hematuria	UA
<i>Gynecological:</i>	Pelvic pain	US
Endometriosis	Cyclical in nature	
Menstrual	Dysmenorrhea	
<i>Vascular:</i>	“Ripping” or “tearing”-like abdominal pain	US, CT
Abdominal aortic aneurysm	Pulsatile abdominal mass	
<i>Psychological:</i>	Disproportionate pain	Typically none
Somatoform disorder		
Malingering		
Central sensitization/chronic pain syndrome		

A/P, anterior/posterior; CBC, complete blood count; CRP, C-reactive protein; CT, computerized tomography; ESR, erythrocyte sedimentation rate; HLA-B27, Human leukocyte antigen-B27; IVDA, intravenous drug abuse; MRI, magnetic resonance imaging; OMT, osteopathic manipulative treatment; PSA, prostatic specific antigen; Rh, rheumatoid; UA, urinalysis; US, ultrasound; UTI, urinary tract infection.

can be confident in making that diagnosis and provide appropriate OMT as part of the management plan.

OSTEOPATHIC PATIENT MANAGEMENT

Biomechanical Model

As stated above, the majority of LBP is mechanical in origin. In general, mechanical LBP is improved with rest and exacerbated with activity. Although the etiology of mechanical LBP can at times be identified, such as with degenerative disc and joint disease, the vast majority of the time it is not. In the setting of a poorly defined etiology, it is thought that injury of muscular and ligamentous structures plays an important role. It likely involves injury of

muscle fibers at the musculotendinous junction that is precipitated by physical activity. The musculature of the lumbar spine can be classified as being anterior or posterior. The anterior musculature comprises the abdominal and iliopsoas muscles. Abdominal muscles include the rectus abdominis, external and internal oblique, and transverses abdominis muscles. These muscles act in concert with one another to produce flexion of the lumbar spine. While it is unlikely that they are a source for LBP, these muscles are very important in providing core stability and are of benefit to strengthen in patients with LBP. Iliopsoas is located deep within the abdomen and pelvis, originating along the lateral aspects of the lumbar vertebrae and intervertebral discs and the iliac fossa and inserting on the lesser trochanter of the femur. It is the primary flexor of the hip

TABLE 69.2

Structure/Function Model of Differential Diagnosis of LBP

	Red Flags: Spinal Pathology (Mechanical)	Somatic Dysfunction (Mechanical, amenable to OMT)	LBP Work-related (Behavioral)	LBP radiating below knee (Neurological)	Inflammatory Disorder (Metabolic)
History	<ul style="list-style-type: none"> • Age of presentation <20 or onset >55 • Violent trauma, e.g., fall from height, MVA • Constant, progressive, nonmechanical pain • Thoracic pain • Past history of carcinoma • Systemic corticosteroids • Drug abuse • HIV • Difficulty with micturition • Fecal incontinence 	<ul style="list-style-type: none"> • Aged 20–55 • Pain may be in lumbar and sacral spine, buttocks and thighs; does not radiate below knee • Mechanical in nature • Lifting and twisting • Pain varies with physical activity and time 	<ul style="list-style-type: none"> • Postural stress • Whole-body vibration • Monotonous work • Lack of personal control • Low job satisfaction • Smoking 	<ul style="list-style-type: none"> • Unilateral leg pain > back pain • Pain generally radiates to foot or toes • Numbness and paresthesias in the same dermatome distribution 	<ul style="list-style-type: none"> • Gradual onset • Marked morning stiffness • Family history
Physical	<ul style="list-style-type: none"> • Systemically unwell • Weight loss • Persisting severe restriction of lumbar flexion • Structural deformity • Loss of anal sphincter tone • Saddle anesthesia around the anus, perineum or genital • Widespread (>one nerve root) or progressive motor weakness in the legs or gait disturbance 	<ul style="list-style-type: none"> • Patient well • Lumbosacral spine and/or pelvis somatic dysfunction present 	<ul style="list-style-type: none"> • Low physical fitness • Inadequate trunk strength 	<ul style="list-style-type: none"> • Nerve root irritation signs • Reduced SLR which reproduces leg pain • Motor, sensory or reflex change is limited to one nerve root 	<ul style="list-style-type: none"> • Iritis, skin rashes (psoriasis), colitis, urethra discharge • Persisting limitation of spinal movements in all directions • Peripheral joint involvement
Lab and x-ray	<ul style="list-style-type: none"> • X-ray: look for vertebral collapse or bone destruction • CT or MRI: look for cauda equina compression 	<ul style="list-style-type: none"> • Nondiagnostic 	<ul style="list-style-type: none"> • Nondiagnostic 	<ul style="list-style-type: none"> • Nondiagnostic or MRI: look for disc herniation with compression of peripheral nerve root 	<ul style="list-style-type: none"> • Nondiagnostic or blood tests: look for Rh factor or seronegative arthropathy; ESR > 25 • X-ray shows evidence of arthritis
Course	<ul style="list-style-type: none"> • If pain not resolved in 6 wk, an ESR and x-ray should be considered 	<ul style="list-style-type: none"> • Prognosis good • 90% recover from acute attack in 6 wk; but most recur throughout life • Manipulation and exercise provide pain relief, improved mobility and may shorten course 	<ul style="list-style-type: none"> • Usually resolves within 6 wk • Responsive to manipulation and exercise, and use of proper posture and ergonomics • Potential for prolonged recovery if there is secondary gain involved 	<ul style="list-style-type: none"> • Prognosis reasonable • 50% recover from acute attack within 6 wk 	<ul style="list-style-type: none"> • Usually resolves with anti-inflammatory medication • Episodic

joint and can act as a lumbar flexor when the hips are fixed. Because it is a postural muscle, it is prone to shortening in the absence of activity. This leads to decreased hip extension and increased lumbar lordosis and anterior pelvic tilt, which may predispose a patient to develop lumbar and pelvic somatic dysfunction and LBP. The posterior muscles are subdivided into superficial, intermediate, and deep layers. The superficial layer comprises the lumbodorsal fascia. This expansive layer of connective tissue provides stability for the thoracolumbar and pelvic regions, as well continuity with the upper limb via its connection with the latissimus dorsi muscle. The intermediate layer consists of the iliocostalis, longissimus, and spinalis muscles. These erector spinae muscles function bilaterally to produce extension and unilaterally to produce sidebending of the lumbar spine. The deep layer consists of those muscles responsible for localized vertebral movement, including lateral flexion (sidebending) with contralateral rotation. They include the multifidi, rotators, and intertransversarii muscles. The deep layer also contains the quadratus lumborum muscle, which connects the pelvis to the spine and produces lumbar extension when contracting bilaterally. If it undergoes overuse due to deconditioning of the erector spinae muscles, it can be a potential source of LBP.

Just as injury to muscle fibers can cause mechanical LBP, so too can injury to ligamentous structures. Like muscle injury, ligamentous injury is characterized by pain that can be either dull and aching or sharp in nature. Two of the most important ligaments are the anterior and posterior longitudinal ligaments, which traverse the respective surfaces of the vertebral bodies and intervertebral discs. They provide stability and respectively prevent hyperextension and hyperflexion of the spine. The posterior longitudinal ligament is of particular interest due to its location within the spinal canal. Its position helps prevent posterior displacement of the intervertebral disc. Because it is richly innervated with nociceptors, it can be a source for LBP (9). It can also succumb to different disease processes, such as ossification, which can cause other disorders of the spine, including spinal stenosis. Like the posterior longitudinal ligament, the ligamentum flavum, which connects the laminae of adjacent vertebrae, is susceptible to ossification. However, since it contains few nociceptors, it is not considered to be an important pain generator.

Because the precise anatomical source of mechanical LBP is not identifiable in the majority of patients, the physical examination is often times used to exclude serious underlying pathology and confirm the diagnosis. In the absence of well-defined spinal pathology and with signs of TART indicative of somatic dysfunction, osteopathic physicians consider somatic dysfunction as the cause of the LBP if its alleviation with OMT relieves the pain and restores normal function.

In addition to assessing the lumbar region for tissue texture changes, asymmetry, increased or decreased range of motion and tenderness, the physical examination should include an assessment of gait and posture, neurological function of the lower limbs, and appropriate provocative tests, such as the straight leg raise and FABERE (hip flexion, abduction, external rotation, and extension) tests. Abdominal and rectal examinations may also be indicated if intra-abdominal or pelvic pathology are suspected. With the continuity that exists between the lower limbs and pelvis and lumbar spine, it is useful to perform an evaluation of gait, as it may give insight into the etiology of the patient's LBP. For example, a patient with a radiculopathy affecting the 5th lumbar nerve root may have weakness of his ankle dorsiflexors that is demonstrated high steppage by gait. Although it is almost always normal in patients with nonradiating mechanical LBP, a neurological examination is essential when assessing any patient with LBP. It involves assessing motor strength and sensation for the L1 to L5 myotomes

and dermatomes, as well as the Achilles and patellar muscle stretch reflexes. The straight leg raising test, as well as other nerve stretching maneuvers (e.g., flexing the knee and passively dorsiflexing the ipsilateral ankle, or squeezing the ipsilateral calf along the midline course of the sciatic nerve), is useful for assessing sciatic nerve inflammation or irritation.

Somatic Dysfunction

Since up to 70% of mechanical LBP may be due to somatic dysfunction, performing an osteopathic structural examination can be quite useful (1). As with other regions of the body, lumbar somatic dysfunction is characterized by asymmetry of structural position, altered range of motion, and palpable tissue texture abnormalities and/or tenderness. There are three primary anatomic sites of somatic dysfunction in the lumbo-sacral-pelvic region that can cause LBP and are amenable to treatment with OMM. Surrounding soft tissues, e.g., lumbar myofascial paraspinal tissues and lumbosacral-pelvic ligaments, are often treated along with the specific lumbar, sacral, or pelvic joint somatic dysfunctions. Box 69.1 lists the soft tissue elements often addressed with OMT, and Table 69.3 lists the three types of somatic dysfunction commonly associated with LBP and the types of segmental somatic dysfunction that are typically found with each one.

As with all osteopathic structural examinations, evaluation of the lumbar spine for segmental somatic dysfunction requires proficiency in palpating the appropriate anatomical landmarks and performing a regional and segmental examination.

From a biomechanical perspective, treatment of LBP seeks to address somatic dysfunction and restore posture and balance so as to allow the musculoskeletal system to operate more efficiently and with less pain. This entails not only addressing lumbar somatic dysfunction, but somatic dysfunction elsewhere in the body, particularly the spine, pelvis, and lower extremities. Because the spine works a functional unit, treating somatic dysfunction that exists in the thoracic and cervical spine will ideally allow for restoration of normal spinal motion. Likewise, the aim of treating lower extremity somatic dysfunction is to improve posture and balance and allow the body to more efficiently cope with the forces of gravity during sitting, standing, and ambulation. Certain anatomic structures that are known to cause or exacerbate LBP should be taken into account when formulating an osteopathic treatment plan. These structures, which are amenable to manipulation, include the lumbar intervertebral joints, myofascial paraspinal soft tissues, sacroiliac joints and iliosacral joints, and lumbosacral and lumbopelvic ligaments.

Muscles, Fascia, and Ligaments (Soft Tissues) Commonly Associated with Lumbosacral Somatic Dysfunctions in Patients with LBP

Superficial layer:

- Lumbodorsal fascia

Intermediate layer:

- Erector spinae

Deep layer:

- Multifidi
- Rotatores
- Intertransversarii
- Pelvic Diaphragm
- Quadratus lumborum

Lower extremities:

- "Hamstrings"
- Piriformis
- Psoas-Iliacus
- Gluteal muscles

Ligaments:

- Interspinous
- Iliolumbar
- Sacroiliac
- Sacrotuberous

TABLE 69.3

Somatic Dysfunctions Associated with LBP

Lumbar Vertebral Joint Somatic Dysfunctions	Lumbosacral—Pelvic (Sacroiliac) Dysfunctions	Ilium—Pelvic (Iliosacral and Pubic) Dysfunctions
<p><i>Type I:</i></p> <ul style="list-style-type: none"> • Neutral, sidebent left or right <p><i>Type II:</i></p> <ul style="list-style-type: none"> • Flexed or Extended, rotated and sidebent right or left 	<ul style="list-style-type: none"> • Sacral Torsion (L/L; L/R; R/L; R/R) • Bilateral or Unilateral Sacral Flexion or Extension • Lumbosacral joint compression • Unlevel sacral base due to anatomic short leg 	<ul style="list-style-type: none"> • Superior or inferior ilial shear • Anterior or posterior rotated ilium • Inflared or outflared ilium • Superior or inferior pubic symphysis shear

Soft tissue and myofascial techniques such as lumbar prone pressure with counter leverage and lumbosacral decompression can be used to address increased tension of the lumbar paraspinal musculature and lack of compliance in the tissues surrounding the lumbosacral junction. Sidelying lumbar articular or HVLA technique is useful for treating lumbar segmental dysfunction at L5. With respect to pelvic dysfunction, muscle energy technique can be used to treat sacral torsions and counterstrain technique for piriformis somatic dysfunction. Care should also be taken to address somatic dysfunction outside of the lumbar and pelvis regions. This may entail treating dysfunction at the atlantooccipital (OA) joint with HVLA and decompression of the OA joint, as well as treating knee or ankle somatic dysfunction with counterstrain technique. This again will allow the osteopathic physician to address somatic dysfunction that may have predisposed the patient to develop LBP and be interfering with structural balance.

Degenerative Disc and Joint Disease

Spondylosis is a term that is used to describe degenerative changes of the spine, including degenerative disc and joint disease. It tends to affect the lumbar spine in particular due to its mobile nature and load bearing responsibilities. There are five lumbar vertebrae, each of which is separated by an intervertebral disc. Each vertebra consists of a body and vertebral arch. The vertebral arch is further composed of a pair of pedicles and laminae and supports a number of additional structures, including the inferior and superior articular processes, transverse processes, and spinous process. It forms the intervertebral foramen, through which the spinal nerves exit, and helps protect the spinal cord by forming part of the spinal canal. The vertebrae articulate with one another via the fibrocartilaginous intervertebral disc and synovial facet joints, which exist on the inferior and superior articular processes. The disc consists of an outer fibrocartilaginous ring, the annulus fibrosus, and inner gelatinous mass, the nucleus pulposus. It acts as a dampening mechanism for forces transmitted along the vertebral column, while simultaneously allowing for movement between the individual vertebrae. Disease or injury to any of these structures can potentially lead to instability of the lumbar spine and LBP. While injuries such as fracture of the vertebral body or arch tend to result in acute LBP, spondylosis tends to be associated with chronic LBP. In general, it is a natural part of the aging process and by 49 years of age, 60% of women and 80% of men have osteophytes and other changes indicative of spondylosis (10). As with acute LBP due to muscular and ligamentous injury, back pain due to degenerative changes is difficult to localize and symptoms and signs tend to be nonspecific. Additionally, radiological findings, both on MRI and plain films,

must be interpreted with caution, since there is poor correlation between radiographic degenerative changes and LBP. For example, disc herniation on lumbar MRI is a common finding in asymptomatic patients (11,12).

Piriformis Syndrome

Although it is not part of the musculature or ligamentous structures of the lumbar spine, the piriformis muscle should be a consideration in the differential diagnosis of LBP due to the fact that pain associated with its dysfunction can be interpreted as low back in origin. Typically, piriformis syndrome—type pain is characterized by aching pain in the gluteal region, especially at the attachment sites of the piriformis muscle. Patients complain of increasing pain after sitting for longer than 15 to 20 minutes. Additionally, because of the close proximity of the piriformis muscle to the sciatic nerve, patients can report paresthesias that radiate down the posterior aspect of the thigh. Having an appreciation for the anatomy of the piriformis muscle, as well as its surrounding structures, is helpful in understanding the possible pathophysiology behind piriformis syndrome and physical examination findings. The piriformis muscle originates on the anterior surface of the sacrum and passes through the sciatic notch before inserting on the upper aspect of the greater trochanter. It is innervated by the first and second sacral nerves and primarily acts as an external rotator of the hip joint. With the hip flexed to 90 degrees, it acts as an abductor of the hip. It is an important structure since all neurovascular structures that exit from the pelvis via the greater sciatic notch do so either inferior or superior to the piriformis muscle. This includes the inferior and superior gluteal nerve and artery and pudendal and sciatic nerves. Even though the mechanism of sciatica or radicular type pain in piriformis syndrome is not completely understood, it is thought that the sciatic nerve may become impinged or compressed by the piriformis muscle. This may be secondary to trauma, such as falling on the buttock, or overuse, both of which can result in inflammation of surrounding tissues and spasm of the piriformis muscle. Additionally, in some patients, the sciatic nerve may pierce the piriformis muscle, rendering the sciatic nerve more susceptible to entrapment and injury. Regardless of the etiology, piriformis syndrome is usually characterized by tenderness in the region of the greater sciatic foramen. Provocative maneuvers that evaluate for piriformis syndrome attempt to induce radicular-type pain by either active contraction of the piriformis muscle in resistance or passively stretching it (13). The straight leg raise test may be positive in piriformis syndrome, but is nonspecific since it does not localize where the nerve is compressed and is typically more indicative of nerve root compression. In the supine position,

a patient may exhibit external rotation of the affected lower limb and range of motion testing may reveal decreased internal rotation of the affected side. The sacrum is typically rotated anteriorly toward the ipsilateral side on a contralateral oblique axis, resulting in compensatory rotation of the lower lumbar vertebrae in the opposite direction (14).

Sacroiliac Joint Pain

Although the sacrum and sacroiliac joints are technically part of the pelvis, they warrant mention here since pain due to dysfunction of these structures can be difficult to distinguish from pain originating in the lumbar spine. In fact, the prevalence of sacroiliac joint pain, as established on the basis of clinical evaluation, varies from 15% to 30% in patients with LBP (15). The sacrum is a triangular-shaped bone that is formed from the fusion of five sacral vertebrae. It articulates with the ilium bones at the sacroiliac joints and fifth lumbar vertebra via the last lumbar intervertebral disc and facet joints. The sacroiliac joints are L-shaped synovial joints that are stabilized by a combination of bony structure and strong ligamentous structures, including the anterior and posterior sacroiliac and sacrotuberous ligaments. As with the lumbar spine, injury, inflammation, degeneration, and somatic dysfunction of the sacroiliac joints can result in LBP. Like mechanical LBP, sacroiliac pain can also be nonspecific and refer to a variety of places, including the low back, buttock, groin, and lower extremity (16). The International Association for the Study of Pain suggests incorporating at least three selective sacroiliac joint stress tests in order to more clearly diagnose sacroiliac pain. These provocative tests include compression, distraction, thigh thrust, Gaenslen test, and Patrick sign. Lastly, performing a pelvic regional and segmental examination is useful in diagnosing sacroiliac and iliosacral somatic dysfunction that may be responsible for a patient's LBP and amenable to treatment with OMM.

Coccydynia

Coccydynia or pain associated with the coccyx (tailbone). The coccyx is located at the terminal end of the spinal column and is specifically attached at the distal sacrum. It usually consists of three to five segments that may or may not be fused. Pain in this area is uncommon. The complaint of pain may follow from sacral trauma (falls onto the buttocks, post childbirth, severe cases of whiplash). Pain is made worse with sitting or having pressure applied to this area and is reduced or relieved with standing or the reduction of pressure to the coccyx. Treatments used to relieve the symptoms depend upon the knowledge base of the practitioner and include OMT in an attempt to reposition the coccyx to its normal position by using either direct or indirect MFR or an assessment and treatment of the sacrum and pelvis to correct any associated dysfunctions. Strain/Counterstrain, balanced ligamentous tension, or a direct pressure applied to the sacrococcygeal ligaments to relieve strains that might be present can be effective. Other techniques utilized include hot packs, ultrasound (US), sitz baths or towels, acupuncture, and injections into the ganglion impar. Strategies used to reduce the pain include the use of pillows or "donuts" to minimize the pressure against the coccyx and also the reduction of time spent in the seated position.

Psoas Syndrome

A chronic psoas spasm can create a persistent strain across the lumbosacral junction and impede resolution of lumbosacral somatic dysfunction in spite of OMT and exercises directed at the L-S region. Treatment of the psoas by relieving the thoracolumbar junction and upper lumbar somatic dysfunction and stretching a

hypertonic psoas muscle facilitates resolution of a long-standing lumbosacral somatic dysfunction. Commonly, the L1 or L2 vertebra is flexed and rotated to the side of the shortened, hypertonic psoas muscle. In the patient above, the thoracolumbar junction has two type I curves, one superior and the other inferior, to the thoracolumbar junction. This indicates a long-term somatic dysfunction in that region, as type I group dysfunctions are often compensatory changes to a longstanding type II segmental dysfunction. Treating the type I spinal somatic dysfunctions with OMT as well as stretching the tight psoas muscle would be a reasonable approach in this patient.

Short Leg Syndrome and LBP

Patients with anatomic short leg syndrome often have sacral base unleveling and sacroiliac and lumbosacral joint dysfunction and pain. (See chapters 41 and 42 for more information regarding anatomic short leg diagnosis and treatment with lift therapy). OMT combined with lift therapy has been shown to relieve LBP in many of these patients (17–19).

Respiratory/Circulatory Model

From a respiratory/circulatory perspective, maximizing oxygenation and delivery of nutrients facilitate the recovery of tissues that may have been injured or compromised in a patient with LBP. Therefore, patients may benefit from OMM that addresses somatic dysfunction of the thoracic diaphragm and pelvic diaphragms and costal cage. The upper lumbar vertebral bodies serve as the sites of insertion for the diaphragm. The diaphragm is most efficient when the lumbar spine is in its natural lordosis in the seated or standing positions. An important goal of osteopathic management therefore is to restore lumbar lordosis to maximize diaphragmatic function. As important as the thoracolumbar junction is to diaphragmatic activity, similarly, normal lumbosacral mechanics are key for pelvic diaphragm function. With each breath, the sacrum should be able to oscillate in its articulation with the ilia. The second sacral segment serves as the attachment of the spinal dura, which is also attached firmly to C1, C2, and the occiput at the foramen magnum. Thus, somatic dysfunction of the lumbosacral spine and sacroiliac joints has an effect upon mechanics in distal spinal segments as well as in the cranium through this "core link" of spinal dura. (see chapter 48). Primary respiratory mechanism motions at the sacrum as well as the occiput are compromised by lumbosacral somatic dysfunction. Evaluating and treating the sacral and occipital somatic dysfunctions using balanced ligamentous tension and osteopathy in the cranial field techniques will improve the motions related to the primary respiratory mechanism and the natural respiratory mobility of the sacrum.

In addition to receiving OMM, patients can benefit from regular cardiovascular exercise. There is evidence supporting the fact that patients with acute, nonspecific LBP who stay active have reduced pain and improvement in function compared to patients who receive bed rest (23).

Neurological Model

Neurogenic LBP is characterized by involvement of the nerve roots, cauda equina, or spinal cord. Symptoms include unilateral or bilateral radiation of pain or paresthesias distal to the knee, or muscle weakness, which may include loss of bowel and bladder sphincter control in the case of cauda equine syndrome. It is far less common than mechanical LBP and comprises approximately

5% to 15% of LBP cases. Because it usually involves compression of a neural structure, it is typically associated with demonstrable pathology, including disc herniation or spondylosis. The two most common types of neurogenic LBP are lumbar radiculopathy and spinal stenosis. The prevalence of lumbar radiculopathy is approximately 3% to 5%, with L5 and S1 radiculopathies comprising 90% of all lumbosacral radiculopathies (20). Unlike mechanical LBP, in which pain is mediated by the anterior and posterior rami of the spinal nerves or sinuvertebral nerves, radicular pain is mediated by the proximal spinal nerves. Radicular pain also differs from mechanical LBP in that the symptoms and signs are more specific and tend to point to a diagnosis of lumbar radiculopathy. Patients describe radicular pain as “burning” or “shooting” in nature and traveling into the leg and foot, sometimes following a dermatomal distribution. Neural tension signs, such as the straight leg test, are helpful in determining if there is compression of a lumbar nerve root. The supine straight leg test has a sensitivity of 91% and specificity of 26%, indicating that when it is negative, a diagnosis of lumbar radiculopathy can be reasonably excluded (21). Because spinal pathology is often present, MRI of the lumbar spine is useful. MRI has been shown to have a sensitivity of 83% and specificity of 78% when assessing for compromise of a neural structure in the lumbar spine (22). However, due to the fact that it is common to find abnormalities such as bulging or protruding discs in asymptomatic patients, it is important to correlate imaging findings with the history and physical examination. A detailed neurologic examination is imperative not only to establish a diagnosis, but to also evaluate for serious findings that may warrant immediate intervention. These can include saddle anesthesia, bladder or bowel dysfunction, or progressive neurological deficits in the lower limbs. These findings must also be kept in mind when evaluating a patient with lumbar spinal stenosis, which is usually the result of spondylosis. Symptomatic lumbar spinal stenosis is characterized by neurogenic claudication, which is defined as aching pain in the lower limbs that is precipitated by walking or standing and alleviated with rest and flexion of the trunk. Somatic dysfunction is often times present in patients with neurogenic LBP. It may be primary in nature or secondary to compression of lumbar spine nerve roots. In secondary somatic dysfunction, nerve root irritation and its associated spinal pathology may be causing spinal facilitation, which in turn leads to maintenance of the somatic dysfunction.

The neurological model takes into consideration the integration of central, peripheral, and autonomic nervous systems and how they may be impacted by somatic dysfunction. Since mechanical LBP is often due to somatic dysfunction, it improves with OMT. This, however, does not mean that neurogenic or nonmechanical LBP cannot be helped with OMT. In these situations, it can be helpful in addressing facilitated segments that are due to nonmechanical pathology. OMT can be helpful in providing information regarding the source of the referred pain. Addressing somatic dysfunction in these cases will ideally lead to a reduction in mechanical stress and the nociceptive input associated with it. This in turn will potentially decrease peripheral sensitization and will in turn lead to decreased spinal facilitation and subsequent improvement in lumbar segmental motion. Also, with decreased pain, the patient may perceive less stress and achieve more balanced function of the autonomic nervous system and neuroendocrine immune network. The body will have a decrease in neuroendocrine activation of the hypothalamic-adrenal axis, resulting in decreased cortisol production and sympathetic tone which will restore autonomic balance. The allostatic load will be diminished, leading to a restoration of homeostasis.

Metabolic-Energy Model

The metabolic, energy expenditure and exchange perspective entails maximizing internal organ functions to support recovery from somatic dysfunction or pathological conditions causing or related to the LBP. Using analgesic medications such as NSAIDs to modulate the pain impulses facilitates healing by decreasing inflammation and allowing the patient to stay active and continue normal daily activities. Bed rest beyond three days is not recommended for patients with acute LBP as muscles begin to atrophy and weaken, impeding healing and recovery of normal function. Rheumatologic conditions are primarily managed with medications, though osteopathic manipulation may have an adjunctive role (30). An inflamed joint, such as the sacroiliac joint (sacroiliitis) found in patients with ankylosing spondylitis, should not be manipulated with direct action OMT as this will aggravate the condition. However, OMT designed to improve lymphatic drainage of swollen joints without moving the joint, and nociceptor “afferent reduction” techniques such as functional, balanced ligamentous tension, and strain-counterstrain may be helpful.

Behavioral Model

The patient evaluated has somatic dysfunction from mechanical LBP. LBP is one of the most common complaints in the outpatient clinic. With a lifetime prevalence of 49% to 70%, most adults will experience an episode of LBP at some point in their life (24). LBP is the third most commonly reported symptom, the second most frequent cause of worker absenteeism, and the most costly ailment of working-age adults in the United States (7). It causes more disability among working-age adults than any other disability and is the most common ailment of working-age adults in the United States (7). Some of the largest components of direct costs include physical therapy, inpatient care, pharmacy, and primary care (25). The economic burden of LBP, both in terms of direct and indirect costs, is great. The combined direct and indirect costs due to LBP are estimated to be \$50 billion (26). Incorporating OMM may allow the osteopathic physician to more efficiently manage patients with LBP and therefore reduce direct costs. It may also help patients return to work earlier and experience a greater sense of satisfaction with their treatment (1).

LBP affects males and females of all ages, disabling those in the 35 to 54 years of age, and also is found in 30% to 50% of teenagers aged 13 to 18 (1,7). Risk factors for the development of acute LBP include increasing age, demanding physical activity (bending, twisting, and lifting movements and prolonged standing), and psychological factors (work dissatisfaction or monotonous work) (1,7). The strongest known predictor of a future episode of LBP is the history of previous episodes (7). Fortunately, the majority of acute back pain cases resolve within 6 weeks, but one third may continue to have intermittent, episodic recurrences (7). When LBP becomes chronic in nature, typically lasting longer than 6 months in duration, certain risk factors may have a more important role. These include a prior episode of LBP, poor job satisfaction, smoking, and poor coping skills. Comorbid conditions are commonly found in chronic LBP patients, and psychological factors play a greater role than anatomical pathology in predicting persistent LBP (7,27).

Age is an important consideration when evaluating a patient with LBP. For example, the patient’s age in and of itself leads the physician toward a particular diagnosis. Because of the anatomical differences in the adolescent and adult spine, each is susceptible to different spinal pathologies. The adolescent spine is still growing and its primary and secondary centers of ossification remain active,

and in the setting of trauma or significant physical activity, this can predispose the adolescent to such spinal disorders as spondylolysis and spondylolisthesis, which can be a significant cause of LBP and instability. On the contrary, an adult spine has a higher likelihood of having spondylosis which may or may not be related to the LBP. Females over 60 years old, as are those who are postmenopausal, are more prone to osteoporosis-related vertebral fractures as a cause of acute LBP.

The behavioral model also addresses the psychological status of a patient and how health may be affected by stress and environmental and socioeconomic factors. It is particularly important to consider in patients with LBP. Systematic review has found psychological and occupational factors to have the highest reliability among prognostic factors with LBP (28). These factors are important to consider in patients with acute LBP, as they may predispose a patient to the development of chronic LBP. There is also strong evidence demonstrating that expectation of recovery is a predictor of work outcome in patients with nonspecific LBP (29). Therefore, it is important to not only understand the life stressors and job satisfaction of patients, but also their expectations and goals with respect to recovering from LBP. Encouraging and assisting the patient in restricting abuse of tobacco and alcohol, engaging in regular exercises, and maintaining normal body weight range will aid in restoration of normal low back neuromusculoskeletal function.

PATIENT OUTCOME

After receiving OMT, the patient noted a reduction in his LBP. He was able to walk and sit without pain and no longer required the use of NSAIDs for pain relief. He was also able to once again sleep comfortably on his back and the right lower limb numbness had nearly resolved.

Treatment focused on resolving somatic dysfunction and addressing postural decompensation. Attention was given to restoring postural balance by correcting thoracic, lumbar, and sacral somatic dysfunctions. The patient's sacral torsion and hypertonic piriformis muscle were treated. Physical therapy aimed at restoring the flexibility and strength of the psoas, erector spinae, and abdominal musculature facilitated restoration of the patient's lumbar lordosis and he reported diminished tenderness in the area of the iliolumbar ligament.

An MRI of the lumbar spine showed a 2-mm broad based protrusion of the L5-S1 disc with mild right-sided neuroforaminal stenosis at L5. EMG and nerve conduction studies were normal. Spinal somatic dysfunction improved with OMT, indicating no persistent viscerosomatic reflexes.

Treatment also addressed somatic dysfunction of the thoracic diaphragm and 12th rib, as well as surrounding structures connecting the costal cage with the pelvis, including quadratus lumborum. This assisted in resolving somatic dysfunction within close proximity to the lumbar region. At the same time, it also helped maximize respiratory and circulatory function and improve the delivery of oxygen and nutrients to and removal of metabolic wastes from the area.

Finally, stressors and ergonomic factors were considered in order to speed recovery and prevent future episodes of LBP.

SPECIALIST REFERRAL

LBP is one of the most common reasons for a visit to the primary care physician's office. However, even more so than the primary care physician, the spine or pain management specialist routinely

evaluates and manages patients with LBP. Fortunately, 90% of acute LBP and 50% of LBP with radicular symptoms resolve within 6 and 4 weeks, respectively (1). It is typically the patient who does not experience a resolution of his or her LBP who is referred to the physician specialist for further evaluation and management. Regardless of whether it is acute or chronic in nature, diagnosis of LBP is oftentimes complex and requires thorough knowledge of the functional anatomy of the lumbar region and pathophysiology of LBP. This must be integrated with an understanding of the risk factors associated with developing LBP and prognostic factors for recovering from it. For example, the overall health and well-being of a patient are important predictors of back pain (31). Additionally, the risk of developing LBP is approximately double for those with a history of LBP, indicating that it may be less likely to spontaneously resolve and more recurrent in nature than once thought (32). Therefore, when performing an evaluation, the physician specialist must not only have an appreciation for the complex etiology of LBP, but also the overall patient and his or her experiences with it.

When evaluating the patient with LBP, one of the most important factors to consider is age. Because certain age groups are more prone to develop certain lumbar spine pathology than others, it is helpful to stratify a patient by age in order to simplify the potential causes of the LBP and eliminate more serious conditions, such as fracture, tumor, or infection. This may be particularly true given the fact that a clear diagnosis of LBP cannot be determined in 85% of patients, given the poor association between symptoms, pathologic changes, and imaging results (33). Although the focus of this chapter is on the evaluation and management of LBP in the adult population, it is important to be able to recognize the primary causes of LBP in the adolescent patient, especially those actively involved in athletics. Unlike adults, it appears that adolescents, particularly those below the age of twelve, have an identifiable cause for their LBP 45% to 50% of the time (34). This is especially true for lumbar spondylolysis, which accounts for 47% of LBP in adolescent athletes versus 5% in adult athletes (35). When evaluating an adolescent, it is therefore important to have a high index of suspicion for an identifiable cause of LBP and low threshold for ordering diagnostic imaging studies, including plain films, CT, and MRI.

As with the adolescent patient, it is also useful for the physician spine or pain management specialist to identify as best possible the anatomical structure responsible for an adult patient's LBP. This can be quite challenging due to the number of structures that can be involved, including lumbar spine musculature, nerves, discs, and zygapophysial joints. Like other regions of the spine, evaluation should begin with a history and physical examination. This includes defining the duration, location, and quality of the LBP, as well as the factors that alleviate and exacerbate it. As mentioned before, it is valuable to gain an overall sense of the patient, their psychological health, and how they are functioning with their pain, since these influence their prognosis for recovery.

As mentioned in the differential diagnosis section, when characterizing pain, it can be particularly helpful to distinguish it as being either mechanical or neuropathic in nature. Mechanical LBP is caused by involvement of the lumbar vertebrae, discs, joints, and myofascial structures, including lumbar muscles and ligaments. It is dull and aching in nature, exacerbated with prolonged standing or sitting, and alleviated with rest. It is also typically associated with lumbar spondylosis and degenerative disease. In contrast, neuropathic pain is shooting and stabbing in nature, radiates into the lower limb and foot, and is indicative of lumbar nerve root irritation or compression. This characterization can be useful, since neuropathic or radicular pain may have a more definable cause, such

as a disc herniation, and requires different treatment (36). When performing the physical examination, the physician can evaluate for lumbar nerve root compression by performing a provocative maneuver such as the straight leg raise test. In fact, in a systematic review, the straight leg raise test was found to be one of the most sensitive tests for radiculopathy (37). Other important components of the physical examination include motor strength and sensory testing and lumbar spine range of motion. The osteopathic structural exam evaluates for asymmetry of structural position, altered range of motion, and tissue texture abnormalities or tenderness.

Although it is beyond the scope of this chapter, it is also essential to evaluate the hip and sacroiliac joints, since pain in the low back can be referred from these neighboring structures. After performing a history and physical examination, diagnostic studies may be indicated to further aid in the diagnosis of LBP. The utility of MRI imaging is limited by the high prevalence of lumbar degenerative changes in adults without LBP. Research has shown that approximately 30% of adults without LBP have evidence of a protruded disc and over 50% have bulging or degenerative discs (38). If the clinical picture is consistent with lumbar spinal stenosis, however, MRI of the lumbar spine can be useful in evaluating for spinal canal narrowing. In general, spinal imaging is typically only indicated if certain conditions are suspected, including fracture, neoplasm, infection, and cauda equina syndrome. Other studies, including lumbar discography and facet injections and electromyography (EMG), can potentially be useful in confirming a diagnosis in patients suspected of having involvement of specific anatomical structures, such as the intervertebral disc or nerve root. Lumbar provocation discography is potentially a useful tool in evaluating chronic lumbar discogenic pain (39). EMG can be used to assess the physiological status of the nerves innervating the lower limbs and diagnose lumbar radiculopathy. In addition to the history and physical examination, it can be helpful in distinguishing LBP that is radicular versus nonradicular in nature. This distinction, along with an assessment for somatic dysfunction and relevant imaging studies, aids in more clearly identifying the cause of a patient's LBP and instituting appropriate treatment.

After completing clinical and diagnostic evaluation and excluding significant pathology, including cervical spine instability or an infectious, neoplastic, or inflammatory process, the physician spine or pain management specialist utilizes a variety of modalities to treat LBP, including medication, physical therapy, interventional procedures, manipulative medicine, and referral for surgical consultation. When addressing chronic LBP that is nonradicular in nature, a multidisciplinary plan that combines pharmacologic and nonpharmacologic therapy is reasonable. Nonpharmacologic therapies with evidence of moderate efficacy for chronic or subacute LBP include cognitive-behavioral therapy, exercise, spinal manipulation, and interdisciplinary rehabilitation (40). Because of compelling evidence supporting its use in the treatment of LBP, OMM should be part of most LBP treatment plans (2). This may entail the physician performing OMM or referring the patient to a neuromusculoskeletal medicine specialist. Meta-analysis of clinical trials examining the efficacy of OMM in the treatment of LBP has demonstrated decreased pain and use of medications when compared to standard medical care (2). Patients with LBP that is radicular in nature may benefit from lumbar epidural steroid injection. Systematic reviews have demonstrated level II-1 evidence for lumbar transforaminal injections providing short-term relief and level II-2 for long-term improvement in the management of lumbar radicular pain (41). There is however no evidence supporting the use of these injections in nonspecific LBP. Likewise, there is no strong evidence supporting the use of injections or radiofrequency

denervation in the treatment of facet-mediated pain. If conservative treatment and interventional procedures fail, referral to a surgical specialist can be considered. This is especially true if the source of the patient's LBP is clear. For example, in patients with lumbar radiculopathy, surgery can reduce pain and improve function, and in those with disc herniation, it can facilitate a quicker return of function. A favorable outcome appears to far less likely in those patients with chronic LBP and common lumbar degenerative changes who undergo surgical intervention (42). Ultimately, it is helpful for the physician to employ specific treatment if the etiology of a patient's LBP is clear and a multidisciplinary approach that incorporates OMM if it is there is evidence of somatic dysfunction.

In July 2009, the American Osteopathic Association House of Delegates passed a resolution in support of submitting a profession-wide interdisciplinary Guideline for Utilization of OMT for patients with LBP. The guideline was based upon a systematic review and meta-analysis of randomized clinical trials of osteopathic manipulation for patients with LBP (2), as well as two other clinical practice guidelines developed by interdisciplinary groups of physicians for treatment of patients with LBP developed by the U.S. Department of Defense and Veteran's Administration in 1999 (43), and the American College of Physicians and American Pain Society in 2007 (6). The AOA's evidence-based guideline recommending that osteopathic physicians utilize OMT to treat somatic dysfunction found in patients with LBP is posted on the AOA's web site, and an abstract is available at the Agency for Healthcare Research and Quality National Guidelines Clearinghouse web site (www.ngc.gov) (44).

PART

V

Approaches to
Osteopathic
Medical
Research

This page intentionally left blank.

KEY CONCEPTS

- The osteopathic profession has supported research since its inception. It founded a research institute in the early 1900s, and while its research efforts have at times been small, it has produced a wide range of research in both the basic and clinical sciences.
- The osteopathic profession is entering an era of globalization of osteopathic research that promises to produce a wider variety of projects not only in the United States but also in several other countries with viable osteopathic movements. In addition, collaboration with other manual medicine professions promises to further expand the profession's research reach.
- Osteopathic research must be defined by the meaning of the research to osteopathic principles and practice. It is up to the investigator to define his/her research as osteopathically relevant by understanding osteopathic medicine sufficiently to make the connections between the research and osteopathic medicine.
- It is important to make every attempt to familiarize scientists coming into the profession's schools with osteopathic philosophy and practice, and for them to make the intellectually honest attempt to understand the profession. This will allow the profession's scientists to orient their research to topics important to the profession.
- The difference between a technique study and a treatment study is a very important distinction. In a technique study, the same thing is done to each patient, whereas in a treatment study, the physician treats what is found and uses the modality best suited to the patient.
- The study question or hypothesis dictates the design of the study, and hence must be clear and concise. The design flows from the question, not the other way around.
- The use of a sham control group in manual medicine studies must be carefully thought out. Improper use of a sham control can seriously weaken the study and may result in no significant outcomes. It must be realized that a sham using touch is actually a form of treatment, and is never neutral, so the comparison is one treatment against another treatment.

DEVELOPMENT OF RESEARCH IN THE OSTEOPATHIC MEDICAL PROFESSION

Early Research (1874 to 1939)

Research began in the osteopathic profession before the formal inception of the profession itself. A.T. Still was a true researcher, practicing observation, questioning his observations, trying new ways of thinking, and refining his hypotheses about his practice. He did not do what would now be regarded as organized research, but in fact, he did research at the basic level in a way that is still at the basis of almost all medical research. He observed, studied, questioned, and constructed testable hypotheses. The ideas and philosophy that have become the osteopathic profession and that undergird much of the research in the profession today came out of his questioning.

Soon after Still founded the first school in Kirksville in 1892, his students began to do formal research into the concepts he espoused. At first, these research endeavors were mainly devoted to inquiries into the anomalies that became known as the "osteopathic lesion," which is now called somatic dysfunction. Skiagraphy, a crude form of x-ray, was used before 1900 to try to find evidence of the structural abnormalities attributed to the osteopathic lesion. Soon after, animal models were used to determine the actual physiologic effects of the palpatory findings that made up the "lesion" (1). In 1906, the American Osteopathic Association (AOA) formed a research center, the A.T. Still Postgraduate

College of Osteopathy, and called for donations to fund it. The name was changed to the A.T. Still Research Institute in 1909, and about \$16,000 was raised to support its efforts. It was not until about 1913, when the Institute opened in a dedicated building in Chicago, that research under Wilborn J. Deason began. Funding continued to be a problem even after Louisa Burns was appointed Director, and the Institute struggled to meet its modest needs, despite calls from the AOA for more research and support. Over the ensuing years, Burns produced a body of work investigating the effects of spinal "lesions" in a rabbit model. The results of her studies indicated that artificially produced strains of specific vertebral segments produced a somewhat reproducible constellation of changes in function of organs and tissues innervated from the area of strain. These changes were later substantiated by Wilbur Cole using various neural stains (2). Burns published four books (3–6), a collected work (7), and several reports from the Institute that, unfortunately, are not widely available today but that contain much of value to the modern researcher. She continued her work until the early 1950s.

During the first third of the 1900s, research in the profession was encouraged at several osteopathic schools (8). This research included studies on basic neural and physiologic mechanisms underlying somatic dysfunction and the effects of osteopathic treatment on symptoms and immune function. Much of this research would only be considered suggestive by today's standards, but formed the basis for lines of study produced later within the profession.

The Second Period of Research (1940–1969)

In 1938, J.S. Denslow began a path of inquiry that would lead to a program of research that literally defined the modern research era in the profession. He became convinced that to bring increased credibility to the profession, research based on the latest research standards and published in highly recognized journals would have to be done. This research would have to show the basic mechanisms underlying the osteopathic lesion (9). He received training from internationally known biomedical scientists, including Ralph Gerard, and began a program of studies aimed at understanding the characteristics of muscle activity in relation to palpatory diagnosis. Joined by I.M. Korr in 1945, and by several others at Kirksville, they expounded the concept of the facilitated segment (10–12). This conceptual framework was to dominate much of the osteopathic thinking about the basis for palpation and treatment to the present day.

During the 1950s and 1960s, the research base of the profession did not expand greatly. The Bureau of Research, founded by the AOA in 1939 to fund research projects, supported fledgling efforts at several schools, but except for the Denslow/Korr project, no research efforts of a full project nature were begun. Several studies, such as those on joint mechanics (e.g., Beckwith), were published (13), but in general, research in the profession progressed slowly during this time. After World War II, the profession was busy training a flood of returning soldiers and adjusting to the new postwar world.

However, in the late 1950s, a threat to the life to the profession emerged. Culminating in the merger of the California Osteopathic and Medical Associations in 1962, the danger that the profession would be eradicated by takeover was very real. The years from 1960 to 1969 were years of uncertainty about the profession's future. However, determined that it would not be taken over, the profession rallied. In 1969, a new osteopathic school was founded in Pontiac, Michigan, as the first of 10 new schools founded between 1969 and 1980. The threat of death by merger was over, and the profession began a period of expansion and organizational prosperity unparalleled in its history.

Unfortunately, it was during this period of uncertainty and threat that the profession missed out on the tremendous expansion of biomedical research facilities and effort that resulted from World War II. The expansion of the National Institutes of Health (NIH), with its emphasis on biomedical research and its funding of new laboratories and programs, fueled an explosive growth of the biomedical research community in the United States. The osteopathic profession was unable to take advantage of this early expansion. By the time new schools with university bases were established in the 1970s, this first wave of biomedical research expansion was over.

The Third Period of Research (1970–2000)

With the founding of new schools and expansion of the five original schools remaining after the California merger (Kirksville, Chicago, Kansas City, Philadelphia, and Des Moines), the profession finally achieved a base for producing increased amounts of research. The schools began to hire more research-trained faculty, and the political arms of the profession began to more actively encourage research endeavors. The AOA began actively promoting research through the Bureau of Research and the annual Research Conference. Awards were established to honor research productivity, such as the Louisa Burns Award (1969), the Gutensohn/Denslow Award (1984), and the Korr Award (1999). Student research efforts were recognized as vital and began to be encouraged more actively with, for example, the establishment of the

Burnett Osteopathic Student Research Award and more recently, the Student Osteopathic History and Identity Essay Award. More importantly, the basis of research programs was established at many of the new schools and rejuvenated at some of the original schools, especially at Kirksville, where, beginning in 1970, Denslow and Korr oversaw the hiring of faculty specifically for research efforts. The Michigan State University College of Osteopathic Medicine formed a Department of Biomechanics specifically devoted to osteopathic research. Many of the other schools began to provide funds from their operating budgets to seed research programs and encouraged faculty and students to engage in research projects. In the early 1970s, NIH funding was awarded for the first time in many years for research in an osteopathic school.

In the years of the 1970s and 1980s, funding for research at osteopathic institutions from sources outside the profession itself grew tremendously, with many NIH and other grants being awarded. With encouragement from the Bureau of Research and individual schools, several osteopathic students undertook joint DO, PhD studies designed to further careers as clinician researchers. Many of these students have entered successful research appointments at osteopathic or other institutions.

Also in the decade of the 1990s, research requirements were instituted in many osteopathic residency programs. These requirements were aimed at familiarizing the residents with research methods and thinking, and have been expanding into some of the Osteopathic Postgraduate Training Institutes within the profession.

Thus, in the beginning of the 21st century, the amount of research being accomplished in the osteopathic profession was at an all-time high. However, a step was missing.

The Fourth Period of Research (2001–2007)

The research efforts in the profession by 2000 were both at an all-time high and increasing rapidly as research efforts at schools and at hospitals reached maturity and gained recognition. However, the profession lacked another element that had characterized many research efforts sponsored by the NIH. In the 1980s and 1990s, the NIH had sponsored a series of centers of excellence as foci for directed research efforts around the nation. The research efforts of the osteopathic profession had not yet matured sufficiently to support such an endeavor. By about 1997, several organizations in the profession, including the Louisa Burns Research Committee of the American Academy of Osteopathy (AAO), the AOA Bureau of Research, the American Association of Colleges of Osteopathic Medicine, and others, were beginning to discuss the formation of such a center. By 1999, it had become evident that NIH funding for such a center would probably not be available and that the profession would have to commit funds from its own resources. By 2000, funds had been secured for this enterprise, and requests for a center were sent to the Osteopathic Medical Schools. Five schools responded with plans for developing a center for osteopathic research. The award, announced at the AOA Research Conference in October 2001, went to the College of Osteopathic Medicine at the University of North Texas Health Science Center. The Texas school had been building its research infrastructure for several years and had a solid research record. The development of a center sponsored by the profession itself and devoted to research in manipulative medicine is the logical next step in the development of a mature research enterprise in the osteopathic profession. This center has now become a coordinating and centralizing force in developing mature research efforts into the fundamental questions facing the profession. It is attracting national funding and fostering collaboration within the osteopathic research community.

Another successful research center has appeared at the A.T. Still University in Kirksville. This center, funded mainly by internal funds, has sponsored several successful research efforts and recently published the outline of a large, multicenter trial of the effects of osteopathic manipulative treatment (OMT) on pneumonia in the elderly, the MPOSE study (14). This study has now been completed and results are being evaluated.

The Fifth Period of Research (2008 Onward)

The profession is now entering a fifth period of research development. This period is characterized by increased participation in research funding by osteopathic foundations and by the entry into the research arena of international players and other manual medicine professions. The Columbus Osteopathic Heritage Foundation has for several years been providing grants and endowments to various osteopathic schools and other organizations. It and other osteopathic foundations are now taking a major role in evolving plans for more organized and multicenter research programs. This centralizing effort along with the research centers that were developed over the fourth period will greatly enhance the ability of the profession to actively pursue research vital to the osteopathic profession.

Over several years, research has quietly expanded to osteopathic movements around the world. In the past 20 years, osteopathy has literally exploded in Europe and even Russia and Japan, to name a few of the prominent countries. Now many of these osteopathic movements are developing research programs that are adding to the fund of osteopathic research knowledge. Much of this research effort is directed to the core aspects of osteopathic practice, since most of the osteopathic movements outside the United States are manipulative only schools; their practitioners are not licensed to practice the full scope of medicine, but only manipulative treatment.

A third characteristic of the dawning fifth period is increased multidisciplinary cooperation. In March 2008, an international and interdisciplinary symposium was held in Texas under the auspices of the Texas Osteopathic Research Center. Funded by the NIH, various osteopathic foundations and the funding organizations for the Chiropractic, Massage Therapy and Physical Therapy professions, this conference represented a breakthrough in interprofessional cooperation. Scientists and clinicians from the United States and several foreign countries met to discuss data bearing on manual therapy and treatment, and the latest findings on somatovisceral interactions. There will be a book published on the conference. This spirit of increasing globalization and interdisciplinary cooperation between various manual medicine professions is a necessary part of increased understanding of the efficacy and mechanisms of OMT.

