Source: Data from Ref. 12–14.

production of walnut is in China. It is distributed all over China except the cold zone in northern China, and the middle and downstream areas of the Yangtze River. The kernel of walnut has higher nutritional and medicinal values. It has been served as food and raw materials in the food industry for a long time (23).

a. Nutrient contents

The protein content of walnut is about 15% of the whole kernel on a dry weight basis. Walnut contains more than 18 amino acids, with phenylalanine, valine, tryptophan, methionine, threonine, lysine, leucine, and isoleucine as the main ones. The fat from walnut kernel has four main types of fatty acids which form tripalmitin with sugar alcohol and glycerin. The walnut lipid is considered a nutrient product. Besides, there are some soluble compounds such as vitamin C, B1, B2, E, and P, and many different minerals including Ca, Mg, Fe, Mn, and Zn in the walnut kernel.

b. Medicinal functions

Walnut has various health functions for people of all ages and for special groups of people. It is believed that the fetus will develop well if pregnant women consume walnut often during their gestational periods. Children eating walnut often may help their growth and the development of intelligence. In addition, eating walnut may lead to longevity suggesting that walnut is also beneficial for the elderly. Walnut has been shown to possess beneficial effects in preventing and curing cardiovascular diseases. One of the reasons is that walnut contains a large quantity of linoleic acid in its kernel which may help soften blood vessels, prevent cholesterol synthesis, and excrete cholesterols out of the body.

TABLE 98.12
Plants as Ingredients of Functional Food Approved by the Ministry of Public Health of China in 2002

Scientific Name	Chinese Name (In Pin Yin)	Family Name	Parts Used
Acanthopanax gracilistylus	Wujiapi	Araliaceae	Dried root bark
Acanthopanax senticosus	Ciwujia	Araliaceae	Dried root and rhizome or stem
Achyrantes bidentata	Niuxi	Amaranthaceae	Dried root
Alisma orientalis	Zexie	Alismataceae	Dried tuber
Allium tuberosum	Jiucai	Liliaceae	Dried ripe seed
Aloe barbadensis	Luhui	Liliaceae	Dried leaf juice
Aloe ferox	Luhui	Liliaceae	Dried leaf juice
Amomun compactum	Baidoukou	Zingiberaceae	Dried fruit
Amomun kravanh	Baidoukou	Zingiberaceae	Dried fruit
Anemarrhena asphodeloides	Zhimu	Liliaceae	Dried rhizome
Angelica sinensis	Danggui	Umbelliferae	Dried root
Apocynum venetum	Luobuma	Apocynaceae	Dried leaf
Arctium lappa	Niubanggen	Compositae	Dried ripe fruit and root
Asparagus cochinchinensis	Tianmendong	Liliaceae	Dried root tuber
Astragalus complanatus	Shayuanzi	Leguminosae	Dried ripe seed
Astragalus membranaceus	Huangqi	Leguminosae	Dried root
Atractylodes macrocephala	Baishu	Compositae	Rhizome
Atractylodes chinensis	Cangshu	Compositae	Dried rhizome
Atractylodes lancea	Cangshu	Compositae	Dried rhizome
Aucklandia lappa	Muxiang	Compositae	Dried root
Bambusa tuldoides	Zhuru	Gramineae	Dried middle shavings of stem
Bletilla striata	Baiji	Orchidaceae	Dried tuber
Cassia acutifolia	Jueming	Leguminosae	Dried leaflet
Cassia angustifolia	Fanxie	Leguminosae	Dried leaflet
Carthamus tinctorius	Honghua	Compostiae	Dried flower
Centella asiatica	Jixuecao	Umbelliferae	Dried herb
Cimicifuga dahurica	Shengma	Ranunculaceae	Dried rhizome
Cimicifuga foetida	Shengma	Ranunculaceae	Dried rhizome
Cimicifuga heracleifolia	Shengma	Ranunculaceae	Dried rhizome
Cirsium japonicum	Daji	Compositae	Dried aerial part or root
Citrus aurantium	Zhi	Rutaceae	Dried fruit
Citrus reticulata	Qingpi	Rutaceae	Dried pericarp of the young or immature fruits
Citrus sinensis	Cheng	Rutaceae	Dried young fruit
Codonopsis pilosula	Dangshen	Campanulaceae	Dried root
Codonopsis tangshen	Dangshen	Campanulaceae	Dried root
Cornus officinalis	Shanzhuyu	Cornaceae	Dried ripe sarcocarp
Cuscuta chinensis	Tusizi	Convolvulaceae	Dried ripe seed
Cyathula officinalis	Chuanniuxi	Amaranthaceae	Dried root
Cyperus rotundus	Xiangfu	Cyperaceae	Dried rhizome
Dendrobium candidum	Shihu	Orchidaceae	Fresh or dried stem
Epimedium brevicornum	Yinyanghuo	Berberidaceae	Dried aerial part
Epimedium koreanum	Yinyanghuo	Berberidaceae	Dried aerial part
Epimedium pubescens	Yinyanghuo	Berberidaceae	Dried aerial part
Epimedium sagittatum	Yinyanghuo	Berberidaceae	Dried aerial part
Epimedium wushanense	Yinyanghuo	Berberidaceae	Dried aerial part
Equisetum hiemale	Muzei	Equisetaceae	Dried aerial part
Eucommia ulmoides	Duzhong	Eucommiaceae	Dried stem bark, leaf
Eupatorium fortunei	Peilan	Compositae	Dried aerial part
Evodia rutaecarpa	Wuzhuyu	Rutaceae	Dried and nearly ripe fruit
Fagopyrum dibotrys	Jinqiaomai	Polygonaceae	Dried rhizome
Fritillaria hupehensis	Hubeibeimu	Liliaceae	Dried bulb
Ginkgo biloba	Yinxing	Ginkgoaceae	Dried Leaf
Glehnia littoralis	Beishashen	Umbelliferae	Dried root
Gynostemma pentaphyllum	Jiaogulan	Cucurbitaceae	Dried herb

	Asparagus cochinchinensis	Lilaceae

Source: Data from Ref. 15–21.

Walnut as a traditional medicine has been used for more than one thousand years in China. Its medicinal functions were reported in many medicinal literatures in ancient China, such as in the Tang Dynasty, Song Dynasty, and Ming Dynasty. The following are some folk remedies using walnut kernel: 1) 15 g of walnut kernels is chewed carefully and swallowed slowly, three times each day to cure hyperchlorhydria, gastritis, and duodenal ulcer; 2) 10–15 g of walnut kernels is roasted with proper brown sugar to be charcoal, decocted in water, and drunk to cure diarrhea; 3) walnuts are pounded with 100 g black sesame and 100 g mulberry leaves to make pills, 7.5 g per pill, two pills each day, one pill each time to cure vertigo, sleeplessness, and poor memory.

3. Yam

Yam (*Dioscorea* spp.) is one of the earliest sources of foods integrated into traditional folklore and ceremonial occasions. It has served as a main sustenance of people living in the tropical and subtropical countries (24). In China, eating the tubers and roots of yam has a long history (25).

a. Nutrient contents

The major components of yam tubers and roots are water and carbohydrates. Starch, the main carbohydrate, consists of amylose and amylopectin in the starch granules. Sugars, proteins, vitamins, minerals, and some polyphenolic compounds as well as certain steroids are also present in the tuber of yam. The major mineral elements in the tuber include calcium, iron, phosphorus, potassium, manganese, zinc, and magnesium (26).

b. Medicinal functions

Yam is a good source of calories for diabetic patients. The main bioactive compounds in the tubers and roots of some yam species such as *Dioscorea zingiberensis* are steroids. One of the bioactive compounds, diosgenin, is widely

used to produce corticosteroids (e.g., cortisone), sex hormones, fertility control compounds, anabolic agents, and cardicatonic glycosides.

4. Angelica

Angelica (*Angelica sinensis*), called *danggui* in Chinese, belongs to the family Umbelliferae. It is one of the most popular traditional medicinal herbs in China. This herb is mainly distributed in Gansu and Shaanxi, the northwestern part of China. The roots are dried and sliced, and used unprepared or stir-baked with wine (27).

a. Nutrient contents

There are many kinds of nutrients in the roots of angelica. One gram of dry root contains approximately 4,025 μg potassium, 520 μg calcium, 96 μg sodium, 698 μg magnesium, 11 μg manganese, 35 μg copper, 68 μg zinc, 90 μg iron and 1 μg cadmium (28). Other nutrient components in angelica include polysaccharides, terpenoids, amino acids, vitamin B_{12} and vitamin A (29).

b. Medicinal functions

The main pharmacological functions of angelica are promotion of blood circulation, proliferation of the blood cells, relieving pain, and moistening the bowels (30, 31). Angelica has been used by patients with the following symptoms: 1) blood deficiency syndrome characterized by sallow complexion, pale lips and tongue, dizziness, palpitation, or pale nails; 2) irregular menstruation, amenorrhea, and menorrhalgia in case of blood deficiency; 3) various kinds of pains due to blood stasis and rheumatic arthralgia; 4) score, carbuncle, or pyogenic skin infections; and 5) constipation due to blood deficiency and dryness of the intestines.

Better pharmacological results may be achieved by the combination of angelica with other medicinal herbs such as *Astragalus* spp., *Rehmannia* spp., and peony (*Paeonia lactiflora*) (31).

5. Sanchi-Ginseng

Sanchi-ginseng (*Panax notoginseng*) is a well-known Chinese medicine belonging to the family Araliaceae. It is mainly distributed in the Yunnan province in the southwestern part of China. Sanchi-ginseng is similar to Asian ginseng (*Panax ginseng*) in many medicinal effects. Its wild resource has become scarcer because of the increasing demand on the market. It has been cultivated by ethnic groups in Wenshan area of Yunnan and served as a useful plant a long time ago. Dai people in Yunnan traditionally cook it with chicken or pork. A wealth of experience of sanchi-ginseng cultivation has been accumulated over the year by the ethnic groups, and no one knows exactly when and how they began its domestication (32).

a. Nutrient contents

There are many compunds in sanchi-ginseng such as saponins (ginsenosides), amino acids, polysaccharides, essential oils, phytosterol, inorganic ions, etc. (33). One of the main compounds of nutritional and pharmaceutical importance is saponin. Therefore, research has been focused on the separation and structural determination of saponin and its derivatives. A number of dammarane types of triterpenoid saponins are contained as the main constituents

in the plant. Sapogenin panaxadiol and panaxatriol have been obtained by hydrolysis of saponins. Some characteristic saponins such as notoginsenosides R1 and R2 appear only in sanchi-ginseng (34).

There are more than 16 amino acids existing in the roots of sanchi-ginseng. A special amino acid, β-N-oxalo-L-α,β-diaminopropionic acid, which was named as dencichine, has shown clear hemostatic activity. The average content of dencichine reaches 0.87% in the roots. Hence, sanchi-ginseng has been used as a hemostatic product in clinical practice. In addition, more than 79 essential oils have been identified in sanchi-ginseng. There are also some bioactive polysaccharides or sanchinins, which can stimulate immunological functions. Besides, some phytosterols such as carotin, stigmasterol, sitosterol, and some trace elements such as calcium, phosphorus, and iron are found in sanchi-ginseng (33, 35).

b. Medicinal functions

Dai and Zhuang people in Yunnan have used sanchi-ginseng as a hemostat for external application for many years. There are many pharmacological actions of sanchi-ginseng. It has clear hemostatic activity and has been shown to increase the number of red blood cells. It also has antiarrhythmic effects, and may lower the blood pressure transiently. The extracts of sanchi-ginseng, saponins, have many beneficial effects on the metabolism of proteins, sugars, RNA, cholesterols, and lipids in experiments using animal models (36). The non-toxicity of sanchi-ginseng to animals makes it possible for wide applications in clinical practices.

Sanchi-ginseng has been used to treat gastric, intestinal, and cranial cavity gynaecological haemorrhages. It is also the most important component of the famous Chinese medicine "Yunnan-Baiyao" which has shown strong hemostatic, hemotonic, and roborant activities. Recently, the roots of sanchi-ginseng have been used to treat coronary heart diseases, hepatitis, high cholesterol, and high blood lipid. Sanchi-ginseng is being developed into a modern medicine based on its traditional use (37).

IV. SAFETY OF EDIBLE PLANTS

Plant foods may contain, in addition to the many well-known major and minor nutrients, many kinds of naturally occurring toxic compounds which are commonly termed "nature's pesticides" because they are often toxic to predators, such as insects and animals including human. Fortunately, plant foods also contain natural chemicals that may counteract the adverse effects of many natural and synthetic toxins. While much work on these "antitoxins" or "chemopreventives" is still needed, the data available thus far are very encouraging, and some plant foods can actually reduce the incidence of certain types of cancer.

The terms "poisonous" and "non-poisonous" are two relative concepts. It is important for us to recognize plants, collect plant parts in a certain period, process materials with appropriate methods, and cook them correctly. Since it is practically impossible to avoid all plant-derived toxins in a normal diet, the best way to minimize potential hazards would be to eat a wide variety of plant foods, but not too much of any one item.

As poisonous plants grow in wild areas with edible-plants, some reference books are helpful to provide basic knowledge in distinguishing edible plants from the poisonous counterparts (38–41). The compositions of poisonous components in certain plants have been recently summarized (42). In addition, pesticide residues in edible plants are also of great concern to consumers (43).

A. Identification of Edible Plants

There are several groups of plants that are either entirely nontoxic or mostly nontoxic with certain qualifications (39, 40). It is certainly the best way to precede learning each plant that is to be consumed with a study of edible wild plants. Nevertheless, studying the edible plant families should not be considered a shortcut approach, since it still necessitates careful observation of all the floral characteristics. For example, there are small differences between the plants poisonous celery (*Cicuta virosa*) and edible water celery (*Oenanthe javanica*) in terms of their morphological characteristics. It is thus necessary to make sure that a given plant has been clearly identified as a member of certain families before sampling any part of it. Some examples of relatively easily recognized plant families that are nontoxic and primarily edible are shown in Table 98.15 (38–41).

B. Natural Toxins and Chemopreventives in Plants

1. Natural Toxins in Plant Foods

a. Canavanine

Canavanine is produced in some legumes such as edible alfalfa (*Medicago sativa*). It is an analog of arginine, and can substitute for this amino acid in cellular proteins, thereby compromising their functions. Canavanine can inhibit the enzyme nitric oxide synthetase (44) and induce heat-shock proteins in human cells *in vitro* (45).

b. Cyanogenic glycosides

Cyanogenic glycosides are cyanide-containing compounds naturally present in seed of apples, apricots, cherries, peaches, and pears, and also in almonds, sorghum, lima beans, cassava, corn, yams, chickpeas, and kirsch (46). It is well known that cyanide is one of the most acutely toxic chemicals. It binds to and inactivates heme enzymes, in particularly mitochondrial cytochrome oxidase, resulting in an acute, life-threatening anoxia. Cases of acute human poisoning from cyanide released from certain varieties of

TABLE 98.15
Plant Families with Nontoxic and Primarily Edible Species

Family Name	Edible Species	Edibility
Amaranthaceae	*Achyranthus* spp.	The young leaves can be eaten raw or cooked. The older leaves should be cooked since they become bitter with age.
Chenopodiaceae	*Beta vulgaris Chenopodium album*	The leaves can be eaten raw in salads. Older greens may need cooking to render them less bitter and more palatable. Seeds of most members can be harvested, winnowed, and used as a flour or flour extender.
Compositae	*Bedens pilosa* *Lactuca* spp. *Sonchus* spp. *Taraxacum officinale*	When young, many of these herbs can be included in salads, or used as the main salad ingredient. They quickly become bitter as they get older and are then best as cooked greens.
Cruciferae	*Brassica* spp. *Lepidium* spp.	Mustard leaves add a spicy flavor to salads and make a good steamed vegetable or spinach-type dish. The flowers, unopened flower buds, and many of the tender fruits can also be added to salads or cooked foods.
Fagaceae	*Castanea henryi* *Castanopsis* spp. *Fagus* spp. *Quercus* spp.	The nuts are eaten. For some nuts such as acorns, leaching out the bitter tannic acid before use is essential. In some cases, the bark and leaves may be used for medicinal purposes.
Juglandaceae	*Juglans regia*	The nuts of all can be eaten, though in many cases, a rock or hammer is required to break the thick, hard shell.
Labiatae	*Mentha* spp. *Salvia* spp.	Some of these plants are more aromatic than others. Many of the leaves are used for making beverages or medicinal teas. The seeds of many can be harvested and used in bread products, ground into flour, or used in tea.
Malvaceae	*Malva* spp. *Hibiscus* spp.	The leaves of all these plants can be eaten raw in salads or cooked like spinach. The roots of some are tender enough to be used. The flowers and fruits are edible raw or cooked.
Portulacaceae	*Portulaca oleracea*	The entire ground plant can usually be eaten raw. It may need to be steamed sometimes for improved palatability. The seeds can also be harvested and eaten.
Rosaceae	*Fragaria* spp. *Prunus* spp. *Rosa* spp.	Many leaves of this group can be eaten, some raw, some when cooked. The petals can be eaten as well as the fruits, if fleshy and palatable. The leaves and seeds of this group may contain cyanide. There is rarely a problem consuming them in small to moderate amounts, but poisonings have occurred when eaten in large amounts.

Source: Adapted from Ref. 38–41.

lima beans, cassava, and bitter almonds are a regular occurrence (47).

c. *Allyl isothiocyanates*

Allyl isothiocyanates are a group of major naturally occurring compounds that confer a pungent flavor to foods, such as mustard and horseradish, where it is present at about 50 to 100 μg/g. It is also present at much lower levels in cruciferous vegetables such as broccoli and cabbage, and in cassava and other tropical staple foods. Isothiocyanates occur in cruciferous vegetables as glucosinolate conjugates that are hydrolyzed when the plant releases enzymes during chewing (48, 49). Isothiocyanates are toxic goitogens that inhibit the binding of iodine in the thyroid hormones thyroxine (T4) and triiodothyronine (T3). Normal dietary exposures to isothiocyanate-containing foods release milligram amounts of isothiocyanates (43).

d. *Pyrrolizidine alkaloids*

Pyrrolizidine alkaloids (PAs) are common plant toxins produced by over 200 species of flowering plants. PA-containing plants pose significant health hazards to people who consume some kinds of herbal teas and traditional folk remedies and those who eat grain-based foods contaminated with PA-containing plant parts (50).

e. *Acetylcholinesterase inhibitors in potatoes*

Members of the family Solanaceae contain a variety of toxic glycoalkaloids. Potatoes (*Solanum tuberosum*) are an important food staple in many parts of the world and, under certain conditions, produce a variety of glycoalkaloids. Potatoes that have been damaged, exposed to light (green), or sprouted contain the glycoalkaloids α-solanine and α-chaconine. Like physostigmine, solanine and chaconine are highly potent inhibitors of the enzyme acetylcholinesterase. Larger amounts of solanine and chaconine are contained in the green parts of potatoes (51).

f. *Tannins*

Tannins occur in nearly every plant-derived food. They have the ability to bind to and/or precipitate proteins. The ability of tannins to bind to proteins is of great toxicological and nutritional concern. Tannins also bind strongly to metals, such as iron, copper, and zinc, and consequently reduce the gastrointestinal absorption of these metals (52).

g. Caffeic acid and chlorogenic acid

Caffeic acid and its quinic acid conjugate chlorogenic acid occur in an extremely wide range of fruits and vegetables. Caffeic acid inhibits 5-lipoxygenase, a key enzyme in the biosynthesis of various eicosanoids, such as leukotrienes and thromboxanes. These eicosanoids are mediators of a wide variety of physiological and disease status, and are involved in immunoregulation, asthma, inflammation, and platelet aggregation (53, 54).

2. Natural Chemopreventives in Plant Foods

a. Isothiocyanates

Isothiocyanates are a large group of natural plant compounds that exhibit promising anticancer properties. Sulforaphane is a recently discovered powerful chemoprotective often found in broccoli and other cruciferous vegetables (55).

b. Indole 3-carbinol

Indole 3-carbinol (I-3-C), also present in cruciferous vegetables, is another promising chemopreventive (43). I-3-C may inhibit carcinogenesis caused by a number of chemicals in rodents and rainbow trout, most likely by multiple mechanisms. It is thought that I-3-C and its derivatives, produced under acid conditions in the stomach, are most likely to be the bioactive compounds.

c. Polyphenols

Many foods are a rich source of chemopreventive polyphenolics, which are a type of plant tannin. Strawberries, blackberries, cranberries, walnuts, and pecans are particularly good sources of the polyphenol compound ellagic acid that is the hydrolysis product of ellagitannins. Ellagic acid has been shown in numerous studies to be a versatile inhibitor of tumors at a number of sites induced by several compounds (56).

V. CONCLUSIONS AND FUTURE PROSPECTS

Many wild edible plants have been eaten as vegetables for a long time in China. More information on these plants should be collected and carefully studied. While recording information on each food plant, it is necessary to know how it is prepared, cooked or eaten raw, consumed as staple or vegetable, what spices and other ingredients may be added in the preparation, eaten regularly, in scarcity or at particular occasions, etc. Ethnobotanical knowledge could be helpful to understanding what Chinese botanicals are edible and beneficial to health (3, 8, 57).

It is also known that many kinds of edible ferns and fungi are nutritious and widely distributed in China, which are not covered in the present chapter. Further readings on these edible ferns and fungi are thus recommended (58–61).

Wild edible plants are receiving more and more attention due to their multiple beneficial functions. As a result, wild edible plants have been in great demand in recent years. Some Chinese edible plants have been exported to other countries (e.g., Japan, South Korea, Europe, and North America). Domestication and cultivation of these wild edible plants have become a new trend. Some species have also been imported from other countries such as *Opuntia ficus-indica* from Mexico (62), *Eutrema wasabi* from Japan (63, 64) and are now cultivated in China. It is very important for the sustainable development of wild edible plant resources so as to maintain their economic and health contributions to mankind.

99 Vegetable and Plant Parts as Legal Dietary Supplements

Joannie Dobbs and C. Alan Titchenal
Department of Human Nutrition, Food and Animal Sciences, University of Hawaii

CONTENTS

I. INTRODUCTION

There is an increasing number of epidemiological studies that support the health benefits of increasing vegetable consumption (1–3). These benefits are generally associated with the typical intake of fresh and cooked vegetables. In addition, there is much interest in potential health benefits from other vegetable components such as fresh and dried culinary herbs, as well as medicinal herbs in the form of dietary supplements (4,5).

This chapter describes many of the known and potential healthful characteristics of typical vegetables consumed as foods or as non-food vegetable components. Also, potential contraindications are identified for the use of various

medicinal plants. In addition, regulations related to the use of vegetable components as dietary supplements are discussed along with the labeling and advertising of these products.

II. BENEFITS AND POTENTIAL RISKS OF VEGETABLES AS DIETARY SUPPLEMENTS

A. Benefits and Risks

With the numerous health-promoting aspects of vegetables and their components, the growing interest in incorporating these into dietary supplements is not surprising. Many of the purported health benefits of commonly consumed vegetables are presumed to be beneficial in dietary supplements that use vegetable products and their components as ingredients (see Chapter 2)(6).

Medicinal herbs of botanical origin extend the use of vegetables into the medical realm. Many plant products have been used in the development of purified drugs with many of the known health benefits claimed by various cultures from traditional use (7,8).

Along with the many benefits, associated health risks related to herbs are quite complicated. Because of the genetic complexities of humans, the variety of potential health/disease conditions, and the addition of an almost limitless number of potential herb and pharmaceutical drug combinations, it is nearly impossible to predict the complete safety of any dietary supplements. And although there is a long history of traditional use for many botanical components of dietary supplements, this is not always the case with new or processed herb products.

1. Culinary Vegetables in Supplement Form

Many popular claims of efficacy and safety are based on beliefs derived from reports of traditional use and ethnobotanical literature. However, when a botanical product is processed into the form of a dietary supplement and used by thousands of people from multiple racial groups for a great variety of health problems, complications are very possible. Manufacturers of herbal dietary supplements can reduce their risk by consulting reliable resources related to the ingredients to be used in a product.

Frequently, assumptions are made that the health benefits of vegetables (as indicated by epidemiological studies) are due to specific compounds in vegetables such as carotenoids, isoflavones, etc. As a major carotenoid in many vegetables, β-carotene has often been considered to be a major beneficial compound. This prompted studies of β-carotene supplements that resulted in the unexpected result of increased incidence of lung cancer in smokers who received the β-carotene supplements (9).

Similarly, traditional use of herbal plant materials does not always translate to similar efficacy and safety when the herb is processed into the form of powders and pills for use as dietary supplements. A highly controversial situation recently developed when the German Federal Institute for Drugs and Medical Devices (BfArM) canceled all registrations for medicinal products containing kava (*Piper methysticum*) due to reports of liver damage. In light of centuries of traditional use of kava or kava-kava in South Pacific cultures, this was unexpected by the supplement industry (10).

2. Functions, Contraindications, Side Effects, and Dangerous Interactions

Major references on botanicals can be contradictory on some issues. It is the authors = opinion that the most reliable science-based references available are *The Complete German Commission E Monographs* (Commission E) published in 1998 and *Herbal Medicine: Expanded Commission E Monographs* (Expanded Commission E) published in 2000 (11, 12). In order for a botanical to be marketed in Germany as an over-the-counter product, approval by the German Commission is required. In addition, these evaluations frequently agree with approvals by both the World Health Organization (WHO) (13) and the European Scientific Cooperative on Phytotherapy (ESCOP)(14).

Commission E includes 380 monographs on various herbs and herbal preparations (11). Expanded Commission E focuses on about 100 of the herbs commonly sold in the United States (12). Each monograph is expanded from the original Commission E monograph to include updated information on botany, history, composition, safety, efficacy, and therapeutic use. Also, extensive references are included that are not included in Commission E. Although many would imply that these references are too limited or outdated, the authors believe that it is important to use a conservative approach both in evaluating function claims based on science and dietary supplement safety.

Table 99.1 provides a list of factors that can affect both the functionality of the botanical and the toxicity of the botanical. The uncontrollable nature of these factors makes standardization of active compounds somewhat of a challenge.

Table 99.2 provides a list of common English names for vegetables and herbs with their botanical (Latin) and pharmacopeial names. Since different species of herbs can sometimes have identical English names, verification of the botanical name for an herb is essential. In addition, various parts of a given plant may be used for very different effects and consequently are not interchangeable. To avoid confusion, the pharmacopeial names identify the plant name and part or type of preparation. For example, the pharmacopeial names basilici herba, basilici folium, and basilici aetheroleum refer to the whole above ground herb, the

TABLE 99.1
Factors that Can Affect the Functionality and Toxicity of Botanical Dietary Supplements

Conditions Affecting Active Compound Concentrations

1. Growing Conditions (soil type and nutrition, climate, weather, and geographical conditions)
2. Processing Effects on Botanical Compounds (powders, extracts, tinctures, dried plant part)
3. Pharmaceutical Quality of Supplement
4. Standardization of Active Ingredients Concentration

Conditions Affecting Botanical Safety for Humans

1. Dosage (per body size, age, gender, health)
2. Mode of Administration (pill, powder, gel, liquid)
3. Health Status of Individual (immune system status, as well as free of illness or injury or already in a disease state)
4. Reproductive State of Individual (pregnancy, lactation)
5. Children and Elderly
6. Intake of Potentially Conflicting Substances (pharmacological drugs, over-the-counter drugs, nutrient dietary supplements, and other botanical dietary products)
7. Duration of Dosage

leaf, and the oil of the herb respectively. See Commission E for a more complete discussion of this nomenclature.

Table 99.2 also identifies the Commission E approval status and provides quick reference to various positive and negative properties that each plant part may have. The table information is derived from three key sources (11, 12, 15) with supplemental information from other respected sources (13, 16). Table 99.2 often reflects that a botanical can have both a positive and a negative effect on the same physiological system depending on dosage, duration of use, or other factors listed in Table 99.1. Contradictory information can be readily identified by comparing stated uses for an entry and the contraindications and side effects given.

Contraindications are conditions with which an herb or other botanical should not be used. Examples of the types of contraindications identified in *Commission E* for various herbs include allergies, children and infants, diabetes, gallstones, HIV, renal inflammation or disease, etc.

Side effects are potential adverse reactions that have been reported for an herb. Similar to purified drugs, the occurrence of an adverse reaction to a particular herb (side effect) may be rare and should not be considered to be an inevitable result of using an herb or herbal product.

Reproduction, lactation, and the effect of botanicals on children are listed in the table only when there has been a known effect. However, it should be cautioned that these populations are at greater risk from potential toxicity side effects of botanicals.

3. Adverse Events Monitoring

The U.S. Food and Drug Administration, Center for Food Safety and Applied Nutrition, Office of Special Nutritionals has established a Special Nutritionals Adverse Event Monitoring System (SN/AEMS). This system obtains and records information from a wide variety of sources with the purpose of identifying emerging public health problems related to marketed products. Since an adverse event associated with a product may or may not have been caused by the product, the system is designed to identify patterns of adverse and unanticipated or unintended safety problems that may call for public health action (17).

B. Additional Sources of Reliable Information

Although there seem to be more sources available that rely on information about traditional use of herbs than on science-based data, there are additional science-based sources available for the public (18–21).

It has become obvious that herbal dietary supplement information on Internet web sites must be used with caution. In July 2002, the Federal Trade Commission (FTC) sent a press release warning consumers about greater than 280 web sites making questionable health claims. This evaluation was made by a 19 member international Internet health network of consumer protection law enforcement agencies led by the Australian Competition and Consumer Commission and can be found at http://www.ftc.gov/opa/2002/07/biopulse2.htm.

Because the area of dietary supplements is changing so rapidly, valid websites may be the best way to stay current. Table 99.3 provides websites of particular interest for dietary supplements.

III. DIETARY SUPPLEMENT HEALTH AND EDUCATION ACT OF 1994

In October 1994, the Dietary Supplement Health and Education Act (DSHEA) was enacted [Public Law 103–417]. This legislation was developed with the intention to provide consumers with the option to include dietary supplements in their overall health choices to decrease both disease and health-care expenses (22).

Rather than view dietary supplements as drugs, DSHEA regulates dietary supplements more like foods. Dietary supplement labels are required on every supplement with a number of similarities to the nutrition facts panel found on foods. In both cases, the manufacturers must ensure that the label information is truthful and not misleading (23).

There are four key features of DSHEA, besides labeling, which include:

1. Legally defines the term dietary supplement.
2. Places the premarket burden of safety on the manufacturers of dietary supplements.
3. Identifies constraints for written information relating to dietary supplement sales requiring that it be scientifically valid and not misleading.

TABLE 99.2
Examples of Edible Botanicals and their Pharmacological Actions when Consumed as a Dietary Supplement

Commission E approval Status: a = approval, u = unapproval, (#) refers to primary source.
Primary Sources Used: 1 = Commission E (Ref. 11); 2 = Commission E, Expanded (Ref. 12); 3 = Mosby's Handbook of Herbs and Natural Supplements (Ref. 15).
Known Functions: presence of a code for a system or function indicates that reasonable evidence exists for potential benefit.
Known Contraindications: presence of a code for a system or function indicates that reasonable evidence exists for potential negative effects.
Known Interactions: presence of a code indicates that evidence exists for potential negative interactions (d = drug; f = food; h = herb; n = nutrient; l = laboratory tests).
( ) = parenthesis around any of the following initials indicates precautionary steps necessary until information indicates otherwise.
CV = Cardiovascular System.
Ca = Cancer.
CNS = Central Nervous System problems.
D = Dermatitis; Da = Allergic reaction including anaphylactic shock.
E = Endocrine Functions; E1 = Diabetes; E2 = thyroid.
G = Gastrointestinal Tract; G1 = Upper GI functions; G2 = constipation; G3 = diarrhea.
H = hematology/lymphatic.
I = Immune system.
L = Liver + Gall Bladder; L1 = liver; L2 = gall bladder.
NP = Neural/Psychological; NP1 = appetite; NP2 = fatigue; NP3 = normal sleep.
NSI = Not Sufficient information to make claims.
O = Ophthalmologic.
R = Respiratory System.
Rh = Muscle/Joint System; Rh1 = muscle; Rh2 = joint; Rh3 = convulsions.
Rp = Pregnancy and lactation; Rpc = Pregnancy, lactation, and children.
U = Urinary tract and kidney; U1 = Bladder; electrolyte balance; U2 = Kidney function.

4. Creates the Office of Dietary Supplements (ODS) in the National Institutes of Health (NIH) to coordinate dietary supplement research within NIH.

It is also the responsibility of ODS to advise other Federal agencies regarding dietary supplements.

A. Dietary Supplement Terminology

FDA traditionally considered dietary supplements to be composed only of essential nutrients including vitamins, minerals, and proteins. In 1990 the Nutrition Labeling and Education Act identified herbs and similar nutritional substances as dietary supplements. In 1994, DSHEA legally defined dietary supplement to include non-nutrients such as herbs, fish oils, psyllium, enzymes, glandulars, and mixtures of these (22).

The short formal definition of a "Dietary Supplement" is a product (other than tobacco) that is intended to supplement the diet that bears or contains one or more of the following dietary ingredients (23):

- A vitamin
- A mineral
- An herb or other botanical
- An amino acid
- A dietary substance for use by man to supplement the diet by increasing the total daily intake. This might include enzymes or tissues from organs or glands.
- A concentrate, metabolite, constituent, extract, or combinations of these ingredients

and

- Is intended for ingestion in pill, capsule, tablet, or liquid form
- Is not represented for use as a conventional food or as the sole item of a meal or diet
- Is labeled as a "dietary supplement"

The expanded definition can be found at web site for the Office of Dietary Supplements National Institutes of Health at http://ods.od.nih.gov/health.aspx.

Botanical ingredients include all plant-derived materials whether fresh, preserved, or dried full plants, plant parts, plant species mixtures, plant extracts, and compounds found in such materials. Items that are commonly termed herbs or herbal products, regardless of whether they meet the dictionary definition of herb or that are comprised of parts, extracts, or preparations of woody plants are included as botanical ingredients. Botanicals also include fungi and algae. Herbs are considered to be flowering plants whose stems above ground do not become woody (24).

Any dietary ingredient that was not marketed in the United States in a dietary supplement prior to October 15, 1994 is considered a "new dietary ingredient" (25). If a "new dietary ingredient" is to be marketed in a dietary supplement, the following conditions must be met:

1. The substance is first considered to be a "dietary ingredient" (26).
   A dietary ingredient is defined as a vitamin; a mineral; an herb or other botanical; an amino acid; a dietary substance for use by man to supplement the diet by increasing total dietary intake; or a concentrate, metabolite, constituent, extract, or combination of any of the above dietary ingredients.
2. The product qualifies for the definition of dietary supplement (see DSHEA terminology above) and is not presently nor has it been authorized for investigation as an approved drug, certified antibiotic, or licensed biologic (26).

Also a dietary supplement containing a "new dietary ingredient" shall be deemed adulterated unless it meets at least one of two requirements:

1. The dietary supplement contains only dietary ingredients which have been present in the food supply as an article used for food in a form in which the food has not been chemically altered.
2. There is a history of use or other evidence of safety establishing that the dietary ingredient when used under the conditions recommended

> or suggested in the labeling of the dietary supplement will reasonably be expected to be safe and, at least 75 days before being introduced or delivered for introduction into interstate commerce, the manufacturer or distributor of the dietary ingredient or dietary supplement provides the FDA with information, including any citation to published articles, which is the basis on which the manufacturer or distributor has concluded that a dietary supplement containing such dietary ingredient will reasonably be expected to be safe (25).

B. DSHEA Responsibilities

1. Manufacturers

The greatest difference between the regulation of food products and dietary supplements is that the manufacturer is responsible for ensuring that their product is safe prior to marketing. Under DSHEA's guidelines, manufacturers also are responsible for ensuring that product information is both truthful and is not misleading.

Manufacturers must also follow FDA's Current Good Manufacturing Practices in manufacturing, packing, or holding dietary supplements (27).

The DSHEA amends the adulteration provisions of the FD&C Act. Under DSHEA a dietary supplement is adulterated if it or one of its ingredients presents "a significant or unreasonable risk of illness or injury" when used as directed on the label, or under normal conditions of use (if there are no directions). A dietary supplement that contains a new dietary ingredient (i.e., an ingredient not marketed for dietary supplement use in the U.S. prior to October 15, 1994) may be adulterated when there is inadequate information to provide reasonable assurance that the ingredient will not present a significant or unreasonable risk of illness or injury. The Secretary of HHS may also declare that a dietary supplement or dietary ingredient poses an imminent hazard to public health or safety. However, like any other foods, it is a manufacturer's responsibility to ensure that its products are safe and properly labeled prior to marketing.

2. Food and Drug Administration

Under DSHEA, FDA's responsibility for dietary supplements begins after a product reaches the market. This responsibility includes evaluating product information on labels, package inserts, and accompanying literature which may make a product unsafe. FDA recently expanded their evaluations to include product information on company websites.

DSHEA also grants FDA the authority to establish Good Manufacturing Practices (GMPs) for dietary supplements that are similar to those used for food products. These GMPs should ensure the safety of dietary supplements throughout formulation, manufacturing, packaging, storage, and shipping.

3. Federal Trade Commission

The Federal Trade Commission (FTC) bears the responsibility of regulating false advertising claims for both food and dietary supplements. Under DSHEA, the FTC is the lead agency to assure that information within and on dietary supplement packages is both truthful and not misleading. This responsibility carries over to accompanying literature as well.

C. Constraints on Written Product Information

There are multiple levels of dietary supplement information available to the consumer, with a significant amount based primarily on traditional uses and "word-of-mouth" testimonials. Prior to passage of DSHEA, information linked to supplement sales was not always based on science, however DSHEA now requires that written information relating to the sale of dietary supplements be scientifically valid and not be misleading to the consumer. This includes constraints on product labeling described below in Section IV-D "Claims."

D. Office of Dietary Supplements

DSHEA's intention is for the Office of Dietary Supplements (ODS) to be the coordinating body for dietary supplement research within NIH. This responsibility includes: 1) promoting scientific research on supplements related to their potential for decreasing the incidence of chronic diseases; 2) becoming a worldwide reservoir for dietary supplement scientific data, and 3) being a scientific advisor to other federal agencies including Human Health Services and FDA.

IV. LABELING OF DIETARY SUPPLEMENTS

A. General Labeling Information

As with food products, there is a set of information that must be supplied on the product label. This includes a descriptive name of the product that clearly identifies the product as a "dietary supplement" on the front label (e.g. Vitamin E Dietary Supplement). Also required is the name and place of business of the manufacturer, packer, or distributor; a complete list of ingredients; and the net contents of the product. To access current information on basic and specific dietary supplement regulations, see Industry Information and Regulations at the U.S. Food & Drug Administration Center for Food Safety & Applied Nutrition Dietary Supplements web site [http://www.cfsan.fda.gov/~dms/ds–ind.html].

All dietary supplements also require a "Supplement Facts" panel and not "Nutrition Facts" even if the dietary supplement is a nutrient. Below the panel, a statement of ingredients should list all dietary ingredients not already identified in the "Supplement Facts" panel (e.g., rose hips as the source of vitamin C). And the ingredient statement should include other food ingredients (e.g., water, oil, and sugar), and technical additives or processing aids (e.g. colors, flavors, gelatin, preservatives, and stabilizers). See http://www.cfsan.fda.gov/~lrd/fr97923a.html.

In addition, it is also required that ingredient statements clearly indicate which part of the plant is used including that in extracts, oils and any other form.

B. Supplement Facts Panel

The "Supplement Facts" must include the quantity for each dietary ingredient per serving. The listing may include the source of a dietary ingredient (e.g., "300 mg. calcium from calcium gluconate"). If an ingredient is listed in the "Supplement Facts" panel, it is not required to also be listed in the statement of ingredients.

For dietary supplements containing significant amounts of nutrients that have recommendations for daily consumption (Daily Values), ingredient lists must list nutrients in the order that FDA has established for labeling (28). See Table 99.4.

For supplements containing botanicals, including proprietary blends, the total quantity of all dietary ingredients in the blend (excluding inert ingredients) must be listed. Also for products containing herbal and/or botanical ingredients, the label must indicate the part of the plant from which the ingredient is derived (e.g. root, leaf, bark).

DSHEA indicates that when an official compendium exists for a dietary supplement, then the supplement must meet the specifications of the compendium or the product can be considered to be misbranded. Three such official compendia include the U. S. Pharmacopeia, the Homeopathic Pharmacopeia of the United States, and the National Formulary.

TABLE 99.4
Reference Nutrient Values for Dietary Supplements

Mandatory			Voluntary		
Nutrient	**Daily Values**		**Nutrient**	**Daily Values**	
Total Fat*	65 g	DRV**	Vitamin D	400 IU	RDI
Saturated fatty acids	20 g	DRV	Vitamin E	30 IU	RDI
Cholesterol	300 mg	DRV	Vitamin K	80 mcg	RDI
Sodium	2400 mg	DRV	Thiamin	1.5 mg	RDI
Potassium	3500 mg	DRV	Riboflavin	1.7 mg	RDI
Total carbohydrate	300 g	DRV	Niacin	20 mg	RDI
Fiber	25 g	DRV	Vitamin B6	2.0 mg	RDI
Protein	50 g	DRV	Folate	400 mcg	RDI
			Vitamin B12	6.0 mcg	RDI
Vitamin A	5000 IU	RDI***	Biotin	300 mcg	RDI
Vitamin C	60 mg	RDI	Pantothenic acid	10 mg	RDI
Calcium	1000 mg	RDI	Phosphorus	1000 mg	RDI
Iron	18 mg	RDI	Iodine	150 mcg	RDI
			Magnesium	400 mg	RDI
			Zinc	15 mg	RDI
g = grams			Selenium	70 mcg	RDI
mg = milligrams			Copper	2.0 mg	RDI
mcg = micrograms			Manganese	2.0 mg	RDI
IU = International Units			Chromium	120 mcg	RDI
			Molybdenum	75 mcg	RDI
			Chloride	3400 mg	RDI

* Based on diets containing about 2,000 calories a day for adults and children over 4 only.

** Daily Reference Values (DRVs).

*** Reference Daily Intake (RDI).

Nutrients in this table are listed in the order in which they are required to appear on a label. The second column of nutrients follows directly after the first column (21 CFR 101.9(c)).

This list includes only those nutrients for which a Daily Reference Value (DRV) has been established in 21 CFR 101.9(c);(9) or a Reference Daily Intake (RDI) in 21 CFR 101.9(c);(8);(iv) [http://www.cfsan.fda.gov/~dms/flg-7a.html]. Revision. Jan 30, 1998

C. Claims

1. Types of Claims

Based on DSHEA, dietary supplement label claims may only be described in relation to: 1) classical nutrient deficiency diseases; 2) the "well-being" achieved by consuming the dietary ingredient or 3) "structure/function" of the dietary supplement on the body. In the case of deficiency diseases, the prevalence of the disease in the United States must be disclosed on the supplement label. A guide for industry on dietary supplement claims can be found http://www.cfsan.fda.gov/~dms/sclmguid.html (29).

As important as the above stipulations, DSHEA mandates that no supplement can claim directly nor can it be implied that the use of a dietary supplement will assist to diagnose, prevent, mitigate, treat, or cure a specific disease (unless approved under the new drug provisions of the FD&C Act). In other words, it is not permissible to imply that a dietary supplement may detoxify the liver nor can a dietary supplement prevent osteoporosis (29, 30). Numerous examples of permitted and prohibited claims can be found at the MLMLAW site [http://www.mlmlaw.com/index.html].

2. Disease Criteria

Disease is defined as "… damage to an organ, part, structure, or system of the body such that it does not function properly (e.g., cardiovascular disease), or a state of health leading to such dysfunctioning (e.g., hypertension); except that diseases resulting from essential nutrient deficiencies (e.g., scurvy, pellagra) are not included in this definition" (30).

Listed below is a summary of ten major criteria that determine if a statement is considered to be a disease claim (30) and additional examples of permissible and non-permissible claims can be found at http://www.mlmlaw.com/saleswatch (31).

A claim is not permissible if it:

1. Claims to have an effect on a disease or class of diseases
2. Claims to have an effect on characteristic symptoms of disease
3. Claims to have an effect on a condition associated with a natural state such as pregnancy
4. Implies to have an effect on a disease because of product name, formulation, or graphics
5. Implies an effect by belonging to a class of products that are intended to diagnose, mitigate, treat, cure, or prevent a disease
6. Portrays a product as promoting health when in reality the function is disease therapy
7. Assists a therapy or drug intended to diagnose, mitigate, treat, cure, or prevent a disease
8. Relates to preventing a disease or to a vector of disease
9. Implies that the product can treat, prevent, or mitigate adverse events associated with a disease therapy
10. Suggests an effect on a disease or diseases

For FDA authorized health claims related to specific nutrients in vegetables (6, 32), a dietary supplement may make the appropriate claim only if the product meets all criteria to bear the claim.

3. Qualified Health Claims

One exception to the above limitations on health claims is the use of FDA approved "qualified health claims." When the FDA finds that significant scientific agreement does not exist for a health claim, but more evidence is in support of the nutrient/disease relationship than against it, a qualified health claim may be appropriate. The FDA reviews proposed qualified health claims on a case by case basis. An example of an approved qualified health claim for selenium is: "Selenium may reduce the risk of certain cancers. Some scientific evidence suggests that consumption of selenium may reduce the risk of certain forms of cancer. However, FDA has determined that this evidence is limited and not conclusive." To use this or other approved qualified health claims, specific criteria must be met. For additional information, see http://www.cfsan.fda.gov/~dms/ds-ltr35.html.

4. Disclaimer and Warnings

To make any claim on dietary supplements, a manufacturer must verify that the statements are truthful and are not misleading. Supplement product labels with a claim must also bear the phrase, "This statement has not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure, or prevent any disease."

Unlike health claims, structure/function statements do not need to be approved by FDA before a manufacturer markets the supplement product bearing the statement. However, the FDA should be notified within 30 days after a product that bears the claim is first marketed (29, 33).

5. Point of Purchase Supporting Literature

To assist the consumer in choosing dietary supplements, DSHEA allows retail outlets to provide "third-party" materials (e.g. book chapters, scientific abstracts) related to any health-related benefits of dietary supplements. These materials may not contain false or misleading information and cannot promote a specific supplement brand or have product promotional literature attached (23).

6. Internet Claims

FDA recently indicated that commercial web sites for a product must comply with the same regulations established for product labels and point of purchase supporting literature. Therapeutic claims that indicate a product is intended for use in the cure, mitigation, treatment, or prevention of disease can force FDA to establish the product as a drug, placing the product under much more stringent regulation (35).

For more information on dietary supplement labeling and claims that can be made, see the Report of the Commission on Dietary Supplement Labels (36).

V. OTHER CONSIDERATIONS

Staying current in the area of dietary supplements will be a challenge for anyone. To prevent wasting valuable time and resources, staying abreast with FDA responses on safety issues will be crucial. For updated warning and safety information on dietary supplements see http://www.cfsan.fda.gov/~dms/ds-warn.html (37).

VI. CONCLUSION

Both the potential benefits and risks associated with the use of vegetable and plant parts in dietary supplements can be compelling. These botanical components range from rather basic and harmless culinary vegetables to powerful herbal extractions that can cause death with inappropriate use. Between these extremes, there is a large grey area. As the studies of this grey area continue, surprises related to both benefits and risks are to be expected.

Developers and manufacturers of dietary supplements need to be aware of the regulatory requirements involved in production and marketing of supplements as well as the rapidly growing body of research literature. Like the products' potential effects on people, the financial benefits and risks to manufacturers can be great. The risks can be extremely great for an uninformed manufacturer. Use of the resources reviewed in this chapter can certainly help to reduce the risks.

ACKNOWLEDGMENT

The information in this chapter has been derived from "Vegetable and Plant Parts as Legal Dietary Supplements," by J. Dobbs and C. A. Titchenal. In *Handbook of Vegetable Preservation and Processing*, editors: Y. H. Hui et al., Marcel Dekker, 2004.

100 U.S. Regulations for Advertising Dietary Supplements, Health and Diet Products and Services

Nanna Cross
Chicago, Illinois

CONTENTS

I. INTRODUCTION

The array of dietary supplements — vitamins and minerals, amino acids, enzymes, herbs, animal extracts and others — has grown tremendously over the years. The number of products — and the variety of uses for which they are promoted — have increased significantly in the last few years. Scientific research on the associations between supplements and health is accumulating rapidly. Although the benefits of some of these products have been

documented, the advantages of others are unproven. Officials at the Federal Trade Commission (FTC) and the Food and Drug Administration (FDA) say health fraud promoters often target people who are overweight or have serious conditions for which there are no cures, including multiple sclerosis, diabetes, Alzheimer's disease, cancer, HIV and AIDS, and arthritis.

The role of the FTC, which enforces laws outlawing "unfair or deceptive acts or practices," is to ensure that consumers get accurate information about dietary supplements so that they can make informed decisions about these products. The FTC and the FDA work together under a long-standing liaison agreement governing the division of responsibilities between the two agencies. As applied to dietary supplements, the FDA has primary responsibility for claims on product labeling, including packaging, inserts, and other promotional materials distributed at the point of sale. The FTC has primary responsibility for claims in advertising, including print and broadcast ads, infomercials, catalogs, and similar direct marketing materials. Marketing on the Internet is subject to regulation in the same fashion as promotions through any other media. Because of their shared jurisdiction, the two agencies work closely to ensure that their enforcement efforts are consistent to the fullest extent feasible. In 1994, the Dietary Supplements Health and Education Act (DSHEA) significantly changed the FDA's role in regulating supplement labeling. Although DSHEA does not directly apply to advertising, it has generated many questions about the FTC's approach to dietary supplement advertising. The answer to these questions is that advertising for any product — including dietary supplements — must be truthful, not misleading, and substantiated. Given the dramatic increase in the volume and variety of dietary supplement advertising in recent years, FTC staff is issuing this guide to clarify how long-standing FTC policies and enforcement practices relate to dietary supplement advertising.