Thus, the next phase of research development in the osteopathic profession has begun. This chapter will provide information on the basics for conceptualizing research on topics germane to osteopathic medicine and some of the challenges faced by investigators designing research in these topics.

WHAT IS OSTEOPATHIC RESEARCH AND WHO DOES IT?

A definition for osteopathic research has eluded politicians and osteopathic researchers since its inception. Why would this question be asked? It is often asked in regard to whether a research project should be funded by an osteopathic funding agency, such as the AOA Bureau of Research. It may be asked to determine whether research should be included in osteopathic publications. It can be

a condition for whether students are to be included in a research project. Whether research is “osteopathic” or not has both political and practical implications. In this regard, several definitions of osteopathic research have been put forward at various times.

Research Under Osteopathic Auspices

Perhaps the broadest definition is that osteopathic research is any research done under osteopathic auspices. This definition implies that any research, basic or clinical, no matter what the subject matter, is osteopathic when performed at an osteopathic institution or under the control of an osteopathic institution. Under this rubric, research on any topic could be considered osteopathic. This is obviously too broad.

Research on Topics of Special Interest to the Profession

Some topics in biomedicine have historically been of greater interest to the osteopathic profession than others. For example, the actions of the nervous system in controlling various autonomic functions and the effects of manipulative treatment on immune function have been topics of investigation for many years. At times, efforts have been made to define lists of such topics as the ones that define osteopathic research. The problem here is that new avenues of inquiry are constantly being found that apply to the clinical and theoretical topics of the profession, and no one list can be devised that will cover or predict them all.

Research on Osteopathic Manipulative Treatment

Definitions of osteopathic research have at times been restricted to those studies attempting to determine efficacy or value of osteopathic treatment. This approach leaves out the entire area of mechanism inquiry that seeks to explain the basis of treatment efficacy. Obviously, this is too narrow a view. In addition, research into mechanisms of action and underlying process is becoming increasingly emphasized by the NIH.

Any Research into Biologic Mechanisms, Because Osteopathy Is Holistic, Therefore Encompasses Everything

Although ecumenical, this is not a definition because it says nothing. It would assume that there are no basic theoretical underpinnings to the osteopathic philosophy or practice that have or should be identified, thus that there is no definition of osteopathic medicine. If this were so, there would be little basis for the profession to exist.

A New Definition of Osteopathic Research

Attempts to define *a priori* the scope or type of research that is considered osteopathic seem doomed to failure. However, perhaps there is one way to determine whether research is osteopathic: To require the investigator to explain how the hypothesis and expected findings of their research would be relevant to the theory, mechanisms, or practice of osteopathic medicine. That is, investigators must have sufficient understanding of the basic principles of osteopathic medicine to explain how the interpretation of their data would impact osteopathic medicine. They must know enough about the perspectives of the profession, its theoretical basis, and/or its clinical practice to coherently build bridges from their studies to the profession. If they cannot do that, then, although their data

may be interesting, important, and even cutting edge, it is not osteopathic. Perhaps someone else can build those bridges, but until that happens, it is not osteopathic research.

It is of great value to have physician researchers and PhD researchers who expend the time and intellectual energy to understand the profession's theoretical and clinical perspectives, because the results of any study must be interpreted within some context. If the context is that of osteopathic medicine, the data are much more likely to be correctly used in understanding the profession's basic questions.

Thus, anyone can do osteopathic research, provided that they make the intellectual effort to become familiar with the profession's clinical, theoretical, and/or historical experience. Otherwise, they are doing interesting research that must be interpreted by others to be useful to the osteopathic profession. The burden of proof that research is osteopathic lies with the investigator.

HOW DO RESEARCHERS BECOME AWARE OF THE THEORY OR CLINICAL ASPECTS OF THE PROFESSION?

Although trained osteopathic physicians can be expected to be familiar with the background necessary to relate research findings to their profession, such is not the case with many basic scientists (including many currently at osteopathic institutions) or researchers outside the profession. Cultivating basic scientists who understand the clinical tenets of the profession and training basic scientists to gain such understanding pays off in increased theory building and data interpretation. One excellent way to begin the process of understanding osteopathic principles and practice is to ask PhD and other non-DO faculty to attend OMT courses. Experience in learning and receiving manipulative treatment is also an enlightening experience. However, researchers are trained to investigate new areas of knowledge and to ask questions of those areas. Basic scientists and others within the profession can easily access books and journals relevant to their osteopathic understanding. This book is a good start in that journey. A second source is the *Journal of the American Osteopathic Association*, where reviews, original research articles, and case studies are available. Other sources, such as Still's *Autobiography* (15) or his *Osteopathy Research and Practice* (16), are useful. Other books, such as Northup's books on the profession (17) and research (2), are useful in helping the basic scientist understand the profession.

As much as the researcher must be expected to find and read materials pertinent to his or her understanding, so must those knowledgeable in the profession be willing to help promote the necessary understanding. Osteopathic physicians and students must be willing to discuss their beliefs and clinical observations with often skeptical scientists. The experience of the 1989 AAO symposium (18) is illustrative of this point. Several internationally known basic scientists were assembled for 2 days of discussion prior to the symposium itself. They questioned the attending osteopathic physicians about the experiences of the profession and consented to having OMT. Rather than being antagonistic to the largely anecdotal clinical observations, they were uniformly supportive and excited by them. Several altered their prepared talks to reflect their new understanding and have maintained active contact with the profession since. In fact, one is actively training DO students in his laboratories. A similar although more limited experience occurred at the 2008 International Symposium between scientists and clinicians. Active and open communication about ideas most often leads to exciting opportunities. Thus, the development of basic scientists who understand the osteopathic profession is a two-way street.

Although much has been accomplished in this area, the cadre of trained clinical and basic science investigators must be expanded to those who understand the principles and clinical experiences of osteopathy so that they can frame their research questions in the light of osteopathic clinical experience and theory. Without this understanding, data will not be examined from the perspective of osteopathic treatment and insight.

ETHICAL CONSIDERATIONS IN OSTEOPATHIC RESEARCH

Human Subjects Protection

Since the end of World War II, there has been a growing understanding of the problems associated with the ethical considerations of research on both human and animal subjects. The horrible experiments performed by physicians on prisoners in the Nazi concentration camps sparked reforms and regulations to control human medical experimentation. Coming out of the Nuremberg Trials and codified in the 1964 Declaration of Helsinki, these regulations have been the subject of continuing review, refinement, and discussion since then (19–21). The researcher who contemplates doing research in osteopathic topics must be aware of and abide by the current human subject regulations. Not only is this the law, but it is the moral and just thing to do. In fact, no reputable journal will publish results of a human study without evidence that applicable human subject guidelines have been scrupulously followed.

The novice investigator must be familiar with not only the principles of ethical treatment of subjects, but also with the procedures in effect in the institution where the research will be done. In the event that a private physician wishes to conduct human subject research in a private office, the research must first be approved by an appropriate human subjects review board, usually known as the institutional review board (IRB). The IRB is a governmentally sanctioned body whose members are appointed by the institutional executive in charge of research and the President or CEO of the institution, and must include individuals with specific interests, including a person who has no other affiliation with the institution.

INSTITUTIONAL REVIEW BOARD AUTHORITY

The IRB has the authority to deny or approve any research proposal involving human subjects. The main purpose of the IRB is to protect the safety of the subjects. It can stop ongoing research if it deems protection not sufficient or uncovers problems in the research. When applications for research are submitted to the IRB, the application can receive expedited review if certain conditions are met, such as that the research uses only data collected in the normal course of office practice and that are not identified with a patient. However, it is not up to the investigator to determine whether the research is exempt, can have expedited review, or must undergo full review. Case reports and retrospective reviews of cases (see discussion below) seen in the routine office practice do not generally need IRB approval unless the patient is identified or if written permission is given prior to release of any information.

MAJOR INSTITUTIONAL REVIEW BOARD CONSIDERATIONS

The major factors in human subject research include:

- Informed consent
- Confidentiality statements
- Risk

- Absence of coercion
- How subjects will be obtained and paid for service

One of the cornerstones of human subject protection is the principle of informed consent. This idea holds that the subject be informed of the study fully and completely and be able to give free consent to participation. If the subject is a minor, incapable of giving consent due to mental or other disability, or a prisoner, special and specific protections are specified.

The principle of subject confidentiality is another vital concern. The subject's confidentiality is to be protected and not divulged without the subject's written consent. Thus, medical and research data are considered private matters when linked to an identifiable subject. Data are usually coded in such a way that they cannot be linked to a particular patient, and great care must be taken that no such link can be inferred. The recently enacted HIPAA standards must be followed to protect patient privacy and confidentiality. (See <http://www.hhs.gov/ocr/hipaa/> for more information on HIPAA.)

Risk to the patient is another factor in human research. Risk to a patient runs from essentially nonexistent to grave. If the risk is anything but incidental, the subject must be fully informed of that risk and have every option to decline participation. The risk must also be justified by potential gain, perhaps not to the individual subject, but to the field. This assessment is difficult to make, and the investigator must therefore justify the study well.

Absence of coercion is a complex topic that is often debated in study design. Is providing a monetary incentive to a subject for time taken by the study coercion? Is the investigator using force of personality or doctor-patient relationship to coerce the subject to enter the study? These questions are difficult to quantify, and the committee and investigator must consider them carefully.

IRBs are usually in existence in osteopathic medical schools and in many hospitals. Each IRB is allowed operating discretion within established NIH guidelines as to how it reviews protocols. Some IRBs meet on a regular basis and others are on call. The potential investigator is responsible for finding the protocols used by the appropriate IRB and fully following these regulations.

It cannot be overemphasized how important it is to be cognizant of current guidelines for human subject protection and to fully adhere to them. (For current and full information, including downloadable human subjects research guidelines, go the NIH web site at: <http://ohsr.od.nih.gov>.)

Animal Protection

No less important in research on human subjects is the protection of subjects in animal research. As is evident from the media, animal rights have become a volatile issue in much of the world. Some of the emotion surrounding animal rights obviously stems from the fact that animals cannot give informed consent or judge risk in a study. In addition, by its nature, animal research often ends in the subject's death. For these and other reasons, some groups use violence to attempt to stop animal research.

Not unlike human subject protection, a well-defined, protective structure has been implemented by the NIH and other groups, such as the American Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC), have promulgated guidelines and rules for the proper use of animals in research studies. The Animal Care and Use Committee (ACUC), a governmentally mandated body, enforces these rules at research institutions. Like the IRB, the ACUC has the authority to shut down research not in compliance with applicable regulations and must approve all animal research prior to its start. The osteopathic researcher

who wishes to use animals in research must first successfully seek ACUC approval. As with the IRB, each ACUC has latitude in its procedures about which the investigator must be informed. Again, as with human research, the investigator must be meticulous in following animal care and use guidelines: first and foremost, for moral and ethical reasons but also because humanely treated and well cared for animal subjects provide more reliable information. (For more information on animal care and use guidelines, visit the NIH Office of Animal Care and Use site at <http://oacu.od.nih.gov/>.) Another useful site is the American Association for Laboratory Animal Science site at www.aalas.org or the AAALAC site at www.aaalac.org.

Applying for Institutional Review Board or Animal Care and Use Committee Approval

The process for applying for research approval for either human or animal research is determined by each committee. Some committees meet monthly or more often; others meet on call. However, at the least, each protocol submitted for IRB or ACUC approval will have to contain the following elements:

- Background literature review
- Justification for the project
- Hypothesis to be tested
- Complete description of the methods to be used
 - Evidence that animals will be legally obtained and humanely housed
 - Evidence that precautions will be taken to minimize any necessary pain or suffering
 - Evidence that other alternatives to animal use are not available
 - Data to be collected
 - Statistical methods for analysis
 - Any pilot data available

These items represent a fair amount of work that must be done prior to submitting a protocol for review. It also means that the investigator will find it necessary to think through the studies prior to getting approval. The appropriate approvals are also necessary before funds are awarded for the proposed research from government agencies.

TYPES OF RESEARCH IN OSTEOPATHIC MEDICINE

Basic Science

Within the purview of osteopathic research, there are several valid types of studies. Perhaps the most basic is research that flows from basic science studies. This research includes studies designed to define the basic functions of the body and mind, and explain how they interact with the environment. These studies are mainstream biomedical research. An increased understanding of the human organism and its function is invaluable in validating osteopathic practice. The osteopathic profession must therefore nurture the basic sciences, but the links between basic research and osteopathic philosophy and practice must be made.

Basic Research in Other Institutions and Professions

Basic science has been performed for many years in most biomedical facilities and research institutes. Most basic research relevant to the osteopathic profession is done not in the educational institutions

of the profession but in other biomedical settings. The amount of research that can be supported directly by the profession is small compared with the amount of such research performed around the world. The total amount of funding available from within the osteopathic profession for support of its research programs is less per year than the annual budgets of many individual laboratories outside the profession. This suggests two things. First, maximal use must be made of data from laboratories outside the profession. Osteopathic researchers and clinicians must cultivate interactions with biochemical researchers at other institutions who can supply data and interpretations. Second, the limited resources of the profession must be put into research endeavors that provide the greatest return in explaining osteopathic experience and theory. This requires, as stated above, that investigators within the osteopathic profession understand the unique and defining concepts of osteopathy within which to interpret their findings. Without this understanding, the investigator is unable to interpret the findings in ways that are useful to the profession, and a large part of the research investment is lost.

The use of data from laboratories outside the profession is certainly a very useful and fruitful endeavor. We have made use of this mechanism in proposing mechanisms for the facilitated segment (22). However, care must be taken in using data generated in studies not specifically designed to answer the question to which the data are now being applied. Unless the limitations and specifics of the data are well known, implications can easily be made that are beyond the scope of the data and hence potentially misleading. It is important to realize these limitations, but to use data and sources from outside the profession whenever possible. Such was the case when the AAO commissioned two international symposia held in 1989 and 1992, which resulted in proceedings publications (18,23) that have been very useful in informing the profession of possible mechanisms for clinical phenomena and the results of manipulative treatment.

Integrative Model Building: Integrating Basic Science and Clinical Observation

A second type of research activity necessary within the profession is the integration of basic science knowledge and clinical observation. This endeavor is extremely valuable and potentially dangerous. A recent article by Van Buskirk (24) illustrates such research. In this article, Van Buskirk builds a theoretical model of somatic dysfunction based on nociceptive input. He marshals an impressive array of basic science data and synthesizes it in a unique way from his clinical understandings and observations. The result is a well-grounded look at one of the central concepts of the osteopathic philosophy of health and disease. This is the valuable aspect of the article.

The dangerous part is that the model will be taken as fact. Van Buskirk goes to great lengths to point out that the model seems to be explanatory but still needs to be subjected to rigorous research verification and clinical observation before it can be accepted as proven. Unfortunately, the pioneering models that came out of the research of Korr and Denslow (11,25) suffered from being taken as factual explanation rather than as models in need of experimental verification. Once a model has been accepted as truth, the perceived need for further research or theory is impeded or stopped, and the model becomes accepted as truth. This can be disastrous if the model is then shown to be erroneous or incomplete because there are then no alternatives to take its place. Integrative model building provides much needed direction for both basic and clinical research but must not be taken at face value without verification and experimental testing.

Thus, the osteopathic profession must continually examine its theories and subject its explanations to close scrutiny. The vast body of clinical evidence demonstrates that the precepts of the osteopathic profession are sound. However, often the profession embraces explanations that are not solidly research based. The result is theory taken for fact with further exploration of alternative theory or factual basis effectively stymied.

Synthesis and Meta-Analysis Research

Two types of scholarly activities that can be of immense benefit to any area are the synthesis review and the meta-analysis. Synthesis papers are efforts to review and critically analyze an area or field of study. In this type of work, the author would select a topic area for analysis and review all available work in that area. Although the review is in itself important, a synthesis then analyzes the work that has been done and attempts to find common themes, areas of agreement or disagreement, and then builds a hypothesis as to what the accumulated knowledge of the area is saying. This type of paper can often point to why seeming contradictions between studies exist, what studies should be done to finalize questions in the field, and so forth. Early in my career, we did such a synthesis for the field of spinal cord learning (26). The insights from that activity directed spinal cord plasticity research for many years—not only in our laboratories, but in other laboratories (27). Often, a good synthesis of an area will open the area for more intensive study and can be an impetus for real advances in an area that was seemingly uninteresting or filled with conflicting data.

The meta-analysis is another useful tool for research. This analysis attempts to accumulate all studies in a field that are deemed sufficiently rigorous and determine the combined power of the results. In this way, by statistically combining smaller studies that are not particularly convincing by themselves, it is often possible to achieve sufficient statistical or analytical power to have confidence in the phenomenon being investigated. Such an analysis was done on the area of spinal manipulation for low back pain and resulted in acceptance of that modality as effective treatment for acute low back pain (28). An analysis of spinal palpatory procedure validity and reliability is currently under way at the Center for Complementary and Alternative Medicine at the University of California Irvine College of Medicine, and is sponsored by the trust fund acquired by that school when the California College of Osteopathic Medicine became the University of California Irvine College of Medicine in 1962. More information on procedures of meta-analysis can be found in many statistical texts (29).

Qualitative Studies in Osteopathy

Valuable information can often be gathered by means of surveys and interviews. Such studies, although not experimental, are often the only way to find trends in populations, practice distributions, or to gather the collected thought of experts in a field. Often, surveys seem simple and easy to perform. The investigator must only write down a few questions on a topic and send them out to some selected individuals and wait for the returns. Such simplicity is illusory. Good surveys must be well planned and executed. The topic must be carefully framed and the questions prepared with precision. Pitfalls in the use of surveys include poorly framed questions, problems in determining to whom the survey should be sent, poor return rates, and others (29). Prior to instituting a survey, an investigator must consult texts and/or experts in survey design and procedure. Within the osteopathic profession, Johnson and Kurtz (30–32) have performed several surveys addressing such issues as

student interests and the use of manipulative treatment. These studies have provided a baseline for the use of osteopathic manipulation in the profession and are invaluable in charting future direction within the profession. These surveys are excellent examples of well-done and analyzed survey studies.

Another instrument that can provide valuable information is the collection and analysis of expert interviews or writings of often long-departed authors. These methods also often seem deceptively simple. In fact, as with surveys, interviews with experts require extensive preparation and careful planning. Both directed and open-ended questions may be asked and answers recorded for later transcription, or the expert may be asked to write on predetermined topics. In any event, the answers must be carefully analyzed for content and other information. The analysis of writings by departed authors can be valuable in translating what may now seem to be arcane jargon into terms understandable in today's terminology. For example, why did Still put so much emphasis on the fasciae of the body? What did he mean by such terms as "fluids of life?" To understand these ideas in the way in which Still did, it would be necessary to find the meaning of those terms in the late 1800s, as well as to look at the context in which he used them. Various means of content analysis are available to help in such a task (34). Both interview analysis and writing analysis can be of great value to osteopathic understanding. A particularly good example of such work can be found in Jane Stark's (35) recent book, *Still's Fascia*. This book came out of a particularly comprehensive thesis done by Stark for her Canadian osteopathic degree and analyzes Still's ideas on fascia in light of his background and his times.

Epidemiology and Outcome Studies

Epidemiologic studies have not been widely used in the osteopathic profession. It should be noted, however, that there are some very important epidemiologic topics awaiting study. Because epidemiology refers to the study of patterns of health and disease and what influences these patterns, those influences on health and loss of health that are of particular interest to osteopathic medicine should be subjected to such studies. One of the most important such study would be the incidence and natural history of somatic dysfunction in normal populations and various subpopulations with defined illness. As with most studies, epidemiologic studies of this entity would require careful planning and execution. However, it could reveal very important information on the potential uses for manipulative treatment modalities. The interested investigator can find more information in such references as *Medical Epidemiology* (35).

Outcome studies are a very important type of research that bridges both epidemiology and at times, experimental studies. In the usual such study, outcome measures are taken or reviewed for patient populations, and the outcomes of one type of treatment outcome, cost, patient satisfaction, and so on are reported. Outcome studies usually require large patient populations to gain sufficient data to be meaningful.

Research on Manipulation

As one of the key elements of osteopathic care, manipulative treatment should be the subject of increasing amounts of research in the profession. In research aimed at investigating the usefulness of manipulative treatment, there is much confusion about proper research methodology. However, the researcher approaching osteopathic manipulation as an independent variable must decide which of the following is to be evaluated: a treatment or manipulative technique, OMT, or osteopathic health care.

Depending on the aspect of manipulation to be studied, different experimental designs will be employed. Too often, investigators fail to distinguish between these three entities and hence have difficulty determining the correct experimental design for their study.

MANIPULATIVE TECHNIQUES

One of the most illustrative studies of manipulative technique is the Irvine study, performed by Buerger and colleagues (36,37) at the School of Medicine at the University of California, Irvine, in the late 1970s and early 1980s. They wished to determine the effects of a single lateral recumbent roll (high-velocity/low-amplitude thrust) on low back pain. The study was elegantly designed and executed, with a result that showed an immediate effect of the lateral recumbent roll on certain measured variables; simply positioning the patient for a lateral recumbent roll and omitting the thrust did not provide the same changes. After a few weeks, however, no differences between the experimental and control groups remained, probably the result of the nature of the presenting complaint, which has a natural history of relief in a few weeks. Nonetheless, an immediate effect of the thrust was seen. The point missed by many readers was that the investigation was not of OMT but of a treatment technique.

THE IRVINE STUDY COMPARED WITH CLINICAL TRIALS OF MEDICAL INTERVENTIONS

In many ways, the Irvine study was similar to drug studies. One specific manipulative technique was used on each patient in the experimental group (and not in the control group), the patients were blinded to whether they received manipulation, and measurable variables were used. In the typical drug trial, the specific effects of a certain chemical compound on the course of a specific set of symptoms are studied. The design of the study controls for other factors that might cause a change in the outcome. This is a legitimate model for the study of a specific technique within manipulative treatment. If the intent of the study is to determine the effect of a specific and repeatable manipulation, the research design should emulate the design of a drug trial, including attempts to blind the patient to whether the technique was delivered. Such studies are useful in instances where there may be reason to suspect that a specific manipulative technique would change a particular condition. Great care must be taken to control for the actual presenting complaint, whether the patient has knowledge of manipulation, and the actual delivery of the technique to make certain that it is given in the same way to each patient.

Such studies can be useful as long as it is recognized that the study's purpose is to evaluate the effect of a specific, single, or small group of physical manipulations on a specific condition. Another recent example of this design was published by Wells et al. (38), who looked at the effects of a set of standard manipulative techniques on gait parameters of patients with Parkinson disease. They found that the standardized techniques produced increased performance in various aspects of gait in these individuals. Such designs, performed correctly, give information on the effects of a technique on some aspect of patient function.

STUDIES OF MANIPULATIVE TREATMENT

This type of research is used to study the effects of OMT on one or more measurable patient parameters. The research design and the goals are somewhat different from those used in technique studies. Korr (39) has elegantly reviewed these differences. Osteopathic

theory and practice holds that the full treatment of an individual by an osteopathic physician entails an interaction between the physician and the patient that is not static but dynamic, changing from treatment to treatment and instant to instant as the treatment progresses. The physician responds to the dynamic changes in the patient's function; the patient responds to the attitudes and touch of the physician. The treatment is not a prearranged set of movements and thrusts given to each patient, but an ongoing stimulus/response synergism between the physician and patient, with the patient's response guiding the actions of the physician.

In this case, the manipulation cannot be predetermined or prescribed by the research protocol but must "go with the flow" in response to the reactions of both physician and patient. The manipulative treatment is properly a "black box." The physician/patient interaction determines what manipulative treatment is performed. The physician is free to do what is deemed best for the interaction. Because one of the basic axioms of osteopathy is that each person responds differently to stress and treatment, this freedom of interaction cannot be removed from the physician without changing the research to a technique investigation. To investigate manipulative treatment rather than a manipulative technique, manipulative treatment must be used.

The recent study on the effects of osteopathic treatment on low back pain by Andersson et al. (40), comparing manipulation with standard of care is a case in point. In this study, treating osteopathic physicians were allowed to use any manipulative techniques necessary for the patient. The study found that there were no differences in outcomes but that the group treated with manipulation required less medication and physical therapy. In this study, unlike in a technique study, the physician chose the treatment that was indicated for the patient.

Technique Versus Manipulative Treatment

Once the difference between these two basic types of research on manipulation is realized, many of the other problems associated with investigating manipulation can be much more easily resolved. Both types of research are valuable and valid. Research on techniques gives information on specific techniques; research on treatment gives information on what the osteopathic physician does in practice. Both are necessary and essential for the future of the profession. Their differences must be recognized and appreciated for appropriate studies to be designed.

Subtypes of Manipulative Treatment

Within the general types of research on manipulative treatment, there can be several subtypes. One aims at the effect of manipulative treatment in general on some aspect of a disease or body function. This could be called the nonspecific design. It is done to improve body function without identifying specific somatic dysfunction in patients with some clinical presenting complaint. The treating physician provides a general manipulative treatment without specifying areas of somatic dysfunction or specific areas to be addressed. By contrast, in specific treatment designs, the physician applies manipulative treatment to specific somatic dysfunction as defined by palpatory diagnosis and documented with such signs as asymmetric motion, tissue texture changes, and so forth. This type of treatment is designed to restore function or ameliorate functional difficulties and may or may not be related to actual presenting complaints (the patient may not be aware of some somatic dysfunction). In each of these study types, appropriate data on what is done must be collected, and specific measures of outcome must be made.

Effectiveness Studies

A third type of study incorporates either of the first two: the effectiveness study, in which manipulative treatment is given to alleviate a specific presenting complaint. The patient is selected for a particular complaint, such as low back pain; the treating physician gives appropriate manipulative treatment. The effect of the treatment on the complaint (e.g., low back pain) is measured. This study type may or may not require the delineation of somatic dysfunction during treatment. Efficacy studies are the most usual in the literature because the measure of results is the most straightforward.

Functional Outcomes of Manipulative Treatment

In the fourth design subtype, the functional outcome design, the effect of manipulative treatment on general physiologic function is assessed. In the philosophy of the osteopathic profession, the origin of disease is believed to be some loss of normal function in the body that then allows for the development of clinical symptoms. This type of study is accomplished on clinically disease-free subjects with somatic dysfunction who are addressed with specific treatment. Measures of outcome are such things as immune system function, tolerance to stress, general activities of daily living assessments (in older subjects), and other measures of normal function that assess general health and function.

Presumably, such studies would find increases in the functional ability or capacity of treated subjects.

TOTAL OSTEOPATHIC CARE STUDIES

Another general study design takes into account the total care given by the osteopathic physician; it is not limited to manipulative treatment. This study type assesses the health status of patients given care by osteopathic physicians and presumably, but not necessarily, includes manipulative treatment over the course of care. Such studies are longitudinal or cross-sectional in nature and include as data such things as disease episodes and measures of total body function and activities of daily living. If the osteopathic philosophy of health is taken seriously, there is a heavy component of preventive care that would include periodic manipulative treatment to correct somatic dysfunction as it occurs. Such care should prevent at least some of the acute disease episodes seen in nonmanipulated subjects. A study of this kind would be expensive and long term, and could be approached in various ways. Research of this type could show whether the application of osteopathic principles to health care is differentiated from disease care. Practitioners applying total osteopathic care to their patients would be used to determine if their outcomes in terms of patient health were different from physicians not using osteopathic care. Obviously, there would be many potentially confounding factors that would have to be analyzed. Interesting results, such as cost/benefit ratios, quality-of-life issues, and others, could be addressed.

DESIGNING AND CONDUCTING OSTEOPATHIC RESEARCH

Understanding the basics of what type of study is to be done is an important step in beginning osteopathic research. Realizing the importance of ethical considerations and data confidentiality is vital. The next steps in a research project are also vital. These steps can be characterized as follows:

1. Observation
2. Literature search

3. Hypothesis building
4. Study design
5. Data collection
6. Data analysis
7. Discussion of results
8. Writing and publication

These steps are all necessary and important in the conduct of research in any field. We will briefly discuss each.

Observation

Virtually all biomedical research stems from clinical observation. The clinician observes patients and their response to illness and treatment. He or she often conducts impromptu “experiments” to see if there is any effect on a patient’s outcome. Such observations are valuable, but rarely conclusive. Observations are usually subject to too many uncertainties, called biases, to lead to definitive conclusions about what actually occurred or whether there was really an effect of a certain treatment on a condition. The realization over many years that observation by itself was rarely useful in establishing reliable cause and effect relationships in fact led to the art of research design. However, observation is the beginning point for investigation. The investigator should begin with observation of his or her practice. What is of special interest to the investigator? One of the most important aspects of doing research is to pick a topic that piques the interest. Once that is accomplished, the basis of a research project is laid. A prime example of observation being the basis for a lifetime of research is that of Lawrence H. Jones (41). He made the observation of a patient with severe muscle spasm that was relieved by placing the patient into an extremely awkward position to alleviate the pain. Instead of dismissing the result as spurious or inconsequential, Jones pursued the observation and developed the area of strain/counterstrain.

Literature Search

The next step in developing a research project is the literature search. This is a very important step and one that is often either slighted or done without sufficient diligence. The first steps in a literature search are to examine texts and other reference works easily available. Do they show that the problem interesting the investigator has already been thoroughly researched? Is there an abundance of literature already available? Or does a preliminary search reveal little or no information? Texts and reference books are called secondary literature because they report second hand on research articles (primary literature). Hopefully, something will easily be found in the secondary literature that will lead to primary research articles or even reviews of the topic.

The search for information will almost invariably lead to the primary literature; to journals in which research findings are presented. The search for primary literature can be greatly simplified by using one of the many computer resources now available. The National Library of Medicine (NLM) has the largest compilation of medical literature in the world. This resource is available to anyone with World Wide Web access. The “search engines” for the NLM database may be accessed free through services like PUBMED or by fee-for-service engines, such as PaperChase. These search engines make searching the many millions of articles in MEDLINE and its associated databases easy and fast. However, the search must be done with some skill in selecting appropriate search terms or author names, or the result may be a return of thousands of often irrelevant articles. Hopefully, the search will be

productive in producing several articles and papers on the topic at hand. The investigator may then proceed to acquire the articles through libraries or by ordering them online, and begin to read about what is known about his or her topic.

The search can be both a time-consuming and strenuous task. In osteopathic medicine, there is only one journal included in the NLM databanks: the *Journal of the American Osteopathic Association (JAOA)*. Because the NLM Medline database only goes back to 1966, it is also important to review articles in earlier issues of the JAOA (as it often is for other journals). This can now be done by searching the online JAOA database at www.jaoa.org. The investigator may have to actually go to a library with holdings of the journal and search back issues, or ask the librarian to review an index of the journal for relevant topics. In addition, other osteopathic source materials should be searched. The AAO has an important collection of osteopathic articles in its Yearbook collection and has now released a CD-ROM with its bibliography in searchable form. This listing should be included in any search. Other osteopathic collections, such as the *Osteopathic Annals* (no longer published), are also valuable sources of information.

Many public libraries have access to many search engines and can assist in locating materials. University libraries usually have electronic access to full-text research journal archives that are very useful. When using any database, it is advisable to keep careful records of articles read and what was in each. A computer database program, such as Reference Manager or Endnote (www.isiresearchsoft.com), is excellent for this purpose, and such programs also allow easy construction of bibliographies when writing papers. In fact, the Endnote program is one of the most useful writing tools in a researchers toolbox.

What should be looked for during a literature search? Obviously, the primary goal is to find articles and information on the topic of interest. What has been found about the topic? What research or observations have already been made? It is also important to find how others have looked at the area. If research has been done, how was it done, and what measures did the investigators use in the studies? What techniques and research designs were used? If other research has been done, it is best to find how it was done, what pitfalls were encountered, and how they were overcome.

Thus, the literature review is a vital and often very poorly done part of any study. Careful literature review will often save the investigator much work and even embarrassment. It is not good to find, after doing a study, that someone else has already done it or one similar.

The literature search allows the investigator to go to the next step of research design: the formation of the research hypothesis.

The Hypothesis

One of the most important aspects of designing any research project, be it quantitative or qualitative, experimental or observational, is forming the hypothesis. The hypothesis is the statement of the question being asked by the study. The hypothesis must be clear and concise. It must state exactly what the research is to investigate. Most beginning researchers try to make the hypothesis too complex or design a hypothesis that is simply not testable. For example, the hypothesis “osteopathic treatment is good for headaches” is not a good hypothesis. Although we would like to think that the statement is true, can we test it? The answer is “no.” What is “osteopathic treatment?” What does “good” mean? What type of headache is to be studied? A good experimental hypothesis is simple, precise, and well defined.

The Hypothesis Dictates the Study Design

The hypothesis also will dictate the design of the study to be done. Too often, an investigator produces an imprecise hypothesis and then has difficulty designing the appropriate study because the actual question and its implications are not clear. If the hypothesis is clear and simple, the design of the study will not only be much more evident, but it will be defensible to others. For example, in the Irvine study referenced (42), the hypothesis was simple and straightforward: "What is the effect of a lateral recumbent roll thrust on measures of well-defined, acute low back pain?" This hypothesis defined the study as a technique study on a well-defined problem, acute low back pain (which was very precisely specified).

Thus, the hypothesis, not a preconceived notion of design, must dictate the study design. Too often, it is assumed that one type of study design is the only one appropriate for some type of research, such as manipulative medicine, when in actuality, the design flows from the question being asked. If the investigator has the question clearly in mind, the research design can be chosen and refined to reflect that question, not some other question that is not being asked.

Once the hypothesis is determined, it is usually converted to the "null hypothesis." The null hypothesis simply states the negative of the experimental hypothesis. Thus, if the experimental hypothesis was that "a lateral recumbent thrust will have an effect on acute low back pain," the null hypothesis would be that "a lateral recumbent thrust will have no effect on acute low back pain." The null hypothesis can be disproved by a study showing an effect, but a study showing no effect does not necessarily prove that no effect exists. Rather, it shows only that an effect was not observed in the present study. Thus, the null hypothesis is the preferred statement with the intent of the study to disprove it. In fact, many study designs provide both null and experimental hypotheses.

Study Design

The design of a research project is vital to the success and value of that project. In osteopathic research, there are many types of studies that can be done, as outlined above in this chapter. Once the investigator has chosen the topic of the study and has at least stated the hypothesis, if not completely refined it, the choice of research designs must be made. Is the research to be observational, epidemiologic, descriptive, or experimental? Each of these types of research has particular requirement for design components (29,33,34,43). The investigator must consult with experienced clinical research designers for appropriate help.

In the area of research on manipulative techniques or treatment, the most usual type of study is either a descriptive or experimental study. In descriptive studies, patients are simply treated, and the results of the treatment are reported.

CASE STUDIES

CASE REPORT

A case study is the report of a single, supposedly unique case, or of a unique treatment of a case. In case studies, a patient's history is given, the treatment is described, and the results are reported. The case study was the staple for medical research many years ago, but is now only infrequently used. Many medical journals will no longer publish case studies except under the most stringent circumstances. Case studies are useful as observations

leading to more complete studies, but rarely stand on their own. The limitations of case studies include poor recording of findings, incomplete history and physical reporting, and in many cases, unconfirmed diagnosis. If the investigator believes that a case is sufficiently unique to warrant publication, a very complete literature review must be done prior to attempted publication to ensure that no such findings have been previously reported. Kaprow and Sandhouse (43) recently reported on the treatment of a case by osteopathic manipulation, an example of a relatively unique treatment of an uncommon complaint.

CASE SERIES: RETROSPECTIVE

Case series are of two types. The first is the retrospective case series. In this design, the investigator searches the office files for all cases of a similar type and attempts, through reviewing the cases, to find commonalities in symptoms, treatment, or outcomes that warrant publication. The retrospective case series brings together similar cases to add credibility to a unique or new clinical entity or treatment regime. The retrospective case series may add weight to an argument that a new or unrecognized clinical syndrome is emerging, or that a new treatment technique is effective, but suffers the same problems as the single case study; the data are usually not uniform and diagnoses may be lacking. In addition, there is little assurance in a retrospective case series that all patients of the targeted type have been included; it is possible that only selected cases have been reported, making the results seem more beneficial than is actually the case.

CASE SERIES: PROSPECTIVE

Prospective case series studies are usually done after the realization that some treatment has a greater impact than thought or can be used on some unique condition. In this study type, nothing new is introduced, but only usual and standard practices may be used in a different manner. However, the means of identifying prospective patients, the data to be collected, and the methods of treatment are clearly specified in advance. All patients who meet the predefined criteria are treated and the data recorded uniformly. Thus, there is some assurance that the patients actually had the specified condition and the data gathered are uniform.

In most cases, case series do not have to be approved by an IRB unless a new treatment is being tried or data not usually collected in the course of practice are being collected. Although somewhat more indicative of effect, the prospective case series fall short of providing convincing arguments for effectiveness, because there is no comparison with other treatments or subjects.

OTHER OBSERVATIONAL STUDY DESIGNS

As mentioned above, various other types of designs, such as interview, epidemiologic, survey, and outcomes designs, are useful for many aspects of osteopathic research and can bring powerful and useful data to bear on such questions as:

- How do the attitudes of osteopathic students toward the profession change over their training?
- How satisfied are the patients of osteopathic physicians?
- What did statements of pioneers in the profession mean?
- How do patients of osteopathic physicians choose their doctors?
- What is the incidence of somatic dysfunction in the normal population?

These and many other questions are awaiting well-planned studies and would produce information valuable for planning the future of the profession.

Experimental Design

The proof of cause-and-effect relationships is very difficult. Humans are very good at recognizing what seem to be correlations between two events, a trait that has undoubtedly been honed over thousands of years. The rustle of grass on a dark night correlates well with the approach of a tiger intent on finding a meal and quickly becomes a signal for retreat to a safe cave. However, the rustle does not cause the cat to eat the unwary human. The human (and other animal) nervous systems are well adapted to recognizing correlation, but poorly designed to establish cause and effect. The art (and some would say, science) of experimental design has been developed to find ways to be able to assign cause-and-effect relationships in all areas of science.

Medical science is one of the most difficult areas in which to assign cause-and-effect relationships. The human organism is very complex, and what may seem like cause-and-effect relationships may be nothing more than random variation in function or disease state, or even the patient's own perception of how they are feeling. For example, the drug Laetrile was for years thought to produce good results for advanced cancer patients, but was finally shown to be useless and perhaps harmful (44). Patients and doctors alike thought that there was a cause-effect relationship between cancer outcomes and Laetrile therapy (that Laetrile cured cancer); in fact, there was neither a cause-effect relationship, nor even a decent correlation.

In experimental studies, a treatment group of some sort is compared with a control group. Ideally, the experimental and control groups differ in only one way; the treatment is given to the experimental group and not to the control group. Although this seems a simple task at first, in reality it is very difficult, especially in medical areas. As the complexity of this task unfolds, remember that when designing a research project, there is no such thing as the perfect design. Research designs always mean making compromises and choices that open the results to other interpretations. The problem is not that the design is not perfect; the problem is in not recognizing the imperfections and dealing with them.

Types of Experimental Designs

Experimental designs for osteopathic research can take several forms, depending on the question being asked. These include:

- Between-subject designs
- Within-subject designs
- Crossover designs
- Variations

The hallmark of an experimental design is the comparison of the treated or experimental group of patients with a group receiving no, or some other, treatment. The experimental study is always prospective, that is, it is planned in advance and must always be approved by an IRB.

BETWEEN-SUBJECT DESIGNS

The simplest experimental design is that comparing a treated group with a historical control. Historical controls would be patients from the practice or from other practices who had received some other form of treatment than the one being investigated. This design is con-

sidered to be weak in its ability to define cause-effect relationships. It is only one step above the prospective case series design, because the control subjects may or may not be comparable to the experimental subjects. However, in some cases, such as very severe disease states or when it is considered unethical to withhold a putative treatment, it may be the only way to attempt to determine the effect of a new or altered treatment regimen.

The most usual of the experimental designs is the two or more group direct comparison design. In this study design, patients fitting the criteria for inclusion in the study are randomly assigned to one group or the other. If the design is an experimental and control group design, the subjects in the experimental group receive the treatment and the subjects in the control group receive either no treatment or some alternative (perhaps community standard) treatment. The results of the two groups are then compared on one or more measures.

Independent and Dependent Variables

The treatment given to the experimental group is the "independent variable," and the measures taken to judge results in both groups are the "dependent variables." Thus, in a study comparing the lateral recumbent thrust, such as the Irvine study, the independent variable was the thrust given to the experimental group, but not the control group. The dependent variables included straight leg raising and judgment of pain before and after the treatment. One of the hardest aspects of research on OMT is finding good dependent variables or measures of results.

Random Assignment to Groups

In experimental studies, it is very important that the two groups of patients be as much alike as possible. For example, if some systematic difference between the groups existed at the beginning of the study, such as the mean age of the experimental group being 24 and the control group being 56, a better result in the experimental group may well be due not to the treatment provided, but to the superior health of the younger patients. The comparability of the groups is usually achieved by "random assignment" of the patients to the groups. The patients are assigned to the groups completely at random, so that neither the investigator's bias nor other factors will result in patients in one group being different in any systematic way from the other group. There are many ways to do random assignment (44), but it is vital that it be done; how it is to be done must be specified prior to the study. Randomization can be as simple as flipping a coin to determine the group a patient is assigned to, but more reliable means are available, such as random number tables in books or on computers.

Blinding

One of the most important aspects of experimental research is the principle of blinding. It is well known that even the most honest investigator can unwittingly affect the results of a study by judging the results of a treated patient as better than an untreated patient. This often slight and unconscious bias or systematic error has often resulted in faulty and unreliable results from an otherwise well-designed study. To preclude this type of error, it is almost always necessary to make sure that the person measuring the outcome of a treatment does not know whether the patient received the experimental treatment (independent variable) or not. If the observer is blind to the patient's group, the study is called a single-blind study. If the patient is also blinded to the treatment given, the study is a

double-blind study. At times, it is also desirable to have others in the study blind to patient group. However, at the absolute least, the observer must be blind to the patient's treatment status. If blinding of this sort cannot be shown or is not feasible, the study has a very serious problem that almost always will make the results suspect. This subject will be further discussed in the section "Special Considerations in Osteopathic Clinical Research".

WITHIN-SUBJECT AND CROSSOVER DESIGNS

The research types reviewed above include mainly those that use planned comparisons between experimental and control groups, or long-term determinations of health status that are then compared with the general population. Many variations on these study types exist. Another group of study types should receive careful attention when the effects of manipulative techniques or treatment are studied. These designs are within-subject designs; they essentially use the same subject as both the control and the experimental group. Keating et al. (45) have summarized this type of design in some detail.

The within-subject study usually involves following a patient for a period of time to determine the baseline symptoms and whether they are fairly stable or changing in some fairly predictable fashion. After the baseline measurement, treatment is introduced and the measurements continued. The measured variables can be compared before and after treatment to see if the treatment had an effect. The baseline measurement period will vary among several subjects, allowing the treatment to be introduced at different times, ensuring that there was no peculiar effect of time on treatment intervention. This is known as the variable baseline, within-subject study design. Frymann (46) used this design type in her study of the effects of osteopathic care of children with neurologic and developmental deficits.

Crossover designs usually use experimental and control groups, but after the control group has finished, these patients are "crossed over" to receive the experimental treatment. Crossing over sometimes satisfies objections that the control group will not get the benefit of a supposedly effective treatment. This design is useful if the illness or disease being studied is not particularly severe and can wait to receive the experimental treatment.

Crossover and within-subject studies are not especially effective if the measurements and symptoms are not fairly stable for a period of time that can be used as the control condition. In addition, there is some problem with establishing whether the manipulative intervention actually did cause any change in the symptoms being measured. However, these designs allow treatment for every subject in the study, whereas the control group does not receive treatment in traditional experimental and control group studies.

The study designs considered here have many variations that must be considered before final design elements are determined. Some of the major issues in design of osteopathic research are considered below in the "Special Considerations" section of this chapter. The investigator is also urged to consult design experts and/or reference texts (29,33).

Data Collection

The actual work of doing the study comes only after careful planning, written statement of the study, and IRB approval. It is absolutely necessary to do the preliminary steps carefully and completely, or the study will almost certainly be useless due to problems of design, execution, or data collection. The entire procedure of the study design must be written out so that all those involved in the

study will fully understand every step. When writing or reviewing a clinical study protocol, I do not consider the design to be complete until the informed reader of the protocol will know from reading the document what happens to the patient all the way through the study.

Data collection is the actual performance of the study. The patients are recruited, assigned to groups, treated (or not), and measurements performed. The data are collected by the appropriate study participant, including measures of somatic dysfunction, functional tests, laboratory results, and so forth. All data must be kept confidential until the study is over (unless it is agreed to look at preliminary data earlier). The study group should meet frequently during the study itself to discuss any problems or concerns. Data analysis is the next step.

Data Analysis

Once data collection has been completed, the task of data analysis begins. Data from most studies must be subjected to some form of statistical analysis as a help in decision making. At most, statistical analysis is a way to help the investigator make informed decisions about the meaning of the data. Statistical tests are of three basic types: descriptive statistics, nonparametric statistics, and parametric statistics.

Descriptive statistics give information about the basic attributes of the collected data, such as the mean, median, and standard deviation. These numbers tell the investigator how each group performed on the dependent variables used. However, to obtain information about whether there might be a difference between the performance means of the experimental and control groups, some form of nonparametric or parametric statistical tests is used. The decisions about whether the independent variable caused a change in the experimental group's responses (dependent variables) rely on the results of tests of significance.

Statistical tests to determine differences between group data rely on the assumption that the experimental or independent variable caused a change in the experimental group that resulted in an actual difference being created between the groups, as measured by the dependent variable(s). According to this view, if the measure was the distance moved by the leg in a straight leg raising test, both groups would have the same average movement prior to treatment, but the treated group would have more movement after treatment. Thus, the treated group would now be a different group or population, as measured by straight leg raising tests. The treatment changed them from what they were before to a group able to perform straight leg raising to a greater level.

Several things determine how well the statistical test is able to indicate this difference. Two of the most powerful of these are the amount of variability in the initial measurements of the groups and the number of subjects in each group (subject numbers are discussed below, under Power). If all subjects initially had exactly the same movement distances, then a very small increase in all the treated subjects would be detected by the statistical test as a significant effect. However, if there was a great deal of variability among the subjects, then a much larger average increase due to the treatment would be necessary before the statistical test could predict that the treatment had produced an effect. Thus, variability is best kept as small as possible between subjects in any study.

Parametric statistical tests, such as the t-test or analysis of variance, make some assumptions about the distributions of the data and the population of subjects, in effect relying on the data to have a "normal" or bell-shaped distribution. If the data do not have roughly such a distribution, it is best to use nonparametric

statistics, such as the Mann-Whitney test, to determine whether the results of the study show a difference due to the independent variable (47).

Many fairly simple computer programs are now available to help with statistical analysis. Such programs as KaleidaGraph (www.synergy.com), InStat (www.graphpad.com), GB Stat (www.gbstat.com), the SPSS packages (such as SYSTAT at www.spss.science.com/SYSTAT), and others are available for both Apple and IBM-compatible computers (see also, e.g., <http://ebook.stat.ucla.edu/>). However, statistical assistance should be sought to avoid mistakes in analysis.

STATISTICAL SIGNIFICANCE

Tests for differences between groups provide an estimate of whether differences in the dependent measures seen between the groups after the study can be relied on to have actually been produced by the independent variable, or whether the differences are more likely to have been the result of random or chance fluctuations. The reliability of the difference is called the significance of the test, or the level of statistical significance. By tradition, and some logic, the usual standard value that must be reached for a difference between the experimental and the control groups to be considered significant is $p = 0.05$. This is the so-called p value, and is a measure that takes into account the variability of the data and the numbers of subjects in the study, among other things. The p value is essentially an estimate of the probability that the study would show a difference as great as or greater than the observed difference purely by chance.

Thus, a p value equal to 0.05 means that only one time in 20 or 5 in 100 would a difference as great or greater than that observed happen by chance alone, if the experimental variable actually had no effect. Thus, p values greater than 0.05 are considered probably due to chance fluctuations in measurement or to weak effects of the experimental variable. If the p value is 0.05 or less, it is assumed that the chances of finding the observed differences by chance are so small that the differences can be accepted as due to the experimental variable.

It is a mistake, however, to assume that if the data show a p value “approaching” 0.05 (e.g., $p = 0.056$), the data are “almost” significant. In many cases, the addition of extra subjects or other refinements of the study produce no more significant results. If the data are close to significance, consider ways to redo the study with less variable data or stronger treatment.

The investigator must generally consult with a biostatistician before finalizing a study design. The statistician will give advice on what data can be successfully analyzed and how the data can best be collected. In addition, due to the number of different statistical tests available, the methods of analysis should be specified before the study is undertaken.

Discussion of Results

Once the data are analyzed, the investigator can undertake a discussion of the results and the study. The results must be considered in light of the background of the study, the results themselves, and the interpretation of those results by the investigator.

Data are only data; they are nothing until interpreted. The results of any study can be looked at in various ways. Consider what happened in the Irvine study. Osteopathic physicians looked at the data and basically said that the study was not important because the independent variable, the thrust, was not osteopathic treatment or spinal manipulation, but only a thrust. Allopathic physicians

viewed the results as insignificant because the thrust and nonthrust groups showed no differences 3 weeks later. However, immediately after the technique, there was a significant difference. Presumably, the thrust patients would have been able to return to work sooner, an important difference to an insurance company paying for time off work. Thus, if the study had been correctly interpreted as a technique study and the immediate effects recognized as important, the study would have made more of an impact.

The discussion or interpretation of the data is where the investigator can state his or her opinion of the outcomes, link them to other data, and interpret them for the osteopathic profession. The discussion should not be too grandiose, claiming that the study had proven everything in the universe (unless it really has), but the investigator should legitimately link the study to the areas of interest and suggest to the reader how the data are important. This is another reason that a good literature review is necessary; without that background, the investigator will not be able to properly interpret the results.

Writing and Publication

If it is not documented, it did not happen. This statement is true for data gathering, observations during a study, orders given for participants of a study, and for publication of the results of a study. If a study is done but not published, it did not happen. It is vital to write a report of a study and publish it in some format. There are numerous books available for the novice scientific writer (47). However, the investigator can follow basically the same format as that given above in the design of a study for writing a scientific paper.

The parts of a research paper, although varying to some extent, are basically:

- Abstract
- Introduction
- Methods
- Results
- Discussion
- Conclusions (sometimes not included)
- References

The abstract of any paper should present a concise and informative overview of the paper. Where the idea came from should be stated; this can be an overview of the literature review or observations that led to the idea for the study. The major methods should be given along with the major findings. The import of these findings finishes the abstract. Such statements as “The results are found below” or “The results will be discussed” are inappropriate. The abstract is the only thing that many people will read, so it must immediately tell the reader why they should look at the rest of the paper. Seeing it as unimportant, many writers dash off an abstract although it is a very important part of the paper.

The introduction is basically the background of the study. It gives an overview of the literature and other information about why the study was conceived. It provides the reader with the rationale for the hypothesis of the study. In fact, the introduction can be conceived of as a funnel with the hypothesis being at the bottom, small end. The introduction starts from the big picture overview and comes down to the hypothesis. The reader can see immediately why the hypothesis makes sense, given the background. Of course, some reports, such as case histories, have no hypothesis, but nonetheless, should have the background presented in the introduction.

The methods section is a fully detailed report of the procedures, tests, manipulative procedures, subject selection criteria, and

so forth of the study. The methods section should allow a reader knowledgeable in the field to reproduce the study. The methods section should present sufficient detail that the reader can make judgments about the validity and usefulness of the study results.

The results section presents the actual data from the study and the analyses of the data. It gives tables and graphics to clearly show the reader the outcomes of the study. Graphs should be presented in formats that clearly show differences, data trends, and group data descriptions. Most graphs showing group data should show error bars so that the reader can see the amount of variability within the data (29,48). As with statistical analysis programs, there are several computer programs available to help with graphic presentations, such as KaleidaGraph (www.synergy.com), GraphPad (www.graphpad.com), GB Stat (www.gbstat.com), and Microsoft Excel. One of the most common errors in presenting data in a paper is to have graphics that are misleading, confusing, or not readily interpretable.

As stated earlier, the discussion section is where the author can express his or her opinions on the outcomes of the study. It is often helpful to begin the discussion section with a bullet recap of the major results. This helps both the writer and the reader to focus on the important aspects of the data. The discussion allows the author a place to express opinions about the meaning of the data and interpret it for the reader. Of course, the reader does not have to agree with the writer's interpretations.

The reference section should list the sources consulted by the author. All references that are cited in the text or that contributed to the ideas in the article should be cited. It is a serious ethical problem to use the material of others and not give attribution to them. Plagiarism is poorly looked on. It is a good idea to be inclusive rather than exclusive in referencing others' work.

The beginning and even the seasoned author can get help in writing articles by consulting the instructions for authors given in most medical journals. The only osteopathic journal fully indexed in the Index Medicus library is the *Journal of the American Osteopathic Association* (JAOA). It publishes full instructions to authors on the internet at the JAOA web site, www.jaoa.org. Other invaluable sources of information on writing style is the *Publication Manual of the American Psychological Association* (49) and the *AMA Manual of Style: A Guide for Authors and Editors*, 10 (50). These invaluable books give not only style guidelines but also information on presenting graphics, writing theses, plagiarism, and much more.

When considering a journal for publication of an article, first choice should be given to journals indexed in the Index Medicus or similar worldwide listings. The target audience should be identified and the chosen journal should target that audience. The journal should be peer reviewed to insure quality of the articles published.

If the study is not sufficient for stand-alone publication, the author should consider presenting the data at a medical or scientific meeting from which abstracts are published. This provides a public reference of the work. The AOA research conference held each year in conjunction with the AOA convention is such a venue. The abstracts of the scientific presentations are published in the *JAOA* and indexed in the world literature.

SPECIAL CONSIDERATIONS IN OSTEOPATHIC CLINICAL RESEARCH

In the sections on research design, several ideas were introduced that require discussion in terms of osteopathic research questions. The areas that are of special interest to the design of osteopathic studies are:

- The "gold standard" for medical research
- The question being asked

- Blinding
- Control groups
- Patient populations
- Pilot studies and statistical power
- Inclusion/exclusion criteria
- Dependent variables

The "Gold Standard" for Clinical Research

The randomized, double-blind, placebo-controlled study has evolved as the "gold standard" for clinical research studies. This design was developed in the 1940s and 1950s as the appropriate design to test the effects of drug treatments. The major elements of this particular design are:

- Randomization of subjects into the treatment groups (or arms)
- Blinding of subjects, drug givers, and data collectors as to treatment given
- Provision to the control subjects of a "placebo" or inactive substance that is indistinguishable from the active drug

This design was developed to answer a very specific question in drug therapy. For practical purposes, the question or experimental hypothesis to be answered is, "What is the effect of this drug on the natural course of a disease process in the human unaware of what drug is given?"

The random assignment of subjects to the experimental or control group hopefully ensures that the experimental and control groups (or more groups if, e.g., a group given neither drug nor placebo is used) have the same characteristics to begin the study. The blinding of the patient to what is being received (active drug or inactive substance) will hopefully ensure that the patients in the experimental group do not feel better simply because they are getting an active drug. In other words, the psychological aspects of the treatment should be equal for the two groups. Blinding the drug giver and caregivers as to which group the patient is in hopefully insures that the treated patients do not get subtle cues that they are being given an active substance; blinding the data gatherers ensures that bias is not introduced by knowing the patients receiving the active drug. Thus, for the question being asked, this design is a good one. Unfortunately, studies of manipulative treatment are not always amenable to this design and may often ask different questions. Thus, we must examine briefly what affects the interpretation of clinical trials.

Validity and Bias

The validity of a study is simply how strongly we can believe that the results are a reflection of what is actually the case. Did the manipulative technique really cause the observed change or was some other mechanism at work? Will the technique work with other patients, or was the result limited to the patients being studied? Many factors can influence how results can be interpreted, and these factors are called biases.

The definition of bias in a research study is basically anything that could interfere with the correct interpretation of the results of the study. If the study asks about the effect of a technique on low back pain, then measuring the pain differently in experimental and control groups would constitute a bias that would invalidate the results. There are many forms of bias that affect the validity of a study.

External Validity

Simply put, an external bias is something that interferes with the generalization of the results of a study from the patients in the

study to other patients (32). If an experimenter wanted to have an externally valid study of the effects of a manipulative technique on asthma in the general population, the study group would be chosen not from a hospitalized population but from the whole group of people with asthma. If the asthma study patients were all hospitalized, the effects of a manipulative technique might well be different than if the technique were performed on patients with a less severe form of the disease. The study would not be externally valid because it would not be generalizable to the whole population of asthma sufferers. Of course, if the intent of the study were to study the effects of manipulative interventions on asthma in hospitalized patients, it would be externally valid. Thus, it is very important to frame the hypothesis with knowledge of whom the subjects will be and to whom the data will be generalized. Many things can affect external validity, including the lack of proper control procedures, improper selection of patients, and the simple length of time the patient is in the study (symptoms may change over time even without treatment).

Biases that threaten the external validity of a study are often fairly easily seen and recognized. For the example above, the bias of using only hospitalized patients as subjects obviously limits the results to that population of patients. Other problems of generalizability are not so obvious. For this reason, the investigator must keep records of the patients and be able to define at least the demographics of the patients so that the reader will be able to judge which population the results are most likely to be applicable to.

Internal Validity

Much more serious are the threats to internal validity. These biases are often very subtle and can make statements about the actual meaning of results difficult if not impossible. A nonblinded observer who takes data in a study and who knows whether or not the subject was treated is an obvious source of bias that will almost surely make interpretation of between-group differences impossible. Other sources of biases threatening internal validity include (32):

- Inappropriate control groups
- Measures that do not accurately determine the response being studied
- Objectivity in the measures being used
- Small numbers of patients in the groups
- Initial differences between experimental and control groups
- Random fluctuations in the course of a disease process
- Regression of symptoms to the mean

Thus, the investigator must pay close attention to issues affecting the internal validity of the study design and would be well advised to consult an experienced clinical trials designer on the issue.

DESIGN OF OSTEOPATHIC CLINICAL TRIALS

Blinding

As noted above, the design of clinical trials of osteopathic manipulation is more complex and may ask different questions than drug trials. Obviously, the person providing the treatment cannot be blinded to whether manipulation is given or not. In some cases, the patient can be blinded to treatment condition, as in the Irvine study. None of the patients included in the study had any experience with manipulative treatment, and results showed that there was no difference between the groups as to their recognition of whether manipulation had been given or not. Blinding was done for the data gatherers, so the study can be considered a blinded trial with

the exception of the treating physician. Although patient blinding is possible in cases of technique studies like the Irvine study, it is not as likely in studies of full treatment effects. In addition, it is difficult to find large numbers of patients in most osteopathic practices who are completely naïve to manipulation. Thus, the question of patient blinding is one that must be examined for each study and dealt with as the study and situation allow. The consequences of not blinding the patients to treatment are considered under the section on control groups, below. In any event, it is imperative to have the data collectors blinded as to group assignment.

Population Selection

In most cases, studies of manipulative treatment will use patients from the investigators' practices. The study design should include recording the demographics of the patients so that there will be a basis to generalize from the study population to other patients. It is obvious that the patients coming to an osteopathic practice are not a random sample of the general population, but a highly self-selected group that may be motivated to seek osteopathic care. Thus, caution must be taken when generalizing results of manipulative trials to the general population, and this bias must be taken into account.

Control Groups

One of the most contentious issues in osteopathic research design is the issue of appropriate control groups. The idea of the control group stems from the necessity of having some way to compare the active treatment with some baseline. As mentioned above, historical controls are sometimes used, but are far from ideal. Historical controls may differ widely from the contemporary study group in many aspects, so give only an impression of effects. Historical controls are used only as a last resort.

The "gold standard" control is the placebo control. Defined above, the placebo control is designed to mask from the patient the knowledge of whether the active drug or the inactive substance is being given. Such a control is meant to take the psychological effects of the patient's knowledge on the interaction between drug and disease natural history out of the therapeutic picture. It has been widely assumed that the simple knowledge of treatment had about a 30% effect on the patients response to the treatment (the "placebo effect") (49). Thus, according to the commonly held view, the simple psychological effect of knowing that a treatment was being given could alleviate symptoms by a large amount. Thus, the placebo control is designed to keep the placebo effect from entering into the difference a drug would make in the course of a disease.

Significant questions are being raised about the placebo as an effective control condition (51–55). For example, is the "placebo effect" really as robust as has been assumed? Is factoring out the psychological effect giving a true picture of the actual effect of a drug or treatment on the course of a disease, or is the placebo control consistently causing an underestimation of the total effect of drug plus knowledge? It is now well known that an individual's psychological status has real and measurable effects on their physiologic processes (see Chapter 8). Is the placebo the best control for treatment studies? The placebo's sister control group, the sham control, is often used in studies of manipulative treatments and techniques. With a sham control, some type of "hands-on" experience is given to the patient so that the physiologic and psychological effects of placing the hands on the patient are equal in the treatment and control groups. The Irvine study is a good example of a sham treatment control. Because the question being

asked was regarding the effectiveness of the thrust alone, a sham was appropriate.

However, what if the question being asked is of the effect of the osteopathic treatment as a total treatment effect? Is it then not appropriate to test the total treatment, including the effect of hands-on and patient knowledge, against giving the patient no treatment? The question being asked determines the control group. If the question is to test the totality of the treatment effect against no treatment, and treatment includes the effect of putting hands on the patient, then the appropriate control is a patient receiving only rest during the treatment time. It may also be appropriate to use the musculoskeletal examination as the “sham” in such cases. Here, both groups would receive the structural examination, but the control group would then rest while the manipulative treatment was given to experimental group. Blinding of the subjects to treatment group in many cases is simply impossible, thus leaving the concept of a “placebo” group as a moot point.

Another control often used in manipulation studies is the “community standard” control in which, for example, low back pain is treated manipulatively in the experimental group, but by drugs, physical therapy, and counseling in the control group. This type of active control group is asking yet another question: Is the effect of manipulation equal to or better than standard care? The recent Andersson study (40) on manipulative treatment for low back pain is a good example of this type of control group. Because of the ethical considerations of giving no care to a patient in a “do nothing” control group, the active or community standard of care control may be the only way some conditions can be examined.

Thus, the osteopathic researcher must carefully determine the actual intent of the experimental question prior to determining the appropriate control group. The myth of the “gold standard” must not be forced onto research designs for manipulation. If the question of the study is whether the manipulative treatment is better than nothing, a rest or nothing control is appropriate. If the question is whether the manipulation is better than community standard care, the appropriate control is the active community standard treatment. If the question is whether the manipulation is better than simply placing hands on the patient, probably the best control is the examination-only control.

Thus, careful consideration of what is being asked will determine the appropriate control group, not a preconceived notion of what a control should be.

Study Size and Power

Studies on the effects of manipulative treatment are in their infancy. It is difficult for an individual investigator to procure sufficient subjects for a large study. In fact, it is now becoming increasingly evident that many studies have not been sufficiently large for their results to be reliable. The term for the probability that a study contains sufficient subjects for an effect to be accurately found if, in fact, there is an effect of the independent variable, is called “power.” The measure of the power of a study is called power analysis (56). The probability that the statistical analysis of a clinical trial will show a significant p value is remarkably large if the number of subjects in the study is small. In a study with few subjects, one subject’s large change in findings may result in a significant effect, although the effect is not general. In this case, a “type I” error will result; the experimental hypothesis that there is a treatment effect will be accepted although no such effect is present. Thus, power analysis gives an estimate of the number of subjects required in a study to be reasonably sure that if there is an effect it will be found. Power

calculations can be made with relatively simple formulas found in standard books (55) or on the internet (e.g., <http://ebook.stat.ucla.edu/calculator/powercalc/>).

Pilot Versus Full Studies

Thus, the Andersson study (40), although well done with about 178 patients, is most likely still lacking sufficient patient numbers to fulfill power requirements. Studies not meeting standard power requirements must be termed “pilot studies,” and their results should be viewed with caution. Pilot studies are very useful in giving indications of what effects may be valuable to further study and in providing data on the amount of variability inherent in outcome measures; therefore, they are very valuable. Studies that meet the required numbers of subjects indicated by power calculations are considered full-scale studies and, other things equal, are more reliable than studies with fewer subjects.

Dropouts

The problem of dropouts can be acute in any clinical study. In studies of manipulation, the investigator must account for patients not finishing the study. This is important because of the potential for causing imbalances between the experimental and the control groups. For example, if all the patients with more severe disease dropped out of the experimental group but stayed in the control group, the results would be inaccurate or biased toward a larger effect in the experimental group. The usual practice is to try to determine the cause of the patient’s failure to finish the study and to carefully examine the drop-outs for commonalities that could affect study results.

Inclusion and Exclusion Criteria

The issue of inclusion/exclusion criteria is also difficult in many studies of manipulative treatment. The inclusion criteria are those things that make the patient eligible for the study, such as low back pain. However, the inclusion criteria must be well specified and measurable prior to the study. In the example of low back pain, the type, duration, and other factors should be carefully delineated. An area that needs special attention in inclusion criteria is that of a well-defined diagnosis. Often, studies of manipulation do not have well-defined structural diagnoses that can be justified and defended to the greater medical community, which results in poor acceptance of the study.

Exclusion criteria are those factors that exclude a patient from a study. These can be age, pregnancy, drug use, and so forth. Exclusion criteria must also be clearly specified in the study design. It had been standard practice to exclude women from many drug studies because of the danger of pregnancy. This practice resulted in a lack of information on the effects of drugs on females (poor external validity), and the effects were often different than the effects on males. It is now unacceptable to simply exclude females; if a study does so, explicit reasons must be given.

Dependent Variables: Selecting Appropriate Measures

The best measures to determine if a manipulative procedure had an effect are often difficult to decide. These measures are known as the dependent variables because their values are supposedly dependent on the experimental treatment. In studies of the efficacy of a manipulative technique or a manipulative treatment on the outcome of a

specific disease process, the measures are presumably some aspect of the disease process or of the natural course of the symptoms. In assessing the contributions of manipulative treatment to resolution of somatic dysfunction or to the maintenance of health, the task of defining sensitive dependent variables becomes more difficult. Some dependent measures include measures of immune system function, studies of the activities of daily living, episodes of loss of health (for long-term studies), and other measures of body function, including reports of feelings of well-being and comfort.

One of the problems in many studies of manipulative treatment is the use of purely subjective, dependent variables in the study. Typically in these cases, an examiner performs a musculoskeletal examination of a patient and records the somatic dysfunction found. The treating physician typically repeats the examination and treats the findings for experimental subjects and simply does nothing for control subjects. The blinded examiner then performs a second examination and reports differences between the two examinations. The problems inherent in this design are mainly a lack of any knowledge of the reliability of the examiner. How much do the findings vary between examinations (repeat reliability) and how do the examinations of the two examiners correlate (interexaminer reliability)? These are significant issues that must be acknowledged in such a study.

The answer to such issues is to use dependent variables that are not dependent on the subjective examination of either a blinded examiner or the treating physician. Such measures can be instrumented measures, such as Doppler blood flow, respiratory volumes, and so on.

Whatever the dependent variable or variables, the measures of manipulative treatment results should include an evaluation of whether the treating physician determined that the treatment given actually did what it was designed to do. Sometimes, the manipulation fails to accomplish the desired immediate outcome in restoring range of motion or proper muscle relaxation. These facts must be recorded and used in analysis of the outcome of the treatment so that unsuccessful treatments can be looked at separately from those judged to achieve the desired end points. This will help reduce the variability of the data.

Another problem in choosing dependent variables is the temptation to simply measure everything available and hope to find a few that change. This may be a good strategy for a preliminary exploration of a treatment technique, but holds many pitfalls. In fact, this is sometimes called “oh heck” research design: Oh heck, let’s do this and see what happens!

Given enough measures, the probability that one or a few will show significant changes is very high. In fact, if 20 dependent measures are chosen for measurement, expect that one will show a significant outcome by chance (when no effect actually exists). Thus, special statistical tests must be used when several measures are studied to guard against chance significant results. It is best to design a study with a few dependent variables that have either been shown to be affected by the independent variable, or to have good reason for suspecting that they may be so affected.

Characteristics of Well-Designed and Pitfalls of Poorly Designed Osteopathic Research

Good osteopathic research will have the characteristics of any well-designed clinical study. These characteristics include:

- A complete and well-documented literature search
- A well-defined working hypothesis
- Research design is logical and fits the hypothesis

- Complete and well-documented methodology
- Statistical methods and data processing procedures defined in advance
- Power calculations completed
- Well-defined inclusion and exclusion criteria
- Both objective and subjective dependent variables
- Adequate statistic and logistic support
- IRB approval obtained

These characteristics of a well-designed osteopathic trial should lead to reliable and believable data.

On the other hand, some of the pitfalls, especially for novice investigators, include the converse of the above, but also some perhaps less-obvious points when planning and conducting research:

- Planning is incomplete and not well documented
- Protocols are not rigorously followed
- Record keeping is not complete
- Time for study completion is underestimated
- Patients cannot be recruited in sufficient numbers
- Study is too complex
- Too many dependent variables

Many of these areas have been covered earlier in the chapter. However, some deserve brief mention here. As a study is carried out, it is very important for the investigator to make sure the protocols are followed at every step. If a mistake is made, it must be noted and any problem corrected. Mistakes will be made in any protocol; difficulties arise if the mistakes are not acknowledged.

Many investigators underestimate the time needed to complete a study. At times, patients cannot be recruited readily or replacement patients must be sought. These things can add significantly to the time required for study completion. A careful investigator plans extra time into the study design. It is good to offer a bonus to key personnel for subject recruitment and for help with the protocol.

As stated in the hypothesis section, a simple study is often the best one. A study with too many hypotheses to be tested or too many dependent variables or measures can become uncontrollable and even impossible to analyze. It is often better to perform several small, well-designed studies that together paint a picture, than one large, complex study that is not interpretable.

SUMMARY

Clinical research in osteopathic medicine is at the cutting edge of research design technology. The uncertainties surrounding controls, dependent variable measures, and interpretation of results makes it a difficult and challenging field. Well-designed studies that make a small contribution to understanding the mechanisms and efficacy of manipulative treatment, such as are now coming out in the osteopathic literature, will eventually paint a compelling and fascinating picture of this treatment modality. The profession must take full advantage of the fifth period of osteopathic research to strengthen its foundation in the coming years. By the results of research the profession will prosper.

Research Priorities in Osteopathic Medicine

BRIAN F. DEGENHARDT AND SCOTT T. STOLL

KEY CONCEPTS

- There is a societal expectation and responsibility within the medical professions for clinicians to provide the best level of patient care based on current knowledge, not to be blinded by or become complacent with current practice outcomes, but to advance the practice of medicine to levels previously unimaginable.
- Although there is a trend in the biomedical research community toward reductionistic science, the osteopathic profession is uniquely positioned to perform research that integrates the principles underlying osteopathic medicine with a cost-effective distribution of its health care services worldwide.
- Researchers and research advocates representing the various constituencies within the profession need the mandate and resources to convene, to inform/educate members of constituency research initiatives, to coordinate goals and resources, to update research priorities, and to assess profession-wide research activities.
- Meaningful research comes from the burning desire to know and understand something better, not from the enthusiasm to “prove” that something works.
- Current evidence has repetitively demonstrated a therapeutic effect from human touch.
- When designing osteopathic manipulative medicine clinical trials, special consideration must be given during the study design phase to the control and/or placebo cohorts (touch vs. no-touch control), the blinding of osteopathic manipulative treatment (OMT) providers, and the selection and training of the OMT techniques that will be used in the study.

INTRODUCTION

Underlying the inception, establishment, and success of the osteopathic profession is its membership's desire to improve patient health. In the 20th century, the level of training of osteopathic physicians and the service provided by those physicians succeeded in placing osteopathic medicine clearly within the biomedical community, a community challenged with the dual responsibility of providing the best level of care based on current knowledge and advancing that knowledge to levels previously unimaginable. The osteopathic profession was established in the late 1800s in response to limitations in the practice of medicine at that time (1) and promoted many concepts that have been accepted in the 20th century (2). As the 21st century unfolds, the questions and challenges that the osteopathic profession needs to address are numerous and predominately relate to how its membership will continue to contribute to the practice of medicine. Will D.O.s recognize their responsibility and opportunity to become leaders in advancing patient care in both practice and research within the health care professions? Will they see health care research as a key component of patient care? Will they have the vision and fortitude to contribute to health care through research? Will training institutions prioritize education that promotes not only health care services but research activities as well? This chapter is intended to provide perspectives to compel profession constituencies to assertively answer these questions.

To establish a strong foundation for meaningful research priorities within the osteopathic profession, the term osteopathic needs to be used more precisely. When the profession transitioned from labeling itself “osteopathy” to “osteopathic medicine,” the act of changing a noun to an adjective created a problem: osteopathic was suddenly used to modify a variety of nouns in an attempt to illustrate distinctiveness. For instance, osteopathic

began modifying research to try to make a distinction between “osteopathic” research and other forms of research, like “allopathic” or biomedical research. Linking osteopathic to research can be confusing and divisive within the scientific community, both within and outside the profession. Is not the goal of osteopathic research to pursue fundamental knowledge about the nature and behavior of living systems and to use that knowledge to extend healthy life while reducing the burdens of illness and disability? Wouldn't another goal of osteopathic research be to develop, maintain, and renew through the highest level of scientific integrity our capacity to prevent disease? While these are clearly osteopathic goals, these are also the explicit goals and mission of the National Institutes of Health (3). It is critical that members of the osteopathic profession who feel it is important to link osteopathic to research remember that a substantial amount of the research that has been identified by the profession as osteopathic was developed, performed, and interpreted by investigators who know nothing about osteopathic principles and practices.

Science and research are intended to be blind to labels. All scientists and clinicians should be united in the pursuit of an evidence base that leads to improved efficiency and quality in the provision of health care. The osteopathic profession, as a recognized member of the biomedical community, needs to fully engage in its dual responsibility of providing the best level of care based on current knowledge and of aggressively advancing that knowledge. The future contributions of the osteopathic profession will and should be judged on the merits of D.O.s within the scientific community in addition to the profession's provision of unique health care services. Osteopathic should be accurately linked to the practice of medicine that promotes patient-centered health care and to professionals who are willing to evaluate scientific outcomes through a set of standards or osteopathic principles that help discern what

best supports the individual's, family's, and community's natural health potential. Further, as the practice of osteopathic medicine benefits from general biomedical research, it should be expected that the profession's scientific contributions will be incorporated into all appropriate levels of the health care system, as intended at the inception of the osteopathic medical profession. The profession's distinctiveness is not through labels that sustain isolation. It is through the complete participation in the biomedical community in ways that are unique and visionary that the true potential of osteopathic principles and practice will become evident.

While there has been an ongoing desire and attempt by the osteopathic profession to contribute to the scientific basis of health care (4–12), some report that the degree and quality of such research has been limited (5,12–14). Some may argue that the profession's resources in the last century have primarily been directed toward training D.O.s (15). As a result, there have been limited resources available to perform credible research. Others may argue that the resources that were available were not used effectively. While recent trends indicate a new level of commitment and success in research by the profession (14), it is clear that without a sustained concerted set of research priorities, a strategic plan that constituencies within the profession can own and consistently engage in, and a broad-based leadership to drive the strategic plan, the influence of the osteopathic profession on the provision of health care will wane and the potential of the application of osteopathic principles to health care will never be realized.

VISIONS OF MEDICAL RESEARCH IN THE 21ST CENTURY

In this era of globalization, it is important to appreciate that science and health care are global activities. As a result, there are personal, family, community, regional, and global considerations that need to be considered as the profession develops its research priorities. Beginning at the national level, in the past decade, two groups of U.S. experts independently convened a series of meetings to determine the major opportunities and gaps within medical research. One group consisted of over 300 nationally recognized leaders and researchers within the health care industry who advised the NIH regarding the future of that Institute's medical research (16). The other group became known as the Osteopathic Research Task Force (ORT), created and supported by key osteopathic educational, research, and professional organizations (13,17) to help foster cooperation and collaboration across the profession in order to enhance the quality and quantity of research evaluating the unique aspects of health care provided by osteopathic physicians. The conclusions from both groups provide a good context for developing research priorities within the osteopathic profession.

The group of experts convened by the director of the NIH recognized the "daunting challenge" of understanding the complexity of life (16). They noted that no single center within the NIH could address the many areas and issues that need to be studied to better understand these complexities. Therefore, the experts developed a set of research priorities, called the roadmap, which was intended to define the Institute's research direction. This group proposed that "progress in medicine requires a quantitative understanding of the many interconnected networks of molecules that comprise our cells and tissues, their interactions, and their regulation." They concluded that it is necessary to more precisely know the combination of molecular events that lead to disease in order to advance medicine. Therefore, they emphasized the need for cellular and molecular/genomic research, heralding

the expected level of influence nanomedicine will have in the future of health care (18).

The ORT, the second group of experts, consisted of representatives from the following organizations: the American Academy of Osteopathy; the American Association of Colleges of Osteopathic Medicine (AACOM); the American Osteopathic Association (AOA); the American College of Osteopathic Family Physicians; the Association of Directors and Medical Educators; the American Osteopathic Hospital Association; the Council of Osteopathic Student Government Presidents; the International Federation of Manual/Musculoskeletal Medicine; the Osteopathic Research Centers at the A.T. Still University's Kirksville College of Osteopathic Medicine, the Philadelphia College of Osteopathic Medicine and the University of North Texas Health Science Center; the National Undergraduate Fellows Academy; and the Postgraduate American Academy of Osteopathy. The ORT identified the lack of a unified, profession-wide research plan to advance the practice of medicine within an osteopathic context. Because within the profession there are limited resources available to support research activities and because there is a significantly better record in obtaining outside funding for basic science research (5,14), the ORT recommended continued support for the AOA directive that the profession make a concerted effort to prioritize research in osteopathic manipulative medicine (OMM) (4,8): "the application of osteopathic philosophy, structural diagnosis and the use of osteopathic manipulative treatment (OMT) in the diagnosis and management of the patient" (19). This consortium of experts produced a white paper consisting of an assessment of the current status of OMM research and a well-organized set of priorities/specific aims with strategies to advance OMM research and a profession-wide culture of research over a 5-year period (20). The ORT identified six domains of deficiencies or challenges within the profession that keep osteopathic medicine from having a scientifically based impact on the current practice of medicine (Table 71.1).

These domains are in research activities, funding and resources, research training, infrastructure, health policy issues, and leadership. The ORT White Paper Summary outlines priorities/specific aims and strategies promoted by the ORT for each domain and suggests potential organizations that seem appropriate to take responsibility for the various strategies based on the organization's representatives at that time.

The ORT White Paper is a significant contribution to the direction of research within the osteopathic profession. It offers a vision created by a broad-based collective from numerous constituencies and so represents the insight of the profession as a whole while challenging the profession to actively participate in fulfilling its research responsibility. Many of the specific aims and strategies of the white paper are related to the fundamentals of creating the infrastructure needed to be able to significantly contribute to the medical evidence base. While some progress has been made in certain domains of the white paper, most of the framework and details of the document are still pertinent as we head into the second decade of the 21st century.

To appreciate the role of the osteopathic profession within the scientific community, it is helpful to compare the NIH roadmap with the ORT White Paper. By doing so, research priorities for osteopathic medicine begin to take shape.

The conclusions presented in the NIH roadmap have significant implications worldwide. First, this vision of medical research is dependent on highly advanced technology, where outcomes will be generalized to establish protocols that create consistent standards for the treatment of patient populations. However, these outcomes may de-emphasize, minimize, or even ignore the individualized

TABLE 71.1

Challenges Facing the Osteopathic Profession in the OMM Research Arena

Domain of Deficiency	Examples of Challenges
Funding and Resources	Lack of adequate money to fund pilot projects.
Research Activities	Insufficient number of OMM research studies underway.
	Inadequate interactions between basic and clinical scientists.
	Inadequate vehicles for disseminating research results.
	Inadequate supply of trained researchers.
	Lack of accountability for researchers.
	Non-OMM DO specialists question OMM research relevance to their practices.
	No universally available central data pool on previous research studies.
Research Training	Insufficient opportunities for research training in OMM.
	No broadly adopted and assessed research objectives/competencies.
	No NIH-supported osteopathic medical scientist training program.
	No identified mechanism to train and support mid career physician scientists.
	No dedicated pool of money for timely resident and student research.
Infrastructure	No commitment from most colleges of osteopathic medicine to foster a culture of research.
Health Policy	General paucity of evidence-based medicine to justify reimbursement.
	Evidence base that does exist not recorded or disseminated to impact stakeholders and health policy decision makers.
	Poor communication between OMM researchers, OMM research-oriented committees and organizations, and the AOA leadership.
Leadership	Unclear OMM research priorities cause lack of cohesiveness in OMM research.
	No broad-based team given formal recognized authority to serve as the strategic leader of OMM research efforts.

biopsychosocial aspects of health and disease, important factors in the provision of osteopathic health care. Second, because of the highly advanced technological resources needed to engage in this kind of research, the number of researchers able to participate is significantly limited. Third, the sophisticated instrumentation and networks required to translate medical advances from this roadmap into health care practices may not be available or affordable in all regions of the world, increasing disparities in health care services worldwide.

Conversely, the ORT supported previous AOA directives (4,8) to focus on research in the area of OMM in order to fill the research void in this area and best utilize profession resources in a concerted effort. This decision has significant global implications. By rigorously evaluating the application of osteopathic philosophy, structural diagnosis, and the use of OMT, positive outcomes from this research can impact society on biological and psychosocial levels on the individual, family, and community levels. Successful outcomes would likely be cost effective and easily distributed since OMM is not linked to expensive or extensive technology.

Although some may see these two research directions as opposing, it serves the osteopathic profession better to see them as complementary. While the NIH roadmap will lead to an expansion

of reductionistic science, the National Center for Complementary and Alternative Medicine (NCCAM), a center within the NIH, demonstrates the Institute's recognition that high-quality research in more holistic and integrative approaches deserves support as well. In 2006 (21), 2007 (22), and 2008 (23), NCCAM supported 318, 306, and 275 projects, respectively, of which 100, 87, and 92 were new projects for each year. The NCCAM budget, while only a fraction of the total annual NIH budget (just over \$20 billion for the past 3 years [24]), still provides the largest resource of funding for research in complementary medicine practices like OMT. For instance, the total costs for NCCAM projects were \$97.3 million in 2006, \$100.2 million in 2007, and \$97.6 million in 2008 (24). Studies that relate to manual therapies are outlined in Table 71.2.

While many factors can be considered when interpreting the extent of federally funded research in osteopathic manipulation, the osteopathic profession has had some success in obtaining NIH funding. As the primary profession that recognizes the value of incorporating both complementary/holistic and medical approaches into patient care, there is a need, and thus an opportunity, for the osteopathic profession to perform and support research that investigates the principles underlying the integrative nature of osteopathic medical care.

TABLE 71.2

NIH Funding of Manual Therapies: 2006 to 2008

Year	Funding Type and ID	Title	Primary Investigator	Location
2006–2008	R01 AT000123	Z Joint Changes in Low Back Pain Following Adjusting	Cramer, Gregory D	National University of Health Sciences
2006	R01 AT000370	Massaging Preterm Infants Enhances Growth	Field, Tiffany M	University of Miami Medical School FL
2006	R01 AT002689	Massage Benefits in HIV+ Children: Mechanisms of Action	Shor-Posner, Gail	University of Miami Medical School FL
2006–2008	R01 AT001927	Effect of Massage on Chronic Low Back Pain	Cherkin, Daniel C	Center for Health Studies
2006–2008	R21 AT001872	Effects of Massage on Immune System of Preterm Infants	Ang, Jocelyn Y	Wayne State University MI
2007–2008	R21 AT002303-02	Treatment Efficacy of OMT for Carpal Tunnel Syndrome	Stoll, Scott T	University of North Texas Health Science Center
2006–2007	R21 AT002560-02	Therapeutic Massage for Generalized Anxiety Disorder	Sherman, Karen J	Center for Health Studies
2006–2008	R21 AT002750-02	Craniosacral Therapy in Migraine Feasibility Study	Mann, J Douglas	University of North Carolina Chapel Hill
2006–2008	R21 AT002324–03	Dose-Response of Manipulation for Chronic Headache	Haas, Mitchell	Western States Chiropractic College
2006	R21 AT002751-02	A Model for the Mechanism of Action of Massage	Rapaport, Mark H	Cedars-Sinai Medical Center
2007	U01 AT001908-02	Dose-Response/Efficacy of Manipulation for Chronic Low Back Pain	Haas, Mitchell	Western States Chiropractic College
2006–2008	U19 AT002023-03	Mechanisms of OMM	Smith, Michael L	University of North Texas Health Science Center
2007–2008	K23 AT003304–02	OMM in Pregnancy: Physiologic and Clinical Effects	Hensel, Kendi Lee	University of North Texas Health Science Center
2007–2008	K24 AT002422-03	Midcareer Investigator Award in CAM-Osteopathic Medicine	Licciardone, John C	University of North Texas Health Science Center
2007–2008	R25 AT003580-01A1	Expanding Evidence-Based Medicine and Research Across the Palmer College of Chiropractic	Choate, Christine M	Palmer College of Chiropractic
2006–2008	R25 AT003579-02	Curriculum and Faculty Development in Evidence-Based Medicine	Laird, Stephen D	A.T. Still University of Health Sciences
2007	R25 AT002877–01A2	Competencies in Research in Manual Medicine and CAM	Cruser, Des Anges	University of North Texas Health Science Center
2006–2008	K30 AT000977	Chiropractic Clinical Research Curriculum	Meeker, William C	Palmer College of Chiropractic
2007–2008	F31 AT002666	Biomechanics of Spinal Manipulation Using a Cat Model	Ianuzzi, Allyson	State University New York Stony Brook

RESEARCH DOMAINS AND STRATEGIES IN OSTEOPATHIC MEDICINE

Many of the current and future research priorities of osteopathic medicine are consistent with those outlined in the ORT White Paper. Consequently, many of the research priorities described in this chapter will be presented with headings crossreferencing the domains and strategies of the white paper. Additional comments on certain specific aims and strategies will not be presented because the description in the white paper is self-explanatory.

Research Leadership

Research leadership requires the ability to direct or facilitate meaningful research activities, a vision to identify pertinent areas of research for society, and the ability to disseminate research outcomes to effect health care policy and the daily practice of medicine. Research leadership in the osteopathic profession has been fulfilled for years by the AOA board, bureaus, and councils (5,7,8,25). The AOA leadership has often been burdened by challenges within the research arena beyond the scope of their typical responsibilities as a membership organization. Alternatively, numerous organizations within the profession have a research arm or committee, but their success has been limited due to time, isolation, and limited resources. Better coordination of the current research-oriented leadership within the various organizations of the profession is critical for success of the osteopathic research enterprise. Although listed as the sixth domain within the white paper, expanding, empowering, and coordinating research leadership must be the first priority of the osteopathic profession. This is vital to the establishment of a productive infrastructure that is required for the profession to become competitive for NIH funding and to be able to produce the quality research needed to impact medical practice and health policy.

An example of insightful, collective leadership was the promotion of osteopathic research centers (ORCs) within the profession (13,17). While only one center at the University of North Texas has been funded thus far, this support has resulted in very positive outcomes (26). Five of the six NCCAM-funded investigational grants to the profession (Table 71.3) were granted to the ORC. Building on the outcomes from one of the R21 grants, in 2009 an R01 was also received by Hodges to study the “mechanisms of lymphatic pump enhancement of immune function.” The ORC has also received seven funded grants from the AOA since 2006 (Table 71.3).

The center funding from many constituencies within the profession has helped the ORC build the needed infrastructure to become a successful contributor to the biomedical community while minimizing the financial burden on any one entity. The original intent of this directive was to establish a consortium of several centers strategically placed throughout the profession (17). Due to the success of the first funded ORC and the lessons learned from it, funding other ORCs is warranted to further promote the establishment of a successful, profession-wide research infrastructure.

The ORT served an important and unprecedented leadership role for a few years, coordinating the Osteopathic Collaborative Clinical Trials Initiative Conferences (OCCCTICs), helping the profession establish an ORC, and developing the white paper. After the ORC was established, the ORT no longer had a clear mandate and disbanded. As a result, the momentum created by the integration of organization leadership diminished and many of the initiatives outlined in the white paper have not been addressed. It is critical to appreciate that the ORT was not designed to take

over any of the current committees or organizations that support research but provided a venue where these constituencies came together, became educated about the activities occurring outside of their immediate focus, and coordinated and strategically planned a vision as articulated in the white paper. For the vision to be achieved, ongoing communication, coordination, timely assessment of successes and failures, and subsequent refinement and updating of the strategic plan is critical. The ORT or a similar body needs to be re-established and supported in the long term for the profession to be able to actively and progressively contribute to the general scientific community.

In addition to the ORT, a greater level of commitment to research must come from other entities. An organization, such as the AACOM, should take a leadership role in advancing the annual reporting of research activities, which could be used to benchmark success and refine strategic planning. Accrediting bodies within the AOA need to demonstrate leadership by emphasizing to colleges and hospitals the importance of promoting and participating in research. If the profession truly agrees that it has the dual responsibility of providing the best level of medical care based on current knowledge while advancing that knowledge, the AOA needs to give accrediting bodies the directive and authority to assess an institution's progress in research activities. Such leadership is necessary because without invigorating research at osteopathic colleges and associated research centers, institutes, or medical facilities, the profession will not succeed in fulfilling its research goals and societal responsibility to improve health care (14,27). Description of the ways in which the colleges can lead in research will be discussed later as specific research priorities are presented. As for practicing physicians, they need to see the value of and join a practice-based research network and support research financially through their alma mater and/or the profession. Future DOs must take the initiative to become involved in research activities, encourage curricular content toward critical thinking, research methodologies, and evidence-based medicine, and consider pursuing secondary degrees in order to expand their clinical research options. Thus, it should be clear that leadership which supports research priorities needs to be shared at all levels of the profession.

OMM Research Activities

Challenges and Opportunities Facing Current Researchers

While the number of practicing DOs is increasing (28), few have adequate training to develop and conduct quality research. In addition, across the biomedical community, the number of clinical researchers is diminishing (29,30). Consequently to deal with the current deficit, it is critical to increase the collaboration between physicians and scientists both within the profession and without.

Each osteopathic medical school has a cohort of basic scientists who can serve as a pool of potential collaborators for OMM research. These basic scientists usually come into the profession with little to no understanding of osteopathic principles or of how their talents could be used to generate meaningful research in the osteopathic practice of medicine. A standardized introductory program highlighting osteopathic principles, practices, and models of research needs to be developed and provided to all professors entering the profession, with modifications at the college level to highlight research opportunities unique to that institution. Productive lines of OMM research have been established between clinicians and basic scientists whose skills appear quite unrelated to OMM (31–36). However, both senior and novice clinical and basic science faculty must be open-minded and think innovatively to create

these associations. The administration and department chairs at each college need to take a leadership role in facilitating these collaborations and in identifying, recruiting, and nurturing clinicians and basic scientists who are willing to participate in these interdisciplinary research teams. Critical for success in fostering these collaborations are college administrators who can provide routine encouragement to the interdisciplinary research teams with meaningful incentives, such as additional research support (technicians, computers), as collaborations become established.

Supporting collaboration with scientists outside of osteopathic colleges requires a different strategy. First, it is important to know what type of researcher or what type of skill set is needed for a particular line of research in OMM. There are disciplines, such as engineering, biomechanics, motor control, neurobehavioral sciences, and pain management, that have overlapping areas of interest with OMM, but associations with researchers in these fields have not been adequately pursued. Osteopathic colleges that exist within large universities with significant research infrastructures have the opportunity to create collaborations with experts from the other colleges within their institution to advance OMM research. Establishing these collaborations will only occur if leadership and initiative comes from the osteopathic profession to create a research question/vision that is meaningful and provocative to these researchers. Resources must be given to key osteopathic personnel, particularly research-trained DOs and PhDs, who can identify external researchers whose skills seem ideal to perform collaborative research within an osteopathic context. Further, the osteopathic researchers must routinely monitor the activities of potential collaborators so that the research direction and instrumentation within those labs are clearly understood. Such knowledge will allow the osteopathic researcher to develop meaningful research questions linking the independent lab's areas of interest to research questions that overlap with osteopathic principles. Then through interactions set up at routine meetings, conferences, or special invitation luncheons, a quality presentation of the research idea can be given and hopefully a productive collaboration initiated.

Limiting the profession's success in promoting research is its lack of awareness of the current DOs participating in research. A profession-wide survey of DOs involved in research activities would be useful to identify the current pool of clinical researchers. The profession could then develop programming to promote dialogue between those researchers. In addition, an underutilized research resource is DOs trained in non-BOA sanctioned residencies and practice in the general biomedical community. These physicians are likely to have the background and connections to facilitate research relationships between the osteopathic profession and other disciplines within the biomedical community. Therefore, these DOs need to be identified, and the profession needs to nurture positive relationships with them. In an era where the number of graduating DOs is dramatically increasing while the number of DO residencies is not, the BOA needs to develop policies that strengthen their relationship with MD trained DOs instead of isolating them.

In previous studies in OMM, osteopathic medical students, predoctoral fellows, residents, and board-certified OMT specialist physicians have participated as treatment providers. Different studies have found positive and negative results from each respective skill level of OMT provider (37–40). A case can be made that if students or residents (relative OMT novices) can have a positive clinical effect within a research study then the osteopathic profession's contention that all DOs have the requisite skills at graduation to help their patients with OMT is supported. Yet achieving positive outcomes in clinical efficacy studies may be more risky when using novice practitioners. The more experienced osteopathic

researchers and research centers in the US utilize board-certified OMT specialists almost exclusively in the provision of OMT for their research trials. At this very early stage of OMT research, treatment protocols and providers should be selected to maximize the likelihood of finding a treatment effect if one actually exists.

Considering the substantial paucity of board-certified OMT specialists, even if OMT provided by these specialists is proven efficacious, the information has limited practical utility since there are only a few providers in practice to make the treatments available to the public. Consequently, if OMT is found to be effective when administered by board-certified providers, a task that should be more likely than with less trained individuals based on face validity, subsequent research should be undertaken to determine whether generalists or physicians-in-training can attain similar results.

Although the current research environment within the profession recommends against the use of student researchers as treatment providers in clinical efficacy studies, there are research projects appropriate for student participation. One area of research ripe for student participation involves investigating the baseline palpatory skills of osteopathic medical students and determining the impact of current training programs on those skills. This area of research is also ideal for establishing interdisciplinary collaborations.

Regardless of the skill level of the OMT provider, all treatment providers should undergo repetitive training (certification) in the specific diagnostic skills, OMT techniques, and any other protocol parameters associated with a particular trial. Such training adds significantly to the perceived and actual validity of the provided OMT.

Over the past several years, the Osteopathic Heritage Foundation (OHF) has been instrumental in supporting current researchers within the profession by establishing endowments that provide resources to augment research programs showing productivity (41). This format has been successful in the general clinical research arena and their establishment within the osteopathic profession demonstrates insightful leadership. Such support needs to continue.

Types of Research: Defining a Meaningful Research Portfolio

A critical goal for research leadership is to create a research portfolio that prioritizes and strategizes research for a period of time (5 year blocks) to optimize utilization of resources and outcomes. This section is offered to help individual researchers, funders, and reviewers have a framework from which to develop personal research and to determine funding priorities.

While not specifically outlined in the ORT White Paper, one purpose of the initial OCCTIC meetings was to prioritize specific areas of research. Much debate ensued over the topics and types of research that should be initiated first, such as clinical efficacy versus mechanistic studies or studies on musculoskeletal conditions versus systemic diseases. This debate continues today.

Clinical Efficacy Versus Mechanistic Research

Generally speaking, clinical efficacy research involves exploring whether or not a particular clinical intervention is beneficial. In contrast, mechanistic research focuses on how a particular clinical intervention is beneficial. Most biomedical research progresses from mechanistic toward clinical research. For example, scientists must first understand the mechanisms by which the body controls blood sugar levels before they can develop treatments for diabetes. Potential treatments based on these mechanisms are then evaluated for safety and optimal dosing in Phase 1 clinical trials, for feasibility and effect size in Phase 2 clinical trials, and for efficacy and possibly cost effectiveness in Phase 3 clinical trials. An understanding of

the underlying physiological and pathophysiological mechanisms is extremely powerful in the development of effective novel clinical interventions. For this reason (and others), the vast majority of research resources in the United States over the last century have been awarded to scientists exploring biological mechanisms. The underlying principle for this approach is that this wealth of knowledge on mechanisms will eventually translate into applied breakthroughs in clinical care. This principle has been reconfirmed in the NIH roadmap.

This sequence of first mechanistic and then clinical research is turned upside down in areas where systems of health care have been practiced for hundreds (if not thousands) of years, are broadly accepted, and are in popular use. These areas include OMT as well as other traditional treatment methods, such as acupuncture, Ayurvedic medicine, and the use of botanicals. Since these traditional treatment methods have weathered the test of time, they are generally accepted as safe especially when they do not prevent the use of modern treatments clearly known to have efficacy. Osteopathic clinical researchers often favor efficacy studies since they do not have the constraint of mechanistic research superseding efficacy research in order of priority and because efficacy studies give them the opportunity to “prove” that OMT works.

There are many factors to consider when choosing between clinical efficacy and mechanistic research. Mechanistic research has in its favor its relative low cost, a defined facility for performing the research (a lab), and the potential for variable control. Efficacy research typically costs more, is more difficult and time consuming, and is perceived as less scientifically rigorous due to the high intrinsic variability within human subjects and the inability to control many significant variables. Even though efficacy research may lack in practicality, it has the potential of being more relevant to health care.

What is most important, no matter which kind of research is chosen, is to develop a research question with a good basis or rationale for why the hypothesis could be true. In the case of current clinical research within OMM, developing research questions is simple since little research has been performed to narrow the field of questions. Yet it can be difficult to have a good basis for the hypothesis when most claims of the efficacy of OMT have been anecdotal and when the parameters for the condition being treated as well as the intervention being performed are poorly defined. Meaningful research does not come from the enthusiasm to “prove” something works but from the burning desire to know and understand something better. Too often, osteopathic research is performed and little is learned because too many assumptions were made in the design of the study. In the back of every researcher’s mind must be the concern that time is short and resources are limited. Poor motives and poor study designs result in poor outcomes as well as wasted time and resources. The availability of time will be gained when small but sequential steps in knowledge are made when answering a question.

This fundamental in science of making small but sequential steps in knowledge challenges clinicians and researchers to observe phenomena thoroughly first so that appropriate questions, rationale, and designs for research can arise from these observations. An observational study design has the potential of identifying what might be efficacious for a specific condition. Based on sound observations, a well-controlled, competitive clinical efficacy study can be developed and the likelihood of achieving meaningful outcomes can be optimized. As a patient-focused profession that promotes optimizing intrinsic health for each individual, establishing well-designed and coordinated procedures to observe characteristics, conditions, and treatment outcomes could and should drive the research agenda, whether it is in clinical efficacy or mechanistic studies.

Musculoskeletal Versus Systemic Disease

OMM was built upon the reports of treatment success for systemic diseases. Yet for decades, the practice of OMM has been directed more toward musculoskeletal diseases. Musculoskeletal disease as an OMM research focus has in its favor the high incidence of musculoskeletal diseases and pain in the general population and the high costs of care for these problems. Low back pain alone has health care costs of over \$100 billion annually in the United States (42). The efficacy of OMT for purely musculoskeletal conditions also has in its favor more easily understandable and defensible theoretical mechanisms of action. It is relatively easy to understand how the application of manually guided forces may affect and align elements of the musculoskeletal system with known discrete elastic, plastic, viscous, and colloidal properties. It is more challenging to suggest that these forces could improve conditions like irritable bowel disease, improve pulmonary function to fight pneumonia, or resolve recurrent ear infections.

However, only the osteopathic profession has the history, incentive, and potential capability to conduct clinical research into the use of manually applied, body-based treatment of systemic diseases. While research on manually applied, body-based treatment of systemic diseases could be seen as an opportunity, there needs to be an open and critical assessment of the training students and recent DOs have received in OMM in order to determine if current osteopathic physicians have adequate training to treat systemic diseases with OMT. Regarding manual diagnostic and therapeutic skills, members of the profession can talk about legacy and licensure, but what are we able to validly report on capability? For visceral diseases, how much training do our students receive in diagnosing the musculoskeletal manifestations of visceral diseases or treating them with OMT? How much training do students receive in the hospital setting treating systemic illnesses? How many cases do students report that they used OMT as part of the care for common visceral diseases? Over the past 30 years, the number of curricular hours in OMM within osteopathic colleges has diminished by 50%. How much confidence does or should the profession currently have regarding the efficacy of OMT? As a result of the dramatic changes in OMM training, are the current therapeutic outcomes from OMT representative of the model itself or of the current training standards? This change in training further emphasizes the need to perform observational studies, as described in the previous section, so that a reasonable assessment of the current therapeutic nature of OMT can be made.

Special Considerations in OMT Clinical Trials

Placebo

Literature on the use of placebo control in clinical trials is amazingly complex and nuanced, and it is beyond the scope of this chapter to provide a review of placebo literature. However, there is active and valid debate within the osteopathic research community as to whether OMT clinical research should even utilize placebo control due to its nuanced complexity. On the one hand, the use of placebo control is so ingrained in the medical research culture that clinical trials lacking this design component are summarily rejected. On the other hand, placebo control in OMT clinical trials is so fundamentally misunderstood that the use of a placebo practically ensures misinterpretation of the associated results.