The FTC's approach to supplement advertising is best illustrated by its Enforcement Policy Statement on Food Advertising (Food Policy Statement). Although the Food Policy Statement does not specifically refer to supplements, the principles underlying the FTC's regulation of health claims in food advertising are relevant to the agency's approach to health claims in supplement advertising. In general, the FTC gives great deference to an FDA determination of whether there is adequate support for a health claim. Furthermore, the FTC and the FDA will generally arrive at the same conclusion when evaluating unqualified health claims. As the Food Policy Statement notes, however, there may be certain limited instances when a carefully qualified health claim in advertising may be permissible under FTC law, in circumstances where it has not been authorized for labeling. However, supplement marketers are cautioned that the FTC will require both strong scientific support and careful presentation for such claims. Supplement marketers should ensure that anyone involved in promoting products is familiar with basic FTC advertising principles. The FTC has taken action not just against supplement manufacturers, but also, in appropriate circumstances, against ad agencies, distributors, retailers, catalog companies, infomercial producers and others involved in deceptive promotions.

Therefore, all parties who participate directly or indirectly in the marketing of dietary supplements have an obligation to make sure that claims are presented truthfully and to check the adequacy of the support behind those claims.

II. APPLICATION OF FTC LAW TO DIETARY SUPPLEMENT ADVERTISING

The FTC's truth-in-advertising law can be boiled down to two common-sense propositions: 1) advertising must be truthful and not misleading, and 2) before disseminating an ad, advertisers must have adequate substantiation for all objective product claims. A deceptive ad is one that contains a misrepresentation or omission that is likely to mislead consumers acting reasonably under the circumstances to their detriment. The FTC's substantiation standard is a flexible one that depends on many factors. When evaluating claims about the efficacy and safety of foods, dietary supplements, and drugs, the FTC has typically applied a substantiation standard of competent and reliable scientific evidence. To determine whether an ad complies with FTC law, it is first necessary to identify all express and implied claims that the ad conveys to consumers. Once the claims are identified, the scientific evidence is assessed to determine whether there is adequate support for those claims. The following sections describe this two-step process with examples illustrating how principles of ad interpretation and substantiation apply in the context of dietary supplement advertising. The examples have been simplified to illustrate one or two specific points. Therefore, advertisers should use these examples as general guidance only.

III. IDENTIFYING CLAIMS AND INTERPRETING AD MEANING

A. Identifying Express and Implied Claims

The first step in evaluating the truthfulness and accuracy of advertising is to identify all express and implied claims an ad conveys to consumers. Advertisers must make sure that whatever they say expressly in an ad is accurate. Often, however, an ad conveys other claims beyond those expressly stated. Under FTC law, an advertiser is equally responsible for the accuracy of claims suggested or implied by the ad. Advertisers cannot suggest claims that they could not make directly. When identifying claims, advertisers should not focus just on individual phrases or statements, but rather should consider the ad as a whole, assessing the "net

impression" conveyed by all elements of the ad, including the text, product name, and depictions. When an ad lends itself to more than one reasonable interpretation, the advertiser is responsible for substantiating each interpretation. Copy tests, or other evidence of how consumers actually interpret an ad, can be valuable. In many cases, however, the implications of the ad are clear enough to determine the existence of the claim by examining the ad alone, without extrinsic evidence.

Example 1

An advertisement claims that "university studies prove" that a mineral supplement can improve athletic performance. The advertiser has expressly stated the level of support for the claimed benefit and is therefore responsible for having "university studies" that document the advertised benefit. Furthermore, the implied reference to scientific evidence likely conveys to consumers the implied claim that the studies are methodologically sound.

Example 2

An advertisement for a vitamin supplement claims that 90% of cardiologists regularly take the product. In addition to the literal claim about the percentage of cardiologists who use the product, the ad likely conveys an implied claim that the product offers some benefit for the heart. Therefore, the advertiser must have adequate support for both representations. Depending on how it is phrased, or the context in which it is presented, a statement about a product's effect on a normal "structure or function" of the body may also convey to consumers an implied claim that the product is beneficial for the treatment of a disease. If elements of the ad imply that the product also provides a disease benefit, the advertiser must be able to substantiate the implied disease claim even if the ad contains no express reference to disease.

Example 3

An ad for an herbal supplement makes the claim that the product boosts the immune system to help maintain a healthy nose and throat during the winter season. The ad features the product name "Cold Away" and includes images of people sneezing and coughing. The various elements of the ad — the product name, the depictions of cold sufferers, and the reference to nose and throat health during the winter season — likely convey to consumers that the product helps prevent colds. Therefore, the advertiser must be able to substantiate that claim. Even without the product name and images, the reference to nose and throat health during the winter season may still convey a cold prevention claim.

Example 4

An ad for a dietary supplement called "Arthricure" claims that the product maintains joint health and mobility into old age. The "before" picture shows an elderly women using a walker. The "after" picture shows her dancing with her husband. The images and product name likely convey implied claims that the product is effective in the treatment of the symptoms of arthritis, and may also imply that the product can cure or mitigate the disease. The advertiser must be able to substantiate these implied claims.

B. When to Disclose Qualifying Information

An advertisement can also be deceptive because of what it fails to say. Section 15 of the FTC Act requires advertisers to disclose information if it is material in light of representations made or suggested by the ad, or material considering how consumers would customarily use the product. Thus, if an ad would be misleading without certain qualifying information, that information must be disclosed. For example, advertisers should disclose information relevant to the limited applicability of an advertised benefit. Similarly, advertising that makes either an express or implied safety representation should include information about any significant safety risks. Even in the absence of affirmative safety representations, advertisers may need to inform consumers of significant safety concerns relating to the use of their product.

Example 5

An advertisement for a multi-vitamin/mineral supplement claims that the product can eliminate a specific mineral deficiency that results in feelings of fatigue. In fact, less than 2% of the general population to which the ad is targeted suffers from this deficiency. The advertiser should disclose this fact so that consumers will understand that only the small percentage of people who suffer from the actual mineral deficiency are likely to experience any reduction in fatigue from using the product.

Example 6

An advertiser for a weight loss supplement cites a placebo-controlled, double-blind clinical study as demonstrating that the product resulted in an average weight loss of fifteen pounds over an eight-week period. The weight loss for the test group is, in fact, significantly greater than for the control subjects. However, both the control and test subjects engaged in regular exercise and followed a restricted-calorie diet as part of the study regimen. The advertisement should make clear that users of the supplement must follow the same diet and exercise regimen to achieve the claimed weight loss results.

Example 7

An advertiser claims that its herbal product is a natural pain reliever "without the side effects of over-the-counter pain relievers." However, there is substantial evidence that the product can cause nausea in some consumers when taken regularly. Because of the reference to the side effects of other pain relievers, consumers would likely understand

this ad to mean that the herbal product posed no significant adverse effects. Therefore, the advertiser should disclose information about the adverse effects of the herbal product.

Example 8

An herbal weight loss product contains an ingredient which, when consumed daily over an extended period, can result in a significant increase in blood pressure. Even in the absence of any representation about the product's safety, the advertiser should disclose this potentially serious risk.

C. Clear and Prominent Disclosure

When the disclosure of qualifying information is necessary to prevent an ad from being deceptive, that information should be presented clearly and prominently so that it is actually noticed and understood by consumers. A fine-print disclosure at the bottom of a print ad, a disclaimer buried in a body of text, a brief video superscript in a television ad, or a disclaimer that is easily missed on an Internet web site, are not likely to be adequate. To ensure that disclosures are effective, marketers should use clear language, avoid small type, place any qualifying information close to the claim being qualified, and avoid making inconsistent statements or distracting elements that could undercut or contradict the disclosure. Because consumers are likely to be confused by ads that include inconsistent or contradictory information, disclosures need to be both direct and unambiguous to be effective.

Example 9

A marketer promotes a supplement as a weight loss aid. There is adequate substantiation to indicate that the product can contribute to weight loss when used in conjunction with a diet and exercise regimen. The banner headline claims "LOSE 5 POUNDS IN 10 DAYS," the ad copy discusses how easy it is to lose weight by simply taking the product 3 times a day, and the ad includes dramatic before-and-after pictures. A fine print disclosure at the bottom of the ad, "Restricted calorie diet and regular exercise required," would not be sufficiently prominent to qualify the banner headline and the overall impression that the product alone will cause weight loss. The ad should be revised to remove any implication that the weight loss can be achieved by use of the product alone. This revision, combined with a prominent indication of the need for diet and exercise, may be sufficient to qualify the claim. However, if the research does not show that the product contributes anything to the weight loss effect caused by diet and exercise, it would be deceptive, even with a disclosure, to promote the product for weight loss. Qualifying information should be sufficiently simple and clear that consumers not only notice it, but also understand its significance. This can be a particular challenge when explaining complicated scientific concepts to a general audience, for example, if an advertiser wants to promote the effect of a supplement where there is an emerging body of science supporting that effect, but the evidence is insufficient to substantiate an unqualified claim. The advertiser should make sure consumers understand both the extent of scientific support and the existence of any significant contrary evidence. Vague qualifying terms — for example, that the product "may" have the claimed benefit or "helps" achieve the claimed benefit — are unlikely to be adequate. Furthermore, advertisers should not make qualified claims where the studies they rely on are contrary to a stronger body of evidence. In such instance, even a qualified claim could mislead consumers.

Example 10

A company has results from two studies suggesting that the main ingredient in its supplement helps to maintain healthy cholesterol levels. There are, however, significant limitations to each of the studies and a better controlled study is necessary to confirm whether the effect is genuine. The company makes a claim in advertising that "scientific studies show that our product may be effective in reducing cholesterol." The use of the word "may" is not likely to be a sufficient disclaimer to convey the limitations of the science. A disclosure that clearly describes the limitations of the research, in language consumers can easily understand, and states directly and unambiguously that additional research is necessary to confirm the preliminary results is more likely to be effective. As discussed in the following section on substantiating claims, the extent to which studies support an unqualified claim will depend largely on what experts in the relevant field would consider to be adequate support.

IV. SUBSTANTIATING CLAIMS

A. Overview

In addition to conveying product claims clearly and accurately, marketers need to verify that there is adequate support for their claims. Under FTC law, before disseminating an ad, advertisers must have a reasonable basis for all express and implied product claims. What constitutes a reasonable basis depends greatly on what claims are being made, how they are presented in the context of the entire ad, and how they are qualified. The FTC's standard for evaluating substantiation is sufficiently flexible to ensure that consumers have access to information about emerging areas of science. At the same time, it is sufficiently rigorous to ensure that consumers can have confidence in the accuracy of information presented in advertising. A number of factors determine the appropriate amount and type of substantiation, including:

1. *The Type of Product.* Generally, products related to consumer health or safety require a relatively high level of substantiation.
2. *The Type of Claim.* Claims that are difficult for consumers to assess on their own are held to a

more exacting standard. Examples include health claims that may be subject to a placebo effect or technical claims that consumers cannot readily verify for themselves.

3. *The Benefits of a Truthful Claim, and The Cost/Feasibility of Developing Substantiation for the Claim.* These factors are often weighed together to ensure that valuable product information is not withheld from consumers because the cost of developing substantiation is prohibitive. This does not mean, however, that an advertiser can make any claim it wishes without substantiation, simply because the cost of research is too high.
4. *The Consequences of a False Claim.* This includes physical injury, for example, if a consumer relies on an unsubstantiated claim about the therapeutic benefit of a product and foregoes a proven treatment. Economic injury is also considered.
5. *The Amount of Substantiation that Experts in the Field Believe is Reasonable.* In making this determination, the FTC gives great weight to accepted norms in the relevant fields of research and consults with experts from a wide variety of disciplines, including those with experience in botanicals and traditional medicines. Where there is an existing standard for substantiation developed by a government agency or other authoritative body, the FTC accords great deference to that standard. The FTC typically requires claims about the efficacy or safety of dietary supplements to be supported with "competent and reliable scientific evidence," defined in FTC cases as "tests, analyses, research, studies, or other evidence based on the expertise of professionals in the relevant area, that have been conducted and evaluated in an objective manner by persons qualified to do so, using procedures generally accepted in the profession to yield accurate and reliable results." This is the same standard the FTC applies to any industry making health-related claims. There is no fixed formula for the number or type of studies required or for more specific parameters like sample size and study duration. There are, however, a number of considerations to guide an advertiser in assessing the adequacy of the scientific support for a specific advertising claim.

B. Ads that Refer to a Specific Level of Support

If an advertiser asserts that it has a certain level of support for an advertised claim, it must be able to demonstrate that the assertion is accurate. Therefore, as a starting point, advertisers must have the level of support that they claim, expressly or by implication, to have.

Example 11

An ad for a supplement includes the statement "Scientists Now Agree!" in discussing the product's benefit. This statement likely conveys to consumers that the state of science supporting the benefit has reached the level of scientific consensus. Unless the advertiser possesses this level of evidence, the claim is not substantiated.

Example 12

An advertiser claims that its product has been "studied for years abroad" and is now the "subject of U.S. government-sponsored research." In addition to the explicit claim that the product has been studied, such phrases likely convey to consumers an implied claim that there exists a substantial body of competently-conducted scientific research supporting the efficacy of the product. The advertiser would be responsible for substantiating both claims.

C. The Amount and Type of Evidence

When no specific claim about the level of support is made, the evidence needed depends on the nature of the claim. A guiding principle for determining the amount and type of evidence that will be sufficient is what experts in the relevant area of study would generally consider to be adequate. The FTC will consider all forms of competent and reliable scientific research when evaluating substantiation. As a general rule, well-controlled human clinical studies are the most reliable form of evidence. Results obtained in animal and in vitro studies will also be examined, particularly where they are widely considered to be acceptable substitutes for human research or where human research is infeasible.

Although there is no requirement that a dietary supplement claim be supported by any specific number of studies, the replication of research results in an independently conducted study adds to the weight of the evidence. In most situations, the quality of studies will be more important than quantity. When a clinical trial is not possible (e.g., in the case of a relationship between a nutrient and a condition that may take decades to develop), epidemiologic evidence may be an acceptable substitute for clinical data, especially when supported by other evidence, such as research explaining the biological mechanism underlying the claimed effect. Anecdotal evidence about the individual experience of consumers is not sufficient to substantiate claims about the effects of a supplement. Even if those experiences are genuine, they may be attributable to a placebo effect or other factors unrelated to the supplement. Individual experiences are not a substitute for scientific research.

Example 13

An advertiser relies on animal and in vitro studies to support a claim that its vitamin supplement is more easily absorbed into the bloodstream than other forms of the vitamin. However, the animal research uses a species of animal that, unlike humans, is able to synthesize the vitamin, and the in vitro study uses a different formulation with a higher concentration of the compound than the product being marketed. In addition, human research is feasible and relatively inexpensive to conduct in light of the potential sales of the product and is the type of research generally accepted in this particular field of study. The substantiation is likely to be inadequate in this case, both because there are significant methodological problems and because, in this particular instance, human research is both feasible and the accepted approach in the field.

Example 14

A company wants to advertise its supplement as helpful in maintaining good vision into old age. There have been two long-term, large-scale epidemiologic studies showing a strong association between life-long high consumption of the principal ingredient in the supplement and better vision in those over 70. Experts have also discovered a plausible biological mechanism that might explain the effect. A clinical intervention trial would be very difficult and costly to conduct. Assuming that experts in the field generally consider epidemiological evidence to be adequate to support the potential for a protective effect, and assuming the absence of any stronger body of contrary evidence, a claim that is qualified to accurately convey the nature and extent of the evidence would be permitted.

Example 15

An advertisement for a supplement claims that the product will cause dramatic improvements in memory and describes the experiences of 10 people who obtained these results. The descriptions of these anecdotal experiences are truthful, but the advertiser has no scientific substantiation for the effect of its product on memory and cannot explain why the product might produce such results. The individual experiences are not adequate to substantiate the claim without confirming scientific research.

D. The Quality of the Evidence

In addition to the amount and type of evidence, the FTC will also examine the internal validity of each piece of evidence. Where the claim is one that would require scientific support, the research should be conducted in a competent and reliable manner to yield meaningful results. The design, implementation, and results of each piece of research are important to assessing the adequacy of the substantiation. There is no set protocol for how to conduct research that will be acceptable under the FTC substantiation doctrine. There are, however, some principles generally accepted in the scientific community to enhance the validity of test results. For example, a study that is carefully controlled, with blinding of subjects and researchers, is likely to yield more reliable results. A study of longer duration can provide better evidence that the claimed effect will persist and resolve potential safety questions.

Other aspects of the research results — such as evidence of a dose-response relationship (i.e., the larger the dose, the greater the effect) or a recognized biological or chemical mechanism to explain the effect — are examples of factors that add weight to the findings. Statistical significance of findings is also important. A study that fails to show a statistically significant difference between test and control group may indicate that the measured effects are merely the result of placebo effect or chance. The results should also translate into a meaningful benefit for consumers. Some results that are statistically significant may still be so small that they would mean only a trivial effect on consumer health. The nature and quality of the written report of the research are also important. Research cannot be evaluated accurately on the basis of an abstract or an informal summary. In contrast, although the FTC does not require that studies be published and will consider unpublished, proprietary research, the publication of a peer reviewed study in a reputable journal indicates that the research has received some measure of scrutiny.

At the same time, advertisers should not rely simply on the fact that research is published as proof of the efficacy of a supplement. Research may yield results that are of sufficient interest to the scientific community to warrant publication, but publication does not necessarily mean that such research is conclusive evidence of a substance's effect. The FTC considers studies conducted in foreign countries as long as the design and implementation of the study are scientifically sound.

Example 16

An advertiser conducts a literature search and finds several abstracts summarizing research about the association between a nutrient and the ability to perform better on memory tests. The advertiser relies on these summaries to support a claim that its supplement, which contains the same nutrient, aids memory. However, without looking carefully at the specifics of the study design, implementation, and results, there is no way for an advertiser to ascertain whether the research substantiates the product claims. (For example, did the research use a comparable formulation of the ingredient? Was the study adequately controlled? Did the study yield results that are statistically significant?) The advertiser should carefully review the underlying science, with the assistance of an expert if necessary, before drafting advertising claims.

Example 17

An advertiser makes an unqualified claim about the anticlotting effect of a supplement that contains a compound

extracted from fruit. There are three studies supporting the effect and no contrary evidence. One study consists of subjects tested over a one-week period, with no control group. The second study is well-controlled, of longer duration, but shows only a slight effect that is not statistically significant. The third study administers the compound through injection and shows a significant anti-clotting effect, but there is some question whether the compound would be absorbed into the bloodstream if administered orally. Because the studies all have significant limitations, it would be difficult to draft even a carefully qualified claim that would adequately convey to consumers the limited nature of the evidence. The advertiser should not base a claim on these studies.

Example 18

The marketer of an herbal supplement claims that its product promotes healthy vision and is approved in Germany for this purpose. The product has been used extensively in Europe for years and has obtained approval by the German governmental authorities, through their monograph process, for use to improve vision in healthy people. The company has two abstracts of German trials that were the basis of the German monograph, showing that the ingredient significantly improved the vision of healthy individuals in the test group over the placebo group. Animal trials done by the company suggest a plausible mechanism to explain the effect. Although approval of the supplement under the German monograph suggests that the supplement is effective, advertisers should still examine the underlying research to confirm that it is relevant to the advertiser's product (for example, that the dosage and formulation are comparable) and to evaluate whether the studies are scientifically sound. Advertisers should also examine any other research that exists, either supporting or contradicting the monograph, especially if it is not possible to identify and review the research on which the monograph is based.

E. The Totality of the Evidence

Studies cannot be evaluated in isolation. The surrounding context of the scientific evidence is just as important as the internal validity of individual studies. Advertisers should consider all relevant research relating to the claimed benefit of their supplement and should not focus only on research that supports the effect, while discounting research that does not. Ideally, the studies relied on by an advertiser would be largely consistent with the surrounding body of evidence. Wide variation in outcomes of studies and inconsistent or conflicting results will raise serious questions about the adequacy of an advertiser's substantiation. Where there are inconsistencies in the evidence, it is important to examine whether there is a plausible explanation for those inconsistencies. In some instances, for example, the differences in results are attributable to differences in dosage, the form of administration (e.g., oral or intravenous), the population tested, or other aspects of study methodology. Advertisers should assess how relevant each piece of research is to the specific claim they wish to make, and also consider the relative strengths and weaknesses of each.

If a number of studies of different quality have been conducted on a specific topic, advertisers should look first to the results of the studies with more reliable methodologies. The surrounding body of evidence will have a significant impact both on what type, amount and quality of evidence is required to substantiate a claim and on how that claim is presented — that is, how carefully the claim is qualified to reflect accurately the strength of the evidence. If a stronger body of surrounding evidence runs contrary to a claimed effect, even a qualified claim is likely to be deceptive.

Example 19

An advertiser wishes to make the claim that a supplement product will substantially reduce body fat. The advertiser has two controlled, double-blind studies showing a modest but statistically significant loss of fat at the end of a six-week period. However, there is an equally well-controlled, blinded 12-week study showing no statistically significant difference between test and control groups. Assuming other aspects of methodology are similar, the studies taken together suggest that, if the product has any effect on body fat, it would be very small. Given the totality of the evidence on the subject, the claim is likely to be unsubstantiated.

Example 20

Advertisements for a fiber supplement make the claim that the product is "proven" to aid weight loss. Although the company has two published, peer-reviewed studies showing a relationship between fiber and weight loss, neither of these studies used the same proportions of soluble and insoluble fiber or the same total amount of fiber as the supplement product. There are numerous controlled, published human clinical studies, however, using the amount and type of fiber in the supplement product, that provide evidence that the product would not result in measurable weight loss. The totality of the evidence does not support the "proven" claim and, given the stronger body of contrary evidence, even a qualified claim is likely to be deceptive.

Example 21

An advertiser runs an ad in a magazine for retired people, claiming that its supplement product has been found effective in improving joint flexibility. The company sponsored a 6-week study of its supplement, involving 50 subjects over the age of 65, to test the product's effect on improving flexibility. The study was double-blinded and placebo controlled and has been accepted for publication in a leading medical journal. The study showed dramatic, statistically significant increases in joint flexibility compared to placebo, based on objective measurements. In addition, several large trials have been conducted by European

researchers using a similar formulation and dose of the active ingredient in the supplement. These trials also found statistically significant results. The advertiser reviewed the underlying European research and confirmed that it meets accepted research standards. The evidence as a whole likely substantiates the claim.

F. The Relevance of the Evidence to the Specific Claim

A common problem in substantiation of advertising claims is that an advertiser has valid studies, but the studies do not support the claim made in the ad. Advertisers should make sure that the research on which they rely is not just internally valid, but also relevant to the specific product being promoted and to the specific benefit being advertised. Therefore, advertisers should ask questions such as: How does the dosage and formulation of the advertised product compare to what was used in the study? Does the advertised product contain additional ingredients that might alter the effect of the ingredient in the study? Is the advertised product administered in the same manner as the ingredient used in the study? Does the study population reflect the characteristics and lifestyle of the population targeted by the ad? If there are significant discrepancies between the research conditions and the real life use being promoted, advertisers need to evaluate whether it is appropriate to extrapolate from the research to the claimed effect. In drafting ad copy, the advertiser should take care to make sure that the claims match the underlying support. Claims that do not match the science, no matter how sound that science is, are likely to be unsubstantiated. Advertising should not exaggerate the extent, nature, or permanence of the effects achieved in a study, and should not suggest greater scientific certainty than actually exists. Although emerging science can sometimes be the basis for a carefully qualified claim, advertisers must make consumers aware of any significant limitations or inconsistencies in the scientific literature.

Example 22

An ad for a supplement claims that a particular nutrient helps maintain healthy cholesterol levels. There is a substantial body of epidemiologic evidence suggesting that foods high in that nutrient are associated with lower cholesterol levels. There is no science, however, demonstrating a relationship between the specific nutrient and cholesterol, although it would be feasible to conduct such a study. If there is a basis for believing that the health effect may be attributable to other components of the food, or to a combination of various components, a claim about the cholesterol maintenance benefits of the supplement product is likely not substantiated by this evidence.

Example 23

A number of well-controlled clinical studies have been conducted to suggest that a mineral supplement can improve mental alertness and memory in subjects with significantly impaired blood circulation to the brain. A claim suggesting that the supplement will improve memory or mental alertness in healthy adults may not be adequately substantiated by this evidence. Advertisers should not rely on research based on a specific test population for claims targeted at the general population without first considering whether it is scientifically sound to make such extrapolations.

Example 24

An advertiser wants to make claims that its combination herbal product helps increase alertness and energy safely and naturally. The product contains two herbs known to have a central nervous system stimulant effect. The advertiser compiles competent and reliable scientific research demonstrating that each of the herbs, individually, is safe and causes no significant side effects in the recommended dose. This evidence may be inadequate to substantiate an unqualified safety claim. Where there is reason to suspect that the combination of multiple ingredients might result in interactions that would alter the effect or safety of the individual ingredients, studies showing the effect of the individual ingredients may be insufficient to substantiate the safety of the multiple ingredient product. In this example, the combination of two herbs with similar stimulant properties could produce a stronger cumulative stimulant effect that might present safety hazards. A better approach would be to investigate the safety of the specific combination of ingredients contained in the product.

Example 25

Several clinical trials have been done on a specific botanical extract showing consistently that the extract is effective for supporting the immune system. The studied extract is a complex combination of many constituents and the active constituents that may produce the benefit are still unknown. An advertiser wishes to cite this research in its advertising, as proof that its product will support the immune system. The advertiser's product is made using a different extraction method of the same botanical. An analysis of the extract reveals that it has a significantly different chemical profile from the studied extract. The advertiser should not rely on these clinical trials alone as substantiation because the difference in extracts may result in significant differences in the two products' efficacy.

V. OTHER ISSUES RELATING TO DIETARY SUPPLEMENT ADVERTISING

In addition to the basic principles of ad meaning and substantiation discussed above, a number of other issues commonly arise in the context of dietary supplement advertising. The following sections provide guidance on some of these issues including: the use of consumer or expert endorsements in ads; advertising claims based on traditional uses of supplements; use of the DSHEA disclaimer in advertising; and the application to advertising of the DSHEA

exemption for certain categories of publications, commonly referred to as "third party literature."

A. Claims Based on Consumer Testimonials or Expert Endorsements

An overall principle is that advertisers should not make claims either through consumer or expert endorsements that would be deceptive or could not be substantiated if made directly. It is not enough that a testimonial represents the honest opinion of the endorser. Under FTC law, advertisers must also have appropriate scientific evidence to back up the underlying claim. Consumer testimonials raise additional concerns about which advertisers need to be aware. Ads that include consumer testimonials about the efficacy or safety of a supplement product should be backed by adequate substantiation that the testimonial experience is representative of what consumers will generally achieve when using the product. As discussed earlier, anecdotal evidence of a product's effect, based solely on the experiences of individual consumers, is generally insufficient to substantiate a claim. Further, if the advertiser's substantiation does not demonstrate that the results are representative, then a clear and conspicuous disclaimer is necessary. The advertiser should either state what the generally expected results would be or indicate that the consumer should not expect to experience the attested results. Vague disclaimers like "results may vary" are likely to be insufficient.

Example 26

An advertisement for a weight loss supplement features a before-and-after photograph of a woman and quotes her as saying that she lost 20 pounds in 8 weeks while using the supplement. An asterisk next to the quotation references a disclaimer in fine print at the bottom of the ad that reads, "Results may vary." The experience of the woman is accurately represented, but the separate, competent research demonstrating the efficacy of the supplement showed an average weight loss of only 6 pounds in 8 weeks. Therefore, the disclosure does not adequately convey to consumers that they would likely see much less dramatic results. The placement and size of the disclaimer is also insufficiently prominent to qualify the claim effectively. One approach to adequate qualification of this testimonial would be to include a disclaimer immediately adjacent to the quote, in equal print size that says, "These results are not typical. Average weight loss achieved in clinical study was 6 pounds." When an advertiser uses an expert endorser, it should make sure that the endorser has appropriate qualifications to be represented as an expert and has conducted an examination or testing of the product that would be generally recognized in the field as sufficient to support the endorsement. In addition, whenever an expert or consumer endorser is used, the advertiser should disclose any material connection between the endorser and the advertiser of the product. A material connection is one that would affect the weight or credibility of the endorsement, or put another way, a personal, financial, or similar connection that consumers would not reasonably expect.

Example 27

An infomercial for a dietary supplement features an expert referred to as a "Doctor" and a "leading clinician in joint health" discussing the effect of a supplement product on the maintenance of healthy joints. The expert is not licensed to practice medicine, but has a graduate degree and is a trained physical therapist, running a sports clinic. The expert has not conducted any review of the scientific literature on the active component of the supplement. In return for appearing in the infomercial, she is given a paid position as an officer the company. The ad is likely to be deceptive for several reasons. First, her qualifications as an expert have been overstated and she has not conducted sufficient examination of the product to support the endorsement. In addition, her connection to the company is one that consumers might not expect and may affect the weight and credibility of her endorsement. Even if she is adequately qualified and has conducted an adequate review of the product, her position as an officer of the company should be clearly disclosed.

Example 28

A best-selling book about the benefits of a supplement product includes a footnote mentioning the most effective brand of the supplement, by name. The manufacturer of the brand cited in the book has an exclusive promotional agreement with the author and has paid him to reference the product by name. The manufacturer's ad touts the fact that its product is the only brand recommended in this best-selling book. The ad is deceptive since it suggests a neutral endorsement when, in fact, the author has been paid by the manufacturer to promote the product.

B. Claims Based on Traditional Uses

Claims based on historical or traditional use should be substantiated by confirming scientific evidence, or should be presented in such a way that consumers understand that the sole basis for the claim is a history of use of the product for a particular purpose. A number of supplements, particularly botanical products, have a long history of use as traditional medicines in the United States or in other countries to treat certain conditions or symptoms. Several European countries have a separate regulatory approach to these traditional medicines, allowing manufacturers to make certain limited claims about their traditional use for treating certain health conditions. Some countries also require accompanying disclosures about the fact that the product has not been scientifically established to be effective, as well as disclosures about potential adverse effects. At this time there is no separate regulatory process for approval of claims for these traditional medicine products under DSHEA and FDA labeling rules. In assessing claims based

on traditional use, the FTC will look closely at consumer perceptions and specifically at whether consumers expect such claims to be backed by supporting scientific evidence. Advertising claims based solely on traditional use should be presented carefully to avoid the implication that the product has been scientifically evaluated for efficacy. The degree of qualification necessary to communicate the absence of scientific substantiation for a traditional use claim will depend in large part on consumer understanding of this category of products. As consumer awareness of and experience with "traditional use" supplements evolve, the extent and type of qualification necessary is also likely to change. There are some situations, however, where traditional use evidence alone will be inadequate to substantiate a claim, even if that claim is carefully qualified to convey the limited nature of the support. In determining the level of substantiation necessary to substantiate a claim, the FTC assesses, among other things, the consequences of a false claim. Claims that, if unfounded, could present a substantial risk of injury to consumer health or safety will be held to a higher level of scientific proof. For that reason, an advertiser should not suggest, either directly or indirectly, that a supplement product will provide a disease benefit unless there is competent and reliable scientific evidence to substantiate that benefit. The FTC will closely scrutinize the scientific support for such claims, particularly where the claim could lead consumers to forego other treatments that have been validated by scientific evidence, or to self-medicate for potentially serious conditions without medical supervision. The advertiser should also make sure that it can document the extent and manner of historical use and be careful not to overstate such use. As part of this inquiry, the advertiser should make sure that the product it is marketing is consistent with the product as traditionally administered. If there are significant differences between the traditional use product and the marketed product, in the form of administration, the formulation of ingredients, or the dose, a "traditional use" claim may not be appropriate.

Example 29

The advertiser of an herbal supplement makes the claim, "Ancient folklore remedy used for centuries by Native Americans to aid digestion." The statement about traditional use is accurate and the supplement product is consistent with the formulation of the product as traditionally used. However, if, in the context of the ad, this statement suggests that there is scientific evidence demonstrating that the product is effective for aiding digestion, the advertiser would need to include a clear and prominent disclaimer about the absence of such evidence.

Example 30

A supplement manufacturer wants to market an herbal product that has been used in the same formulation in China as a tonic for improving mental functions. The manufacturer prepares the product in a manner consistent with Chinese preparation methods. The ad claims, "Traditional Chinese Medicine — Used for Thousands of Years to Bring Mental Clarity and Improve Memory." The ad also contains language that clearly conveys that the efficacy of the product has not been confirmed by research, and that traditional use does not establish that the product will achieve the claimed results. The ad is likely to adequately convey the limited nature of support for the claim.

Example 31

A supplement manufacturer markets a capsule containing a concentrated extract of a botanical product that has been used in its raw form in China to brew teas for increasing energy. The advertisement clearly conveys that the energy benefit is based on traditional use and has not been confirmed by scientific research. The ad may still be deceptive, however, because the concentrated extract is not consistent with the traditional use of the botanical in raw form to brew teas and may produce a significantly different effect.

Example 32

A supplement ad claims that a supplement liquid mineral solution has been a popular American folk remedy since early pioneer days for shrinking tumors. The ad is likely to convey to consumers that the product is an effective treatment for cancer. There is no scientific support for this disease benefit. Because of the potential risks to consumers of taking a product that may or may not be effective to treat such a serious health condition, possibly without medical supervision, the advertiser should not make the claim.

C. Use of the DSHEA Disclaimer in Advertising

Under DSHEA, all statements of nutritional support for dietary supplements must be accompanied by a two part disclaimer on the product label: that the statement has not been evaluated by FDA and that the product is not intended to "diagnose, treat, cure or prevent any disease." Although DSHEA does not apply to advertising, there are situations where such a disclosure is desirable in advertising as well as in labeling to prevent consumers from being misled about the nature of the product and the extent to which its efficacy and safety have been reviewed by regulatory authorities. For example, a disclosure may be necessary if the text or images in the ad lead consumers to believe that the product has undergone the kind of review for safety and efficacy that the FDA conducts on new drugs and has been found to be beneficial for the treatment of disease. Failure to correct those misperceptions may render the advertising deceptive. At the same time, the inclusion of a DSHEA disclaimer or similar disclosure will not cure an otherwise deceptive ad, particularly where the deception

concerns claims about the disease benefits of a product. In making references to DSHEA and FDA review, advertisers should also be careful not to mischaracterize the extent to which a product or claim has been reviewed or approved by the FDA. Compliance with the notification and disclaimer provisions of DSHEA does not constitute authorization of a claim by FDA and advertisers should not imply that FDA has specifically approved any claim on that basis.

Example 33

A company markets a supplement for "maintaining joint flexibility." The product packaging is similar in color and design to a nonprescription drug used to treat joint pain associated with arthritis and the product name is similar to the drug counterpart. The ad includes statements urging consumers to "ask their pharmacist" and "accept no generic substitute." The various elements of the ad may lead consumers to believe that the supplement is, in fact, an approved drug, or may give consumers more general expectations that the product has been subjected to similar government review for safety and efficacy. A clear and prominent disclaimer may be necessary to indicate that the product has not been evaluated by FDA and is not an approved drug product.

Example 34

An advertisement for an herbal supplement includes strong, unqualified claims that the product will effectively treat or prevent diabetes, heart disease, and various circulatory ailments. The advertiser does not have adequate substantiation for this claim, but includes the DSHEA disclaimer prominently in the ad. In face of the strong contradictory message in the ad, the inclusion of the DSHEA disclaimer is not likely to negate the explicit disease claims made in the ad, and will not cure the fact that the claims are not substantiated.

Example 35

A dietary supplement advertisement makes a number of claims about the benefits of its product for supporting various body functions. The ad also includes the statement, "Complies with FDA notification procedures of the Dietary Supplement Health and Education Act." This statement may suggest to consumers that FDA has authorized the claims made in the ad or that it has reviewed the support for the claims and found the product to be effective. Because there is no review and authorization process for such claims under DSHEA, this would be deceptive.

D. Third Party Literature

Dietary supplement advertisers should be aware that the use of newspaper articles, abstracts of scientific studies, or other "third party literature" to promote a particular brand or product can have an impact on how consumers interpret an advertisement and on what claims the advertiser will be responsible for substantiating. For purposes of dietary supplement labeling, Section 5 of DSHEA provides an exemption from labeling requirements for scientific journal articles, books and other publications used in the sale of dietary supplements, provided these materials are reprinted in their entirety, are not false or misleading, do not promote a specific brand or manufacturer, are presented with other materials to create a balanced view of the scientific information, and are physically separate from the supplements being sold.

The FTC will generally follow an approach consistent with the labeling approach when evaluating the use of such publications in other contexts, such as advertising. Although the FTC does not regulate the content or accuracy of statements made in independently written and published books, articles, or other non-commercial literature, FTC law does prohibit the deceptive use of such materials in marketing products. The determination of whether the materials will be subject to FTC jurisdiction turns largely on whether the materials have been created or are being used by an advertiser specifically for the purpose of promoting its product. As a practical matter, publications and other materials that comply with the elements of the DSHEA provision, particularly with the requirement that such materials be truthful, not misleading and balanced, are also likely to comply with FTC advertising law.

Example 36

An author publishes a book on the curative properties of an herb. The book title is "The Miracle Cancer Cure." The book does not endorse or otherwise mention any particular supplement brand. The author/publisher does not sell the herbal supplement and does not have any material connection to any marketers of the herb. As non-commercial speech, the book itself would not be subject to the FTC's jurisdiction over advertising. However, if a marketer of the herb referred to the book in advertising materials (for instance, by quoting the title and using excerpts to describe the anti-cancer benefits of its product), such references would likely be considered advertising. The advertiser would be responsible for substantiating any claims about the advertiser's product that are conveyed by these references.

VI. GOVERNMENT'S ROLE IN THE WEIGHT LOSS MARKETPLACE

The FDA regulates the labeling of prescription and over-the-counter weight loss drugs and approves new drugs. While, the FTC and the state attorneys general combat misleading advertising claims for weight loss products and programs. The FDA and the FTC share statutory authority over the promotion and advertising of drugs and supplements. The FDA has primary jurisdiction over prescription drug advertising by manufacturers or on behalf of manufacturers as well as jurisdiction over drug labeling.

The FTC regulates the advertising of weight loss products and programs, including dietary supplements for weight loss under Section 5 of the Federal Trade Commission Act. The FTC has filed more than 150 cases against such products and programs since 1927, and 75 of these have been filed since 1990. Most of these cases were filed administratively, but in nearly a dozen of them, the agency sued directly in federal district court to obtain injunctions and monetary redress.

Issues that the FTC addressed in the program cases of the early 1990s included misleading use of consumer testimonials, deceptive claims about costs and credentials of program staff, misleading comparisons of programs, and failure to substantiate success claims for weight loss or weight loss maintenance. Consent orders entered in those cases include remedies that require substantiation for weight loss or weight maintenance claims, disclosures triggered by maintenance claims ("For many dieters, weight loss is temporary"), disclosure of total costs, and prohibitions against misrepresenting staff credentials. As a result of monitoring compliance with the consent orders, the agency is seeing in general that companies are avoiding broad-based maintenance claims, and where maintenance claims are made, they are narrowly focused on discrete subgroups of dieters. Also, companies appear to be making the order-required disclaimers that are intended to limit the applicability of testimonials. The agency continues to work with companies to assure that such disclaimers are featured in a clear and prominent manner.

The offices of the state attorneys general have played a prominent role in pursuing advertisers and promoters of fraudulent pills, nostrums and devices — the bottom-feeders of the weight-loss industry — as well as more mainstream companies. States review diet ads under both their false and deceptive practices statutes as well as state food and drug laws. In addition, some states, have statutes that apply to advertising by medical professionals and prohibit false advertising and advertising for unsubstantiated treatments.

The following summaries represent disclosure models, either in place or recommended, for providing information to prospective clients/patients of weight loss programs. Some states have adopted standards for information disclosure. Additionally, the FTC (through triggered disclosures in individual case-generated consent orders) has defined information consumers should know about weight loss methods in order to understand certain efficacy and success claims. Finally, the Center for Science in the Public Interest, in its petition for rulemaking filed before the FTC, has set out a detailed disclosure model.

Most models require affirmative disclosures of costs, health risks and staff credentials untriggered by specific claims or the need for consumers' first to request the information. The exceptions is the New York City Consumer Bill of Rights where, except for an affirmatively disclosed warning about the risk of rapid weight loss, the consumer is informed of his/her right to receive certain information upon request. The FTC orders require outcome disclosures only when triggered by express or implied success or efficacy claims. The Connecticut statute is based in part upon the FTC model, requiring triggered outcome disclosures but also requiring that the diet program contract affirmatively disclose information about costs, staffing and program duration. The only in-place model that calls for any sort of untriggered outcome data disclosure is Michigan's that requires that consumers receive, through informed consent, information about the likely long term success of the program.

VII. VOLUNTARY GUIDELINES FOR PROVIDERS OF WEIGHT LOSS PRODUCTS OR SERVICES

A. Definitions

The *Partnership for Healthy Weight Management* is a coalition composed of representatives from science, academia, the health care professions, government, commercial enterprises, and organizations promoting the public interest. The Partnership encourages weight loss providers to adopt the *Partnership's Voluntary Disclosure Guidelines for Providers of Weight Loss Products and Programs* and does not endorse any particular product or program for weight loss or weight management.

"Providers" includes any individual or organization involved in providing weight loss services or products to the public, including, but not limited to, physicians, clinical psychologists, dieticians, nutritionists, and commercial programs, as well as any one else selling products or publications designed to cause weight loss or result in weight maintenance.

Providers of a weight loss product should note that use of statements about the risks associated with overweight and obesity, the risks associated with the product, or about outcomes may render the product adulterated, misbranded, or unapproved under the Federal Food, Drug, and Cosmetic Act and relevant regulations promulgated by the Food and Drug Administration.

B. Format and Distribution

These *Voluntary Guidelines* represent a consensus of voluntary consumer disclosure practices reached by a panel of weight management companies, weight loss professionals, and consumer protection groups. They are not binding, do not represent legal standards or interpretation of any legal requirements, and are not sponsored or issued by any government agency. Providers should only make these disclosures to the extent that they are permissible under applicable state and federal law. In order to assure compliance, these guidelines should be placed in the program/procedures

policy manual or such other written guidance provided to program staff.

Providers that subscribe to these *Voluntary Guidelines* may be flexible in tailoring the Guidelines to the structure and needs of their own programs. Different programs will comply in different ways with various portions of the Guidelines. However, providers should not represent, directly or indirectly, in advertising or otherwise, that they subscribe to or comply with the Voluntary Guidelines unless they make all disclosures that are applicable to their particular program or product. The examples set forth in the *Voluntary Guidelines* are provided for the purpose of illustration, and are not intended to represent a required or preferred form or format. Different providers and types of providers may utilize varying formats for disclosure.

Providers following these guidelines should make all disclosures clearly and prominently. Providers that obligate purchasers to make payments in the future or that collect non refundable payments in advance for products or services to be consumed or provided in the future, should make all disclosures in a single document that is given to all prospective clients/patients on their first visit to the center and prior to purchase. Providers that charge for products and services as they are used by the purchaser — "pay-as-you-go programs" — or that collect refundable payments in advance of delivery of the services, should also include all disclosures covered by these guidelines in a single document except that cost information may be provided either as part of the document or on clear and prominent postings at each center. Providers who post notices of costs should do so in a manner that renders them consistently viewable by consumers during their visit and permits consumers to notice and read the contents upon first entering the area occupied by the provider's customer representatives or recruiters.

Providers should instruct their staff to encourage prospective clients/patients to read all disclosures prior to enrolling in the program. Services actually provided should not be inconsistent with the content of these disclosures. (For example, a provider should not offer advice of a medical nature if the disclosures state that medical advice is not provided.) In addition, written or oral representations contained in advertising or any other materials or presentations should not be inconsistent with or contradict these disclosures.

C. Information Content

Providers of weight management services should, at a minimum, voluntarily provide to prospective patients/clients the following information:

1. Staff Qualifications and Central Components of the Program

This includes a description of the program content and goals and pertinent information about the weight management training, experience, certification and education of the customer service personnel where the service, including distribution of products, is being provided, and which is appropriate to the program. The disclosure should include wording that encourages prospective patients/clients to ask additional questions about the qualifications of the provider and should not be deceptive or misleading.

Example 1

Our Staff at the "Weight Away Diet Center" program consists of diet, exercise, and behavioral modification. Program leaders who have successfully used the Weight Away program to lose weight monitor your weekly progress. Staff is required to have completed Weight Away program as well as a six-week in-house staff training program covering nutrition, weight-loss dynamics, customer service, and presentation. One or more Weight Away counselors will see you on an individual or group basis at each meeting. Our staff does not offer medical or psychological counseling. Please feel free to ask for more details about any particular leader's training or experience.

Example 2

Our Staff at the "Community Hospital Obesity Clinic" provides a medically supervised weight loss program for patients with severe disorders related to obesity or whose obesity places them at risk of developing such disorders. The program consists of optional low or very low-calorie diet plans, exercise, and lifestyle education. During this program, patients following a very-low-calorie diet will receive a protein supplement diet formula to substitute for regular meals and a multi-vitamin supplement. Our staff is comprised of one physician who is board-certified in endocrinology, two registered nurses (RNs), three registered dietitians (RDs), one masters level exercise physiologist and one clinical psychologist (Ph.D.) Usually, patients will visit with the dietitians and exercise physiologist. Other professional staff are available for consultation if professional intervention is indicated. Prospective patients are encouraged to ask about staff experience and training and how much time various staff members spend with individual patients.

2. Risks Associated with Overweight and Obesity, and the Benefits to be Derived from Modest Weight Loss

For example, obesity and overweight are associated with increased risk of heart disease, diabetes, some forms of cancer, gall bladder disease, osteoarthritis, stroke, and sleep apnea, among other illnesses, and moderate amounts of weight loss (five to ten percent of total body weight) can reduce many of the risks. While most providers will likely want to include information about the risks of obesity and the benefits of weight loss, any such disclosure is optional, and the failure to provide such a statement will not be considered inconsistent with the guidelines.

3. Risks Associated with the Provider's Product or Program

This includes for programs, the risks associated with any drugs, devices, dietary supplements, or exercise plans that are provided in the course of the program or treatment. In addition to program/product-specific risks, the information provided should indicate that:

1. Consultation with a medical professional is advisable for people who are under treatment for specific medical conditions or taking prescribed medications.
2. Unless medically indicated, weight loss after the first two or three weeks of dieting should not exceed a rate of three pounds or approximately one and one-half percent of body weight per week. More rapid weight loss may cause an increased risk of developing gallbladder disease, a risk which is believed to be higher than the risk of developing gallbladder disease as a result of staying overweight/obese. People who are considered medically appropriate for more rapid weight loss should have their progress monitored by a physician.
3. Very-low-calorie diets (<800 kcal per day) are designed to promote rapid weight loss in people whose obesity has resulted in, or has put them at medical risk of, developing serious health complications. Rapid weight loss may also be associated with some medical problems. This program provides medical supervision to minimize risks associated with rapid weight loss.
4. People undergoing weight loss can experience physical changes in the body (dizziness, interruptions in the menstrual cycle, hair loss, for example) that may indicate more serious conditions. People noticing such changes should be advised to talk immediately to their primary care physician.

Example 3

For providers whose programs are designed to produce weight loss at a rate of approximately two pounds per week.

What You Need To Know About the Safety of the "Healthy Weight Loss Clinic" Diet.

This diet has been designed to promote weight loss of no more than two pounds -or one percent of total body weight — a week. Medical authorities recommend that losing weight at such a rate reduces risk of health problems that have been associated with more rapid weight loss (greater than three pounds per week). Some people may lose weight at a slightly higher rate. However, we will monitor your progress and modify your diet if your rate of weight loss after the first two or three weeks exceeds a rate of three pounds — or one and one-half percent of body weight — a week. Children and adolescents, pregnant or breast feeding women, and people with significant health problems such as bulimia, heart disease, kidney disease, diabetes or psychiatric disorder, should not begin this program without written authorization by their primary care provider. People under treatment for other conditions or taking medications prescribed by their health care provider should tell their providers that they have begun this diet because, in some cases, adjustments to medications or modifications to the weight loss program may be appropriate.

Weight loss can produce physical changes in the body such as interruptions in the menstrual cycle, temporary hair loss, and dizziness. Such changes may indicate more serious health complications. Report any such changes that you notice to your primary care provider.

Remember, people who are overweight or obese are at increased risk of developing heart disease, diabetes, some forms of cancer, gall bladder disease, osteoarthritis and sleep apnea. Losing even small amounts of weight (five to ten percent of body weight), may reduce these risks. The side effects and complications that some people may experience while losing weight by following a healthy eating plan and exercise program are usually minor compared to the risks of overweight and obesity.

4. Information about Program Costs

This includes (1) total program costs, including all fixed costs (administrative fees, entry fees, renewal fees, as appropriate), (2) periodic costs such as weekly attendance fees or mandatory food purchases (expressed for food purchases at the option of the provider as either average approximate costs or a high/low range of costs per scheduled payment unit or per week), (3) optional costs (such as fees charged for re-entering the program or for any optional maintenance program), and (4) discretionary costs (medical tests, for example). Providers should also identify, clearly and prominently, any non-refundable costs. If practicable, providers should disclose total approximate program costs averaged across all dieters. A single, non refundable entry fee or registration fee that does not exceed 150 percent of the fee charged for a single visit or session in an otherwise pay-as-you-go program does not remove the program from pay-as-you-go status.

In the case of telephone sales, inasmuch as providers cannot give written disclosures to prospective patients/clients until they visit a center, sales should not be considered final until the prospective patient/client has received the disclosures and had a chance to read them. Alternatively, providers may include with the disclosures, a clear and conspicuous notice of their right to rescind such a sale within at least five days.

Example 4

"BYE-BYE BMI Weight Loss Centers" Cost Schedule:
Mandatory Charges:
One-Time Entry Fee $xx.xx
Each Weekly Meeting (attended) $xx.xx
Average (approximate) cost of food per week $xx.xx
Nutritional Supplements (30 day supply) $xx.xx
Discretionary Additional Charges (if Center deems necessary)
Blood tests, Physician Exam, EKG $xx.xx
Optional Additional Charges (if client chooses) $xx.xx
Re-entry fee (after absence of at least __ consecutive visits) $xx.xx
Optional Maintenance Program $xx.xx
ALL COSTS NON-REFUNDABLE

5. Outcome Information

Consumers of weight loss products and services are entitled to receive outcome information that would allow people to make informed choices among weight loss products and services.

These guidelines encourage but do not mandate outcome disclosures in terms of weight loss and weight maintenance. Weight loss programs differ, and at the current time, there is no consensus on what the content and the format of such disclosures should be. Research is lacking as to what consumers need and how they interpret or use such information. The Partnership for Healthy Weight Providers are encouraged to collect data, e.g., how much weight consumers of a particular product or program have lost and how long they kept off all or part of their weight loss, and disclose weight loss and maintenance information to prospective clients/patients before they enroll. Providers subscribing to these guidelines should include within the document containing the other disclosures the statement, "Most people who lose weight are likely to find it difficult to keep the weight off. They can improve their chances by adopting a lifelong commitment that includes:

1. Increased frequent and regular physical activity of at least moderate intensity, and
2. Healthy eating in accordance with the Dietary Guidelines for Americans, emphasizing a reduction in total calories, a lowered fat consumption, and an increase in vegetables, fruits and whole grains," and
3. Information about the health benefits of modest amounts of weight loss (5–10 percent of body weight, 10–20 pounds).

Example 5

For providers that make specific disclosures.

Patients under Dr. Doe's weight loss treatment lost, on average, 17.5 pounds, and after 18 months, they kept off 55 percent of their weight loss. This measurement includes all patients who remained in active weight loss for at least three weeks. Most people who lose weight are likely to find it difficult to keep the weight off. They can improve their chances by adopting a lifelong commitment that includes:

1. Increased frequent and regular physical activity of at least moderate intensity, and
2. Healthy eating in accordance with the Dietary Guidelines for Americans, emphasizing a reduction in total calories, a lowered fat consumption, and an increase in vegetables, fruits and whole grains.
3. Moreover, maintaining a modest amount of weight loss over time has been shown to have health benefits.

Example 6

For providers that choose not to make specific disclosures.

Most people who lose weight are likely to find it difficult to keep the weight off. They can improve their chances by adopting a lifelong commitment that includes:

1. Increased frequent and regular physical activity of at least moderate intensity, and
2. Healthy eating in accordance with the Dietary Guidelines for Americans, emphasizing a reduction in total calories, a lowered fat consumption, and an increase in vegetables, fruits and whole grains.
3. Moreover, even weight loss of as little as ten percent of body weight, if maintained over time, has been shown to be beneficial.

VIII. REPRESENTATIVE DIETARY SUPPLEMENT ADVERTISING CASES 1984 — JULY 15, 2003

Michael S. Levey; Gary Ballen; Bentley Myers International Co.; Publisher's Data Services, Inc.; and Nutritional Life, Inc.; Civ. Action No. CV-03-4670 GAF (AJWx) (C.D. Cal.) (Filed 6/30/03) Complaint for Civil Penalties, Injunctive and Other Relief. Alleged false or unsubstantiated efficacy and safety claims for weight loss products containing ephedra, "Zymax" and "MillinexES," or St. John's wort, "Serotril," and unsubstantiated arthritis cure and other claims for a dietary supplement product containing glusosamine and chondroitin, "CartazyneDS." Alleged violation by Michael S. Levey of 1993 FTC order in C-3459.

Health Laboratories of North America, et al., Civ. Action No. 03 1457, (D.D.C.) (Filed 07/01/03) Complaint and Stipulated Final Judgment and Order for a Permanent Injunction and Monetary Relief. Alleged false and unsubstantiated weight loss claims for "Berry Trim Plus" dietary supplement products containing Hydroxycitric Acid or "HCA" and ephedrine alkaloids from Ma Huang and unsubstantiated safety claims for "Berry Trim Plus." Order requires payment of $195,000 in consumer redress.

Seasilver USA, Inc.; Americaloe, Inc.; Bela Berkes; Jason Berkes; Brett Rademacher, individually and dba

Netmark International and Netmark Pro; and David R. Friedman, Civ. Action No. CV-S-03-0676-RLH-LRL, Complaint for Injunctive and Other Equitable Relief (filed June 12, 2003) (D. Nev.) Alleged false and unsubstantiated disease treatment and cure claims and weight loss claims for "Seasilver" liquid supplement. Inventories of Seasilver seized by the Food and Drug Administration.

Unither Pharma, Inc., and United Therapeutics Corp., File No. 022 3036, (June 12, 2003) (Consent Agreement subject to final approval of the Commission following public comment period) Alleged deceptive claims that "HeartBar," a food bar containing the amino acid L-Arginine, is effective against cardiovascular diseases.

Kevin Trudeau; Robert Barefoot, Shop America (USA), LLC, and Deonna Enterprises, Inc. Civ. Action No. 03 C 904 (June 9, 2003) (N.D. Ill.) (Complaint for Permanent Injunction and Other Equitable Relief) Alleged false and unsubstantiated claims that Coral Calcium Supreme can treat or cure cancer and other diseases, such as multiple sclerosis and heart disease, and is superior to other calcium supplements.

A. Glenn Braswell; JOL Management Co.; G.B. Data Systems, Inc., Gero Vita International, Inc., Theraceuticals, Inc.; and Ron Tepper; Civ. Action No. CV 03-3700 DT (PJWx) (C.D. Cal.) (filed May 27, 2003) (Complaint for Permanent Injunction and Other Equitable Relief) Alleged false and unsubstantiated advertising claims for numerous dietary supplements marketed under the Gero Vita and Theraceuticals brand names.

ValueVision International, Inc., Civ. Action No. 03-2890 District of Minnesota (entered April 17, 2003) (Consent Decree and $215,000 Civil Penalty) (Agreement settles charges that company violated a previous 2001 FTC order [C-4022] by making unsubstantiated health claims for Physician's RX, a dietary supplement containing a variety of vitamins, minerals, and antioxidants. In addition to paying the civil penalty, ValueVision will be enjoined from violating the FTC order.)

Snore Formula, Inc., et al., File No. 022 3247 (April 15, 2003) (Consent agreement pending final approval following public comment period) Alleged unsubstantiated claims that "Dr. Harris' Original Snore Formula" herbal supplement tablets were effective in preventing sleep apnea in adults and children and significantly reduced snoring. Alleged failure to disclose material information, specifically, the importance of seeing a physician for people with symptoms of sleep apnea because the condition may be fatal.

Rexall Sundown, Inc., Civ. Action No. 00-7016-CIV-Martinez, (S.D. Fla.) Stipulated Final Order for Permanent Injunction and Settlement of Claims for Monetary Relief (March 31, 2003) Alleged false and unsubstantiated claims that its dietary supplement, Cellasene™, would reduce or eliminate cellulite.

Slim Down Solution, LLC, et al., and Maderia Management, Inc., et al., Civ. Action No. 03-80051-CIV-PAINE (S.D. Fla.), Complaint for Permanent Injunction and Other Equitable Relief and Stipulated Order for Preliminary Injunction (01/21/03) Alleged false and unsubstantiated claims for a purported weight-loss product containing D-glucosamine.

Dr. Clark Research Association, et al., *dba Dr. Clark Zentrum*, Civ. Action No. l:03CV0054, (N.D.Ohio) Complaint for Permanent Injunction and Other Equitable Relief (filed 01/08/03) Alleged unsubstantiated AIDS, terminal cancer, and other disease cure claims for dietary supplements and devices.

Mark Nutritionals, Inc., Harry Siskind, and Edward G. D'Alessandro, Jr., Civ. Action No. SA02CA1151EP, U.S. District Court, Western District of Texas, San Antonio Division, (Complaint for Permanent Injunction and Other Equitable Relief and Stipulated Order for Preliminary Injunction Between Mark Nutritionals, Inc., and FTC filed December 5, 2002) (Stipulated Order for Preliminary Injunction with asset freezes entered against individual respondents on December 23, 2002) Alleged false and unsubstantiated claims for "Body Solutions Evening Weight Loss Formula" in English and Spanish radio ads and website.

David L. Walker, dba DLW Consulting, Inc., File No. X020041, Civ. Action No. C02-5169 RJB, (filed October 28, 2002) U.S. District Court for the Western District of Washington at Seattle, Stipulated Final Judgment and Order, (Complaint alleging unsubstantiated claims on web site and in seminars regarding the efficacy of Walker's purported cancer cure, the "CWAT — Treatment: BioResonance Therapy and Molecular Enhancer." was filed in March, 2002.)

No. 9068-8425 Quebec, Inc. aba Bio Lab, Cellu-Fight, and Quick Slim, and Jean-Francois Brochu, Civ. Action No. 1:02:CV-1128, U.S. District Court, Northern District of NY (September 3, 2002) (Complaint for Permanent Injunction and Other Equitable Relief) Alleged false weight-loss and cellulite-treatment claims by Canadian company marketing dietary supplements to U.S. consumers using mainstream U.S. media.

Interstate Bakeries Corp., File No. 012 3182 (March 6, 2002) Consent Agreement subject to final FTC approval following public comment period. Alleged unsubstantiated claims that its Wonder Bread containing added calcium could improve children's brain function and memory.

Campbell Mithun LLC (Advertising agency for Interstate Bakeries Corp. [IBC]), File No. 012 3182 (March 6, 2002) Consent Agreement subject to final FTC approval following public comment period. Alleged unsubstantiated claims in advertisements developed for IBC that Wonder Bread containing added calcium could improve children's brain function and memory.

Kris A. Pletschke, dba Raw Health, File No. C-4040, (February 22, 2002) Consent Order. (Alleged unsubstantiated claims on "rawhealth.net" web site that its colloidal

silver product could treat or cure 650 different diseases, eliminate all pathogens in the body, and was medically proven to kill every destructive bacterial, viral, or fungal organism in the body, including anthrax, Ebola, and flesheating bacteria. Consumer refunds must be offered under terms of the order.)

TechnoBrands, Inc., et al., File No. 992 3034 (February 19, 2002) Consent Agreement subject to final FTC approval following public comment period. Alleged false and unsubstantiated claims concerning weight-loss products, pain-relief magnets, air cleaners, and hairgrowth stimulants. ($200,000 in consumer redress required by the Consent Agreement) In a separate action, filed in federal district court, TechnoBrands agreed to pay more than $200,000 in consumer redress for its role in the deceptive telemarketing of a buyer's club service after completing the sale of its own products. (Stipulated Final Order for Permanent Injunction and Settlement of Claims for Monetary Relief, Civ. Action No.: 3:02-CV-86, Eastern District of Virginia, Richmond.)

Natural Organics, Inc., et al., D. 9294 (September 6, 2001) (Consent Order) (Alleged unsubstantiated claims that company's dietary supplement, "Pedi-Active A.D.D.," treats or mitigates Attention Deficit Hyperactivity Disorder and improves attention span and scholastic performance of children who have difficulty focusing on their schoolwork.)

Liverite Products, Inc., et al., Civil Action No.: SA 01-778 AHS (ANx) (August 20, 2001) (Complaint and proposed Stipulated Final Order filed in U.S. District Court for the Central District of California, Southern Division) (Alleged unsubstantiated claims on Internet, radio, and print ads about the ability of "Liverite" dietary supplement products to treat or prevent a wide range of liver diseases or disorders, including cirrhosis and hepatitis ($60,000 in redress required).

Panda Herbal International, Inc., et al., File No. C-4018 (Consent Order) (July 30, 2001) (Alleged unsubstantiated efficacy claims for "Herbal Outlook," a dietary supplement containing St. John's Wort, and for "HerbVeil 8," a topical ointment; alleged false claim that Herbal Outlook has no known contraindications or drug interactions. Order requires Panda to pay full refunds upon request to consumers who purchased HerbalVeil 8 during a specified time period.)

ForMor, Inc., et al., File No. C-4021 (Consent Order) (July 30, 2001) (Alleged false and unsubstantiated safety and efficacy claims for dietary supplement products containing St. John's Wort, colloidal silver, and shark cartilage. Order requires ForMor to pay refunds upon request to consumers who purchased colloidal silver and "Ultimate II Shark Cartilage Concentrate" during a specified time period.)

MaxCell BioScience, Inc., et al., doing business as Oasis Wellness Network, File No. C-4017 (Consent Order) (July 30, 2001) (Alleged false and unsubstantiated anti-aging claims for "Longevity Signal Formula," a dietary supplement product containing the hormone DHEA, and for an at-home urine test, "Anabolic/Catabolic Index™²," to gauge overall health and youthfulness. Order requires payment of $150,000 in consumer redress.)

Robert C. and Lisa M. Spencer, dba Aaron Company, File No. C-4019 (Consent Order) (July 30, 2001) (Alleged false and unsubstantiated safety and efficacy claims for dietary supplement products, Colloidal Silver, and Chitosan with Vitamin C; and unsubstantiated claims that "Ultimate Energizer," a product containing ephedra (ma huang), is safe and has no side effects. Order requires warning labels on products containing ephedra sold by respondents in the future).

Western Botanicals, Inc., et al., Civ. Action No. CIV.S-01-1332 DFL GGH, (July 13, 2001) (Complaint and Stipulated Final Order) (Alleged unsubstantiated claims that dietary supplement products containing comfrey were beneficial in the treatment of a variety of serious diseases and health conditions and false claims that the products were safe. A judgment of $50,800 was suspended, but could be reinstated if the court finds defendants made misrepresentations or omissions on their financial statements.)

Christopher Enterprises, Inc., et al., Civ. Action No. 2:01 CV-0505 ST, District of Utah, Central Division (Stipulated Final Order for Permanent Injunction and Settlement of Claims for Monetary Relief filed November 29, 2001) The order would prohibit the defendants from marketing any comfrey product for ingestion, for use as a suppository, or for external use on open wounds, unless they have evidence that the product is free of pyrrolizidine alkaloids and that it is safe. The defendants would also be required to place a warning disclosure in any ad, promotional material or product label for any confrey products intended for topical use. The specific claims challenged in the complaint would also be prohibited by the order. (Complaint for Permanent Injunction and Other Equitable Relief and Stipulated Order for Preliminary Injunction filed July 3, 2001) (Alleged false safety claims and unsubstantiated efficacy claims for products containing the herbal ingredient comfrey.)

Streamline International, Inc., et al., Civil Action No. 01-6885-CIV-Ferguson (Complaint filed in U.S. District Court for the Southern District of Florida) (June 20, 2001) (Alleged false and deceptive earnings claims by operators of fraudulent business opportunity pyramid marketing scheme purportedly distributing a line of dietary supplements and health-care products. Complaint also alleges false and misleading claims that the company sells only dietary supplement products containing ingredients that appear on the FDA's list of ingredients generally recognized as safe. In fact, a number of products contain the herbal ingredient comfrey, which is not on that list and is known to pose a significant risk to humans, including liver damage, when used internally or externally on open wounds.

Western Dietary Products Co., et al., Civ. Action No. CO1-0818R, (U.S. District Court for the Western District of Washington, in Seattle) (Stipulated Final Judgment and Order filed with the court on December 26, 2001) (Complaint filed June 4, 2001, alleged unsubstantiated claims that their products, "Black Walnut Tincture," "Wormwood Tincture," and "Cloves Tincture," and an electrical unit called the "Zapper," were effective in the treatment and cure of cancer, Alzheimer's, diabetes, arthritis, and HIV/AIDS; and that their herbal products would make surgery and chemotherapy unnecessary for persons with cancer.)

Weider Nutrition International, Inc. (File No. C-3983) (Consent Order) (November 15, 2000) (Alleged unsubstantiated efficacy and safety claims in ads for weight loss dietary supplement products called "PhenCal" and "PhenCal 106." $400,000 in consumer redress required by the consent order.)

Lane Labs-USA, et al., (Civ. Action No. CV-00-3174 (WGB), U.S. District Court, District of New Jersey) (Stipulated Final Order for Permanent Injunction as to Cartilage Consultants, Inc., and I. William Lane entered July 6, 2000) (Stipulated Final Order for Permanent Injunction and Settlement of Claims for Monetary Relief as to Lane Labs-USA, Inc., and Andrew J. Lane) (Entered by the court on September 26, 2000) ($1 Million judgement: $550,000 for redress or disgorgement; and the remaining $450,000 to be used to pay for shark cartilage and a placebo in a clinical study of shark cartilage sponsored by the National Cancer Institute and Lane Labs.) (Alleged unsubstantiated claims about the efficacy of "BeneFin," a shark cartilage product, and "SkinAnswer," a skin cream, in the prevention, treatment and cure of cancer. Lane Labs was the manufacturer and distributor of these products.)

Cartilage Consultants, Inc., et al., (Civ. Action No. CV-00-3174 (WGB), U.S. District Court, District of New Jersey) (Entered by the court on July 6, 2000) (Stipulated Final Order for Permanent Injunction) (Complaint alleged that working in conjunction with Lane Labs-USA, Cartilage Consultants, Inc., supplied consumers with information on how to use BeneFin and SkinAnswer to treat cancer)

Michael D. Miller, dba Natural Heritage Enterprises, File No. C-3941 (May 16, 2000) (Consent Order and $17,500 in consumer redress) (Alleged unsubstantiated claims on Internet sites that Essiac Tea is effective in curing a number of diseases, such as cancer, diabetes, AIDS/HIV and feline leukemia.)

CMO Distribution Centers of America, File No. C-3942 (May 16, 2000) (Consent order; company must offer refunds to consumers who purchased the product for personal use or that of their families.) (Alleged unsubstantiated claims that CMO™ (cetylmyristoleate) capsules would regulate and normalize the immune system, cure arthritis and reverse the effects of the disease, and be effective in treating other conditions such as asthma and cancer. Complaint also alleged that certain claims about scientific studies were false.)

EHP Products, File No. C-3940 (May 16, 2000) (Consent order; company must offer refunds to consumers who purchased the product for personal use or that of their families.) (Alleged unsubstantiated efficacy claims for its CMO product, Myristin®, including claims that the product provides long term relief from arthritis symptoms and may prevent rheumatoid arthritis and osteoarthritis, and misrepresentations that scientific studies or the issuance of patents prove the effectiveness of Myristin®.)

J & R Research, Inc., File No. C-3961 (July 19, 2000) (Consent Order) (Alleged unsubstantiated efficacy claims for the product Pycnogenol, marketed and sold by the company for the mitigation or cure of the effects of Attention Deficit Disorder (ADD) or Attention Deficit Hyperactivity Disorder (ADHD).

Rose Creek Health Products, Inc., File No. CS-99-0063-EFS, (May 4, 2000) (Consent decree issued in settlement of Complaint for Permanent Injunction and Other Equitable Relief filed March 1999 in U.S. District Court for the Eastern District of Washington; $375,000 in consumer redress.) (False and unsubstantiated health claims in advertisements for a nutritional supplement called "Vitamin O")

Enforma Natural Products, Inc., et al., Civ. Action No.: 04376JSL (CWx), U.S. District Court, Central District of California, (filed April 25, 2000) Complaint and Stipulated Final Order filed with the court; $10 million in consumer redress ordered. (False and unsubstantiated weight loss claims alleged for "Fat Trapper" and "Exercise in a Bottle" containing the dietary supplements chitosan and pyruvate, respectively)

The Quigley Corp., (File No. C-3926) (February 10, 2000) (Consent order) (Allegedly unsubstantiated claims by Quigley that Cold-Eezer and Cold-Eeze brand zinc lozenges that it manufactures can prevent colds and alleviate allergy symptoms and that Kids-Eeze Bubble-Gum can reduce the severity of cold symptoms in children.)

AST Nutritional Concepts and Research, Inc., *et al*., (Civ. No. 99-WY-2197, U.S. District Court for the District of Colorado) (May 4, 2000) (Permanent Injunction) (Alleged unsubstantiated safety claims made for purported body-building supplements that contain androstenedione, "androgen," and other steroid hormones, and in some cases, stimulants.

Met-RX USA, Inc., et al., (Civ. No. SACV99-1407 DOC (ANX), U.S. District Court for the Central District of California) (Nov. 24, 1999) (Stipulated Final Order For Permanent Injunction and Other Equitable Relief) Unsubstantiated safety claims made for purported body-building supplements that contain androstenedione, "androgen," and other steriod hormones, and in some cases, stimulants.

Arthritis Pain Care Center (APCC), et al., File No. C-3896 (September 7, 1999) (Consent order) (unsubstantiated health benefit claims regarding dietary supplements and false claims regarding scientific studies)

SlimAmerica, Inc., FTC v., No. 97-6072-Civ-Ferguson (S.D. Fla. June 30,1999) (Final Judgment for Permanent Injunction and Damages; $8,374,586 in redress) (Deceptive claims that "Super-Formula" diet product can "blast" up to 49 pounds off user in only 29 days, "obliterate" 5 inches from waistlines, and "zap" 3 inches from thighs, without dieting or exercising)

Bogdana Corp., File No. C-3820 (July 28, 1998) (consent order) (Cholestaway calcium carbonate supplement to lower cholesterol, blood pressure, cause weight loss, treat heart disease;

Western Direct Marketing Group, Inc., C-3821 (July 28, 1998) (consent order) (ad agency for Bogdana Corp.)

Herbal Worldwide Holdings, Inc., File No. C-3827 (September 16, 1998) (consent order) (unsubstantiated weight loss claims for "Fattache," a purported dietary product, in advertisements run on Spanish-language television stations)

TrendMark International, Inc., File No. C-3829 (September 23, 1998) (consent order) (unsubstantiated claims for "THIN-THIN" diet program, consisting of Neuro-Thin weight loss supplement made primarily of amino acids and Lipo-Thin weight loss product made of "chitin," a natural fiber made from the ground-up hydrolyzed exoskeletons of shellfish)

Venegas Inc., C-3781 (Jan. 23, 1998) (consent) (health claims for dietary supplement Alen, including delaying aging process, eliminating anemia, controlling addiction to excess fats and sweets, and helping diabetics to naturally produce insulin – Spanish language)

Mega Systems International, Inc., File No. C-3811 (June 8, 1998) (consent order and $500,000 in consumer redress) (Eden's Secret Nature's Purifying Product to clean and purify body's blood supply and to cure PMS and other illnesses, and to cause significant weight loss, advertised in infomercials) AND Civ. Action No. 98C 8009 (Dec. 15, 1998) (Complaint for Injunctive and Other Relief filed in U.S. District Court for failure to pay $500,000 in consumer redress) (Jan. 4, 2002) (Commission authorized filing of a stipulated judgment in a bankruptcy court action to resolve the Complaint for Injunctive and Other Relief. Under terms of the settlement, the FTC will receive $30,000 now and share in any distribution of assets at the conclusion of the bankruptcy case.

Metagenics, Inc., D. 9267 (Oct. 23, 1997) (consent) (OTC calcium supplement to restore lost bone, eliminate pain)

Global World Media Corp., C-3772 (Oct. 9, 1997) (consent) (explicit safety and no side effects claims for Ecstacy supplement advertised to produce a natural "high," in media with large youth audiences, and without disclosing health and safety risks)

Kave Elahie/M.E.K. International, C-3770 (Sept. 19, 1997) (consent) (NutraTrim Bio-Active Cellulite Control Cream and Weight Loss Tablets with aminophylline — Spanish language)

Rogerio Monteiro and Eliana Crema (Leeka Products), C-3767 (Sept. 12, 1997) (consent) (Super Formula Reductora supplement with chromium picolinate for weight control by regulating metabolism, reducing appetite, burning or dissolving fat — Spanish language)

Efficient Labs, Inc., C-3768 (Sept. 12, 1997) (consent) (Venoflash dietary supplement with vitamins and plant derivatives to remove dangerous clogs in circulatory system and treat symptoms of varicose veins and hemorrhoids — Spanish language)

Nu Skin International, Inc., United States v., No. 2:97-CV-0626G (D. Utah Aug. 6, 1997) (stipulated permanent injunction and $1.5 million civil penalty for violation of 1994 order) (fat loss, muscle maintenance, and other claims for dietary supplements, Metabotrim, OverDrive, GlycoBar, Appeal Lite, and Breakbar, containing chromium picolinate and L-carnitine)

Nutrition 21, C-3758 (Jul. 11, 1997) (consent) (weight loss and health benefit claims for chromium picolinate)

Mountain Springs L.L.C., FTC v., 97-4649 SVW (C.D.Cal. Jun. 25, 1997) (stipulated permanent injunction) (Manaxx Una de Gato (cat's claw) for treatment or prevention of various diseases by strengthening the immune system; effectively treats inflammation; reduces the abnormal irritation of body tissue; cures acne; and is void of any toxic effects — Spanish language)

Amerfit, Inc., C-3747 (Jun. 16, 1997) (consent and $100,000 in disgorgement) (Fat Burners System for weight loss, with tablet and, drink)

Interactive Medical Technologies, Ltd./Effective Health, Inc., C-3751; William Pelzer, Jr., C-3750; and William E. Shell, M.D., C-3749 (Jun. 16, 1997) (consents and $55,000 in consumer redress) (Lipotrol cellulose-bile weight loss product and SeQuester)

Dean Distributors, Inc., C-3755 (Jun. 16, 1997) (consent) (Food for Life Weight Management System and Cambridge Diet low calorie and very low calorie weight loss programs, with formula drinks)

Abbott Laboratories, C-3745 (May 30, 1997) (consent) (many doctors recommend Ensure nutritional beverages as a meal supplement and replacement for healthy adults)

Universal Merchants, Inc., C-3707 (Jan. 23, 1997) (consent) (weight loss and health benefit claims for chromium picolinate)

Zygon International, Inc., C-3686 (Sept. 24,1996) (consent and up to $195,000 in consumer redress for all products) (SuperBrain Nutrient Program to improve intelligence and memory, and to enhance the intelligence

of the children of pregnant women; Fat Burner pills for weight loss; and Day and Night Eyes pills to improve day vision and night blindness, among others)

Home Shopping Network, Inc., D. 9272 (Sept. 26, 1996) (consent) (health-related claims for three vitamin sprays, including prevention of the common cold and reduction of the risk of infectious diseases; and efficacy claims for a stop-smoking spray, including elimination of the anxiety and weight gain associated with quitting smoking — advertised on Home Shopping Network)

Third Option Laboratories, Inc., C-3628 (Nov. 29, 1995) (consent and $480,000 in consumer redress) (Jogging in a Jug apple juice, grape juice, and vinegar beverage for heart disease, arthritis, dysentery, constipation, lowering serum cholesterol and triglycerides, cancer, leukemia, viral disease, blood sugar levels, and other ailments)

National Dietary Research, Inc., D. 9263 (Nov. 7, 1995) (consent and $100,000 in disgorgement) (Food Source 1 weight loss product and Vancol 5000 cholesterol reducing product)

Live-Lee Productions, Inc./Ruta Lee, C-3620 (Oct. 10, 1995) (consent) (health related claims made by television personality Ruta Lee on Home Shopping Network for three vitamin sprays and a stop-smoking spray) (See Home Shopping Network)

Body Wise International, Inc., C-3617 (Sept. 25, 1995) (consent) (dietary supplements for weight loss and cholesterol reduction; failure to disclose that healthcare professionals and others who gave testimonials for the products had a financial interest in promoting them)

Nature's Bounty, Inc., C-3593 (Jul. 21, 1995) (consent and $250,000 in consumer redress) (health related claims for 26 nutrient supplements, including Sleeper's Diet for weight loss during sleep; L-Arginine and L-Ornithine to increase muscle mass while decreasing body fat; L-Cysteine to promote hair growth; Octacosanol to improve reaction time, reduce cholesterol levels, and strengthen muscles; New Zealand Green Lipped Mussel Extract to prevent arthritis and relieve its symptoms; Eye-Vites to reduce the risk of developing cataracts; and Ginsana to improve physical endurance and mental alertness)

Taleigh Corp. (*Choice Diet Products, Inc.*), 119 F.T.C. 835 (1995) (consent agreement, with the requirement that the owner post a $300,000 performance bond to be used for consumer redress should he engage in deceptive practices when marketing weight loss or stop-smoking products in the future) (FormulaTrim 3000, MegaLoss 1000, and MiracleTrim pills for weight loss without diet or exercise, and without nervous jitters, insomnia, or any other side effects; deceptive consumer endorsements and failure to disclose that certain consumer endorsers had been compensated)

Bee-Sweet, Inc., 119 F.T.C. 57 (1995) (consent) (bee pollen products for anemia, back pain, allergies, arthritis, fatigue, and other ailments)

RN Nutrition, 119 F.T.C. 25 (1995) (consent) (BoneRestore calcium product to build bone better than estrogen, slow or stop bone loss, prevent and heal osteoporosis, and restore lost bone)

Schering Corp., 118 F.T.C. 1030 (1994) (consent) (weight loss claims for Fibre Trim supplement, as well as claims that the product provides the health benefits associated with a fiber-rich diet)

Redhead, FTC v., No. 93-1232-JO (D. Ore. Sept. 9, 1994) (stipulated permanent injunction against defendants Demlow, Danek, Lifeline, Inc.) (Imuno-Plex algae-based supplement to cure or treat HIV disease, AIDS, and AIDS related complex)

General Nutrition, Inc., United States v., No. 94-686 (W.D. Pa. Apr. 28, 1994) (permanent injunction and $2.4 million civil penalty for violation of 1970 and 1989 orders) (Protabalase ME, Cybergenics Phase I, Hot Stuff, and others for faster muscle development, improvement of endurance, strength, and stamina; New Zealand Green Lipped Mussel Extract to cure, treat, prevent, or reduce the risk of developing any disease; Quick Shot Energy Pak and other vitamins to prevent, relieve, or treat listlessness; Fat Burners and other weight control and appetite suppressant products)

Nature's Cleanser, Inc., 116 F.T.C. 718 (1993) (consent) (Lady's Comfort herbal remedy to relieve menstrual pain, discomfort in menopause; and Nature's Cleanser herbal remedy for weight loss and weight control)

Nu-Day Enterprises, Inc., 115 F.T.C. 479 (1992) (consent and $30,000 in consumer redress) (Nu-Day diet program with Nu-Day Meal Replacement Formula, and Nu-Day Herbulk, a dietary fiber supplement, for weight loss without exercising; failure to disclose that the infomercial was a commercial, not an independent consumer news program)

Amerdream Corp., FTC v., No. 91-0505 PHX RCB (D. Ariz. Nov. 5, 1991) (permanent injunctions and $50,000 in consumer redress) (Ultimate Solution Diet Program and Night-Trim Diet Tablets for significant weight loss and for reducing cholesterol and blood pressure levels)

International White Cross, Inc., FTC v., No. C-91-0377-TEH (N.D. Cal. Oct. 21, 1991) (stipulated permanent injunction) (Immune Plus nutritional supplement to cure patients with AIDS or AIDS-related complex or help them go into remission, eliminate or reduce AIDS or ARC symptoms, and cause an individual who had tested HIV-positive to become HIV-negative)

Miles, Inc., 114 F.T.C. 31 (1991) (consent) (One-A-Day multiple vitamins to renew essential minerals lost due to strenuous exercise and stress; and to protect lungs against adverse effects of air pollution)

Allied International Corp. (Fat Magnet), FTC v., No. 90-0120 CBM (Kx) (C.D. Cal. Nov. 14, 1990) (stipulated permanent injunction) (Fat Magnet diet pills for weight loss without dieting or exercise)

American Life Nutrition, Inc., 113 F.T.C. 906 (1990) (consent) (bee pollen, fish oil, royal jelly, vitamin, oyster

shell, and calcium food supplements to prevent or treat diseases such as breast cancer, heart disease, diabetes, rubella, arthritis, colds, tuberculosis, asthma, kidney disease, high blood pressure, cerebral apoplexy, low sex drive, among others)

TV Inc., 113 F.T.C. 677 (1990) (consent) (bee-pollen products to prevent, alleviate, or cure allergy symptoms, the aging process, impotence and sexual dysfunction; to promote weight loss; and to relieve pain; failure to disclose that the infomercial was a commercial, not an independent and objective television program)

Nature's Way Products, Inc., 113 F.T.C. 293 (1990) (consent agreement and $30,000 to National Institutes of Health for research in candidiasis) (Cantrol capsules to control yeast infections; Cantrol's diagnostic yeast test can demonstrate that a person is likely to have a yeast infection)

General Nutrition, Inc., 111 F.T.C. 387 (1989) (consent agreement and $600,000 in nutrition, obesity, and physical fitness research) (dietary supplement for reducing the risk of some forms of cancer; six food supplements, including L-Arginine and L-Ornithine, to promote weight loss and muscle growth or retard aging)

Kingsbridge Media & Marketing, Inc., FTC v., No. CIV-88-0003 PHX EHC (D. Ariz. Jun. 8, 1988) (stipulated permanent injunction and $1.1 million in consumer redress) (Dream Away weight reduction pills for weight loss while sleeping and without dieting or exercising)

Great Earth International, Inc., 110 F.T.C. 188 (1988) (consent) (Tri-Amino Plus P.M., L-Ornithine, and L-Arginine, for weight reduction while sleeping, muscle building, protection against mental and physical fatigue, promotion of healing, and strengthening of the immune system)

Viobin Corp., 108 F.T.C. 385 (1986) (consent) (wheat germ oil to improve physical fitness or performance)

Intra-Medic Formulations, Inc., FTC v., No. 85-2819-Civ-Nesbitt (S.D. Fla. Feb. 26, 1986) (permanent injunction) (weight control and baldness-cure products)

Weider Health and Fitness, Inc., 106 F.T.C. 584 (1985) (consent and $400,000 in consumer redress) (Anabolic Mega-Pak and Dynamic Life Essence nutritional supplements for rapid and substantial muscular development and strength)

P. Leiner Nutritional Products Corp., 105 F.T.C. 291 (1985) (consent) (Octacol 4 wheat germ oil capsules to improve endurance, stamina, vigor, and overall athletic performance or physical fitness)

PharmTech Research, Inc., FTC v., 576 F. Supp. 294 (D.D.C. 1983) (preliminary injunction), 103 F.T.C. 448 (1984) (consent) (Daily Greens dehydrated vegetable tablet for reducing the risk of some forms of cancer; claimed support from National Academy of Sciences' report on diet and cancer).

IX. CONCLUSION

Marketers of dietary supplements should be familiar with the requirements under both DSHEA and the FTC Act that labeling and advertising claims be truthful, not misleading and substantiated. The FTC approach generally requires that claims be backed by sound, scientific evidence, but also provides flexibility in the precise amount and type of support necessary. This flexibility allows advertisers to provide truthful information to consumers about the benefits of supplement products, and at the same time, preserves consumer confidence by curbing unsubstantiated, false, and misleading claims. To ensure compliance with FTC law, supplement advertisers should follow two important steps: 1) careful drafting of advertising claims with particular attention to how claims are qualified and what express and implied messages are actually conveyed to consumers, and 2) careful review of the support for a claim to make sure it is scientifically sound, adequate in the context of the surrounding body of evidence, and relevant to the specific product and claim advertised. The FTC works for the consumer to prevent fraudulent, deceptive and unfair business practices in the marketplace and to provide information to help consumers spot, stop, and avoid them.

101 Food Allergy: A Synopsis

Venu Gangur
Department of Food Science and Human Nutrition, The National Food Safety and Toxicology Center, The Nutritional Immunology Program, Michigan State University

CONTENTS

I. INTRODUCTION

Adverse reactions to foods may be classified as those that are induced by biologically active microbial toxins (e.g., shiga toxin, vomitoxin, etc.) contained in the foods and those that are triggered by specific food constituents by nontoxic mechanisms [1–3]. Some of the nontoxic adverse reactions to foods are mediated by the immune system while others are not. Food induced adverse reactions mediated by the immune system are generally grouped as food induced hypersensitivity reactions.

Whereas the primary role of the immune system is host-defense, some of the activation pathways of the immune responses often results in significant host-damage. Such immune-mediated tissue damages were originally classified by Coombs and Gell as hypersensitivity reactions [4, 5]. The basis underlying this classification, including relevant examples, is summarized in Table 101.1. Accordingly, hypersensitivity reactions mediated by IgE antibodies are classified as classical allergic reactions (or immediate hypersensitivity reaction or Type-I hypersensitivity reaction). Airways allergies and most food allergies belong to this group. Antibodies of other isotypes (IgG, IgA) mediate Type-II or Type-III HS reactions, and contribution of these HS reactions to food induced adverse reactions is unclear. In contrast, those HS reactions that are mediated by specific immune cells are classified as Type-IV HS reactions (or delayed or cell-mediated hypersensitivity reactions). A classical example for the cell mediated adverse reaction to food is gluten enteropathy (or coeliac disease) [6].

Although IgE is associated with many food allergies, IgE independent mechanisms, many of which are unclear at present, appear to underlie other types of food allergies [7–9]. To complicate the matter further, some food allergies may involve mixed type of immune mechanisms involving both IgE antibodies and immune cells. One such condition often seen in infants and children is food-induced atopic dermatitis [7–9]. This disease often begins in infancy. Earliest lesions are erythematous, weepy patches on the cheeks with subsequent extension to other parts of the body including the face, neck, wrists, hands, and abdomen. Similar to food allergies, recent evidence also suggests that other atopic diseases (e.g., atopic rhinitis, dermatitis, and asthma) may also be classified as IgE dependent or independent [10]. There is controversial evidence that conditions such as irritable bowel syndrome and migraines may also be

TABLE 101.1
Coombs and Gell Classification of Hypersensitivity Reactions

	Type I	Type II	Type III	Type IV
Other names	Immediate hypersensitivity Classical allergic reaction Anaphylactic reaction	Cytotoxic reaction	Immune complex reaction Arthus reaction	Delayed hypersensitivity Contact "allergic" reaction
Major immune component involved	IgE antibody	IgG antibody	IgG, IgA antibody	Antigen specific T-lymphocyte
Antigen	Allergens (usually soluble proteins)	Transfused blood cells Altered host cells	Auto antigens or Soluble antigens	Soluble antigen or cell associated antigens
Major tissue damaging mechanism	Mast cell Basophil Eosinophil	Complement mediated cytolysis Phagocytosis	Immune complex deposition Phagocytosis	T-lymphocytes Monocytes and macrophages
Examples	Classical allergies Allergic asthma Most food and drug allergies	Transfusion reactions Some drug hypersensitivity	Lupus IgA nephropathy	Celiac disease (or gluten enteropathy), Nickel "allergy"

References: 4, 5, 9, 6.

TABLE 101.2
Immune System Dependent Food Induced Adverse Reactions

Type of Adverse Reaction	Onset of Symptoms in Sensitized Host When Exposed to Food	Implicated Mechanism	Examples
True food allergy including anaphylaxis (immediate hypersensitivity reaction)	Minutes (most reactions occur within 1 h; most reported severe reactions occur within 1–3 h)	IgE antibody mediated	Peanut allergy Chicken egg allergy Cow's milk allergy Food induced anaphylaxis
Delayed hypersensitivity reaction (non-IgE mediated reactions)	24–48 h	Cell mediated (e.g., T lymphocytes)	Gluten enteropathy (or Celiac disease) Food induced pulmonary hemosiderosis (or Heiner's syndrome) Contact dermatitis Dermatitis herpetiformis Dietery (or food) protein induced enterocolitis Dietery (or food) protein induced proctitis
Mixed hypersensitivity reactions	Variable	IgE plus cell mediated	Food induced atopic dermatitis Allergic eosinophilic gastritis Allergic eosinophilic gastroenteritis Allergic eosinophilic esophagitis
Uncharacterized/controversial food-induced reactions	Unknown	Unknown	Migraine headaches Irritable bowel syndrome

References: 3, 6–9, 11, 12, 19, 41.

related to food [11, 12]. The various types of immune system-dependent food induced adverse reactions with implicated mechanism and relevant examples are summarized in Table 101.2.

Food intolerance is a condition that is often mistaken for food allergy. As opposed to food allergy, food intolerance is not mediated by the immune system. For instance, lactose deficiency leads to milk intolerance [9, 13, 14]. Similar to lactose intolerance, alcohol intolerance is also a consequence of a precise metabolic defect rather than being immune system-mediated [15] (Table 101.3). Furthermore, there are allergy-like food induced adverse reactions that occur due to the formation of histamine or histamine-like substances in certain foods during storage [16]. For instance, histidine can undergo chemical conversion to histamine in presence of histidine decarboxylase produced by certain bacteria [17]. Consequently, consumption of food containing histamine and other pharmacologically active amines can result in allergy-like reactions [2, 3] (Table 101.3). Scombroid fish poisoning is a classic example of this category [18]. As will be discussed later, histamine is one of the major mediators of allergy symptoms. Therefore these conditions that are immune system-independent should be distinguished from actual food allergies as well.

TABLE 101.3
Immune System Independent Adverse Reactions to Foods

Type of Adverse Reaction	Mechanism	Examples
Allergy-like reactions	Preformed histamine in food causes allergy like symptoms (e.g., itching, swelling or hives, diarrhea etc.)	Fermented aged cheese, Scombroid fish poisoning
Food intolerance	Lactase deficiency Aldehyde dehydrogenase deficiency	Lactose (milk) intolerance Alcohol intolerance

II. PREVALENCE AND SIGNIFICANCE OF FOOD ALLERGY

Current prevalence of food allergies that are relatively common among many western countries has been estimated to be ~2% among adults and ~7% among children [19, 20]. As seen for several other allergic diseases, some recent reports suggest that incidence of some food allergies may be increasing, particularly among children [19, 21]. For instance, a recent study conducted in the Isle of Wight suggested that sensitization to peanut had increased between 1989 and 1994 to 1996 and that there was a strong but statistically nonsignificant trend for increase in reported peanut allergy [22]. Thus, more data is warranted to test this hypothesis and to examine whether this may be true for all types of food allergies in addition to that of peanut allergy.

Notably, there are an estimated 29,000 emergency room visits and 150–200 deaths per year in the U.S. due to food-induced systemic anaphylaxis — a generalized hypersensitivity response involving multiple organ systems including circulatory system, that can be fatal within minutes to hours after the onset of symptoms if untreated [19]. Because most of the victims are children, food allergy is a major public health problem facing day care centers, pre-schools, and schools [23–26]. Furthermore, food allergies also pose a serious challenge to food industries (i.e., food producers, retailers, and restaurants), as well as regulatory agencies (FDA, EPA) and service providers (such as the airline industry) [20, 27–30]. Thus, these incurable chronic diseases exert a significant negative impact on the economy as well as society at large.

III. ALLERGENIC FOODS vs. FOOD ALLERGENS

Any food can cause allergic reaction in a sensitized individual (i.e., someone who has produced IgE antibodies to the food in question). About an estimated over 100 different types of foods have been documented to trigger an allergic reaction in sensitized subjects [31]. According to the Food and Agriculture Organization (FAO) and the Food Allergy Task Force of the International Life Sciences Institute (ILSI), Europe, 90% of food allergies are caused by only eight food types: Chicken egg, cow's milk, peanut, soybean, wheat, tree-nuts (almond, hazelnut etc.), fish, and shellfish [8, 31–33]. Consequently, these food types have been regarded by the food regulatory agencies as "big eight" or "red flag" allergenic foods [27, 34]. These food allergies appear to be not restricted to any geographical region in particular but rather are widespread in the world [8, 31–33] (Table 101.4). In contrast, some other food allergies appear to be relatively common in certain countries. For instance, rice allergy — a rare form of allergy in the U.S., is relatively common in Japan, where rice is a staple food [35, 36] (Table 101.4). Allergy to sesame, often expressed as systemic anaphylaxis similar to peanut allergy, has been reported to be more common in Israel [37, 38]. A recent recommendation by the ILSI expert panel states that sesame meets the necessary requirements of a major food allergen and therefore may need to be included in this group of major allergenic foods [39]. It has been suggested that the geographical variation in the prevalence of food

TABLE 101.4
Commonly Allergenic Food Types and the Prevalence of Food Allergies

Food Type	Geographic Prevalence	Usually Outgrown
Red-Flag or Big Eight Food Types		
Cow's milk	Global*	Yes
Chicken egg	Global	Yes
Wheat	Global	Yes
Soy	Global	Yes
Peanut	Global	No**
Fish (salmon, cod, less often tuna)	Global	No
Shellfish (crustaceans: shrimps, crayfish, crabs, lobsters)	Global	No
Tree nut (almond, hazelnut/ filberts, walnut, pecans, pistachios, cashews, pine nuts, macadamia etc.)	Global	No
Other Allergenic Foods		
Celery	Mostly in Europe	UN
Buckwheat	Southeast Asia	UN
Rice	Japan	UN
Sesame	Israel	UN

* Global, meaning many countries but not necessarily all countries.
** Some peanut-allergic individuals outgrow peanut allergy over time (47, 67).
UN, Unknown.
References: 7–9, 19, 31, 34, 40–42, 45, 56.

allergies may very well be related to the exposure levels of an allergenic food in the local population [35, 36, 40–42].

A food that triggers an allergic reaction in a sensitized host is regarded as an allergenic food. Notably, not all constituents of an allergenic food are necessarily food allergens. Whereas most proteins in chicken egg are allergenic, only three proteins of peanut are known to be allergenic for most peanut allergic people [32, 33]. Classical allergens are typically proteins or glycoproteins that elicit production of specific IgE antibodies and physically and specifically bind to them. Although this definition of allergen was originally developed for aeroallergens, it has been widely used in the literature for food allergens as well [33].

Following are some of the salient features associated with many food allergens. Thus many food allergens are (i) proteins (usually glycoproteins); (ii) heat resistant (for instance, roasting does not abolish IgE binding ability of peanuts); (iii) acid stable (pH $\leqslant$2.0); (iv) resistant to pepsin digestion; (v) water soluble; and (vi) present in a given food at $\geqslant$1% level of total protein content [7, 32, 43]. Although these characters appear to associate with many food allergens, they do not absolutely predict the allergenic potential of a given protein *per se* [7, 8, 43].

IV. FOOD ALLERGY: CLASSIFICATION

Clinically food allergic reactions are expressed within minutes of exposure with a variety of symptoms. These include urticaria (skin rashes), hives (or raised rashes), angioedema, rhinoconjunctivits, vomiting, diarrhea, airway allergy symptoms (such as asthma, runny and itchy nose) or systemic anaphylaxis and shock. Accordingly, based on the target organ involvement, food allergies have been classified as (i) gastrointestinal food allergy; (ii) dermatological form of food allergy; (iii) respiratory form of food allergy; and (iv) food-induced systemic anaphylaxis involving multiple organ systems including the cardiovascular system [2, 9]. Some food allergies manifest themselves following exercise immediately after eating, presumably due to increased absorption and distribution of allergens via enhanced circulation [19, 44]. Notably, foods such as peanut, tree-nuts, fish, and shellfish are more often associated with systemic anaphylactic reactions than other food types [8, 19, 20].

Clinically food allergies are also expressed in two distinguishable forms: (i) transient food allergies (that are commonly outgrown); and (ii) persistent food allergies (that are rarely outgrown). Allergies to chicken egg, cow's milk, soy, and wheat typically start during childhood and are outgrown before adulthood [9, 24, 45, 46]. In contrast, peanut, tree nut, fish, and shellfish allergies although may start early in life but tend to remain during adult hood and are rarely outgrown [9, 24, 45, 46]. Consequently, these types of food allergies are overrepresented among adults. Notably, a recent study reported that a small but significant number of peanut allergic children ($\sim$20%) may outgrow their clinical disease over time [47].

Antigen/allergen specificity is one of the hallmarks of immune responses. Generally IgE antibodies produced against a given allergen are specific in nature (i.e, they generally do not physically bind to most other unrelated proteins). Consequently, if a given person is allergic to peanut alone, his peanut-specific IgE antibodies do not usually bind to other food types and therefore this individual is not expected to exhibit allergic reaction to foods other than peanut.

In some cases, there are cross-reacting IgE antibodies that bind to more than one allergenic protein due to similarities in the primary and quaternary structure (i.e., three-dimensional structure) shared by these proteins [48]. For instance, many patients allergic to hazel pollen or birch pollen exhibit pollen-specific IgE antibodies that also physically bind to hazelnut proteins (i.e., cross reacting antibody) [49–56]. The presence of such cross-reacting IgE antibodies is associated with hazelnut allergy in some patients [57]. Similarly some grass or ragweed pollen-allergic patients exhibit oral allergy symptoms (such as tingling, burning sensation in the mouth, etc.) when they consume fresh fruits and vegetables [58–61]. This has been proposed to be due to cross-reacting IgE antibodies elicited following exposure to grass or ragweed pollen allergens that also bind to proteins from certain fruits and vegetables [62]. Immune cross-reactivity between latex and many food types has also been described [63]. Food allergies caused by such cross-reacting antibodies have been classified as Type-2 food allergies [9]. Some of the clinical syndromes attributed to immune cross-reactivity are summarized in Table 101.5.