Central to this debate is an understanding of how a placebo intervention is selected for use in an OMT clinical trial. Theoretically, subjects in the placebo arm of a clinical trial should experience everything identically to the subjects in the OMT arm with one notable exception; they do not receive the active ingredient

inherent in OMT. The specific placebo selected depends on what one hypothesizes is the active ingredient in OMT for a particular trial. In order of increasing specificity, the active ingredient in OMT could include physician time and attention, therapeutic touch, nonspecific musculoskeletal mobilization (jostling), and/or reversal of specific somatic dysfunctions. If the research question is to determine whether the difference a DO makes includes all of these potential mechanisms (effects) of OMT, then a placebo should be selected that includes none of these clinical interactions (e.g., an educational brochure). It is rational to promote that placebo interventions could include: (1) a DO simply spending extra time with the patient (without physical contact) to test effect of OMT versus touch, jostling, and somatic dysfunctions reversal; (2) a DO providing light touch (without movement or intent to treat) to test effect of OMT versus jostling and somatic dysfunctions reversal; or (3) a DO providing nonspecific musculoskeletal mobilizations (without the physician intending to produce a therapeutic treatment) to test the effect of OMT versus somatic dysfunctions reversal alone. Yet most NIH reviewers and clinicians do not understand that OMT may actually positively impact health through a combination of these potential mechanisms. Evidence indicates that touch itself is therapeutic (43), and so by its very nature, cannot be considered as a placebo but as an alternative yet overlapping form of treatment. Consequently, research designed to compare OMT to a light-touch group is not an adequate placebo design. A no-touch control is required in manual medicine research. A design without a no-treatment, light touch control group will likely require a larger number of subjects than commonly predicted in order to demonstrate efficacy because the touch, nonmanipulation group will have therapeutic results representing a portion of the therapeutic effects of the OMT intervention.

This understanding explains the results of many placebo-controlled manual therapy clinical trials where the touch-only placebo intervention produces results that fall between the results of the OMT group and those of the no-treat controls (39,40). Since the term placebo is so ubiquitously associated with a sham, fake, or false treatment, the interpretation that OMT produces results comparable to placebo is the most common and possibly most misleading conclusion. Since placebo controls are standard and customary in clinical research but are oversimplified and misunderstood, placebos should be used properly within OMM clinical efficacy studies but interpreted and discussed cautiously and insightfully in OMT clinical trial grant applications and publications.

Blinding

It is commonly accepted that a Phase 3 clinical trial must be double blind. This expectation is another significant hurdle for OMT clinical trial research. Simply defined, double blind means that both the patient and the doctor (provider) are blind to research intervention group assignments, so neither the patient nor their doctor knows which treatment group the patient is in. This is a fundamental design element in double-blind studies because knowledge of group assignment by anyone involved in care or data collection has the potential to bias results. However, it is impossible for certain therapeutic interventions to be administered without the provider knowing that a given treatment is the real treatment and not the placebo. This predicament exists for clinical research on surgical interventions, exercise prescriptions, therapeutic ultrasound, and, of course, OMT. In fact, clinical trials of medications or nutraceuticals represent some of the few types of interventions that can truly be double blind by the above definition.

In OMT research, the goal is to blind everyone possible. Although the actual OMT provider must be unblinded, the

patient, all other clinical personnel (nurses, therapists, front office staff, etc.), the clinical trial coordinators, the data entry staff, and the principal investigator(s) should be kept blind. Further, if the presence or severity of somatic dysfunction is used as a clinical outcome measure, then an osteopathic physician other than the OMT provider should perform all pre- and post-OMT palpatory assessments of somatic dysfunction. Although this addition greatly increases the complexity and cost of an OMT clinical trial, it is the only way to eliminate the potential for bias from the unblinded OMT provider.

OMT Technique Selection

For many clinical conditions, an OMT prescription will include a variety of techniques intended to address different elements of the disease pathophysiology and will be selectively tailored in response to a given patient's palpated specific somatic dysfunction. According to osteopathic principles and practices, an osteopathic researcher would likely hypothesize that the greatest therapeutic effect would occur when OMT is utilized in this individualized, pragmatic, and holistic fashion. On the surface, this method seems inconsistent with best research practices, which dictate that interventions in clinical research trials must be standardized. However, on closer examination and with a better understanding of OMT, it becomes apparent that a somewhat individualized approach using multiple techniques in multiple body regions is most appropriate and even critically necessary for quality OMT research at this stage of its development.

Using research that investigated OMT in the treatment of pneumonia as an example, most clinicians who regularly use OMT for this condition would advocate a whole-body treatment that included different techniques to (1) improve the biomechanics and mobility of the rib cage (bellows), (2) normalize autonomic nervous function, (3) remove diaphragmatic impediments to fluid flow, (4) minimize the overall body burden of somatic dysfunction, and (5) enhance lymphatic circulation and immune function (44). This kind of treatment protocol would be performed in a clinical trial by having the treatment providers repetitively trained and certified to accurately and consistently provide this constellation of techniques, individualized to each given patient's specific somatic dysfunction. In addition to specifying the time allowed and expected for OMT, these providers should be given latitude, based on their training and clinical judgment, in order to provide an additional 5 minutes of treatment for any additional OMT necessary to enhance the patient's health and recovery. Critics of this methodology argue that, in the end, regardless of how positive the clinical outcome, this kind of trial is valueless as nothing can be known about which techniques caused the improvements.

Proponents of this multifaceted OMT design emphasize that until it has been proven that OMT is actually effective, there is no reason to design a trial with methodology focused on underlying mechanisms. With so very little definitive OMT clinical trial research completed at this time, the highest research priority at present is to design trials that first determine whether OMT, under even the most ideal circumstances, can have a positive clinical effect. Once this has been determined, research efforts and resources can be directed to those elements of OMT that contribute the most to the positive effect.

Interpreting Results

There are two fundamental types of research errors, Type 1 and Type 2, which should be considered when interpreting study results. An example of a Type 1 error in the context of OMT pneumonia research would be to conclude that OMT helps pneumonia

patients when it actually does not. A Type 1 error is the most common research error due, in part, to investigator biases and the incentives associated with positive research findings and publications. An example of a Type 2 error in OMT pneumonia research would be to conclude that OMT does not help pneumonia patients when it actually does. The osteopathic profession must make it a priority to be particularly careful not to make Type 2 errors. Out of confusion regarding the true research question and a misguided perception that the above described OMT technique selection is insufficiently standardized (unscientific), osteopathic researchers tend to address important clinical questions with overly restrictive OMT research protocols. Consequently, early investigations into important questions regarding the clinical efficacy of OMT have ended with negative results (possibly Type 2 errors). Negative results (erroneous or otherwise) significantly reduce future funding opportunities and investigator interest. Nothing could be more detrimental to our quest for truth regarding the effects of OMT than this kind of Type 2 error generated by well-meaning, misguided osteopathic researchers. Both types of errors need to be considered when designing a study and interpreting the results.

Improving Research Sophistication

Maturing OMM research sophistication from pilot studies through large, multicenter trials is critical to establish a successful research enterprise and expand the current OMM evidence base to a level consistent with current scientific standards. More and more, clinical studies are reporting on sample sizes in the thousands and tens of thousands of subjects instead of tens or hundreds. To achieve this level of sophistication, collaboration throughout the profession is essential. Young, enthusiastic researchers with a promising area of research must be given adequate support and resources to generate sound pilot data from which these larger studies can be developed. Research teams need to use well-designed studies and perform multicenter studies within the profession, including especially the smaller or younger osteopathic schools or colleges who may not have the expertise or resources to develop and oversee such rigorous study designs but who can, with mentorship, establish productive data collection sites and develop skills necessary to build a productive research infrastructure.

Conferences

Conferences designed to support the osteopathic research community are an important issue to consider. Currently, there are numerous society and professional conferences within the general biomedical community, where leading researchers present the outcomes of their investigations. These conferences are a fundamental part of the scientific establishment and are invaluable in helping all researchers refine and create methodologies that will withstand critical peer evaluation. These meetings are also instrumental in identifying researchers with similar interests and establishing relationships that could lead to fruitful collaborations. The profession should be cautious and not develop alternative scientific conferences, thinking that OMM research requires methods or outcome measures that are different from the general biomedical community. Instead, the osteopathic profession should encourage researchers in osteopathic principles or practices to identify the best research-oriented society and its associated conference that fits their area of interest and should help them regularly attend and present their work at these premier research conferences.

During the past 10 years, there have been two conferences that focus on research sponsored by the osteopathic profession, the AOA

Annual Scientific Conference and the OCCTIC. While there is a long history to the AOA Annual Scientific Conference, its format has varied, and its outcomes/participation has been quite variable. OCCTIC, coordinated initially by the ORT and most recently by the ORC, has had success in developing programs for research training and in coordinating research priorities and strategies in OMM research. The last OCCTIC in 2008 was quite successful as an interdisciplinary research conference focusing on manual therapies. The planning committee for that conference recognized that the osteopathic profession is positioned to be a leader and facilitator for establishing and continuing such a conference. At that OCCTIC meeting, which focused on somatovisceral interactions, osteopathic physicians, chiropractors, physical therapists, massage therapists, and basic scientists were in attendance. The conference was sponsored by all the professions in attendance and by the NIH through NCCAM. A book of proceedings from this conference will be in press soon (45). While osteopathic medicine has a historical claim of rejuvenating the field of manipulative medicine, D.O.s represent just one of many disciplines that utilize the hands as part of their therapeutic armamentarium. Providing the leadership to advance the understanding of the therapeutic potential of palpation should be considered an important goal and responsibility of the profession.

Previous interdisciplinary research-oriented conferences have been sponsored by the American Academy of Osteopathy over the past two decades and have been very well received by both clinicians and scientists. Each resulted in a book of conference proceedings (46,47). Unfortunately, outcomes have been limited due to a lack of regular interactions between the attendees. Sustaining such venues on a regular basis, perhaps on a triennial basis, would be quite fruitful for the profession.

To develop a productive research conference format and schedule, stakeholders must be supported in order to develop a coordinated, invigorated, novel, and fiscally responsible conference schedule. This leadership is also needed to create a 5- to 10-year integrated conference plan that will provide the necessary education and exposure to advance the profession's research infrastructure.

OMM RESEARCH FUNDING AND RESOURCE ALLOCATION

Currently, there is funding for OMM research from the AOA through the Osteopathic Research and Development Fund (ORDF) and from several specialty societies, such as the American Academy of Osteopathy, the Cranial Academy Foundation, and several osteopathic foundations like the OHFs. Expanding and coordinating these funding resources is vital for the success of research within the profession. As a result of the ORT White Paper, one goal has already been achieved. The OHFs provided matching funds in 2009 with the annual AOA funding for grants. As a result (Table 71.3), the number of funded grants has doubled and the scope of the grants has increased in comparison to recent years. It is projected that these matching funds will improve the design and outcomes of these studies and the subsequent potential for funding from federal sources.

Personal experience has shown that a successful NCCAM grant application requires an experienced research team, good pilot data, and an outcome that will have a clear impact on medical knowledge and care. Unfortunately, it is not always apparent to reviewers how or why osteopathic practices would improve medical knowledge and practice. Consequently, it is critical for the AOA to continue to expand the funding of pilot studies so that the potential influence of osteopathic practice on medical care can be shown. Further, as a result of the grants being critically reviewed and screened through

the strategic priorities and portfolio established within the AOA, funded grants should be better prepared to successfully compete at the NIH level.

While coordination of funds is having a positive impact on the profession's research efforts, the financial infrastructure for supporting research is weak. The ORDF, established in the 1980s to support research through AOA membership dues, is not receiving new funds and is, thus, greatly influenced by stock market forces. For example, within the past 10 years when the market was low, funding of grants was suspended for 2 years until the market improved. Each member of the profession should have an invested interest in sustaining a successful research enterprise. In order to support the ORDF, reinitiating and sustaining dues allocation for research must remain an ongoing priority.

Expanding the resources available for research needs to go beyond the AOA to include the schools, colleges, and universities where DOs are trained. Each institution must take a leadership role and seriously consider its fiscal responsibility as a center of higher learning, with the goal of promoting scholarly activity and expanding the knowledge base of the practice of medicine, while not focusing solely on the granting of diplomas and the revenue it brings to the institution. Establishing or expanding internal funds for pilot projects, especially ones that help provide experience to future clinicians and interdisciplinary teams, would greatly improve the chances of this profession having an impact on the health care industry in this century.

Promoting dual-degree programs, especially ones that foster research and promote clinical research careers, also needs to be prioritized throughout the profession's training programs. While many colleges offer dual degrees, enrollment in those programs must be encouraged. As numerous allied health professions increase the rigor of their programs and grant higher levels of degrees (48), there is also a greater need to advance the level of physician training. Earmarking institutional scholarships as well as seeking external funding and fellowships to support the development of future osteopathic clinical researchers is a critical investment for the profession.

Meetings that coordinate priorities and strategies between the profession's successful research teams and research leaders, like the ORT, are important and require a funding stream of support. Providing resources to maintain an interdisciplinary research conference in manual therapies should be considered as well. And finally, a funding strategy that includes many stakeholders within the profession needs to be developed to achieve success.

OMM RESEARCH TRAINING

While the focus of the ORT's recommendation in the white paper was on OMM research, it seems more appropriate when discussing this domain to maintain a broader focus, including aspects of research topics associated with OMM without being limited solely to those topics.

The focal point for research training lies primarily with the colleges of osteopathic medicine and begins in the selection process of applicants to DO programs. In a supporting role, AACOM can help disseminate the research opportunities for potential students within the colleges, but the pipeline for identifying and nurturing students through dual-degree programs and providing various research experiences throughout the medical school experience clearly lies within the purview of the colleges. While it is common that the colleges harness the excitement and idealism of youth to encourage students to become good clinicians and lifelong learners, students also need to be given the opportunity throughout their medical education to observe the nature and behavior of living

systems (30,49,50) through the eyes of a clinician researcher and to experience the excitement of asking new questions and finding answers that will advance health and the practice of medicine. Clinical activities, like behaviors, are difficult to change once they have been established. Preliminary data suggest that the sooner research activities are initiated within the educational experience, the more interested the students will be in participating in such activities (30,49,50). Consequently, clinician researchers must be grown in order for a profession-wide culture of research to be developed, where clinicians will be driven to sustain proven health care practices and develop new ones that extend healthy life while reducing the burdens of illness and disability.

Even though several specialty colleges recommend or require residents to engage in research activities, meaningful outcomes from those activities have been quite limited (51). A new paradigm should be considered that coordinates residents in the same research project, either at the same time or over time, in order to generate more meaningful training experiences and outcomes that will have value within the scientific community. This type of programming would require longitudinal and possibly multicenter mentorship and coordination. Developing such programs within specialty colleges or Osteopathic Post-graduate Training Institutions should be considered. One of the profession's research centers/institutes could assist in this endeavor by providing the consultative services necessary to ensure projects are rigorously designed and support the implementation and interpretation of results.

SUMMARY

For many within this profession, much of the information presented in this chapter will seem very familiar. In fact, some of these priorities were identified and reported decades ago (5). Herein lies the greatest issue facing the profession regarding research: priorities are supposed to be important and aggressively addressed. There is an urgency to have them accomplished or incorporated into routine activities and expectations. Certainly, there are challenges and finite resources that must be considered as the profession engages its research priorities. It is a daunting challenge to better understand the complexity of life, but with a clear and unified vision, good coordination of available resources and responsibilities, and adequate accountability, this profession can become a leader in the advancement of health care in both practice and research. The outcomes from the ORT demonstrate the potential of having a unified vision and profession-wide coordination. By reconstituting and expanding a forum where leading researchers and research advocates can meet to inform each other of independent research activities and initiatives; to confirm, update, and advance profession-wide research priorities; and to coordinate resources and action plans, the profession will establish the infrastructure needed to become a productive member of the research community. A key constituent within the profession that needs to take on a leadership role in achieving research priorities is the colleges of osteopathic medicine. A greater level of commitment and participation is needed from each of the colleges for success to be achieved.

As the direction of research at the NIH becomes more technologically driven in molecular, submolecular, and genomic arenas, the osteopathic profession has the opportunity to remain true to its legacy by focusing on research in medical care that is broadly applicable, holistic, and patient centered. Successful outcomes in holistic, patient-centered research will have the potential of influencing public health policy not just nationally, but globally due to the minimal level of technology needed to implement OMM approaches. Further, funding for research in osteopathic medicine

is currently available through NCCAM at an unprecedented level. The successes over the past several years in obtaining NIH funding illustrate the opportunities and possibilities available to the profession, while highlighting the deficiency within the profession in generating fundable research proposals. The profession needs to have the foresight to invest in its present and future members by establishing an infrastructure dedicated to expanding the evidence base for osteopathic medical care. This infrastructure can be quickly built by facilitating interdisciplinary collaborations between basic and clinical scientists, both within and outside the profession. Concurrently, facets within the profession must relinquish the posturing of the past that isolates us from the greater biomedical community and is divisive within the profession itself.

While the membership of the profession needs to understand the importance of research and participate in research activities in general, we must also recognize that our resources should be used to promote research that is important to osteopathic principles since the level of potential funding is limited compared to other areas of biomedical research. While all scientists and clinicians should be united in the pursuit of an evidence base that leads to improved efficiency and quality in the provision of health care, special interests do enter into this process. Therefore, it is critical that all osteopathic physicians have training in research methodologies and critical thinking in order to discern strong versus weak research and to remain true to the profession's founding principles by advocating for health care approaches that prioritize and promote intrinsic health for every individual.

There truly is an important role for the osteopathic profession and its principles in modern scientific activity. Society waits to see if and how the osteopathic profession chooses to fulfill its dual responsibility of providing the best level of care based on current knowledge while advancing that knowledge to levels previously unimaginable.

Development and Support of Osteopathic Medical Research

HOLLIS H. KING

KEY CONCEPTS

- The focus of osteopathic research is more than manual medicine and osteopathic manipulative treatment. The osteopathic medical philosophy, described elsewhere, provides the underpinning for the research done, which addresses the unique and distinctive elements brought to the health care arena by osteopathic physicians.
- Evidence-based osteopathic research has a history as old as the osteopathic profession itself. Published osteopathic research was comparable to any research done in a particular era and included several large-scale projects. Highlights of over a hundred years of osteopathic research are described and development of the osteopathic terminology based on the research is described.
- Clinical trials utilizing osteopathic manipulative medicine have been accomplished and are being developed. The focus on the need for clinical trials research resulted in the establishment of the Osteopathic Research Center.
- Principles of developing uniquely osteopathic research are based on traditional basic and clinical science design models. Due to limited resources and availability of trained researchers, a number of unique adaptations have been required to accomplish the osteopathic research agenda. Resources for research grant development and writing, “grantsmanship,” and collaboration development are presented.
- Uniquely osteopathic research has not received extensive federal funding such as from NIH. Funding from these sources has increased in the last 10 to 15 years but remains a very small proportion of biomedical research in the United States. Osteopathic research has been funded primarily by osteopathic foundations and institutions.

UNIQUELY OSTEOPATHIC RESEARCH

The focus of this chapter is clinical research done and documented from a uniquely osteopathic perspective. Many faculty members at colleges of osteopathic medicine (COMs) have produced significant research studies in areas not directly related to osteopathic principles and practice (OPP), osteopathic manipulative medicine (OMM), and osteopathic manipulative treatment (OMT). Examples of this is the work at Michigan State University College of Osteopathic Medicine done by Justin McCormick, Ph.D., in cancer research (3,4); by Andres Amalfitano, D.O., in genetics research (5,6); and at the University of North Texas Health Science Center (UNTHSC), Texas College of Osteopathic Medicine by Albert O-Yurvati, D.O., in cardiovascular function (7,8). At these and other COMs, the presence of the basic and clinical scientists like Drs. McCormick, Amalfitano, and O-Yurvati has helped to create a research environment in which uniquely osteopathic research is more likely to be carried out and at a higher level of quality.

The development of OMM-related research is enhanced in institutions that have faculty who are experienced and well-funded basic and clinical science researchers in areas other than OMM-related research. The influence and collegiality created by interactions with active researchers enhance the atmosphere likely to lead to higher quality research in both the clinical and basic science arenas. As discussed later, the collaboration between researchers is often central to furthering the research capability of the collaborators. This is particularly true for osteopathic clinicians who forge collaborations with basic scientists whose areas of research can be related to OPP/OMM/OMT, which has been a key to the development of osteopathic research.

The American Osteopathic Association (AOA) has a long history of promoting and supporting osteopathic research. Crucial to the current state of osteopathic research was the establishment

of the AOA Research Task Force, which published two guiding documents that facilitated the establishment of, and guidance for, the Osteopathic Research Center (ORC) (9,10). In the 2005 AOA Research Task Force Report, *Research Strategic Direction for the American Osteopathic Association* (9), the statement is made, “The Task Force recognizes the value of areas of biomedical research. However, the recommendation is that the AOA focuses its research funding exclusively on those areas of research that investigate the unique aspects of osteopathic medicine with an emphasis on OMM. The breadth of this research focus may include but is not limited to:

- Mechanisms of action of OMM
- Clinical efficacy of OMM
- Interrater and intrarater reliability of palpatory assessment
- Osteopathic physician and patient interactions
- Cost-effectiveness of osteopathic health care
- Methods of teaching palpation and OMM

Based on the prominence of the members and groups represented by the AOA Research Task Force, also more commonly referred to as the Osteopathic Research Task Force (ORT), this is the most authoritative guide given to date as to the nature of uniquely osteopathic research, and for the sake of discussion comprises the topics that are the focus of this chapter. These topics have all received research scrutiny in the past but are now receiving priority as new OMM-related research projects are planned.

The increased emphasis on and urgency to produce uniquely osteopathic research by the osteopathic medical profession was articulated in the National OMM Research Synergy White Paper, *Osteopathic Manipulative Medicine Research: A 21st Century Vision* (10), where it is stated, “In this era of modern health care, insurers, policy makers and consumers are interested in evidence-based

medicine. Therefore, it is of paramount importance for physicians to document, through well-designed and well-executed research studies, which specific aspects of the clinical care they provide to patients are proven to be beneficial. This is particularly true in osteopathic medicine. Instead of saying, ‘we know it works because patients get better,’ the profession must channel its resources to determine through scientific research studies whether osteopathic manipulative medicine (OMM) does indeed improve patient outcomes in a broad range of specific situations. The profession must also elucidate the mechanisms by which this unique, hands-on approach to patient care works.”

In an era of increasing costs for health care, insurance companies and other third-party payers are demanding evidence of health benefit for OMM, as reimbursement requests for these services are submitted by osteopathic physicians. As described later, this financially driven imperative is gradually receiving empirically based answers. However, there exist other reasons to generate this research, including clarifying the distinctiveness of osteopathic medicine, demonstrating the value of osteopathic medical care as well as the financial reimbursement for OMM services.

Another compelling reason to generate the evidence base for OMM is the very confidence with which OPP/OMM/OMT are taught in the first 2 years of osteopathic medical curricula and perception of OMM by rank and file osteopathic physicians. Osteopathic medical students (OMSs) are entering their medical training with a generally higher awareness of, and in many cases experience in, research. From the author’s experience in teaching at the OMS-I and OMS-II levels, there are more questions being asked by students about the research underpinnings for OMM/OMT. Further, when quality evidence-based OMM research is presented, there is a much greater attentiveness to and practice of the OMM/OMT lessons by the students.

Furthermore, based on discussions at AOA conventions and the AOA House of Delegates with a wide geographic and professional diversity of osteopathic physicians, as more uniquely osteopathic research is published, the application of OMM/OMT increases in clinical practice. Discussion at coding and reimbursement seminars at the AOA and American College of Osteopathic Family Physicians (ACOF) conventions and the American Academy of Osteopathy (AAO) convocation also suggest a trend toward increased likelihood of reimbursement based on citation of evidence for OMM/OMT benefit, although the greatest success in obtaining reimbursement is based on dealing with the complicated, detailed and diverse rules for claim submission. This informed observation is shared by many who are involved in OMM-related clinical research and is based on input and requests from osteopathic physicians who want to do more OMM but are constrained by reimbursement issues based on insurance and managed care panels who cite the lack of research support for the medical necessity for OMM services.

DEVELOPING OSTEOPATHIC RESEARCH: A HISTORICAL PERSPECTIVE

From Still Through Korr—Studies and Funding

The heuristic value of Andrew Taylor Still’s osteopathic philosophy, principles, and practice has never been in doubt. That is, Still’s philosophy and teaching were the source of ideas for the generation of research hypotheses. A careful examination of early osteopathic research suggests that it was comparable to medical research performed by others of that era. Just as with allopathic medical and basic scientific research, there were shortcomings in comparison

to today’s standards, such as adequate definition of procedures and utilization of control groups.

In the early days, osteopathic research was largely observational and the question was how those receiving osteopathic medical care fared in their health as compared with those receiving care by allopathic physicians. Examples of some of these studies had relatively large sample sizes and comparison groups. In 1911, Whiting (11) reported on the impact of OMT on labor and delivery outcomes. She reported data for a sample size of 223 women in which 198 received OMT and 98 did not. The outcome was that the labor times for the women receiving OMT were dramatically shorter. At the Still Research Institute (funded by the AOA at that time) also in the area of OMT and obstetrics, S.V. Robuck reported in 1933 a chart analysis of 13,816 women who received OMT during pregnancy and found the maternal mortality rate to be much lower, with only one-third as much of the maternal mortality reported in “government bulletins.” (12) While caution is advised in the interpretation of the data (13), Smith (14) reported an observational study with 110,120 influenza patients in 1918 to 1919 who received OMT and suffered a much lower mortality rate than the general population. While such studies may have lacked the rigor of modern research design, they were certainly at or above the standards of the day and are cited here to make the point that large-scale studies have been carried out in osteopathic research from the beginning of the profession.

Other aspects of modern day research emphases are seen in very early osteopathic research. The current “bench to bedside” model of translational research was pioneered in the work of Louisa Burns, D.O., who developed an animal model, primarily rabbits, for exploration of the impact of OMT on visceral function (15,16).

Still’s teaching that OMT had an impact on the whole body, visceral physiology as well as the musculoskeletal system, was the heart of this early translational research. Dr. Burns also described the impact of OMT on humans and its effect on heart rate and blood pressure (15). Dr. Burns’ work is still highly regarded for its contribution to the establishment of credibility for OMT and distinguished research awards bear her name. However, Wilbur V. Cole, D.O. (17), who worked with Louisa Burns in the 1940s, acknowledged the difficulty Dr. Burns had in describing the “boney lesion” in operationally defined terms that are now routine through the application of technology (18).

If the early work of Burns, Cole, and others initiated and maintained a research consciousness in the osteopathic medical profession, the work of John Stedman Denslow, DO, and Irvin M. Korr, Ph.D., marked the beginning of the modern renaissance of osteopathic research. In the 1940s, technology had advanced and after World War II was affordable so that the research laboratory at the Kirksville College of Osteopathic Medicine (KCOM) was able to produce significant research describing the concept of the “osteopathic lesion,” which we now know as “somatic dysfunction” (19–23). In their work, the Kirksville group forged an early pattern of research article submission to journals outside the osteopathic profession, which is a goal reiterated in the present day as a way to “spread the word and findings” of uniquely osteopathic research to the medical/scientific community as a whole.

The funding for the Kirksville group’s research was primarily from the AOA, the A.T. Still Osteopathic Foundation and the KCOM. However, as early as 1958, federal funding came from the Public Health Service and Office of Naval Research (23,24). Through the 1960s and 1970s, funding initially came from the National Institutes of Health (25,26). Then when formed, came from the National Institutes of Neurological Diseases and Stroke (27,28). Current research funding trends mirror the pattern started

in the late 1950s and early 1960s but with different proportions and significant support added from foundations supportive of osteopathic medicine.

From Korr to the Osteopathic Research Center

The work of William L. Johnston, D.O. and Myron C. Beal, D.O., at Michigan State University College of Osteopathic Medicine, and Albert F. Kelso, Ph.D., at the Chicago College of Osteopathic Medicine, together and individually, kept up the momentum of OMM-related research through the 1980s and 1990s. A review of the annual AOA Research Conferences proceedings in the *Journal of the American Osteopathic Association* during this period showed that these individuals provided the leadership for the conferences themselves as well as leadership to develop and define a number of the terms now at the center of osteopathic terminology such as TART (Tissue texture changes, Asymmetry, Restriction, Tenderness) and somatic dysfunction.

The importance of interrater and intrarater reliability of palpatory assessment was the hallmark work of these researchers (29–32). Review and development of the somato-visceral interactions was also a great contribution (33,34). They also lead in research on the impact of OMM on systemic disorders (35–38). Perusal of their published papers reveals that the funding for their research was primarily from the AOA along with some financial support from their respective institutions. Given the breadth of their work, it is hard to imagine what could have been done had foundation and government funding been available.

CONSOLIDATING RESOURCES: OSTEOPATHIC RESEARCH CENTER

Since the late 1990s, the osteopathic medical profession began to deal with the need for more and higher quality osteopathic research. The ORT was constituted and was composed of representatives from AOA, AAO, American Association of Colleges of Osteopathic Medicine (AACOM), the American College of Osteopathic Family Physicians (ACOF), and American Osteopathic Foundation (AOF). The ORT supported and convened a research conference titled Osteopathic Collaborative Clinical Trials Initiative Conference (OCCTIC). The first OCCTIC was in 1999, and through discussions carried on at subsequent OCCTIC meetings, the decision to establish a national ORC was made in 2001 (2). Through a competitive application process, the ORC was placed on the campus of the UNTHSC, Texas College of Osteopathic Medicine.

The mission of the ORC is “Fostering nationwide collaborative OMM research.” The ORC, in collaboration with key members of the ORT, has conducted a number of “Focused Research Forums.” Bringing together researchers and funders in “focused” discussions have resulted in specific research projects described below. In this way, the creation and existence of the ORC have significantly forwarded the research agenda of the osteopathic medical profession.

In addition to the ORC, the osteopathic medical profession is fortunate to have other research organizations that have received significant external funding. One of these, the A.T. Research Institute, is located on the campus of the A.T. Still University in Kirksville, MO. The A.T. Still Research Institute is actively involved in OMM-related research, especially in the area of interrater and intrarater reliability of palpatory assessment. It also served as the Clinical Trial Coordinating Center (CTCC) for the Multi-Center Osteopathic Pneumonia Study in the Elderly (MOPSE). The A.T. Still Research Institute has received external funding from the Osteopathic Heritage Foundation (OHF) and NIH National Center

for Complementary and Alternative Medicine (NIH-NCCAM) and internally from A.T. Still University.

Multi-Center Osteopathic Pneumonia Study in the Elderly

The MOPSE project is a prototype for what is hoped will be a number of multicenter clinical trials based on the application of OMM/OMT with a specific disorder or subject population. Through a process of several Focused Research Forum meetings, the consensus was developed that the osteopathic treatment of pneumonia in the elderly was the strongest area in which OMM/OMT could be expected to have impact when examined by a multicentered clinical trial.

The focused research forum reviewed the research literature and clinical experience with the treatment of pneumonia. There were the experiences of the 1918 to 1919 influenza pandemic (14) and two preliminary clinical trials that showed benefit of OMT as adjuvant treatment in cases of pneumonia in elderly hospitalized patients (39,40). Donald Noll, D.O., was selected by the CTCC to be the principle investigator and a grant proposal was assembled and submitted in September 2002. The MOPSE study was funded at \$1,504,871 for a 2-year study by the OHF and a number of other osteopathic-supportive foundations, with funding coordination by the Foundation for Osteopathic Health Services (FOHS). Five clinical sites were determined and included hospitals in Kirksville, MO; Stratford, NJ; Columbus, OH; Mount Clemens, MI; and Fort Worth, TX.

For MOPSE, the ORC provided oversight on behalf of the funders and the A.T. Still Research Institute served as the CTCC, selecting the principle investigator, providing direction for conduct of the study, and making multiple site visits to train the treatment providers and audit charts for the results. The MOPSE study is registered on ClinicalTrials.gov and had an active Data and Safety Monitoring Board (DSMB). One of the initial challenges was to obtain Institutional Review Board (IRB) approvals at each of the involved hospitals, and all approvals were acquired.

One other challenge encountered during MOPSE was the difficulty recruiting subjects at all the sites. This was indeed one of the “lessons learned” as far as estimating numbers of subjects and timetables for study completion. The nature of treatment for pneumonia changed from the time the initial OMM/pneumonia studies were conducted and in 2005 when MOPSE was in full progress, with fewer patients admitted to hospitals for pneumonia. Consequently, a 1-year extension to complete MOPSE was carried out by the investigators and their institutions to ensure that an acceptable number of patients were enrolled. The direct and indirect financial contributions by these institutions increased the total cost for MOPSE, and additional foundation funding was provided to engage a clinical trial organization to consult regarding data analysis and publication submission.

At the time of submission of this chapter, the MOPSE data had been locked, analyzed, and a primary paper and a protocol paper were developed by the MOPSE Publication Committee and primary investigators. Discussions pertaining to the osteopathic contribution to treatment of an avian flu possibility prompted development and submission of the MOPSE OMT treatment protocol for publication (41,42). Also at the time of completion of this chapter, the primary MOPSE study manuscript was under review by a high impact journal that the MOPSE Publication Committee determined would provide the greatest distribution for the findings. Discussions are underway for a larger clinical trial proposal to be submitted to NIH. Such a trial, if positive and with

a significantly larger number of subjects, would have the potential to impact the standard of practice for the treatment of pneumonia in the hospitalized elderly.

Research Projects Developed by the Focused Research Forum Process

Otitis Media

To date, the MOPSE study constitutes the largest multisite prospective clinical trial in the osteopathic medical profession. Previous studies with tens of thousands of subjects were retrospective observational studies (12,14). Once the MOPSE study was underway, another set of focused research forums were hosted by the ORC on the topic of OMT for the treatment of otitis media. It was felt by osteopathic research leaders to have high clinical research potential based on published literature and clinical practice (43–46).

A six-site multicenter clinical trial proposal was developed through the focused research forum process and submitted to osteopathic-supportive foundations as the Multi-Center Osteopathic Otitis Media Study (MOMS). However, MOMS was not funded by the osteopathic foundations due in part to considerations brought to light with lessons learned from the MOPSE study. However, a reduced scope, two-site clinical trial proposal titled Osteopathic Otitis Media Research Study (OOMRS) was submitted to the AAO's Louisa Burns Osteopathic Research Committee (LBORC) and was funded with \$100,000 for 2 years.

At the time of submission of this chapter, OOMRS was in its second year of recruitment of subjects. This trial is registered on ClinicalTrials.gov (48), has an active DSMB, and has oversight by AAO-LBORC. If results are positive, the data collected will constitute the basis for submission of a grant proposal at the R21 award level probably to the NIH-NCCAM.

Cervical Spine Manipulation: Safety and Efficacy

Utilizing the focused research forum process, the ORC responded to requests from the AOA Council on Scientific Affairs to examine the AOA Position Paper on Osteopathic Manipulative Treatment of the Cervical Spine, based on some reports of neurological damage and even death from cervical spine manipulation (49,50). The ORC convened a “blue ribbon” panel of researchers in 2006 and again in 2007. Reports of these focused research forums were made to the AOA Council of Scientific Affairs in 2006 and to the AOA Bureau of Scientific Affairs in 2007 (51). The AOA House of Delegates accepted the reports and recommended funding of a clinical trial on the efficacy of OMT for neck pain. At the time of this writing, there have been no grant applications submitted to the AOA Council of Research on this topic.

Concerns about cervical spine manipulation resulted in some professional liability insurance companies to temporarily curtail issuing policies to osteopathic physicians who did OMT on more than 25% of their patients. Negotiations with these insurance companies by the AOA were successful in resolving these concerns. The ORC reports (51) pointed out that the preponderance of reported and litigated instances of adverse events from cervical spine manipulation involved providers not trained in or licensed to practice osteopathic medicine.

Observational Studies on the Effects of Osteopathic Medicine

This initiative has grown out of interest by leaders of osteopathic-supportive foundations, primarily the OHF and FOHS. Using

the precedent of the cervical spine manipulation focused research forum process, there have been five meetings of a panel of OMM research and foundation leaders held during meetings of the AOA, AAO, and OCCTIC research conferences to discuss the best approach to this concept.

Identified as the “Practice Based Research Network (PBRN),” a plan is in development that includes the potential recruitment of several hundred physicians who will systematically record standardized data on a number of their patients over a multiple-year period. A professional clinical trials consulting company has provided a proposal to the panel of osteopathic researchers. In the author's opinion, this would be the most appropriate direction to take in osteopathic research. This direction toward an observational study reflects a maturing process in the sophistication and focusing of research resources within the osteopathic medical profession and is a logical continuation of the ORT consultations begun in the late 1990s.

Status of OMM Research

The foregoing discussion of specific OMM-related research projects, planned and partially completed, represents application of many of the research development procedures discussed subsequently. Also, while not exhaustive, the studies cited are good examples of the progress of OMM research from professional beginnings to the present. The *Synergy* (10) document and ORT-guided collaborative efforts have produced results as discussed in the foregoing sections. Further progress is dependent to some degree on the actualization of the potential of the ORC and other research centers as well as support of OMM-related research in COMs and postdoctoral training. Some of the channels by which research has been developed are discussed next and may provide some insight to the reader as to ways to accomplish uniquely osteopathic research.

DEVELOPMENT OF OSTEOPATHIC RESEARCH “FROM THE GROUND UP”

As reviewed above, the osteopathic medical profession has embraced research from its beginning and has produced a relatively large body of research, given the size and resources available within the profession. The research history recounted above often reflected the interests of the researcher as well as the resources available to support a given research idea.

By the time of the work of Denslow and Korr, there were certain topics that were deemed priorities for research, such as the experimental delineation of the “osteopathic lesion” now termed somatic dysfunction. Gradually, OMM-related research priorities have been developed and appear to have been influenced by perceived needs such as delineated above (9,10). Chapter 71 gives a fuller discussion.

It is hoped that the series of discussions in this “Research” section of the *Foundations for Osteopathic Research, 3e*, will constitute a solid basis for understanding that will enable the reader to appreciate from where the osteopathic profession has come and where it needs to go with regard to OMM research. One of the oft-elucidated clinical dictums given to OMSs is to “think osteopathically.” This phrase is well understood to mean that considerations of a holistic body-mind-spirit, as well as structure-function relationships, are integrated into the thought process of an osteopathic medical clinician/practitioner. In an effort to apply similar logic to the research endeavor, basic clinical research principles are presented next.

Principles of Research—An Osteopathic Adaptation

The realization by the ORT and other key researchers and research funders that a research consciousness needed to be developed within the osteopathic profession was the motivation behind the mission statement adopted by the ORC, “Fostering nationwide collaborative OMM research.” There have been a number of efforts to present research skills training opportunities to OMM faculties and particularly to students and residents.

Comprehensive programs have been provided at the AOA Research Conference at the 2005 AOA Convention, featuring a half day devoted to “Clinical Research Training Program: Designing Residency Research.” Again at the Research Conference at the 2006 AOA Convention, there were featured presentations on “Osteopathic Research—Training at our Colleges,” and “Getting Published: What You Need to Know about Reporting Research in Biomedical Journals.” In 2006, at the OCCTIC-VII program, “Developing Excellence in Osteopathic Research” held in Birmingham, AL, there were panels and presentations on the development of research ideas into viable research projects. The program for OCCTIC-VIII in Colorado Springs was completely devoted to the development of research and was titled “Research Opportunities in Osteopathic Manipulation: Training Our Residents and Undergraduates Now! (ROOM TO RUN).” There have been other similar programs offered at state and society meetings and more are planned as the numbers of osteopathic clinical researchers who can provide training grow and the quality of OMM research attracts more students and residents to consider a research career or becoming involved in active OMM clinical research.

The essence of these research skills training programs centers on several main issues:

- Types of research
- Defining a research question
- Assessing resources for a project
- Biostatistical and design issues
- Mentors and collaborators
- Grant writing and “grantsmanship”
- Pilot studies
- Leveraging pilot studies into larger projects and grants
- Conducting a clinical trial—IRB and research coordinators

Types of Research

From the perspective of evidenced-based medicine, there is a hierarchy of the types of research in an ascending order as to the strength of the evidence for a particular subject. The generally accepted order is (52) (a) expert opinion, (b) case reports or series, (c) case-control studies, (d) cohort studies, (e) randomized controlled trial, and (f) systematic review, with systematic review being the strongest form of evidence.

While there have been many systematic reviews of various forms of treatment of musculoskeletal disorders, there has been only one done on OMT (53). This systematic review was supportive of the benefit of OMT for low back pain.

Defining a Research Question

Essential to defining a research question is knowledge of the area under consideration. Skill at doing a literature search is essential. Databases related to OMM are described in some detail in Chapter 74. Researchers who have published in a particular area are also valuable resources for the novice researcher as well for some-

one who may not be very familiar with a particular topic but is interested in exploring research possibilities.

Assessing Resources for a Project

In all the OMM research training workshops mentioned above, the point has been made that the project must be conceived and carried out within the limits of available resources. This includes funding for subject compensation, treatment providers, research coordinators, and technical assistance. Also included in the resource availability considerations are the clinics from which subjects would be recruited, to determine whether or not there will be an appropriate number of subjects, and if the investigators have the time and assistance to recruit and consent the subjects. These considerations are essential for planning successful research and are based on recent experience at the ORC, as each item has been a source of challenge in one or more of the OMM research projects completed or currently under way.

Biostatistical and Design Issues

No matter the design of the project, training in and the availability of experienced biostatistical consultation are crucial to address the myriad of questions regarding outcome measures. For example, questions regarding “before and after” or “serial measures,” whether or not you are doing a “prospective” or “retrospective” study, are issues that impact the kind of statistical analysis that can be used. Since some statistical tests are “stronger” than others, this becomes a critical matter for which expert guidance is needed.

Mentors and Collaborators

One element of the ROOM TO RUN conference of OCCTIC was the opportunity to make contact with mentors and collaborators. For the young investigators, students, and residents, the contact with a mentor or senior collaborator is most helpful, if not necessary to begin the process of OMM-related research. Most COMs have basic scientists on faculty who are willing to mentor, but OMM mentorship from a clinician may be harder to find. The ORC has limited time resources to provide mentorship but has consulted on many questions of research design and networked to build research collaborations, the essence of its mission statement. This topic of mentorship is of nearly universal interest in the world of biomedical research and has received much consideration (54).

One means of locating a collaborator, especially if you have an idea about a biomarker or outcome measure for the effects of OMM/OMT, is the Computer Retrieval of Information on Scientific Projects database (55). Another resource is the National Science Foundation Web site (56). At the 2007 AACOM Annual Meeting, an excellent panel titled “Collaboration on a Shoestring Budget or None at All” dealt with the collaboration issue in several presentations and is another fine resource to access (57).

Grant Writing and “Grantsmanship”

The NIH form SF424 (R&R) is necessary for electronic submissions to most NIH award programs (58). This electronic format is based on form PHS 398, which is the basic format for most external research grant applications to foundations and state and federal agencies that do not require electronic grant submissions (59). Familiarity with these forms helps to focus the writing process, as a research proposal is formulated. Some COMs have a grants management office that can assist in the writing process,

but the purpose of the present discussion is to encourage the reader to integrate this aspect of “research work” into their awareness and training.

The process of “grantsmanship” includes getting to know the agency, institute, or foundation to which you would likely submit a grant proposal. What have they funded? What are the submission guidelines? Who do you know that was successful in a grant submission to the entity you are considering and can tell you the types of issues to be covered? In most grant submission processes, the investigator will receive feedback from reviewers on their particular submission, and this feedback should help guide future submissions.

With regard to grant writing, NIH-NCCAM has provided a grant writing workshop that dealt with all these issues and will remain posted substantially beyond publication of this book (60). An agenda, outline, and some content of this grant writing workshop are also available online (61).

Two other valuable resources for research with an OMM perspective are the *Manual of Basic Tools for Research in Osteopathic Manipulative Medicine* (62) published by the ORC and the *AOA Research Handbook* published by the AOA (63). These two publications provide detailed guidance on research conduct and grant development.

In a broader context, but with application for OMM researchers contemplating submission to NIH, there have been several articles and reviews that give further insight, based on experience, about the grant application process (64–66). As more and more foundations and agencies pattern their grant application process after NIH’s, these articles may be very helpful in any context.

Pilot Studies

Prototypical of government and foundation funded pilot projects is the NIH R21 “Exploratory” grant mechanism. The R21 mechanism for a clinical trial typically allows for 2 years of support and requires a proposal with a number of subjects at 60 or more, with active intervention, sham intervention, and no-treat control group. What researchers have found is that to be competitive for an R21, there must be considerable “preliminary data” to suggest that there is efficacy to the intervention to be studied. This requirement is usually met by intramural seed grants funded by a researcher’s institution or sometimes by the AOA, AAO or, in some cases, by an osteopathic-supportive foundation. Only a few COMs have allocated the resources for pilot studies, but when they have, as described below, there is often reward in funding at the higher levels afforded by foundations and governmental agencies.

Leveraging Pilot Studies into Larger Projects and Grants

This consideration is an amplification of the pilot study discussion, but mention of this concept is placed here to emphasize its importance in the research planning process. Specifics are discussed subsequently and illustrated in citations of student and resident research projects that have been published in peer-reviewed journals and, in some cases, leveraged into larger research projects.

Conducting a Clinical Trial—IRB and Research Coordinators

As the osteopathic medical profession progresses in its OMM-related research endeavors, appreciation of the complexity and infrastructure needed for the completion of successful studies has

revealed what has been a part of every clinical trial done in the last 20 or more years. IRB requirements for the protection of the public have become a major consideration and require considerable preparation and often a back-and-forth process between research team and IRB to obtain final approval for a project.

Research coordinators often are skilled at the IRB review process and are of invaluable assistance as a part of the research team in this respect. The recruitment and consent of subjects are an increasingly complex process as the consent form approved by the IRB can be lengthy and requires careful presentation to a prospective subject.

Even to experienced researchers, the IRB approval and subject recruitment issues can be challenging. For newer researchers, it will be helpful to become as familiar as possible with these aspects of the research process.

In depth consideration of several of these research issues is made in Chapter 74. Some overlap in content may be fruitful in stressing crucial themes and skills necessary to carry out successful OMM-related research

Osteopathic Applications of Research Development Principles

Research Done During Residency Training

Virtually every medical resident trained in the United States has had to fulfill a requirement to do a research or scholarly activity project. It is difficult to do a full-fledged clinical trial while completing residency requirements, but certain fruitful lines of research pertaining to OMM/OMT have begun during residency training.

In the last 10 years, several clinical studies completed during residency have reached publication. Three noteworthy studies were carried through to publication by the resident. An emergency medicine resident at St. Barnabus Hospital in Bronx, NY, published findings that OMT in the emergency department benefited acute ankle injuries (67). At the Michigan Hospital and Medical Center, Detroit, MI, a family practice resident published findings suggestive of benefit of OMT in reducing length of hospitalization for patients with pancreatitis (68). At the Kirksville College of Osteopathic Medicine (KCOM, now the A.T. Still University), an OMM resident published findings on the nature of the musculoskeletal system of a newborn from the cranial manipulation perspective (69). At the Osteopathic Medical Center of Texas in Fort Worth, an OMM resident joined with a mentor to publish an elucidation of the impact of OMT as a credible intervention. Active OMT intervention is perceived as more credible than sham OMT (70).

All of these published studies have been cited in subsequent studies and have provided the basis for trials of related disorders using OMT. All of these publications were preceded by poster or abstract presentations and received some financial support from the institutions in which the residency program operated.

Research Done During Medical Student Training

There is a wide variety of research backgrounds found in each year’s new group of OMSs. Some matriculate with extensive research backgrounds including having multiple publications. A number of student research projects develop from ideas of mentors who have already published in a certain area and are initially presented as abstracts at research conferences. An example is the study on the impact of the CV4 maneuver on autonomic nervous system balance during paced breathing done by students and their mentors at the Western University of Health Sciences (71). Another example of student-involved research initially presented as a poster/abstract

is a study carried out at the University of Medicine and Dentistry New Jersey School of Osteopathic Medicine, which found that the use of certain OMT technique may have benefit in the treatment of acute otitis media (72).

Student-involved studies can be of sufficient merit to be published in a peer-reviewed journal. A student at the New York College of Osteopathic Medicine worked with a mentor on a research project that demonstrated the patency of certain cranial sutures well into advanced age and offered an explanation based on the activity of neck muscles and the masticatory process (73). This was an exceptional study involving a student. Most student-involved research of this caliber has been done in dual-degree programs.

Research Done in Dual-Degree Programs

Several COMs have dual DO/PhD programs. The typical process is for the student to take the first 2 years of medical curriculum and then the next 2 years are devoted to the PhD work, usually in one of the basic sciences. Upon completion of the PhD, the student then completes the last 2 years of medical training and proceeds to residency training.

Two outstanding publications involving OMM were done by students in the dual DO/PhD program at the UNTHSC, Texas College of Osteopathic Medicine and in the Integrative Physiology Department of the Graduate School of Biomedical Science. Empirical demonstration that the lymphatic pump technique actually does increase lymphatic flow was done on instrumented conscious dogs (74). The second significant study documented the autonomic nervous system impact of the cranial manipulation maneuver known as the CV4 (75). Both of these studies have spawned a number of related research projects, some of which are noted below.

Most DO/PhD dissertation projects are in some area of basic science not directly related to OMM, but it is hoped that as the benefits of OMM/OMT are further documented, there will be an expansion in many basic science labs to include OMM related projects. At the UNTHSC, there is a dual-degree program in the OMM Department where the PhD is in "Osteopathic Manipulative Medicine Research and Education." Currently, there are two students in this program. One student, already an osteopathic physician in the OMM Department and staff of the ORC, received a K23 grant award from the NCCAM to study "Osteopathic Manipulative Medicine in Pregnancy: Physiological and Clinical Effects." This study is an example of leveraging of previous pilot work into an NIH-NCCAM grant award. Preliminary data for this K23 included research had been published (76,77) and had been presented at a research conference (78).

Based in part on the Knott et al. (74) work, another DO/PhD student became involved with research on the impact of OMT on the immune system. These studies are being carried out in the laboratory of the OHF Basic Science Chair holder of the ORC who is one of the faculty in the Molecular Biology and Immunology Department at UNTHSC (75). This exciting work has been funded in part by a U19 Developmental Center grant awarded to the ORC and in part by a grant awarded by the AOA. An initial publication demonstrated that the lymphatic pump treatment increased the leukocyte count and flux in the thoracic duct lymph in dogs (80). Further research by this DO/PhD student using a rat model showed that lymphatic pump treatment enhanced immunity and reduced pulmonary disease during experimental pneumonia infection (81). More recent work from this lab showed that the leukocytes came from gut-associated lymphoid tissue as they travel to the thoracic duct upon application of the lymphatic pump treatment (82).

A number of DO/MS students, primarily in the Pre-Doctoral Fellowship program in the OMM Department at UNTHSC-TCOM, have produced Master's degree theses and abstracts that have provided pilot data for research grants and explored research topics that otherwise might never be considered. Central to an NCCAM R21 grant submission that was awarded to an investigator at the ORC on "Treatment Efficacy of OMT for Carpal Tunnel Syndrome," were two master's theses that generated the preliminary data showing the OMT benefits for reducing pain and improving nerve conduction. These two Master's degree theses results were best accessed by the citations to research conference abstracts (83,84).

One topic that started with student and master's thesis research is showing the effects of OMM on physiologic functions such as heart rate variability (HRV). A student project (85) was completed almost simultaneously with a master's thesis (86), both showing improvement in HRV after OMT. Interest in this topic has been high, as a research project related to OMT and HRV did not show any differences between OMT and Sham OMT (87) but suggested that the trend may produce significance, had the sample size been larger.

Other ideas that were explored at the student and master's thesis level of research were the impact of OMT on postoperative nausea and vomiting (88), the immediate effects of splenic pump on blood cell counts (89), and the role of OMT in the treatment of fibromyalgia syndrome (90). All of these studies reported insignificant results, but that is beside the point. What is significant is that these studies were carried out in the first place. It is at this very preliminary phase of research that ideas are explored, and the published report, abstract, or poster may point the way to a better design or deter further study as likely unfruitful.

The fact is that a number of studies do not produce significant results and that these results are published is a healthy sign. Not only does this speak to the integrity of the research effort but it also shows the research energy and high quality of effort put forth by osteopathic students, residents, and physicians who are involved in OMM research. Some level of preliminary data are always required for NIH, federal government funding agency, or foundation research grant submission. Research "from the ground up" is the status for a profession that has received relatively little external funding compared to allopathic institutions. This discussion is intended to give the reader at every level of research background, medical student through experienced researcher, a fuller idea of how OMM research has been synergistic and often interactive.

Model for Support of Student and Resident Research Projects

These studies are cited as representative of efforts made through the osteopathic profession to promote research by undergraduate OMSs, residents, and dual-degree students. Perhaps the largest program for support of such research is that of the Center for Osteopathic Research and Education (CORE) located in the state of Ohio, with administrative offices at the Ohio University College of Osteopathic Medicine (91). The research support to students and residents located in Ohio is very strong and well staffed and serves as a model to be emulated. The CORE program is funded by Ohio University, the participating training hospitals, and the Osteopathic Heritage Foundation.

While not all states have enough osteopathic physicians and institutions to replicate the Ohio CORE program, it is a fine model to replicate if only in certain pieces by another state or consortium of states through the respective Osteopathic Post-Graduate Training Institutes.

Clinician and Basic Science Collaboration

The model set by Denslow and Korr, Johnston and Kelso, and others is still a benchmark to be emulated by researchers in the present time. It has not been easy to garner collaboration between OMM clinical researchers and basic scientists who come out of traditional academic settings and whose interests and dissertation work may not relate directly to OMM or any other aspect of musculoskeletal disease. However, this goal is a high priority for OMM research, especially in the mechanisms of actions for OMM and impact of OMM on systemic disorders.

When such collaborations are forged, good results come about. Certain examples already cited are the mechanism of action research on lymphatic flow (74) and impact of OMM on immune system processes (80–82). Concurrent with other collaborations going on at Michigan State University College of Osteopathic Medicine at the time, two neuroscientists collaborated with an OMM clinician to demonstrate experimentally induced cranial bone motion in cats (92).

More recent basic scientist-clinician collaborations have been forged at the New York College of Osteopathic Medicine with work on the impact of OMT on Parkinson disease (93) and the effect of muscle energy technique on cervical spine range of motion (94). At Midwestern University Chicago College of Osteopathic Medicine, a series of studies were carried out by a basic scientist-clinician team, which established a possible means by which cranial bone motion could be measured (95,96) and then related such motion to the physiologic process known as the Traube-Hering-Mayer phenomenon (97).

Funded by the Osteopathic Heritage Foundation, a team of basic scientist-clinician researchers at the Ohio University College of Osteopathic Medicine have measured the beneficial effects of OMT on Achilles tendinitis (98) and plantar fasciitis (99) and developed a virtual reality program, which has been added to the medical student curriculum to train medical students in osteopathic palpatory diagnosis (100). At the A.T. Still Research Institute in Kirksville, MO, a basic scientist-clinician team showed the effect of OMT on altering pain biomarkers (101). As part of a Developmental Center Grant (U19 Award) from NCCAM, work was carried out, first at the Midwestern University Arizona College of Osteopathic Medicine and then at the University of Arizona Medical School in Phoenix, showing the impact of simulated OMT on tissue fibroblasts in vitro. This exciting work on human fibroblast showed significant changes in cytokine production (102).

Some of these promising basic scientist-clinician collaborations continue, but it is hoped that more will be developed. This will be made more likely as more OMM-related research is generated at all levels.

FINANCIAL SUPPORT FOR OSTEOPATHIC RESEARCH

U.S. funding of biomedical research in 2003 was 94.3 billion USD (103), and in 2008 alone, the research departments at allopathic academic medical centers averaged 85 million USD (104). The total research for all the COMs in 2004 was 101.3 million USD (105). These figures are for all research funding and suggest that there is much more research taking place at COMs than might have been imagined; however, it was necessary to lump all the COMs together to achieve a figure that could rival just one allopathic academic medical center.

With regard to NIH funding alone, the *JAOA* reported that combined NIH funding to all COMs in 2004 ranked 163rd

among funding totals provided by the NIH to the top 500 research institutions (106). The *JAOA* article (105) went on to report that the largest COM research funding in 2004 was almost 32 million USD at the UNTHSC/Texas College of Osteopathic Medicine.

In the context of these figures for all biomedical research, even in osteopathic institutions, the funding amounts for OMM-related research are very small by comparison. There is no one source that keeps records of OMM-related research funding, and indeed from review of lists of funding, it is not always possible to tell from a project title whether or not the research pertained to OMM in any way.

In preparation for this chapter, contact was made with the AOA Department of Quality and Research and a list of all research projects funded by the AOA was requested. AOA staff was very cooperative, and a list of all research funding from 1989 to 2007 was provided. These were projects reviewed by the AOA Council on Research and recommended for funding and approved by the AOA Board of Trustees. The funding amounts reported varied from year to year and came primarily from the Osteopathic Research Development Fund (ORDF), which was originally accumulated from contributions from osteopathic physicians. The corpus of the ORDF is approximately 7 million USD and annual funding depends on the performance of investments in this fund. The total research funding from 1989 to 2007 was \$3,276,363, with no funding provided from 2002 to 2006 because of investment portfolio decreases.

From a close review of the titles of the projects funded by the AOA, the amount awarded to OMM-related topics was \$2,667,062. This amount was 81.4% of all the funds awarded to research by the AOA. It is worthy to note that the membership organization of the osteopathic medical profession does indeed invest the majority of its research funding into OMM-related projects. Most of the research funds since the beginning of OMM-related research have come from sources internal to the osteopathic profession, that is, the AOA, AAO/LBORC, COMs, and osteopathic-supportive foundations.

The current major funding provider for projects and programs supporting osteopathic medical research is the Columbus, Ohio-based Osteopathic Heritage Foundation, oft mentioned in the foregoing discussions. Data published on the OHF Web site document a number of the awards provided since 2000 (107). The total amount awarded during this period to support osteopathic research such as the Ohio CORE program, specific OMM-related research projects, capital research investments, endowed research chairs, and programs such as the ORC was nearly \$30 million. To those involved in the development of quality research that provides the evidence base for OMM, the contribution of the OHF has been the capstone and central to the recent progress reported above (105,108). One objective of this Foundation, in accord with the ORT strategic plan (105,108), is to provide the necessary support to enable the ORC and future possible regional ORCs to become self-sustaining with external funding. In light of the leveling off of NIH research funding and reductions in certain areas, it has become an even more difficult task to obtain external funding, which makes the contributions of this Foundation much more significant.

The FOHS and a consortium of osteopathic-supportive foundations have contributed significantly to the MOPSE study and other projects. FOHS leadership is involved in support of OCCTIC and in projects such as the osteopathic observational research project.

By the time of the publication of this edition of the *Foundations for Osteopathic Medicine* book, there may be additional data on OMM-related research funding. There are other entities that

need to be cited for their significant contributions to OMM research funding. AACOM and AOF as well as the AOA continue to provide infrastructure funding to the ORC. Securing the funds to support OMM-related research is an ongoing process. The comments in this section are an attempt to describe the history and current status of funding support for OMM research, which is in part an outgrowth of the realization by the osteopathic profession of the need to establish the evidence base for OMM (10,105,108).

ACKNOWLEDGEMENTS

In preparation of this chapter, extensive review and confirmation of accuracy of financial data were made by Richard A. Vincent, President, Osteopathic Heritage Foundation, and Sharon McGill, Director of American Osteopathic Association Department of Quality and Research.

KEY CONCEPTS

- Biobehavioral mechanisms alter health and disease through three basic pathways: physiologic responses to stress that lead to disease, behavioral choices that increase or decrease health risk, and behavioral reactions to disease that alter surveillance activities or adherence with medical interventions.
- The major behavioral factors that have been studied and shown to have clear associations with health and disease include diet, exercise, sleep, cigarette smoking, tobacco use, alcohol use, and prevention of excessive sun exposure.
- Placebos are also a biobehavioral mechanism that must be addressed in most forms of research. Behavioral research strategies must consider the effects of race, direct suggestion, patient belief in the treatment, trust in the physician, genetic variation, environmental effects, and nonspecific cause–effect relationships with placebos.
- As with other types of research, the biobehavioral research process begins with the acquisition of measurement data and the development of a hypothesis about the mechanisms involved with the processes under consideration. Selection of the study design, subjects, and analysis methods to be used constitute the major components of the process and lead to a systematic analysis of the data.
- Biobehavioral research and evidence-based knowledge will provide effective and proven treatment strategies and render valuable insight into the impact of osteopathic principles and practice. Major topics in biobehavioral measurement and research will likely focus on behaviors leading to the development of somatic dysfunction, behaviors resulting from somatic dysfunction, quality-of-life (QOL) issues, the effects of pain on function, and relationships between somatic dysfunction, and patient self-managing of self-defeating behaviors.

INTRODUCTION

Biobehavioral research involves the investigation of behaviors on the maintenance of health and the development of disease. The onset of disease is a complex phenomenon that incorporates the tissue pathology (musculoskeletal abnormalities), psychosocial and behavioral response to that physical insult, and the environmental factors that maintain or reinforce that disability (even after the initial cause has been resolved). A large portion of the measurable variance in an individual response to any disease outcome is accounted for by the individual's unique behavior and emotional response to the stress of the illness (1). In fact, the majority of today's health woes—obesity, cancer, and anxiety disorders to heart disease, hypertension, and adult-onset diabetes—are actually relatively new “diseases of civilization” brought on by our behavioral choices and mind-body interactions. Although the concepts that the mind influences disease processes have long been a part of osteopathic medicine, research strategies to describe the mechanisms of disease modification through biobehavioral interactions have only recently become a part of evidence-based medicine.

Our current understanding of biobehavioral interactions suggests that these processes are a complex interplay between psychologic, physiologic, environmental, and behavioral factors that influence health and disease (2). Behavioral mechanisms can alter the musculoskeletal, immune, neurologic, and endocrine systems, directly and indirectly, thereby influencing such medical illnesses as cancer and cardiovascular disease. Diet, exercise, drugs, alcohol, and tobacco use, along with a variety of other behaviors, modify disease progression and/or disease risk. Finally, behaviors directly related to seeking or avoiding medical care can have important consequences on prevention, early detection, and adherence with medical regimens. Thus, the implication is that biobehavioral

factors may significantly affect health care and health maintenance through a variety of direct and indirect mechanisms (2), and these effects should be addressed in osteopathic research and clinical practice (3–5).

BIOBEHAVIORAL MECHANISMS IN HEALTH

Behavioral components of the mind-body interaction manifest in cognitive processes, emotions, and/or physical behaviors. The study of cognitive processes (e.g., language acquisition, reading, emotional appraisal, memory, attention, mental models or representations, learning and cognition, problem solving, ascribing meaning, abstraction, and action) primarily focuses on acquisition, understanding, retention, and processing of information. However, under most circumstances, thoughts, emotions, and cognitive processes must transmit information, be translated into motor actions, or have identifiable physiologic responses before a behavior can be identified. It is for these reasons that many consider mental phenomena to be a special form of physical phenomena (i.e., biobehavioral) and therefore inseparable from physiologic processes.

Biobehavioral factors exert their influence through three defined pathways, which are illustrated in Figure 73.1 (2,6). In the first of these pathways, *cognition and emotional reactions* are creating physiologic alterations that contribute to the pathophysiology of the disease. An example is the classical stress response (described in Chapters 17 and 18) that is associated with increases in blood pressure and heart rate displayed as part of global sympathetic arousal. Chronic arousal creates dysregulation. These sympathetic alterations can, in turn, contribute directly to the development of cardiac disease and sudden death. Excessive or unwanted stress that creates inescapable demands, whether induced by external events or internal mental processes, can create a sense of powerlessness and alter

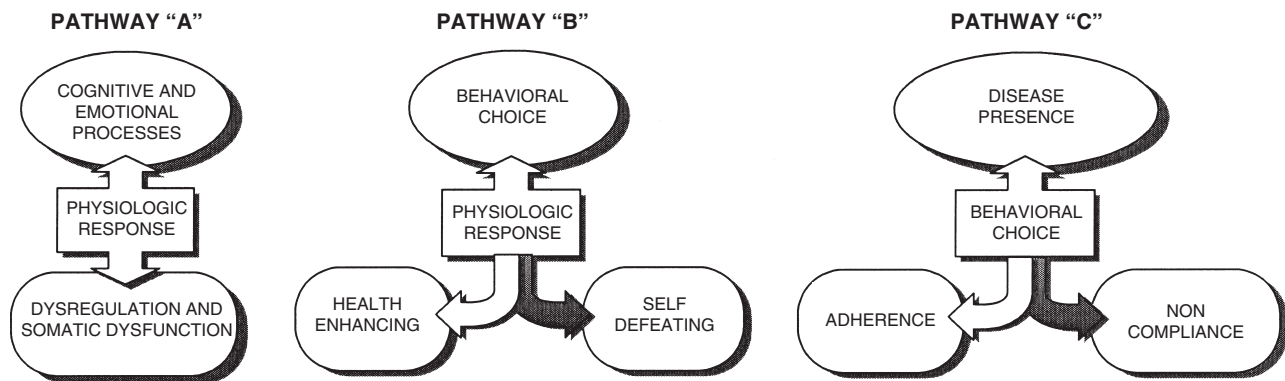

Figure 73-1 Common biobehavioral pathways in health and disease.

neural and hormonal responses, leading to enhanced vulnerability to infection and inappropriate response to disease (i.e., viral infections, wound healing, and cancer).

The second pathway for biobehavioral interactions involves behaviors in response to illnesses that are associated with increasing or minimizing health risk. These particular behaviors are referred to as “high-risk” or “health-enhancing” behaviors. Examples of health-enhancing behaviors include diet and exercise (due to their ability to minimize the development cardiovascular disease and cancer). Tobacco use and alcohol abuse are examples of high-risk behaviors typically associated with adverse effects that frequently lead to emphysema, lung cancer, and cardiovascular disease. Other examples include drug use and high-risk sexual activity. Each of these activities conveys a risk or benefit to an alteration of the underlying physiology and/or exposure.

The third and final pathway involves behaviors that occur in response to the *possibility* that a disease is present. For self-managing individuals, these behaviors lead to early detection include ongoing surveillance (i.e., retained breast examinations, sigmoidoscopy, etc.), recognition of symptoms, and the decision to actively participate in medical care or follow-up care. If a disease or a symptom is identified and a medical regimen is prescribed, adherence with the medical regimen (or lack thereof) is a behavior that can affect the outcome of the disease process. On the other hand, high-risk behaviors can lead to the sudden discontinuation of medications or their erratic administration that can only hinder the effectiveness of standard evidence-based medical regimens; such behaviors may also create secondary adverse consequences.

There are many situations under which this theoretic disease development pathway would be applicable to biobehavioral research and might offer distinct advantages in understanding the relevant pathophysiologic relationships. The consideration of such pathways is in keeping with known stress responses of the somatic musculature. This theoretic framework is also consistent with the biologic and behavioral responses of individuals with acute and chronic pain.

Disease Development (Pathway “A”)

The major biobehavioral interactions on disease development that have been studied involve the effects of stress on health or illness. Because of the vast scope of data involving stress, physiologic response, and behavioral issues, our intent is to discuss the learned mechanisms wherein stress responses affect selected diseases and how these variables can be measured and researched.

From an evolutionary standpoint, most neural events can be considered to develop and have been selected by evolutionary process associated with species survival (2). In this viewpoint, stress responses and other emotional patterns are hardwired into the central nervous system (CNS) and modified by learning and experience. Thus, content and environmental conditions give rise to particular responses that can modify the emotional or cognitive response. Essentially, our bodies “learn” about the external correlates of internal responses much like a baby learns that food and eating extinguish the uncomfortable response later labeled as hunger. This process of “learning” can be significantly affected by the intensity and chronicity of the stress response under which the learning occurred. Less intense and intermittent stressors allow more complex and appropriate coping strategies to be learned; whereas more severe and prolonged stressors may cause a conditioned biobehavioral response that is less adaptable. In this sense, learning may be either adaptive or maladaptive and may affect predisposition to disease.

CARDIOVASCULAR DISEASE

Previous research has shown that stress, whether physical or emotional, perceived or real, often results in characteristic physiologic and behavior responses (Table 73.1). The physiologic and behavioral correlates may trigger acute, disease-related events and alter the pathophysiology of the disorders (7). Acute cardiovascular events, such as ischemic episodes, heart attacks, arterial occlusion, and arrhythmias, have been shown to occur with anxiety, bereavement, and anger (3,8,9). Similar effects are also seen with strong positive emotions associated with desirable events (e.g., weddings). Several mechanisms have been proposed to account for these responses, including alteration of sympathetic-parasympathetic balance, activation of platelets, alterations of intravascular flow dynamics, and changes of endothelial function (10,11).

Within these hardwired responses, maladaptive behaviors may lead to secondary physiologic responses that may have additional adverse consequences. For example, when assessing cardiovascular responses, physiologic reactivity is measured by the magnitude and the duration of the particular response. Studies have shown that increased cardiac reactivity may be a direct index of the underlying predisposition toward developing cardiovascular disorders or may reflect the activity of mediators of cardiovascular risk (12). In several studies, exaggerated blood pressure responses identified individuals at risk for developing hypertension and atherosclerosis

TABLE 73.1

Summary of Major Responses to Stress

Behavioral Responses

Moderate/Short Duration	Severe/Long Duration	Physiologic Response
Increased attention	Diminished attention	Increased heart rate
Increased alertness	Anxiety	Increased sympathetic activity (both neural and humoral)
Enhanced memory and problem-solving skills	Irritability	
	Reduced retention and recall	Increased blood pressure
	Diminished problem solving	Increased catabolism
	Insomnia	Altered immune function (dependent on the duration and intensity of the stressor)

(13–15). Similarly, other behaviors may have adverse effects on serum lipid composition, silent ischemia oxidative damage (9,16) (such as that seen with smoking), personality styles (e.g., type A), and altered coping mechanisms (17). Through the use of biobehavioral research approaches, cardiovascular researchers are now beginning to enhance our understanding of the statistical relationships between the cognitions, emotions, and behaviors in the development and progression of cardiovascular disease (6,9).

IMMUNE FUNCTION AND INFECTIOUS DISORDERS

Immunologic activity has also been shown to be altered by behavioral responses; the impact on disease development is described in the Basic Sciences Section of this book. Some of the difficulty in making assessments regarding immune function involves the variability of the stressors and the dynamic nature of the immune system. For instance, natural killer cells have a different response to acute and chronic stress exposures (18), and these responses are also subject to circadian variations. Changes in latent viral activity, lymphocyte proliferation, and natural killer cell activity have all been demonstrated in response to stress (19–21). These changes in immune function and cell numbers may also occur with physical stress, such as severe exercise (22). Several immunologic responses may also promote facilitating responses. The activation of inflammatory mediators, such as interleukin-6 and proinflammatory cytokines, may alter neural processes to enhance aspects of the CNS stress response (23).

Behaviors can have a more direct effect on the development of disease by altering bodily functions associated with disease risk (24). Perhaps the most classic example involves human immunodeficiency virus (HIV) disease. The transmission of HIV typically occurs during sexual activity, intravenous drug use, or through other forms of direct contact with bodily fluids. An attenuation of these behaviors or the addition of protective measures can result in substantial decreases in the risk of acquiring HIV. Conversely, increases in risky behaviors or the occurrence of impulse behaviors, as can occur with individuals with certain types of mental health problems (25) or during drug and alcohol use (26,27), can change routine behaviors of the individual and increase the risk of acquiring

HIV. In this setting, stress or drug use may initiate impulsive behaviors or may inhibit intentions to avoid the risky behaviors (28) leading to impaired judgment, a lack of attention to details, or in some instances, disregarding the potential consequences of their actions (29).

SLEEP AND CIRCADIAN BIOLOGY

Sleep and sleep wake activities also constitute a major biobehavioral mechanism that may lend themselves to biobehavioral research. Sleep deprivation and sleep fragmentation result in excessive daytime sleepiness, chronic fatigue, and other symptoms. Many of the symptoms are measurable and distinguishable from depression, and they may have some of the same adverse consequences on medical adherence as depression does (30). More recently, studies have suggested that alterations of sleep wake schedule may contribute to the development of disease. In one recent study, Bursztyn et al. (31) assessed daytime napping in an older patient cohort ($n = 455$). The findings suggested that an afternoon nap appeared to be an independent predictor of mortality with a risk odds ratio of 2.1. In a separate study using self-administered questionnaires on health status and lifestyle (32), the investigators identified that significantly longer and shorter sleep times, compared with 7 to 8 hours, were associated with increases in total mortality in men. In addition, female users of sleeping pills and those with self-reported poor sleep quality also shared an increased risk of mortality independent of sleep duration. Similar findings have been noted by others (33) and were noted to be unaffected by later arousal times. However, a recent review of the literature on shift work, an extreme form of late risers, suggested there is an overall increase in cardiovascular risk of 40%. These data suggest that disrupted sleep or significantly altered sleep schedules may have adverse effects on medical outcomes through measurable biobehavioral interactions.

PAIN SYNDROMES

Specific diseases need not be the only focus of biobehavioral investigations. Major symptoms, and specifically chronic pain, may benefit from a biobehavioral approach to investigations (34–36). In a review from an NIH-sponsored workshop, the current status

and major directions for biobehavioral pain research were outlined. Pain was identified as a subjective experience that could only be quantified through behavior (37), and there are many measurable behavioral responses to chronic pain that impacted treatment and recovery. Consistent with the NIH initiative, investigators demonstrated that biobehavioral models offer significant insight into the mechanisms active in chronic pain (38,39). Several studies suggest that dysfunctional information processing occurs, accentuating the perception of pain, and reinforcing the concept that learning plays a significant role in pain syndromes (38,40). Such mechanisms may also be actively involved in the disability associated with several disorders (e.g., osteoarthritis and cardiac pain) (5,41), and research in this area may have a significant impact in our understanding of the neurophysiology of somatic dysfunction (42).

Disease Risk (Pathway "B")

Several behaviors exert their primary effect by modifying disease risk or factors associated with disease risk. The major behavioral factors within this category that are also supported by substantial data include diet, exercise, sleep, cigarette smoking, tobacco use, alcohol use, and the prevention of excessive sun exposure. In general, modifications of diet, exercise, sleep, and relaxation constitute factors associated with a protective influence over physiologic sources of risks. They also function in an indirect manner by minimizing the effects of stress and enhancing coping mechanisms. Smoking, excessive alcohol consumption, and drug abuse typically fall into the category of health-impairing behaviors that directly influence disease processes and have secondary effects on mood and other behaviors. Physical behaviors (e.g., exercise, aerobics, and other types of physical exertion) often exert a protective influence and therefore fall in the category of health-enhancing behaviors. The consequences of these physical behaviors may directly or indirectly affect pain syndromes, medical interventions, and the natural history of disease. For example, an individual attempting to undergo a weight control regimen without substantial lifestyle changes that include increases in activity may experience difficulty in achieving and maintaining weight loss (43,44).

In general, the preponderance of data demonstrating association between diet and disease outcomes is found in the cardiovascular literature. Weight gain, obesity, excessive salt consumption, and fat or cholesterol intake are major contributors in the development of coronary artery disease, hypertension, and stroke. Interventions directed at weight loss and weight maintenance have engendered some success when the interventions were maintained (45) and when the interventions target specific ethnic or socioeconomic groups (46). These interventions recognize that adherence and cultural affects were an important part of an effective regimen.

The role of dietary influence on cancer risk is more speculative than the data regarding cardiovascular disease. For example, there appears to be an association between fat/fiber content in the diet and the mammography profile associated with breast cancer (47) or recurrence of breast cancer among women with estrogen receptor-positive tumors (48). Whether patients can effectively alter their fat intake and weight has also been studied by investigators. Several studies have shown that diet can be effectively modified (49), secondarily leading to an increase in consumption of healthier food (50). These programs appear to be more effective when there is good research evidence to support the dietary changes and the individuals are aware of the evidence (51).

Exercise appears to exert beneficial effects by reducing stress and increasing caloric consumption. The increasing caloric consumption

is important in designing effective weight management programs. There are data to suggest that routine exercise programs reduce the relative risk of developing cancer (52) through either a reduction in sedentary activities or weight loss (53). Exercise also appears to be an effective coping strategy for stress (22). These effects may be related to alterations in mood and a reduction in perceived stress that occurs with routine exercise (54). The latter of these effects may relate more specifically to an attenuation of physiologic reactivity. Unfortunately, for many individuals, increasing stress reduces the amount of physical activity undertaken (55). Reduction of stress and an improvement in the physiologic adaptability have also been cited as possible mechanisms by which exercise could exert its effect in cancer.

Our knowledge of the effects of tobacco use dates back to the early 1960s. Since that time, extensive data have demonstrated the adverse health consequences of cigarette smoking and tobacco use. The habitual use of tobacco relates to physiologic responses to nicotine (e.g., sense of well-being, arousal, and appetite suppression) and the avoidance of or the relief from withdrawal (56). Smoking contributes to the development of atherosclerosis, coronary artery disease, hypertension, stroke, emphysema, bronchitis, and several malignancies through recognized physiologic mechanisms (57). Even secondhand smoke may carry some of the habituating and cardiovascular responses related to nicotine exposure (58). In this regard, prevention may be a more effective strategy for limiting cigarette smoking and its adverse health consequences (59). However, in individuals who smoke, stress appears to be a significant contributor to the amount and frequency of tobacco use (55), as well as to relapse after smoking cessation. Thus, the combination of stress and tobacco use is a self-reinforcing behavioral pattern that is complicated by nicotine addiction. Behavioral strategies designed to alter tobacco use must address these interactive behaviors to be effective (60).

Understanding the issues and relevant research on the health consequences of sun exposure is illustrative of the complexity of some biobehavioral interactions. Ultraviolet (UV) radiation in sunlight has been linked to the development of basal-cell cancers, squamous-cell cancers, and melanomas (61–63). For basal-cell and squamous-cell cancers, the risk parallels cumulative lifetime UV exposure. Routine use of avoidance measures or sunscreen can substantially decrease the risk of skin cancer. Unfortunately, despite increased awareness and research evidence on skin cancer, there has been little change in individual behavior. One reason is the belief that sun tanning makes an individual look healthier and that exposure to the sun is healthy (64). This persistence of irrational beliefs and behaviors underlies these high-risk behaviors. Solid research and education is the foundation for changing behavior. For the osteopathic physician, healthy lifestyle changes and the formation of adaptive daily habits form the cornerstone of the restoration and maintenance of health.

Disease-Related Biobehavioral Activities (Pathway "C")

The final general mechanism relating behavior with disease involves behaviors that occur when illness is present, suspected, or where there is grave risk of illness. Many factors influence individual behaviors under the threat of severe pathology. When significant illnesses are suspected or where there is the potential for illness, the perception of "harm" (e.g., fear), and the potential impact (e.g., loss of function) may significantly alter the coping response of the individual. Socioeconomic factors, issues involved with physician support or confidence, the perception of risk, and emotional reaction

of the individual all significantly affect surveillance efforts (65,66). Health beliefs, perceptions of risk, and generalized anxiety regarding disease or illness greatly contribute to avoidance on the part of the patient (65,67). Consistent with these concepts, Lerman et al. (67) reported heightened anxiety about developing breast cancer in association with intrusive thoughts and demonstrated some relationship with adherence (68). Similar findings were noted in women undergoing genetic counseling for breast cancer (69). However, the distress associated with disease risk does not have a consistent effect on surveillance activities (70). These findings have also been noted in screening for HIV. Studies have linked the associated anxiety with undergoing screening and failure to follow-up for test results. In general, stress, emotional responses, and past stress coping behaviors are often the best predictors (71) of adherence.

A variety of behaviors related to the presence of illness may arise. Two major behavioral mechanisms affect outcomes in individuals with existing disease. The first of these mechanisms relates to adherence. Medical regimens are rarely effective when patients are nonadherent. However, nonadherence may arise from many sources, including inadequate understanding (72), forgetfulness, confusion, health beliefs, personal (naïve) theories of illness, and cost (73). There are few reliable predictors of adherence; however, high-quality communication, patient supervision, social support, and the recognition measurement and management of underlying impairments, especially depression (30), all contribute to improving adherence (30,73).

PLACEBO AS A BIOBEHAVIORAL MECHANISM

Improvement of a condition during clinical trials or treatment can be attributable to one of three causes: natural history, specific effects of the intervention, and nonspecific effects of intervention. The latter of the three causes is typically termed a “placebo effect” (74). If this effect were to be represented in graphic form with the spectrum of intervention along the horizontal axis and clinical improvement along the vertical axis, the placebo effect would be represented by gradual improvement in the clinical condition. The perceived drug effect would be represented by a more significant clinical improvement over the same course of treatment. The difference between the placebo and perceived drug effect would then be considered the active drug effect (75). Because of the possibility that new interventions could show improvement simply due to a placebo effect, this has typically been cited as a major reason for including a placebo control in most biobehavioral research studies.

Measurable factors that need to be included in the design of a study and have been shown to affect the placebo response include race, direct suggestion, belief in the treatment, trust in the physician, genetic variation, environmental effects, and nonspecific cause-effect relationships all interact creating a placebo effect. Environmental effects include personal interactions (e.g., the doctor-patient interaction), perceptions based on relevant previous experiences, and the influence of the setting (76). Each of these must be considered when planning research protocols, especially in light of the potential for interactions between the researcher, an examiner, or an intervention. The importance of such effects has recently been reviewed with regard to cardiovascular disease (75) and pain treatment (74). Some major mechanisms that have been proposed to explain the placebo effect include decreased anxiety, altered expectations, learning or classical conditioning, and endogenous opium release (74–76). In each of these mechanisms, there appears to be interaction between the behavioral aspects of the

individual and the placebo, resulting in a biologic improvement. However, in a recent review of over 130 clinical trials, Hrobjartsson and Gotzsche (77) concluded that there is little evidence to support the contention that placebos have powerful clinical effects. In their review, the authors concluded that placebos had no significant effects in most studies with measurable *objective* variables or simple binary outcomes. However, placebo effects were noted in trials involving continuous measurements of *subjective* outcomes and those trials involving the treatment of pain. In addition, there was a greater likelihood of identifying a placebo effect when the experimental and control group sizes were relatively small.

Placebos can generally be categorized into pharmacologic, physical, or psychological (77). For the purpose of investigating manipulative interventions, an appropriate placebo control is both essential and difficult to achieve. For individuals who previously have undergone manipulative interventions, there is an element of learning on the part of the subject that may allow them to differentiate a placebo from an active intervention. Even when naive individuals can be used, the physical component of touching a patient or subject has an active component known as an active placebo that creates difficulty in designing clinical trials. In some instances, as has occurred with studies investigating antidepressant therapy (78), the placebo effect has a measurable physiologic effect that must be considered in the interpretation and the research paradigm.

OVERVIEW OF THE BIOBEHAVIORAL RESEARCH PROCESS

The biobehavioral research process can be broken down into arbitrary steps beginning with the development of a research question and ending with a written report of the research findings (Table 73.2) (79). The choices involved in the process are not unique to biobehavioral research but have some methodological considerations that should be understood by all researchers. Decisions made about the methodologies employed and measurements obtained will significantly affect the value and validity of any research (80). Overall, the primary goal of the medical researcher and clinician is to provide greater understanding of the relationship between biologic processes and behavior and to communicate those results effectively to both the professional and lay readership.

Osteopathic medicine is being challenged to provide evidence of efficacy for osteopathic manipulative treatment. The evidence-based outcomes important to third-party payers, clinical professionals, and patients all involve biobehavioral aspects that must be incorporated into any research design. Further, solid experimental research will need to prove that osteopathic treatment is less costly than other alternatives, or that it is an effective alternative with objective measurable outcome improvement. Improvement means restoring function, quality of life (QOL), and a lessening of symptoms. In treatment settings, using biobehavioral measures and research may provide a more effective treatment paradigm and may render valuable insight into the impact of osteopathic principles and practice.

Basic Research Paradigms

The essence of a *descriptive research* design is to identify the characteristics of a system or an intervention applied, in this context, to a patient or subject. Often, comparisons include intensity, magnitude, frequency, or duration of a characteristic (e.g., symptom or clinical finding) across different phases of the treatment or across time. Such research paradigms do not routinely give mechanistic insight.

TABLE 73.2

Steps in Research Design and Implementation

Process Steps	Considerations
1. Develop the hypothesis and the components of the hypothesis	Is there sufficient published or preliminary data to develop a hypothesis? Is the hypothesis consistent with the available data? Is the hypothesis testable? Has the hypothesis been tested before? Would testing the hypothesis add to the current body of scientific knowledge? Refine the hypothesis
2. Determine the methods necessary for testing the hypothesis	Determine the biologic and behavioral effects pertinent to the hypothesis Determine the most optimal method for measuring the processes. Under some circumstances, this may require that methods be developed and validated before performing the research Determine the conditions for the assessment
3. Determine the research design that can be employed	Determining the necessary comparisons Assess the need for blinding and placebos Determine the subject-selection process Perform a power analysis
4. Perform the project and analyze the results	Identify unforeseen problems with the methods or study design Modify the processes to improve the study
5. Evaluate the hypothesis in light of the results and the limitations of the study	What were the major findings of the study? How do the data support or refute the hypothesis? Are these data consistent with prior investigations?
6. Identify the major findings of the research that verify previous findings and those that add new information.	What are the implications of the study and how generalizable are the results? What were the limitations of the study and how do they affect the conclusions?
7. Communicate the results.	Determine the most appropriate venue for presentation of the study Identify areas for future investigation

Hypothesis-driven research proposes that a certain intervention or perturbation will yield a specific result on the basis of prior knowledge of the system, disease, or condition being studied. The research hypothesis is based on an understanding of an active mechanism(s) and is designed to assess how a particular intervention exerts a specific effect. For example, a researcher might propose using a drug that affects a specific enzyme known to be the cause of a particular disease using an outcome measure pertinent to that disease. In this setting, the goal is to see whether there are differences in the groups that can be accounted for by the treatment delivered.

In any research, the selection of subjects and other factors may affect the outcome or validity of the study. Some research designs use *random selection* of subjects while others may use a highly selected population or matched samples to minimize the variance

and increase the likelihood of finding a significant effect. Other factors that need to be considered include the effect of preexisting conditions (covariants), the blinding of researcher and/or subjects, effect size, the power of the study (i.e., a determination of the number of subjects needed to have a valid study), and the utility of the outcome measures. Nonetheless, hypothesis-driven research is critical in developing new knowledge about cause and effect, and it is the backbone of good osteopathic medicine.

Basic research paradigms are illustrated in Figure 73.2.

Starting the Research Process

Before a hypothesis may be developed, the researcher must review or be knowledgeable about the current body of scientific knowledge related to the research question. Occasionally, a paucity of

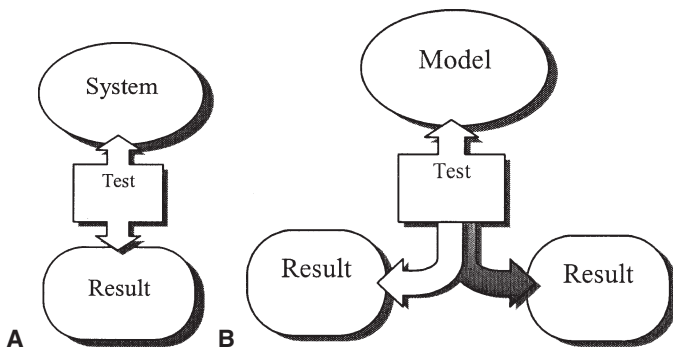

Figure 73-2 Basic research paradigms. **A.** Descriptive research. Descriptive research typically involves identifying the frequency of occurrence and/or characteristics of a system, condition, or population under specified conditions across time. **B.** Hypothesis-driven research. Hypothesis-driven research uses known data about a system, condition, or population to generate a mechanistic model of interaction. Using this model, predictions about the behavior of the system or causal relationships between variables are generated. Testing conditions and measurements are then selected to determine the predictive validity of the model.

data exists sufficient so that a mechanistic hypothesis cannot be developed. In that circumstance, the initial research may be descriptive rather than mechanistic, but should be directed toward developing a sufficient body of knowledge to advance to mechanistic investigations.

The research process begins with a question in the form of hypothesis about the mechanism of an effect (81). In general, the hypotheses should center around testing mechanisms as opposed to descriptive research or, “what happens if ...,” as discussed above. This simple understanding of the difference between these two approaches is difficult for many individuals. In descriptive research, a system is studied under a given test condition to determine the effect or the impact. This style of research is most appropriate for situations where basic background information or assessments are needed before a more precise experimental model of mechanisms can be undertaken. Hypothesis-driven research will typically formulate a research question that may have two or more potential outcomes, depending on the mechanism that is active and the design that is being employed for the research. The researcher then chooses conditions and measurements that allow the clearest delineation between the potential outcomes.

Depending on the type of biobehavioral research employed, major interactions between biology and behavior must be addressed. In simplest form, these interactions may be summarized as behavior affecting the physiologic response, a physiologic response affecting a behavior, or behaviors arising in relation to a disease process. The relationship that is hypothesized constitutes a possible cause-and-effect relationship and how to measure the constructs around variables and which the research plan will be initiated.

To observe the cause-and-effect relationship, the exact behavioral and physiologic variables that are involved need to be specified. In addition, the conditions under which these measured variables interact must also be specified in significant detail. The research model selected must include controls for the confounding effects found in the interaction between the variables being studied and the behavioral/biologic measurements. Essentially, specifying the specific conditions, behaviors, and biologic processes that are involved is necessary to limit outside interactions or

variance within the measurements, determine cause and effect, and not jeopardize the validity of the study. There are six factors that may jeopardize validity, confound the results, and decrease the validity of any conclusions.

Selection into Groups

Groups formed for experimental reasons, with a specific illness, seeking medical care, and willing to participate in a hypothesis-driven design where they may receive a sham or no treatment do not represent the universe of patients with that particular illness. We know, for example, that chronic pain patients who are enrolled in multidisciplinary pain clinics are a very unique group of self-selected patients with whom results do not generalize to the overall chronic pain population (40).

Intent to Treat

There is a natural loss of subjects during a study from the beginning to the end. The dropout rates are critical, but of particular importance is the question of, “who were the people who dropped out and why?” For example, they may have dropped out because the treatment was actually detrimental; if those scores were included, it would have substantially altered the conclusion. Scores not collected often cause a “type II” or false-positive statistical conclusion.

Multiple Treatment Interference

The effects of *prior* treatments are usually not erasable when multiple treatments are applied to the same person. Such is the case with manipulative treatment.

Maturation

Internal cognitive/emotional processes operating during the experiment, including learning, getting tired, unintended reinforcement or punishment for certain behaviors, and so on, affect future scores.

Instrumentation

Any change in the measuring instruments or in an observer’s use of the instruments or scoring methods produces changes in the obtained measurement over time and confounds results.

Measurement Variance

This is the most common factor invalidating research results. Most patients are treated and selected into the treatment groups by *extreme* scores to begin with. For example, they may have high pain scores, severe impairment in range of motion, or activities of daily living, mood, on so forth. Because they were selected on an extreme of a bell-shaped curve, they will show subsequent test scores that are improved simply as a function of moving from the tail of the curve toward the mean average, which is a statistical artifact in measuring. In other words, if you take the worst of the worst and measure them at that point and do anything to them and remeasure in the future, some will have better scores on retesting and will have moved toward the average by chance.

For these reasons, the exact specifications for the behaviors to be studied and the methods for the measurement of intensity, frequency, and duration of symptoms are especially important in biobehavioral research. These characteristics of each behavioral measurement are important variables that must be quantified for the study design. Under some circumstances, the characteristics may either be dependent or independent variables, as determined by the specific interaction that is being identified in the design of the study and how the variable is quantified and measured.

Qualitative Measurements

Measurements of behavior may be either quantitative or qualitative. Quantitative measurements typically convert the behavior to a categorical or numeric scale. The major benefit of using numeric measurements is that they are more amenable to statistical analysis. Categorical scales may be used to place subjects or behaviors into particular categories on the basis of specific characteristics. Under some circumstances, categorical scales may be based on qualitative or subjective assessments. Thus, the investigators should consider that qualitative tools requiring subjective interpretation may be affected by examiner bias, and need to be applied in a uniform fashion to obtain reliable numeric results. Qualitative measurements are typically based on the assessment of particular characteristics that allow them to be placed in discrete categories or transformed into a numeric scale. Quantitative measurements should not be assumed to be better than qualitative assessments. The caveat that is best followed is to choose the most appropriate measurement tool for the physiologic and behavioral components given the study participants and situation under investigation. Frequently, the researcher may benefit from the work of other investigators and use known, standardized tools that have established validity and reliability. Some standardized tools may be used to obtain self-reporting of the data. In many instances, these tools can be easily administered, completed, and scored in a standardized fashion. There are many standardized measurement instruments available, but they should be carefully selected to address the specific needs of the research.

Quantitative Measurements

Measurement of behavior requires that we employ a quantification system to reliably describe and identify characteristics of behavior in the context being studied. The spectrum of potential behaviors that may be studied in biobehavioral research is exceptionally broad and ranges from physical behaviors that may be objectively quantified to particular thoughts, or thought patterns that must be indirectly inferred. The assessment of subjective constructs may be further complicated by languages, dialects, cultures, age, socioeconomic status, gender, race, and other situational considerations. Previous experience or familiarity with many interventions or measurements may alter the conditions for a research project, complicating or invalidating the results. For example, a subject's familiarity with osteopathic interventions may invalidate a research design using a placebo control because the patient is able to identify therapeutic intervention and is not blinded to the study's designed placebo control.

Biobehavioral Measurement Data

The basic data resulting from any measurements are a series of numbers. These numbers represent the numerical value of some biobehavioral characteristic, and the measurements are often obtained from one or more groups of individuals. We can seldom make much sense out of these numbers if we leave them in their raw form. For that reason, we use *statistical procedures* to answer questions we have raised about the basic data. We want to put some kind of order into our numbers. We can graph the numbers, look at percentiles, rank order numbers, and see how group patterns are made clearer by sorting the raw data into frequency distributions and looking at the mean average. The arithmetic *mean* is simply the result of adding up all of the measures and dividing by the number of measures. We can look at the *mode*, which is defined as the score that occurs most frequently, and the *median*, which is a label for the point at which 50% of scores fall below and 50% of the scores fall

above. We can look at how individuals and groups vary and deviate from the mean score for each raw score obtained. This is called the *variance*. You find the variance by subtracting the mean average from each raw score, squaring that number, then dividing by the total number of scores. Find the square root of the variance, and you have the *standard deviation*. It is from the *mean and standard deviation that all further statistical techniques evolve*.

The simple goal of statistical techniques is to answer the question of whether the changes in scores obtained would have occurred by chance. In these statistical procedures, we set our *confidence intervals* at usually five times out of a 100 (i.e., 0.05 level). This means that we would be satisfied that the scores obtained would have happened by chance only five times out of a 100. This is a basis for common tests, such as the *t*-test for two groups and *analysis of variance*, for more than two experimental groups. These two tests are commonly used statistical methods in biobehavioral research. Researcher's interest may also rest in the aggregate set of measures rather than on any one single measure considered apart from the others. The logic, algebra, distribution theory, numerical analysis, and computer programs for these types of analyses are all described elegantly and available at most computer and research facilities.

Designing a Study

A wide variety of designs may be employed in biobehavioral research. One of the more common study designs involves *comparisons among groups*. In this setting, there may be two or more or groups wherein the comparison occurs. The specific design chosen will affect the number of independent variables that may be considered and the precision and power of the statistical analysis. Knowledge about the variance of the independent measurements that are being made allows the investigator to determine the number of subjects that will be needed within each group. The process of determining the number of subjects necessary for a particular design is referred to as *power analysis*. Another fundamental type of study design involves the assessment of effects across time or a comparison over time. This type of design paradigm is typically used to assess cumulative effects or gradually developing changes in the system. Designation of members within a group must also be considered by the researcher. Determining whether the population should be limited to a particular gender, race, or age may significantly affect the study design and measurements that may be employed. In some instances, variation in underlying physiology, such as with sleep wake cycles and circadian biology, may affect the time of the day, the time of the month, and the time of the year the study or component of the study may be performed. These possible confounding variables can be controlled by the design of the study and by the predetermined statistical analysis.

Statistical Analysis

Although the statistical analysis is performed after the actual study has been completed (or at least partially completed), the statistics to be employed must be determined before the study is implemented. In some instances, significant biobehavioral differences found among groups require additional separation to determine exactly which group is different. This additional data analysis procedure is referred to as a post hoc analysis, is only employed if the main effect studied was significant. The goal of the post hoc analysis is to detail exactly what specific factors account for the overall differences found in the main study. Occasionally, researchers employ other statistical identifying techniques in identifying subgroups

with significant differences when the main effect model *failed* to show significance. This process is used when the subgroup analyses were planned as part of the original research proposal and appropriate accommodations for the small group size were undertaken. Once all statistics are completed, a judgment is made about whether the research results confirm or refutes the initial hypothesis.

Generally, the results of the research study, if well designed, should be fairly clear. The statistical analyses should show whether changes found in the measured biobehavioral variables were significant or not. If the analyses confirmed the initial hypothesis, then the investigator should undertake the process of analyzing the results in light of other investigations. Comparing differences in techniques, the selected populations, and limitations in methodology is a valuable exercise in analyzing the results of the study. The investigator should then assess the implications or generalizability of the research findings. Elements of the study or the theoretical framework on which the study is based that were unclear or undefined can then be identified for future investigation. Once all these elements have been completed, the study and analyses should be communicated to the appropriate scientific audience. Under most circumstances, this occurs in the form of a peer-reviewed publication in a scientific journal and adds to the evidence-based knowledge, which is the bedrock of osteopathic practice.

OPPORTUNITIES FOR OSTEOPATHIC RESEARCHERS

Biobehavioral interactions present the osteopathic researcher a somewhat novel and rich environment for the development of investigations. Despite the variety of investigations that could be undertaken, a review of the literature demonstrates paucity of studies addressing biobehavioral mechanisms or effects in osteopathic principles and practice. Major topics in this area will likely focus on behaviors leading to the development of somatic dysfunction, behaviors resulting from somatic dysfunction, QOL effects of pain, and relationships between locomotor function, somatic dysfunction, and subsequent behavior (82).

Manipulative intervention (83), alone or in combination, may have as much affect on subsequent behaviors as other types of medical intervention, and should not be ignored when considering a biobehavioral research paradigm. For instance, the improvement in locomotor function or a decrement in pain resulting from manipulative intervention could result in substantial behavioral adjustments or improvements in QOL that may not be immediately apparent without biobehavioral research. In this regard, considering a biobehavioral research approach would enhance the ability to detect improvements related to the manipulative intervention and may give additional insights into the true treatment effects of osteopathic principles and practice.

The biobehavioral approach will require clear and creative research designs directed more toward behavioral outcomes rather than physiologic measurements or end point assessments, as is commonly done. In this regard, all major types of biobehavioral designs should be considered, including those associated with *chronic illness*, not commonly the focus of osteopathic research. Avoidance or development of emotional issues (e.g., depression), QOL, and changes in behavioral responses to chronic illness in relationship to osteopathic principles and practice represent investigations potentially adhering to the third pathway described above. This type of investigation may be less concerned with the direct effects of the disease process and more directly interested in the secondary effects on the behavior of patients (when adherence with medical regimens and tolerance of side effects are improved). Quantifying

these relationships or the effect on QOL becomes the major issue in developing a biobehavioral research design and might even include developing a specific osteopathic QOL instrument. Other types of investigations could focus on the interrelationship between somatic dysfunction or manipulative interventions and cognitive performance, health status, or other neurobehavioral manifestations. From these investigations, one could inquire about other biophysiological relationships and whether somatic dysfunction could serve additional diagnostic roles yet to be determined, or answers to questions not previously envisioned. The field of biobehavioral research is wide open for future osteopathic research to develop the evidence-based foundations for the uniqueness of the osteopathic approach.

SUMMARY

Biobehavioral interactions are a complex interplay between genetic, physiologic, environmental, and behavioral factors that have been shown to influence health and disease through many different pathways. Three major pathways for the effects of behavior to manifest on health and disease are ripe for research. Some types of disorders manifest these interactions more directly than others; but in each case, we find that behavior alters the physiologic “landscape,” and physiologic alterations result in significant behavioral accommodations that affect health and disease outcomes. Thus, physiologic phenomena are inseparable from their behavioral counterparts and must be considered as part of the process wherein disease develops. For the osteopathic researcher, biobehavioral interactions and research may play a significant role in advancing our understanding of our patients, improving treatment regimens, and advancing the evidence-based understanding of osteopathic principles in medicine.