V. MECHANISMS OF FOOD ALLERGY: IMMUNE RESPONSE MODEL

As opposed to food allergy, immune mechanisms underlying other types of allergies such as allergic rhinitis and allergic asthma are very well established [46, 64–67]. Allergies in general are regarded as complex heterogeneous genetic disorders involving interaction between multiple genetic susceptibility genes and environmental factors [68–70]. Similar genetic susceptibility is thought to underlie food allergies as well [64, 66, 67, 71]. However, environmental exposure to allergen is essential for initiation of an allergic immune response as well as expression and maintenance of the clinical disease [65, 68].

Although food allergies are immune system-mediated, specific mechanisms underlying individual types of food allergies are unclear at present [9, 64]. One currently proposed mechanism for peanut allergy is illustrated in Figure 101.1. According to this model, exposure to peanut leads to peanut antigen presentation by professional antigen-presenting cells of the immune system to peanut-specific T helper (Th) cells. This results in the formation of Th2

TABLE 101.5
Type-2 Food Allergy: Food Allergies Attributed to Immune Cross-Reactivity to Aero Allergens

Type of Food Allergy	Implicated Foods	Aero-Allergens that Exhibit Immune Cross-Reactivity
Celery–mugwort–spice syndrome	Celery, carrot, apple, hazelnut, potato, kiwi fruit	Birch tree; pollen allergens from birch tree and mugwort
Birch pollen–hazelnut allergy syndrome	Hazelnut	Pollen allergens from hazel, birch, and alder
Latex–food allergy syndrome	Avocado, banana, chestnut, kiwi, raw potato, tomato, stone fruits (e.g., peach, cherry), hazelnuts, melons, celery, carrot, apple, pear, papaya, and almond	Latex
Oral allergy syndrome	Honeydew melon, banana, cantalope, watermelon	Pollen allergens from ragweed, grass, and birch tree

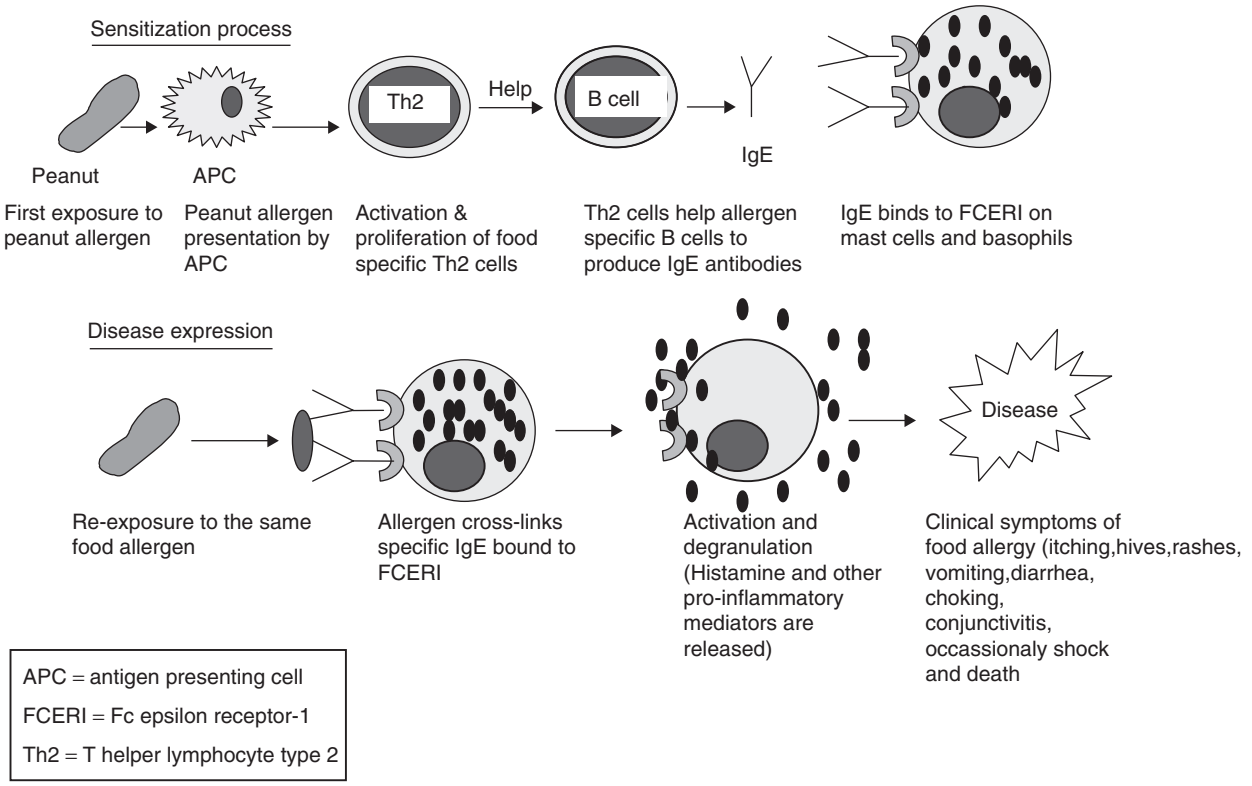

FIGURE 101.1 Mechanism of peanut allergy: immune response model. Exposure of a genetically susceptible individual to peanuts results in presentation of peanut allergens by antigen presenting cells (APC) to T helper (Th) lymphocytes. A consequence of this is the proliferation and activation of peanut specific Th-2 lymphocytes that help peanut-specific B cells to produce peanut-specific IgE antibodies. IgE antibodies bind to the high affinity IgE receptor present on cells such as mast cells that are rich in histamine and other proinflammatory mediator containing granules. Subsequent exposure to the same allergen (peanut in this case) results in cross-linking of surface IgE receptors on mast cells results in cellular activation, degranulation. Host response to histamine and other mediators results in the expression of clinical symptoms of food allergy within minutes of exposure to allergens.

lymphocytes that help peanut-specific B-lymphocytes to produce peanut-specific IgE antibodies [46, 66, 67]. These events are thought to occur when a susceptible individual comes in contact with the peanut for the first time. Once formed, most IgE antibodies in the system bind to high affinity IgE receptor (Fc epsilon receptor I, FCERI) on mast cells and basophils through their Fc portion [8, 72]. These immune cells are equipped with granules containing histamine and other pro-inflammatory mediators [72, 73]. Once these events occur, the individual is regarded as being sensitized to the relevant food. Subsequent encounter with the same food allergen (peanut allergen in this case) results in cross-linking of cell surface-bound IgE molecules by peanut allergens leading to activation and degranulation of mast

cells and basophils. The release of inflammatory mediators results in expression of clinical symptoms of disease. In extreme cases, this reaction could be widespread, involving multiple organs (referred to as systemic anaphylaxis and shock) that is often fatal if untreated [19].

In contrast to peanut allergy (and some other IgE mediated food allergies), mechanisms underlying many IgE independent food allergies are less clear. Food protein-induced enterocolitis syndrome (FPIES) is a group of conditions particularly common among infants and children [1, 74–76]. Commonly implicated foods in these diseases are cow's milk and soy. A recent study suggests that cereals, vegetables, and poultry meats, typically regarded as of low allergenic potential, must be considered in the evaluation of FPIES, particularly in infants previously diagnosed with FPIES to cow's milk or soy, and as an initial cause in patients who have been exclusively breastfed [76]. Notably food-specific IgE antibodies are not usually detectable in the circulation of these patients. Specific mechanisms of disease are not clear, although many appear to involve delayed hypersensitivity reactions. Furthermore, the disease-eliciting food components also remain to be characterized.

One well-characterized non-IgE mediated food-induced disease is gluten enteropathy (or celiac disease). It afflicts children as well adults and is particularly prevalent among Caucasians (1 in 200 individuals) [6]. Gluten is a component of many cereals such as wheat, rye, and barley. Wheat gluten in particular consists of a complex mixture of many gliadins and glutenin polypeptides. Gliadins are monomers and glutenins are polymers. There is clear evidence that celiac disease patients have T cells infiltrating the intestinal mucosa that react to deamidated gluten peptides [6]. Thus, gluten-specific T lymphocytes appear to be involved in the pathogenesis of this disease [6, 77]. However, there is evidence suggesting that the disease mechanism may have an autoimmune component as well. Thus, celiac disease patients on a gluten-containing diet produce IgA and IgG autoantibodies specific to tissue transglutaminase (TG)-2 [78]. The TG2 is an enzyme that deamidates gluten peptides so that T cells can recognize it in complex with the host human leukocyte antigen class II gene products [6, 79].

VI. FOOD ALLERGY: PREVENTION, DIAGNOSIS, AND THERAPY

Currently there is neither a cure nor an effective preventive method such as a vaccine available for food allergy. Strict avoidance of contact with the food allergen is the only recommended preventive method at present [8, 9]. In addition, following are some of the strategies especially for decreasing risk of atopy (i.e., tendency to develop an IgE antibody response) in infancy: (i) prolonged exclusive breast-feeding; (ii) maternal avoidance of commonly allergenic foods so as to prevent transfer of these proteins via breast milk to infants; (iii) delayed introduction of solid foods for the first 6 months of life; and (iv) use of hydrolyzed infant formulas (commonly referred to as hypoallergenic foods) [3, 24, 41, 74]. For food allergy in particular, novel prophylactic approaches are under experimental stages (for peanut allergy) in mouse models. Some of these are summarized in Table 101.6.

Food allergies are typically diagnosed with clinical history in combination with one or more of the following diagnostic tests. (i) Skin prick test: a small amount of allergen is placed on the surface of the skin and a quick prick is done to enable the allergen to cross the skin barrier and reach the underlying mast cells. If an individual has IgE antibodies specific for the allergen bound to the mast cells, it leads to IgE cross-linking, mediator release, and a wheal (swelling) and flare (redness) reaction at the site of allergen prick within 20–30 minutes. A saline solution is used as a negative control and a histamine solution as a positive control. Comparison of wheal size is made to determine the diagnosis. (ii) Double-blind placebo-controlled oral food challenge (DBPCFC) test: this is the gold standard test for food allergy diagnosis. However, the risk of severe reactions such as anaphylaxis makes this a difficult (and potentially very dangerous) choice for individuals with such a history. (iii) Food-specific IgE antibody measurement: immunoassay-based tests (such as radio allergosorbent test, or RAST) are available to determine the level of food-specific IgE antibody levels in the peripheral blood [7]. Recent studies suggest that determination of peanut allergen epitope recognition by IgE antibodies provides an additional tool to diagnose symptomatic peanut allergy, especially in children with peanut-specific IgE below diagnostic decision levels [80]. Furthermore, quantification of food-specific IgE was reported to be a useful test for diagnosing symptomatic allergy to egg, milk, peanut, and fish in the pediatric population and could eliminate the need to perform double-blind, placebo-controlled food challenges in a significant number of children [81]. Given the high rate of false positive reactions for skin testing and the problems with DBPCFC, this might prove useful clinically.

Following are the currently used therapeutic approaches for allergic diseases in general including food allergies. (i) Antihistamines are widely used for most allergic reactions. Antihistamines block histamine binding to H1 receptor and prevent cellular response to histamine. (ii) Corticosteroids are general anti-inflammatory agents that can be used locally or systemically. (iii) Epinephrine injections (intramuscular) are recommended for severe food-induced reactions such as systemic anaphylaxis. Epinephrine is the only life-saving medicine available to treat them. It can save life provided it is administered early in the reaction [3, 82]. It works as follows: constricts blood vessels and restores blood pressure, dilates bronchi and prevents choking, and increases heart action. Notably, as opposed to epinephrine, antihistamines have no demonstrated life-saving properties. (iv) Allergy shots: a technique

TABLE 101.6
Experimental Prophylactic and Therapeutic Approaches for Peanut Allergy

Method	Host System	Route of Administration	Results	References
Prophylactic Approaches				
Gene therapy (allergen-encoding plasmid DNA + chitosan nanoparticles)	Mouse	Oral	Decreased SPT Decreased IgE, plasma histamine, vascular leakage, decreased anaphylaxis	112
Recombinant IL-12 (in liposome)	Mouse	Oral	Decreased specific IgE, Increased IFN-g; Prevented and reversed anaphylactic symptoms Decreased histamine release	113
Therapeutic Approaches				
Humanized IgG1 monoclonal anti-IgE antibody therapy	Human	Subcutaneous injection	Increased the threshold of sensitivity to peanut on DBPCOFC from 178 mg to 2805 mg per person	88
Recombinant IL-12 (in liposome)	Mouse	Oral	Decreased specific IgE, Increased IFN-g Prevented and reversed anaphylactic symptoms Decreased histamine release	113
Chinese herbal formula (FAHF-1)	Mouse	Oral	Decreased specific IgE, IL-4, IL-5, and IL-13 Complete blocked anaphylactic symptoms Decreased histamine release and mast cell degranulation	114
Ara h1-3 plus heat-killed *Escherichia coli*	Mouse	Subcutaneous	Persistent protective effects	116
Ara h1-3 plus heat-killed *Listeria monocytogenes*	Mouse	Subcutaneous	Decreased frequency and severity of anaphylaxis Decreased specific IgE, IL-5 and IL-13 Decreased histamine release Bronchial constriction	115

called Preventive Allergy Treatment (PAT) (also called desensitization) has been used clinically for treating airway allergies. However, they are not recommended for food allergies due to serious risk of systemic anaphylaxis [3, 7, 82].

A number of experimental therapeutic approaches are currently being evaluated for allergies in general [83–86]. These may also be relevant for food allergies. They include the following. (i) Using allergen derived peptides that activate only T cells but fail to bind IgE antibodies and induce tolerance. (ii) Inhibition of IL-4, IL-5, IL-13 responses so that IgE synthesis can be inhibited or reduced. (iii) Use of cytokines such as IFN-gamma, IFN-alpha, IL-10, IL-12, and TGF-beta that can inhibit IgE antibody synthesis. (iv) Use of antibodies to IgE so that IgE can be removed from the system; a recent clinical study suggested that use of anti-IgE antibodies as a therapeutic method may be of some benefit in peanut-allergic subjects by increasing the threshold of the peanut dose required to elicit symptoms [87, 88]. (iv) Use of chemokine receptor (CCR3) antagonists to inhibit allergic inflammation by interfering with immune cell recruitment (i.e., chemotaxis) to sites of tissue damage. (v) Use of anti-leukotriene to block late-phase responses that contribute to chronic inflammation as in allergic asthma [84, 85].

Some recently reported experimental therapeutic approaches with interesting results in mouse models for peanut allergy are summarized in Table 101.6.

VII. FOOD ALLERGY AND FOOD INDUSTRY

The primary focus of the food industry has been on IgE-mediated food allergies. This is mainly because most potentially fatal food allergies are IgE mediated. In this regard, the food industry faces several challenges as listed Box 101.1. According to the United States Food and Drug Agency (US FDA), presence of "big eight" allergenic foods in a product needs to be identified on the label [27]. Absence of such information on the label is the reason for large number of class I food recalls in the U.S. [27].

In view of the current regulations, the food industry needs to ensure that their product is free from known eight commonly allergenic foods if they are not identified on the food label. Because many processing units share machinery, there is a real chance of cross-contamination between food products. One way to address this problem is by strictly following the recommended Good Manufacturing Practices (GMP) for food allergens as described in detail earlier [89]. Some of these in principles include (i) segregating allergenic

Box 101.1

Labeling issue

Is there a threshold for allergenic foods?

How to determine whether exotic (or nontraditional) food is/is not allergenic?

Genetically modified food: will they be allergenic?

Does food processing increase allergenicity?

foods from non-allergenic foods in the production lines; (ii) scheduling allergenic foods processing at the end of the day after non-allergenic food processing, followed by adequate cleaning; and (iii) frequent testing of the production lines for contamination of allergenic foods using appropriate methods. Availability of commercial rapid immunoassay (ELISA) screening kits to detect allergenic foods in field samples has helped this process enormously.

Most commercial immunoassays for allergenic foods typically have a detection sensitivity of $\geqslant$10 ppm. However, whether such a detection level is sufficient to ensure safety for consumers is not entirely clear. According to the US FDA, there are no recommended or suggested threshold or cutoff levels for allergenic food contamination of food products. There are two major reasons for this stand: (i) clinical symptoms of allergy can be elicited by "very small" quantities of food exposure in sensitized individuals, and (ii) there are no scientifically validated and well accepted threshold levels for common allergenic foods in different populations.

There have been, however, efforts to determine the threshold levels for various allergenic foods. For example, there are reports that 100 µg total peanut protein or 6 µg of the major peanut allergen (*Ara h2*) are threshold doses in patients by DBPCFC test [90, 91]. Another report suggested that the lowest observed reactive threshold was at 250 µg of peanut protein (equivalent to 1 mg whole peanut). Similar efforts have been recently reviewed for other foods as well [92]. These data suggest existence of dose thresholds and that they are unlikely to be a single dose for all allergenic food types for all age groups.

A number of concerns have been raised on the potential of food processing in increasing allergenicity of proteins and/or creating "neo-allergens" in processed foods [93–95]. There is some evidence that, as opposed to boiling or frying, dry roasting of peanuts increases its allergencity [96]. Other processing methods such as Maillard reaction (a chemical reaction between sugar and proteins) have also been proposed to increase IgE binding property of both allergenic and non-allergenic protein (lectin) in peanuts [97, 98]. In contrast, other processing methods such as protease treatment of soybeans and boiling of milk have been shown to reduce allergenicity of these foods [99–101]. Thus, more work is needed to further study the specific impact of different processing methods on allergenicity of proteins in different food types.

VIII. PREDICTING ALLERGENICITY OF NOVEL FOODS

Exposure to allergens is a critical step in the sensitization process as well as for allergy disease expression. Consequently, it is critical that new allergenic foods are not introduced into the food chain due to application of biotechnology in genetic modification of foods [28, 34]. Thus another significant problem faced by the food industry is to ensure that novel foods are tested for potential allergenicity before being introduced into the food chain (Box 101.1). Novel foods could be exotic/nontraditional foods or genetically engineered food proteins.

As alluded to earlier, food allergens in general are proteins in nature. Since genetically engineered foods express a new protein, potential allergenicity of this new protein is an important issue [8, 43, 92, 102]. This is especially critical if the new gene comes from sources such as peanuts, which are known to be lethally allergenic. In addition to foods, allergens can come from other sources such as insects (house dust mites, cockroaches), pollen from grass, trees, or weeds, and helminth parasites (such as round worms). In the U.S., the FDA requires labeling for a food that contains a new protein derived from known allergens or if a given food contains any of the eight "red flag" allergenic foods [27].

The difficult issue is the assessment of allergenic potential of novel proteins without any allergenic history available, particularly because the characteristics of an allergenic protein that would predictably distinguish it from non-allergenic proteins are largely unknown at present [8, 43, 92, 102]. This is an area of tremendous interest for the regulatory agencies (US FDA, EPA), federal health agencies (NIH), as well as food industries that are developing a variety of genetically engineered foods. The recent episode of StarLink™ corn vs. allergy/asthma has increased awareness and concern among public, regulatory agencies and the food industry on this issue, although the currently available investigative data on whether StarLink™ corn is indeed allergenic is inconclusive [103] (Box 101.2).

There have been extensive efforts to develop and validate methods to predict allergenicity of novel foods. Some of the currently pursued methods are summarized in Box 101.3. Limitations for some of the methods are listed

Box 101.2

StarLink™ Corn: Is This Genetically Modified Food Allergenic in Humans?

1996: Aventis Corporation (Bridgewater Crossing, NJ) produced this genetically modified corn; no product made after 2000

It contained Cry 9c, a pesticidal protein from *Bacillus thuringiensis* (Bt); Cry 9c is thermostable compared to other *Bt* proteins; therefore potential allergencity could not be ruled out based on available scientific knowledge at that time

1998: US EPA approved this corn only for animal feed September 2000: reports confirmed that StarLink had contaminated the human food supply (e.g., DNA was detectable in taco shells)

2001: US FDA, US EPA and USDA Food safety and inspection service asked National Food Processors Association to collect data on consumption, consumer contacts, allergy health contacts, and allergy related product recalls that might be potentially related to StarLink

2001: US Centers for Disease Control conducted analyses of samples from suspected cases; found no evidence for IgE antibody reactivity to Cry 9c in any of the serum samples; however, the test was limited because it used a recombinant Cry 9c protein produced in bacteria rather than the protein that is expressed in plants;

allergenic potential of this genetically modified remains inconclusive

in Box 101.3. It has been reported that results from methods such as stability to digestion do not necessarily correlate with allergenicity, and that such correlations are not absolute [104]. Predicting allergenicity of novel proteins based on primary amino acid and/or nucleotide sequence homology is also challenging, especially for discontinous or nonlinear epitopes [43, 105]. A recommendation from an FAO/WHO expert panel suggests that animal studies will contribute important information on the allergenicity of foods derived from biotechnology [34]. Readers are referred to excellent articles that discuss these issues in detail [43, 106].

There has been a recent effort to test the hypothesis that commonly allergenic foods are relatively more immunogenic than rarely allergenic or non-allergenic foods in mice using a multiple food sensitization protocol [107]. Mice were immunized with protein extracts from commonly allergenic foods (chicken egg, peanut, almond, filbert/hazelnut, walnut, soy, and wheat) or rarely/non-allergenic foods (coffee, sweet potato, carrot, white potato, cherry, lettuce, and spinach) plus alum as an adjuvant. Immunogenicity was measured as a function of the ability of each food type to elicit food-specific IgG1 antibody responses. The hierarchy of immunogenicity in this model of multiple food sensitization was found be: almond = filbert > spinach ≥ peanut ≥ sweet potato > cherry > lettuce > walnut > chicken egg > carrot ≥ white potato > wheat = coffee = soy. Thus there was no evidence supporting the hypothesis that allergenic foods are more immunogenic relative to non-allergenic foods. These data also demonstrated for the first time that (i) food types vary widely in relative immunogenicity in this mice strain; and (ii) relative immunogenicity in this model does not distinguish common vs. rare/non-allergenic food types. Consequently, the results also caution that evaluating immunogenicity of novel foods in mouse using the multiple sensitization method is unlikely to provide useful information on their potential allergenicity among humans.

Box 101.3

Methods for Assessment of Allergenic Potential of Food

Stability to pepsin digestion (pH 2.0)

Heat stability (90°C, 5 minutes)

Primary amino acid and/or nucleotide sequence homologies (6 consecutive amino acid match; or 35% identity)

Double-blind placebo-controlled oral food challenge test (in exposed population)*

Testing in food allergy animal models

* Ethical concerns have been raised on using this method in humans

A. Assessment of Allergenic Potential of Genetically Engineered Food: Decision Tree Approach

Food allergy is an international problem of critical significance. Consequently, there have been extensive international efforts in developing decision trees (i.e., flow charts) with the objective of helping predict the allergenic potential of novel proteins. The International Life Science Institute/International Food Biotechnology Consortium developed a decision tree approach for examining allergenic potential of genetically engineered (GE) foods in 1996 [31]. Subsequently a number of criticisms were made against this decision tree. To address some of these concerns, the FAO/WHO convened a special expert panel in 2001. The

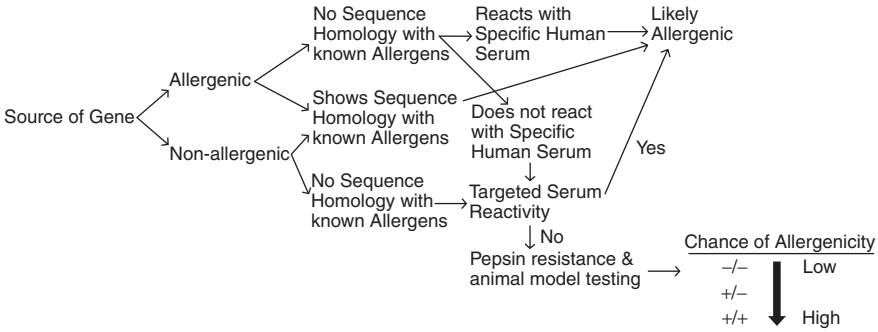

FIGURE 101.2 WHO/FAO Decision tree for assessment of allergenic potential of foods derived from biotechnology. The figure illustrates the principles of the decision tree approach developed by the FAO/WHO expert committee. (For more details, see <ftp://ftp.fao.org/es/esn/food/allergygm.pdf>.)

revised decision tree includes additional methods such as the use of animal models to assess allergenicity [34]. Principles underlying the latest FAO/WHO decision tree for assessment of allergenicity of novel foods is shown in Figure 101.2.

IX. CHALLENGES AND FUTURE DIRECTION

Since only a few (eight) foods account for a vast majority (~90%) of food allergies, one simplistic possibility to deal with food allergy is to eliminate one or more allergenic foods from the food chain. However, this appears to be an impractical solution because of the economic stature of the peanut business in the U.S. Peanut production in the U.S. is ~2 million tons per year (~10% of global peanut production). This translates to consumption of 2.9–3.6 kg per person per year. In addition to this economic importance, peanuts and other nuts offer nutrient (e.g., protein content) and health benefits (e.g., use of almonds in reducing risk of coronary heart disease [108, 109] and the use of nut and peanut butter in lowering risk of type 2 diabetes in women [110]. Thus it would be unwise to consider eliminating one or more of these food types from the food chain.

Alternative strategies are therefore necessary to deal with food allergy. Several areas of current research needs are (i) to develop improved methods to detect the presence of "hidden" allergens in food, (ii) to develop non-allergenic foods (e.g., non-allergenic soybeans and peanuts by producing them without the allergenic proteins; there is some recent success in this effort [111], (iii) to develop and validate methods to accurately predict allergenic potential of novel foods, and (iv) to develop effective preventive and/or therapeutic methods for food allergies.

X. CONCLUSIONS

Food allergies are a large and complex group of immune system-mediated diseases with little understood molecular mechanisms, although some have begun to be uncovered. Extensive research efforts are under way not only to understand the disease process, but also to study the potential utility of novel therapeutic and prophylactic methods such as gene therapy [112–116]. Since these diseases can be potentially fatal, they pose a serious challenge to consumers, food industries, and food regulatory agencies. Assessment of allergenic potential of genetically modified foods is another area that has received international attention. This has resulted in the availability of an FAO/WHO-proposed "decision tree" approach for assessment of allergenicity of novel foods. Clearly, coming years would test the utility of such approaches for predicting allergenic potential of genetically modified foods in humans before they are introduced in to the food chain. With advances in basic and clinical aspects of allergy and immunology and improved biotechnology, there is enormous hope and potential for effective prevention and management of food allergies in the twenty-first century.

ACKNOWLEDGMENTS

This work was supported by funding from the Michigan State University (CANR, MAES, CVM, and MSU Foundation) and the U.S. Environmental Protection Agency.

Author would like to thank Dr. Kent HayGlass (University of Manitoba, Canada) and Dr. Wilfried Karmaus (Michigan State University) for a critical review of the manuscript, and Dr. Lalitha Navuluri, Mr. Caleb Kelly, and Ms. Jankhana Subhashchandra (Michigan State University) for assistance with manuscript preparation.

Food Science and Technology

HANDBOOK OF FOOD SCIENCE, TECHNOLOGY, AND ENGINEERING

Volume 2

The **Handbook of Food Science, Technology, and Engineering, Four Volume Set** is a single source guide to the latest advances available in food science, technology, and engineering. It presents this information in a thorough, straightforward manner and contains contributions provided by international experts from industry, government, and academia.

Volume Two, Food Science: Ingredients, Health, and Safety divides its content into five parts to facilitate understanding and ease of use. *Food Attributes* delineates food features in relation to sensory science, database concepts, flavor, texture, and color. *Fermentation Principles* covers basic concepts, quality, flavor, meat, milk, cultured products, cheese, yeasts, and pickles. *Food and Workers Safety, Food Security* addresses U.S. food standards, codes and grades, protection methods, filth, pathogens, migratory chemicals, plant sanitation, retail food sanitation, establishment safety, animal feeds and drugs, and bioterrorism. *Functional Food Ingredients* are examined in the fourth part of this volume with topics such as food additives, food processing biofilms and antimicrobial agents, antioxidants, synthetic colorants, natural flavors, spices and herbs, phytates, sorbates, emulsions and emulsifiers, and enzymes and functional ingredients. The final part concentrates on *Nutrition and Health,* considering Chinese edible botanicals, vegetable and plant parts as legal dietary supplements, U.S. regulations for advertising dietary supplements, health and diet products and services, and food allergies.

Each volume in the *Handbook of Food Science, Technology, and Engineering* series contains approximately 1000 pages of scientific and technical data, making it an authoritative reference that is unique in its depth and breadth of scope.

Preface for Volumes 3 and 4

In the last 30 years, progress in food science, food technology, and food engineering has advanced exponentially. As usual, information dissemination for this progress is expressed in many media, both printed and electronic. Books are available for almost every specialty area within these three disciplines, numbering in the hundreds.

Collective works on the disciplines are also available, though in smaller number. Examples are encyclopedia (food science, food engineering, food packaging) and handbooks (nutrition, food processing, food technology). Since handbooks on these topics are limited, this four-volume treatise is released by Taylor & Francis to fill this gap. The title of these four volumes is *Handbook of Food Science, Technology, and Engineering* with individual volume titles as follows:

- Volume 1: Food Science: Properties and Products
- Volume 2: Food Science: Ingredients, Health, and Safety
- Volume 3: Food Engineering and Food Processing
- Volume 4: Food Technology and Food Processing

This preface introduces Volumes 3 and 4. Each volume contains approximately 1000 printed pages of scientific and technical information. Volume 3 contains 46 chapters and Volume 4 contains 54 chapters. Volume 3 presents the following categories of topics, with the number of chapters indicated:

- Units of food processing, 1
- Food drying, 4
- Thermal processing, 5
- Freezing, 6
- New technology, 12
- Packaging, 6
- Ingredients technology, 5
- Modeling, 4
- Waste management, 3

Volume 4 presents the following topics, with the number of chapters indicated:

- Food categories, 28
- Food fermentation, 8
- Food microbiology, 6
- Water technology, 4
- Food safety and security, 8

Each topic in the two volumes deals with selected subject matters in the discipline. A brief discussion of the coverage for each volume is described below.

In Volume 3, most topics are related to food or chemical engineering. An introduction covers the units of operation in food engineering and food processing. Food drying discusses the basic principles of food dehydration and freeze drying. Two examples are provided: drying tropic fruits and drying pears.

The thermal processing of food covers basic engineering principles. Four examples are provided: heat transfer, temperature-time relationship, modeling, and deep-fat frying. Food freezing is discussed in relationship to: principles and food components, frozen storage, and frozen dough. Two examples are given: microwave and frozen foods and the quality and shelf-life of frozen meat.

The new engineering technology in food processing covers: minimal processed food, modified atmosphere packaging, ohmic and inductive heating, ultra sound, ultra light, aseptic packaging, irradiation, microwave, pulsed electric field, nanotechnology, sensors, and genetic engineering. Food packaging will be discussed from the following

perspectives: plastics, paper, new development, and edible films and coatings. Two special examples include: packaging of frozen foods and thermal processing of packaged foods. Modeling in food engineering is explored in several fronts: kinetics, experimental design, and model building.

Two other topics covered in Volume 3 are: ingredient technology and waste management in food processing. Five areas in ingredient technology are: spices and seasonings, sweet flavors application, emulsion, gums, and pectin. Waste management in food processing covers: water waste, poultry waste, and meat waste.

Volume 4 covers major topics in the application of technology in food processing. The first topic concentrates on the different categories of food products including, but not limited to, bakery products, chocolate confectionery, mozzarella cheeses, processed cheese, yogurt, eggs, frozen dessert, edible fats and oils, hydrogenation of fats, Asian noodles, pasta, seafood processing, fish paste, surimi, caviar, roe, thermal processing of meat, frozen meat processing equipment, dry-cured ham, poultry carcass, canned poultry ham, poultry nugget and pâté, snacks, extrusion, coatings, vegetables horticulture and processing, tofu, beer, Chinese wine, wine biotechnology, and whiskey.

There are two important topics related to food microbiology in food processing. One is fermented food which covers: basic principles, starter culture, and products manufacture. Five examples are covered: sour cream, cheese, meat, Mexican chili, and sourdough. The second topic is analytical methodology in pathogens detection. The topics covered are: conventional techniques, immunology, genetic engineering, and methods for detecting viruses, parasites, and mold.

The role of water in food and beverage processing is a frequently neglected topic. Water technology is discussed in relation to: sources, properties, purification, distribution, chemistry, analysis, and beverage plant sanitation. The last section of the book relates to food safety and food security: contaminants, personal hygiene, cleaning a processing plant, food plant equipment, frozen food plant sanitation, oil and fat plant sanitation, United States guidances for food security, and safety and security guidelines for the transportation and distribution of meat, poultry, and egg products.

When studying the information, please note two important considerations:

- Although major topics in the discipline are included, there is no claim that the coverage is comprehensive.
- Although the scientific information is applicable worldwide, a small number of topics with legal implications are especially pertinent in the United States.

These two texts are the result of the combined effort of more than 150 professionals from industry, government, and academia. They are from more than 15 countries with diverse expertise and background in the discipline of food science. These experts were led by an international editorial team of 12 members from 7 countries. All these individuals, authors and editors, are responsible for assembling 2000 printed pages of scientific information of immense complication and complexity. In sum, the end product is unique, both in depth and breadth, and will serve as an essential reference on food technology and food engineering for professionals in government, industry, and academia.

The editorial team thanks all the contributors for sharing their experience in their fields of expertise. They are the people who make this book possible. We hope you enjoy and benefit from the fruits of their labor.

We know how hard it is to develop the content of a book. However, we believe that the production of a professional book of this nature is even more difficult. We thank the editorial and production teams at Taylor & Francis for their time, effort, advice, and expertise. You are the best judge of the quality of this book.

CONTENTS

I. BACKGROUND

Food processing technology to date has made it possible for the U.S. to lead the way in providing the most nutritious, affordable, and safe food supply (Table 102.1). Despite these achievements, new challenges and issues continue to emerge and must be addressed to ensure that our food supply continues in this manner. For example, as the demand for convenient, nutritious, and healthful food products for both targeted groups and the general public continues to grow, of particular interest is the design and optimization of integrative processes that could be used to lead to effective food preservations and productions with enhanced food quality and improved safety (1). Moreover, the food industry is challenged to produce new products with longer shelf life that also possess quality attributes that are more reminiscent of the fresh or native state of a given food. Therefore, the need for improved processing steps continues to grow with consumers' demands for increased convenience and improved quality at an affordable cost.

Food processing, which involves a wide variety of industrial processes with a correspondingly large variety of products, is at a crossroads where proper application of technologies is able to develop and produce palatable products, retain nutritious food constituents, prevent microbial contamination, and ensure proper handling throughout the storage and distribution chain, while operation and energy costs remain a constant concern of all intervenients in the chain. This issue has now become global, as both functional and ethnic foods keep gaining popularity worldwide because of their nutritional values and variety in flavor and taste (2–4). To take on the challenges accompanying these opportunities, it is vital for food scientists to have a clear understanding of the operation of processing units that are crucial to achieving proper preservation of foods.

TABLE 102.1
Methods for Food Preservation

- **(1) Temperature Control**
  - (1) Cold storage (milk, meat, fruits, and vegetables)
  - (2) Frozen storage (poultry, fish, ice cream, juices)
  - (3) Controlled atmosphere (transport of fruit)
- **(2) Heat Processing**
  - (1) Blanching (vegetables and fruits)
  - (2) Pasteurization (milk and fruit juice)
  - (3) Sterilization
    - (i) Canning (batch process for vegetable, meat, fish)
    - (ii) Ultra-High-Temperature-Short time/Aseptic packaging
    - (iii) Radiation preservation (still experimental)
- **(3) Water Removal**
  - (1) Concentration (tomato paste, puree)
  - (2) Vacuum evaporation (milk, orange- and tomato juice)
- **(4) Drying and Dehydration**
  - (1) Solar and wind drying (fish, fruit, fruit slices)
  - (2) Oven drying (cereals, potato chips)
  - (3) Roller drying: low cost process (animal feed)
  - (4) Freeze drying: high cost (instant coffee and tea)
  - (5) Spray drying (large scale processing of dry milk and instant coffee)
- **(5) Microbial Preservation**
  - (1) Yeast fermentation/alcohol production (beer and wine)
  - (2) Lactic acid fermentation (yogurt, cheese, pickles)
  - (3) Complex fermentations (coffee, tea and cocoa)
- **(6) Chemical Preservation**
  - (1) Addition of sugar (jams and jellies)
  - (2) Addition of salt (salted meat or fish)
  - (3) Addition of acids (pickles, soft drinks)
  - (4) Addition of preservatives (soft drinks, wine)
  - (5) Smoking (fish, meat, cheese)
- **(7) Packaging**
  - (1) Protection against contamination
  - (2) Protection against deterioration
    - (i) Loss of moisture (meat, vegetables, cheese)
    - (ii) Gain of moisture (cereals, potato chips)
    - (iii) Loss of aroma (coffee, tea, cocoa)
    - (iv) Oxygen barrier (frying oil, butter)
    - (v) Odor barrier (cheese, fish, some fruits)

II. MATERIALS HANDLING

Correct and efficient materials handling is the key to savings in storage and operating space, better stock control, improved product quality, reduced processing time, lower costs of production, and less wastage of materials and operator time. It also could significantly improve working conditions, while reducing risk of accidents. A food processing worker has to be familiar with the principles of materials handling and control and automation of equipment.

A. General Considerations

Apple in 1977 (5) pointed out that industrial materials handling is concerned with the five elements: Movement—Time—Place—Quantity—Space. Over the last few decades materials handling technique has improved rapidly. A set of rules summarized by Brennan et al. in 1990 (6) that provide guides to action in planning, selection, and operation remain generally applicable in today's industry. Equipment employed for materials handling could be categorized into five main groups, including conveyors, elevators, cranes and hoists, trucks, and pneumatic equipment. It is important to follow the First-In-First-Out (FIFO) principle, while each processing company has to define its own materials handling needs and specify the requirements in its Good Manufacturing Practice (GMP).

B. Shape and Size Sorting

Shape sorting of foods such as potatoes and cucumbers is important in assessing their suitability for mechanized processing (e.g., peeling, blanching, pitting, and coring) as well as their retail value. Size sorting (sieving or screening) is

the separation of solids into two or more fractions on the basis of differences in size. In size sorting, the rate of separation is closely related to the nature of the sieve material, the shape and size distribution of the particles, the amplitude and frequency of shaking, and the effectiveness of methods used to prevent sieve blockage. Drum screen, with its capacity increasing with their speed of rotation up to a critical point, is commonly used for sorting small particulate foods such as peas or beans that have sufficient mechanical strength to withstand the tumbling action inside the screen. Sorted foods are necessary in processes in which uniformity of heat transfer is critical (e.g., sterilization and pasteurization) and they give better control over the weights filled into standard sale containers.

C. Weight and Density Sorting

Used for more valuable foods such as eggs, cut meats, fish fillets, and some tropical fruits, weight sorting is considered more accurate than other methods, since the weight of a food unit is proportional to the cube of its characteristic dimension. Recent developments in weight sorting machines involve the use of electro-mechanical and hydrostatic transducers to sense weight differences and computer-controlled devices to direct the weighed units into collection chutes. Automated weighing systems commonly comprise a load cell, which uses strain gauges bonded to a short metal beam rigidly clamped at one end, linked to a microprocessor linked to recording and control equipment. Density or buoyancy sorting, which exploits differences in hydrodynamic behavior, may be used to separate bruised and sound fruit such as apples, while peas of different maturity (size and density) could be separated in brines of different density.

D. Photometric and Color Sorting

Photometric sorting embraces most of the electromagnetic spectrum, ranging from gamma- and X-rays through ultraviolet, visible light, infra-red, microwaves, and radio frequencies to measurements of resistance at main frequency (6). The reflectance and transmittance characteristics of foods are important indicators of their processing suitability. Reflectance properties could be used to indicate product quality such as raw material maturity (e.g., the color of fruit, vegetables, meat, etc.); the presence of surface defects (e.g., worm-holed cereals or bruised fruits); and the extent of processing (e.g., of biscuits, bread, and potato chips). Transmittance measurements of foods are used to determine their internal properties such as ripeness or core defects in fruits, extraneous matter inclusions, and blood spots in eggs.

Color sorting equipment controlled by microprocessors has been used to sort small particulate foods automatically at very high rates. By manipulating the angle, shape, and lining material of the chute, the velocity of the pieces passing a photo-detector could be precisely controlled. Photo-detectors, which measure the reflected color of each piece and compare it with pre-set standards, send amplified signals to the microprocessor, which then communicates with a short blast of compressed air to separate defective foods or whenever a pre-selected color is used to distinguish between different colored foods that are to be processed separately.

III. CLEANING

Cleaning is the unit operation in which contaminating materials are removed from the food and separated at the earliest opportunity in a food process to leave the surface of the food in a suitable condition for further processing. With adequate cleaning in place, damage to subsequent processing equipment could be prevented, loss of time and money in processing contaminants could be reduced, and the safety hazards as well as loss of bulk products due to microbial growth during storage could also be minimized. A variety of cleaning methods have been adopted due to the wide variety of contaminant encountered in raw food materials and the low tolerances permitted for these contaminants (6).

A. Dry Cleaning

Dry cleaning methods such as screening, brushing, aspiration, abrasion, and magnetic separation have the advantages of relative cheapness and convenience while the cleaned surface is left in a dry condition. Used to remove contaminants of different size from that of the raw material, screens come in different forms, such as rotary drum screens (also referred to as trammels, centrifugal screens or reels) and flat-bed screens. Generally, rotary drum screens have good capacity and are relatively inexpensive to install, maintain, and operate. Flat-bed screens are excellent for cleaning fine materials such as flour and ground spices, since they are not easily blinded. Screening effectiveness is a function of the shape-regularity of the working substance.

Abrasion between food particles or between the food and moving parts of cleaning machinery, such as trommels, tumblers, vibrators, abrasive discs, and rotating brushes, is commonly used to loosen and to remove adhering contaminants. Aspiration cleaning is widely used in removing debris differing in buoyancy from the desired material. Typical applications include combine-harvesters, pea-viners, and bean-harvesters, in which the material to be cleaned is fed into a stream of air at controlled velocity when separation into two or more streams (e.g., light, middle, and heavy) is effected. Magnetic cleaning involves cascading the contaminated product stream over one or more magnets (both permanent magnets and electromagnets are used) that are usually located in the conveyor

trunking. In dry cleaning, recontamination remains a concern unless considerable care is exercised to minimize the spread of dust. Careful control of dust is important in the food industry in general (e.g., in milling, high-speed conveying, etc.) but especially so in dry cleaning where dusty conditions are most likely present in conjunction with stones and tramp metal that generate sparks. Therefore, dust-proofing of equipment, dust extraction, and rigorous housekeeping must be seriously exercised.

B. Wet Cleaning

For raw materials such as vegetables or fruits that are usually covered with soil, mud, and sand, a careful cleaning is needed before processing, whereas a second wash must be done after peeling and/or cutting (7). Washing after peeling and cutting removes microbes and tissue fluid, thus reducing microbial growth and enzymatic oxidation during storage. Washing in flowing or air-bubbling water is preferable to dipping into still water, and the washing water used must be good and its temperature at preferably below 5°C (8). To reduce microbial numbers and to retard enzymatic activity, which improves the product shelf life, preservatives such as chlorine can be used in washing water. The effectiveness of chlorine can be enhanced by using a combination of low pH, high temperature, pure water, and correct contact time (9). Alternatives to chlorine include chlorine dioxide, per acetic acid ozone, trisodium phosphate, and hydrogen peroxide (10).

Soaking, which is the simplest method of wet cleaning, is often used as a preliminary stage in the cleaning of root vegetables and other foods that are heavily contaminated. The efficiency of soaking could be leveraged if warm water is used; if water is moved relative to the product by means of caged propeller-stirrers built into the tank; or if the product is moved relative to the water either using slow-moving paddles or by feeding the raw material into a horizontal perforated drum that rotates and partially submerged in the soak tank. Chlorination is commonly used in soak tank water to decrease its bacterial loadings; however, its high chemical oxygen demand (COD) and blackening on foods such as potatoes have to be taken into consideration. The most widely used wet cleaning method is spray washing, whose efficiency is dependent on the water pressure employed, the volume of water used, the water temperature, the distance of the food from the spray-jet, the time of exposure of the food to the sprays, and the number of spray-jets used. While a small volume of water at high pressure is the most effective combination, damage may be caused to ripe soft fruits and to delicate vegetables. Flotation washing, which depends on a difference in buoyancy between the desired and undesired parts of the food to be cleaned, has been used by fluming the fruit into a tank and collecting the overflow of sound fruit to remove bruised or rotten fruit that sink in water.

In the food industry, cleaning methods are generally used in combination. Many cleaning machines involve several stages combined as a single unit. A typical example or a combination procedure is the cleaning process used for producing cleaned wheat for milling into flour. In addition, accompanying the cleaned product is the excess water that coats product surface. Occasionally it is necessary to resort to drying procedures. For example, with washed cereals or with wet-cleaning fruits that is to be stored or is to be sold as a finished foodstuff.

IV. SEPARATION

Separation is a major operation in food processing, where different components of a product are separated based on certain physicochemical principles (11).

A. Sedimentation

Sedimentation uses gravitational forces to separate particulate material from fluid streams. The particles are usually solid, but they can be small liquid droplets, and the fluid can be either a liquid or a gas. Sedimentation is very often used in the food industry for separating dirt and debris from incoming raw material, crystals from their mother liquor and dust or product particles from air streams. In sedimentation, particles are falling from rest under the force of gravity. Therefore in sedimentation the familiar form of Stokes' Law exists:

$$v_m = D^2 g(\rho_p - \rho_f)/18\mu \qquad (102.1)$$

Note that Equation (102.1) is not dimensionless and so consistent units must be employed throughout. For example, in the SI system D would be m, g in m s^{-2}, ρ in kg m^{-3} and μ in N s m^{-2}, and then v_m would be in m s^{-1}. Particle diameters are usually very small and are often measured in microns (micro-meters) = 10^{-6} m with the symbol μm.

Stokes' Law applies only in streamline flow and strictly only to spherical particles. In the case of spheres the criterion for streamline flow is that Reynolds number (Re) = 2, and many practical cases occur in the region of streamline flow, or at least where streamline flow is a reasonable approximation. Where higher values of the Reynolds number are encountered, more detailed references should be sought (12). In addition, Stokes' Law applies only to cases in which settling is free, that is where the motion of one particle is unaffected by the motion of other particles. Where particles are in concentrated suspensions, an appreciable upward motion of the fluid accompanies the motion of particles downward. So the particles interfere with the flow patterns around one another as they fall. Stokes' Law predicts velocities proportional to the square of the particle diameters. In concentrated suspensions, it is found that all particles appear to settle at a uniform velocity once a

sufficiently high level of concentration has been reached. Where the size range of the particles is not much greater than 10:1, all the particles tend to settle at the same rate. This rate lies between the rates that would be expected from Stokes' Law for the largest and for the smallest particles. In practical cases, in which Stokes' Law or simple extensions of it cannot be applied, the only satisfactory method of obtaining settling rates is by experiment.

B. Centrifugation

The separation by sedimentation of two immiscible liquids, or of a liquid and a solid, depends on the effects of gravity on the components. Sometimes this separation may be very slow because the specific gravities of the components may not be very different, or because of forces holding the components in association, for example as occur in emulsions. Much greater forces can be obtained by introducing centrifugal action, in a centrifuge. Gravity still acts and the net force is a combination of the centrifugal force with gravity as in the cyclone. Because in most industrial centrifuges, the centrifugal forces imposed are so much greater than gravity, the effects of gravity can usually be neglected in the analysis of the separation. The centrifugal force on a particle that is constrained to rotate in a circular path is given by

$$F_c = mr\omega^2 \qquad (102.2)$$

where F_c is the centrifugal force acting on the particle to maintain it in the circular path, r is the radius of the path, m is the mass of the particle, and ω is the angular velocity of the particle. Or, since $\omega = v/r$, where v is the tangential velocity of the particle

$$F_c = (mv^2)/r \qquad (102.3)$$

Rotational speeds are normally expressed in revolutions per minute ($\omega = 2\pi N/60$), so that Equation (102.2) can also be written as

$$F_c = mr(2\pi N/60)^2 = 0.011\, mrN^2 \qquad (102.4)$$

where N is the rotational speed in revolutions per minute. If this is compared with the force of gravity (F_g) on the particle, which is $F_g = m_g$, it can be seen that the centrifugal acceleration, equal to $0.011\, rN^2$, has replaced the gravitational acceleration, equal to g. The centrifugal force is often expressed for comparative purposes as so many "g."

The centrifugal force depends upon the radius and speed of rotation and upon the mass of the particle. If the radius and the speed of rotation are fixed, then the controlling factor is the weight of the particle so that the heavier the particle the greater is the centrifugal force acting on it. Consequently, if two liquids, one of which is twice as dense as the other, are placed in a bowl and the bowl is rotated about a vertical axis at high speed, the centrifugal force per unit volume will be twice as great for the heavier liquid as for the lighter. The heavy liquid will therefore move to occupy the annulus at the periphery of the bowl and it will displace the lighter liquid towards the centre. This is the principle of the centrifugal liquid separator. The simplest form of centrifuge consists of a bowl spinning about a vertical axis. Liquids, or liquids and solids, are introduced into this and under centrifugal force the heavier liquid or particles pass to the outermost regions of the bowl, whilst the lighter components move towards the centre. If the feed is all liquid, then suitable collection pipes can be arranged to allow separation of the heavier and the lighter components. Various arrangements are used to accomplish this collection effectively and with a minimum of disturbance to the flow pattern in the machine.

Whereas liquid phases can easily be removed from a centrifuge, solids present much more of a problem. In liquid/solid separation, stationary ploughs cannot be used as these create too much disturbance of the flow pattern on which the centrifuge depends for its separation. One method of handling solids is to provide nozzles on the circumference of the centrifuge bowl. These nozzles may be opened at intervals to discharge accumulated solids together with some of the heavy liquid. Alternatively, the nozzles may be open continuously relying on their size and position to discharge the solids with as little as possible of the heavier liquid. These machines thus separate the feed into three streams, light liquid, heavy liquid and solids, the solids carrying with them some of the heavy liquid as well (Table 102.2).

C. Crystallization

Crystallization is an example of a separation process in which mass is transferred from a liquid solution, whose composition is generally mixed, to a pure solid crystal. Soluble components are removed from solution by adjusting the conditions so that the solution becomes supersaturated and excess solute crystallizes out in a pure form. This is generally accomplished by lowering the temperature, or by concentration of the solution, in each case to form a supersaturated solution from which crystallization can occur. The equilibrium is established between the crystals and the surrounding solution, the mother liquor. The manufacture of sucrose, from sugar cane or sugar beet, is an important example of crystallization in food technology. Crystallization is also used in the manufacture of other sugars, such as glucose and lactose, in the manufacture of food additives, such as salt, and in the processing of foodstuffs, such as ice cream. In the manufacture of sucrose from cane, water is added and the sugar is pressed out from the residual cane as a solution. This solution is

TABLE 102.2
Applications for Centrifugal Equipment in the Food Industry

Type	Application
Tubular-bowl centrifuges	• Edible oil refining in degumming, neutralisation and washing stages • Clarification of fruit juices, cider and sugar syrup
Disc-bowl centrifuges	• Dairy industry for cream separation • Edible oil refining for separation of soapstocks and washings • Clarification of vegetable, citrus oils and fruit juices
Decanting centrifuges	• Recovering animal and vegetable protein • Harvesting single cell protein • Separating coffee, tea and cocoa slurries • Desludging fish oils • Separating fish blood water and fish press liquor • Fat separation from comminuted meat • Meat deboning • Olive oil extraction • Dewaterin trub in brewing • Clarifying liquor and recovering tartrates in winemaking
Filtering centrifugals	• Sugar refining for recovering, washing and drying sugar crystals • Juice separation from comminuted fruits and vegetables • Vegetable protein recovery • Starch separation from potato slurry • Freeze concentration operations

purified and then concentrated to allow the sucrose to crystallize out from the solution. Once crystallization is concluded, equilibrium is set up between the crystals of pure solute and the residual mother liquor, the balance being determined by the solubility (concentration) and the temperature. The driving force making the crystals grow is the concentration excess (supersaturation) of the solution above the equilibrium (saturation) level. The resistances to growth are the resistance to mass transfer within the solution and the energy needed at the crystal surface for incoming molecules to orient themselves to the crystal lattice.

Crystallizers can be divided into two types: crystallizers and evaporators. A crystallizer may be a simple open tank or vat in which the solution loses heat to its surroundings. The solution cools slowly so that large crystals are generally produced. To increase the rate of cooling, agitation and cooling coils or jackets are introduced and these crystallizers can be made continuous. The simplest is an open horizontal trough with a spiral scraper. The trough is water jacketed so that its temperature can be controlled. During crystallization, the crystals are grown from solutions with concentrations higher than the saturation level in the solubility curves. Above the supersaturation line, crystals form spontaneously and rapidly, without external initiating action. This is called spontaneous nucleation. In the area of concentrations between the saturation and the supersaturation curves, the metastable region, the rate of initiation of crystallization is slow; aggregates of molecules form but then disperse again and they will not grow unless seed crystals are added. Seed crystals are small crystals, generally of the solute, which then grow by deposition on them of further solute from the solution. This growth continues until the solution concentration falls to the saturation line. Below the saturation curve there is no crystal growth, crystals instead dissolve.

When a solution is cooled to produce a supersaturated solution and hence to cause crystallization, the heat that must be removed is the sum of the sensible heat necessary to cool the solution and the heat of crystallization. When using evaporation to achieve the supersaturation, the heat of vaporization must also be taken into account. Because few heats of crystallization are available, it is usual to take the heat of crystallization as equal to the heat of solution to form a saturated solution. Theoretically, it is equal to the heat of solution plus the heat of dilution, but the latter is small and can be ignored. For most food materials, the heat of crystallization is positive, i.e. heat is given out during crystallization. Note that heat of crystallization is the opposite of heat of solution. If a material takes in heat, then the heat of crystallization is positive. Heat balances can be calculated for crystallization (12).

D. Solid-Liquid Extraction

Solid-liquid extraction is a basic operation to separate one or more components contained in a solid phase by a liquid phase or solvent. Liquids have a capacity to dissolve solids up to an extent, which is determined by the solubility of the particular solid material in that liquid. Solubility is a function of temperature and, in most cases, solubility increases with rising temperature. A solubility curve can then be drawn to show this relationship, based on the equilibrium concentration in solution measured in convenient units, for example g kg^{-1}, as a function of temperature (12). The first stage in an extraction process is generally mechanical grinding, in which the raw material is shredded, ground or pressed into suitably small pieces or flakes to give a large contact area for the extraction.

Important applications of the solid-liquid extraction in the food industry include: extraction of animal and vegetable oils and lipids, washing precipitates, obtaining extracts from animal or vegetable materials, obtaining sugar, and manufacturing tea and instant coffee (13). For example in sugar-cane processing and in the extraction of vegetable

oils, a substantial proportion of the desired products can be removed directly by expression at this stage and then the remaining solids are passed to the extraction plant. Fluid solvents are easy to pump and so overflows are often easier to handle than underflows and sometimes the solids may be left and solvent from successive stages brought to them. In the same way and for the same reasons as with counter flow heat exchangers, a counter current (or counter flow) extraction system provides the maximum mean driving force, the log mean concentration difference in this case, contrasting with the log mean temperature difference in the heat exchanger. This ensures that the equipment is used efficiently. In some other extractors, the solids are placed in a vertical bucket conveyor and moved up through a tower down which a stream of solvent flows. Other forms of conveyor may also be used, such as screws or metal bands, to move the solids against the solvent flow. Sometimes centrifugal forces are used for conveying, or for separating after contacting.

E. Electrodialysis and Ion Exchange

Electrodialysis (ED) is defined as the transport of ions through membranes as a result of an electric driving force. The membranes used have anion and cation exchange functions respectively, which gives the ED process a capability to reduce the mineral content of a process liquid, for example seawater or whey. A major limiting factor for using ED in dairy processing is the cost for the replacement of membranes, spacers, and electrodes, which constitutes 35–40% of the total running costs in the plant. The need for replacement is caused by the fouling of the membranes, which in turn is caused by the precipitation of low-soluble calcium phosphate on the cation membrane surfaces and the deposition of protein on the anion exchange membrane surfaces, which is the main factor reducing the life length of the anion membrane. Although frequent high-pH cleaning removes most of the deposits, disassembly of the stack for manual cleaning is recommended with two- to four-week intervals. On the other hand, the processing cost of ED depends very much on the demineralization rate. Increasing the capacity in steps from 50% to 75% to 90% doubles the processing cost per step. This means that it is four times as expensive per kilo of product solids to demineralize to 90% than to 50% and this is due to the reduction in plant capacity when working with 90% demineralization.

In contrast to ED, ion exchange (IE) is a fixed-bed technique involving the use of resins, which have a discrete capacity for the absorption of minerals. When this capacity is used up, the absorbed minerals have to be removed from the resin and the resin regenerated before it can be used again. IE resins are macromolecular porous plastic materials, formed into beads with diameters in the range of 0.3 to 1.2 mm for technical applications. Chemically they act as insoluble acids or bases which, when converted into salts, remain insoluble. The main characteristic of IE resins is their capacity to exchange the mobile ions they contain for ions of the same charge sign, contained in the solution to be treated. Demineralization using IE has long been an established process for water treatment but has, during the last 15 years, also obtained interest for de-ashing of whey, which is not a uniform product as to composition. Whey from an acid casein/cheese curd has a pH of 4.3 to 4.6. The pH of sweet whey is 6.3 to 6.6. The main difference between these two types of whey, apart from the acidifying medium, is the high level of calcium phosphate of the acid whey. Thus, whey can consequently be characterized as a liquid with a high salt load which, as a consequence, results in short cycles when IE is applied. This in turn results in high costs for regeneration chemicals, if they are not recovered.

F. Reverse Osmosis and Ultrafiltration

Reverse osmosis (RO) and ultrafiltration (UF) are both unit operations in which water and some solutes in a solution are selectively removed through a semi-permeable membrane. The main advantages of membrane concentration over concentration by evaporation are: (1) the food is not heated, and there is therefore negligible loss of nutritional or eating quality and particularly less loss of volatiles, (2) in contrast with boiling, membrane concentration doses not involve a change in phase and therefore uses energy more efficiently, and (3) lower labor and operating costs: simple installation, operation with a single control valve, and no requirement for steam boilers (14).

The two processes are similar in that the driving force for transport across the membrane is the pressure applied to the feed liquid. Specifically, RO is concerned mainly with solutions containing smaller molecules such as simple sugars, salts, monosaccharides, and aroma compounds at higher molar concentrations, which exert higher osmotic pressures. To overcome these osmotic pressures, high external pressures have to be exerted, up to the order of 100 atmospheres (4000–8000 kPa). Movement of molecules through RO membranes is by diffusion and not by liquid flow. The molecules dissolve at one face of the membrane are transported through the membrane and then removed from the other face. The flow rate of liquid (the flux) is determined by the solubility and diffusivity of the molecules in the membrane material, and by the difference between the osmotic pressure of the liquid and the applied pressure. Limitations to increased flow rates arise in this case from the mechanical weaknesses of the membrane and from concentration of solutes which causes substantial osmotic "back" pressure. Applications in the food industry are in separating water from solutions such as fruit juices.

UF membranes, on the other hand, have a higher porosity and retain only large molecules (for example proteins or colloids) that have a low osmotic pressure (15). Smaller

solutes are transported across the membrane with the water. UF therefore operates at lower pressures (50–2000 kPa). The main requirement of an UF membrane is the ability to form and retain a "microporous" structure during manufacture and during operation under thermal and mechanical stress. The material and methods used for the manufacture of the microporous structure are the most important factors in determining the properties of the membrane. Rigid or glassy polymers, which are thicker than RO membranes (0.1–0.5 μm), are commonly used. For food applications, membranes should be capable of being cleaned and sanitized. Suitable materials include polysulphones, polyamides, poly(vinyl chloride), polystyrene, polycarbonates, polyethers, and rigid cellulose esters.

The equipment for these membrane separation processes consists of the necessary pumps, flow systems and membranes. In the case of UF, the membranes are set up in a wide variety of geometrical arrangements, mostly tubular but sometimes in plates, which can be mounted similarly to a filter press or plate heat exchanger. Flow rates are kept high over the surfaces and recirculation of the fluid on the high pressure, or retentate, side is often used; the fluid passing through, called the permeate, is usually collected in suitable troughs or tanks at atmospheric pressure. In the case of RO, the high pressures dictate mechanical strength, and stacks of flat disc membranes can be used one above the other. Another system uses very small diameter (around 0.04 mm) hollow filaments on plastic supports; the diameters are small to provide strength but preclude many food solutions because of this very small size. The main flow in reverse osmosis is the permeate. The systems can be designed either as continuous or as batch operations. One limitation to extended operation arises from the need to control growth of bacteria. After a time bacterial concentrations in the system, for example in the gel at the surface of the ultrafiltration membranes, can grow so high that cleaning must be provided. This can be difficult as many of the membranes are not very robust either to mechanical disturbance or to the extremes of pH which could give quicker and better cleaning.

V. DISINTEGRATION

Disintegration is a common unit operation in food processing. The usual concerns when cutting agricultural raw materials include sanitation and the hazard of metal contamination. It is the point stones or other objects could be introduced to damage processing equipment. Prescreening, inspection, and cleaning are important, as well as downstream metal detection.

A. Peeling, Cutting, and Shredding

It is generally agreeable that peeling should be as gentle as possible. However, on an industrial scale, peeling of fruits or vegetables such as carrots, apples or potatoes is normally accomplished mechanically (e.g., rotating carborundum drums), chemically or in high-pressure steam peelers (16). Since adverse effects of carborundum, steam peeling, or caustic acid are known to enhance the possibilities of microbial growth and enzymatic changes, it is a common practice in the industry to combine carborundum (a first stage of rough peeling) and knife peeling (a second stage of finer peeling). Successful enzymatic peeling was also reported in the case of oranges (17). From a microbiological and sensory point of view, many studies show that the cutting and shredding of fruits and vegetables must be performed with knives or blades as sharp as possible and made from stainless steel. Vibration of a slicing machine should be minimized in order not to impair the quality of the sliced surfaces, while mats and blades used in slicing should be disinfected with a 1% hypochlorite solution (18).

B. Size Reduction of Solid Foods

Grinding and cutting reduce the size of solid materials by mechanical action, dividing them into smaller particles. The most extensive application of grinding in the food industry is in the milling of grains to make flour, but it is used in many other processes, such as in the grinding of corn for manufacture of corn starch, the grinding of sugar, and the milling of dried foods (12). Size-reduction processes may be divided into those that produce random particles or pieces and those that produce pieces that are more uniform (19). A random process produces a size distribution. In some cases, the extremes—the smallest or the largest—may be undesirable, while in others the mix can be used completely. If only one portion of the size distribution is sought, there must be a separation or fractionation process. If smaller particles are desired, the larger ones may be screened out and recycled. Very fine particles are often discarded as waste but in some cases may be treated to create larger particles. An example of this situation is sugar grinding followed by granulation to create a size distribution suitable for tableting or compacting.

When a uniform particle is crushed, after the first crushing the size of the particles produced will vary a great deal from relatively coarse to fine and even to dust. As the grinding continues, the coarser particles will be further reduced but there will be less change in the size of the fine particles. Careful analysis has shown that there tends to be a certain size that increases in its relative proportions in the mixture and which soon becomes the predominant size fraction. For example, wheat after first crushing gives a wide range of particle sizes in the coarse flour, but after further grinding the predominant fraction soon becomes that passing a 250 μm sieve and being retained on a 125 μm sieve. This fraction tends to build up, however long the grinding continues, so long as the same type of machinery, rolls in this case, is employed.

VI. PUMPING

Many raw materials for foods and many finished foods are in the form of fluids. These fluids have to be transported and processed in the factory. The transfer is usually accomplished by pumping the materials through pipeline systems. Thus, food technologists must be familiar with the principles that govern the flow of fluids and with the machinery and equipment that is used to handle fluids. In addition, there is an increasing tendency to handle powdered and granular materials in a form in which they behave as fluids. Fluidization has been developed because of the relative simplicity of fluid handling compared with the handling of solids.

A. Control of Fluid Flow

Viscosity is the property of a fluid that gives rise to forces that resist the relative movement of adjacent layers in the fluid. Viscous forces are of the same character as shear forces in solids and they arise from forces that exist between the molecules. In many instances in practice non-Newtonian characteristics are important, and they become obvious when materials that it is thought ought to pump quite easily just do not. They get stuck in the pipes, or overload the pumps, or need specially designed fittings before they can be moved. Sometimes it is sufficient just to be aware of the general classes of behavior of such materials. In other cases it may be necessary to determine experimentally the rheological properties (Newtonian or non-Newtonian) of the material so that equipment and processes can be adequately designed (20).

B. Pipeline and Pump Selection

The ease and cost of pumping are largely dependent on the design of the piping system. The liquid flow rate, vertical lift, and increase in downstream pressure to be overcome are normally fixed by the processes. However, energy losses due to friction and shock losses could be minimized by careful selection of components fabricated. In order to minimize energy losses in a piping system, it is recommended that the total length of the pipe-run is as short as possible; the same pipe diameter is maintained throughout the length of the pipe-run whenever possible; the correct type of fitting for a specific duty is used; and the number of pipe-fittings is kept to a minimum. In addition, a suitable pump matched to suit the system must be selected.

The pump is the heart of the fluid transfer process. Upon choosing a pump, factors such as the volumetric flow rate of liquid to be transferred, the total system head against which the liquid is to be pumped, the fluid properties (e.g., consistency, density, temperature, shear deformation, and lubricating properties), the type of prime mover (electric, steam, or compressed air), and hygienic requirements need to be considered. Pumps are commonly classified as either (1) positive displacement pumps (reciprocating and rotary types) or (2) centrifugal pumps. All positive displacement pumps operate by trapping a certain volume of fluid within the body or the pump and forcing it from the inlet side to the outlet at higher pressure. Centrifugal pumps, the most widely used liquid transfer pump in the general process industries, are also widely used in the food industry because they are relatively cheap and simple. A centrifugal pump consists of an impeller rotating in a casing having inlet and exit ports. Fluid normally enters axially into the eye of the impeller that rotates at a constant speed. The fluid is accelerated and thrown from the tips of the impeller blades at high velocity, passing into an increasing area for flow where the velocity energy is converted into pressure energy. The fluid leaving the pump flows through the pipe system by virtue of the pressure or head imparted by the pump.

VII. MIXING

Mixing is the dispersing of components, one throughout the other. It occurs in innumerable instances in the food industry and is probably the most commonly encountered of all process operations. Unfortunately, it is also one of the least understood. There are, however, some aspects of mixing which can be measured and which can be of help in the planning and designing of mixing operations. The production of fully mixed small volumes, which can be taken or sampled for measurement, is what mixing is all about. Sample compositions move from the initial state to the mixed state, and measurements of mixing must reflect this.

A. Particle Mixing

If particles are to be mixed, starting out from segregated groups and ending up with the components randomly distributed, the expected variances of the sample compositions from the mean sample composition can be calculated. The degree of mixing that is achieved depends on:

- the relative particle size, shape and density of each component,
- the efficiency of a particular mixer for those components,
- the tendency of the materials to aggregate, and
- the moisture content, surface characteristics, and flow characteristics of each components.

The mixing of particles varying substantially in size or in density presents special problems, as there will be gravitational forces acting in the mixer which will tend to segregate the particles into size and density ranges. In such a case, initial mixing in a mixer may then be followed by a measure of (slow gravitational) un-mixing and so the time of mixing may be quite critical.

Mixing is simplest when the quantities that are to be mixed are roughly in the same proportions. In cases where very small quantities of one component have to be blended uniformly into much larger quantities of other components, the mixing is best split into stages, keeping the proportions not too far different in each stage. For example, if it were required to add a component such that its final proportions in relatively small fractions of the product are 50 parts per million, it would be almost hopeless to attempt to mix this in a single stage. A possible method might be to use four mixing stages, starting with the added component in the first of these at about 30:1. In planning the mixing process it would be wise to take analyses through each stage of mixing, but once mixing times had been established it should only be necessary to make check analyses on the final product.

B. Liquid Mixing

The component velocities induced in liquids by a mixer include: (1) a radial velocity which acts in a direction perpendicular to the mixer shaft; (2) a longitudinal velocity (parallel to the mixer shaft); and (3) a rotational velocity (tangential to the mixer shaft). To mix low-viscosity liquids adequately, turbulence must be induced throughout the bulk of the liquid to entrain slow-moving parts within faster moving parts. A vortex should be avoided because adjoining layers of circulating liquid travel at a similar speed and entrainment does not take place. The liquids simply rotate around the mixer. In high-viscosity liquids, pastes, or dough, a different action is needed. Mixing occurs by kneading the material against the vessel wall or into other material, folding unmixed food into the mixed part, and shearing to stretch the material. Efficient mixing is achieved by creating and recombining fresh surfaces in the food as often as possible. However, because the material does not easily flow, it is necessary either to move the mixer blades throughout the vessel or to move the food to the mixer blades.

The rate of mixing is characterized by a mixing index (M). The mixing rate constant (K) depends on the characteristics of both the mixer and the liquids. The effect of the mixer characteristics on K is given by:

$$K \propto \frac{D^3 N}{D_t^2 z} \tag{102.5}$$

where D is the agitator diameter (m), N is the agitator speed (s^{-1}), D_t is the vessel diameter (m), and z is the height of liquid (m). The rheology of the liquid also is crucial to the overall mixing efficiency and as discussed in Section VI.A.

C. Emulsification and Homogenization

Emulsification may be defined as that operation in which two normally immiscible liquids are intimately mixed, one liquid (the discontinuous, dispersed or internal phase) becoming dispersed in the form of small droplets or globules in the other (continuous, dispersing or external phase). In most emulsions the two liquids involved are water and oil. The water phase may consist of solutions of salts, sugars or other organic and colloidal materials (hydrophilic materials). The oil phase may consist of oils, hydrocarbons, waxes, resins, and other substances which behave like oil (hydrophobic materials). In order to form a stable emulsion a third substance, known as an emulsifying agent or an emulsifier, needs to be included. The emulsion formed tends to exhibit most of the properties of the liquid that forms the external phase. Thus two emulsions of similar composition can have quite different characteristics depending on whether the oil or water is the external phase. The factors which influence the type of emulsion formed include the type of emulsifying agent used, the relative proportions of the phases, and the method of preparation.

The essential feature of an emulsion is the small size of the dispersed phase droplets. This can be achieved by imposing very high shearing stresses upon the liquid that is to be dispersed and the shearing forces break the material into the multitude of fine particles. Homogenization is the term used to describe the operation in which the desired reduction in the size of the droplets of the internal phase is brought about by forcing the crude emulsion through a narrow opening at high velocity. The size of the dispersed phase droplets is commonly of the order 1–10 μm diameter. Below 0.1 μm droplet diameter, the dispersion is often spoken of as colloidal. Coalescence of the dispersed phase droplets is hindered by increased viscosity in the continuous liquid phase. The nearer the densities of the components are to each other, the less will be the separating effect of gravitational forces. Stokes' Law gives a qualitative indication of the physical factors that influence the stability of an emulsion. This is because the relative flow of the particles under gravitational forces may break the emulsion, so stability is enhanced by small settling velocities.

VIII. HEAT EXCHANGING

In a heat exchanger, heat energy is transferred from one body or fluid stream to another. In the design of heat-exchange equipment, heat-transfer equations are applied to calculate this transfer of energy so as to carry it out efficiently and under controlled conditions (12). The equipment goes under many names, such as boilers, pasteurizers, jacketed pans, freezers, air heaters, cookers, ovens, and so on. The range is too great to list completely. Heat exchangers are found widely scattered throughout the food process industry.

A. Continuous-Flow Heat Exchanger

It is convenient to use heat exchangers in which one or both of the materials that are exchanging heat are fluids,

flowing continuously through the equipment and acquiring or giving up heat in passing. One of the fluids is usually passed through pipes or tubes, and the other fluid stream is passed round or across these. At any point in the equipment, the local temperature differences and the heat-transfer coefficients control the rate of heat exchange. The fluids can flow in the same direction through the equipment, this is called parallel flow; they can flow in opposite directions, called counter flow; they can flow at right angles to each other, called cross flow. Various combinations of these directions of flow can occur in different parts of the exchanger. Most actual heat exchangers of this type have a mixed flow pattern, but it is often possible to treat them from the point of view of the predominant flow pattern.

The rate of heat transfer can be calculated using the heat transfer coefficient, the total area, and the log mean temperature difference. This same result can be shown to hold for parallel flow and counter flow heat exchangers in which both fluids change their temperatures. In parallel flow, at the entry to the heat exchanger, there is the maximum temperature difference between the coldest and the hottest stream, but at the exit the two streams can only approach each other's temperature. In a counter flow exchanger, leaving streams can approach the temperatures of the entering stream of the other component and so counter flow exchangers are often preferred. A popular heat exchanger for fluids of low viscosity, such as milk, is the plate heat exchanger, where heating and cooling fluids flow through alternate tortuous passages between vertical plates. The plates are clamped together, separated by spacing gaskets, and the heating and cooling fluids are arranged so that they flow between alternate plates. Suitable gaskets and channels control the flow and allow parallel or counter current flow in any desired number of passes. A substantial advantage of this type of heat exchanger is that it offers a large transfer surface that is readily accessible for cleaning. The banks of plates are arranged so that they may be taken apart easily. Overall heat transfer coefficients are of 2400–6000 $J\,m^{-2}\,s^{-1}\,°C^{-1}$.

In some food processes, quick heating is required in the pan, for example, in the boiling of jam. In this case, a helical coil may be fitted inside the pan and steam admitted to the coil. This can give greater heat transfer rates than jacketed pans, because there can be a greater heat transfer surface and also the heat transfer coefficients are higher for coils than for the pan walls. One type of heat exchanger, which finds considerable use in the food processing industry particularly for products of higher viscosity, consists of a jacketed cylinder with an internal cylinder concentric to the first and fitted with scraper blades. The blades rotate, causing the fluid to flow through the annular space between the cylinders with the outer heat transfer surface constantly scraped. Coefficients of heat transfer vary with speeds of rotation but they are of the order of 900–4000 $J\,m^{-2}\,s^{-1}\,°C^{-1}$. These machines are used in the freezing of ice cream and in the cooling of fats during margarine manufacture.

IX. EVAPORATION

Evaporation is the concentration of a solution by boiling off solvent and has received major applications in the food industry. The basic factors that affect the rate of evaporation are the rate at which heat can be transferred to the liquid, the quantity of heat required to evaporate each kg of water, the maximum allowable temperature of the liquid, the pressure at which the evaporation takes place, and the changes that may occur in the foodstuff during the course of the evaporation process. Considered as a piece of process plant, the evaporator has two principal functions, to exchange heat and to separate the vapor that is formed from the liquid. Important practical considerations in evaporators include: (1) the maximum allowable temperature, which may be substantially below 100°C; (2) promotion of circulation of the liquid across the heat-transfer surfaces, to attain reasonably high heat transfer coefficients and to prevent any local overheating; (3) viscosity of the fluid which will often increase substantially as the concentration of the dissolved materials increases; and (4) tendency to foam which makes separation of liquid and vapor difficult.

A. Evaporator Configuration

Evaporation systems may be single-stage or multiple-stage (also called "effect") with 2, 3, or more evaporator or vacuum units. The typical evaporator is made up of three functional sections: the heat exchanger, the evaporating section, where the liquid boils and evaporates, and the separator in which the vapor leaves the liquid and passes off to the condenser or to other equipment. In many evaporators, all three sections are contained in a single vertical cylinder. In the centre of the cylinder there is a steam-heating section, with pipes passing through it in which the evaporating liquors rise. At the top of the cylinder, there are baffles, which allow the vapors to escape but check liquid droplets that may accompany the vapors from the liquid surface. In the heat exchanger section, steam condenses in the jacket and the liquid being evaporated boils on the inside of the tubes and in the space above the upper tube plate. The resistance to heat flow is imposed by the steam and liquid film coefficients and by the material of the tube walls. The circulation of the liquid greatly affects evaporation rates, but circulation rates and patterns are very difficult to predict in any detail. Values of overall heat transfer coefficients that have been reported for evaporators are of the order of 1800–5000 $J\,m^{-2}\,s^{-1}\,°C^{-1}$ for the evaporation of distilled water in a vertical-tube evaporator using condensing steam. However, with dissolved solids in increasing quantities as evaporation proceeds leading to increased viscosity and poorer circulation, heat

transfer coefficients in practice may be much lower than this.

As evaporation proceeds, the remaining liquors become more concentrated and because of this the boiling temperatures rise. The rise in the temperature of boiling reduces the available temperature drop, assuming no change in the heat source. And so the total rate of heat transfer will drop accordingly. Also, with increasing solute concentration, the viscosity of the liquid will increase, often quite substantially, and this affects circulation and the heat-transfer coefficients leading again to lower rates of boiling. Yet another complication is that measured, overall, heat transfer coefficients have been found to vary with the actual temperature drop, so that the design of an evaporator on theoretical grounds is inevitably subject to wide margins of uncertainty. For the evaporation of liquids that are adversely affected by high temperatures, it may be necessary to reduce the temperature of boiling by operating under reduced pressure. When the vapor pressure of the liquid reaches the pressure of its surroundings, the liquid boils. The reduced pressures required to boil the liquor at lower temperatures are obtained by mechanical, or steam jet ejector, vacuum pumps, combined with condensers for the vapors from the evaporator. Mechanical vacuum pumps are generally cheaper in running costs but more expensive in terms of capital than are steam jet ejectors. The condensed liquid can either be pumped from the system or discharged through a tall barometric column in which a static column of liquid balances the atmospheric pressure. Vacuum pumps are left to deal with the non-condensables, which are much less in volume but still have to be discharged to the atmosphere.

B. Heat Transfer and Liquid Boiling Point

Boiling is evaporation that occurs throughout a liquid, as a contrast to a surface phenomenon. Heat transfer in evaporators is governed by the equations for heat transfer to boiling liquids and by the convection and conduction equations. The heat must be provided from a source (e.g., condensing steam in most cases) at a suitable temperature. The steam comes either directly from a boiler or from a previous stage of evaporation in another evaporator. Major objections to other forms of heating, such as direct firing or electric resistance heaters, arise because of the need to avoid local high temperatures and because of the high costs in the case of electricity. In some cases the temperatures of condensing steam may be too high for the product and hot water may be used. Low-pressure steam can also be used but the large volumes create design problems.

While lower evaporation temperatures reduce heat damage to the products, in evaporators that are working under reduced pressure, a condenser to remove the bulk of the volume of the vapors by condensing them to a liquid often precedes the vacuum pump. Condensers for the vapor may be either surface or jet condensers. Surface condensers provide sufficient heat transfer surface, pipes for example, through which the condensing vapor transfers latent heat of vaporization to cooling water circulating through the pipes. In a jet condenser, the vapors are mixed with a stream of condenser water sufficient in quantity to transfer latent heat from the vapors.

X. DRYING

Drying is one of the oldest methods of preserving food. Primitive societies practiced the drying of meat and fish in the sun long before recorded history. Today the drying of foods is still an extremely important food preservation operation. The distinguishing features between drying and concentration are the final level of water and nature of the product (11). Dried foods have water content sufficiently low to give solid characteristics, thus can be stored for long periods without deterioration occurring. The principal reasons for this are that the microorganisms which cause food spoilage and decay are unable to grow and multiply in the absence of sufficient water and many of the enzymes which promote undesired changes in the chemical composition of the food cannot function without water. Preservation is the principal reason for drying, but drying can also occur in conjunction with other processing. For example in the baking of bread, application of heat expands gases, changes the structure of the protein and starch and dries the loaf. Losses of moisture may also occur when they are not desired, for example during curing of cheese and in the fresh or frozen storage of meat, and in innumerable other moist food products during holding in air.

A. Moisture in Foods and Dehydration Principles

Drying of foods implies the removal of water from the foodstuff. In drying, water molecules must make their way through the food product to the surface in contact with drying air. Once at the surface, water molecules are transferred into the air based on the difference in vapor pressure between the air and the surface. When the vapor pressure in the air reaches the same value as the vapor pressure of water at the surface of the food, drying ceases. Understanding the behavior of water is important to reach effective water removal and to obtain a high-quality product. In most cases, drying is accomplished by vaporizing the water that is contained in the food, and to do this the latent heat of vaporization must be supplied. There are, thus, two important process-controlling factors that enter into the unit operation of drying: (1) transfer of heat to provide the necessary latent heat of vaporization, and (2) movement of water or water vapor through the food material and then away from it to effect separation of water from foodstuff.

Water activity (a_w), often defined as the ratio of the vapor pressure of water measured at the food surface (p_w) to the saturation vapor pressure of pure water at the same temperature (p_w^o), is commonly used by food technologists to describe how water interacts in food products. However, since this definition is only true for ideal solution at thermodynamic equilibrium, water activity based on vapor pressure measurements is only an approximation. Recently, use of the state diagram to depict conditions of water in foods has been employed, and its use has improved our knowledge of drying technology (21). It is important to note that, as a food product dries, both moisture content and water activity change. At any given relative humidity of air used for drying, there is an equilibrium water content with the product. However, it has been found that the nature of this relationship depends on whether the food product is being dried or allowed to pick up moisture from the air. In general, water that is removed during processing of foods cannot be replaced in exactly the same manner to yield a product identical to the original material.

B. Drying Methods

There are many factors that influence the rate of drying. These are related to either: (1) the process conditions present during drying, as determined by dryer type and operating conditions (e.g., temperature, air velocity, relative humidity, and pressure), or (2) the nature of the food product placed into the dryer (e.g., surface area, constituent orientation, cellular structure, and type and concentration of solutes). Drying processes based on the type of heating medium used fall into three categories: (a) Air and contact drying under atmospheric pressure. In air and contact drying, heat is transferred through the foodstuff either from heated air or from heated surfaces. The water vapor is removed with the air. (b) Vacuum drying. In vacuum drying, advantage is taken of the fact that evaporation of water occurs more readily at lower pressures than at higher ones. Heat transfer in vacuum drying is generally by conduction, sometimes by radiation. (c) Freeze drying. In freeze drying, the water vapor is sublimed off frozen food. The food structure is better maintained under these conditions. Suitable temperatures and pressures must be established in the dryer to ensure that sublimation occurs.

Osmotic dehydration is already considered a valuable tool in minimal processing of food. It is the partial removal of water by direct contact of plant or animal tissue with a suitable hypertonic solution, i.e., highly concentrated solutions of sugars, salts, sugar/salt mixtures, etc. It can be applied either as an autonomous process or as a processing step in alternative processing schemes leading to a variety of end products. During osmotic dehydration two major countercurrent flows take place simultaneously. Under the chemical potential gradients existing across product-medium interface, water flows from the product into the osmotic medium, while osmotic solute is transferred from the medium into the product. A third transfer process, leaching of product solutes (sugars, acids, minerals, vitamins) into the medium, although quantitatively negligible, is recognized as affecting the sensorial, nutritional, and functional characteristics of the final product.

Most of the work done so far refers to osmotic processing of fruits and vegetables with emphasis on the manipulation of process parameters to control product dehydration or impregnation. Recent recognition of direct formulation possibilities has opened a whole new world of potential applications in conventional and new processes for plant and animal products. The osmotic treatment is now viewed as a complex solid-liquid system that has to be analyzed and modeled as a basic unit operation. In this context, fundamental findings such as properties and behavior of biological materials, mass transfer mechanisms, and process modeling, will be directly applicable to every solid/liquid process. Since transfer mechanisms have to be studied at cell level, newly acquired knowledge on physical, physicochemical, and biological properties of biomaterials has to be taken into account. Extensive industrial applications are awaiting a successful address of fundamental issues, such as adequate process modeling, microbiological process validation, and efficient, environmentally friendly osmotic solution management.

XI. COMBINED OPERATIONS

A. Enzymatic Time-Temperature Integrators

Thermal processing, including blanching, pasteurization, and sterilization, has been and still is one of the most widely used physical methods of food preservation. In the context of food preservation, the quantitative measurement of the impact of a thermal process in terms of food safety is of utmost importance in process design, optimization, evaluation, and control. Consumer demands for higher-quality convenience products and the striving of food companies for energy savings and better process control have resulted in the optimization of existing and the development and application of new heating technologies, such as continuous processing in rotary retorts, aspectic processing, ohmic and microwave heating, and combined processes. However, the commonly used process evaluation techniques, including *in situ* and the physical-mathematical approach, have serious limitations with regard to their applicability in these technologies.

A TTI can be defined as "a small measuring device that shows a time-temperature dependent, easily, accurately, and precisely measurable irreversible changes that mimics the change of a target attribute undergoing the same variable temperature exposure." The development of enzymatic time-temperature integrators (TTIs) allows fast, easy, and

correct quantification of the thermal process impact in terms of food safety without the need for detailed knowledge of the actual temperature history of the product. The experimental work involves extensive kinetic studies of α-amylase at different environmental conditions under steady state and non-steady state conditions. After careful isothermal calibration and validation under variable temperature conditions, several TTIs are successfully applied as wireless device to (1) determine the influence of process and/or product parameters on the spatial distribution of process-lethality in a particulate model food system and to (2) evaluate the lethality distribution and hence determine the coldest zone in a retort. Moreover, TTIs are sufficiently sensitive to distinguish between in-pack spatial variations of the lethal impact, indicating that TTIs can be used in monitoring critical control points (i.e., determination of the in-pack coldest point or evaluation of the coldest zone in a retort) as part of a hazard analysis critical control points (HACCP) program.

B. Computational Fluid Dynamics for Thermal Process Optimization

In many thermal food processes, several product units are processed simultaneously, in batch or continuously. To ensure a uniform quality and microbial inactivation in all units, the heat transfer must be as uniform as possible throughout the heating equipment. However, optimization of the design of the processing unit is a difficult task, because of the interaction of many physical phenomena on a relatively small scale in a complex geometry. Thus, analytical solutions exist only in a small number of simplified cases. The most common approach is to use simplified equations, which result from a combination of approximations and require considerable experimental input. At this scale of detail, experiments become very time-consuming and costly.

With the increasing computational power and memory capacity of computers and the development of efficient numerical algorithms, the numerical solution of the governing fluid flow, mass, and energy equation has become possible. This approach of using computers for solving fluid flow problems is known as computational fluid dynamics (CFD). For example, CFD has been applied to thermal food processing in a forced convection oven. CFD was applied to solve the boundary layer near the surface of complexly shaped food products. Although CFD cannot be used as a stand-alone solution but requires experimental inputs to adjust the turbulence models and also careful validation of the results, it has the advantage of ease of use once a reliable model has been established. Then CFD produces quick answers to complex questions and gives details of all the variables involved. The availability of commercial codes with easy-to-use interfaces and flexible pre- and post-processing facilities has cleared the path for the extensive use of CFD in many applications.

C. Minimal Processing with Electric Heating Methods

Three major types of electric heating processes are available: ohmic heating, high frequency heating, and microwave heating. Thermal treatments are known to produce undesirable changes such as loss of vitamins and minerals, formation of thermal reaction components of biopolymers, and, in minimal processing term, loss of fresh appearance, flavor, and texture of food. The electric heating methods directly transfer the energy from the electromagnetic source to the food, without heating up heat transfer surfaces, etc., in the heat processing equipment. This direct energy transfer is of major advantage, as it gives excellent opportunities for high-energy utilization. The ohmic system has been installed for pasteurization and sterilization of a number of food products with resulting excellent quality. The largest application in the food industry for high frequency heating is in the finish drying or post-baking of biscuits and other cereal products. The interest in high frequency defrosting has increased again in the last number of years. Industrial applications of microwave heating, on the other hand, are found for most of the heat treatment operation in the food processing industries.

In electric resistance (ohmic) heating, the food itself acts as a conductor of electricity. The food may also be immersed in a conducting liquid, normally a weak salt solution of similar conductivity to the food. Heating is accomplished according to Ohm's law, where the conductivity, or the inverse, the resistivity, of the food will determine the current that will flow between the ground and the electrode. High frequency heating is done in the MHz region of the electromagnetic spectrum. Foods are heated by transmitting electromagnetic energy through the food placed between an electrode and the ground. Microwaves used in the food industry for heating are mainly due to the dielectric heating mechanism up to moderated temperatures. Polar molecules, the dominant water, of the food is an important factor for the microwave heating performance of foods, especially the penetration ability of the microwave in foods is limited. An important requirement on microwave equipment and microwave energy application in the food industry is the ability to properly control the heating uniformity. A number of new applications in the microwave heating area have been reported recently in patent literature, often involving the use of the unique heating properties of microwaves with higher energy fluxes and direct heating of the interior. However, electric heating equipment for the food industry has to be designed and operated according to international and national safety standards. The levels of allowable leakage vary over the frequency range according to these standards.

D. High Pressure/Temperature

Non-thermal processes are currently receiving considerable attention from consumers as well as from producers

and researchers. Processes that are under evaluation or development include high hydrostatic pressure treatment, the utilization of high electric field pulses, high-intensity light pulses, the application of supercritical carbon dioxide, or the use of magnetic fields. In addition, treatments with biopolymers or with natural antimicrobials are being applied or attempted. Also various combinations of the above mentioned unit operations with thermal processes are being evaluated. To date, the development of high hydrostatic pressure treatment has come close to commercialization. Processing opportunities integrating high-pressure treatment as a processing step can involve preservation as well as modification or separation processes and can lead to product development opportunities. Therefore, it will most likely be the first nonthermal process with applications in oriental foods.

Key process advantages of high pressure application to food systems are the independence of size and geometry of the samples during processing, possibilities for low temperature treatment, and the availability of a waste-free, environmentally friendly technology. Opportunities for effective and relevant utilization of the potential of high hydrostatic pressure center around preservation processes, product modifications, and processes based on phase transitions or membrane permeabilization. A vast amount of empirical information is available regarding the effects of high hydrostatic pressure on a wide range of vegetative microbial cells. Bottlenecks such as the baroresistance of microorganisms within environments of low water activity could be overcome by combinations with mild heat or by pretreatment with ultrasound. However, challenges exist while adapting the technology for specific products. Scientific challenges are the lack of kinetic data, little understanding of mechanisms involved in high pressure effects on food systems, limited knowledge regarding the role of food constituents, and storage-related changes of pressure-treated products. Technical challenges of commercial application of high-pressure technology include material handling, process optimization, sanitation, cleaning, and disinfections as well as package design. Engineering aspects to be dealt with are process inhomogeneities such as heat transfer issues and temperature distribution within pressure vessels. In addition, work on pathogenic microorganisms is still scarce in the published literature and needs continued attention.

XII. SUMMARY

Using new technological solutions, new packaging materials and technologies, or combinations of different (mild) treatments, a variety of products much closer to fresh and wholesome products is increasingly reaching the market. High-pressure treatment is another very promising technology, of a more severe nature, but that has proven successful in preserving quality attributes. However, it must be borne in mind that the development of new technologies is being made while facing a very conventional industry sector, where less technological ability means that optimization of conventional technologies will have greater potential impact, in the short term. In addition, it is equally important to promote the integration of knowledge drawn from different disciplines required to design quality-efficient food processes for the modern food industry and consumer markets.

Worldwide, the food industry is facing relatively stagnant markets in terms of quality—the most important markets for most food companies still are in the part of the world where population is not growing. Economic success is greatly linked to the ability to pay off investments at attractive rates and is basically associated with growth scenarios. Therefore, the interest in market segments involving higher value-added products and with great growth potential is evident. The changes in lifestyle, consumption habits and patterns, and in the diet-health perception are the basic contours of such opportunities. Hence, the focus of researchers and industrialists on technologies and processing approaches and methodologies that can efficiently lead to adequate responses to the newer market demands. While it is likely that the bulk of food production may differ slightly from what it is today for many years, the greater interest for development lies in paths that may lead us to a completely new way of understanding and producing food products, even if market niches are at the moment comparatively small.

Food Drying

103 Dehydrated Vegetables: Principles and Applications

Stefan Grabowski and Michele Marcotte
Food Research and Development Center, Agriculture and Agri-Food Canada

Hossahali Ramaswamy
Department of Food Science, McGill University

CONTENTS

I. INTRODUCTION

Natural or artificial dehydration is the most traditional method of vegetable preservation. Nature provides man with preserved vegetables, fruits and herbs in the form of sun-dried products. Dehydration accomplishes preservation of such foods in two major ways: (1) it removes the water necessary for growth of microorganisms and for enzymatic activity and (2) by removing water, it increases the osmotic pressure by concentration of salts, sugars and

acids, creating a chemical environment unfavourable for the growth of many microorganisms.

According to the standard definition, dehydration is rather general water removal process, independently of the type of mechanism and driving forces, such as air moisture content or osmotic pressure differences, etc. Drying is rather air-involved process with driving force of the air humidity difference. However, both of the names are used exchangeable.

The largest end-uses for dried vegetables are seasonings, ingredients of soups and ready meals, sauces, gravies and many other food additives. To fulfill the role of the healthy ingredient of our menu, vegetables we consume have to be of high nutritional value, without any microbial and chemical contaminations (pathogenic bacteria, mycotoxins, pesticides, heavy metals, etc.). The same conditions apply to the dried vegetables with some additional requirements such as a high rehydration rate and extended shelf life. Vegetables dried by a proper method and in appropriate process condition, should preserve the maximum nutritional value and quality of a fresh product. Thus, the selection of the drying method and drying conditions should be mainly based on the required quality of the final product. Additionally, for the massive production scale, the energy consumption, and environmental impact of the greenhouse gases production, are the aspects of some special consideration.

General principles of drying are well described in many resources such as "Handbook of Industrial Drying" [1] edited by Mujumdar (1995), "Drying: Principles, Applications and Design" [2] by Strumillo and Kudra (1986), "Industrial Drying of Foods" [3] edited by Baker (1997), "Dehydration of Foods" [4] by Barbosa-Canovas and Vega-Mercado (1996), "Advanced Drying Technologies" [5] by Kudra and Mujumdar (2001), etc. Thus, in this chapter the only specific drying characteristics for vegetable and vegetable products will be considered and for the basic knowledge of the dehydration process the reader is asked to refer to the above handbooks or other widely available food engineering books or book chapters. Also, drying of potato and potato products will be excluded from this chapter as a separate chapter for this important commodity is presented.

II. PRINCIPLES OF VEGETABLE DEHYDRATION

Freshly harvested vegetables are relatively very perishable and further processing, such as dehydration, freezing, canning and fermentation, should be performed almost immediately after the harvest to prevent or reduce quality deterioration. Most vegetables are dehydrated to very low moisture levels (2 to 3%) for increased stability [6, 7].

A key parameter in the food dehydration is a water activity (a_w), defined as the ratio of water vapor pressure (p) of the food system to the vapor pressure of pure water (p_0) at the same temperature.

$$a_w = p/p_0 \tag{103.1}$$

The microbial stability of dehydrated foods, or more precisely, of foods stabilized by a reduced water activity, results from interruption of vital processes essential to microbial growth or spore germination which is mediated by a depressed availability of water in the food. The number and types of microorganisms, which may be associated with foods, is extremely large and may not remain constant during the life of a food. These microorganisms may originate from the raw material or from contamination (by people, animals and insects, water or air, contact surfaces, etc.). Every microorganism has an optimum and a minimum water activity for growth. A reduction of a_w below optimum delays spore germination and decreases the growth rate, and reduction of a_w below the minimum, presented in Table 103.1, totally inhibits the growth or spore germination. However, the reduction of water activity is not sufficient to prevent the growth of all microorganisms. During air drying the increased temperature of the food could affect the living forms of the microorganisms but not the spores of such the species as *Bacillus* and *Clostridium*. For example, dried onion may contain a heavy load of *Clostridium perfringens* spores, which can cause food poisoning when used in a poultry stuffing [8], while *Shigella* is one of the most common gram-negative food pathogen for almost all vegetables and fruits.

TABLE 103.1
Minimum Water Activity for the Grow of Some Microorganisms in Food

Group of Microorganisms	Examples	Minimum Water Activity
Normal bacteria, viruses	*Clostridium botulinum, Salmonella, Bacillus, Pseudomonas, Escherichia, Lactobacillus, Vibrio*	0.91
Normal yeasts	*Candida, Torulopsis*, most *Saccharomyces,* (Also *Staphylococcus aureus*)	0.88 0.80–0.87
Normal molds	Mycotoxigenic penicillia	0.80
Halophilic bacteria	Most halophilic bacteria	0.75
Some molds	Mycotoxigenic aspergilli	0.75
Xerophilic molds	*Aspergillus chevalieri, A. candidus, Wallemia sebi* (Also yeast *S. bisporus*)	0.65
Osmophilic yeasts	*Saccharomyces rouxi* (Also molds: *A. echinulatus,* and *Monoascus bisporus*)	0.60

Source: [8, 9].

It should be noted that the drying process does not necessarily destroy the food toxins occurring as contaminants prior to or during drying. In the case of the food intoxicated by toxins produced by some food poisoning bacteria (*Clostridium botulinum, Staphylococcus aureus*, *Bacillus cereus*) this food should be excluded from the drying process and consumption.

Other typical microorganisms as viruses, protozoa, algae and prions do not grow on food so the only aspects of importance are their pathogenicity or toxigenicity and their resistance to thermal drying procedures as they can be transferred to a human body and develop some diseases [8]. Almost all of these microorganisms are more heat-sensitive than the average vegetative bacterium.

The effect of water activity on microbial growth is influenced by many other factors, such as temperature, pH, nutrients availability, preservatives and other components of food, oxygen supply, etc. With the same water content in the food, several different water activity values can be achieved by changing the food composition. Table 103.2 presents some examples of maximum water activity values, which are permissible for certain types of dehydrated foods. Practical relation between water activity and water content in the food is given by so-called food stability map, introduced first by Labuza [11]. At present, the measurement of water activity is easy with the use of several types of commercially available single or multi-channel instruments; however, moisture content (wet or dry basis) still remains the most practical criterion in the food drying technology. The water activity of fresh vegetables falls in the range 0.97–0.99. Dried vegetables with the moisture content of 14–24% have water activity of 0.7–0.77. The water activity of most dehydrated foods is below the minimum water activity values of food pathogens, which are inhibited at a water activity of 0.9 (only *Staphylococcus aureus* is capable to growing at a_w values down to 0.85). Most other microorganisms such as food spoilage type bacteria and fungi, which can grow at lower water activities, multiply very slowly in this low a_w condition or require a special environment for the growth. In case of fungi (yeasts and molds) they tend to grow more slowly than bacteria and they are often out-competed in many types of food spoilage, unless bacterial growth is limited, e.g., by drying below their minimum water activity, presence of preservatives, etc. In general, yeasts and molds tend to be more resistant than bacteria to harsh environmental conditions (low a_w) and so cause spoilage under such conditions. The nature of this type of spoilage may be similar to that caused by bacteria, except that the growth may be much more pronounced. As some molds may produce toxins (especially mycotoxins) that can result in a variety of acute or chronic toxicity syndromes in man and animals. The foods that may be affected by molds associated with mycotoxins production are, for example, grains, nuts, figs, cocoa, coffee, etc. Production of mycotoxins is generally associated with poor handling practices during harvesting, drying or storage of these foods.