The Future of Osteopathic Medical Research

MICHAEL M. PATTERSON

KEY CONCEPTS

- The profession has a long history of research, but faces an uncertain future as it tries to realign research priorities to new health care realities. Shifts in federal research funding may make the profession even more reliant on its own resources for initial research development.
- The osteopathic teaching institutions, especially the COMs, must lead the way in developing organized research efforts. While a number of the schools are or have developed the necessary infrastructure to support at least modest research programs, several have not and have no plans to do so. Research is vital to good teaching faculty, and must be encouraged, not discouraged.
- The faculty at osteopathic institutions need to understand the philosophy and practice of osteopathic medicine and to design research studies that will bear on the questions that come from osteopathic clinical practice and philosophy. Research done in osteopathic institutions that has no bearing on the issues of osteopathic medicine, while good research does little to further the osteopathic profession.
- Osteopathic students need to be better informed about the history of osteopathic research, the opportunities for osteopathic research, and research training. There is a proposed curriculum for schools to follow in training students in basic research principles, but it needs to be put into practice more fully. Several initiatives have been taken to provide interested students with research information and training, and some grant funds are being made available for student research by foundations and individual schools.
- The profession has developed its first research center and must continue to support it as well as develop other national research efforts. Osteopathic foundations who have a mission to support and broaden osteopathy are increasingly stepping up to fund major research efforts. Foundation support is often the only way for researchers to reach the level necessary to apply for further NIH funding.
- The development of collaborative efforts is vital to large-scale clinical trials. The Osteopathic Research Center (ORC) is organized to do such efforts as shown by the MPOSE study. Other such trials must be organized. The Osteopathic Postgraduate Training Institute organizations and confederations of solo practitioners can gather data from practice that can be useful in illuminating the practice efficacy of osteopathic medicine.
- There is a great potential for increased research collaboration with foreign osteopathic movements. Osteopathic schools in England, Germany, Italy, and elsewhere are beginning research efforts that will produce valuable information, especially if aided by U. S. osteopathic institutions.
- Designing studies of osteopathic manipulative therapy is a difficult task. The question being asked must be very clear and the study designed to answer the question being asked. The use of sham controls is especially difficult as any "sham" in manipulative medicine is actually a form of treatment and hence should be evaluated against no treatment to assess the actual effect of the "sham." To assume that a sham treatment has no effect and hence can be thought of as neutral is simply not acceptable. The use of a sham contrast control is actually comparing one form of treatment with another.
- It is tempting to say that all research that can be done is important and no area should be singled out above others. However, some suggestions can be made as to areas that may be most valuable in determining the usefulness and value of osteopathic theory and practice.
- The philosophical basis of osteopathy medicine should be used to drive the main research programs of the profession.

INTRODUCTION

In his 1962 Andrew Taylor memorial lecture, Northup (1) stated, "we are on the precipice of either our greatest success or ultimate defeat. This success or failure depends not on the policy of organized medicine, but on the decisions and integrity of organized osteopathy."

These words were spoken at the darkest hour in the history of the osteopathic profession. There was a real question about the continued survival of the profession as an organization. The California merger had occurred and pressure was mounting to turn even more of the profession over to allopathic control. One of the

profession's six schools had been lost, and about 10% of its members had been granted an M.D. degree in California. Indeed, the decisions and integrity of the leaders, as well as the rank-and-file members, would decide its fate.

Over the next few years, the decisions of the profession and its leaders led to a revival and rebuilding of both the physical plant and the organization of osteopathic medicine. The profession's members responded to the challenges and supported a renaissance of unprecedented proportions. Between 1969 and 1996, 13 new schools were founded, about half university based. Today, the profession is growing at an unprecedented rate and enjoys

support from the government and private sectors. It now has 28 open osteopathic schools, including the branch campuses, with several more scheduled to open in the next 2 to 3 years.

However, today the osteopathic profession faces a future still filled with unknown and unpredictable forces that will shape and challenge it in many ways. It is increasingly challenged to show that the claims it makes for its unique philosophy and practice are beneficial to the patients it serves. Government and third-party insurance carriers mandate that the outcomes of health care be used as evidence of the quality of service. Osteopathic physicians who utilize manipulative treatment are finding it increasingly difficult to attract reimbursement for these services as government tries to cut health care costs. The existence of osteopathy as a unique and separate profession rests on its ability to continually demonstrate that its practices are efficacious and its theories are sound. The overriding challenge for the profession is to show through well-conducted research that the services it provides are both efficacious and cost effective and to show a logical rationale for manipulative treatment.

Meeting these challenges is not a simple task or one to be taken for granted. To achieve this goal, all components of the profession must to take an active role. These institutions include:

- Educational institutions
- Osteopathic foundations
- Hospitals
- Affiliated societies
- Individual physicians in practice

However, the greatest challenge now facing the profession is that of building its research base to support and expand its claims of efficacious and unique practice. Without demonstrable substantiation of its claims to a unique role in health care, the osteopathic profession risks its existence.

It is not that data do not exist to show that the osteopathic profession has made unique contributions to health care and that its philosophy is sound. Research began in the profession with its inception and has continued since. Louisa Burns performed studies showing viscerosomatic and somatovisceral interactions long before the medical world recognized their importance. The research from the Kirksville group in the 1940s and 1950s, data from the Chicago College and other osteopathic schools, and papers published in the *Journal of the American Osteopathic Association (JAOA)* over the years show that the osteopathic contribution to health care is substantial. However, further substantiating the unique contributions and emerging quality of osteopathic care requires new and innovative ways to measure health and clinical outcomes, as well as the development of new and innovative research techniques. The art of clinical research is a relatively new endeavor, and its practices are just now developing to the point of being able to show the unique features of osteopathic medicine.

This chapter summarizes the present state of research in the profession, the opportunities and challenges ahead, and the areas critical to understanding the unique role of osteopathic medicine in human health and disease.

OSTEOPATHIC RESEARCH: 2008

Late in 2008, the research efforts of the osteopathic profession are set to enter their fifth era. The fourth era began in 2001 with the founding of the first osteopathic research center at North Texas State Health Science Center College of Osteopathic Medicine (see Chapter 70 for a summary of these eras). Since 1970, the profession's research had been expanding as new schools, many university

based, began to mature and begin research programs. Recent developments in the building of research programs have been evident throughout the profession. Research programs at the Texas COM had been strongly fostered for many years, allowing that school the infrastructure to support a research center. At about the same time, the founding school at Kirksville pledged several hundred thousand dollars in internal funding for expansion of its already successful research programs, with the funds to go preferentially to research directed to the elucidation of osteopathic principles and practice. Several other schools have pledged funding for basic and clinical research and have established mechanisms for active research. Unfortunately, some of the newer schools have not built active research efforts into their plans.

While the academic research base of the profession has been growing and maturing, other efforts were being made to foster research among osteopathic physicians. Some of the specialty colleges have had some form of research requirement in their programs for several years. This requirement has fostered an understanding of the research process in students that was not given during undergraduate training. More recently, some of the Osteopathic Postgraduate Training Institutes (OPTIs) have instituted research training in their programs. Although only beginning, these efforts to train more practitioners in the art and process of research are another way to increase not only the development of research programs but also an appreciation of its importance.

Other organizations of the profession have begun to take a more active role in research development and support. The AOA has, since 1951, had the Bureau of Research to promote and support research development. This group has taken an increasingly active role not only in granting research funds, but also in developing new programs. It now supports the training of osteopathic students in D.O./Ph.D. programs. Such combined degree programs are also available at several of the university-based COMs. The bureau also sponsored the development of an osteopathic bibliographic database as a joint venture between the Texas and Kirksville COMs. This database, known as OSTMED, was to be the premier repository for references to osteopathic literature that is generally very difficult to find and access. Unfortunately, the funding for the project was not renewed and the database, while still accessible, has not been added to for at least 2 years. On a positive note, the *JAOA* has been placed online and all back issues are either available or their contents can be searched.

The AOA's Louisa Burns research committee has become increasingly active in developing research protocols and initiatives, such as the online SOAP note project and SOAP note forms that may allow collection of large clinical databases in the near future. The American Association of Colleges of Osteopathic Medicine (AACOM) has led the organization and funding efforts for three national meetings to discuss research development, out of which came the osteopathic research center. Leaders within the organizations of the profession, especially the AACOM and the AOA, have increased their contacts with governmental funding agencies in efforts to secure federal funds and recognition for the profession's research efforts.

However, most notable in the dawning of the fifth era of osteopathic research is the increased role of the osteopathic foundations, especially the Columbus, Ohio-based Osteopathic Heritage Foundation. The Heritage Foundation, along with the other osteopathic foundations, has become increasingly active in sponsoring research efforts endowing research chairs, providing infrastructure at schools, and supporting meetings and conferences aimed at furthering the osteopathic research agenda.

The fifth era now emerging is one of expanding the reach and recognition of both osteopathic research and of osteopathic philosophy and practice. In 1989 and 1992, symposia that included internationally known scientists from around the world were held (2,3). These symposia generated publications, but perhaps more importantly, knowledge of osteopathic philosophy and practice in a number of scientists who had never before heard of osteopathic medicine. Several of them continued their interest in the profession and have provided support and even training opportunities for young osteopathic physicians. In early 2008, another international symposium was sponsored by the Texas Osteopathic Research Center, with support from the osteopathic profession, the NIH (NCCAM) and the chiropractic, massage therapy and physical therapy professions. Most importantly, this meeting brought together not only osteopathic scientists interested in somatovisceral interactions, but also scientists and clinicians from the chiropractic, massage therapy and physical therapy professions as well as leading scientists involved in somatovisceral research. The osteopathic profession, in organizing such a unique meeting, demonstrated that it was willing to broaden its scope of interactions to include other manual medicine areas. This effort must be the beginning of the expanded interactions necessary for osteopathic research to tap the resources and information available. In this way, the philosophy and practice of osteopathy can be increased by using insights and findings from other professions to enhance understanding of osteopathic practice. This expansion of interactions should be the hallmark of the fifth era of osteopathic research efforts.

These and other accomplishments have taken place over the last several years and point to an unprecedented effort to organize and support a profession-wide research effort. Although these efforts have been remarkable in a profession devoted to training practitioners since its founding, they are only the beginning. The increasing interactions between osteopathic researchers and clinicians that hopefully will expand are evidence that the profession has begun to tap larger resources and is a sign of a maturing discipline. However, it is only the beginning of the maturation process. What are the challenges now facing further development of quality research efforts?

INSTITUTIONAL CHALLENGES FOR RESEARCH DEVELOPMENT

Academic Challenges: The Schools

Clearly, some of the teaching institutions of the profession have made great strides in the last 30 years in developing nationally competitive research efforts. As pointed out in the first chapter in this section, the profession's schools were not in a position to take advantage of the immense expansion of biomedical research infrastructure during the 1950s and 1960s. In fact, it was not until the 1980s that a few of the COMs were able to develop sufficiently strong research initiatives that they could attract significant federal funding. In 1974, the first RO1 NIH research grant was awarded to a researcher in an osteopathic institution. Since then, a number of large federal and private grants have been awarded to several of the COMs. The ORC at Texas has emerged as a nationally competitive institution, attracting NIH funding.

The challenge for all the academic institutions now lies in seeing the urgent need to show the efficacy and mechanisms of manipulative treatment. They must provide time for research and provide incentives to their faculty, thus harnessing the expertise of researchers now in place or being brought into the institutions. The

institutions that have done this most effectively have made several commitments:

- A stated commitment to an osteopathic research environment
- Internal funding for startup research
- Committed time for research
- Support personnel
- Encouragement to take research risks
- Recognition that research is a long-term commitment that simply cannot be hurried

In any endeavor, experience has shown that one of the best ways to get started on a process of change is to publicly commit to the process. This provides an impetus for planning and goal setting against which the outcomes can be measured. A public announcement shows the commitment and produces expectations that are harder to shirk than if the commitment is private.

Although the announcement of intent is laudable, providing the means to begin the task is necessary. The days of having a good idea and simply going to the NIH or National Science Foundation and asking to be funded are simply gone. Public and private funding sources require demonstrated research capability (pilot data) before funding a project. Therefore, the commitment must be backed up with a dollar support to seed research efforts. The college administration must be willing to provide dollars to insure that researchers are able to do the necessary work on which to base their grant proposals. Often, such seed periods, especially in newer areas of inquiry, take several years before external funding is successfully garnered. In addition, even seasoned investigators at times need infusions of funds to continue between grants, start new research projects, or for unexpected needs. The institution must be capable of meeting these needs.

As important as funds are for the beginning researcher, it is often the lack of committed time that impedes a fledgling research program. If a researcher has sufficient funds to do a project, but the blocks of time are not available, the project will fail or the researcher will lose interest. Unlike such things as committee meetings, patient care, and even teaching, the research endeavor requires large blocks of time on a regular basis. First, the researcher must be allowed time to look into the background of the project, to reflect on the available information, and to synthesize its meaning. This literature review and synthesis means a substantial intellectual effort that cannot be done in 5-minute periods between patients or classes. The investigator must be allowed the free and unencumbered time to become an expert in the field—not only his or her field of training, such as internal medicine or osteopathic principles and practice, but in research design and practice. The administration can relieve the prospective researcher of some committee duties, give lighter teaching or patient care loads, and not expect the faculty member committed to research to attend all administration functions. Of course, the quid pro quo will be research productivity.

There must be support personnel for research efforts. A faculty member pursuing a fledgling research effort must expect to initially do much of the footwork in getting a program under way. However, support is needed in terms of technical help, secretarial backup, and patient scheduling. As a research effort develops, support must be provided for grant writing and grant budget administration, as well as for keeping up on the latest federal, state, and local regulations. It is not logical or financially responsible to expect researchers to spend much of their productive time typing letters or purchase orders, rather than reading the latest literature or doing the actual study. The level of support personnel will be rewarded in exponential gains in research productivity.

The institution must also make it clear that it understands that not all research efforts are successful. Research studies by their very nature are trips into the unknown. The researcher, especially the beginner, will have studies that do not show significant results. The institution must show that its support is not only for successful studies, but also for the effort. Without this understanding, the researcher will not be free to undertake anything but the most mundane and predictable efforts. The institution, by showing that it rewards not only research efforts, but also risk taking in research, will foster a higher level of research endeavor. This can be shown by providing raises commensurate with cutting-edge research projects, granting advancement to those willing to take risks, and publicly acknowledging such activities.

For any research endeavor to be anything but an isolated event, to become a program of research, not an isolated study, the researcher must become committed to continuing over an extended time. No one research study will tell a story about an area. Several studies will begin to weave a tapestry that will answer meaningful questions. Research programs evolve with time and continued effort, not isolated, brief efforts. The institutional commitment to its researchers and research programs must be long term. Only then will a research effort make a meaningful contribution to showing the basis and efficacy of osteopathic medicine.

The academic institutions of the osteopathic profession are beginning to build the bases for the long-term commitments necessary for meaningful research programs. Some have advanced further than others, as evidenced by the founding of the center for osteopathic research at the Texas school. Others are only starting the task and need the encouragement and support of the rest of the profession as they proceed.

Academic Challenges: The Faculty

In Chapter 70 "Foundations of Osteopathic Research," we made the observation that the definition of osteopathic research must come from the investigator and cannot be determined a priori. This means that the researcher, basic scientist, or clinician must become sufficiently familiar with the background and clinical experience of osteopathic medicine that he or she can link the ideas and results of their research to the needs and experiences of the profession. Although data from studies not constructed or performed to test the tenets and clinical observations of the osteopathic profession can be used for that purpose, it is far more efficient and less risky of incorrect interpretation to perform studies stemming directly from questions generated by osteopathic theory and experience.

Basic scientists, both from the biomedical tradition and from the social sciences, have been incorporated into the osteopathic profession in increasing numbers, especially since 1970. Earlier, it had been the usual custom in osteopathic teaching institutions to use D.O.s to teach most of the basic science subjects, as well as the clinical areas. With the explosive growth in numbers of schools in the 1970s and heightened expectations for subject experts in the basic sciences, faculty trained in nonosteopathic settings were increasingly hired. Many of these professors had research backgrounds, as well as backgrounds in their disciplines.

These faculty face difficult challenges in doing research meaningful to the osteopathic profession. Although it is often argued that any research is valuable, the profession's research resources seem best spent on research projects that can be expected to provide information useful in giving answers to the theoretical and

clinical underpinnings of osteopathic medicine. Some of the challenges faced by basic science researchers include:

- Lack of knowledge of the history, theory, and basis of osteopathic medicine
- Difficult or impossible access to the literature of the osteopathic profession
- Lack of access to the clinical experience of osteopathic medicine
- Difficulty in understanding the practice or jargon of osteopathic clinicians
- Insecurity of switching from an established research program to an unfamiliar one
- Unwillingness to make the effort to explore an unfamiliar and seemingly out-of-the-mainstream topic

These challenges are severe but surmountable. The osteopathic profession is moving to provide the materials needed to acquaint its basic scientists with its background, theoretical basis, and research data. The Texas bibliographic project, while now dormant, still provides references to much of the early research and philosophical writing of the profession and thus provides greater access to the literature of the profession. With the growth of older books and articles available on the web, it is increasingly easy for scientists to access previously unavailable osteopathic resources. The AAO, as mentioned earlier, has provided its literature bibliography on CD-ROM. Such sources as this book and others now appearing provide the willing basic scientist with useful information.

Despite increased reference availability, ready access to the profession's older research literature is poor. Ways must be found to make those sources more available, not only to basic scientists, but to clinician researchers and students as well. Many of the works of Burns and other early anatomists and physiologists investigating basic mechanisms of manipulation are available in only a few college libraries. This is a continuing challenge to the profession, but may be solved by scanning older literature to be made available on the web.

A basic scientist trained in conventional settings coming into an osteopathic school to teach is faced with the task of teaching in a profession about which he or she usually knows nothing. In this case, the only option is to teach a topic in the same way it was taught elsewhere. The osteopathic profession thinks of itself as a unique entity, implying that the teaching of its students should be somehow different from the experience of other medical students. How can that occur if the basic scientist does not know the basis of the profession? One way is to integrate osteopathic physicians into the teaching of the sciences. Of course, another is to inform the basic scientists of the profession. Clinicians and others knowledgeable of the profession can provide seminars and workshops on osteopathic medicine for their colleagues. Basic scientists can be encouraged to sit in on the osteopathic courses. Clinicians can take basic scientists as shadows in their practices and discuss the unique aspects of osteopathic medicine with them. Administrators can provide expectations and rewards for basic scientists who show a willingness to avail themselves of opportunities to become knowledgeable about the profession. In general, the profession has not held sufficiently high expectations for its basic scientists nor has it provided good opportunities for them to become familiar with the theory and practice of osteopathic medicine.

A basic scientist coming into the profession with a budding or established research program faces real obstacles in retooling or realigning that program to the needs of osteopathic medicine. Funding may not be as readily available. The switch or realignment may take several years to accomplish. The comfort of a known research enterprise is lost. The schools can help this transition

by providing funding for the transition, understanding that productivity may decrease for a time, and finding clinicians to supply information and experience to the investigator. In addition, the expectation should be clear that such a transition will be rewarded in tangible ways. Korr (4–11) has published several articles on the challenges posed by osteopathic theory and practice that can be given to entering faculty.

Although the school and profession can do much to help an investigator realign their research and intellectual efforts toward the questions of osteopathic medicine, there is also an onus on those coming into the profession to make an effort to gain this understanding. Intellectual honesty would seem to demand of a person coming into a profession that knowledge of that profession be acquired. The investigator should have some intellectual curiosity and desire to find out about what it is he or she is getting into. Thus, an investigator may be expected to make efforts to seek out opportunities to become familiar with the backgrounds, theoretical underpinnings, and research basis of the profession. Too often, this does not happen, but should be encouraged. Osteopathic clinicians can be very helpful in this by offering manipulative treatment to their basic science colleagues. Osteopathic students can challenge their basic science professors to investigate the profession. In this way, a healthier interaction can be accomplished.

But what about osteopathic clinician researchers within the profession? They also need help in meeting the challenges of research. They often are not schooled in research methods and skills. They are pressured for time and are expected to provide patient care to generate income, not research studies. These individuals also need to be given the time, resources, and encouragement to pursue the difficult and often discouraging field of research. They need to have the backing of their administrators for time and resources to acquire research skills and protected time for intellectual pursuits. They need to become aware of the long-term nature of a research endeavor. They need collaborations with their basic science colleagues in designing and carrying out osteopathically oriented studies. In short, they have the same needs as do the basic scientists. The D.O. making a transition to research is venturing into unknown and uncertain territory, just as is the basic scientist trained in other institutions. Support and understanding are needed for both groups.

Academic Challenges: The Students

In planning for the long-term health of osteopathically oriented research, the role of the students must be considered. At present, in most osteopathic schools, little attention is given to providing the students with a background in prior research of the profession, let alone in the basics of research design and process relevant to the profession. One of the best ways to increase research power in the profession is to orient its students early in their training to the basic properties and needs for research. Only a small percentage will become researchers, but only a few are needed to make a large difference. If only one student per class aspired to become a full-time researcher in the profession and were provided sufficient support to pursue that goal, the profession would soon have an abundance of trained and functioning researchers in its institutions.

The schools can implement lectures on research background, methodology, and process for all students. For those showing more interest, mentors can be provided to work with the more motivated students to provide initial training, research opportunities, and support. These students can be integrated into ongoing investigations of osteopathic manipulation and technique. There have been some efforts to provide a model research curriculum to all the schools,

and this should be encouraged. Too often, the schools are attracting students with research interests, only to destroy that interest by failing to provide opportunities and training.

In addition, opportunities can be made available for graduate training for students interested in well-recognized laboratories outside the profession. However, it is imperative that such opportunities incorporate aspects of research particularly pertinent to the profession, lest the student be discouraged from building the knowledge bridges to the important issues of the profession. An osteopathic student trained in traditional research institutions who goes into research that does not build on osteopathic principles and practice does little to further the osteopathic profession.

The profession is beginning to take steps to add a research basis to the curriculum. In late 2001, a workshop was held at the Osteopathic Clinical Trials Initiative Conference (OCCTIC) meetings for the purpose of outlining a research curriculum for the years of osteopathic medical training. The results of this meeting have been endorsed by the Educational Council on Osteopathic Principles and made available to the schools. Should the schools adopt these guidelines for research training, a real step forward in producing research-oriented students will have been taken. However, 8 years later, it is not clear that most schools have adopted the guidelines. The recommended research curriculum consists of the following:

By the end of osteopathic medical school years 1 and 2, the student should have the following capabilities:

- History of osteopathic research
- Knowledge of research vocabulary
- Ability to do a literature search
- Knowledge of basic statistics
- Understanding of research problems that are uniquely osteopathic (OMT)
- Awareness of support resources available consistent with level of competency expected

By the end of osteopathic medical school years 3 and 4, the student should have the following capabilities:

- Ability to review and summarize journal articles
- Ability to formulate a research question/hypothesis
- Awareness of support resources available consistent with level of competency expected

By the end of postgraduate years 1 through 3, the student should have the following capabilities:

- Understand the process of design and implementation of a research project
- Ability to critique journal articles
- Ability to write a manuscript suitable for publication or a grant application
- Awareness of support resources available consistent with level of competency expected

One of the additional steps that has been taken by the profession is the establishment of a biannual research training workshop, Room to Run, to be held every other year as the OCCTIC meeting. The first was held in 2007 and provided a premiere experience in osteopathic research training to students at all levels of training. When combined with other research training opportunities, this meeting, if continued regularly, will greatly increase the research capabilities of the younger members of the profession. Another very promising development over the recent years is the growth of the SOAR (Student Osteopathic Association of Research). Most osteopathic

schools now have a SOAR chapter that provides opportunities for osteopathic students to discuss research interests and to interact with interested faculty.

Organizational Challenges: Other Osteopathic Institutions

As the profession moves into its fifth research era, it is increasingly evident that the challenges of providing a research basis for osteopathic theory and practice cannot be met by the COMs alone. The establishment of the Center for Osteopathic Research was not an isolated effort of one or more schools. It was an effort spanning several years and with its roots in the early days of the profession with the A. T. Still Research Institute. Several institutions of the profession came together to promote and fund the center's formation, including the AOA, AAO, AACOM, the American College of Osteopathic Family Physicians, and the American Osteopathic Healthcare Association. These and other organizations within the profession have realized the necessity of promoting a research culture in the profession. These institutions, the profession's leaders, and the rank and file of the profession must continue to support (in concept and financially) the development of researchers who understand the osteopathic profession and can apply their skills and intellectual abilities to answering the vital questions posed by this unique philosophy and practice. Without continued support and encouragement from all, a research-friendly atmosphere will not flourish.

There is another vital source of research support now operating in the profession—the various osteopathic foundations, such as the Osteopathic Heritage Foundation of Ohio. These foundations have in the past several years become more involved in actively supporting research projects and symposia. Such support is becoming increasingly vital as a bridge between COM supported pilot research and NIH-supported studies. It is no longer possible to attain NIH major research support without a proven track record of data and research productivity. Often, the only way for a researcher or research team to get to the point of being competitive for NIH funds is to obtain midlevel funding from one of the foundations. The support of several osteopathic foundations has made possible the Multi-Center Osteopathic Pneumonia Study in the Elderly (MOPSE) study, directed by the Texas Osteopathic Research Center. This study was only possible with foundation support.

Collaborative Challenges: Building Research Networks

As the research efforts of the profession mature, clinical trials of the effects and efficacy of osteopathic techniques, osteopathic manipulative treatment, and osteopathic care will move from the pilot study format to full-blown clinical trials. These trials will be expensive and time consuming. A full clinical trial often requires hundreds of subjects and many practitioners. The osteopathic profession is, despite its rapid growth, still a small profession. The conduct of full trials will require collaboration between multiple sites and practitioners. Such collaboration has now been successfully done in the MOPSE study (see above) coordinated by the ORC, which with its mandate to conduct studies on osteopathic manipulative themes, is an appropriate venue for such planning. However, there exist other avenues that can begin the process in preparation for these trials. One such avenue lies in the OPTI networks. These confederations of hospital training sites affiliated with osteopathic colleges provide ready-made resources for pilot studies of collaborative trials. Some OPTIs already have provision for research efforts and research training. The OPTI networks can be valuable testing grounds for collaborative efforts in the next few years. In addition, encouraging practitioners in their office practices to join research networks would lead to more viable clinical trials.

Recent developments in clinical research stimulated by the acquired immunodeficiency syndrome (AIDS) epidemic are also useful models for the osteopathic profession to follow. In the past, there has been little clinical research performed outside major research centers. In response to increasing pressure for clinical data on the AIDS epidemic, there has been an increasing use of smaller neighborhood clinics and solo practitioners to collect data on the disease (Goldstein M, Personal Communication, 1992). It is becoming evident that there is an important role for the practicing physician in collecting data for clinical studies. Studies using this important resource for data collection must be designed to take advantage of the practice of medicine in the office setting so as not to disrupt the daily flow of the practice. However, it is here that the real practice of osteopathic medicine takes place. It is here that there is the best chance to ask such questions as:

- What is the incidence of somatic dysfunction?
- What is its natural course?
- What is the effectiveness of manipulative treatment on it?

The questions of real life in osteopathic medicine can be approached at the office level. Such research must be encouraged. That such research can be accomplished is seen in the recent report from the office of Frymann et al. (12) on the effects of osteopathic care on neurologic development in children. Other office-based studies that include many practitioners would provide important data on the basis for and efficacy of osteopathic care. The recent development by the American Academy of Osteopathy Louisa Burns Research Committee of several data forms may make the collection of office data feasible, especially when they become web based.

Collaborative Challenges: Isolation

The osteopathic profession began in the United States but quickly spread to other countries. Early in the 1900s, osteopathy was established in the United Kingdom; in 1916, an osteopathic school was established there. Currently, there are osteopathic movements in many countries of the world, some nascent, as in Russia, and some well developed, as in the United Kingdom. Although the practitioners of most of these schools are licensed to practice manipulation only, they are valuable resources for research collaboration. In addition, many countries have active allopathic groups who have traditions of manual medicine, and some have become well trained in osteopathic techniques and theory, as is the case in Germany. The International Federation of Manual Medicine, or FIMM, has an active research component. Canadian students of osteopathy, in fact, must complete an extensive research thesis, practically comparable to a U.S. doctoral thesis before becoming certified as diplomats in osteopathy.

The U.S. osteopathic movement has an opportunity to greatly enhance its research efforts by encouraging interactions with these movements. In fact, it may be that, taken together, these organized osteopathic schools outside the United States have more potential for research on efficacy and outcomes than does the U.S. profession. Clearly, there are aspects of osteopathic care that can only be studied in the United States, because only here at present are osteopathic doctors fully licensed physicians; however, technique, reliability, and treatment studies can be collaboratively studied with many other sections of the world osteopathic community. These types of collaboration should not be wasted by isolationism.

CHALLENGES OF RESEARCH DESIGN

The design of osteopathic clinical research faces unique challenges. The design of clinical research is actually in its infancy, beginning

only about 60 to 70 years ago. Clinical research grew up around the testing of drug efficacy, and the gold standard design for such studies is the randomized, placebo-controlled, double-blind (RPCDB) study. The two major challenges facing the osteopathic and manipulative medicine communities are as follows:

1. Is the RPCDB methodology appropriate for studies of osteopathic manipulative treatment?
2. What research designs are appropriate for studies of osteopathic manipulative treatment?

These questions cannot be answered in a vacuum. The design of any study should flow from an understanding of the research question and the available research techniques. Parts of this challenge have been examined in Chapter 70: "Foundations for Osteopathic Research," but other aspects will be discussed here.

Shams and Placebos

One of the most interesting issues facing the design of research in osteopathic manipulative treatment or techniques is whether to use placebo or sham controls and, if so, what to use. The use of placebo is well known and documented in clinical research literature (as is the use of sham controls), but these are being called into question (13,14). The placebo treatment was initially developed for research on the effectiveness of drugs, and entails the delivery of a substance that is, from the standpoint of the patient and physician, indistinguishable from the drug being tested. Such a placebo is often in the form of a capsule that is the same color, size, and weight as the capsule containing the drug, but the placebo contains only inert substances. The patient is given either the drug-containing capsule or the inert-substance capsule, not knowing which is being given. The sham is a procedure given to the patient that has been shown or is thought to have no effect on the symptoms being treated. With both placebos and shams, the intent is to keep the patient from knowing whether he or she is receiving an active or inactive drug or procedure. This should keep the expectations of both the experimental and control groups equal and thus allow the effect of the active ingredient or procedure to be seen, independent of patient expectations.

In the case of drug tests or for testing specific manipulative techniques, placebo and sham controls are entirely appropriate. The intent of such studies is to ascertain the effect of the active ingredient alone. They look at the effect of either a certain molecule (or, more precisely, many millions of molecules) on the natural course of something like a bacterial invasion of the body, or of a particular procedure (such as a lateral recumbent roll) on the course of a particular symptom (15). The patient's expectations and conscious processes are not at issue. The use of placebo or sham procedures as control groups against which the drug or procedure groups can be compared gives the researcher a measure of the effectiveness of the drug or technique alone.

Thus, in the design of manipulative technique research, it seems entirely appropriate to use sham treatment control groups. Here, the rationale is to test the effectiveness of a certain specific technique that is administered in the same way to each patient for presumably the same symptom or symptoms. The treating physician has no leeway in how the maneuver is accomplished, and the patients are screened closely so that the symptoms are much the same from patient to patient.

However, at the heart of osteopathic philosophy is the premise that treatment should be aimed at normalization of function by removing the barriers to the body's ability to optimize its function. Once these barriers are removed, the body can regain its optimal function and return to or maintain health. To think that this is

purely a physiologic function and has nothing to do with conscious processes or the mind (i.e., the patient's expectations, desires, beliefs, and will) is to return to a belief in mind/body dualism holding that the mind has nothing to do with physiologic function, and vice versa. It is to deny the most vital part of the whole equation of health and disease: the patients themselves. In addition, the treating physician is a part of the equation. Both the skill and the manner of the treating physician affect the results of the treatment, because both the patient's tactile and mental perceptions of the physician influence how the patient responds to the treatment.

In osteopathic treatment, the treatment is an interaction between patient and physician, each responding to the other throughout the treatment. The osteopathic physician relies on the very effect that is labeled placebo or expectation in drug testing to help with the alteration he or she is attempting to produce—that of normalized function. The patient's expectation is an important and vital factor in OMT; it must not be cast off as some spurious side effect. It is also a real and unusually safe therapeutic tool. There are few deleterious side effects to positive expectations.

In addition, the use of a sham treatment group in which the patient is exposed to a treatment that is considered ineffective presents another real problem for the evaluation of OMT (again, as contrasted to the evaluation of a particular technique). It is assumed that in the sham control group, the treatment of a body area distant from a particular somatic dysfunction does not influence the resolution of a diagnosed dysfunction being treated in the experimental group. Many available data show that the simple act of touching and moving an individual produces real changes in function and response. The act of manipulative treatment involves touching and moving the patient as an integral part of the process. To compare a manipulation group with some sham group that has also received touch and movement may well lead to an underestimation of the effects of manipulative treatment, unless it can be shown that the sham treatment had no effect on the total mind and body function of the patient.

Thus, initial attempts to evaluate the true effectiveness of manipulative treatment (as opposed to techniques) on either the progression of symptoms or on total body function require the use of a control group that either receives some standard medical therapy not requiring manipulation or the use of a totally untreated control group that would simply undergo the natural course of the malfunction being studied. This could be done by simply requiring control subjects to come to the physician's office for diagnostic measurements. To try to factor out the mental process involved in manipulative treatment is to deny much of the actual treatment. It is akin to studying the effectiveness of a drug by giving only a partial dose.

To study the effects of osteopathic manipulation, one must study osteopathic manipulation as it is given, as an interaction between physician and patient, with all components intact and functioning. To factor out any particular component, such as the so-called hands-on effect, and call it an artifact is to underestimate the effect of manipulative treatment and deny that the natural power of cognitive and recuperative processes is a factor in the effects of OMT. It must be understood that unless the sham treatment has been actually shown to have no effect on any aspect of the patient's function, a study contrasting manipulation with a sham is really comparing one form of treatment with another form of treatment.

Once the overall effects of manipulative treatment have been established, studies can be designed to tease apart the various components of the treatment, including the effects of touching the patient, and so forth. However, to try to parse out various aspects of a complex treatment in the absence of demonstrated effects is both inefficient and impractical. The study of OMT must flow from

the philosophy of osteopathy and not from some other philosophic orientation.

One example of a study using a sham control was published recently by Yelland et al. (16). They compared the effects of active prolotherapy with similar injections of saline on nonspecific low back pain. The results showed no difference between the irritant prolotherapy-injected group and the saline-injected group. Both groups showed the same reduction in low back pain over the 24-month study. In point of fact, it seems likely that no conclusions can be drawn from the study, because there was no way of ascertaining whether the decreased overall pain levels would have occurred anyway or even if the interventions resulted in less pain decrease over the time of the study than would have occurred had nothing been done. The only conclusion that may be able to be drawn is that irritant injections and saline injections cause no different results, but it may be that neither one did anything for nonspecific low back pain. This study shows the problems of assuming that a treatment is a sham (having no effect) without actually testing it against no treatment.

The investigator designing studies of OMT must determine what is really being asked of the study so that the appropriate contrast control can be used. Using the incorrect control may result in underestimation of the effect of manipulative treatment, although the same control may be the appropriate one for evaluation of a manipulative technique. The decision rests on whether the total response of the individual to the interaction between patient and physician is being evaluated or whether manipulative technique is being studied as a procedure. The challenge here is to actively defend the use of appropriate designs for osteopathic manipulative research, and not to be forced into inappropriate designs by preconceived notions of how research is done.

PRIORITY CHALLENGES: WHAT RESEARCH IS MOST IMPORTANT?

Basic Research

Research on the mechanisms underlying osteopathic practice begins with either the theoretical underpinnings of the profession, or clinical observations of practitioners. As an example, Korr (17) followed both theory and clinical observation when beginning his line of research on transsynaptic delivery of proteins from nerve to muscle tissue. The nurturing of tissues by their nerve supply had long been a theme in osteopathic medicine, but almost ignored in other Western traditions. Clinical observations showed that muscles deprived of nerve supply would degenerate, but those only deprived of nerve activity would only atrophy. Korr's research program was driven by osteopathic clinical and theoretical considerations.

Clearly, some of the vital areas in the traditions and clinical experiences of the profession can lead to distinctive basic research programs. Examples of such areas include:

- The interactions between somatic and visceral structures are vital issues that are receiving attention in laboratories now, but are very underresearched.
- How does the mechanoreceptor input from muscle affect sympathetic outflow?
- How does sympathetic activity affect somatic structure and function?
- How can virus and bacterial activity be influenced by sympathetic activity?
- What is the structure and function of the fasciae of the body?

- How do strains in the somatic structures affect visceral function over time?
- What are the effects of various osteopathic procedures on visceral function?

Certainly one of the most basic questions in the area of osteopathic basic research is the prevalence and incidence of the entity known as somatic dysfunction. This is perhaps one of the most pressing and most difficult questions that remain unanswered in the profession. It actually crosses the bounds of basic and clinical areas.

The list of questions generated by osteopathic theory and clinical experience is almost endless. However, to tap these areas, the researcher must be able to see how they apply to the osteopathic experience.

Clinical Research

As long as is the list of questions in the basic sciences flowing from the osteopathic theory and practice, it is perhaps longer in the clinical arena. Various lists of the most important areas of clinical research have been generated, but consensus has not been reached. Areas that seem to be especially critical, although not prioritized, are included here.

Teaching Techniques in Osteopathic Manipulation

The area of research on educational techniques, although not clinical, would provide important information on how to pass on the techniques and skills of osteopathic medicine. Research into how to best teach palpation, recognition of tissues texture alterations, and so forth, is badly needed.

Inter- and Intraexaminer Reliability Studies

One of the basic unknowns in osteopathic medicine (and manual medicine in general) is how to assess and improve the reliability between the examination skills of practitioners, and indeed, how reliable the same individual is when examining the same patient twice. There are studies available on the reliability between examiners of the same patient (e.g., 17,18), but the studies vary widely in quality and findings. In addition to being an important question in terms of how much value can be placed on palpatory findings, studies on the factors influencing the reliability within and between palpators would help inform the teaching of these skills. This is an area that probably should be a priority in the profession and on which several projects are being mounted.

Outcomes and Cost Effectiveness of Osteopathic Manipulative Treatment

Although seemingly obvious, simple outcome studies that look at what happens to patients, without the use of controls, is needed. One such study is under way at present in Maine (the Maine Osteopathic Outcomes Study, or MOOS), and more may be planned. However, with the amount of data collected by state, federal, and private entities, the numbers of epidemiologically related studies that are now possible are immense. Models for these types of studies must be generated more frequently in the profession.

Comparing Osteopathic Treatment Techniques with Other Forms of Manual Medicine

Many other forms of manual medicine exist. How do treatment techniques generated by the osteopathic profession compare with

these? Is a manipulative treatment driven by osteopathic theory more effective than that given by other practitioners of manual medicine? Such questions are not only fascinating, but also vital to understanding the value of osteopathic medicine.

Comparing Different Modalities of Osteopathic Treatment

There are several major treatment modalities used in the profession. How do they compare in outcomes when used on a common disease process? Is a high-velocity/low-amplitude thrust better than a muscle treatment for a sore neck? Comparing one modality with another would produce interesting insights into the potential mechanisms of the different modalities, as well as their efficacy in various conditions.

Effects of Manipulation on a Somatic Dysfunction

Just as the questions of prevalence and incidence of somatic dysfunction are basic to the profession, so are the questions surrounding the actual influence of a manipulative treatment on a well-delineated somatic dysfunction. How do such parameters as chronicity and cause affect the outcome? Although it is assumed that an osteopathic treatment corrects somatic dysfunction, how long does the effect last in chronic cases, and how susceptible is the dysfunction to reoccurrence?

Effects of Manipulation on Diagnosed Disease Entities

This question has been debated for years and is, in fact, a basic question for payment for services. Actually, the list of conditions to target for such research has received much attention. At a recent meeting, several conditions were targeted for special consideration:

- Chronic low back pain
- Headache (type unspecified)
- Asthma
- Otitis media

These conditions have a history of study in and outside the profession, and may be more amenable to tight research designs than many other conditions.

There is a wide range of studies either under way or in planning stages at osteopathic schools and other institutions. All should be encouraged, as each will add to the body of design knowledge about how to do research in osteopathic manipulative treatment. It is likely that a few conditions will have to be selected for full-scale studies due to cost and manpower limitations. Pilot studies will pave the way for selecting those conditions most likely to provide meaningful information on the large-scale effects of osteopathic treatment.

OSTEOPATHIC PHILOSOPHY AND LARGER RESEARCH QUESTIONS

Although these specific areas of research are important, the role of the osteopathic philosophy in shaping even larger questions, and directions of osteopathic research must be mentioned.

Basic to the philosophy and theory of osteopathy is the idea that the body is an integrated functional unit. This unit includes the physical, cognitive, and spiritual aspects of the individual. Indeed, there is a growing body of evidence suggesting positive effects

of spiritual interventions, such as prayer, in the healing process (18–23). How these elements interact within the total individual and with the external environment determine the long-term health status of the person. From the beginning of osteopathic medicine, osteopathic practitioners have held that there was an entity that would adversely affect a person's health status. This entity, which could be palpated and specifically treated with manipulation, was first known as the osteopathic lesion and then, more recently, as somatic dysfunction. In the 1940s and 1950s, Denslow, Korr (24), and their colleagues postulated that a major component of the osteopathic lesion was the facilitated segment. The facilitated segment concept arose from the data gathered by these researchers, which showed that, in most individuals, there was no uniform excitability throughout the spinal cord. The areas of hyperexcitability were shown to react more strongly to afferent input, exposing innervated structures, both visceral and somatic, to increased activation. This break in body unity was postulated to lead to early breakdown and malfunction over time—in short, to disease. Clinical disease was, then, a consequence of earlier body dysfunction. Indeed, this was a data-based theory that truly embodied one of Still's basic insights; that clinical disease was a manifestation of body malfunction rather than a primary event.

DETERIORATION OF NORMAL FUNCTION AS A CENTRAL CONCEPT

That clinical disease is a result of earlier deterioration of normal function is central to osteopathic philosophy. It is perhaps best manifest in the treatment of somatic dysfunction, an entity not recognized by most medical practitioners as a clinical entity at all. Why treat it? Because it is the beginning of disease, the start of body breakdown. To treat the root of disease would seem to be more cost effective than waiting until the final breakdown of clinical disease has occurred before beginning treatment.

OTHER ROLES FOR SOMATIC DYSFUNCTION

Given this view, osteopathic research should be aimed at elucidating the relationships between disturbances of body function and health status:

- How does the presence of somatic dysfunction predict the health status of the individual?
- What is the incidence of serious somatic dysfunction and its natural history?
- What environmental and lifestyle attributes seem to contribute to the incidence of somatic dysfunction?
- How does lifestyle contribute to the incidence of somatic dysfunction in old age?
- Flowing from these questions are even larger questions that should be at the forefront of osteopathic thinking.
- What is the contribution of early lifestyle or events that happen to the person and the health status of the individual in old age?
- What regime of manipulative treatment in early life will contribute most to deterring the deterioration of health usually associated with old age?
- More simply, why are some very old people vital and healthy and others completely overtaken by deterioration and disease?
- What role does long-lasting somatic dysfunction play in the presence or absence of vitality in old age?

These questions are complex and not easily answered. The critical point is that at least some research of the profession should take

as its starting point body unity and the concept that the start of disease is the deterioration of that functional unity, not a bacterial or viral invasion.

INTEGRATION AND SELF-REGULATION IN HEALTH

These questions suggest several important areas of research for the osteopathic profession. In the basic sciences, increasing attention must be paid to understanding the integration of body systems and what can cause the fine-tuned integration of body function to deteriorate. The capacity of the body to self-regulate (homeostasis) and the limits of that capacity in both the short term and the long term must be better understood. Research aimed at elucidating the fine control and adaptation of body function would be especially useful. Integration of basic science data with data from studies of cognitive function gives a greater understanding of the role of the physician in the health maintenance process. A greater understanding of the effects of afferent input and cognitive function on the immune system, and how manipulative treatment can affect this system, would be useful.

HEALTH BENEFITS OF MANIPULATIVE TREATMENT

Within the clinical research areas, there must be studies of the efficacy of manipulative techniques and manipulative treatment. Measurements of the effects of manipulation on specific disease entities, such as those listed above, need to be carried out to demonstrate that manipulation can be used effectively in treating specific disease processes. To rely on such demonstration studies to show the most significant benefits of manipulation would, however, be unwise. The most beneficial and lasting effects of manipulation and, indeed, of osteopathic care should be searched for in the effects on total functional capacity of individuals and in their long-term health status. The current health care system is preoccupied with the treatment of disease, especially in the chronic degeneration of old age. It is by no means clear that the chronic diseases commonly associated with old age are inevitable. What are the enabling or protective roles of early and continued normal body function in the aging process? Osteopathy is ideally suited by its philosophy and clinical experience to look at the effects of early disruptions of body unity on the deterioration of old age. This is a golden opportunity for osteopathic research.

TOTAL NATURE OF SOMATIC DYSFUNCTION

Clinical research should continue to look at the effects of manipulation on specific disease processes. Such studies can be effectiveness studies, such as the use of manipulative treatment in low back and chronic pain syndromes. These studies could have fairly quick and valuable outcomes for the profession. Other less specific studies, such as the effects of manipulation on sympathetic tone, vasomotor reactivity, and muscle spasticity, contribute to an understanding of the more general effects of manipulation on body function. Studies of the effects of somatic dysfunction and its etiology, prevalence, and contributions to the long-term health of the individual form a solid base for a greater understanding of the fundamental dynamics of health and disease. Investigations of the effects of manipulation on somatic dysfunction and of osteopathic care on old age health status are probably the most important area of study to which the profession can aspire.

SUMMARY

Northup (1) wisely noted that the future of the profession rested in the decisions and integrity of organized osteopathy. Organized osteopathy now must rise to the challenge of mounting and sustaining a research enterprise that will test the central tenets and beliefs of the profession. These studies must be done on the playing fields of the profession, not on those of other professions. The studies must test the profession's questions and assumptions and be interpreted by those knowledgeable in the theories and practices of osteopathic medicine, not by others. The risk of allowing others to do the studies or interpret the results from other points of view is simply unacceptable. The future of the profession now rests as much on its research endeavors as on its teaching and clinical endeavors. The three legs of the profession's stool are equal, and all are vital.

By closely following the basic philosophy of osteopathy and the insights from its years of clinical experience, the research efforts of the profession can truly add to the most beneficial aspects of health care to which osteopathy is fundamentally dedicated: the maintenance of health and optimal function of the total person throughout life.

GLOSSARY OF OSTEOPATHIC TERMINOLOGY

The result of many years' work by members of the Educational Council on Osteopathic Principles (ECOP), the *Glossary of Osteopathic Terminology* (Glossary) was first published in the *Journal of the American Osteopathic Association* April 1981 (No. 80, pages 552–567). The appearance of *Foundations for Osteopathic Medicine*, Ward RC (ed.); Williams & Wilkins, Baltimore, MD led to inclusion of the Glossary in the first edition (1997, pp. 1126–1140) and the second edition (2003, pp. 1229–1253).

The revision process for the Glossary is ongoing, conducted by members of the ECOP Glossary Review Committee. Definitions are sought which are uniquely osteopathic in their origin or common word usage. Other considerations include distinctiveness in the osteopathic usage of a common word, and/or importance in describing osteopathic principles, philosophy, and osteopathic manipulative treatment. The Glossary is expected to be useful to students and practitioners of osteopathic medicine, and helpful to authors and other professionals in understanding and making proper use of osteopathic vocabulary. The most current and revised

version is available on two websites: American Association of Colleges of Osteopathic Medicine (AACOM) in PDF format at www.aacom.org and the American Osteopathic Association (AOA) at www.osteopathic.org.

The April 2009 glossary review was performed by John Glover, D.O., F.A.A.O., ECOP Chairman, Lisa DeStefano, D.O., William Devine, D.O., Walter Ehrenfeuchter, D.O., F.A.A.O., David Eland, D.O., F.A.A.O., Heather Ferrill, D.O., Tom Fotopoulos, D.O., Eric Gish, D.O., Rebecca Giusti, D.O., John Glover, D.O., F.A.A.O., Laura Griffin, D.O., F.A.A.O., David Harden, D.O., Kurt Heinking, D.O., F.A.A.O., Jan Hendryx, D.O., F.A.A.M.A., Kendi Hensel, D.O., Ph.D., Robert Kappler, D.O., F.A.A.O., Jon Kirsch, D.O., Bradley Klock, D.O., F.A.A.O., William Lemley, D.O., F.A.A.O., David Mason, D.O., F.A.C.O.F.P., William Morris, D.O., Evan Nicholas, D.O., Paul Rennie, D.O., F.A.A.O., Mark Sandhouse, D.O., Harriet Shaw, D.O., Karen Snider, D.O., Melicien Tettambel, D.O., F.A.A.O., Greg Thompson, D.O., Kevin Treffer, D.O.

GLOSSARY

A

abbreviations (types of osteopathic manipulative treatment):

ART: articular treatment
BLT: balanced ligamentous tension treatment
CR: osteopathy in the cranial field
CS: counterstrain treatment
D: direct treatment
DIR: direct treatment
FPR: facilitated positional release treatment
HVLA: high velocity/low amplitude treatment
I: indirect treatment
IND: indirect treatment
INR: integrated neuromusculoskeletal release treatment
LAS: ligamentous articular strain treatment
ME: muscle energy treatment *MFR*: myofascial release treatment
NMM-OMM: neuromusculoskeletal medicine
OCF: osteopathy in the cranial field/cranial treatment
OMTh: osteopathic manipulative therapy (non-US terminology)
OMT: osteopathic manipulative treatment
PINS: progressive inhibition of neuromuscular structures
ST: soft tissue treatment
VIS: visceral manipulative treatment

accessory joint motions: See *secondary joint motion*.

accessory movements: Movements used to potentiate, accentuate, or compensate for an impairment in a physiologic motion (e.g., the movements needed to move a paralyzed limb).

accommodation: A self-reversing and nonpersistent adaptation.

active motion: See *motion, active*.

acute somatic dysfunction: See *somatic dysfunction, acute*.

allopathy: A therapeutic system in which a disease is treated by producing a second condition that is incompatible with or antagonistic to the first (*Stedman's*).

allopath, allopathic physician: 1. A term originated by Samuel Hahnemann, MD, to distinguish homeopaths from physicians practicing traditional/orthodox medicine. 2. In common usage, a general term used to differentiate MDs (medical doctors) from other schools of medicine. See *allopathy, osteopathic physician*.

anatomical barrier: See *barrier (motion barrier)*.

angle:

Ferguson a., See *angle, lumbosacral*.

lumbolumbar lordotic a., an objective quantification of lumbar lordosis typically determined by measuring the angle between the superior surface of the second lumbar vertebra and the inferior surface of the fifth lumbar vertebra; best measured from a standing lateral x-ray film (Fig. 1).

lumbosacral a., represents the angle of the lumbosacral junction as measured by the inclination of the superior surface of the first sacral vertebra to the horizontal (this is actually a sacral angle); usually measured from standing lateral x-ray films; also known as Ferguson angle (Fig. 2).

lumbosacral lordotic a., an objective quantification of lumbar lordosis typically determined by measuring the angle between the superior surface of the second lumbar vertebra and the superior surface of the first sacral segment; best measured from a standing lateral x-ray film (Fig. 3).

anterior component: A positional descriptor used to identify the side of reference when rotation of a vertebra has occurred; in a condition of right rotation, the left side is the anterior component; usually refers to the less prominent transverse process; See also *posterior component*.

anterior compression test: See *ASIS (anterior superior iliac spine) compression test*.