TABLE 103.2
Maximum Permissible Water Activity for Some Dry Vegetables, Fruits and Additives (20°C)

Dry Product	Maximum a_w
Potato flakes	0.11
Dry soup mix	0.60
Peas	0.25–0.45
Beans	0.12–0.80
Sucrose	0.85
Fructose	0.63
Dextrose	0.83
Maltose	0.92
Sorbitol	0.55–0.65
Honey	0.75
Soluble coffee	0.45

Source: [8–10].

A dehydrated product remains stable only as long as it is protected from water, air, sunlight and contaminants. For small packages of dehydrated vegetables, the use of an in-package desiccant (to bring the moisture content of the storage environment to 1% or lower) permits the storage for six months or more at room temperatures without significant losses of vitamins. Some useful information on proper storage condition of dried foods is presented by Labuza [11].

Extending the shelf life of foods is not the only objective of the drying process, however, it is the most important. Other rationales for controlled vegetable drying are [12]: to reduce the product seasonality, to improve transportability and reduce the costs of transport, to improve storage capability and to reduce nutritional fluctuations.

These advantages of vegetables as well as fruits and herbs drying are associated with some negative changes occurring during drying [13, 14], as for example, some "heat damage" of heat-sensitive constituents like vitamins, enzymes, etc., browning, shrinkage, "case hardening," irreversible loss of ability to rehydration, loss of volatile constituents, and changes in moisture distribution within the product. Generally, these negative aspects of drying are at least in the same order of magnitude as those encountered in other preservation methods (canning, aseptic processing or freezing), and drying of vegetables remains a popular method of food preservation.

III. PRACTICAL VEGETABLE DRYING TECHNIQUES

Drying of the agricultural products could be natural, based on a natural action of sun and wind (field-sun drying), artificial (air drying, contact drying, osmotic dehydration, etc.)

or mixed (solar-assisted air/contact drying) which use both natural and artificial energy sources, as for example, in a hybrid solar dryer [15]. All these drying methods are playing an important role in vegetables, spices and herbs dehydration. The heat necessary for the drying is transferred from the energy source to the material by means of conduction, convection, internal generation (microwaves, radio-frequency), surface radiation (sun, light) or by combination of all these. According to the latest trends, in many existing conventional drying systems, solar, wind and other natural energy is increasingly being considered to provide part or the whole energy required for the drying process.

Figure 103.1 presents a general scheme of vegetables, herbs or spices drying. As the variety of these products is extremely large, in individual cases, some of the processing steps may be omitted or others added. In this chapter, only the drying operation, which is the main part of the full processing scheme, will be considered.

A. Sun and Solar Drying

Field sun drying, used for large tonnages of vegetables or fruits, can be very inexpensive in areas of adequate climatic conditions and additionally (but not necessarily, as for example in California) where labor costs are low. No costs are incurred to heat or to circulate the air. Additionally, the solar energy is natural, abundant and environment friendly. Typically, fruits, herbs, spices and to a lesser extent vegetables are spread out in the sun and wind on the field, special mats, concretes, etc. The radiant energy of the sun provides the heat to evaporate the water while the wind helps to move

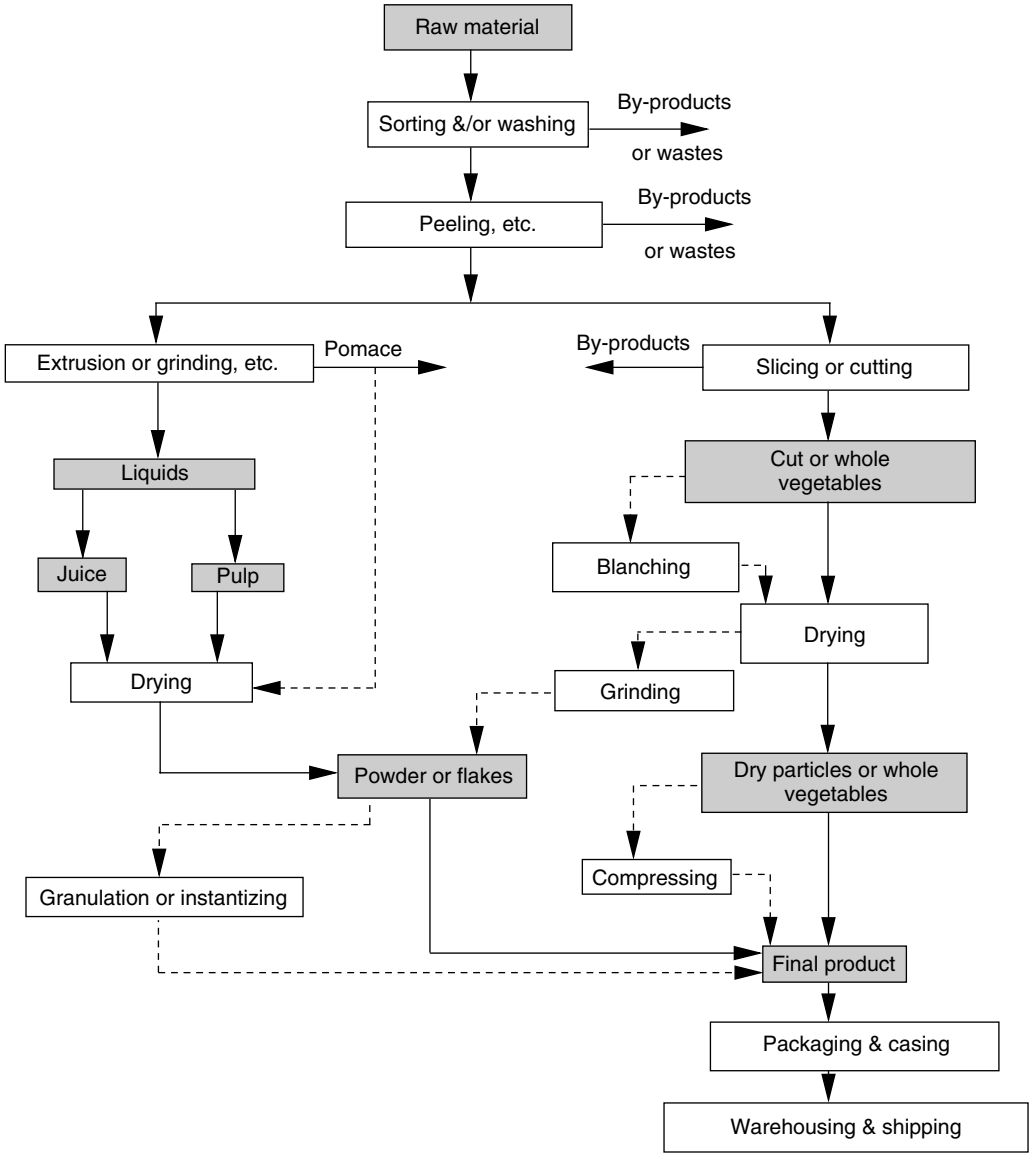

FIGURE 103.1 A general scheme for vegetable drying.

the moisture and accelerates the process. This type of drying performs well in warm and dry conditions on the field or other locations (like shadows for light-sensitive products like herbs, spices, etc.). At night and during the rainy periods, this type of drying cannot be used. The temperature of the food during sun drying is usually 5–15°C above ambient temperature [16]. Sun drying techniques are based mainly on experience and tradition. Thickness of the wet material layer, drying time and material handling before, during and after drying are the conditions normally standardized based on practice and can differ from one location to another. Some very approximate prediction of the sun drying performance could be based on the energy balance from available data on the distribution of solar energy radiation throughout the world, absorbency/reflectance characteristic of the wet and the dry material [16], local climatic conditions such as ambient air temperature, speed and humidity, rainfall frequency and intensity [17]. For example, the thermal efficiency of sun drying of Colombian coffee beans, calculated as a ratio of heat necessary to remove the moisture to the total solar radiation heat, was reported to be in the range, 13.7–22.6% [18].

The time of sun drying depends on the product characteristics and drying conditions and typically ranges from 3 to 4 days, but can be longer [16]. During this time, the product has to be protected from the rain, insects, birds, animals, etc. Several practical methods have been developed to reduce the length time of drying. One of the most important, especially for larger production scale, is the application of different product pretreatment before sun drying. Several pretreatment methods and materials are used for this purpose, for example, steaming, immersion in boiling water or sugar and/or salt solutions or the use of ethyl-, methyl- or sodium oleate, etc.

Another way to reduce sun drying time is to use solar energy concentrators with or without natural or forced airflow inside the dryer. This technique is normally called solar drying. More detailed description of solar drying principles, equipment and conditions may be found in selected publications [19, 20, 21, etc.]. Some practical values of the efficiency of solar drying collectors are given by Hall [22]. Examples of solar dryers developments for vegetables, herbs and spices are detailed below.

1. Solar Natural Dryers (Cabinet, Tent, Greenhouse, etc.)

Solar cabinet is the simplest type of solar natural dryer and very popular in many locations. It is dedicated rather to a small production (family) scale. The wet product is placed in an enclosure and the solar heat, generated through a conversion of solar radiation into low-grade heat, accelerates the evaporation of moisture from the product. The airflow inside the cabinet is driven by natural convection. The dryer throughput and the drying time are estimated from practice (Table 103.3), however considerable effort has been made to model solar collector performance [21]. The thermal efficiencies of solar drying were reported to be from 11 to 13% [24] with the highest value at the beginning of the drying run. These are not the general values for all solar drying applications and an individual level of this parameter should be estimated in each specific drying process.

The quality of the dried product is the most important parameter in the drying technology. Patil [25] compared the quality of peppers after sun drying, polyethylene solar drying and solar cabinet drying. He found that the solar cabinet drying offers some advantages over direct sun drying in terms of better quality and faster rate of drying. Jayaraman et al. [26] compared ascorbic acid retention in cauliflower, cabbage and bitter gourd dried by three different methods: (1) directly under the sun, (2) under the sun in a black polyethylene tent, and (3) in a drying cabinet with three solar collectors. They reported (Table 103.4) that the direct exposure of these products to the sun decreased the quality factors like vitamin retention. The use of solar energy in an indirect way could improve the quality of the final product. In some cases, this was not practical because of large costs of solar collectors. Less expensive solar tents or covers are often used for bigger production scale. Also solar greenhouses, terrace or room dryers are very practical for the larger productions as they are simple in construction and relatively low in investment

TABLE 103.3
Solar Cabinet Drying Throughput*

Product	Amount of Fresh Matter Dried Per Unit Time**	Maximum Allowable Temperature (°C)
Garlic	2.6 kg/per 2 days	60
Grapes	5.7 kg/per 4 days	88
Okra	3.0 kg/per 2 days	66
Onions	3.0 kg/per 2 days	71
Apricots	4.0 kg/per 2 days	66

costs. Figure 103.2 presents two examples of low-cost solar dryers for relatively larger production scale.

2. Dryers with Solar Collectors and Natural or Artificial Airflow

Some vegetable, fruit and spice dryers utilize both direct and indirect solar radiation. In these dryers, radiant energy from the sun falls directly onto the product being dried. In addition, an air-preheater (solar collector) is also used to raise the drying air temperature. The circulation of air in the solar pre-heater is either free convection or using a fan. In both situations, this air stream accelerates significantly the drying rate. Figure 103.3 presents two examples of very simple and inexpensive dryers of this type. According to published data [21, 23], a family-scale dryer (Figure 103.3a) works well for drying mushrooms, apricots, apples, etc., usually in one day. Similarly, adding a wind-driven fan for more intensive airflow (Figure 103.3b), a higher throughput of the dryer can be achieved. The fan provides air circulation in the dryer and pulls the air up through the product. Dampers can be installed in the stack to control airflow rate, thus also controlling the amount of heat build-up. Several other modifications of this concept are in use for drying purposes in tropical and hot-climate areas. Further extension of the dryer throughput can be achieved by applying forced convection airflow. Another solution in this type of installation is the use of very long metal air-preheater pipes [28] or large surface solar collectors [29]. The flow of air is then artificial with the use of powerful fans. In one construction design [28], the length of the solar air-preheating pipe was about 7 miles. The heating rate of this preheater was reported to be sufficient for proper operation of a solar-assisted sonic dryer for several fruits and vegetables.

3. Solar-Assisted Artificial Dryers

For commercial applications, where a large tonnage of product needs to be dried, some source of auxiliary energy is needed to initiate forced air movement and/or to provide

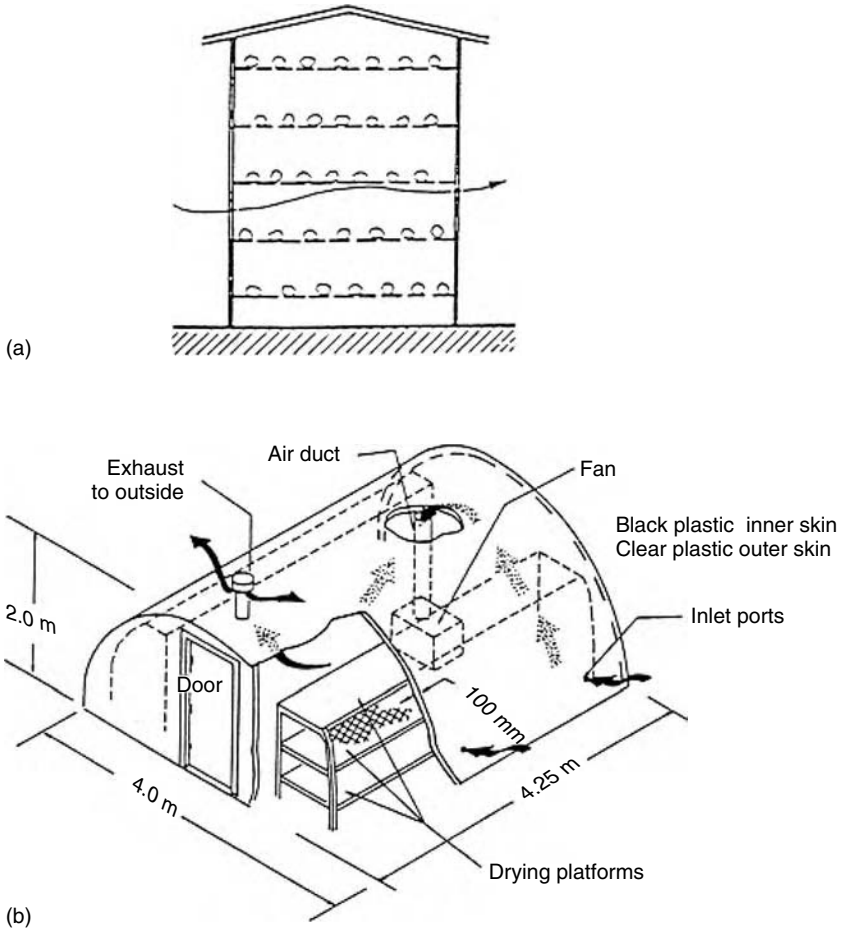

FIGURE 103.2 Examples of large-scale solar dryers: (a) Australian type dryer, and (b) plastic-tent solar dryer. (From References 19 and 21).

the supplemental energy. In this scenario, the solar drying equipment is part of a whole drying system and generally assists operation of a typical air dryer, supplying it some amount of heat. Construction of solar-assisted artificial drying system could be simple or combined with other elements, such as a source of stored heat, heat pumps, etc. In the simplest system the solar energy is directly used to provide a part of the heat required for moisture evaporation in a conventional air dryer. The drying of the food is normally intensive during sunshine hours, while at night or low radiation periods an auxiliary heat source supplements the heat energy. Several conventional types of dryers could be combined with solar energy collectors. For example, Smith et al. [30] describe commercial convective air-drying installation for the final dehydration of potato cubes from 11% down to 4% moisture (wet basis). This system utilizes solar double-glazed collectors and an auxiliary gas burner to heat the drying air. The solar collectors operate at about 40°C above the ambient temperature. In another example, considerable reduction of the fuel-gas was reported by West Growers and Packers [27], when a tunnel dryer was modified for utilization of solar radiation and by using exhaust air to preheat inlet air to the dryer. Another technique that has not been fully explored is the use of a

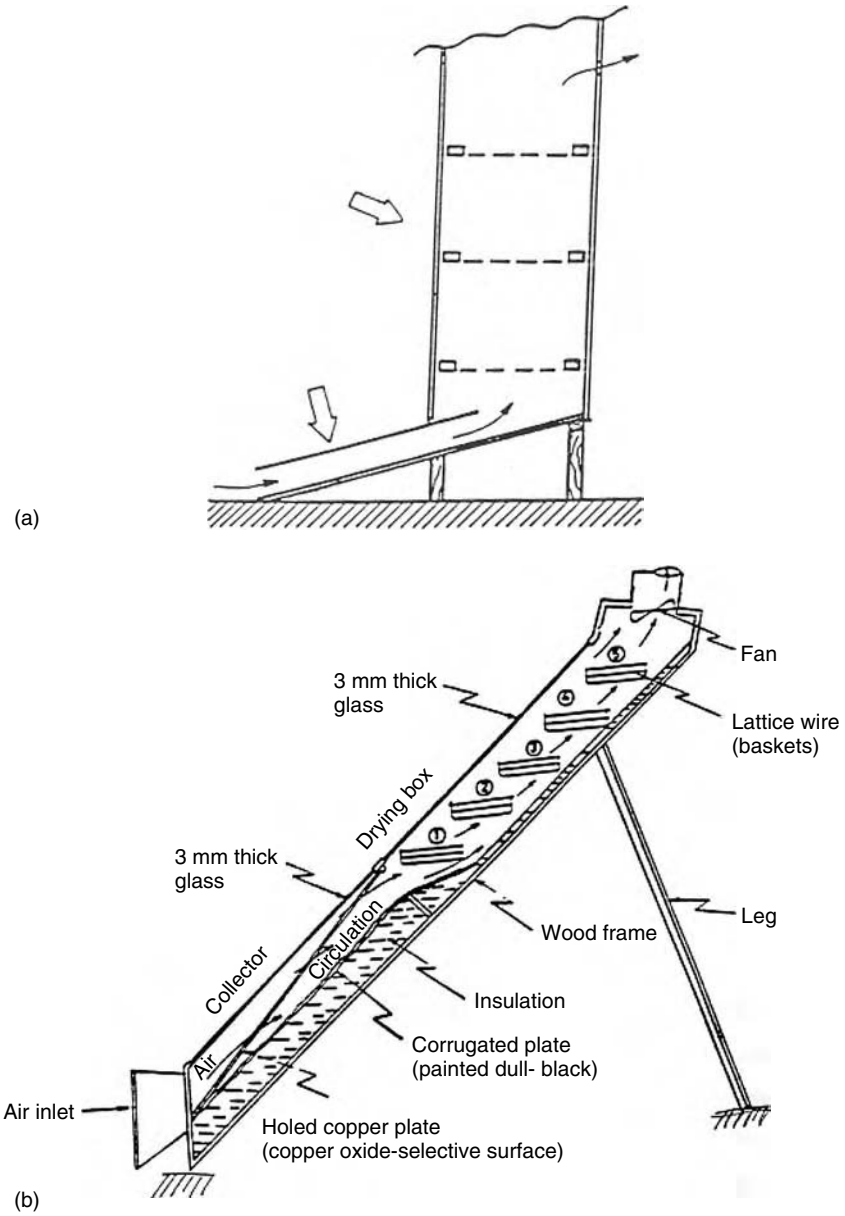

FIGURE 103.3 Low-cost fruit and vegetable solar dryers. (Reproduced with permission of Brace Research Institute, McGill University, Montreal, Canada).

desiccant to remove moisture from the drying agent (used for dehydration of heat sensitive foods), and then solar energy to regenerate the desiccant.

To reduce the effect of periodicity of solar radiation several physical heat storage systems have been developed for drying applications. Water-type and rock-bed type heat storage are the most typical [20].

Proposed schemes of solar energy application should integrate into other drying systems. More generally, solar energy should be applied as much as possible in energy consuming processes such as drying. Active research and development of various methods and components of solar drying systems have been taking place internationally, especially for the reduction of an investment cost associated with solar collectors and adequate control systems [20, 31].

B. Hot Air Dryers

Artificial hot air drying of vegetables and spices covers a very wide range of methods and installations of different production scales. The main mechanism of drying in this case is moisture migration from inside the wet material to the surface and then evaporation to the surrounding air. The drying rate is a function of several parameters such as temperature, humidity and velocity of drying air, moisture content of the moist and dry product, rheological characteristics, specific surface and geometrical form of the initial product, etc. Some general types constructions of the hot air dryers suitable for drying of vegetables and spices will be presented below.

1. Tray, Cabinet, Kiln and Bin Dryers

A tray or cabinet dryer is the simplest type of drying equipment. The operation of the dryer is periodical and the moist product is subjected to unsteady-state process. The dryer allows processing of different products, from liquid slurries to solid piece-form materials. A typical cabinet dryer consists of an insulated chamber into which trayloads of prepared food are placed. A fan pushes or pulls air through a heater and then either horizontally between the trays or vertically through them. By means of a damper system, part of the air may be recycled and part discharged to the atmosphere. Such dryers vary in size from very small units, containing one or few trays to very large units used singly or in groups with a throughput of fresh material up to 20 tons per day. The material to be dried is placed in relatively thin layers (1 to 6 cm thick). Good control of drying conditions is possible. A main disadvantage of these dryers is the large amount of manual work needed to operate the dryer and the relatively low intensity of the drying. However, a wide variety of materials can be dried in these dryers. Because of its versatility, their use is widespread in the food industry. An example of modeling of this type of drying process is given in reference [32].

Bin-type finishing dryers are sometimes used for the final drying and equilibration of some dried vegetables, although often with large modern conveyor dryers they are no longer needed. They are essentially large vertical cylindrical bins with perforated bottoms through which a constant stream of warm air is blown [33].

2. Tunnel Dryers

Tunnel dryers possess all advantages of tray dryers. In addition, they have a semi-continuous operation. This type of dryer is very popular for drying vegetables and fruits. As compared to a tray dryer, the investment costs are higher. A typical dryer may be more than 20 m long with a square or rectangular cross-section of approximately 2 m × 2 m. The wet material is loaded in trays that are stacked on trolleys (Figure 103.4). The trolleys are introduced periodically into one end of the tunnel (the "wet" end), advance through the tunnel and removed at the other end (the "dry" end). A typical tunnel dryer can be operated in co-current or counter-current flow of air and trolleys. Two-stage dryers are also used featuring a short co-current stage followed by longer counter-current stage. In cross-flow designs the drying air moves at right angles to the path of the trays of food. Basic modeling principles for this type of drying are similar to that of a cabinet dryer. The drying times are similar to those in cabinet tray drying while the air flow-rate is linked to the total number of trays. The dimensions of the tunnel are calculated based on the necessary drying throughput, necessary drying time and the dimensions and capacity of a single trolley. More information on the design, construction

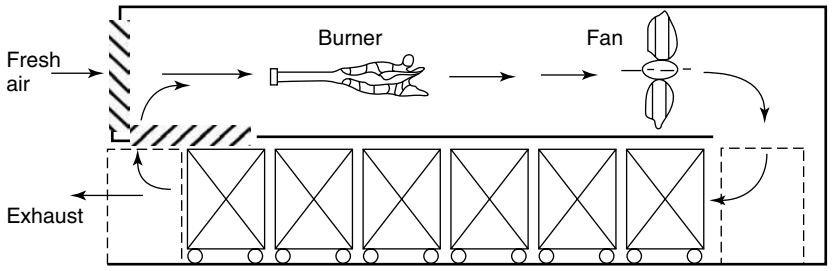

FIGURE 103.4 Simple co-current tunnel dryer with partial air recirculation.

details and operation of this type drier can be found elsewhere [13, 16, 34, etc.].

3. Conveyor-Type Dryers

Fully continuous drying operation is achieved in conveyor, belt or band dryers. This type of dryer is also very popular in vegetable processing industry. The wet product formed or placed in a bed of different thickness is carried through a tunnel on perforated (mesh, slotted or louvered) conveyors. Heated air is directed up or down through the conveyor and the layer of the product; usually up in the early drying stages and down toward the dry product exit, or directed across the material surface for products in thin layers on a non-perforated band. Some models consist of two or more conveyors in a series. Also, either co-current or counter-current configurations can be used. Such dryers are limited to foods that form a porous bed (cut, granulated or naturally particulate foods). For vegetable drying, multiple conveyors (up to 5), one above the other (Figure 103.5) can be used. The wet product is introduced onto the top conveyor and progress downwards from one conveyor to the next. Air circulation is usually a combination of cross-flow and through-flow. A final drying step for some vegetables is provided often in this type of dryer. Gradually, the conveyor dryers are replacing drying trays in tunnels for vegetable pieces such as carrots, onions and potatoes [22]. Infrared, microwave or radio frequency energy is sometimes additionally supplied to the product conveyed through the dryer. The drying unit may operate under vacuum or atmospheric conditions.

4. Fluidized-Bed Dryers

Particles vegetables (whole or diced) may be dried in fluidized bed dryers or several of its modifications: vibro-fluidized, pulsed fluidized or spouted bed dryers [35, 36, etc.]. The main advantage of this type of drying is its short time as a result of high intensity heat and mass transfer achieved due to enhanced air turbulence in fluidized bed. Batch or continuous systems are typical for the drying of food particles in range of 10 to 20 mm. Peas, beans, diced carrots, onions and potatoes are typical vegetables dried in this type of driers. If the particle size of the food covers a wide range, uniform fluidization of the product may be difficult. In such cases, mechanically or pneumatically (pulsed fluidization) induced vibration may overcome the problem. The frequency of the vibration is usually in the range 5–25 Hz with amplitude of few millimeters [36]. This type of drier is often used as a second stage powder dryer or as a granulator after, for example, spray drying in a first stage.

Another modification of the fluidized bed dryer, a spouted bed dryer, may be used in some practical applications, as for example for paprika breaks, carrot cubes, mushrooms and tomato seeds drying [37]. Spouted bed technique could be also used for vegetable or fruit concentrate or paste drying, when it is spread into a bed of inert particles (Teflon, alumina, etc.) circulating as a fountain inside a drying chamber. Pulsed fluidized bed drier, adopting regular pulsations of the drying air (Figure 103.6) as well as other fluidized bed modifications, swirl-fluidizer and centrifugal fluidized bed dryer [35], are still in a development stage. However, they could offer a promising

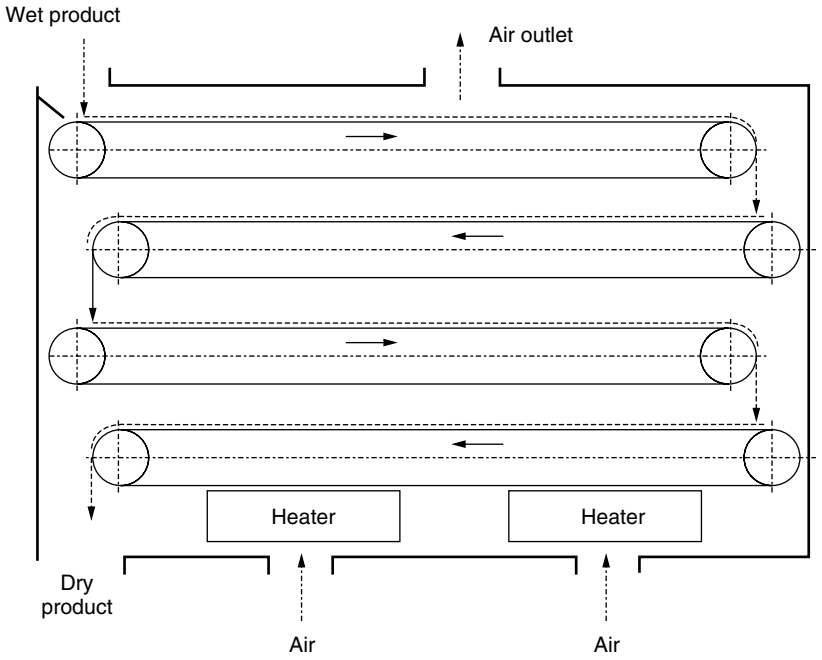

FIGURE 103.5 Diagram of multiple-conveyor dryer.

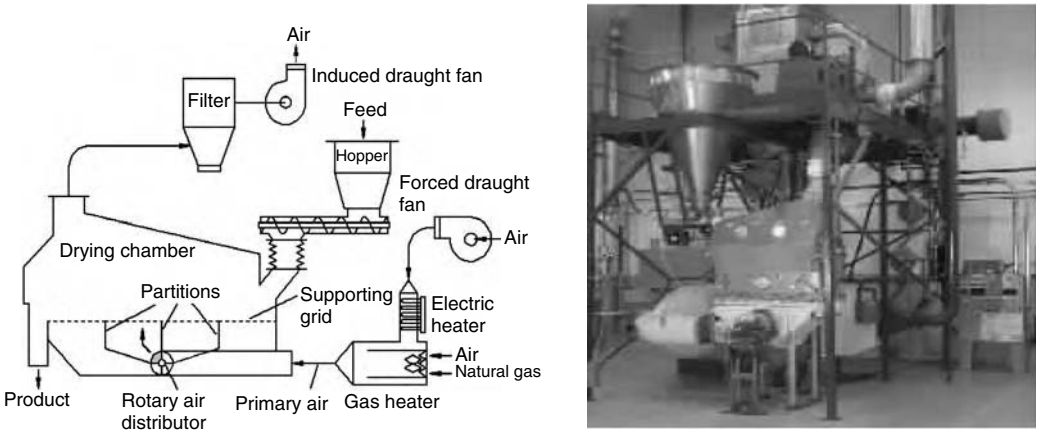

FIGURE 103.6 Schematic diagram and picture of the pilot-scale pulsed fluidized bed dryer (Courtesy of CANMET, Varennes, Canada).

technology for wide range of diced or flaked vegetables: bell pepper, beet, carrot, cabbage, onion and mushrooms [5, 38]. Much more details on fluidized bed drying technique can be found elsewhere [1, 2, 22, 35, etc.].

5. Spray Dryers

Some vegetable powders are produced from juices, concentrates or pulps using a spray drying technique. Dry powders can be directly used as important constituents of dry soups, mixtures or additives. Principles of spray drying are well documented in the literature [39, 40, etc.]. However, its application to vegetable or fruit pastes poses several problems. For example, stickiness, caking and hygroscopicity of the final products must be overcome. Drying of tomato pulp is a typical example of a difficult process as the dried tomato powder tends to become soft and sticky while still warm. The drying is achieved by spraying of the slurry into an air stream at a temperature of 138–150°C and either introducing cold dry air into the outlet end of the dryer or to cool down the dryer walls to 38–50°C [1, 9]. A wide range of vegetable powders can be dried, agglomerated and instantized in spray drying units, specially equipped with internal static fluidized bed, integral filter or external vibro-fluidizer [41].

A typical spray drying unit consists of large volume drying chamber, feed atomizer, hot air supply and dry product recovery/dust collection systems. Three consecutive steps of the process can be distinguished: (1) atomization of the feed, (2) spray-air mixing and moisture evaporation, and (3) separation of the dry product from the exit air.

Atomization is the most critical operation in the spray drying operation. Three general types of atomizers are available with many other individual developments. The most commonly used are rotary wheel atomizers and single-fluid pressure nozzle atomizers. Pneumatic two-fluid (compressed air/liquid feed) nozzles are used rarely in very special applications (slurries, past-like materials, etc.). Co-current, counter-current or mixed flow of the droplets and drying air is typical in spray drying chambers. The geometry of the drying chambers depends mainly on the type of atomizer used. It is generally short and wide (conical type) for rotary wheel atomizers and long and narrow (tall type) for nozzle atomizers. The dry product is collected at the bottom of the drying chamber and/or in cyclones, bag filters or electrostatic precipitators. The final wet separation of the powder from the exhaust air is provided in wet scrubbers, wet cyclones or irrigated fans [39, 40]. Some spray drying systems, equipped with special atomizing devices, are used for drying paste-like materials such as vegetable concentrates.

6. Other Hot Air Dryers

Pneumatic conveying dryers are generally used for finish drying of powders and granulate of vegetable and fruit products. It is extensively used for making potato granules. As the material entering the dryer must be conveyable in an air stream, the incoming material usually is predried in another way (spray, fluidized, spouted bed dryers, etc.) to a moisture level below 40% (w.b.).

Also, rotary dryers may be sometimes used for drying of particulate solid foods. In these dryers, the wet solids (particles, crystals, etc.) enter one end of a rotating drum, move down the drum length cascading from peripherally mounted lifting flights, and exit at the other end suitably dried. The drying medium is either hot air or combustion gases that flow co-currently or counter-currently to the direction of the solids through the drum length. The size of these dryers varies from approximately 0.3 m in diameter by 2 m length to 5 m diameter by 90 m length. Many details of these last techniques are given in the literature [13, 22, 42, etc.].

C. Contact Dryers

Hot surface of the contact dryer is the source of heat necessary to evaporation of moisture from the vegetable or

fruit concentrates, pulps, pastes or slurries. This type of drying is more economical than for example spray drying but the dry product has usually different characteristics than that from a spray dryer. A typical example of the contact dryer is a drum dryer with a single, double or twin drums. The single-drum dryer comprises only one roll. A double-drum dryer comprises two rolls, which rotate toward each other at the top. This gives the possibility to adjust the feed thickness layer by changing the space between them. The twin-drum dryer is similar in appearance to the double-drum dryer, but is quite different in its operation. The two drums occupy the same general position as in a double-drum dryer but rotate away each other at the top and are not spaced closely together. The vegetable pulp is fed onto the metal surface of the drums by mean of various types of feeders. Doctor blades remove the dry product. Depending on the material properties, the product is removed in the form of powders, flakes, or webs. The drum system can be entirely enclosed in a hood for vacuum operation or for supplying with the necessary amount of drying air. Thus, organic solvents or volatile can be recovered in this process. A typical example of single-drum drying operation is the drying of mashed potato. Double-drum or twin-drum dryers are in commercial use for drying tomato and pumpkin purees, mashed white potatoes, etc.

Special types of contact dryers — plate dryers with rotating radial arms are dedicated to drying of solid particulate materials [38]. All contact drying units may operate under vacuum, at atmospheric pressure or in gas-tight chambers.

D. Foam Drying

Two different foam-drying methods are of practical importance: foam mat and foam spray drying. Foam-mat dried vegetable or fruit powders have less heat-induced changes in color and flavor as compared with conventional spray-dried or drum-dried products. A product with density less than that in a conventional drier is obtained. The product density is about equal to the density of instantized or agglomerated powder.

Stable gas-liquid foam is the primary condition for a successful foam drying. Glycerol monostearate, solubilized soya protein and propylene glycol monostearate are the typical additives for the fruit and vegetable foam formulation from juice or pulp. Foam mat drying involves drying a thin layer (0.1–0.5 mm) of the stabilized foam in air at 65–70°C within few minutes only, as the foam structure decreases drying time to about 1/3. The foam is spread on perforated floor craters as the airstream is forced through the bed. A continuous belt tray dryer as well as slightly modified spray dryer [22] can also be used to this process. Good quality tomato powder can be produced using this technique. Optimal initial concentration of feed solids is in the range of 30% for tomato pulp. The cost of such a drying process may be higher than spray or drum drying, although lower than vacuum and freeze-drying. More technical details on foam-mat drying are given in van Arsdel et al. [13].

E. Explosion Puffing

Overheating of a wet food product in a pressurized chamber, called gun, followed by a quick release of the pressure to atmospheric condition is the technique, called explosion puffing, which allows to produce a good quality, porous dry material. The amount of water contained typically in fresh vegetables and fruits, is usually too large to evaporate entirely during the explosion puffing process. An initial pre-drying of the fresh product is therefore necessary when using this technology. Table 103.5 presents some examples of practical values of this initial moisture content for the explosion puffing of selected vegetables and fruits along with some other necessary processing conditions [1, 13]. The average moisture content of vegetables and fruits in order to start the process should be brought down to 15–35%. Such partly dried food pieces are put into a puffing gun. The gun is sealed and pressurized by heating directly (superheated steam) or indirectly, through the walls (gas flame, electric heater, etc.). As the pressure and temperature inside the chamber reach a certain level (Table 103.5), the door of the gun is suddenly opened and explosion of the moisture from the food occurs. The advantages of this technique include shorter drying time (which may be lower by a factor of two or three as compared with conventional air drying), good reconstitution characteristics because of the porous structure, and good organoleptic properties. A final-stage drying is sometimes necessary after the explosion puffing.

A simple batch explosion-puffing gun is essentially a cylindrical pressure chamber with quick-release lid, and is heated internally or externally. A more sophisticated continuous explosion puffing system also has been developed which allows up to 44% reduction in steam consumption as compared with conventional dehydration [43].

F. Vacuum and Freeze-Drying

To intensify moisture removal and lower the drying temperature to protect heat sensitive food components, vacuum drying technique is employed. Some vegetables as well as herbs and spices are often dried using this technique. Typical batch or continuous drying equipment is used with some modifications to sustain vacuum created by a pump connected through a moisture condenser.

A special case of a vacuum drying, i.e., freeze-drying, is very important in food drying operations. Removal of the moisture is a result of sublimation, without of a phase change from solid (ice crystals) to liquid. Figure 103.7 presents a phase diagram of the water with an indication of

TABLE 103.5
Explosion-Puffing Processing Conditions of Some Vegetables and Fruits

Commodity	Moisture Content Before Puffing (% wb)	Steam Pressure (kPa)	Temp. of Process (°C)	Dwell Time (s)	Rehydration Time (s)
Beets	20–26	276	163	120	5
Carrots	25	275	149	49	5
Celery	25	275	149	39	5

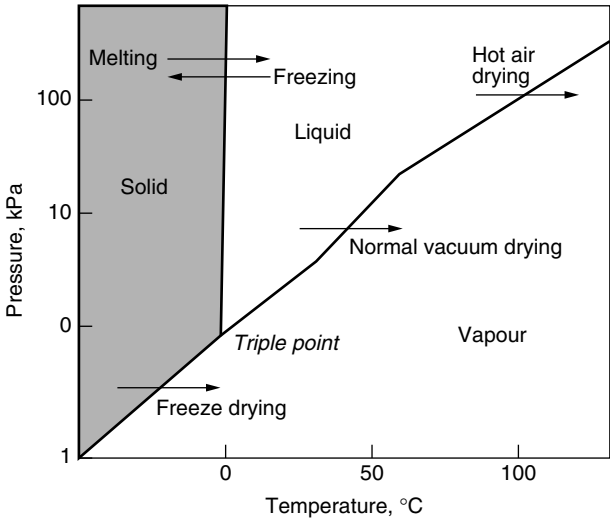

FIGURE 103.7 Phase diagram of water in application to drying process.

conditions for normal pressure air drying, vacuum drying, and freeze-drying processes. The advantage of freeze-drying over other methods of drying is the superior quality of the product obtained. Little or no shrinkage occurs. The dry product will have a porous structure and a color almost as fresh as with the raw material. The only disadvantage of this process is the high equipment and operational costs — the highest amongst all typical drying methods. This explains why the freeze-drying is only used for more expensive products such as coffee extracts, instant dry soups, powders of exotic fruits, spices and herbs. Examples of vegetable freeze-dried products are: tomato, vegetable juices and flavors, asparagus, beans, cabbage, cauliflower, celery, mushrooms, onions, peas, parsley, chives and many herbs.

FIGURE 103.8 Picture of pilot-scale freeze dryer.

There are two main stages in the freeze-drying process: (1) freezing of the food, when most of the water is converted into ice, and (2) sublimation, when the bulk or all of the ice is transferred into vapor under very low pressure or high vacuum, and this vapor is removed from the dryer. In some cases, additional final drying, in the same or other equipment, is necessary. Cabinet or tunnel batch type dryers are typically used with pressures in the range 13.5–270 Pa. Commercial high performance freeze-drying cabinets are fitted with heated shelves on which trays of frozen food are placed (Figure 103.8). Necessary to sublimation heat is transferred from the heated shelves by conduction while microwave or infrared radiation heat is sometimes additionally supplied [44]. In a tunnel freeze dryer the food is placed on specially designed trays, which are assembled on tracks. The tracks enter the tunnel through a vacuum lock. In the main tunnel, the trays move between stationary heated plates and exit through another lock at the dry end. Fully continuous freeze dryers are developed for some specific applications. Particulate

solids are conveyed by a screw, belt or vibrating plates through vacuum chambers. Spray [10] and fluidized-bed atmospheric freeze dryers [45] are examples of modifications of the typical freeze-drying process. All details on the freeze drying technique can be found in several handbooks, manuals, prospects, etc. [1, 44, 46].

G. Radiative and Acoustic Drying

Microwave drying is becoming steadily more popular in drying technology. However, research is needed, especially for bigger production scale. Drying of potato chips, peas, onions, beans and vegetable juice concentrates are examples of such applications [10].

Infrared drying is used for thin layer drying of some foods and especially spices [10]. These products are conveyed beneath infrared radiators on belts or vibrating plates. Some research work was done by Karuri [47] for infrared drying of potatoes and carrots.

Acoustic drying with waves of 12–19 kHz and intensities between 128 and 132 dB was applied to drying of green rice in a fluidized bed at 20 and 40°C. Successful combination of solar and acoustic energy for drying of different agricultural products was also reported [28].

H. Osmotic Dehydration

An example of minimal processing dehydration method of foods, especially vegetables, fruits and meats, is osmotic dehydration. The process is based on a tendency to reach equilibrium between osmotic pressure inside the biological cells (vegetable, meat, fruit, etc.) and the surrounding osmotic solution, which has an increased osmotic pressure by high concentration of soluble osmotic agent. Molecular diffusion of water through semi-permeable cell membrane takes place and the product will loose its water. The osmotic dehydration process is stopped when the osmotic pressure inside the tissue reaches osmotic pressure of the surrounding syrup. Theoretically, molecules of the solute, being large in size, do not migrate en mass from the osmotic syrup into the product. Practically, however, some migration (infusion) of the solute occurs. A net mass loss is therefore a difference between water removal and solids gain. Osmotic dehydration can provide the reduction of the water activity to some extent, which is limited mainly by the water activity of the osmotic syrup itself. For example, typical osmotic syrup, such as a sucrose solution of 60°Brix, has a water activity of about 0.85. This means that food osmotically dehydrated in the above solution would be equilibrated to a water activity of 0.85 and therefore is not necessarily safe from a microbial point of view, and a second stage of drying is often necessary. This second stage could be a typical hot air drying, solar drying as well as vacuum, freeze, microwave or any other type of drying. Several two-step drying processes, with osmotic dehydration in the first step, have been developed for some vegetables and fruits. For example, high quality dry carrot and potato products have been produced while dehydrated celery has not given satisfactory results [48].

FIGURE 103.9 Pilot-scale continuous osmotic dehydration unit (Courtesy of Food Research and Development Centre, Saint-Hyacinthe, Canada).

Typical batch-type osmotic dehydration equipment consists of a mixer tank for the syrup with heating elements to maintain temperature around 50°C; however, higher or lower temperatures are possible depending on the type of dehydrated product. Continuous osmotic dehydration units have also been developed. Figure 103.9 shows a pilot scale continuous osmotic dehydration unit applied to carrot as well as other fruits and vegetables. More detailed data on practical and theoretical aspects of fruit and vegetable osmotic dehydration can be found elsewhere [1, 15, 49, 50, etc.]. Osmotic infusion of some additives as for example caffeine, vitamins, etc., prior to regular drying, is a technique used for fortified new dry foods [51].

IV. DRYING OF SELECTED VEGETABLES

A. Carrot

Carrots can be crosscut or crinkle-cut as rings and dried as such. Starch coating may be used to extend the shelf life of the dry product because oxidation of carotene together with off-flavor and odor can be a significant problem during storage. Typically, steam-blanched and sulfited or steam-blanched and starched dices are spread onto trays at a loading of about 6 kg/m^2. Carrots are then dried in the tunnel or on continuous single or multi-conveyor driers to

a final moisture content of about 4% (w.b.). Hot air temperature in such a typical counter flow tunnel dryer is 71°C and about 7 h of drying is necessary to achieve an optimal moisture content of 8% (w.b.) in the product. Additional bin drying at 60°C through 7 h gives a final product moisture content of 4% (w.b.). A relatively fast drying (50 min) of diced carrot in continuous belt-through dryers was reported [13]. Freeze drying (temperature –33°C and absolute pressure 0.2 mmHg) as well as explosion puffing, are other drying techniques employed for carrot on a limited scale. Low-oxygen packages (vacuum, nitrogen or carbon dioxide atmosphere) with O_2-levels lower than 2% are necessary to prevent carotenoid deterioration during storage.

Sethi and Anand [52] prepared intermediate moisture (IMM) carrot slices using an osmotic solution containing sugar, glycerol, water, acid and preservatives. The processed product has good color, flavor and texture. The slices treated with 500 ppm of SO_2 and 0.45% potassium sorbate remained free from microbial spoilage at 39.2% moisture level (water activity 0.85). At low temperatures (1–3°C), the ready-to-serve product remained acceptable for 6 months in a glass container with a beta-carotene retention of 40%. More details of carrot drying technology can be found elsewhere [13, 53, etc.].

B. Beets

Peeled beets are sliced, diced or strip-cut to specific size. Steam blanching for about 6 min is used in many cases, but not always. Sulfiting of the raw beets is not practical. Tunnel and conveyor dryers of different configurations are typically used. Relatively high drying air temperatures (95–100°C) may be used in the first drying stage, however, a lower temperature of air (71°C) is desirable in the second stage. Final moisture content of beets in such a dryer is 11% (w.b.) and normally an additional drying to 5% (w.b.) in stationary bins is necessary.

Explosion puffing of dices is commercially used for a good quality dry product. Air pre-dried diced beets of 45% moisture (w.b.) are processed in a puffing gun. They are heated to the pressure of 0.3 MPa in steam and then the pressure is quickly released to the atmospheric level. The exploded product, which has lost about 5% moisture, is then finish-dried on trays, continuous belt, etc. The porous structure of the final product results in much lower dehydration time than conventional drying techniques.

C. Onion and Garlic

Dried root vegetables, onion, garlic, potato, etc. have found extensive use in food manufacturing both in dry product formulation and as well as ingredients for wet soups, baby foods and ready or canned meals [6, 13].

a. Onion

Onions are generally dehydrated and pickled. The cultivars with 15–20% total solids content (dry matter) are preferred for dehydration. Onions used for processing should have high pungency, since the dehydrated product is primarily used as a flavoring agent and some pungency is lost during the drying process. Southport White Globe and White Creole are suitable cultivars for dehydration. Sliced, flaked or kibbled onions are mostly dried on continuous belt conveyors or tunnels to a target moisture content of 5% (w.b.) or less. Onions are normally not blanched to avoid the flavor loss that would otherwise occur during this process. When dried in tunnel-type dryers, the sliced onions are automatically spread on wooden trays with a unit load of about 5 kg/m^2. The trays are automatically stacked on cars and conveyed through a typical two-stage tunnel dryer. In the first (co-current) stage, hot air of temperature 70–88°C is normally used and in the second (countercurrent) it is 55–60°C. After 10–15 h the dry material has 5–7% moisture, which may then be dried, in bins to the final moisture less than 5%.

A more practical equipment for onion drying is a multistage continuous belt-conveyor. A stainless-steel perforated belt is normally used with hot air flowing through the belt and a bed of onion slices of 10–15 cm in thickness. The temperature of the drying air is gradually reduced from about 80° to 55°C as the sliced onions move through the dryer. The average drying time is 6 h with a final moisture content of 6% (w.b.). An additional drying (12–30 h) in stationary bins using partially dehumidified air of 43.3–50°C gives the final product of 4% moisture or less. The product may be passed between revolving metal rolls to flake and screened to remove fines (small broken pieces).

A small proportion of dry onion is produced by freeze-drying. Sun-drying of sliced onions is carried out in some areas [6].

For commercial use, sliced, chopped, minced, granulated, or powdered dry onion is produced. High hygroscopic dry onion products require special low air-humidity atmosphere in the final processing stages such as screening, grinding and packaging. A variety of moisture-resistant containers, such as plastic or aluminum bags, jars, clipboard boxes and metal cans, are used for the retail market.

b. Garlic

In the North America the bulk of the garlic production is dehydrated. Garlic is a basic flavoring for multitude of dishes ranging from vegetable soups and sauces, meats, salads, tomato products, spaghetti, sausages, pickles, etc. Fast food restaurants and steak houses invariably offer garlic bread, garlic butter and salt. All other forms and types of dry garlic products, as for onion, are commercially available.

Drying technology of garlic is almost the same as that of onion [6, 13]. The garlic bulbs are broken into individual

cloves, washed, sliced, and then dried up to 8 or 6.5% (w.b.). Compared to the onion, garlic has a considerably lower initial moisture content. The garlic is dried for a short time in an unheated air current to separate the cloves. They are then passed between large rubber rolls, taking care that the cloves are not crushed and the clumps of garlic are broken up into individual cloves. After separating pieces of paper husks, cloves are graded into several sizes. Pieces of skin and other light debris are also separated by floating the cloves in water one to two times. The cloves are separated from water by dewatering screens. They are next sliced by special revolving, very sharp knives and spread automatically on trays or on perforated stainless steel belt of a continuous dryer. Two-stage dehydration is employed in tray-and-tunnel dehydration. The sliced garlic is dried to about 8% moisture, the drying being completed in bins at 43.3 to 48.9°C to less than 6.5% moisture to produce all forms of dried product.