Figure 1 Lumbolumbar angle (L2-L5)

Figure 2 Lumbosacral angle (S1-horizon) (Ferguson's angle).

Figure 3 Lumbosacral lordotic angle.

anterior iliac rotation: See *ilium, somatic dysfunction of, anterior (forward) innominate (iliac) rotation*.

anterior nutation, See *nutation*.

anterior rib: See *rib somatic dysfunction, inhalation rib dysfunction*.

ART: See *TART*.

articular pillar: 1. Refers to the columnar arrangement of the articular portions of the cervical vertebrae. 2. Those parts of the lateral arches of the cervical vertebrae that contain a superior and inferior articular facet.

articulation: 1. The place of union or junction between two or more bones of the skeleton. 2. The active or passive process of moving a joint through its permitted anatomic range of motion. See also *osteopathic manipulative treatment, articular treatment (ART) system*.

Figure 4 ASIS compression test.

articular pop: The sound made when cavitation occurs in a joint. See also *cavitation*.

articular technique: See also *technique*. See *osteopathic manipulative treatment, articular treatment (ART) system*.

asymmetry: Absence of symmetry of position or motion; dissimilarity in corresponding parts or organs on opposite sides of the body that are normally alike; of particular use when describing position or motion alteration resulting from somatic dysfunction. NB: *This term is part of the TART acronym for an osteopathic somatic dysfunction.*

axis: 1. An imaginary line about which motion occurs. 2. The second cervical vertebra. 3. One component of an axis system.

axis of rib motion: See *rib motion, axis*.

ASIS (anterior superior iliac spine) compression test: 1. A test for lateralization of somatic dysfunction of the sacrum, innominate or pubic symphysis. 2. Application of a force through the ASIS into one of the pelvic axes to assess the mechanics of the pelvis. See also *sacral motion, axis of* (Fig. 4).

axis of sacral motion: See *sacral motion, axis of*.

axoplasmic flow: See *axoplasmic transport*.

axoplasmic transport: The antegrade movement of substances from the nerve cell along the axon toward the terminals, and the retrograde movement from the terminals toward the nerve cell.

B

backward bending: Opposite of forward bending. See *extension*.

backward bending test: 1. This test discriminates between forward and backward sacral torsion/rotation. 2. This test discriminates between unilateral sacral flexion and unilateral sacral extension.

backward torsion: See *sacrum, somatic dysfunctions of, backward torsions*.

balanced ligamentous tension technique: See *osteopathic manipulative treatment, balanced ligamentous tension*. See also *osteopathic manipulative treatment, ligamentous articular strain*.

barrier (motion barrier): The limit to motion; in defining barriers, the palpatory end-feel characteristics are useful (Fig. 5).

anatomic b., the limit of motion imposed by anatomic structure; the limit of passive motion.

elastic b., the range between the physiologic and anatomic barrier of motion in which passive ligamentous stretching occurs before tissue disruption.

pathologic b., a restriction of joint motion associated with pathologic change of tissues (example: osteophytes). See also *barrier, restrictive b.*

physiologic b., the limit of active motion.

restrictive b., a functional limit that abnormally diminishes the normal physiologic range.

batwing deformity: See *transitional vertebrae, sacralization*.

bind: Palpable resistance to motion of an articulation or tissue. Synonym: resistance. Antonyms: ease, compliance, resilience.

biomechanics: Mechanical principles applied to the study of biological functions; the application of mechanical laws to living structures; the study and knowledge of biological function from an application of mechanical principles.

Concepts Regarding Joint Motion in a Single Plane

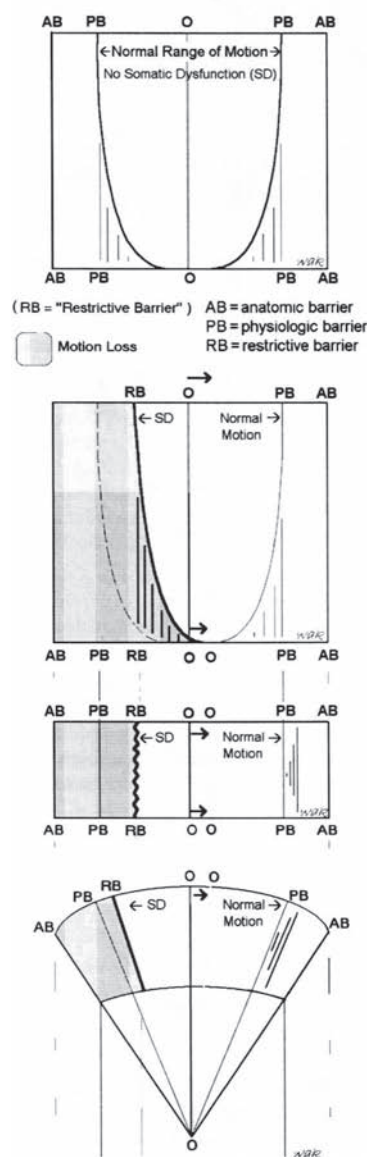

Figure 5 Somatic dysfunction in a single plane: three methods illustrating the "restrictive barrier" (the restrainer): AB, anatomic barrier; PB, physiologic barrier; RB, restrictive barrier; SD, somatic dysfunction (From *Foundations for Osteopathic Medicine*, Baltimore, Williams & Wilkins, 1997:484.)

body unity: One of the basic tenets of the osteopathic philosophy; the human being is a dynamic unit of function; See also *osteopathic philosophy*.

bogginess: A tissue texture abnormality characterized principally by a palpable sense of sponginess in the tissue, interpreted as resulting from congestion due to increased fluid content.

bucket handle rib motion: See *rib motion, bucket handle*.

C

caliper rib motion: See *rib motion, caliper rib motion*.

caudad: Toward the tail or inferiorly.

caught in inhalation: See *inhalation rib dysfunction*.

caught in exhalation: See *exhalation rib dysfunction*.

cavitation: The formation of small vapor and gas bubbles within fluid caused by local reduction in pressure. This phenomenon is believed to produce an audible "pop" in certain forms of OMT.

cephalad: Toward the head.

cephalad pubic dysfunction: See *pubic bone, somatic dysfunctions of, superior pubic shear*.

cerebrospinal fluid, fluctuation of: A description of the hypothesized action of cerebrospinal fluid with regard to the craniosacral mechanism. cervicolumbar reflex: See *reflex, cervicolumbar r.*

Chapman reflex: 1. A system of reflex points that present as predictable anterior and posterior fascial tissue texture abnormalities (plaque-like changes or stringiness of the involved tissues) assumed to be reflections of visceral dysfunction or pathology. 2. Originally used by Frank Chapman, DO, and described by Charles Owens, DO.

chronic somatic dysfunction: See *somatic dysfunction, chronic*.

circumduction: 1. The circular movement of a limb. 2. The rotary movement by which a structure is made to describe a cone, the apex of the cone being a fixed point (e.g., the circular movement of the shoulder).

combined technique: See *osteopathic manipulative treatment, combined method*.

common compensatory pattern: See *fascial patterns, common compensatory pattern*.

compensatory fascial patterns: See *fascial patterns, common compensatory pattern*.

complete motor asymmetry: Asymmetry of palpatory responses to all regional motion inputs including rotation, translation and active respiration.

compliance: 1. The ease with which a tissue may be deformed. 2. Direction of ease in motion testing.

compression: 1. Somatic dysfunction in which two structures are forced together. 2. A force that approximates two structures.

conditioned reflex: See *reflex, conditioned r.*

contraction: Shortening and/or development of tension in muscle.

concentric c., contraction of muscle resulting in approximation of attachments.

eccentric c., lengthening of muscle during contraction due to an external force.

isokinetic c., 1. A concentric contraction against resistance in which the angular change of joint motion is at the same rate. 2. The counterforce is less than the patient force.

isolytic c., 1. A form of eccentric contraction designed to break adhesions using an operator-induced force to lengthen the muscle. 2. The counterforce is greater than the patient force.

isometric c., 1. Change in the tension of a muscle without approximation of muscle origin and insertion. 2. Operator force equal to patient force.

isotonic c., 1. A form of concentric contraction in which a constant force is applied. 2. Operator force less than patient force.

contracted muscle: The physiological response to a neuromuscular excitation. See also *contractured muscle*.

contracture: A condition of fixed high resistance to passive stretch of a muscle, resulting from fibrosis of the tissues supporting the muscles or the joints, or from disorders of the muscle fibers.

Dupuytren c., shortening, thickening and fibrosis of the palmar fascia, producing a flexion deformity of a finger (*Dorland's*).

contractured muscle: histological change substituting noncontractile tissue for muscle tissue, which prevents the muscle from reaching normal relaxed length. See also *contracted muscle*.

core link: The connection of the spinal dura mater from the occiput at the foramen magnum to the sacrum. It coordinates the synchronous motion of these two structures.

coronal plane: See *plane, frontal*.

costal dysfunction: See *rib, dysfunction*.

counternutation: Posterior movement of the sacral base around a transverse axis in relation to the ilia. See also *nutation*.

counterstrain technique: See *osteopathic manipulative treatment, counterstrain*.

cranial manipulation: See *osteopathic manipulative treatment, cranial manipulation*.

cranial rhythmic impulse (CRI): 1. A palpable, rhythmic fluctuation believed to be synchronous with the primary respiratory mechanism. 2. Term coined by John Woods, DO, and Rachel Woods, DO.

cranial technique: See *osteopathic manipulative treatment, osteopathy in the cranial field*. See also *primary respiratory mechanism*.

craniosacral manipulation: See *osteopathic manipulative treatment, osteopathy in the cranial field*.

craniosacral mechanism: 1. A term used to refer to the anatomical connection between the occiput and the sacrum by the spinal dura mater. 2. A term coined by William G. Sutherland, DO. See also *extension, craniosacral extension and flexion, craniosacral flexion*.

C-SPOMM: Certification Special Proficiency in Osteopathic Manipulative Medicine. Granted by the American Osteopathic Association through the American Osteopathic Board of Special Proficiency in Osteopathic Manipulative Medicine from 1989 through 1999. See also *NMM-OMM*.

creep: The capacity of fascia and other tissue to lengthen when subjected to a constant tension load resulting in less resistance to a second load application.

CV-4: See *osteopathic manipulative treatment, CV-4*.

D

Dalrymple treatment: See *osteopathic manipulative treatment, pedal pump*.

decompensation: A dysfunctional, persistent pattern, in some cases reversible, resulting when homeostatic mechanisms are partially or totally overwhelmed.

depressed rib: See *rib somatic dysfunction, exhalation rib dysfunction*.

dermatome: 1. The area of skin supplied by cutaneous branches from a single spinal nerve. (Neighboring dermatomes may overlap.) 2. Cutis plate; the dorsolateral part of an embryonic somite (Figs. 6 and 7).

diagnostic palpation: See *palpatory diagnosis*.

diagonal axis: See *sacral, oblique axis, diagonal*.

direct method (technique): See *osteopathic manipulative treatment, direct treatment*.

Figure 6 Dermatomal map (anterior). (Modified from Agur AMR, *Grant's Atlas of Anatomy*, 9th ed. Baltimore, Md: Williams & Wilkins; 1991:37).

Figure 7 Dermatomal map (posterior). (Modified from Agur AMR, *Grant's Atlas of Anatomy*, 9th ed. Baltimore, Md: Williams & Wilkins; 1991:37).

DO: 1. Doctor of Osteopathy (graduate of a school accredited by the American Osteopathic Association). 2. Doctor of Osteopathic Medicine (graduate of a school accredited by the American Osteopathic Association). 3. Diplomate in Osteopathy (The first degree granted by American School of Osteopathy). 4. Diplomate of Osteopathy, a degree granted by some schools of osteopathy outside the United States (not accredited by the American Osteopathic Association).

drag: See *skin drag*.

E

ease: Relative palpable freedom of motion of an articulation or tissue. Synonyms: compliance, resilience. Antonyms: bind, resistance.

easy normal: See *neutral, definition number 2*.

-ed: A suffix describing status, position, or condition (e.g., extended, flexed, rotated, restricted).

effleurage: Stroking movement used to move fluids.

elastic deformation: Any recoverable deformation. See also *plastic deformation*.

elasticity: Ability of a strained body or tissue to recover its original shape after deformation. See also *plasticity and viscosity*.

elevated rib: See *rib somatic dysfunction, inhalation rib dysfunction*. See also *rib motion, exhalation rib restriction*.

end feel: Perceived quality of motion as an anatomic or physiologic restrictive barrier is approached.

enthesitis: 1. Traumatic disease occurring at the insertion of muscles where recurring concentration of muscle stress provokes inflammation with a strong tendency toward fibrosis and calcification (*Stedman's*). 2. Inflammation of the muscular or tendinous attachment to bone (*Dorland's*).

ERS: A descriptor of spinal somatic dysfunction used to denote a combination extended (E), rotated (R), and sidebent (S) vertebral position.

ERS left, somatic dysfunction in which the vertebral unit is extended, rotated and sidebent left; usually preceded by a designation of the vertebral unit(s) involved (e.g., T5 ERS left or T5 ERLSL).

ERS right, somatic dysfunction in which the vertebral unit is extended, rotated and sidebent right; usually preceded by a designation of the vertebral unit(s) involved (e.g., C3-5 ERS right or C3-5 ERRSR).

exaggeration method: See *osteopathic manipulative treatment, exaggeration method*.

exaggeration technique: See *osteopathic manipulative treatment, exaggeration technique*.

exhaled rib: (Archaic) using positional (static) diagnosis. See *rib somatic dysfunction, exhalation rib dysfunction*.

exhalation rib dysfunction: See *rib somatic dysfunction, exhalation rib dysfunction*.

exhalation rib restriction: See *rib motion, exhalation rib restriction*. See also *rib somatic dysfunction, inhalation rib dysfunction*.

exhalation strain: See *rib somatic dysfunction, exhalation rib dysfunction*.

extension: 1. Accepted universal term for backward motion of the spine in a sagittal plane about a transverse axis; in a vertebral unit when the superior part moves backward. 2. In extremities, it is the straightening of a curve or angle (biomechanics). 3. Separation of the ends of a curve in a spinal region; See *extension, regional extension*.

craniosacral e., motion occurring during the cranial rhythmic impulse when the sphenobasilar symphysis descends and sacral base moves anteriorly (Fig. 8).

regional e., historically, the straightening in the sagittal plane of a spinal region; also called Fryette's regional extension (Fig. 9).

sacral e., posterior movement of the base of the sacrum in relation to the ilia (Fig. 10). See also *flexion, sacral flexion*.

Figure 8 Craniosacral extension.

Figure 9 Regional extension.

Figure 10 Sacral extension.

Figure 12 Uncommon compensatory fascial pattern (Zink).

extrinsic corrective forces: Treatment forces external to the patient that may include operator effort, effect of gravity, mechanical tables, etc. See also *intrinsic corrective forces*.

F

FAAO: 1. Fellow of American Academy of Osteopathy. 2. This fellowship is an earned postdoctoral degree conferred by the American Academy of Osteopathy. Those who earn the FAAO degree must have demonstrated their commitment to osteopathic principles and practice through teaching, writing, and professional service, performed at the highest level of professional and ethical standards.

facet asymmetry: Configuration in which the structure, position and/or motion of the facets are not equal bilaterally. See also *facet symmetry and tropism, facet*.

facet symmetry: Configuration in which the structure, position and/or motion of the facets are equal bilaterally. See also *facet asymmetry and symmetry*.

facilitated positional release: See *osteopathic manipulative treatment, facilitated positional release*.

facilitated segment: See *spinal facilitation*.

facilitation: See *spinal facilitation*.

fascial patterns: 1. Systems for classifying and recording the preferred directions of fascial motion throughout the body. 2. Based on the observations of J. Gordon Zink, DO, and W. Neidner, DO.

common compensatory pattern (CCP), the specific finding of alternating fascial motion preference at transitional regions of the body described by Zink and Neidner (Fig. 11).

uncommon compensatory pattern, the finding of alternating fascial motion preference in the direction opposite that of the common compensatory pattern described by Zink and Neidner (Fig. 12).

uncompensated fascial pattern, the finding of fascial preferences that do not demonstrate alternating patterns of findings at transitional regions. Because they occur following stress or trauma, they tend to be symptomatic.

Figure 11 Common compensatory fascial pattern (Zink).

fascial release technique: See *osteopathic manipulative treatment, myofascial release*.

fascial unwinding: See *osteopathic manipulative treatment, fascial unwinding*.

Ferguson angle: See *angle, lumbosacral*.

flexion: 1. Accepted universal term for forward motion of the spine, in its sagittal plane about a transverse axis, where the superior part moves forward. 2. In the extremities, it is the approximation of a curve or angle (biomechanics). 3. Approximation of the ends of a curve in a spinal region; also called Fryette regional flexion. See *flexion, regional flexion*.

craniosacral flexion, motion occurring during the cranial rhythmic impulse, when the sphenobasilar symphysis ascends and the sacral base moves posteriorly. (Fig. 13)

regional f., historically, is the approximation of the ends of a curve in the sagittal plane of the spine; also called Fryette regional flexion. See *flexion*. (Fig. 14)

sacral f., anterior movement of sacral base in relation to the ilia (Fig. 15). See also *extension, sacral extension*.

flexion left: See *sidebending*.

flexion right: See *sidebending*.

flexion tests: Tests for iliosacral or sacroiliac somatic dysfunction.

seated flexion test, a screening test that determines the side of sacroiliac somatic dysfunction (motion of the sacrum on the ilium).

standing flexion test, a screening test that determines the side of iliosacral somatic dysfunction (motion of ilium on the sacrum).

forward bending: Reciprocal of backward bending. See *flexion*.

forward torsions: See *sacrum, somatic dysfunctions of, forward torsions*.

FRS: A descriptor of spinal somatic dysfunction used to denote a combination flexed (F), rotated (R), and sidebent (S) vertebral position.

FRS left, somatic dysfunction in which the vertebral unit is flexed, rotated and sidebent left; usually preceded by a designation of the vertebral unit(s) involved (e.g., T5 FRS left or T5 FRLSL).

Figure 13 Craniosacral flexion.

Figure 14 Regional flexion.

Figure 15 Sacral flexion.

FRS right, somatic dysfunction in which the vertebral unit is flexed, rotated and sidebent right; usually preceded by a designation of the vertebral unit(s) involved (e.g., C3-5 FRS right or C3-5 FRRSR).

frontal plane: See *plane, frontal*.

Fryette laws: See *laws, Fryette*. See *physiologic motion of the spine*.

Fryette principles: See *physiologic motion of the spine*.

Fryette regional extension: See *extension, regional extension*.

Fryette regional flexion: See *flexion, regional flexion*.

FSR: A descriptor of spinal somatic dysfunction used to denote a combination flexed (F), sidebent (S), and rotated (R) vertebral position. See *FRS*.

functional method: See *osteopathic manipulative treatment, functional method*.

functional technique: See *osteopathic manipulative treatment, functional method*.

G

gait: a forward translation of the body's center of gravity by bipedal locomotion. (*DeLisa*)

Galbreath treatment: See *osteopathic manipulative treatment, mandibular drainage*.

gravitational line: Viewing the patient from the side, an imaginary line in a coronal plane which, in the theoretical ideal posture, starts slightly anterior to the lateral malleolus, passes across the lateral condyle of the knee, the greater trochanter, through the lateral head of the humerus at the tip of the shoulder to the external auditory meatus; if this were a plane through the body, it would intersect the middle of the third lumbar vertebra and the anterior one third of the sacrum. It is used to evaluate

Figure 16 Gravitational line.

the A-P (anterior-posterior) curves of the spine. See also *mid-malleolar line* (Fig. 16).

H

habituation: Decreased physiologic response to repeated stimulation.

health: Adaptive and optimal attainment of physical, mental, emotional, spiritual and environmental well-being.

hepatic pump: See *osteopathic manipulative treatment, hepatic pump*.

high velocity/low amplitude technique (HVLA): See *osteopathic manipulative treatment, high velocity/low amplitude technique (HVLA)*.

hip bone: See *innominate*. See also *innominate, somatic dysfunctions of*.

homeostasis: 1. Maintenance of static or constant conditions in the internal environment. 2. The level of well-being of an individual maintained by internal physiologic harmony that is the result of a relatively stable state or equilibrium among the interdependent body functions.

homeostatic mechanism: A system of control activated by negative feedback (*Dorland's*).

Hoover technique: See *osteopathic manipulative treatment, Hoover technique*.

hysteresis: During the loading and unloading of connective tissue, the restoration of the final length of the tissue occurs at a rate and to an extent less than during deformation (loading). These differences represent energy loss in the connective tissue system. This difference in viscoelastic behavior (and energy loss) is known as hysteresis (or "stress-strain"). (*Foundations, 2nd ed, p. 1158*).

hypertonicity: 1. A condition of excessive tone of the skeletal muscles. 2. Increased resistance of muscle to passive stretching.

I

ILA: See *sacrum, inferior lateral angle of*.

ilia: The plural of ilium. See *ilium*.

ilial compression test: See *ASIS compression test*.

ilial rocking test: See *ASIS compression test*.

iliosacral motion: Motion of one innominate (ilium) with respect to the sacrum. Iliosacral motion is part of pelvic motion during the gait cycle.

iliosacral dysfunction: See *innominate somatic dysfunctions*.

ilium: the expansive superior portion of the innominate (hip bone or os coxae).

indirect method: See *osteopathic manipulative treatment, indirect method*.

inferior ilium: See *innominate, somatic dysfunctions of, inferior innominate shear.*

inferior lateral angle (ILA) of the sacrum: See *sacrum, inferior lateral angle.*

inferior pubis: See *pubic bone, somatic dysfunctions of, inferior pubic shear.*

inferior transverse axis: See *sacral motion axis, inferior transverse axis.*

inhalation rib: See *rib somatic dysfunction, inhalation rib dysfunction.*

inhalation rib restriction: See *rib somatic dysfunction, inhalation rib dysfunction.*

inhalation strain: See *rib somatic dysfunction, inhalation rib dysfunction.*

inhibition: See *osteopathic manipulative treatment, inhibitory pressure technique.*

inhibitory pressure technique: See *osteopathic manipulative treatment, inhibitory pressure technique.*

innominate: The os coxae is a large irregular shaped bone that consists of three parts: ilium, ischium and pubis, which meet at the acetabulum, the cup shaped cavity for the head of the femur at the hip (femoroacetabular) joint. Also called the innominate bone or pelvic bone. See also *hip bone.*

innominate rotation: Rotational motion of one innominate bone relative to the sacrum on the inferior transverse axis.

innominate somatic dysfunctions: anterior innominate rotation, a somatic dysfunction in which the anterior superior iliac spine (ASIS) is anterior and inferior to the contralateral landmark. The innominate (os coxae) moves more freely in an anterior and inferior direction, and is restricted from movement in a posterior and superior direction (Fig. 17).

downslipped innominate, See *inferior innominate shear.*

inferior innominate shear, a somatic dysfunction in which the anterior superior iliac spine (ASIS) and posterior superior iliac spines (PSIS) are inferior to the contralateral landmarks. The innominate (os coxae) moves more freely in an inferior direction, and is restricted from movement in a superior direction (Fig. 18).

Figure 17 Anterior right innominate. Forced anterior rotation can also result in an inferior pubic shear.

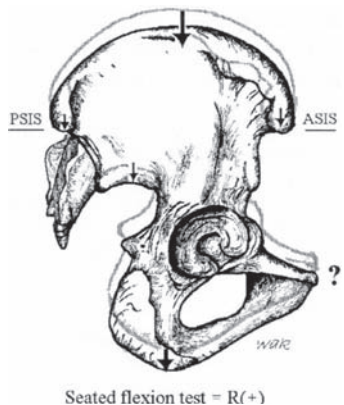

Figure 18 Right inferior innominate shear. This also may or may not result in an inferior pubic shear.

inflared innominate, a somatic dysfunction of the innominate (os coxae) resulting in medial positioning of the anterior superior iliac spine (ASIS). The innominate moves more freely in a medial direction, and is restricted from movement in a lateral direction (Fig. 19).

outflared innominate, a somatic dysfunction of the innominate (os coxae) resulting in lateral positioning of the anterior superior iliac spine (ASIS). The innominate moves more freely in a lateral direction, and is restricted from movement in a medial direction (Fig. 20).

posterior innominate rotation, a somatic dysfunction in which the anterior superior iliac spine (ASIS) is posterior and superior to the contralateral landmarks. The innominate (os coxae) moves more freely in a posterior and superior direction, and is restricted from movement in an anterior and inferior direction (Fig. 21).

Figure 19 Inflared right innominate.

Figure 20 Outflared right innominate.

Figure 21 Right posterior innominate. Forced posterior rotation may or may not result in a superior pubic shear.

Figure 22 Right superior innominate shear. This also may or may not result in a superior pubic shear.

superior innominate shear, a somatic dysfunction in which the anterior superior iliac spine (ASIS) and posterior superior iliac spines (PSIS) are superior to the contralateral landmarks. The innominate (os coxae) moves more freely in a superior direction, and is restricted from movement in an inferior direction (Fig. 22).

upslipped innominate, See *superior innominate shear*.

integrated neuromusculoskeletal release: See *osteopathic manipulative treatment, integrated neuromusculoskeletal release*.

intersegmental motion: Designates relative motion taking place between two adjacent vertebral segments or within a vertebral unit that is described as the upper vertebral segment moving on the lower.

intrinsic corrective forces: Voluntary or involuntary forces from within the patient that assist in the manipulative treatment process. See also *extrinsic corrective forces*.

isokinetic exercise: Exercise using a constant speed of movement of the body part.

isolytic contraction: See *contraction, isolytic c.*

isometric contraction: See *contraction, isometric c.*

isotonic contraction: See *contraction, isotonic c.*

J

Jones technique: See *osteopathic manipulative treatment, counterstrain*.

junctional region: See *transitional region*.

K

key lesion: The somatic dysfunction that maintains a total dysfunction pattern including other secondary dysfunctions.

kinesthesia: The sense by which muscular motion, weight, position, etc. are perceived.

kinesthetic: Pertaining to kinesthesia.

kinetics: The body of knowledge that deals with the effects of forces that produce or modify body motion.

klapping: Striking the skin with cupped palms to produce vibrations with the intention of loosening material in the lumen of hollow tubes or sacs within the body, particularly the lungs.

kneading: A soft tissue technique that utilizes an intermittent force applied perpendicular to the long axis of the muscle.

kyphoscoliosis: A spinal curve pattern combining kyphosis and scoliosis. See also *kyphosis*. See also *scoliosis*.

kyphosis: 1. The exaggerated (pathologic) A-P curve of the thoracic spine with concavity anteriorly. 2. Abnormally increased convexity in the curvature of the thoracic spine as viewed from the side (*Dorland's*).

kyphotic: Pertaining to or characterized by kyphosis.

L

lateral flexed vertebral body: See *sidebent*.

lateral flexion: Also called lateroflexion. See *sidebending*.

lateral masses (of the atlas): The most bulky and solid parts of the atlas that support the weight of the head.

lateroflexion: See *sidebending*.

law:

Fryette I., of motion, See *physiologic motion of the spine*.

Head I., when a painful stimulus is applied to a body part of low sensitivity (e.g., viscus) that is in close central connection with a point of higher sensitivity (e.g., soma), the pain is felt at the point of higher sensitivity rather than at the point where the stimulus was applied.

Lovett I., An observed association between the superior and inferior vertebrae, which are paired two by two. The cervical and superior thoracic biomechanics act in a synchronous manner with the lumbar and inferior thoracic biomechanics. For example, if C1 is in a right posterior positional lesion, L5 also moves into a right posterior position. In this case, L5 is the "Lovett partner" of C1. The treatment of L5 helps to stabilize C1 and the skull by changing the lines of gravity (French usage).

Sherrington I., 1. Every posterior spinal nerve root supplies a specific region of the skin, although fibers from adjacent spinal segments may invade such a region. 2. When a muscle receives a nerve impulse to contract, its antagonist receives, simultaneously, an impulse to relax. (These are only two of Sherrington's contributions to neurophysiology; these are the ones most relevant to osteopathic principles.)

Wolff I., every change in form and function of a bone, or in its function alone, is followed by certain definite changes in its internal architecture, and secondary alterations in its external conformations (*Stedman's, 25th ed*); (e.g., bone is laid down along lines of stress).

lesion (osteopathic): See *osteopathic lesion*. See *somatic dysfunction*

ligamentous:

1. **articular strain**, any somatic dysfunction resulting in abnormal ligamentous tension or strain. See also *osteopathic manipulative treatment, ligamentous articular strain technique*.

1. **articular strain technique**, See *osteopathic manipulative treatment, ligamentous articular strain technique*.

1. **strain**, motion and/or positional asymmetry associated with elastic deformation of connective tissue (fascia, ligament, membrane). See *strain and ligamentous articular strain*.

line of gravity: See *gravitational line*.

linkage: See *somatic dysfunction, linkage*.

liver pump: See *osteopathic manipulative treatment, hepatic pump*.

localization: 1. In manipulative technique, the precise positioning of the patient and vector application of forces required to produce a desired result. 2. The reference of a sensation to a particular locality in the body.

longitudinal axis: See *sacral, sacral motion axis, longitudinal axis*.

lordosis: 1. The anterior convexity in the curvature of the lumbar and cervical spine as viewed from the side. The term is used to refer to abnormally increased curvature (hollow back, saddle back, sway back) and to the normal curvature (normal lordosis). (*Dorland's*). 2. Hollow back or saddle back; an abnormal extension deformity; anteroposterior curvature of the spine, generally lumbar with the convexity looking anteriorly (*Stedman's*).

lordotic: Pertaining to or characterized by lordosis.

lumbarization: See *transitional vertebrae, lumbarization*.

lumbolumbar lordotic angle: See *angle, lumbolumbar lordotic*.

lumbosacral angle: See *angle, lumbosacral*.

lumbosacral lordotic angle: See *angle, lumbosacral lordotic*.

lumbosacral spring test: See *spring test*.

lymphatic pumps: See *osteopathic manipulative treatment, lymphatic pump*. See also *osteopathic manipulative treatment, pedal pump*. See also *osteopathic manipulative treatment, thoracic pump*.

lymphatic treatment: Techniques used to optimize function of the lymphatic system. See *osteopathic manipulative treatment, lymphatic pump*. See also *osteopathic manipulative treatment, pedal pump*. See also *osteopathic manipulative treatment, thoracic pump*.

M

mandibular drainage technique: See *osteopathic manipulative treatment, mandibular drainage technique*.

manipulation: Therapeutic application of manual force. See also *technique*. See also *osteopathic manipulative treatment*.

manual medicine: The skillful use of the hands to diagnose and treat structural and functional abnormalities in various tissues and organs throughout the body, including bones, joints, muscles and other soft tissues as an integral part of complete medical care. 1. This term originated from the German *Manuelle Medizin* (manual medicine) and has been used interchangeably with the term manipulation. 2. This term is not identical to manual therapy, which has been used by nonphysician practitioners (e.g., physical therapists).

massage: Therapeutic friction, stroking, and kneading of the body. See also *osteopathic manipulative treatment, soft tissue treatment*.

membranous articular strain: Any cranial somatic dysfunction resulting in abnormal dural membrane tensions.

membranous balance: The ideal physiologic state of harmonious equilibrium in the tension of the dura mater of the brain and spinal cord.

mesenteric lift: See *osteopathic manipulative treatment, mesenteric release technique*.

mesenteric release technique: See *osteopathic manipulative treatment, mesenteric release technique*.

middle transverse axis: See *sacral motion axis, middle transverse axis (postural)*.

mid-heel line: A vertical line used as a reference in standing anteroposterior (A-P) x-rays and postural evaluation, passing equidistant between the heels.

mid-gravitational line: See *gravitational line*.

mid-malleolar line: A vertical line passing through the lateral malleolus, used as a point of reference in standing lateral x-rays and postural evaluation. See also *gravitational line*.

mirror-image motion asymmetries: A grouping of primary and secondary sites of somatic dysfunction describing a three-segment complex fundamental to dysfunction in a mobile system. Each adjacent segment, above and below the primary locus, demonstrates opposing asymmetries to that locus. For example, if the primary locus resists rotation right, the segments above and below resist rotation left.

mobile point: In counterstrain, the final position of treatment at which tenderness is no longer elicited by palpation of the tender point. **mobile segment:** A term in functional methods to describe a bony structure with its articular surfaces and adnexal tissues (neuromuscular and connective) for segmental motion which affects movement, stabilizes position and allows coordinated participation in passive movement.

mobile system: An osteopathic construct associated with functional methods in which the body as a whole is viewed as a centrally integrated system in which all of the individual elements (e.g., mobile segments) have coordinated and specific motion characteristics. See also *functional methods*.

mobile unit: See *mobile segment*.

models of osteopathic care: Five models that articulate how an osteopathic practitioner seeks to influence a patient's physiological processes.

structural model, the goal of the structural model is biomechanical adjustment and the mobilization of joints. This model also seeks to address problems in the myofascial connective tissues, as well as in the bony and soft tissues, to remove restrictive forces and enhance motion. This is accomplished by the use of a wide range of osteopathic manipulative techniques such as high velocity-low amplitude, muscle energy, counterstrain, myofascial release, ligamentous articular techniques and functional techniques.

respiratory-circulatory model, the goal of the respiratory-circulatory model is to improve all of the diaphragm restrictions in the body. Diaphragms are considered to be "transverse restrictors" of motion, venous and lymphatic drainage and cerebrospinal fluid. The techniques used in this model are osteopathy in the cranial field, ligamentous articular strain, myofascial release and lymphatic pump techniques.

metabolic model, the goal of the metabolic model is to enhance the self-regulatory and self-healing mechanisms, to foster energy conservation by balancing the body's energy expenditure and exchange, and to enhance immune system function, endocrine function and organ function. The osteopathic considerations in this area are not manipulative in nature except for the use of lymphatic pump techniques. Nutritional counseling, diet and exercise advice are the most common approaches to balancing the body through this model.

neurologic model, the goal of the neurologic model is to attain autonomic balance and address neural reflex activity, remove facilitated segments, decrease afferent nerve signals and relieve pain. The osteopathic manipulative techniques used to influence this area of patient health include counterstrain and Chapman reflex points.

behavioral model, the goal of this model is to improve the biological, psychological and social components of the health spectrum. This includes emotional balancing and compensatory mechanisms. Reproductive processes and behavioral adaptation are also included under this model.

motion: 1. A change of position (rotation and/or translation) with respect to a fixed system; 2. An act or process of a body changing position in terms of direction, course and velocity.

active m., movement produced voluntarily by the patient.

inherent m., spontaneous motion of every cell, organ, system and their component units within the body.

m. barrier, See *barrier (motion barrier)*.

passive m., motion induced by the osteopathic practitioner while the patient remains passive or relaxed.

physiologic m., changes in position of body structures within the normal range. See also *physiologic motion of the spine*.

translatory m., motion of a body part along an axis. See also *translation*.

muscle energy technique: See *osteopathic manipulative treatment, muscle energy*.

myofascial release technique: See *osteopathic manipulative treatment, myofascial release*.

myofascial technique: See *osteopathic manipulative treatment, myofascial technique*.

myofascial trigger point: See *trigger point*.

myogenic tonus: 1. Tonic contraction of muscle dependent on some property of the muscle itself or of its intrinsic nerve cells. 2. Contraction of a muscle caused by intrinsic properties of the muscle or by its intrinsic innervation (*Stedman's*).

myotome: 1. All muscles derived from one somite and innervated by one segmental spinal nerve. 2. That part of the somite that develops into skeletal muscle (*Stedman's*).

N

neurotrophicity: See *neurotrophy*.

neurotrophy: The nutrition and maintenance of tissues as regulated by direct innervation.

neutral: 1. The range of sagittal plane spinal positioning in which the first principle of physiologic motion of the spine applies. See also *physiologic motion of the spine*. 2. The point of balance of an articular surface from which all the motions physiologic to that articulation may take place (Fig. 23).

Figure 23 Neutral spinal position.

NMM-OMM: Osteopathic neuromusculoskeletal medicine certification is granted by the American Osteopathic Association through the American Osteopathic Board of Neuromusculoskeletal Medicine. First granted in 1999.

non-neutral: The range of sagittal plane spinal positioning in which the second principle of physiologic motion of the spine applies. See also *extension*. See also *flexion*. See also *physiologic motion of the spine*.

normalization: The therapeutic use of anatomic and physiologic mechanisms to facilitate the body's response toward homeostasis and improved health.

NSR: A descriptor of spinal somatic dysfunction used to denote a combination neutral (N), sidebent (S), and rotated (R) vertebral position; similar descriptors may involve flexed (F) and extended (E) position.

nutation: Nodding forward; anterior movement of the sacral base around a transverse axis in relation to the ilia.

O

oblique axis: See *sacral motion axis, oblique (diagonal)*.

OMM: See *osteopathic manipulative medicine*.

OMTh: See *osteopathic manipulative therapy*.

OMT: See *osteopathic manipulative treatment*.

ONM: See *NMM-OMM*.

OP&P: Osteopathic principles and practice. See also *osteopathic philosophy, Archaic*.

OPP: Osteopathic principles and practice. See also *osteopathic philosophy*.

os coxae: See *innominate*.

osteopath: 1. A person who has achieved the nationally recognized academic and professional standards within her or his country to independently practice diagnosis and treatment based upon the principles of osteopathic philosophy. Individual countries establish the national academic and professional standards for osteopaths practicing within their countries (International usage). 2. Considered by the American Osteopathic Association to be an archaic term when applied to graduates of U.S. schools.

osteopathic lesion (osteopathic lesion complex): Archaic term used to describe somatic dysfunction. See *somatic dysfunction*.

osteopathic manipulative medicine (OMM): The application of osteopathic philosophy, structural diagnosis and use of OMT in the diagnosis and management of the patient.

osteopathic manipulative therapy (OMTh): The therapeutic application of manually guided forces by an osteopath (nonphysician) to improve physiological function and homeostasis that has been altered by somatic dysfunction.

osteopathic manipulative treatment (OMT): The therapeutic application of manually guided forces by an osteopathic physician (U.S. usage) to improve physiologic function and/or support homeostasis that has been altered by somatic dysfunction. OMT employs a variety of techniques including:

active method, technique in which the person voluntarily performs an osteopathic practitioner-directed motion.

articular treatment, (Archaic). See *osteopathic manipulative treatment, articular treatment system*.

articulatory (ART), a low velocity/moderate to high amplitude technique where a joint is carried through its full motion with the therapeutic goal of increased range of movement. The activating force is either a repetitive springing motion or repetitive concentric movement of the joint through the restrictive barrier.

balanced ligamentous tension (BLT), 1. According to Sutherland's model, all the joints in the body are balanced ligamentous articular mechanisms. The ligaments provide proprioceptive information that guides the muscle response for positioning the joint, and the ligaments themselves guide the motion of the articular components. (*Foundations*) 2. First described in "Osteopathic Technique of William G. Sutherland," that was published in the *1949 Year Book of Academy of Applied Osteopathy*. See also *ligamentous articular strain*.

Chapman reflex, See *Chapman reflex, combined method*, 1. A treatment strategy where the initial movements are indirect; as the technique is completed the movements change to direct forces. 2. A manipulative sequence involving two or more different osteopathic manipulative

treatment systems (e.g., Spencer technique combined with muscle energy technique). 3. A concept described by Paul Kimberly, DO.

combined treatment, (Archaic). See *osteopathic manipulative treatment, combined method*.

compression of the fourth ventricle (CV-4), a cranial technique in which the lateral angles of the occipital squama are manually approximated slightly exaggerating the posterior convexity of the occiput and taking the cranium into sustained extension.

counterstrain (CS), 1. A system of diagnosis and treatment that considers the dysfunction to be a continuing, inappropriate strain reflex, which is inhibited by applying a position of mild strain in the direction exactly opposite to that of the reflex; this is accomplished by specific directed positioning about the point of tenderness to achieve the desired therapeutic response. 2. Australian and French use: Jones technique, (correction spontaneous by position), spontaneous release by position. 3. Developed by Lawrence Jones, DO in 1955 (originally "Spontaneous Release by Positioning," later termed "strain-counterstrain").

cranial treatment (CR), See *primary respiratory mechanism*. See *osteopathy in the cranial field*.

CV-4, abbreviation for compression of the fourth ventricle. See *osteopathic manipulative treatment, compression of the fourth ventricle*.

Dalrymple treatment, See *osteopathic manipulative treatment, pedal pump*.

direct method (D/DIR), an osteopathic treatment strategy by which the restrictive barrier is engaged and a final activating force is applied to correct somatic dysfunction.

exaggeration method, an osteopathic treatment strategy by which the dysfunctional component is carried away from the restrictive barrier and beyond the range of voluntary motion to a point of palpably increased tension.

exaggeration technique, an indirect procedure that involves carrying the dysfunctional part away from the restrictive barrier, then applying a high velocity/low amplitude force in the same direction.

facilitated oscillatory release technique (FOR), 1. A technique intended to normalize neuromuscular function by applying a manual oscillatory force, which may be combined with any other ligamentous or myofascial technique. 2. A refinement of a long-standing use of oscillatory force in osteopathic diagnosis and treatment as published in early osteopathic literature. 3. A technique developed by Zachary Comeaux, DO.

facilitated positional release (FPR), a system of indirect myofascial release treatment. The component region of the body is placed into a neutral position, diminishing tissue and joint tension in all planes, and an activating force (compression or torsion) is added. 2. A technique developed by Stanley Schiowitz, DO.

fascial release treatment, See *osteopathic manipulative treatment, myofascial release*.

fascial unwinding, a manual technique involving constant feedback to the osteopathic practitioner who is passively moving a portion of the patient's body in response to the sensation of movement. Its forces are localized using the sensations of ease and bind over wider regions.

functional method, an indirect treatment approach that involves finding the dynamic balance point and one of the following: applying an indirect guiding force, holding the position or adding compression to exaggerate position and allow for spontaneous readjustment. The osteopathic practitioner guides the manipulative procedure while the dysfunctional area is being palpated in order to obtain a continuous feedback of the physiologic response to induced motion. The osteopathic practitioner guides the dysfunctional part so as to create a decreasing sense of tissue resistance (increased compliance).

Galbreath treatment, See *osteopathic manipulative treatment, mandibular drainage*.

hepatic pump, rhythmic compression applied over the liver for purposes of increasing blood flow through the liver and enhancing bile and lymphatic drainage from the liver.

high velocity/low amplitude technique (HVLA), an osteopathic technique employing a rapid, therapeutic force of brief duration that travels a short distance within the anatomic range of motion of a joint, and that engages the restrictive barrier in one or more planes of motion to elicit release of restriction. Also known as thrust technique.

- Hoover technique,** 1. A form of functional method. 2. Developed by H.V. Hoover, DO. See also *osteopathic manipulative treatment, functional technique*.
- indirect method (I/IND),** a manipulative technique where the restrictive barrier is disengaged and the dysfunctional body part is moved away from the restrictive barrier until tissue tension is equal in one or all planes and directions.
- inhibitory pressure technique,** the application of steady pressure to soft tissues to reduce reflex activity and produce relaxation.
- integrated neuromusculoskeletal release (INR),** a treatment system in which combined procedures are designed to stretch and reflexly release patterned soft tissue and joint-related restrictions. Both direct and indirect methods are used interactively.
- Jones technique,** See *osteopathic manipulative treatment, counterstrain*.
- ligamentous articular strain technique (LAS),** 1. A manipulative technique in which the goal of treatment is to balance the tension in opposing ligaments where there is abnormal tension present. 2. A set of myofascial release techniques described by Howard Lippincott, DO, and Rebecca Lippincott, DO. 3. Title of reference work by Conrad Speece, DO, and William Thomas Crow, DO.
- liver pump,** See *hepatic pump*.
- lymphatic pump,** 1. A term used to describe the impact of intrathoracic pressure changes on lymphatic flow. This was the name originally given to the thoracic pump technique before the more extensive physiologic effects of the technique were recognized. 2. A term coined by C. Earl Miller, DO.
- mandibular drainage technique,** soft tissue manipulative technique using passively induced jaw motion to effect increased drainage of middle ear structures via the eustachian tube and lymphatics.
- mesenteric release technique (mesenteric lift),** technique in which tension is taken off the attachment of the root of the mesentery to the posterior body wall. Simultaneously, the abdominal contents are compressed to enhance venous and lymphatic drainage from the bowel.
- muscle energy,** a form of osteopathic manipulative diagnosis and treatment in which the patient's muscles are actively used on request, from a precisely controlled position, in a specific direction, and against a distinctly executed physician counterforce. First described in 1948 by Fred Mitchell, Sr, DO.
- myofascial release (MFR),** a system of diagnosis and treatment first described by Andrew Taylor Still and his early students, which engages continual palpatory feedback to achieve release of myofascial tissues.
- direct MFR,** a myofascial tissue restrictive barrier is engaged for the myofascial tissues and the tissue is loaded with a constant force until tissue release occurs.
- indirect MFR,** the dysfunctional tissues are guided along the path of least resistance until free movement is achieved.
- myofascial technique,** any technique directed at the muscles and fascia. See also *osteopathic manipulative treatment, myofascial release*. See also *osteopathic manipulative treatment, soft tissue technique*.
- myotension,** a system of diagnosis and treatment that uses muscular contractions and relaxations under resistance of the osteopathic practitioner to relax, strengthen or stretch muscles, or mobilize joints.
- Osteopathy in the Cranial Field (OCF),** 1. A system of diagnosis and treatment by an osteopathic practitioner using the primary respiratory mechanism and balanced membranous tension. See also *primary respiratory mechanism*. 2. Refers to the system of diagnosis and treatment first described by William G. Sutherland, DO. 3. Title of reference work by Harold Magoun, Sr, DO.
- passive method,** based on techniques in which the patient refrains from voluntary muscle contraction.
- pedal pump,** a venous and lymphatic drainage technique applied through the lower extremities; also called the pedal fascial pump or Dalrymple treatment.
- percussion vibrator technique,** 1. A manipulative technique involving the specific application of mechanical vibratory force to treat somatic dysfunction. 2. An osteopathic manipulative technique developed by Robert Fulford, DO.
- positional technique,** a direct segmental technique in which a combination of leverage, patient ventilatory movements and a fulcrum are used to achieve mobilization of the dysfunctional segment. May be combined with springing or thrust technique.
- progressive inhibition of neuromuscular structures (PINS),** 1. A system of diagnosis and treatment in which the osteopathic practitioner locates two related points and sequentially applies inhibitory pressure along a series of related points. 2. Developed by Dennis Dowling, DO.
- range of motion technique,** active or passive movement of a body part to its physiologic or anatomic limit in any or all planes of motion.
- soft tissue (ST),** A system of diagnosis and treatment directed toward tissues other than skeletal or articular elements.
- soft tissue technique,** a direct technique that usually involves lateral stretching, linear stretching, deep pressure, traction and/or separation of muscle origin and insertion while monitoring tissue response and motion changes by palpation. Also called myofascial treatment.
- Spencer technique,** a series of direct manipulative procedures to prevent or decrease soft tissue restrictions about the shoulder. See also *osteopathic manipulative treatment (OMT), articular treatment (ART)*.
- splenic pump technique,** rhythmic compression applied over the spleen for the purpose of enhancing the patient's immune response. See also *osteopathic manipulative treatment (OMT), lymphatic pump*.
- spontaneous release by positioning,** See *osteopathic manipulative treatment, counterstrain*.
- springing technique,** a low velocity/moderate amplitude technique where the restrictive barrier is engaged repeatedly to produce an increased freedom of motion. See also *osteopathic manipulative treatment, articular treatment system*.
- Still technique,** 1. Characterized as a specific, nonrepetitive articular method that is indirect, then direct. 2. Attributed to A.T. Still. 3. A term coined by Richard Van Buskirk, DO, PhD.
- Strain-Counterstrain,** 1. An osteopathic system of diagnosis and indirect treatment in which the patient's somatic dysfunction, diagnosed by (an) associated myofascial tenderpoint(s), is treated by using a passive position, resulting in spontaneous tissue release and at least 70% decrease in tenderness. 2. Developed by Lawrence H. Jones, DO, in 1955. See *osteopathic treatments, counterstrain*.
- thoracic pump,** 1. A technique that consists of intermittent compression of the thoracic cage. 2. Developed by C. Earl Miller, DO.
- thrust technique (HVLA),** See *osteopathic manipulative treatment, high velocity/low amplitude technique (HVLA)*.
- toggle technique,** short lever technique using compression and shearing forces.
- traction technique,** a procedure of high or low amplitude in which the parts are stretched or separated along a longitudinal axis with continuous or intermittent force.
- v-spread,** technique using forces transmitted across the diameter of the skull to accomplish sutural gapping.
- ventral techniques,** See *osteopathic manipulative treatment, visceral manipulation*.
- visceral manipulation (VIS),** a system of diagnosis and treatment directed to the viscera to improve physiologic function. Typically, the viscera are moved toward their fascial attachments to a point of fascial balance. Also called ventral techniques.
- osteopathic medicine:** The preferred term for a complete system of medical care practiced by physicians with an unlimited license that is represented by a philosophy that combines the needs of the patient with the current practice of medicine, surgery and obstetrics. Emphasizes the interrelationship between structure and function, and has an appreciation of the body's ability to heal itself.
- osteopathic musculoskeletal evaluation:** The osteopathic musculoskeletal evaluation provides information regarding the health of the patient. Utilizing the concepts of body unity, self-regulation and structure-function interrelationships, the osteopathic physician uses data from the musculoskeletal evaluation to assess the patient's status and develop a treatment plan. (AOA House of Delegates)
- osteopathic philosophy:** a concept of health care supported by expanding scientific knowledge that embraces the concept of the unity of the living organism's structure (anatomy) and function (physiology). Osteopathic philosophy emphasizes the following principles: 1. The human being is a dynamic unit of function. 2. The body possesses self-regulatory mechanisms

that are self-healing in nature. 3. Structure and function are interrelated at all levels. 4. Rational treatment is based on these principles.

osteopathic physician: A person with full unlimited medical practice rights who has achieved the nationally recognized academic and professional standards within his or her country to practice diagnosis and treatment based upon the principles of osteopathic philosophy. Individual countries establish the national academic and professional standards for osteopathic physicians practicing within their countries.

osteopathic postural examination: The part of the osteopathic musculoskeletal examination that focuses on the static and dynamic responses of the body to gravity while in the erect position.

osteopathic practitioner: Refers to an osteopath, an osteopathic physician or an allopathic physician who has been trained in osteopathic principles, practices and philosophy.

osteopathic structural examination: The examination of a patient by an osteopathic practitioner with emphasis on the neuromusculoskeletal system including palpatory diagnosis for somatic dysfunction and viscerosomatic change within the context of total patient care. The examination is concerned with finding somatic dysfunction in all parts of the body, and is performed with the patient in multiple positions to provide static and dynamic evaluation.

osteopathy: Archaic usage. No longer a preferred term in the United States. See *Osteopathic Medicine*.