D. Other Vegetables

Many other vegetables are being dried. However, it is to a much less extent than what was described above. Generally, similar drying methods and conditions can be used for most vegetables. Gentle drying conditions are recommended as vegetable tissues are very heat sensitive.

a. Green beans

Green beans are dried on the trays of tunnel dryers or in belt dryers, either while still frozen or in a thawed state. A two-step tunnel drying is recommended; first at 90°C and then at 62°C. A final moisture content of 5% (w.b.) is typically a target value.

b. Cabbage

Cabbage, typically, is cored, trimmed, washed and shredded by kraut cutters before blanching and sulfiting. The pre-treated material is dried in a two-stage tunnel dryer with an inlet air temperature of about 80°C in the first (parallel air flow) stage, and 60°C in the second (counter-current air flow) stage. A finish drying step from the moisture content of about 7 to 4% (w.b.) is provided in stationary bin dryers, supplied with an air at 50°C. A strong compression of the dry product before packing was a standard procedure for cabbage packed in cans during World War II, but this procedure is not in use anymore.

c. Sweet potato

The sweet potatoes are peeled before dehydration in abrasive peelers, steam, or lye-peeled in 15 to 20% sodium hydroxide lye solution. Peeled sweet potatoes are then washed thoroughly, trimmed, sliced or cut into strips or diced. After thorough steam-blanching for about 7 min, they are dehydrated on trays at about 71°C to a moisture content of less than 7%. The tray load is about 5–8 kg/m^2. A cultivar, Goldrush, is recommended for a freshly dehydrated product of highest quality [6].

d. Mushrooms

They are processed into more durable products in various ways. They can be air-dried, freeze-dried, canned or frozen. The processed mushrooms are prepared as buttons, whole or sliced. Being very perishable, mushrooms should be processed as soon as they are harvested, within a period of few hours. More expensive mushroom varieties are freeze-dried while less expensive air-dried. For use in dehydrated soups and specialty products they are mainly freeze-dried (6).

A lot of practical information of other vegetable dehydration procedures can be find in specialized literature and recent publications [1, 6, 13, 54, 55, etc.].

V. SPICES

The quality of dry spices, culinary herbs and spice blends is strongly affected by the drying method and drying conditions that are applied. The main attribute of spices is the improvement of food flavor and taste by some characteristic components, especially volatiles. These components are very heat-sensitive and they should be preserved (to prevent evaporation or decomposition) to the maximum level during all processing steps. The drying process involves some thermal treatment, so the drying method and the conditions should be very delicate and individually chosen for each type of spice or herb. Low temperature natural or artificial drying is the common practice.

The measurement of moisture content in spices presents some unusual problems. Moisture is usually measured in food products by measuring the weight loss of a sample during a drying test at elevated (around 100°C) temperature or under the vacuum. The volatile oils, typically existing in spices, are also lost during drying and this weight loss would be measured as moisture. To resolve this problem, the trade has adopted a co-distillation method for most spices. In this test, the spice is covered with toluene and the toluene brought to its boiling temperature. The moisture in the spice co-distills with the toluene and as the toluene is condensed, the moisture separates from the toluene and is measured. Karl Fisher titration could be also employed for some spices while for other spice products (paprika and other capsicum, etc.) a standard drying oven test is sufficient. Vacuum drying techniques are also frequently used to evaporate moisture at lower temperatures.

The final moisture level in dry spices is of practical importance, as for all other perishable foods. It should be low enough to prevent microbiological growth but not too low to overcome some unfavorable changes in an over-dry tissue such as color losses and increased hardness. An

average of 10% moisture content (w.b.) is desirable for most spices. Detailed data on several typical dry spice chemical and physical specifications and applications are presented by Charalambous [56], Tainter and Grenis [57], Richard [58], Farrell [59], Rosengarten [60] and Purgelove et al. [61].

Sun and field drying of spices and herbs is the oldest and still the most typical drying method for the majority of these products. In many cases direct exposure to the sun can create discoloration of the spice or herb tissue so shadow-open-air or cabinet drying is applied. Larger scale drying of spices and herbs is performed as for drying of typical fruits and vegetables (e.g., tunnel and conveyor dryers). Multi-step processing, with hot air temperatures decreasing with the advance of drying (for example, 110°C initially, then 60°C and 40°C at the end of drying) is very typical. More details of preparation, drying, characteristics and application of the spices can be found in other references [56–61].

VI. CONCLUDING REMARKS

Vegetables as well as fruits, spices and herbs play an extremely important role in human nutrition. Additionally, the recognition that the intake of nutrients, minerals, and antioxidants (vitamin C, E, etc.) may have a protective role against illnesses and tiredness will mean that vegetables and fruits — a potent source of relevant nutrients, minerals and vitamins — will be in demand. However, these have to be preserved in a form that protects these constituents. It is likely that the market for fresh, frozen and properly dried vegetables and fruits will outgrow other forms of processing in the short term. For drying technology, this means that only the methods giving an appropriate quality of the final products may have good practical perspectives. Research should be dedicated to the development of proper drying processes. An improvement of existing as well as the introduction of new drying techniques are equally important aspects of the drying research. For spices, it is well known that they have not only the taste and flavor effect on the food, but some antioxidant and microorganism inhibition activity too. Proper drying techniques have to be applied to each individual product to ensure the highest quality in the product. Energy and environmental aspects of this process should also be considered.

CONTENTS

I. INTRODUCTION

Tropical fruits are defined as those fruits that grow well in the tropical region (between the Tropic of Cancer in the north and the Tropic of Capricorn in the south), the region where the temperature and the length of the day varies little throughout the year and frosting scarcely occurs. The fruits are rich sources of vitamins, especially A and C, minerals, carbohydrates and flavour for the people of the tropical regions and beyond. Although most tropical fruits are cultivated for fresh consumption, a few of them including avocado, banana, carambola, coconut, guava, kiwi, lychee, mango, papaya, passion fruit and pineapple undergo significant processing before consumption (1). However, they are highly perishable and in the absence of adequate modern handling, transportation and storage facilities in these regions, there is considerable loss due to spoilage which is aggravated by high ambient temperatures

(22–32°C) and humidity and prevailing unhygienic handling practises (2). Among the several process technologies, the major ones being canning, freezing and dehydration, which have been employed on an industrial scale to preserve fruits, dehydration is especially suited for developing countries with poorly established low-temperature and thermal facilities. Drying brings about substantial reduction in weight and volume, minimising packing, storage and transportation costs, and storability of the dried product under ambient temperatures, features that are especially important for developing countries (3).

Fruits may be dried in one of the following forms (4): as whole forms (e.g., various berries) using sun drying, solar cabinet drying and hot air drying; as sliced, chopped or particulate forms (e.g., banana, mango, papaya, kiwi) using hot air drying (with conveyors or trays), freeze drying, and vacuum drying; and as pastes or suspensions using spray-, drum-, and solar drying.

The aim of this chapter is to present an overview of techniques and applications developed for the drying of tropical fruits and their products. The current trends in drying, involving combination drying methods are presented in as far as tropical fruits are concerned. The reader is referred to the literature cited for further details about the methods.

II. METHODS OF DRYING TROPICAL FRUITS

A. Sun and Solar Drying

The traditional open-air sun drying of agricultural crops has been practised since the beginning of civilisation and is by far the most widely practised agricultural processing operation in the developing countries (5). In sun drying, the product is spread on floors or raised platforms and exposed to the direct sun radiation and natural air currents. Occasional stirring of the product is done to expose most of it to the sun and thus speed up the removal of saturated air from the product (6).

The long history of sun drying has not been without drawbacks, which limit its use for large scale production. The drawbacks include: difficulty in controlling the drying rate, the requirement of more land and labour for spreading the product, infestation by insects and microbial contamination (7). Some of these drawbacks however, can be addressed by using solar drying, since this gives improved quality products and has significantly less drying time than open-air sun drying (8).

Solar dryers are identified according to their method of collecting solar energy and transferring it to the product as indirect, direct and mixed-type (also known as convective, radiative and radiative-convective dryers respectively) (9). Solar dryers that use air as the main transport of heat to the drying product may be either free- or forced- convection type.

FIGURE 104.1 Direct solar dryer at NARO-National Banana Research Programme, Kawanda, Uganda.

In the direct solar dryer, the product absorbs direct sun radiation, which passes through a transparent cover or side panels. Evaporation takes place principally from the top surface of the product, which also conducts some of the absorbed heat to the interior of the product. A direct solar dryer is shown in Figure 104.1.

Indirect dryers have a separate compartment, the collector, in which air from the ambient passes through and is heated before passing through the drying chamber. The hot air performs two functions; it supplies the necessary heat to evaporate moisture from the product as well as carry away the evaporated moisture.

The mixed-mode type of dryer combines the features of both the direct and indirect type of dryers (10). The product is therefore dried by a combination of both direct radiation with conduction of heat into the top product and convection of hot air from the collector entering the bottom of the drying bed. Mixed-mode solar dryers give higher drying rates compared with other types of solar dryers (11–13). A mixed-mode solar dryer is shown in Figure 104.2.

Although the use of solar drying has advantages such as free, non-polluting and renewable energy source, the periodic nature of solar energy requires an auxiliary source of energy from fuel or electricity for use during periods of no or low radiation (8). Bolin and Salunkhe (14) have reviewed solar drying methods with and without auxiliary energy source. Further, part of the energy gained during radiation periods can be stored and used later during no or low radiation periods.

Pablo (15) studied the comparative performance of a polyethylene solar dryer with sun drying for drying banana, jackfruit, mango and papaya and found that the polyethylene dryer produced fruits with a better colour and texture than sun drying. Furthermore, the solar dryer reduced the drying time by 25–40%. Similarly, Kalra and Bhardwaj (16) dried mango slices and leather in two solar

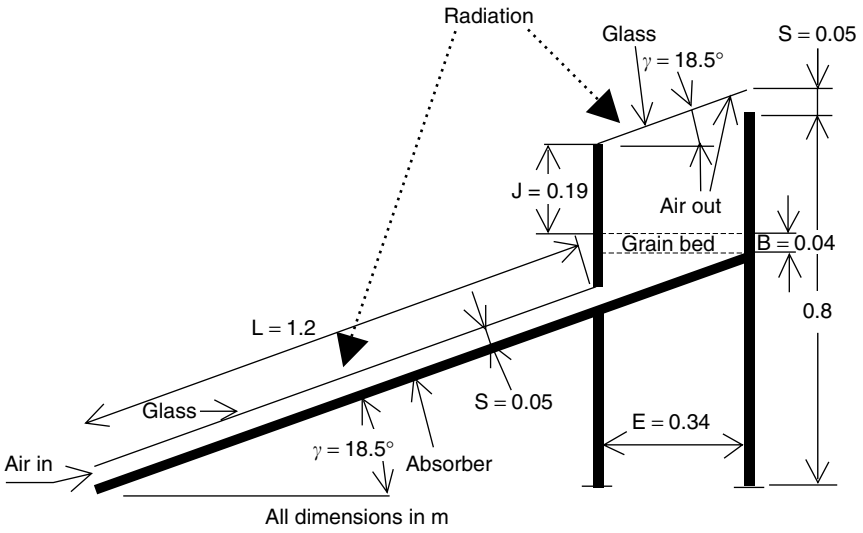

FIGURE 104.2 Schematic representation of mixed mode solar dryer (source ref. 10).

dryers, a direct type and an indirect type, which were suitable for small scale industries and for use in rural areas, and compared their performance to open-air drying. The direct dryer attained temperatures of 10–20°C while the indirect one attained 20–25°C above ambient temperature. The direct dryer reduced the moisture content to 7% in 8 hours while the indirect type reduced it to 6% in 7 hours compared to a reduction to 8% in 9 hours for open-air drying.

Coleman (17) dried mango slices in two small scale solar dryers, one using natural convection and the other using forced air circulation and found that the drying rate was higher with the forced circulation dryer. Higher drying rates for forced convection dryers compared to natural convection have also been reported by Wilhelms and Mullins (18) for drying apples, and Trim and Ko (19) for drying capsicum peppers.

In a study (20) to determine the effect of SO_2 on the quality of solar dried mango, mango slices were soaked in various concentrations of sodium bisulphite followed by solar drying and hot air drying. It was found that fruits prepared for solar drying required greater concentration of sodium bisulphite than those prepared for hot air drying. Also, the SO_2 treated solar dried fruits had better flavour than the hot air dried ones.

Other studies on solar and sun drying of tropical fruits related to modelling, quality of the dry product, production of snacks, fruit leathers and bars, and performance of dryers are given in Table 104.1 in references (21) to (38).

B. Hot Air Drying

In convective drying systems, the drying process takes place in an enclosed chamber where hot air is passed over the product which results in simultaneous heat and mass transfer between the air and the drying product. Energy is supplied from the air stream to provide the heat for evaporation of moisture from the product and at the same time, the evaporated moisture is carried away from the product by the air stream (3). The most common of these dryers used for fruits are cabinet, kiln, belt and tunnel dryers (4).

A typical cycle of air drying comprises three stages, namely: the equilibrium stage in which the food is heated to the drying temperature, the constant rate period in which water is evaporated from the saturated surface of the food at a rate proportional to the moisture content and the falling rate stage starting after the critical moisture content is reached, in which moisture is held internally within the food and the moisture has to overcome a resistance to flow through the porous food material to the surface (39). Factors to be considered when drying heat

sensitive solids are that during the constant rate period, the solid surface temperature becomes equal to the wet-bulb temperature corresponding to the air temperature and humidity at the same location and, during the falling rate period, the temperature of the solid approaches the dry-bulb temperature of the air (40).

Fruit leather, one of the traditional fruit products that has evoked renewed interest in recent years because of its convenience, ease of preparation, shelf stability, simple packaging requirements and nutrition, is prepared by air drying (commonly tray drying) of fruit puree in the form of sheets (41). In improved and standardized methods for mango leather production reported by Rao and Roy (42), the puree is spread evenly at a thickness of 1 cm on a metal tray that has been smeared with glycerine. The puree is then heated at 50–80°C for 2–20 hours until a leathery product with 15–20% moisture content is obtained.

Jayaraman (2) used a cabinet dryer to dry fruit bars with a soft gel like structure which were suitable for direct eating, from the pulp of several tropical fruits. To the pulp was added sugar and pectin before cabinet drying in three phases as follows: initially at 80°C for 1 hour, then at 70°C for 2–3 hours and finally at 65°C for 5–6 hours.

Other studies on hot air drying of tropical fruits related to modelling and drying kinetics, quality and storage of dry products, production of dry fruit products and performance of dryers are given in Table 104.2 in references (43) to (69).

C. Drum Drying

Drum dryers are generally used to produce powdered and flaked ingredients widely used in bakery products, beverages, cereals and dairy products. In this system of drying, the product to be dried, usually fluid, slurry, or paste like form, or in suspension or solution if it is solids, is spread in a thin layer on the surface of an internally heated revolving drum with the dryer comprising either a single or double drum and the drying operation typically continuous (70). Although the drying rate is affected by the thickness of the film applied to the drum surface, the speed of rotation and the temperature of the drum, drum dryers have high drying rates and use heat economically (71). Figure 104.3 shows a double drum dryer.

Mao (72) studied drum drying of banana puree, with special reference to factors influencing the quality of the dried product. Drum rotation rate and drum temperature influenced the colour, moisture content and flavour of the dried product, but had no effect on texture. Drum speeds greater than 2 revolutions per minute and drum temperature less than 142°C gave the best results. Drum clearance influenced the texture and moisture content of the product. Monostearin and lecithin emulsifiers when added to the puree gave excellent film formation on the drum, excellent rehydration properties, and excellent texture of the rehydrated puree, but brittle and powdery dried flakes. Egg yolk gave excellent texture of both the dried and the reconstituted product.

A double drum dryer was used by Brekke *et al.* (73) to produce mango flakes and powder to a moisture content of less than 3% under the operating conditions of steam pressure of 4.2 kg/cm^2, drum spacing of 0.254 mm and residence time of 25 s.

Kitson and MacGregor (74) found that with drum drying, fruit purees with a relatively high fibre content (e.g., banana, guava, papaya) could be successfully dried without additives while low fibre ones required the addition of fibre (e.g., less than 1% low methoxyl pectin) to aid sheet formation at the doctor blade.

Travaglini, Carvalho, Ruiz and Shirose (75) dried mango puree using a convectional drum dryer and found the process to be suitable for the production of mango

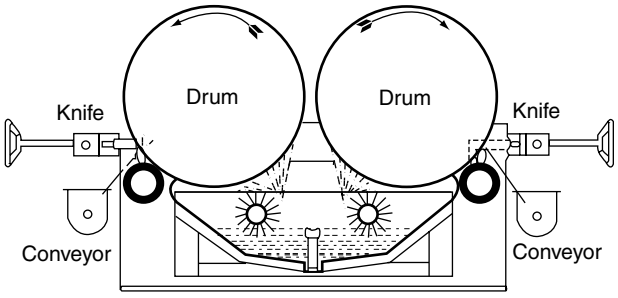

FIGURE 104.3 Double drum dryer (source ref. 70).

flakes. Under operating conditions of steam pressure of 60 psig, drum spacing of 0.06 inches and residence time of 20 s, improved quality flakes were obtained with ascorbic acid and beta-carotene retention of approximately 90%. Furthermore, an addition of 1% glycerol monostearate (MSG) and 4% corn starch to the puree improved the drying process.

D. Spray Drying

Spray drying process is used to transform feed from fluid form into droplets and then into dried particles by continuously spraying it into a heated drying medium. With this method, high drying air temperatures can be applied, resulting in high evaporation rates which maintain a low droplet temperature, and very short drying time compared to other drying processes, thus making it suitable for drying very heat sensitive materials (76).

A two-stage process, consisting of a combined spray-drying and through-flow bed stage was used to produce pineapple solids with less than 2% moisture content (77). The fruit juice is atomized under high pressure as it enters the spray-drying chamber. The atomized particles are mixed with heated air and fall onto a mesh-type conveyor belt where the partially dried particles form a porous mat through which the drying air from the chamber passes. The combination process enables dry crystalline sugars to be obtained on a continuous basis from sucrose, dextrose and lactose syrups.

King (78) added milk or soy milk to an equal volume of banana products diluted with various amounts of water and spray dried at different inlet temperatures. Drying rate and productivity both increased with increasing inlet temperature. At the same inlet temperature, the best drying rate and productivity were with 3x water dilution for banana-milk (BM) samples and with 2x and 1x water dilution respectively, for banana-soy milk (BSM) samples. Hygroscopicity and bulk density of the powdered product decreased with increase of drying air temperature, and the higher the drying rate the lower was the bulk density. The powdered products were light yellow in colour, and had good flavour and taste.

Parameters for the production of instant mango juice powder were studied by Khalil and Sial (79). Mango juice of 23°Brix, with or without addition of 0.25 or 0.5% sodium alginate or glyceryl monostearate, was spray dried with drying outlet temperature of 70–80 or 80–90°C, and voltages of 200 or 250 (which influenced atomization speed). Colour, flavour and taste were good only in the samples without additives.

A study (80) in which dehydrated fruits and fruit powders were prepared by osmotic drying, foam-mat drying and spray drying, and used in suitable combinations along with puffed cereals in the formulation of recipes for compressed ready-to-eat fruited cereals is reported. The products from banana, mango, pineapple and tomato were highly acceptable. The formulations packaged in an inner wrap of cellophane and an outer pouch of paper-aluminium foil-polyethylene laminate were acceptable at more than 6 months at 37°C and for 1 year storage under ambient conditions (20–30°C) except those with osmotic dried fruits wherein hardening of the fruits due to moisture transfer was noticed beyond 6 months under ambient conditions. Microbiological levels in the ingredients and formulations were within safe limits for direct consumption.

E. Osmotic Dehydration

Osmotic dehydration is a process involving partial removal of water from cellular materials like fruits and vegetables by immersing these materials in concentrated solutions of soluble solutes such as sucrose for fruits, and sodium chloride, for vegetables (81, 82). Figure 104.4 shows a flow chart of the osmotic dehydration process.

In this process, a chemical potential of the solute is created and this causes mass transfer of the solvent from a dilute to a concentrated solution through a semi-permeable membrane in order to equalize the potential (83). The nature of the cellular structure of fruits and vegetables is to act as non-perfect semi-permeable membranes resulting in not only transfer of water and small solutes from the tissue into the solution but also a smaller counter transfer of solutes from the solution into the tissue cells (84–86).

The rate at which osmotic dehydration takes place depends on the concentration and temperature of the osmotic solution, the nature and molecular weight of the osmotic solution, the product geometry and size, the product structure (e.g., porosity), the ratio of the mass of the product to that of the osmotic solution, the rate of agitation of the osmotic solution, and pressure (high pressure, ambient or vacuum) (87–91).

Heng, Guilbert and Cuq (92) studied the effect of temperature, concentration and nature of dehydration solution and preliminary calcium adjunction or blanching during osmotic dehydration of papaya cubes. They found that

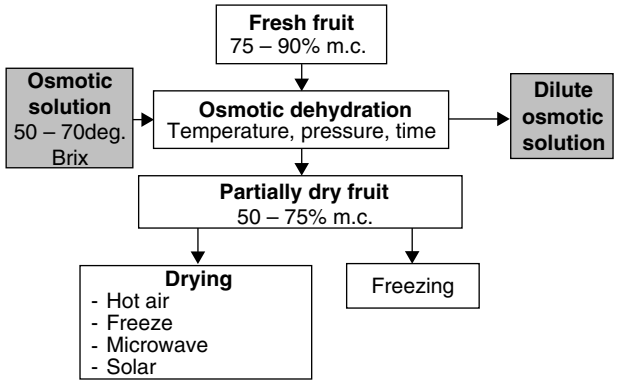

FIGURE 104.4 Flow chart of osmotic dehydration process.

increasing the temperature (from 30 to 70°C), increasing the concentration of the dehydration solutions (45 to 72°Brix), addition of calcium (0.05 M), no preliminary blanching and/or substitution of sucrose with a low DE glucose syrup, all increase water loss without increasing sugar penetration. Similarly, Waliszewski, Texon, Salgado, and Garcia (93) studied the effects of temperature (50, 60 and 70°C), sucrose concentration (50, 60 and 70°Brix) and pH (6, 7 and 8) on the mass transfer during osmotic dehydration of banana chips. They found that temperature and osmotic solution concentration favour faster water loss yielding also higher water loss/sugar gain ratio. Furthermore, water loss and sugar gain took place in parallel and the rate of water loss was always higher than the rate of solute gain. Panagiotou, Karathanos, and Maroulis (94) investigated mass transfer phenomena during osmotic dehydration of banana and other fruits in glucose and sucrose osmotic solution. They found that low molecular weight solute (glucose) leads to higher water loss and solids uptake than high molecular weight solute (sucrose) of osmodehydrated fruits under the same solution concentration.

The osmotic dehydration process may occur at low temperatures such as at ambient and does not involve a phase change thereby minimizing heat damage to the quality attributes like flavour, colour and texture of the product (95). Other advantages of osmotic dehydration include elimination of chemical pre-treatment, efficiency in energy use, reduction in packaging and distribution costs and, product stability in terms of quality and nutrient retention during storage (96, 97).

The osmotic dehydration process does not result in a product that can be considered shelf-stable and further drying by other methods such as air, freeze, or vacuum drying is done to make the product shelf-stable, or the process can be a pre-treatment for canning, freezing and minimal processing operations (98).

Other studies on effects of osmotic dehydration process variables on colour, mass transfer, storage of the dried product and rehydration, and modelling the osmotic dehydration process of some tropical fruits are given in Table 104.3 in references (99) to (133).

F. Freeze Drying

In freeze drying, the substance to be dried is usually frozen and the water is removed from the substance as a vapour by sublimation from the frozen material in a vacuum chamber (134). Although freeze drying is considered as the reference process for the high quality of dehydrated products, the process entails relatively high costs, as much for investment (vacuum technology) as running costs, and these are the reasons why its use in food is limited to high value added products (135).

G. Emerging Technologies

1. Microwave Drying

Microwave heating of foods is accomplished by the absorption of microwave energy by rotation of dipolar water molecules and translation of ionic components of food. When a microwave field that rapidly changes direction is imposed on the dipolar water molecule, the dipole tries to align itself with the field direction. Some response time is required for the water molecule to overcome the inertia and the intermolecular forces in the water, resulting in energy loss to the random thermal motion of the water and giving a temperature rise. The thermal energy developed in the material is related to the frequency of the electric field, the electric field strength in the material and to the dielectric loss factor of the material (136).

Garcia, Leal and Rolz (137) carried out drying tests for ripe and green banana slices and for a foam made from ripe banana puree in (i) a household microwave oven and (ii) a laboratory forced draft warm air oven. They found that the drying time in (i) was 17–20 times lower than that in (ii) and the drying energy efficiency in (i) was about 30%.

However, for initial drying operations, in particular with very high moisture products, conventional drying is

TABLE 104.3

more economic and efficient which makes microwave drying more suitable for finish drying operations (138).

It is therefore usual to combine microwave drying with hot air drying because this usually improves the efficiency and economics of the drying process, with the hot air being relatively efficient at removing free water at or near the surface and the unique pumping action of microwave drying providing an efficient way of removing internal free water as well as bound water (139).

2. Heat Pump Drying

There has been great interest in recent years to look at heat pump drying system as a substitute for freeze drying where, low temperature drying and well-controlled drying conditions are required to enhance the quality of products (140). The advantages of a heat pump dryer are: higher energy efficiency, better product quality, wide range of drying conditions and excellent control of drying environment. Its limitations are: use of CFCs in the refrigerant which pollute the environment, need for regular maintenance, increased capital costs, limited drying temperature and need for process control and design.

Prasertsan and Saensaby (141) dried bananas in an experimental heat pump drier (HPD). The moisture extraction rates (MER) and the specific moisture extraction rates (SMER) of banana drying decreased rapidly with the drying time but the compressor power was relatively constant. Banana drying yielded the highest average MER of 2.710 kg/h when the drying load was highest. The corresponding SMER was 0.540 kg/kWh. Economic analyses of the HPD compared to an electrically heated hot air dryer and a direct-fired dryer revealed that the HPD had the lowest operating cost.

Moisture and ascorbic acid (vitamin C) contents of batch-dried skinned, peeled and sliced guava were measured under several cyclic temperature profiles of the drying air maintained at constant humidity (8.9 g/kg dry air) using a two-stage heat pump dryer (142). Results on ascorbic acid degradation in guava during drying followed first-order kinetics for both isothermal and non-isothermal drying air conditions. Cyclic air-temperature drying yielded higher retention of ascorbic acid.

Chua, Hawlader, Chou and Ho (143) studied the effects of different time-temperature profiles on the drying time and colour change of bananas and guavas, using a tunnel heat pump dryer capable of providing less than or equal to 14.6 kW of cooling capacity. Samples of banana and guava were dried in batches in a 2-stage heat pump drier. Effects of starting temperature (20–35°C) of a selected profile and cycle time (60–120 minutes) on drying kinetics and product quality were studied. Results indicated that by employing a step change in drying air temperature with the appropriate starting temperature and cycle time, it was possible to reduce markedly food drying time required to reach the desired moisture content with improved product colour.

III. COMBINED METHODS OF DRYING TROPICAL FRUITS

A. Osmotic and Sun/Solar Drying

The combination of osmotic dehydration and sun/solar drying has potential for widespread application in drying tropical fruits with good quality and at reduced costs. Firstly, there is a growing and urgent need for simple inexpensive processes to preserve fruits and vegetables in developing countries in tropical regions to minimise losses due to spoilage, and intermediate moisture food technology involving soaking fruits/vegetables in sugar solution, is appropriate for such regions (2). Secondly, the availability of solar energy and the operational marketing and economy reasons offer a good opportunity for using solar drying in the developing countries (8).

Levi, Gagel and Juven (144) studied the effects of short heat (boiling temperature) treatments, consisting of 'blanching' in concentrated sucrose (70%) solution (I), or plain water (II), or osmotic dehydration in cold (room temperature) (III), or hot (boiling) sucrose (70%) solution (IV), and a combination of (III) following (I) or (II), on drying behaviour of papaya, dehydrated to the intermediate moisture (IM) range. Significant increases were observed in dry matter content of I, III, IV, or III following I or II, with the obvious increase in expected production yields and probable reduction of heat energy needed for drying. The drying behaviour of papaya as a raw material for IM products, during and after the above treatments, as well as following hot-air (cabinet) or direct-sun drying, was studied. Drying time needed for cabinet or solar drying following osmotic treatments was considerably shortened, and therefore a significant saving in heat energy could be expected. The optimal treatments to achieve a considerable short drying time, without reducing the quality of IM papaya, seemed to be syrup 'dipping,' or a combination of water or syrup blanching and cold osmotic dehydration. The results are shown in Figure 104.5.

In another study (145), papaya slices were pre-treated as follows: (i) no treatment, (ii) syrup blanch (5 minutes boiling at 70°Brix), (iii) 5 minutes boiling water blanch, (iv) 90 minutes boiling syrup (70% sugar), (v) cold syrup immersion for 24 hours, and (vi) combined (iii)/(v) followed by treatment with/without 5000–10 000 ppm potassium sorbate solution (10–15 min contact time in dip) then dehydration by cabinet or sun drying to about 70% dry matter. Samples were analysed for total soluble solids, acidity, pH, ascorbic acid (AA), colour, pectin esterase activity, total carotenoids, water activity, and microbial quality (total aerobic counts, viable count of 'sugar tolerant' micro organisms). The highest ascorbic acid retention (66–91%)

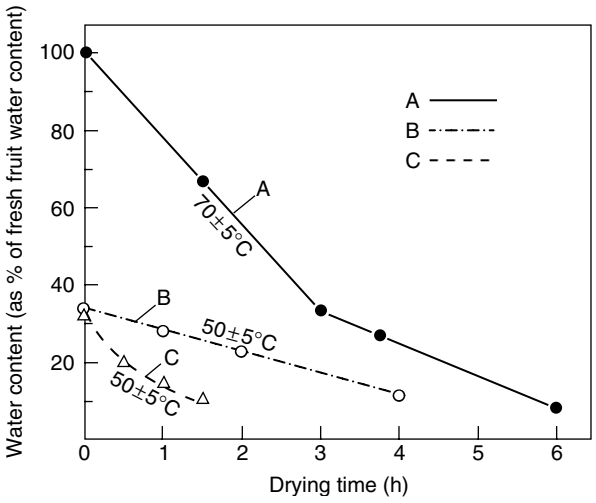

FIGURE 104.5 Drying behaviour of cabinet dried papaya (A — direct drying; B — after 75 min in boiling sugar (70%) syrup; C — after 22 hr in cold syrup) (source ref. 144).

TABLE 104.4
Effect of Pre-Treatments and Drying Method on the Ascorbic Acid (mg/100 g Product) Content of Intermediate Moisture Papaya Slices (Adapted From (145))

Treatment No.	Pre-Treatment	Drying Method	
		Cabinet	Sun
I	None	441	193
II	Syrup blanch (5 min boiling 70% sugar)	263	156
III	Boiling water blanch 5 min	269	134
IV	Boiling syrup (90 min; 70% sugar)	68	–
V	Cold syrup (70% sugar)	161	144
VI	Combined III and V	74	73

was observed in papaya slices directly dried in a cabinet, followed by those that were water blanched + cabinet dried (58–73%) (see Table 104.4). Significantly lower retention of ascorbic acid was observed in sun dried samples. Most products maintained their typical orange colour and their carotenoid content. Total carotenoids content of sun dried slices was lower than that of cabinet dried samples. The relationship between moisture content and water activity value suggests that intermediate moisture papaya products with a moisture content of 28% will be relatively stable microbiologically. They concluded that intermediate moisture papaya products are a promising means of utilizing surplus papayas in developing countries, due to their attractive colour, flavour and other quality characteristics.

Design and construction of a solar osmotic dryer to test the utilization of solar energy in a two step osmovac dehydration of papaya is reported (146). The samples dried by solar osmotic procedure had higher drying rates and sucrose uptake than those dried without solar. Furthermore, drying rates obtained with solar vacuum drying were twice those of vacuum drying without solar.

Uzuegba and Ukeka (147) investigated the combination of osmotic and cabinet or sun drying. Fully-ripe banana, mango and pawpaw slices were cabinet dried or sun dried to 15% moisture, with or without predrying by holding them in saturated sugar solutions (21 kg sugar/10 l water) containing 0 or 1% potassium metabisulphite (PMBS) for 24 hours. Moisture and ascorbic acid concentration of the slices were determined before and after drying and after 12 months of storage in sealed cellophane film at 28–30°C; flavour was evaluated by 8 judges after storage. The best treatment for ascorbic acid preservation and flavour retention appeared to be osmotic dehydration in 1% PMBS solution followed by cabinet drying.

B. Osmotic and Hot Air Drying

Osmotic dehydration has been combined with conventional methods of drying such as hot air drying with the aim of producing better quality shelf-stable products than would be obtained with convectional methods alone. Jackson and Mohamed (148) osmotically dried some mangoes and bananas followed by air drying and found that osmotic dehydration of fruit reduces heat damage to colour and flavour, and loss of fresh fruit flavour, and also prevents enzymatic browning of the fruit and that the process could be carried out with very simple equipment. However, treatment of papaya and guava was not successful.

Rahman and Lamb (149) analysed the air drying behaviour of fresh (non-osmosed) and osmosed pineapple. Pineapple slices of 6.5 mm thickness were osmodried in sucrose solution of 40–60% (m/v) for 5 hours after which they were dried in air at 10% relative humidity, 4 m/s air velocity and 60°C temperature. Non-osmosed samples gave the highest drying rate while osmosed samples at 60% sugar solution and 60°C gave the lowest drying rate. The lower drying rate was due to solute uptake, which resulted in higher internal mass transfer resistance.

In an experiment to determine the effect of initial water activity of mango slices on air drying behaviour at 50, 60 and 70°C with osmotic dehydration pre-treatment, Welti, Palou, Lopez-Malo and Balseira (150) found that the time needed to reach a moisture content of 0.7 g water/g dry solid was 50–75% lower for osmotically dehydrated mango slices than for fresh ones.

Osmotically dehydrated banana slabs were air dried in a cabinet type tray drier to near equilibrium conditions at fixed temperatures from 40 to 80°C and at a constant air speed of 0.62 m/s (151). The drying air temperature was found to significantly enhance the drying rate and the drying constant except at 80°C when the rates fell, possibly due to case hardening of the slabs. The drying rate was also

improved by reducing the slab thickness, but increasing the air speed to 1 m/s did not have any profound effect.

Osmotic dehydration can be applied as a pre-treatment for fruit or fruit pieces, whereby the fruits are soaked in a sugar syrup of 75°Brix at 60–70°C for 1 hour to remove some of the water before further drying or freezing (152). The resultant fruit retains most of the fresh fruit flavour. Enzymatic browning is reduced, the colour is improved without using SO_2, and the loss of fresh fruit flavour is reduced because of the sugar layer surrounding the fruit or fruit pieces. For example, banana slices dehydrated in 70°Brix syrup for 10 hours and then dried in a vacuum-shelf dryer at 10 mm Hg pressure at 70°C for 6 hours resulted in dry slices that were porous, crisp and had retained very nearly their original size and shape.

A combined osmotic drying and air drying process for bananas is described (153). Banana slices (10 mm thickness) were soaked in 2 successive sucrose baths with concentrations of 35 and 70°Brix and both at pH of 3.5. The first bath contained 1% $CaCl_2$ to enhance firmness and this solution was initially heated at 85°C and then cooled slowly to room temperature over 24 hours. A fruit to solution mass ratio of 1:6 was used in the first soaking process. The second soaking in the solution at 70°Brix was conducted at room temperature using a fruit to solution ratio of 1:4. This second treatment served to increase the sugar content of the banana slices, extend the degree of water loss, and maintain good texture and shape in the product. The combined osmotic drying process resulted in a weight reduction of 60% and a solute gain of 2%. Slices were then subjected to air drying at 40°C and relative humidity of 60% for 72 hours. The final dried product had a moisture content of 16%, an average water activity of 0.54 at 25°C and a highly acceptable colour without any brown pigmentation.

C. Osmotic and Microwave Drying

Information on combined osmotic and microwave drying of tropical fruits is not available. However, a study (154) on the combination of osmotic and microwave drying of blueberries gave a faster drying rate and better quality product compared to air drying. In another study (155), the effect of combined osmotic and microwave dehydration of apple on texture, microstructure and rehydration characteristics was done. Osmotic dehydration of apple was found to be a beneficial pre-treatment since it shortened the time of final air-drying in combination with microwaves. It produced dehydrated samples of improved appearance, softer rehydrated texture and lower rehydration capacity compared to the products obtained without osmotic pre-treatment. Rehydration in yoghurt and water gave different results depending on the pre-treatment, implying that the choice of the rehydration medium was important when aiming at restoring the original texture.

D. Sun/Solar and Hot Air Drying

Dehydration of tropical fruits by solar energy followed by hot air drying has not been reported. However, studies (156) conducted in a radiation/convection composite solar dryer for peaches gave high rate of drying during the initial stages of drying which could be considered in relation to possible use of a solar system to produce an intermediate moisture product, which may then be further dried in a conventional dryer.

E. Microwave and Sun/Solar Drying

The feasibility of improving the sun-drying process of grapes by microwave drying was investigated (157). Sultana seedless grapes, dipped in alkali solution (2.5% K_2CO_3 plus 0.5% olive oil, to increase water permeability of the grape skin), were pre-treated in a domestic microwave oven and then dried by direct solar radiation. Microwave pre-treatment reduced the moisture content by 10–20%. The microwave-treated grapes dried nearly two times faster than the controls. Blanching in boiling water had the same effect on the drying rate as microwaves. Colour and appearance of the treated grapes were comparable to the commercial products. It was concluded that microwave pre-treated grapes have an improved colour after drying and this was due to a reduction in enzymatic browning, as enzymes were partially inactivated by the absorption of microwave energy.

F. Microwave and Vacuum Drying

A vacuum microwave oven was used for drying pineapple and passion fruit juice and banana paste (158). In order to produce a stable foam with small diameter bubbles suitable for drying at 45°C and 6–8 torr, raw materials were thickened by addition of sucrose and malto-dextrins to 59°Brix. The percentage retention of total volatiles was 57 for pasteurized, 68 for fresh pineapple juice and 82 for passion fruit juice, compared to 33 for freeze dried and 11 for spray dried passion fruit juice.

The combination of microwave and vacuum drying of banana slices was investigated by Drouzas and Schubert (159). The slices were put in a glass vessel in the interior of a domestic microwave oven and vacuum conditions applied by means of a vacuum pump. The Magnetron power was kept constant for a period of 10 s, followed by a pause of 20 s, and this procedure was repeated several times. Compared to freeze drying, no substantial differences in the samples were observed as far as colour, taste, aroma and shape were concerned. The microwave dried sample absorbed twice as much moisture as that obtained by conventional drying during rehydration. They concluded that microwave dried fruits were more appropriate for use in bakery or related products (cereals, snacks, etc.).

A vacuum microwave dehydration process is described for drying fresh mango and pineapple fruit pieces at low temperature (160). The resulting product, which cannot be achieved using conventional air drying techniques, has a 'fresh,' uncooked flavour and a unique crunchy texture with little or no associated shrinkage.

G. Air and Microwave-Vacuum Drying

Comparative studies (161) were conducted on 5 combined methods for drying of banana slices (25 mm diameter, 6 mm thick): air drying/microwave drying; osmotic drying/air drying; vacuum impregnation/osmotic drying/air drying; osmotic drying/air drying/microwave drying; and vacuum impregnation/osmotic drying/air drying/microwave drying. These combined drying techniques were compared with air drying method as a control. The fastest drying was achieved by the combination of air drying/microwave drying. Combined processes that include vacuum impregnation and/or osmotic drying are slower than conventional air drying, but may improve yield and give dried banana products with improved stability and/or sensory properties.

In a study (162) to characterize the behaviour of 16 volatile compounds of banana during a combination of air drying (AD) and vacuum microwave drying (VMD) of banana chips, samples were subjected to AD to remove 60, 70, 80 or 90% of moisture (wet basis) and then subjected to VMD to achieve a final moisture content of 3% (dry basis). The slices were also dehydrated using only AD, VMD or freeze drying (FD) for comparison. It was found that samples that underwent more VMD had significantly lower levels of volatile compounds, which was attributed to the decreased formation of an impermeable solute layer on the surface of the chips. The optimum process of 90% AD/10% VMD yielded crisper banana chips with markedly higher volatile levels and sensory ratings than the AD ones.

IV. QUALITY OF DRIED TROPICAL FRUITS

Lewicki (163) has reviewed the effects of pre-drying treatment, drying and rehydration on plant tissue properties. The properties that are affected by drying are shrinkage, porosity, biopolymer structure and biochemical activity, and those affected by rehydration are water absorption and leaching of solutes.

A. Texture

The viscoelastic behaviour of dehydrated banana during rehydration was examined under uniaxial compression tests by Krokida, Kiranoudis and Maroulis (164). The samples were dehydrated with 4 different drying methods: conventional, vacuum, freeze and osmotic drying after which they were rehydrated in an air dryer at 50°C and 80% air humidity. It was concluded that dehydrated products do not keep their viscoelastic behaviour after rehydration due to structural damages that occur during drying. Specifically, freeze dried materials loose their elasticity and become more viscous but osmotic pretreament seems to help freeze dried materials to keep their elastic nature, probably due to solids gain, and that air and vacuum dried materials keep their viscoelastic characteristics during rehydration close to those of dried materials. In another study (165), air dried banana samples pretreated by osmotic dehydration, exhibited a viscous rather than elastic behaviour which indicated that the infusion of sugars causes plasticity of the structure of the fruit. Krokida and Maroulis (166) further dried banana samples using 5 different methods (conventional, vacuum, freeze, microwave and osmotic drying) then rehydrated them in an air dryer at 50°C and 80% RH. Then they examined the samples for structural properties (true density, apparent density, porosity and specific volume) during rehydration to moisture contents ranging from 0.01 to 3.5 kg/kg (dry basis). The samples were found to have not recovered the properties due to structural damage that happened during drying and the hysteresis phenomenon that happened during rehydration.

Osmotic dehydration of papaya pieces followed by fast drying in a cryogenic freezer using liquid N_2 (−63°C for 10 minutes) was found to preserve fruit texture better than slow freezing rate in an air blast freezer (−28°C for 1.5 hours) (167).

B. Colour

Effects of sucrose concentration (50–70°Brix), pH (6–8) and temperature (50–70°C) on colour changes in raw papaya slices exposed to 4 hours osmotic dehydration were evaluated (168). It was found that the 3 optimal treatments for changing greenish colour of raw papaya to yellow-orange colour were 60°Brix/60°C with pH 7 or 8, and 70°Brix/60°C with pH 7. Similarly, the effect of chitin on colour during osmotic dehydration of banana slices was studied (169). Banana slices of 0.6 cm thick were placed in sealed jars with 6x their weight of a sucrose solution for up to 4 hours. Chitin was added to syrups at 0.01, 0.05 or 0.1%, and the following conditions of drying were applied: 50°Brix, 70°C and pH 6; 60°Brix, 50°C and pH 6; 60°Brix, 70°C and pH 7; 60°Brix, 60°C and pH 8; and 70°Brix, 50°C and pH 8.3. Slices were removed from each batch every 30 min and analysed for colour values and polyphenol oxidase activity in inner and outer sections. Chitin at 0.01% reduced the tendency of colour L* values to decrease (darkening) during drying (in both inner and outer sections of slices), without affecting the natural drop in polyphenol oxidase activity, or the chroma, hue and total colour difference changes. These changes in L* value were independent of osmotic drying

conditions. In another experiment (170), osmotic drying of banana slices was carried out under 5 sets of conditions (50–70°Brix, 50–70°C, pH 6–8) to determine the effect of EDTA on colour. EDTA was added to the syrup solution at 5 concentrations of 0.01, 0.05, 0.1, 0.5 or 1% w/w. EDTA did not affect polyphenol activity decrease or chroma, hue and total colour difference changes. However, EDTA affected L value decrease in the inner and outer part of the banana slice, independent of osmotic dehydration conditions. It is recommended that EDTA is used during osmotic drying of some fruit that undergo undesirable darkening.

Effect of sucrose concentration (50–70°Brix), pH (6–8) and temperature (50–70°C) on colour changes in raw papaya slices during up to 4 hours of osmotic dehydration followed by air drying was examined (171). The slices were air dried at 50–70°C with air velocity of 0.5–1.5 m/s. Sucrose concentration and pH had no significant effect upon colour changes in the final product. During this combined drying of papaya slices, chroma exhibited a tendency to increase and hue to decrease, indicating that fruit maturity before processing is very important.

The effect of drying conditions on colour changes of banana and other fruits during conventional and vacuum drying were investigated by Krokida, Tsami and Maroulis (172). The Hunter colour scale parameters redness, yellowness and lightness were used to estimate colour changes during vacuum and conventional drying at 50, 70 and 90°C and air humidity of 15, 30 and 40%. The air temperature affected redness and yellowness, but not lightness (see Figure 104.6). Furthermore, the rate of colour deterioration

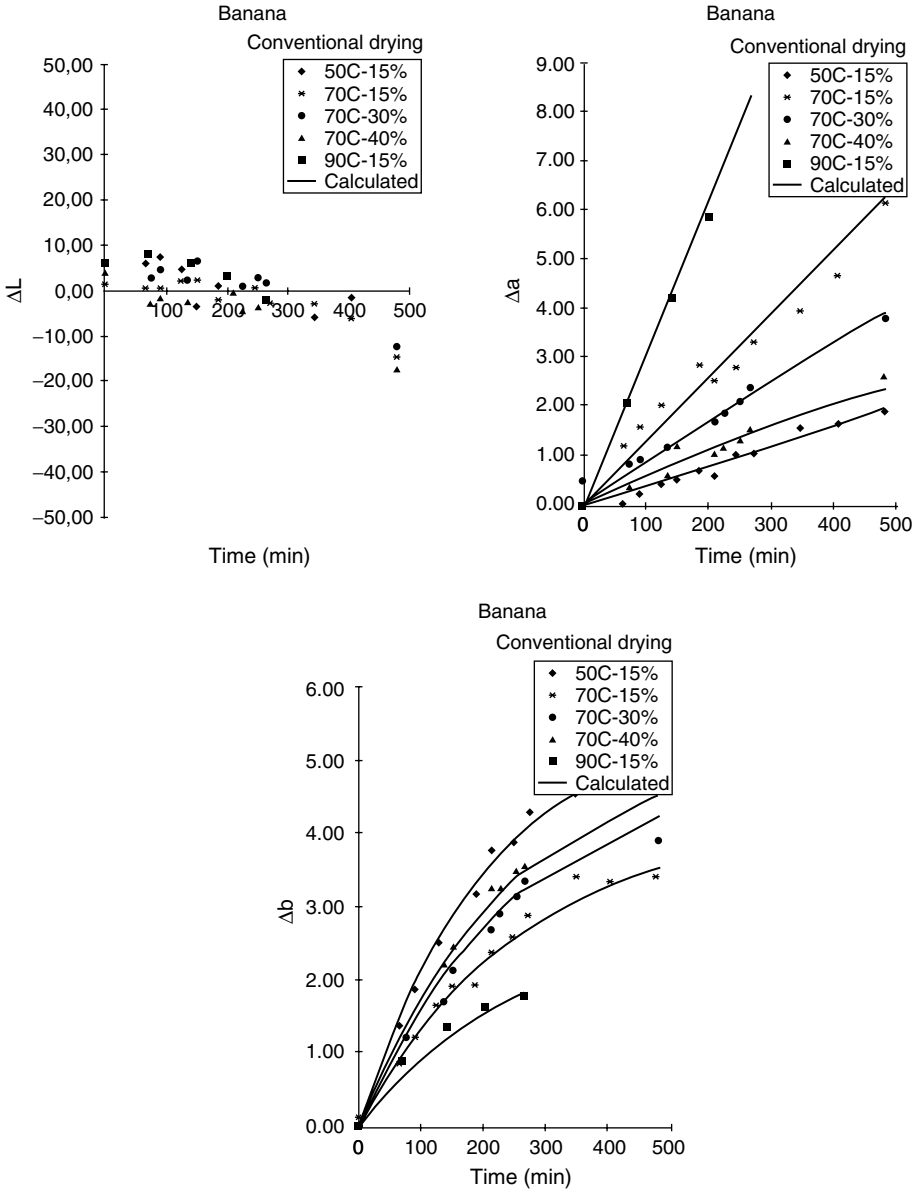

FIGURE 104.6 Changes in lightness ΔL, redness Δa and yellowness Δb (source ref. 172).

was found to increase as temperature increased and humidity decreased, for both drying methods and all the samples examined.

Effects of cyclical variations of air temperature on drying kinetics and colour changes during the drying of banana and guava pieces were investigated (173). Drying was performed in a two-stage heat pump drier capable of precise control of air humidity. Air temperature variations tested were a cosine profile, a reversed cosine profile and 3 different square wave profiles with peak-to-valley variations from 20 to 40°C. Cycle time was approximately 60 minutes and the drying time was approximately 300 minutes. The use of the different temperature profiles allowed individual colour parameters and the overall colour changes in the food products to be controlled. Banana pieces (high in sugar) favoured a sinusoidal temperature wave profile with a starting temperature of 30°C. Overall, results showed that with appropriate choice of temperature-time variations, it is possible to reduce the overall colour change of these products significantly while maintaining high drying rates.