P

palpation: The application of the fingers to the surface of the skin or other tissues, using varying amounts of pressure, to selectively determine the condition of the parts beneath.

palpatory diagnosis: A term used by osteopathic practitioners to denote the process of palpating the patient to evaluate the structure and function of the neuromusculoskeletal and visceral systems.

palpatory skills: Sensory skills used in performing palpatory diagnosis and osteopathic manipulative treatment.

passive method: See *osteopathic manipulative treatment, passive method*.

passive motion: See *motion, passive motion*.

patient cooperation: Voluntary movement by the patient (on instruction from the osteopathic practitioner) to assist in the palpatory diagnosis and treatment process.

pedal pump: See *osteopathic manipulative treatment, pedal pump*.

pelvic bone: See *hip bone*.

pelvic declination (pelvic unleveling): Pelvic rotation about an anterior-posterior (A-P) axis.

pelvic girdle dysfunction: See *pelvic somatic dysfunction*.

pelvic index (PI): Represents a ratio of the measurements determined from postural radiograph: One (y) beginning from a vertical line originating at the sacral promontory to the intersection with the horizontal line from the anterosuperior position of the pubic bone. The second measurement (x) is along this same horizontal line. Normal values are age-related and increase in subjects with sagittal plane postural decompensation. Pelvic index (PI) equals x/y (Fig. 24).

pelvic rotation: Movement of the entire pelvis in a relatively horizontal plane about a vertical (longitudinal) axis.

pelvic sideshift: Deviation of the pelvis to the right or left of the central vertical axis as translation occurs along the horizontal (z) axis. Usually observed in the standing position.

pelvic somatic dysfunctions: a group of somatic dysfunctions involving the sacrum and innominates. See *sacral somatic dysfunction and innominate somatic dysfunction*.

pelvic tilt: Pelvic rotation about a transverse (horizontal) axis (forward or backward tilt) or about an anterior-posterior axis (right or left side tilt).

pelvis: Within the context of structural diagnosis, the pelvis is made up of the right and left innominates, (hip bone or os coxae) the sacrum and coccyx.

percussion vibrator technique: See *osteopathic manipulative treatment, percussion vibrator technique*.

pétrissage: Deep kneading or squeezing action to express swelling.

physiologic barrier: See *barrier, physiologic barrier*.

physiologic motion: See *motion, physiologic motion*.

physiologic motion of the spine: The three major principles of physiologic motion are:

Figure 24 Pelvic index (PI). (Modified from Kuchera WA, Kuchera ML, *Osteopathic Principles in Practice*, Greyden Press, Columbus, OH, 1994:263).

I. When the thoracic and lumbar spine are in a neutral position (easy normal; See *neutral* Fig. 23), the coupled motions of sidebending and rotation for a group of vertebrae are such that sidebending and rotation occur in opposite directions (with rotation occurring toward the convexity) (Fig. 25). See *somatic dysfunction, type I s.d.*

II. When the thoracic and lumbar spine are sufficiently forward or backward bent (non-neutral), the coupled motions of sidebending and rotation in a single vertebral unit occur in the same direction (Fig. 26). See *somatic dysfunction, type II, s.d.*

III. 1. Initiating motion of a vertebral segment in any plane of motion will modify the movement of that segment in other planes of motion. 2. Principles I and II of thoracic and lumbar spinal motion described by Harrison H. Fryette, DO (1918), Principle III was described by C.R. Nelson, DO (1948). See *rotation*. See also *rotation of vertebra*.

plane: A flat surface determined by the position of three points in space. Any of a number of imaginary surfaces passing through the body and dividing it into segments (Fig. 27).
AP plane, See *plane, sagittal plane*.

Figure 25 Physiologic motion of the thoracic or lumbar spine resulting from a neutral spinal position (Type I motion).

Figure 26 Physiologic motion of the thoracic or lumbar spine resulting from a non-neutral spinal position (Type II motion).

Figure 27 Planes of the body.

coronal plane (frontal plane), a plane passing longitudinally through the body from one side to the other, and dividing the body into anterior and posterior portions.

frontal plane, See *plane, coronal plane*.

horizontal plane, See *plane, transverse plane*.

sagittal plane, a plane passing longitudinally through the body from front to back and dividing it into right and left portions. The median or midsagittal plane divides the body into approximately equal right and left portions.

transverse plane (horizontal plane), a plane passing horizontally through the body perpendicular to the sagittal and frontal planes, dividing the body into upper and lower portions.

plastic deformation: A nonrecoverable deformation. See also *elastic deformation*.

plasticity: Ability to retain a shape attained by deformation. See also *elasticity*. See also *viscosity*.

positional technique: See *osteopathic manipulative treatment, positional technique*.

posterior component: A positional descriptor used to identify the side of reference when rotation of a vertebral segment has occurred. In a condition of right rotation, the right side is the posterior component.

It usually refers to a prominent vertebral transverse process. See also *anterior component*.

posterior nutation: See *counternutation*.

post-isometric relaxation: Immediately following an isometric contraction, the neuromuscular apparatus is in a refractory state during which enhanced passive stretching may be performed. The osteopathic practitioner may take up the myofascial slack during the relaxed refractory period.

postural axis: See *sacral motion axis, postural axis*.

postural balance: A condition of optimal distribution of body mass in relation to gravity.

postural decompensation: Distribution of body mass away from ideal when postural homeostatic mechanisms are overwhelmed. It occurs in all cardinal planes, but is classified by the major plane(s) affected. See *planes of the body*. (Fig. 27)

coronal plane p. d., causes scoliotic changes.

horizontal plane p. d., may cause postural changes where part or all of the body rotates to the right or left. When viewed from the right or left sides, alignment appears asymmetrical.

sagittal plane p. d., causes kyphotic and/or lordotic changes.

postural imbalance: A condition in which ideal body mass distribution is not achieved.

posture: Position of the body. The distribution of body mass in relation to gravity.

primary machinery of life: 1. The neuromusculoskeletal system. A term used to denote that body parts act together to transmit and modify force and motion through which man acts out his life. This integration is achieved via the central nervous system acting in response to continued sensory input from the internal and external environment. 2. A term coined by I.M. Korr, PhD.

primary respiratory mechanism:

1. A conceptual model that describes a process involving five interactive, involuntary functions:
 - (1) The inherent motility of the brain and spinal cord.
 - (2) Fluctuation of the cerebrospinal fluid.
 - (3) Mobility of the intracranial and intraspinal membranes.
 - (4) Articular mobility of the cranial bones.
 - (5) Mobility of the sacrum between the ilia (pelvic bones) that is interdependent with the motion at the sphenobasilar synchondrosis.

This mechanism refers to the presumed inherent (primordial) driving mechanism of internal respiration as opposed to the cycle of diaphragmatic respiration (inhalation and exhalation). It further refers to the innate interconnected movement of every tissue and structure of the body. Optimal health promotes optimal function and the inherent function of this interdependent movement can be negatively altered by trauma, disease states or other pathology.

2. This mechanism was first described by William G. Sutherland, DO, in 1939 in his self-published volume, "The Cranial Bowl." The mechanism is thought to affect cellular respiration and other body processes. In the original definition, the following descriptions were given:

primary, because it is directly concerned with the internal tissue respiration of the central nervous system.

respiratory, because it further concerns the physiological function of the interchange of fluids necessary for normal metabolism and biochemistry, not only of the central nervous system, but also of all body cells.

mechanism, because all the constituent parts work together as a unit carrying out this fundamental physiology. See also *osteopathic manipulative treatment (OMT), osteopathy in the cranial field*.

prime mover: A muscle primarily responsible for causing a specific joint action.

progressive inhibition of neuromuscular structures (PINS): See *osteopathic manipulative treatment, Progressive Inhibition of Neuromuscular Structures*.

prolotherapy: See *sclerotherapy*.

pronation: In relation to the anatomical position, as applied to the hand, rotation of the forearm in such a way that the palmar surface turns backward (internal rotation) in relationship to the anatomical position. Applied to the foot: a combination of eversion and abduction movements taking place in the tarsal and metatarsal joints, resulting in lowering of the medial margin of the foot. See also *supination*.

prone: Lying face downward (*Dorland's*).

psoas syndrome: A painful low back condition characterized by hypertonicity of psoas musculature. The syndrome consists of a constellation of typically related signs and symptoms:

typical posture, flexion at the hip and sidebending of the lumbar spine to the side of the most hypertonic psoas muscle.

typical gait, Trendelenburg gait.

typical pain pattern, low back pain frequently accompanied by pain on the lateral aspect of the lower extremity extending no lower than the knee.

typical associated somatic dysfunctions, as a long restrictor muscle, psoas hypertonicity is frequently associated with flexed dysfunctions of the upper lumbar, extended dysfunction of L5, and variable sacral and innominate dysfunctions. Tender points typically are found in the ipsilateral iliacus and contralateral piriformis muscles.

pubic bone, somatic dysfunctions of:

anterior pubic shear, a somatic dysfunction in which one pubic bone is displaced anteriorly with relation to its normal mate.

inferior pubic shear, a somatic dysfunction in which one pubic bone is displaced inferiorly with relation to its normal mate (Fig. 28).

posterior pubic shear, a somatic dysfunction in which one pubic bone is displaced posteriorly with relation to its normal mate.

pubic abduction, See *pubic gapping*.

pubic adduction, See *pubic compression*.

pubic compression (pubic adduction), a somatic dysfunction in which the pubic bones are forced toward each other at the pubic symphysis. This dysfunction is characterized by tenderness to palpation over the pubic symphysis, lack of apparent asymmetry, but associated with restricted motion of the pelvic ring (Fig. 29).

pubic gapping (pubic abduction), a somatic dysfunction in which the pubic bones are pulled away from each other at the pubic symphysis. This dysfunction is frequently seen in women following childbirth (Fig. 30).

superior pubic shear, a somatic dysfunction in which one pubic bone is displaced superiorly with relation to its normal mate (Fig. 31).

Figure 28 Right inferior pubic shear.

Figure 29 Pubic compression.

Figure 30 Pubic gapping (pubic abduction).

Figure 31 Right superior pubic shear.

pubic symphysis, somatic dysfunctions of: See *pubic bone, somatic dysfunctions of*.

pump handle rib motion: See *rib motion, pump handle motion*.

R

range of motion technique: See *osteopathic manipulative treatment, range of motion technique*.

reciprocal inhibition: The inhibition of antagonist muscles when the agonist is stimulated. See also *laws, Sherrington's*.

reciprocal tension membrane: The intracranial and spinal dural membrane including the falx cerebri, falx cerebelli, tentorium and spinal dura.

red reflex: See *reflex, red r*.

reflex: An involuntary nervous system response to a sensory input. The sum total of any particular involuntary activity. See also *Chapman reflexes*.

cephalygic reflex, See *oculocephalygic r*.

cervicolumbar r., automatic contraction of the lumbar paravertebral muscles in response to contraction of postural muscles in the neck.

conditioned r., one that does not occur naturally in the organism or system, but that is developed by regular association of some physiological function with a related outside event.

myotatic r., tonic contraction of the muscles in response to a stretching force, due to stimulation of muscle receptors (e.g., deep tendon reflex).

oculocephalygic r., (oculogyric reflex, cephalogyric reflex), automatic movement of the head that leads or accompanies movement of the eyes.

oculogyric r., See *oculocephalygic r*.

red r., 1. The erythematous biochemical reaction (reactive hyperemia) of the skin in an area that has been stimulated mechanically by friction. The reflex is greater in degree and duration in an area of acute somatic dysfunction as compared to an area of chronic somatic dysfunction. It is a reflection of the segmentally related sympathicotonia commonly observed in the paraspinal area. 2. A red glow reflected from the fundus of the eye when a light is cast upon the retina.

somatosomatic r., localized somatic stimuli producing patterns of reflex response in segmentally related somatic structures.

somatovisceral r., localized somatic stimulation producing patterns of reflex response in segmentally related visceral structures.

viscerosomatic r., localized visceral stimuli producing patterns of reflex response in segmentally related somatic structures.

viscerovisceral r., localized visceral stimuli producing patterns of reflex response in segmentally related visceral structures.

regenerative injection therapy (RIT): See *sclerotherapy*. **region:** 1. An anatomical division of the body defined either by natural, functional or arbitrary boundaries. 2. Body areas for the diagnosis and coding of somatic dysfunction as defined in the International Classification of Diseases (currently ICD-9 CM) using the codes:

- 739.0 somatic dysfunction, head
- 739.1 somatic dysfunction, cervical
- 739.2 somatic dysfunction, thoracic
- 739.3 somatic dysfunction, lumbar
- 739.4 somatic dysfunction, sacrum
- 739.5 somatic dysfunction, pelvis
- 739.6 somatic dysfunction, lower extremity
- 739.7 somatic dysfunction, upper extremity
- 739.8 somatic dysfunction, rib cage
- 739.9 somatic dysfunction, abdomen/other

See also *transitional region*.

regional extension: See *extension, regional extension*.

regional motor inputs: Motion initiated by an osteopathic practitioner through body contact and vector input that produces a specific response at each segment in the mobile system.

resilience: Property of returning to the former shape or size after mechanical distortion. See also *elasticity*. See also *plasticity*.

respiratory axis of the sacrum: See *sacral motion axis, superior transverse axis*.

respiratory cooperation: An osteopathic practitioner-directed inhalation and/or exhalation by the patient to assist the manipulative treatment process.

restriction: A resistance or impediment to movement. For joint restriction, See *barrier (motion barrier)*. *NB: This term is part of the TART acronym for an osteopathic somatic dysfunction.*

retrolisthesis: Posterior displacement of one vertebra relative to the one immediately below.

rib lesion: (Archaic) See *rib somatic dysfunction*.

rib motion:

axis of rib motion, an imaginary line through the costotransverse and the costovertebral articulations of the rib.

anteroposterior rib axis, (Fig. 32) See also *bucket handle rib motion*.

bucket handle motion, movement of the ribs during respiration such that with inhalation, the lateral aspect of the rib moves cephalad resulting in an increase of transverse diameter of the thorax. This type of rib motion is predominantly found in lower ribs, increasing in motion from the upper to the lower ribs (Fig. 33). See also *rib motion, axis of*. See also *rib motion, pump handle*.

caliper rib motion, rib motion of ribs 11 and 12 characterized by single joint motion; analogous to internal and external rotation.

exhalation rib restriction, involves a rib or group of ribs that first stops moving during exhalation. The key rib is the bottom rib in the group. See also *rib somatic dysfunction, inhalation rib dysfunction*.

inhalation rib restriction, involves a rib or group of ribs that first stops moving during inhalation. The key rib is the top rib in the group. See also *rib somatic dysfunction, exhalation rib dysfunction*.

pump handle motion, movement of the ribs during respiration such that with inhalation the anterior aspect of the rib moves cephalad and causes an increase in the anteroposterior diameter of the thorax. This type of rib motion is found predominantly in the upper ribs, decreasing in motion from the upper to the lower ribs (Fig. 34). See *rib motion, axis of*. See also *rib motion, bucket handle motion*.

transverse rib axis, (Fig. 35) See *rib motion, pump handle rib motion inhalation*. See also *rib motion, inhalation rib restriction*. See also *rib motion, exhalation rib restriction*.

rib somatic dysfunction: A somatic dysfunction in which movement or position of one or several ribs is altered or disrupted. For example, an elevated rib is one held in a position of inhalation such that motion toward inhalation is freer, and motion toward exhalation is restricted. A depressed rib is one held in a position of exhalation such that motion toward exhalation is freer and there is a restriction in inhalation. See also *rib motion, inhalation rib restriction*. See also *rib motion, exhalation rib restriction*.

exhalation rib dysfunction, 1. Somatic dysfunction characterized by a rib being held in a position of exhalation such that motion toward exhalation is more free and motion toward inhalation is restricted. Synonyms: inhalation rib restriction depressed rib. 2. An anterior rib tender point in counterstrain. See also *rib motion, inhalation rib restriction*.

inhalation rib dysfunction, a somatic dysfunction characterized by a rib being held in a position of inhalation such that motion toward inhalation is more free and motion toward exhalation is restricted. Synonyms: inhaled rib, anterior rib, elevated rib.

ropiness: A tissue texture abnormality characterized by a cord-like feeling. See also *tissue texture abnormality*.

rotation: Motion about an axis.

rotation dysfunction of the sacrum, See *sacrum, somatic dysfunctions of*.

rotation of sacrum, movement of the sacrum about a vertical (y) axis (usually in relation to the innominate bones).

Figure 32 The functional anterior-posterior rib axis.

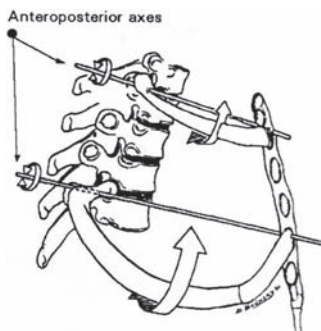

Figure 33 Bucket handle rib motion.

Figure 34 Pump handle rib motion.

Figure 35 The functional transverse rib axis.

Figure 36 Rotation of a vertebra (lumbar).

rotation of vertebra, movement about the anatomical vertical axis (y axis) of a vertebra; named by the motion of a midpoint on the anterior-superior surface of the vertebral body (Fig. 36).

rule of threes: A method to locate the approximate position of the transverse process (TP) of a thoracic segment by using the location of the spinous process (SP) of that same vertebra. The relationship is as follows:

T1 to T3,	TP is at the same level as tip of the SP
T4 to T6,	TP is one half vertebral level above the tip of the SP
T7 to T9,	TP is one full vertebral level above the tip of the SP
T10,	TP is one full vertebral level above the tip of the SP
T11,	TP is one half vertebral level above the tip of the SP
T12,	TP is at the same level as tip of the SP.

S

sacral base: 1. In osteopathic palpation, the uppermost posterior portion of the sacrum. 2. The most cephalad portion of the first sacral segment (*Gray's Anatomy*).

sacral base anterior: See *sacrum, somatic dysfunctions of, bilateral sacral flexion*.

sacral base declination (unleveling): With the patient in a standing or seated position, any deviation of the sacral base from the horizontal in a coronal plane. Generally, the rotation of the sacrum about an anterior-posterior axis.

sacral base posterior: See *sacrum, somatic dysfunctions of, bilateral sacral flexion*.

sacral base unleveling: See *sacral base declination*.

sacralization: See *transitional vertebrae, sacralization*.

sacral movement axis: Any of the hypothetical axes for motion of the sacrum (Figs. 37 and 38).

anterior-posterior (x) axis, axis formed at the line of intersection of a sagittal and transverse plane.

inferior transverse axis (innominate), 1. The hypothetical functional axis of sacral motion that passes from side to side on a line through the inferior articular surface of the sacrum and ilia, and represents the axis for movement of the ilia on the sacrum. 2. A term described by Fred Mitchell, Sr, DO (Fig. 37).

Figure 37 Sacral transverse axes (lateral view).

Figure 38 Axes of sacral motion (posterior view).

longitudinal axis, the hypothetical axis formed at the line of intersection of the midsagittal plane and a coronal plane, See *sacral motion axis, vertical (y) axis longitudinal* (Fig. 38).

middle transverse axis (postural), 1. The hypothetical functional axis of sacral nutation/counternutation in the standing position, passing horizontally through the anterior aspect of the sacrum at the level of the second sacral segment. 2. A term described by Fred Mitchell, Sr, DO (Fig. 37).

oblique (diagonal), 1. a hypothetical functional axis from the superior area of a sacroiliac articulation to the contralateral inferior sacroiliac articulation. It is designated as right or left relevant to its superior point of origin. 2. A term described by Fred Mitchell, Sr, DO (Fig. 38).

postural axis, See *sacrum, middle transverse axis (postural)* (Fig. 37).

respiratory axis, See *sacrum, superior transverse axis (respiratory)* (Fig. 37).

superior transverse axis (respiratory), 1. The hypothetical transverse axis about which the sacrum moves during the respiratory cycle. It passes from side to side through the articular processes posterior to the point of attachment of the dura at the level of the second sacral segment. Involuntary sacral motion occurs as part of the craniosacral mechanism, and is believed to occur about this axis. 2. A term described by Fred Mitchell, Sr, DO (Fig. 37).

transverse (z) axes, axes formed by intersection of the coronal and transverse planes about which nutation/counternutation occurs (Fig. 37).

vertical (y) axis (longitudinal), the axis formed by the intersection of the sagittal and coronal planes (Fig. 38).

sacral somatic dysfunction: See *sacrum, somatic dysfunctions of*.

sacral sulcus: A depression just medial to the posterior superior iliac spine (PSIS) as a result of the spatial relationship of the PSIS to the dorsal aspect of the sacrum (Figs. 39 and 40).

sacral torsion: 1. A physiologic function occurring in the sacrum during ambulation and forward bending. 2. A sacral somatic dysfunction around an oblique axis in which a torque occurs between the sacrum and

Figure 39 Anatomical sacral divisions.

Figure 40 Clinical sacral divisions: sacral sulcus at the base, and inferior lateral angles (ILA).

innominates. The L5 vertebra rotates in the opposite direction of the sacrum. 3. If the L5 does not rotate opposite to the sacrum, L5 is termed maladapted. 4. Other terms for this maladaptation include: rotations about an oblique axis, anterior or posterior sacrum and a torsion with a non-compensated L5 (Archaic use). See also *sacrum, somatic dysfunctions of.*

sacroiliac motion: Motion of the sacrum in relationship to the innominate(s) (ilium/ilia).

sacrum, inferior lateral angle (ILA) of: The point on the lateral surface of the sacrum where it curves medially to the body of the fifth sacral vertebrae (*Gray's Anatomy*) (Figs. 39 and 40).

sacrum, somatic dysfunctions of: Any of a group of somatic dysfunctions involving the sacrum. These may be the result of restriction of normal physiologic motion or trauma to the sacrum. See also *TART.*

anterior sacrum, a positional term based on the Strachan model referring to sacral somatic dysfunction in which the sacral base has rotated anterior and sidebent to the side opposite the rotation. The upper limb (pole) of the SI joint has restricted motion and is named for the side on which forward rotation had occurred. Tissue texture changes are found at the deep sulcus. (The motion characteristics of L5 are not described.) (Fig. 41).

anterior translated sacrum, a sacral somatic dysfunction in which the entire sacrum has moved anteriorly (forward) between the ilia. Anterior motion is freer, and the posterior motion is restricted (Fig. 42).

backward torsions, 1. A backward sacral torsion is a physiologic rotation of the sacrum around an oblique axis such that the side of the sacral base contralateral to the named axis rotates posteriorly. L5 rotates in the direction opposite to the rotation of the sacral base. 2. Referred to as non-neutral sacral somatic dysfunctions (Archaic use). 3. A term by Fred Mitchell, Sr, DO, that describes the backward torsion as being nonphysiologic in terms of the walking cycle.

bilateral sacral extension (sacral base posterior), 1. A sacral somatic dysfunction that involves rotation of the sacrum about a middle transverse axis such that the sacral base has moved posteriorly relative to the pelvic bones. Backward movement of the sacral base is freer, forward movement is restricted and both sulci are shallow. 2. The reverse of bilateral sacral flexion (Fig. 43).

Figure 41 Anterior sacrum left. Motion of L5 is not described. There is tissue texture change (t) over the left sacral base. The superior pole of the left sacroiliac joint is affected and the left sacral base will not move posteriorly when an anterior test pressure is applied over the right lower sacrum.

Figure 42 Anterior translated sacrum.

Figure 43 Bilateral sacral extension. (Sacral base posterior)

Figure 44 Bilateral sacral flexion. (Sacral base anterior)

bilateral sacral flexion (sacral base anterior), 1. A sacral somatic dysfunction that involves rotation of the sacrum about a middle transverse axis such that the sacral base has moved anteriorly between the pelvic bones. Forward movement of the sacral base is freer, backward movement is restricted and both sulci are deep. 2. The reverse of bilateral sacral extension (Fig 44).

forward torsions, 1. Forward torsion is a physiologic rotation of the sacrum around an oblique axis such that the side of the sacral base contralateral to the named axis glides anteriorly and produces a deep sulcus. L5 rotates in the direction opposite to the rotation of the sacral base. 2. Referred to as neutral sacral somatic dysfunctions (Archaic use). 3. A group of somatic dysfunctions described by Fred Mitchell, Sr, DO, based on the motion cycle of walking.

left on left (forward) sacral torsion, refers to left rotation torsion around a left oblique axis (Fig. 45). See also *sacral torsion.*

left on right (backward) sacral torsion, refers to left rotation around a right oblique axis. Findings: The left superior sacral sulcus is posterior or shallow, and the right ILA is anterior or deep. There is a positive

Figure 45 Left on left sacral torsion. (Left on left forward torsion)

Figure 48 Right on left backward torsion. (Right on left sacral torsion)

Figure 46 Left on right sacral torsion. (Left on right backward torsion)

Figure 49 Posterior translated sacrum.

Figure 47 Posterior sacrum right. Motion of L5 is not described. There is tissue texture change (t) over the right sacroiliac joint (SI). The inferior pole of the right SI joint is affected. During motion testing, there is resistance to an anterior/superior test pressure applied over the right lower sacrum.

Figure 50 Right on right forward torsion.

seated flexion test on the left. L5 is non-neutral SRRR. Left superior sacral sulcus will be restricted when springing. The lumbosacral spring test is positive, and the sphinx test is positive (Fig. 46). See *sacral torsion*.

posterior sacrum, a positional term based on the Strachan model referring to a sacral somatic dysfunction in which the sacral base has rotated posterior and sidebent to the side opposite to the rotation. The dysfunction is named for the side on which the posterior rotation occurs. The tissue texture changes are found at the lower pole on the side of rotation (*Foundations*). (The motion characteristics of L5 are not described.) (Fig. 47). right on left (backward) sacral torsion, refers to right rotation on a left oblique axis. Findings: The right superior sacral sulcus is posterior or shallow, and the left ILA is anterior or deep. The seated flexion test is positive on the right. L5 is nonneutral SLRL. The right superior sacral sulcus is restricted when springing. The lumbosacral spring test is positive. The sphinx test is positive (Fig. 48). See *sacral torsion*.

posterior translated sacrum, a sacral somatic dysfunction in which the entire sacrum has moved posteriorly (backward) between the ilia.

Posterior motion is freer, and anterior motion is restricted (Fig. 49). Right on right (forward) torsion, refers to a right rotation about a right oblique axis (Fig. 50). See *sacral torsion*.

rotated dysfunction of the sacrum, a sacral somatic dysfunction in which the sacrum has rotated about an axis approximating the longitudinal (y) axis. Motion is freer in the direction that rotation has occurred, and is restricted in the opposite direction (Fig. 51).

sacral shear, a complex translational motion of the sacrum in its relationship to the innominates. (Sometimes described as a sidebending in one direction and rotation in the opposite direction. Alternatively described as a unilateral movement along the arc of the L-shaped curve of the sacroiliac joint.) See also *sacrum, somatic dysfunctions of, unilateral sacral flexion and sacrum, somatic dysfunctions of, unilateral sacral extension*.

Figure 51 Right rotated dysfunction of the sacrum. (Right rotation about a vertical axis)

Figure 52 Right unilateral sacral extension. (Right superior sacral shear)

Figure 53 Right unilateral sacral flexion. (Right inferior sacral shear)

unilateral sacral extension, a sacral somatic dysfunction described as a superior shear of one side of the sacrum resulting in a shallow (full) sacral sulcus and ipsilateral superior-anterior inferolateral angle of the sacrum (Fig. 52). See *sacrum, somatic dysfunctions of, sacral shear*.

unilateral sacral flexion, a sacral somatic dysfunction described as an inferior shear of one side of the sacrum resulting in a deep sacral sulcus and ipsilateral inferior-posterior inferolateral angle of the sacrum (Fig. 53). See *sacrum, somatic dysfunctions of, sacral shear*.

sagittal plane: See *plane, sagittal plane*.

scan: An intermediate detailed examination of specific body regions that have been identified by findings emerging from the initial examination.

scaphocephaly: Also called scaphoid head or hatchet head, it is a transverse compression of the cranium with a resultant mid-sagittal ridge.

scaphoid head: See also *scaphocephaly*.

sclerotherapy: 1. Treatment involving injection of a proliferant solution at the osseous-ligamentous junction. 2. Treatment involving injection of irritating substances into weakened connective tissue areas such as fascia, varicose veins, hemorrhoids, esophageal varices, or weakened ligaments. The intended body's response to the irritant is fibrous proliferation with shortening/strengthening of the tissues injected.

sclerotome: 1. The pattern of innervation of structures derived from embryonal mesenchyme (joint capsule, ligament and bone). 2. The area of bone innervated by a single spinal segment. 3. The group of mesenchymal cells emerging from the ventromedial part of a mesodermal

somite and migrating toward the notochord. Sclerotomal cells from adjacent somites become merged in intersomatically located masses that are the primordia of the centra of the vertebrae (Fig. 54).

sclerotomal pain: Deep, dull achy pain associated with tissues derived from a common sclerotome (Fig. 54).

scoliosis: 1. Pathological or functional lateral curvature of the spine. 2. An appreciable lateral deviation in the normally straight vertical line of the spine (*Dorland's*) (Fig. 55).

screen: The initial general somatic examination to determine signs of somatic dysfunction in various regions of the body. See also *scan*.

secondary joint motion: Involuntary or passive motion of a joint. Also called accessory joint motion. segment: 1. A portion of a larger body or structure set off by natural or arbitrarily established boundaries, often equated with spinal segment. 2. To describe a single vertebrae or a vertebral segment corresponding to the sites of origin of rootlets of individual spinal nerves. 3. A portion of the spinal cord segmental diagnosis: The final stage of the spinal somatic examination in which the nature of the somatic problem is detailed at a segmental level. See also *scan*. See also *screen*.

segmental dysfunction: Dysfunction in a mobile system located at explicit segmental mobile units. Palpable characteristics of a dysfunctional segment are those associated with somatic dysfunction. (See also *STAR, TART and ART*) Responses to regional motor inputs at the dysfunctional segment support the concepts of complete motor asymmetry and mirrorimage motion asymmetries.

segmental mobile unit: A unit of the human movement system consisting of a bone, with articular surfaces for movement, as well as the adnexal tissues that create movement, allow movement and establish position under motor control.

segmental motion: Movement within a vertebral unit described by displacement of a point at the anterior-superior aspect of the superior vertebral body with respect to the segment below.

sensitization: Hypothetically, a shortlived (minutes or hours) increase in central nervous system (CNS) response to repeated sensory stimulation that generally follows habituation.

shear: An action or force causing or tending to cause two contiguous parts of an articulation to slide relative to each other in a direction parallel to their plane of contact. See also *pubic bone, somatic dysfunctions of*. See also *innominates, somatic dysfunctions of, inferior innominate shear*. See also *innominates, somatic dysfunction of, superior innominate shear*. See also *sacrum, somatic dysfunctions of, sacral shear*.

Sherrington law: See *law, Sherrington*.

sidebending: Movement in a coronal (frontal) plane about an anterior-posterior (x) axis. Also called lateral flexion, lateroflexion, or flexion right (or left).

sidebent: The position of any one or several vertebral bodies after sidebending has occurred (Fig. 56). See also *sidebending*.

skin drag: Sense of resistance to light traction applied to the skin. Related to the degree of moisture and degree of sympathetic nervous system activity.

soft tissue (ST): See *osteopathic manipulative treatment, soft tissue*.

soft tissue technique: See *osteopathic manipulative treatment, soft tissue technique*.

somatic dysfunction: Impaired or altered function of related components of the somatic (body framework) system: skeletal, arthrodiastal and myofascial structures, and their related vascular, lymphatic, and neural elements. Somatic dysfunction is treatable using osteopathic manipulative treatment. The positional and motion aspects of somatic dysfunction are best described using at least one of three parameters: 1). The position of a body part as determined by palpation and referenced to its adjacent defined structure, 2). The directions in which motion is freer, and 3). The directions in which motion is restricted. See also *TART*. See also *STAR*.

acute s. d., immediate or short-term impairment or altered function of related components of the somatic (body framework) system. Characterized in early stages by vasodilation, edema, tenderness, pain and tissue contraction. Diagnosed by history and palpatory assessment of tenderness, asymmetry of motion and relative position, restriction of motion and tissue texture change (*TART*). See also *TART*.

Figure 54 Anterior and posterior sclerotomal innervations. (Modified from *Foundations for Osteopathic Medicine*, Ward RC—Ed., Williams & Wilkins; 1997:644).

chronic s. d., impairment or altered function of related components of the somatic (body framework) system. It is characterized by tenderness, itching, fibrosis, paresthesias and tissue contraction. Identified by TART. See also *TART*.

Figure 55 Scoliosis.

linkage, dysfunctional segmental behavior where a single vertebra and an adjacent rib respond to the same regional motion tests with identical asymmetric behaviors (rather than opposing behaviors). This suggests visceral reflex inputs.

primary s. d., 1. The somatic dysfunction that maintains a total pattern of dysfunction. See also *key lesion*. 2. The initial or first somatic dysfunction to appear temporally.

secondary s. d., somatic dysfunction arising either from mechanical or neurophysiologic response subsequent to or as a consequence of other etiologies.

type I s. d., a group curve of thoracic and/or lumbar vertebrae in which the freedoms of motion are in neutral with sidebending and rotation

Figure 56 Sidebent.

in opposite directions with maximum rotation at the apex (rotation occurs toward the convexity of the curve) based upon the Principles of Fryette.

type II s. d., thoracic or lumbar somatic dysfunction of a single vertebral unit in which the vertebra is significantly flexed or extended with sidebending and rotation in the same direction (rotation occurs into the concavity of the curve) based upon the Principles of Fryette.

somatogenic: That which is produced by activity, reaction and change originating in the musculoskeletal system.

somatosomatic reflex: See *reflex, somatosomatic r.*

somatovisceral reflex: See *reflex, somatovisceral r.*

spasm: (compare with hypertonicity) a sudden, violent, involuntary contraction of a muscle or group of muscles, attended by pain and interference with function, producing involuntary movement and distortion (*Dorland's*).

Spencer technique: See *osteopathic manipulative treatment, Spencer technique.*

sphenobasilar synchondrosis (symphysis), somatic dysfunctions of: Any of a group of somatic dysfunctions involving primarily the inter-relationship between the basilar portion of the sphenoid (basisphenoid) and the basilar portion of the occiput (basiocciput). The abbreviation, SBS, is often used in reporting the following somatic dysfunctions:

SBS compression, somatic dysfunction in which the basisphenoid and basiocciput are held forced together significantly limiting SBS motion.

SBS extension, sphenoid and occiput have rotated in opposite directions around parallel transverse axes; the basiocciput and basisphenoid are both inferior in SBS extension with a decrease in the dorsal convexity between these two bones (Fig. 57).

SBS flexion, sphenoid and occiput have rotated in opposite directions around parallel transverse axes; the basiocciput and basisphenoid are both superior in SBS extension with an increase in the dorsal convexity between these two bones (Fig. 58). lateral strain, sphenoid and occiput have rotated in the same direction around parallel vertical axes. Lateral strains of the SBS are named for the position of the basisphenoid, right or left (Fig. 59).

Figure 57 Extension (SBS).

Figure 58 Flexion (SBS).

sidebending-rotation, sphenoid and occiput have rotated in opposite directions around parallel vertical axes and rotate in the same direction around an A-P axis. SBS sidebending-rotations are named for the convexity, right or left (Fig. 60).

torsion, sphenoid and occiput have rotated in opposite directions around an anterior-posterior (A-P) axis. SBS torsions are named for the high greater wing of the sphenoid, right or left (Fig. 61).

vertical strain, sphenoid and occiput have rotated in the same direction around parallel transverse axes. Vertical strains of the SBS are named for the position of the basisphenoid, superior or inferior (Fig. 62).

Figure 59 Right lateral strain (SBS).

Figure 60 Left sidebending/rotation (SBS).

Figure 61 Right torsion (SBS).

Figure 62 Superior vertical strain (SBS).

spinal facilitation: 1. The maintenance of a pool of neurons (e.g., premotor neurons, motor neurons or preganglionic sympathetic neurons in one or more segments of the spinal cord) in a state of partial or subthreshold excitation; in this state, less afferent stimulation is required to trigger the discharge of impulses. 2. A theory regarding the neurophysiological mechanisms underlying the neuronal activity associated with somatic dysfunction. 3. Facilitation may be due to sustained increase in afferent input, aberrant patterns of afferent input, or changes within the affected neurons themselves or their chemical environment. Once established, facilitation can be sustained by normal central nervous system (CNS) activity.

splenic pump technique: See *osteopathic manipulative treatment, splenic pump technique*.

spontaneous release by positioning: See *osteopathic manipulative treatment, counterstrain*.

sprain: Stretching injuries of ligamentous tissue (compare with strain). First degree: microtrauma; second degree: partial tear; third degree: complete disruption. springing technique: See *osteopathic manipulative treatment, springing technique*. See also *osteopathic manipulative treatment, articular treatment system*.

sphinx test: See *backward bending test*.

spring test: 1. A test used to differentiate between backward or forward sacral torsions/rotations. 2. A test used to differentiate bilateral sacral extension and bilateral sacral flexion. 3. A test used to differentiate unilateral sacral extension and unilateral sacral flexion.

S.T.A.R.: A mnemonic for four diagnostic criteria of somatic dysfunction: sensitivity changes, tissue texture abnormality, asymmetry and alteration of the quality and quantity of range of motion.

static contraction: See *contraction, isometric contraction*.

Still, MD, DO: Andrew Taylor. Founder of osteopathy; 1828–1917. First announced the tenets of osteopathy on June 22, 1874, established the American School of Osteopathy in 1892 at Kirksville, MO.

still point: 1. A term used to identify and describe the temporary cessation of the rhythmic motion of the primary respiratory mechanism. It may occur during osteopathic manipulative treatment when a point of balanced membranous or ligamentous tension is achieved. 2. A term used by William G. Sutherland, DO.

Still Technique: See *osteopathic manipulative treatment, Still Technique*.

strain: 1. Stretching injuries of muscle tissue. 2. Distortion with deformation of tissue. See also *ligamentous strain*.

Strachan model: See *sacrum, somatic dysfunctions of, anterior sacrum*. See *sacrum, somatic dysfunctions of, posterior sacrum*.

Strain-Counterstrain: See *osteopathic manipulative treatment, counterstrain*.

stretching: Separation of the origin and insertion of a muscle and/or attachments of fascia and ligaments.

stringiness: A palpable tissue texture abnormality characterized by fine or stringlike myofascial structures.

structural examination: See *osteopathic structural examination*. subluxation: 1. A partial or incomplete dislocation. 2. A term describing an abnormal anatomical position of a joint which exceeds the normal physiologic limit, but does not exceed the joint's anatomical limit.

superior (upslipped) innominate: See *innominate, somatic dysfunctions of, superior innominate shear*.

superior pubic shear: See *pubic bone, somatic dysfunctions of*. See also *symphyseal shear* (Fig. 31).

superior transverse axis: See *sacral motion axis, superior transverse axis (respiratory) and (z) axis*.

supination: 1. Beginning in anatomical position, applied to the hand, the act of turning the palm forward (anteriorly) or upward, performed by lateral external rotation of the forearm. 2. Applied to the foot, it generally applies to movements (adduction and inversion) resulting in raising of the medial margin of the foot, hence of the longitudinal arch. A compound motion of plantar flexion, adduction and inversion. See also *pronation*.

supine: Lying with the face upward (*Dorland's*).

symmetry: The similar arrangement in form and relationships of parts around a common axis, or on each side of a plane of the body (*Dorland's*).

Sutherland fulcrum: A shifting suspension fulcrum of the reciprocal tension membrane located along the straight sinus at the junction of the falx cerebri and tentorium cerebelli. See also *reciprocal tension membrane*. See also *osteopathic manipulative treatment, Osteopathy in the Cranial Field (OCF)*.

symphyseal shear: The resultant of an action or force causing or tending to cause the two parts of the symphysis to slide relative to each other in a direction parallel to their plane of contact. It is usually found in an inferior/superior direction but is occasionally found to be in an anterior/posterior direction (Figs. 28 and 31).

T

tapotement: Striking the belly of a muscle with the hypothenar edge of the open hand in rapid succession in an attempt to increase its tone and arterial perfusion.

TART: A mnemonic for four diagnostic criteria of somatic dysfunction: tissue texture abnormality, asymmetry, restriction of motion and tenderness, any one of which must be present for the diagnosis.

technic: See *technique*.

technique: Methods, procedures and details of a mechanical process or surgical operation (*Dorland's*). See also *osteopathic manipulative treatment*.

tenderness: 1. Discomfort or pain elicited by the osteopathic practitioner through palpation. 2. A state of unusual sensitivity to touch or pressure (*Dorland's*). *NB:* This term is part of the TART acronym for an osteopathic somatic dysfunction.

tender points: 1. Small, hypersensitive points in the myofascial tissues of the body that do not have a pattern of pain radiation. These points are a manifestation of somatic dysfunction and are used as diagnostic criteria and for monitoring treatment. 2. A system of diagnosis and treatment originally described by Lawrence Jones, DO, FAAO. See also *osteopathic manipulative treatment, counterstrain*.

terminal barrier: See *barrier, physiologic b. thoracic aperture (superior)*. See *thoracic inlet*.

thoracic outlet: 1. The functional thoracic inlet consists of T1-4 vertebrae, ribs 1 and 2 plus their costicartilages, and the manubrium of the sternum. See *fascial patterns*. 2. The anatomical thoracic inlet consists of T1 vertebra, the first ribs and their costal cartilages, and the superior end of the manubrium.

thoracic pump: See *osteopathic manipulative treatment, thoracic pump*.

thrust technique: See *osteopathic manipulative treatment, thrust technique*. See also *osteopathic manipulative treatment, high velocity/low amplitude technique (HVLA)*.

tissue texture abnormality (TTA): A palpable change in tissues from skin to periarticular structures that represents any combination of the following signs: vasodilation, edema, flaccidity, hypertonicity, contracture, fibrosis, as well as the following symptoms: itching, pain, tenderness, paresthesias. Types of TTA's include: boggy, thickening, stringiness, ropiness, firmness (hardening), increased/decreased temperature and increased/decreased moisture. *NB:* This term is part of the TART acronym for an osteopathic somatic dysfunction.

toggle technique: See *osteopathic manipulative treatment, toggle technique*.

tonus: The slight continuous contraction of muscle, which in skeletal muscles, aids in the maintenance of posture and in the return of blood to the heart (*Dorland's*).

torsion: 1. A motion or state where one end of a part is twisted about a longitudinal axis while the opposite end is held fast or turned in the opposite direction. 2. A physiologic motion pattern about an antero-posterior axis of the sphenobasilar symphysis/synchondrosis. See also *sphenobasilar synchondrosis (symphysis), somatic dysfunctions of, torsion*.

torsion, sacral: See *sacral torsion*. See also *sacrum, somatic dysfunctions of, sacral torsions*.

traction: A linear force acting to draw structures apart.

traction technique: See *osteopathic manipulative treatment, traction technique*.

transitional region: Areas of the axial skeleton where structure changes significantly lead to functional changes; transitional areas commonly include the following:

Figure 63 The pedicle (B) is the key structure from which other vertebral parts can be identified. (Ward RC, Ex. Ed., *Foundations for Osteopathic Medicine*, Second Edition, Lippincott Williams & Wilkins, Philadelphia, 2003:730.)

Figure 64 Vertebral unit.

occipitocervical region (OA), typically the OA-AA-C2 region is described.

cervicothoracic region (CT), typically C7-T1.

thoracolumbar region (TL), typically T10-L1.

lumbosacral region (LS), typically L5-S1.

transitional vertebrae: A congenital anomaly of a vertebra in which it develops characteristic(s) of the adjoining structure or region.

lumbarization, a transitional segment in which the first sacral segment becomes like an additional lumbar vertebra articulating with the second sacral segment.

sacralization, 1. Incomplete separation and differentiation of the fifth lumbar vertebra (L5) such that it takes on characteristics of a sacral vertebra. 2. When transverse processes of the fifth lumbar (L5) are atypically large, causing pseudoarthrosis with the sacrum and/or ilia(um), referred to as batwing deformity, if bilateral.

translation: Motion along an axis.

translatory motion: See *motion, translatory motion*.

transverse axis of sacrum: See *sacral, sacral movement axis, transverse (z) axis* (Fig. 37).

transverse process: Projects laterally from the region of each pedicle. The pedicle connects the posterior elements to the vertebral body (Fig. 63).

transverse rib axis: See (Fig. 35). See also *rib motion, pump handle rib motion* (Fig. 34).

Traube-Herring-Mayer wave: An oscillation that has been measured in association with blood pressure, heart rate, cardiac contractility, pulmonary blood flow, cerebral blood flow and movement of the cerebrospinal fluid, and peripheral blood flow including venous volume and thermal regulation. This whole-body phenomenon, which exhibits a rate typically slightly less than and independent of respiration, bears a striking resemblance to the primary respiratory mechanism.

Travell trigger point: See *trigger point*.

treatment, active: (Archaic). See *osteopathic manipulative treatment, active method*.

treatment, osteopathic manipulative techniques: See *osteopathic manipulative treatment*.

Trendelenburg test: The patient, with back to the examiner, is told to lift first one foot and then the other. The position and movements of the gluteal fold are watched. When standing on the affected limb the gluteal fold on the sound side falls instead of rising. Seen in poliomyelitis, un-united fracture of the femoral neck, coxa vara and congenital dislocations.

trigger point (myofascial trigger point): 1. A small hypersensitive site that, when stimulated, consistently produces a reflex mechanism that gives rise to referred pain and/or other manifestations in a consistent reference zone that is consistent from person to person. 2. These points were most extensively and systematically documented by Janet Travell, MD, and David Simons, MD. trophic: Pertaining to nutrition, especially in the cellular environment (e.g., trophic function—a nutritional function).

trophicity: 1. A nutritional function or relation. 2. The natural tendency to replenish the body stores that have been depleted.

trophotropic: Concerned with or pertaining to the natural tendency for maintenance and/or restoration of nutritional stores.

-tropic: A word termination denoting turning toward, changing or tendency to change.

tropism, facet: Unequal size and/or facing of the zygapophyseal joints of a vertebra. See also *facet asymmetry*.

type I somatic dysfunction: See *somatic dysfunction, type I s.d.* See also *physiologic motion of the spine*.

type II somatic dysfunction: See *somatic dysfunction, type II s.d.* See also *physiologic motion of the spine*.

U

uncommon compensatory pattern: See *fascial patterns, uncommon compensatory pattern*.

uncompensated fascial pattern: See *fascial patterns, uncompensated fascial pattern*.

V

v-spread: See *osteopathic manipulative treatment, v-spread*.

velocity: The instantaneous rate of motion in a given direction.

ventral technique: See *osteopathic manipulative treatment, visceral manipulation*.

vertebral unit: Two adjacent vertebrae with their associated intervertebral disk, arthrodial, ligamentous, muscular, vascular, lymphatic and neural elements (Fig. 64).

visceral dysfunction: Impaired or altered mobility or motility of the visceral system and related fascial, neurological, vascular, skeletal and lymphatic elements.

visceral manipulation: See *osteopathic manipulative treatment, visceral manipulation*.

viscerosomatic reflex: See *reflex, viscerosomatic r. viscerovisceral reflex: See reflex, viscerovisceral r.*

viscosity: 1. A measurement of the rate of deformation of any material under load. 2. The capability possessed by a solid of yielding continually under stress. See also *elasticity*. See also *plasticity*.

W

weight-bearing line of L3: See *gravitational line* (Fig. 16). Vertical axis: See *sacral motion axis, vertical (y) axis (longitudinal)*.

- Vertebral unit, 558, 558, 1110
- definition, 431, 431
 - Fryette type I mechanics, 433
 - Fryette type II mechanics, 433
 - Fryette's principles, 431–432
 - movements, 432t
 - neutral range, 432, 432
 - nonneutral mechanics, 432, 433b
 - somatic dysfunction, 434
 - spinal mechanics
 - classic, 433
 - laws of, 433–434, 434
 - type I dysfunctions, 433
 - type II dysfunctions, 433
- Vertigo, 498, 509
- Vestibular Schwannoma. *See* Acoustic neuroma.
- Vestibular system, 911–912, 912–914
- Vestibulocollic reflex (VCR), 913
- Vestibuloocular reflex, 913
- Vestibulospinal reflex, 913
- Virulence and pathogenicity, 12
- Viscera
- abdominal, 1003
 - dysfunction, 539
 - fascia, 78–80, 82, 83
 - gall bladder, 580
 - ligaments, 80–81
 - lymphoid tissues, 790
 - manipulation
 - bronchus and airways, 848, 848–849
 - case study, 845, 849
 - definition, 845
 - history, 845–846
 - indications, contraindications and complications, 848
 - key concepts, 845
 - palpation and diagnosis, 848
 - theoretical considerations, 846–847
- pelvic, 965
- small-fiber system, 234
- structures, abdominal region, 664, 665
- thoracic, 536, 537
- Viscerosomatic integration, 53
- Viscerosomatic reflexes, 896
- Viscoelasticity
- of articular cartilage, 100
 - in biomechanics, 96–97, 97
 - of ligaments and tendons, 101, 101
- Visual analogue scale, 543
- Visual and proprioceptive systems, 912–913
- Vitamin E deficiency, 887
- W**
- Walk cycle, 585–587
- Wallace, Alfred Russel, 13
- “Warming up,” and muscle contraction, 104
- Warmth provocative test, 792, 793
- Water cure, 25
- Wear damage, articular cartilage, 100
- Wheezing, 885
- Whiplash, 525
- Whiplash-associated disorder (WAD), and neck pain, 982
- Whole patient assessment, end of life care, 388
- Wind-up phenomenon, 126, 128
- Wiplash-associated disorder (WAD), 913
- Wolff law, 702
- Wrist
- anatomy, 641, 651, 651, 652
 - INR and MFR release, 721, 721
 - motions, 641, 642t
 - muscles and nerves of, 644t
 - somatic dysfunction of, 655–656, 656
- Wristberg ganglion, 144
- Writing and publication of research, 1033–1034
- X**
- Xiphoid process, primary and endpoints, 826
- X-rays
- cervical spine, 522–523
 - of lumbar spine, 570
- Y**
- Yeast infections, in infants, 922
- Yergason test, 1007
- Z**
- Zinc deficiency, 304
- Zygapophyseal joint tropism, 548