Drying characteristics, colour and rehydration of banana samples dried by hot air, microwave and combined hot air/microwave (microwave finish) treatments were investigated (174). It was found that drying of banana slices took place in the falling rate drying period with all the methods; constant drying rate period was not observed under any studied conditions. Hot air drying took the longest time to dry samples, but when microwave finish treatment was used, drying time was reduced by approximately 64%. The drying rate increased sharply with microwave oven power output. Microwave finish drying had little effect on colour and rehydration capacity of dried banana samples; whereas the colour scores were poorer and rehydration values lower in samples subjected to hot air or microwave drying alone.

Osmotic dehydration as a pre-treatment to air drying has been found to suppress browning during drying of banana (175). In another study, the feasibility of minimizing colour degradation and drying times during osmotic dehydration and subsequent continuous convective air drying with or without intermittent infrared treatment (IR) of pineapple was done by Tan, Chua, Mujumdar and Chou (176). Samples were osmotically dehydrated by soaking in 30, 50 or 70°Brix sugar solutions for 7 hours. Colour changes in pineapple during osmosis were similar irrespective of sugar concentration; all samples turned darker. Osmotically pre-treated pineapple samples retained their colour during air drying, whereas untreated samples browned markedly. However, higher concentration of osmotic solutions affected the magnitude of any colour change whereas lower concentration stabilized colour. Introducing intermittent IR heating increased the initial drying rate by 4–5 times for osmotically treated pineapple, but it also reduced colour degradation compared to continuous heating. Osmotic pre-treatment resulted in a shift in sorption isotherms for both products. They concluded that with the appropriate choice of IR intermittency as well as osmotic pre-treatment, it is possible to reduce overall colour change whilst maintaining high drying rates.

Gujral and Khanna (177) studied the effects of addition of soy protein concentrate, skim milk powder and sucrose at different levels on the drying rate, colour, texture and sensory properties of mango leather. Soy protein concentrate, skim milk powder and sucrose were added to mango pulp at 0, 4.5 and 9%. Control samples were dried at 60°C and the time required for the mango leather to reach 10% moisture content was 7.6 hours. Drying rate was lowered by the addition of all the ingredients tested, with soy protein concentrate having the most pronounced effect. Extensibility and energy required for rupture were markedly reduced with all three ingredients. Sucrose improved the colour of mango leather and samples containing 4.5% skim milk powder and 4.5% sucrose each exhibited the highest acceptability scores.

C. Rehydration

The keeping quality and rehydration characteristics of mango pieces treated with $CaCl_2$, were studied during storage in brine and during sun drying (178). The quality of pickles prepared from the treated dry mango pieces was also studied. Raw mango pieces treated with $CaCl_2$-brine kept well for 1 year and exhibited maximum retention of texture and colour. Pickles prepared from the treated mango also had good texture and colour and no microbial contamination was found. The $CaCl_2$-treated pieces maintained their shape and appearance during sun drying, whereas the control pieces shrivelled and became discoloured. The quality of the treated dried pieces was maintained during storage for 14 months in polyethylene bags. The best rehydration was achieved with a ratio of 1:4 between mango pieces and rehydration medium. Incorporation of $CaCl_2$ into this medium improved the texture of pickles prepared from rehydrated $CaCl_2$-treated pieces but not that of pickles prepared from control pieces.

Candelaria and Raymundo (179) used three different drying methods (convection, vacuum and vacuum puff drying) to process banana and mango and compared the drying efficiency and quality of the dried products. Vacuum puff drying produced the most acceptable product with a significantly shorter drying time (6 hours regardless of raw material) than that obtained with convection drying (17–20 hours) or vacuum drying (10–12 hours). Rehydration ratio and rehydration rates were also significantly higher for products subjected to vacuum puff drying. In further studies (180), optimum conditions for predrying treatments and vacuum dehydration of banana and mango to give products that would rehydrate rapidly were determined. Diced ripe fruit was heated at different pressure and temperature combinations in a vacuum oven. The best

puffing results were obtained at 40 kPa/110°C. Heating times required to reach maximum tissue temperature were 6 minutes for banana and 8 minutes for mango. Optimum dehydration conditions were 6–7 hours at 45–50°C under 70–80 kPa. Rehydration ratios for vacuum-puffed banana and mango were 8.2 and 8.9, with corresponding rehydration rates of 1.8 and 1.7 g/min respectively.

V. CONCLUSION

Dehydration of tropical fruits is a practical alternative to freezing and refrigeration in reducing the wastage of fruits during gluts as well as making them available in a variety of forms during off-season periods. Consumers' demand for quality products and the need to satisfy export requirements of tropical fruits from developing countries will continue to drive development of new drying methods with improved performance.

A lot of research into improved drying methods aimed at producing fruit products with reduced loss of quality, have been done during recent years. Of particular interest to the developing countries in the tropical regions is combination drying methods, which have the potential to address not only quality but also other fundamental problems like long periods of transporting fresh fruit from rural areas to factories in the towns due to poor road infrastructure in most cases. A technique like osmotic dehydration is simple to perform at the farm level in rural areas and by the farmers as the method does not require sophisticated equipment. The semi-processed fruit can then be transported, at a reduced cost and in a more shelf-stable form, to central processing places in the towns for further processing by solar, convection hot air or microwave drying.

105 Drying Pears

Raquel de Pinho Ferreira Guiné
Department of Food Engineering, Polytechnic Institute of Viseu

CONTENTS

I. INTRODUCTION

The fruits that have been traditionally dried are essentially grapes, figs, plums, apricots and peaches, but some other species have recently gained increased importance, like apples, mango, pawpaw, pineapple, banana and pears. The production of dried pears has some relevance in countries like Australia, South Africa, Chile, Argentina and Portugal (1).

It is essential to study the phenomena taking place during drying in order to optimise the process and make it a profitable and competitive production method, offering the consumer products of unquestionable quality. The study of the drying kinetics is therefore essential for the development of reliable process models for such unit operation (2, 3).

In the case of fruits, and of pears in particular, the sugar concentrations are relatively high (60 to 75% dry basis) and increase very significantly as the water evaporation proceeds, offering an additional resistance to the movement of moisture throughout the fruit. Thus, it becomes important to study the influence of this property in the moisture diffusion coefficient along the drying process (4).

Success in food and storing strongly depends on the isothermal relationship between the water content of the food material being processed and its water activity. Therefore, the knowledge of such relations, often represented in the form of sorption isotherms, both at the drying as well as at the storage temperatures, is of unquestionable importance for the food industry (5).

The factors that influence the end of the drying process are the high concentration of sugar and low moisture content as well as the energetic optimisation of the process. The desirable amount of water present at the end of the drying varies according to the type of fruit, and the smaller the fruit the less shall be its final moisture content. However, the choice of the final moisture content must not only have in mind the stability of the fruit but also the final physical and chemical properties that characterize its quality (4).

The dehydration of foods generally involves a series of interdependent unit operations like blanching, pasteurisation or pre-concentration, all of which contribute to the overall quality of the final product, and to improve the efficiency of the process. In ideal dehydration of food products the process of water removal should be reversible, however this is not true due to the inevitable loss of nutritional and functional attributes, which depends on the type and extension of dehydration and the sensitivity of the specific food components (6).

II. SHRINKAGE CHARACTERISTICS

Recently, much attention has been paid to the quality of the food products, which is strongly influenced by the processing conditions. In particular, during drying the water present evaporates in a rather important extension, originating phenomena such as shrinkage, that influences significantly the food physical structure and properties, like texture, contributing for its final quality standards (7, 8).

When studying the physical properties of foods, and particularly fruits, is very important to know with some accuracy the estimations for the size, volume, density and superficial area. Some methods based on the longitudinal and transversal sections of the material were developed for the determination of shape and size. The experimental measurements usually are made with photographic cameras, and include a millimetre scale which is photographed with the object. Other more sophisticated methods have also been developed, based on computer aided image processing. Volume and density are normally determined by liquid displacement, due to the irregularity of the products (9, 10).

In most cases, the shape can be approximated to known geometric forms and its volume and superficial area are thus calculated using the appropriate equations. It is possible to quantify some parameters associated to shape, like sphericity ($= d_e/d_c$, with d_e the diameter of a sphere with the same volume as the object and d_c the diameter of the smallest circumscribing sphere or usually the longest diameter of the object) and roundness ($= A_p/A_c$, where A_p is the largest projected area of object in natural rest position and A_c is the area of the smallest circumscribing circle) (9, 11).

The shrinkage of porous materials during drying is very dependent on the internal vapour pressure and the quality of these products depends on the shrinking behaviour. On the other hand, shrinking of biological products such as foods during drying occurs simultaneously with the water evaporation process, affecting the moisture diffusion and water removal rate, as well as the apparent density. Therefore, knowing the shrinkage behaviour assumes an important role on understanding and modelling drying processes and controlling the characteristics of the food. Within literature various models have been proposed to describe shrinkage of foods in drying, and it has been shown that either volumetric shrinkage or dimensional shrinkage have a strong dependency on the moisture content (12).

The shape of the pears has been observed to correspond to a combination of known geometric forms, after which is possible to estimate their volume and superficial area, assuming that during the drying process the shape does not change. Based on the pear geometry defined in Figure 105.1, the theoretical expressions for volume and superficial area are given by:

$$\text{Volume} = \tfrac{1}{2}\ \text{volume of sphere} + \text{volume of cone} \quad (105.1)$$

$$V = \tfrac{1}{2}\left(\tfrac{4}{3}\pi r^3\right) + \tfrac{1}{3}\ \pi r^2 h = \tfrac{\pi}{3}\ r^2\,(2r + h) \quad (105.2)$$

and,

$$\text{Superficial area} = \tfrac{1}{2}\ \text{area of sphere} + \text{area of cone} - \text{area of base of cone} \quad (105.3)$$

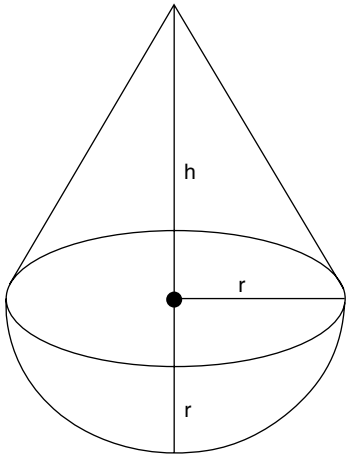

FIGURE 105.1 Approximation of the shape of the pears to known geometries.

$$A_s = \tfrac{1}{2}(4\ \pi r^2) + \pi r(\sqrt{r^2+h^2} + r) - \pi r^2 = \pi r(2r + \sqrt{r^2+h^2}) \quad (105.4)$$

where r is the radius of the semi-sphere and h the height of the cone.

To evaluate the evolution of the pear dimensions during the process of drying, the pears (*pyrus communis*, variety "D. Joaquina") were photographed over a millimetre scale paper, and the dimensions read directly from the scale. The water content was determined with a Halogen Moisture Analyser (Mettler Toledo HG53) and density was determined by liquid displacement, using picnometry (two different solvents were used in the analysis and the results obtained were analogous). The volume of the pears was calculated using two different methodologies: (a) known the mean values of the dimensions, calculate volume from the theoretical formula deduced (Equation (105.2)); (b) directly measure the volume by liquid displacement (the solvents used were water and toluene).

Figures 105.2 and 105.3 show the evolution of the pear dimensions and superficial area as the process of drying proceeds and the corresponding moisture content diminishes. All the three variables obey an exponential raise law described by Equations (105.5) to (105.7), and the quality of the fitting is relatively good as shown by the values of R^2.

$$r = 0.0129 + 0.0268\,(1 - \exp(-0.1281\,W)) \quad R^2 = 0.923 \quad (105.5)$$

$$h = 0.0339 + 0.0180\,(1 - \exp(-0.3598\,W)) \quad R^2 = 0.951 \quad (105.6)$$

$$A_s = 0.0017 + 0.0057\,(1 - \exp(-0.3081\,W)) \quad R^2 = 0.987 \quad (105.7)$$

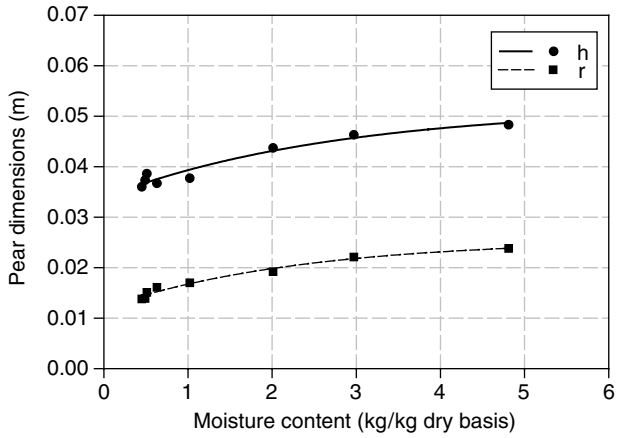

FIGURE 105.2 Evolution of pear dimensions during drying.

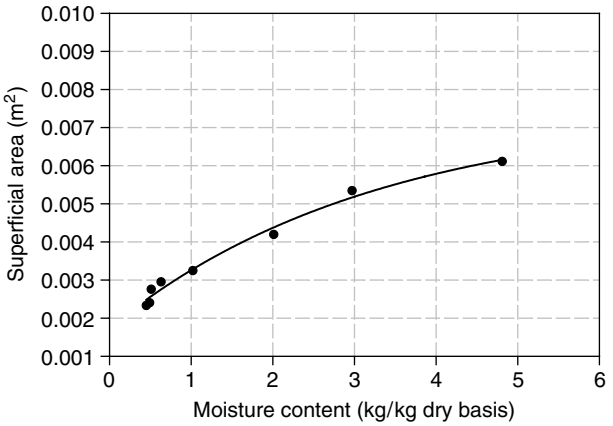

FIGURE 105.3 Variation of superficial area with moisture content.

where r is the radius and h the height of the pears (m), A_s is the superficial area (m^2) and W is the dry basis moisture content.

In Figure 105.4 the variation of the relative density of the pears, dr, with moisture content is presented, and the function that represents this variation is an exponential growth of the form:

$$d_r = 0.2247 \exp(-2.7168\,W) + 1.1527 \exp(-0.0255\,W) \quad R^2 = 0.898 \qquad (105.8)$$

where d_r is dimensionless.

In Figure 105.5 the values obtained for volume by using the two different methodologies described earlier are plotted against moisture content, and a linear relationship between these two variables is very clear, as the value of R^2 highlights. The linear function of Equation (105.9) was obtained by regression using the two sets of data plotted in the graph of Figure 105.5.

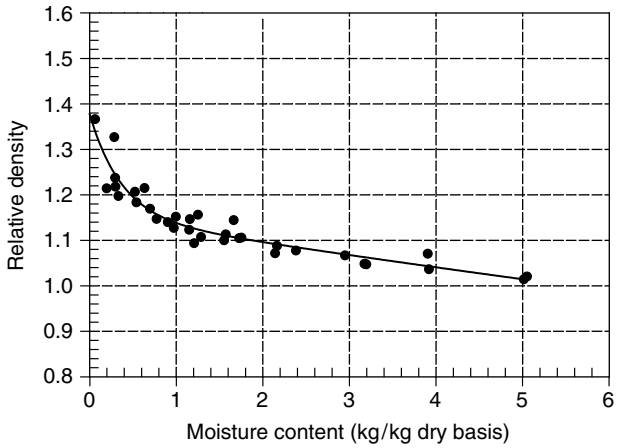

FIGURE 105.4 Variation of density with moisture content.

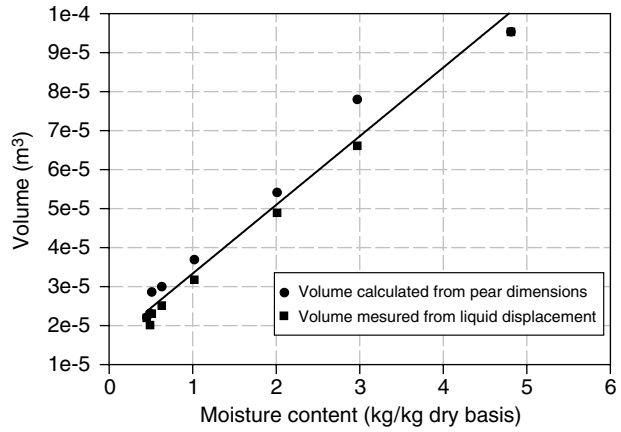

FIGURE 105.5 Variation of volume with moisture content.

$$V = 1.5711\text{e-}5 + 1.7617\text{e-}5\,W \quad R^2 = 0.972 \qquad (105.9)$$

where V is the volume (m^3).

To express the shrinking behaviour during drying, a bulk shrinkage coefficient was defined as the ratio of the sample volume at any stage to the initial volume ($S_b = V/V_0$). This was determined following two different methodologies: (a) S_b was calculated as the ratio of V/V_0 with V given by Equation (105.9), thus obtaining the relation expressed in Equation (105.10), which is in some accordance with the model suggested by Kilpatrick in literature ($S_b = (0.8 + W)/(0.8 + W_0)$) (12, 13); (b) S_b was determined by linear regression applied to the observed values of V/V_0 when plotted against the dimensionless moisture content (W/W_0), as shown in Figure 105.6, thus obtaining the model in Equation (105.11).

$$S_b = \frac{0.89 + W}{0.89 + W_0} \qquad (105.10)$$

$$S_b = 0.1694 + 0.8651\,\frac{W}{W_0} \quad R^2 = 0.990 \qquad (105.11)$$

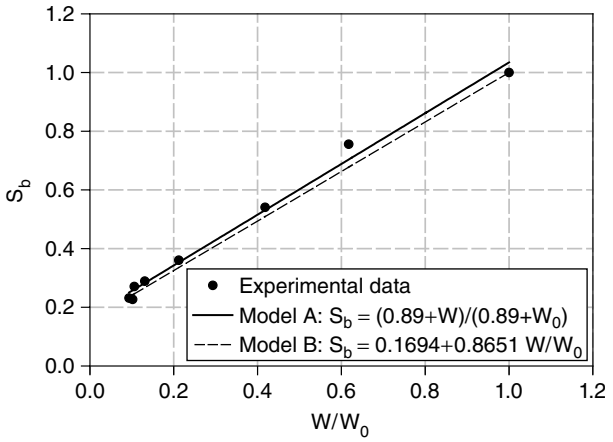

FIGURE 105.6 Evolution of shrinkage coefficient along the drying process.

The linear relation between S_b and W/W_0 is well reported in literature, and Equation (105.11) is quite similar to the one presented by Raghavan and Silveira (14) for the microwave drying of strawberries at 0.2 W/g power level ($S_b = 0.0741 + 0.8121\ (W/W_0)$).

III. SORPTION ISOTHERMS OF PEARS

Equilibrium moisture data provided by sorption isotherms is very important for the determination of optimal storage conditions as well as the prediction of thermodynamic equilibrium models. In drying they are of great importance to properly choose the end-point of the process, corresponding to the optimum residual moisture content of the final product. In fact, a high residual moisture content obtained with a short drying time leads to reduced stability, whereas drying the material to a moisture content below its optimum value leads to energy wasting with no apparent benefit. Such isotherms also give information on how strongly the water is bound to the material and thus are essential for the prediction of the drying and rehydration rates (15, 16).

At the end of the drying process, the moisture content of the food becomes stationary, reaching an equilibrium moisture content with the surrounding atmosphere. The moisture sorption isotherms are obtained when the equilibrium moisture content is plotted against the corresponding water activity of the food product, over a certain range of values and for a constant temperature. Brunauer *et al.* (17) classified adsorption isotherms in terms of the van-der Walls adsorption of gases into five different types, that are illustrated in Figure (105.7). Types I and II have been assigned special names, Langmuir and Sigmoid respectively, but no special names have been attached to the others. For most foods sorption isotherms are nonlinear, usually sigmoidal, as type II in Figure (105.7), however, for foods rich in soluble components such as sugars, the type that best seems to describe the sorption behaviour is type III (6, 16).

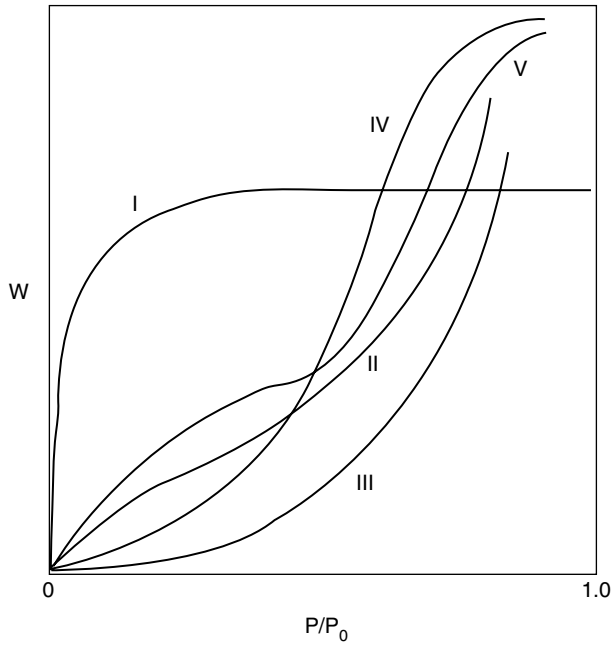

FIGURE 105.7 The different types of adsorption isotherms (adapted from Brunauer *et al.* (17)).

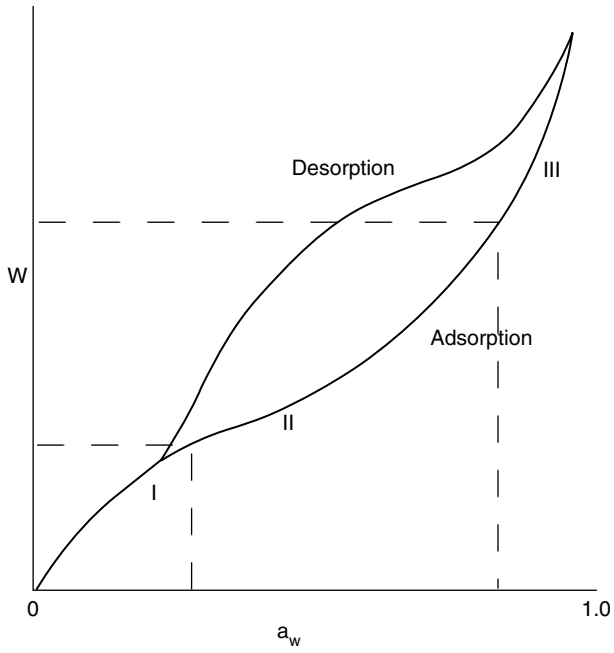

FIGURE 105.8 Sorption isotherm with adsorption and desorption curves (adapted from Fellows (39)).

Another behaviour commonly observed is that different paths are followed dependent upon the direction from which equilibrium is approached, resulting in a hysteresis (see Figure 105.8). The desorption isotherm lies above the adsorption isotherm and therefore more moisture is retained when the approach to equilibrium is made from a wetter state than from a drier one, at a given relative

humidity. In fact, in the original form of the food, the polar sites are almost completely occupied by adsorbed water molecules, whereas upon drying with shrinkage effect, the water holding capacity of the structure is diminished. Therefore, taking into consideration that rehydration is never as complete as the original wet condition of the food, for a specific relative humidity the material holds a higher moisture content along the desorption process as compared to the adsorption one (9).

In Figure 105.8 the isotherm is divided into three different regions, according to the type of water present: (I) bound water or monolayer region, corresponding to absorption of up to a monomolecular layer of water; (II) intermediate water or multiplayer region, corresponding to adsorption of additional layers of water over the monolayer; (III) free water or capillary absorption region, referring to the water held in the pores of the material (9).

Many different models can be found in literature to describe the sorption of water on capillary materials (about 77 (6)), most of them represented by semi-empirical equations with a variable number of parameters. Because water is associated with the food matrix in different ways for different activity regions, is well expected that one sorption model may not be enough to represent the sorption behaviour over the entire water activity range. The quality of fitting of a determined sorption model to the experimental data does not necessarily reveal the nature of the sorption process.

In Table 105.1 some of the more commonly used sorption isotherm models are presented.

In the different models, W_e is the equilibrium moisture content (dry basis), W_m is the monolayer moisture content (dry basis), a_w is the water activity, R is the gas constant ($R = 8{,}31451\ J{\cdot}mol^{-1}{\cdot}K^{-1}$) and T is absolute temperature. In Table 105.1 some models have an explicit temperature dependency (Chung-Pfost, Halsey, Henderson) while some others have parameters that are temperature dependent (Chen, BET, GAB). In the Iglesias-Chirife and Oswin models, the temperature dependency is not considered. The Iglesias-Chirife model, corresponding to a type III curve (see Figure 105.7), proved to be quite adequate to describe the sorption behaviour of many sugar-rich foods, such as most fruits, where the monolayer is completed at a very low moisture content and the dissolution of sugars takes place (6).

The adsorption is an exothermic process while desorption is endothermic. Generally, higher temperatures result in a reduction of adsorbed molecules and therefore, adsorption decreases with increasing temperature, although this dependency is usually small. However, this behaviour is not universal as temperature affects many different phenomena and an increase in temperature can in fact increase the rates of adsorption, hydrolysis and recrystallization processes. Food rich in soluble solids, such as sugars, seem to exhibit antithetical temperature effects for higher values of a_w due to their increase solubility in water (6).

The sorption behaviour of pears was investigated for constant drying temperatures of 20, 25 and 30°C, and the experimental data obtained with the measurement of the moisture content (with a Mettler Toledo, HG53 Halogen moisture analyser) and the corresponding water activity (with a Rotronic Hygrometer) allowed the estimation of the parameters in the different models considered.

The estimation of the parameters in all models was done using an Orthogonal Distance Regression algorithm

(ODR), where the unknown errors are taken into account in both dependent and independent variables. The software package used to compute the parameters was ODRPACK, developed by the Center for Computing and Applied Mathematics of the National Institute of Standards and Technology (USA) (27). The estimation of the parameters was done using the explicit ODR algorithm with the derivatives approximated by central finite differences.

In Table 105.2 the values of the parameters estimated and the corresponding standard deviation are presented for the models that do not have an explicit dependency on temperature (Chen, BET, GAB, Iglesias-Chirife, Oswin) as well as the statistical information (sum of square of errors, Σe^2, and residual standard deviation, SD). In these cases, the experimental data in the form of sets (W, a_w) was treated separately for the three different temperatures studied, and the number of observations for the temperature of 20°C was 42 sets, for the temperature of 25°C was 40 and for the temperature of 30°C was 56.

In Table 105.3 the values of the parameters estimated with the corresponding standard deviation are presented for the models that have an explicit dependency on temperature (Chung-Pfost; Halsey; Henderson) as well as the statistical information. In these cases, the experimental data in the form of sets (W, a_w, T) was treated all together, and the number of observations was 138.

In Figures 105.9 and 105.10 the sorptions isotherms for the temperature of 30°C, for example, are represented using the 8 different models considered, along with the experimental data. From Figure 105.9 is possible to observe the similarity between the BET and GAB models, that seem to be quite good at predicting the sorption behaviour of the pears for this temperature. The Chen and Chung-Pfost models are also quite similar but apparently are not so adequate to this particular case. In Figure 105.10 all the models are more or less equivalent, although the Iglesias-Chirife model shows a less good approximation to the experimental data.

In Figure 105.11 the isotherms are represented for different temperatures (20, 50 and 80°C) using one of the

temperature dependent models, the Halsey model, and is possible to observe that at constant moisture content an increase in temperature enhances water activity. This behaviour has been reported to most solid fruits (2, 28).

IV. DRYING KINETICS

Dehydration consists in the penetration of heat into the food product and the removal of moisture by evaporation into an unsaturated gas phase. This process involves heat, mass and momentum transfer, which are quite difficult to predict with accuracy. In foods such as fruits, with a capillary-porous structure, the food matrix has interstitial spaces, capillaries and cavities filled with gas, and many different mechanisms of mass transfer can be considered, and may act in different combinations. These mechanisms include liquid diffusion due to concentration gradients, liquid transport due to capillary forces, vapour diffusion due to partial vapour pressure gradients, liquid or vapour transport due to the difference in total pressure caused by external pressure and temperature, evaporation and condensation effects, surface diffusion, and liquid transport due to gravity (6, 29).

The most important when developing process models is unquestionably the determination of the drying kinetics, which accounts for the mechanisms of moisture removal and the influence of certain variables during the process (2). In air drying processes two drying stages are usually present: an initial constant rate period corresponding to pure water evaporation and a falling rate period where the moisture transfer is essentially limited by internal resistances.

Figures 105.12 and 105.13 illustrate the different ways of representing the drying behaviour of foods, and show respectively a moisture content versus time plot and the drying rate versus time and moisture content plots.

It is common procedure to interconvert between the three different types of drying curve, as usually the type of data recorded from experiments (moisture-time) is not in the best form to fit mathematically. In fact, the Krischer rate-moisture curve, which is obtained from the

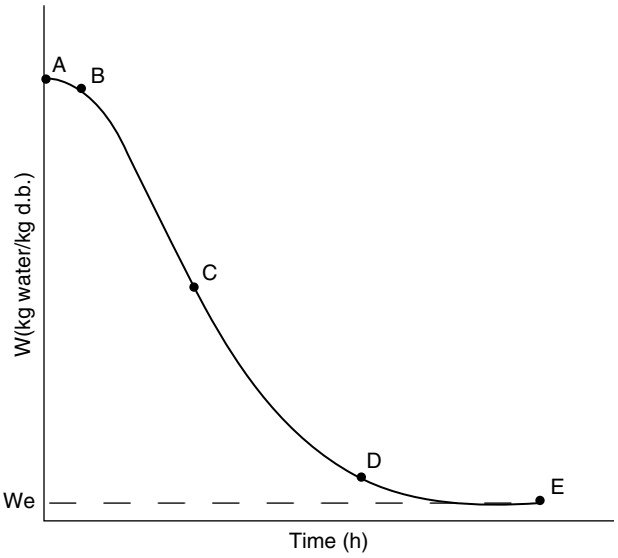

FIGURE 105.12 Drying curve, showing the variation of moisture content with drying time (adapted from Rizvi (6)).

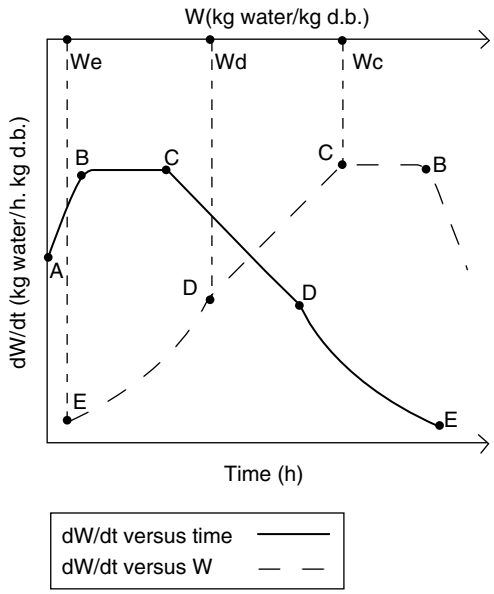

FIGURE 105.13 Drying rate curves, showing the rates of moisture removal as a function of time and moisture content (adapted from Rizvi (6)).

batch drying curve and its differentiation (the drying rate curve), is actually the most suitable form of treating the drying data in terms of the characteristic curve scaling method (30).

In Figures 105.12 and 105.13 some important points, *A* to *E*, are marked in the curves, allowing the visualisation of the different stages of the drying process. The induction stage, that goes from *A* to *B*, corresponds to the initial unsteady-state heating period, and in most cases represents an insignificant portion of the total drying cycle. The unhindered drying or constant rate period is represented by *BC*, and during this phase the drying surface is saturated with water as the rate of migration of water from the inside to the surface equals the rate of evaporation at the surface. The factors that influence the drying rate during this period are the surface area, the temperature and moisture gradients between the surface and the surrounding air and the heat and mass transfer coefficients. In food systems where moisture movement is controlled by capillary and gravity forces the constant rate period is significant and its extension is determined by the food structure and the mechanisms that govern the internal liquid movement. As drying proceeds, a critical moisture content is reached (Wc, corresponding to point *C*) where the rate of migration of water from the interior to the surface is reduced to a degree that no longer is sufficient to saturate the entire surface, and this begins to dry. The critical moisture content usually increases with increasing thickness and drying rate. After point *C* the surface temperature starts to increase and the hindered drying or falling rate period starts. This generally involves two different stages: the first falling rate period, *CD*, and the second falling rate period, *DE*. After point C the rate of moisture migration to the surface is less than the rate of evaporation, originating a continually drier surface. This proceeds until finally all the evaporation from the interior of the food is completed, in point *D*. In the second falling rate period, the path for heat and mass transfer becomes longer and more tortuous as the moisture content diminishes, and the limiting moisture content is reached where the vapour pressure of the food equals the partial vapour pressure of the drying air, thus ending the drying process. This is known as the equilibrium moisture content, We (6, 31).

In typical industrial applications, the kinetic models developed are mostly empirical rather than being mechanistic, due to the complexity of the phenomena involved. However, some empirical kinetic models include parameters of phenomenological nature related to the most appropriate driving force, which can lead to rather good prediction of drying kinetic although they do not have a physical meaning (2).

To determine the drying rate curves, the pears were peeled and left in convective dryers at constant temperature. The temperatures investigated were 30, 40 and 50°C, and every 24 hours two samples were collected from each dryer to analyse their moisture content (with a Mettler Toledo HG53 Moisture Analyser). The water activity was also analysed with a Rotronic Hygrometer. All experiments were carried out until the moisture content of the pears reached about 20%, thus obtaining pears with optimum physical properties like texture, consistency and elasticity, as well as chemical composition that influences their taste and preservation capacity (4).

The batch drying curves (dry basis water content plotted against drying time) are shown in Figures 105.14 and

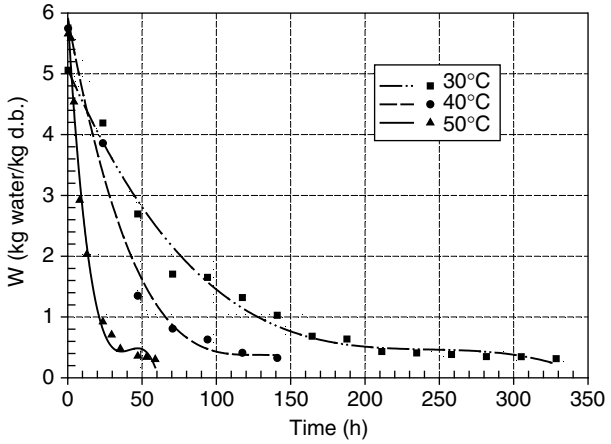

FIGURE 105.14 Drying curves for 30, 40 and 50°C with cubic fit.

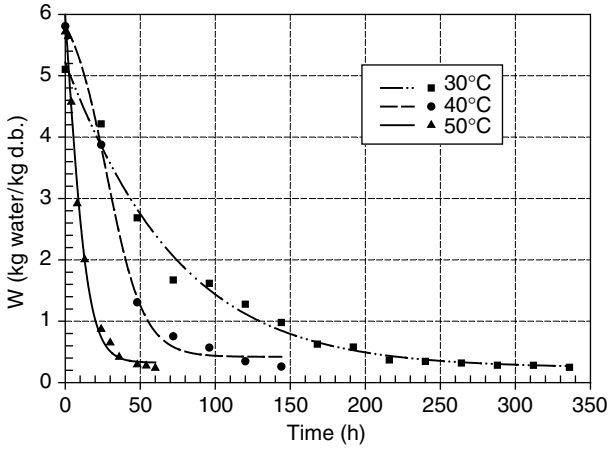

FIGURE 105.15 Drying curves for 30, 40 and 50°C with sigmoidal fit.

TABLE 105.4

R	0.9941	0.9985	0.9961

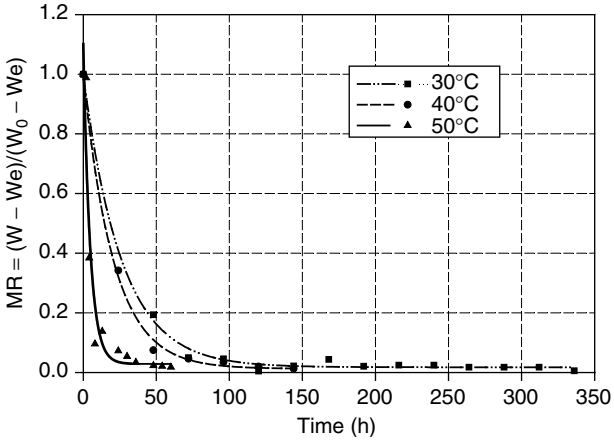

FIGURE 105.16 Moisture ratio curves for 30, 40 and 50°C with exponential fit.

105.15. It is possible to verify that all curves follow the general pattern of a drying curve, and that for higher temperatures the changes in the water content are sharper, because the evaporation process is highly accelerated.

The data was fitted to cubic polynomials as suggested by Kemp *et al.* (30) (Equation 105.12) and also to sigmoidal functions (Equation 105.13):

$$W = y_0 + at + bt^2 + ct^3 \qquad (105.12)$$

$$W = y_0 + \frac{a}{1 + \exp[(x_0 - t)/b]} \qquad (105.13)$$

where W is the dry basis moisture content and t is the drying time in hours. The fitting was done with the software Sigma Plot, version 5.0 (SPSS, Inc.) and the resulting values for the parameters as well as the correlation coefficients are presented in Table 105.4.

From Table 105.4 is possible to verify that the correlation coefficients are higher for the sigmoidal fit, and the best quality of this fitting is quite visible in Figure 105.14 as the cubic fit introduces some degree of instability to the final stage of the drying curve.

The plots of moisture ratio (defined as $MR = (W - W_e)/(W_0 - W_e)$ versus time were also produced, to fit the data to a first order kinetics of the form (32):

$$MR = y_0 + a \exp(-bt) \qquad (105.14)$$

where t is expressed in hours.

The variation of the moisture ratio with the drying time is presented in Figure 105.16 for the three temperatures studied, and the effect of increasing temperature on accelerating the drying process is quite visible. The fitting of the plots MR-time was done with Sigma Plot and the results

are presented in Table 105.5. The correlation coefficient (R) is also presented to show the quality of the fitting.

V. MOISTURE DIFFUSIVITY PREDICTION

Moisture diffusivity is an unquestionably important transport property necessary for correct modelling and understanding of the food drying processes. The determination of a variable diffusion coefficient is quite complex, not only because of the experimental difficulties that arise, but also due to the mathematical solution of the diffusion equation.

The drying of pears is critically dependent of the temperature as well as of the water and sugar concentrations inside the fruit along drying. In fact, as the drying proceeds, some migration of the sugars occurs with the water that flows from the inside to the surface of the pears. That, combined with the shrinking of the fruit, originates an increase on the sugar concentration close to the surface, offering an extra resistance to the water diffusion (4).

The drying of pears, as the majority of the food products, is complex and the coupled heat and mass transfer phenomena have to be taken into account. The physical characteristics often change significantly along the drying process and despite the complexity of the moisture transfer process, it has been reported by many researchers that Fick's law seems to be fairly good to predict the moisture distribution inside many food materials during drying (33, 34).

For the transient diffusion, assuming a uniform initial distribution of moisture content and a uniform concentration at the surface for $t > 0$, the solution of Fick's Law can be approximated by (35):

$$(W-W_e)/(W_0-W_e) = (8/\pi^2)^3 \exp[-D_e\, t\, (\pi^2/4)\, (1/L_x^2+1/L_y^2+1/L_z^2)] \quad (105.15)$$

where D_e is effective diffusivity, W is the dry basis moisture content at time t, W_e is the equilibrium moisture content, W_0 is the initial moisture content and L_x, L_y, and L_z represent one half the size of the sample in the three spatial dimensions. Thus, the values of D_e can be obtained from the slope of a semi-log plot of the moisture ratio $((W - W_e)/(W_0 - W_e))$ versus time.

The evolution of the pear dimensions along drying was studied by measuring the values of the pear radius and height as the moisture content diminished, and the values for L_x, L_y and L_z were thus calculated from the following equations:

$$L_x = L_y = 0.0129 + 0.0268 * (1 - \exp(-0.1281 * W)) \quad R^2 = 0.923 \quad (105.16)$$

$$L_z = 0.0168 + 0.0099 * (1 - \exp(-0.3285 * W)) \quad R^2 = 0.945 \quad (105.17)$$

that were obtained by adjusting the experimental data with Sigma Plot 5.0 (SPSS, Inc.), and where L_x and L_y are both equal to the pear radius and L_z is the height, expressed in meters.

The temperature and moisture content dependency of the effective diffusivity is represented by a modified Arrhenius relationship of the form (36, 37):

$$D_e = D_0(1 + B\, W) \exp[-E/(RT)] \quad (105.18)$$

where D_0, B and E are parameters to estimate, T is absolute temperature, W the dry basis moisture content and R the gas constant ($R = 8.31451$ J/mol·K). In the above equation E represents the activation energy for moisture diffusion (J/mol).

From the experimental data obtained for W[1] and from the relations that express the evolution of the pear dimensions, different values for diffusivity were estimated for different temperatures (between 30°C and 50°C) and for different dry basis moisture contents (between 0.22 and 4.36). These data were adjusted to the model in Equation (105.18) in the form of triplets (D_e,W,T), and a orthogonal regression algorithm was used, particularly the explicit ODR with the derivatives approximated by central finite differences, and the results of the estimation are presented in Table 105.6. The values of diffusivity obtained with this model vary from 1.174×10^{-10} to 1.909×10^{-9} m^2/s, and the activation energy ($E = 44.234$ KJ/mol) stands in the range of values reported for other food products (15–95 kJ/mol) (6, 35, 36).

As it was stated earlier, this particular drying problem is strongly affected by the sugar concentration, and therefore a modification is suggested to the model of Equation (105.19), to introduce a component that accounts for the dependency of the water diffusivity in relation to the sugar concentration present, S (kg of sugar/kg dry solids):

$$D_e = D_0\,(1+ B\, W)/(1+ C\, S) \exp[-E/R\, T] \quad (105.19)$$

The determination of the parameters of Equation (105.19) was based on the experimental data obtained for

[1] W was measured with a halogen moisture analyser, Mettler Toledo HG53.

CONTENTS

In freeze-concentration and freeze-drying processes water is first frozen in the material. Ice is removed by mechanical means during freeze-concentration leaving a concentrated liquid, while ice is removed by sublimation in freeze-drying yielding a dried material. The removal of water by these methods would yield high quality products, but in both processes it is a very expensive operation due to the high consumption of energy. Knowledge of the theoretical principles behind these processes is necessary for minimization of detrimental changes, operating strategies, or optimization purposes. Thus, the fundamental aspects of freeze-concentration and freeze-drying are presented in this chapter with special emphasis on food preservation processes.

I. FREEZE-CONCENTRATION

A. Introduction

Freeze-concentration is the term used to describe the solute redistribution in an aqueous solution with an initial relatively low concentration by the partial freezing of water and subsequent separation of the resulting ice (1, 2). Freeze-concentration is based on the freezing temperature-concentration diagram (Figure 106.1) (3). Freeze-concentration has been applied to preconcentration for analytical purposes (4), desalinitation, concentration of juices (5), concentration of dairy products (6) and waste water treatment (7).

It is necessary to briefly review the physicochemical changes that occur during a freezing process before relating them to the freezing of foods. The phase diagram (Figure 106.1) allows identifying different phase boundaries in a mixture. It consists of the freezing curve (AB), solubility curve (CE), eutectic point (E), glass transition curve (DFG),

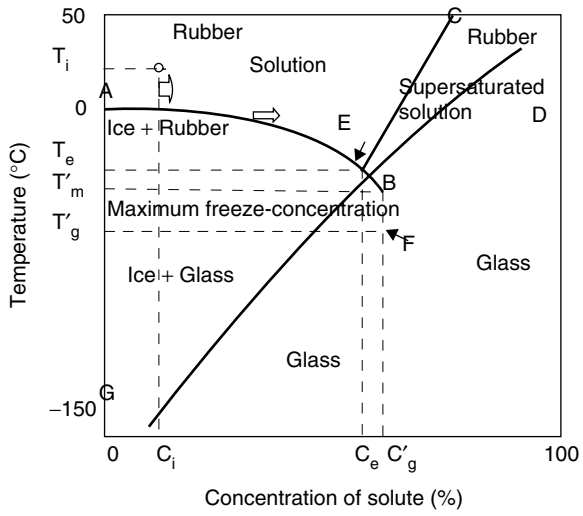

FIGURE 106.1 Typical solid-liquid state diagram for a food system.

and conditions of maximal freeze-concentration. The freezing curve corresponds to solution-ice crystals equilibrium. Along this curve, as water is removed as ice, the concentration of solute increases during the freeze-concentration process. The solubility curve represents equilibrium between the solution and supersaturated solution in a rubbery state. The freezing and solubility curves intersect at the eutectic point E (C_e, T_e), which is defined as the lowest temperature at which a saturated solution (liquid phase) can exist in equilibrium with ice crystals (solid phase). The water content at point E is the unfreezeable water. Below T_e only ice crystals embedded in a solute-water glass exist. The point F (C'_g, T'_g) lower than point B (C'_g, T'_m) represents a characteristic transition in the state diagram. The glass transition curve (DFG) represents the glass-rubber transition of the solute-water mixture, and the type and concentration of the solute and the temperature define it. Above the DFG curve, solutions are in an unstable rubbery or liquid state, below the DFG curve, solutions transform into the glassy state (amorphous solid). The maximum freeze concentration (maximum ice formation) only occurs in the region above T'_g but below the equilibrium ice melting temperature of ice (T'_m) (8, 9). The liquid solute-water mixture is the maximum freeze concentrated and has become glassy. The glass transition temperature of this unfrozen glassy mixture is designated T'_g, and C'_g is the solid content of this glass (3, 8–11). Figure 106.1 also shows the aqueous solution with initial concentration and temperature C_i and T_i undergoing freeze-concentration.

B. Freeze-Concentration System

A typical freeze-concentration system (Figure 106.2) consists of three fundamental components: (a) a crystallizer or freezer, (b) an ice-liquid separator, a melter-condenser, and (c) a refrigeration unit.

In the freeze-concentration system, a solution is usually first chilled to a pre-freezing temperature in a cooler (Figure 106.2), then the solution enters the crystallizer where part of the water crystallizes. Cooling causes ice crystal growth and an increase in solute concentration. The resulting mixture of ice crystals and concentrated solution is pumped through a separator where crystals are separated and the concentrated solution is drained off. Ice crystals are removed and melted by hot refrigerant gas. The final products are cold water and concentrated solution, which flow separately (1, 12, 13).

1. Crystallizers

The heat of crystallization can be taken out directly or indirectly. In direct-contact crystallizers the original solution is allowed to get in contact with the refrigerant, and heat is withdrawn by vacuum evaporation of part of the water, usually at pressures below 3 mm Hg, and by evaporation

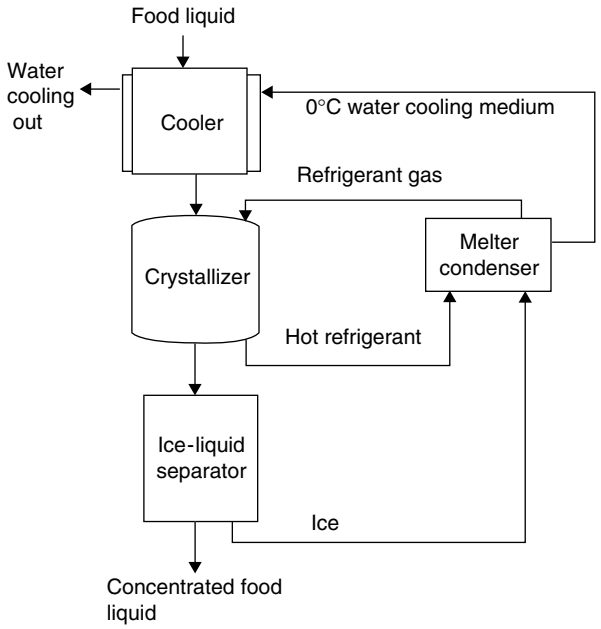

FIGURE 106.2 Schematic diagram for the freeze-concentration process of foods.

of the refrigerant. The refrigerants (CO_2, C_1–C_3 hydrocarbons) form ice-like gas hydrates, which sequester water at temperatures above 0°C. A disadvantage of this method is that part of the aromas will be lost during the evaporation. Direct heat removal is applied in seawater desalinization, but is not suitable for liquid foods, due to the aroma losses and deterioration of the product by the refrigerant. In crystallizers with indirect heat removal, the refrigerant (R22 or ammonia) is separated from diluted solution by a metal wall. So, crystallization takes place on chilled surfaces, from which ice crystals are removed by a scraper. This kind of process has been used commercially for orange juice and coffee concentration (1, 12, 13).

2. Separators of Ice-Concentrated Solution

The separation of ice crystals from concentrated solutions can be performed by use of presses, centrifuges, and washing columns, operating either in batch or continuous mode (12).

Hydraulic and screw presses are used for pressing ice-concentrated slurries to form an ice cake. Pressures around 100 kg/cm^2 are needed to avoid occlusion of solids in the cake, which is the limiting factor of this method. Since the presses are completely closed, aroma loss is negligible (1, 14).

Ice and concentrated solutions may be separated by centrifugation at about 1000 G. Centrifugation must be conducted under inert atmospheres to reduce oxidation and aroma loss. Solute losses may occur if concentrated solution remains adhered to the crystals surface, but washing of the cake with water minimizes such losses. This washing stage is a more efficient centrifugation operation than pressing (1, 2, 14). Application of progressive freeze-concentration (PFC) is used to improve the traditional freeze-concentration process. With PFC, only a single ice crystal is formed as a sheet on a cooled surface immersed in the liquid, thus, the separation of ice crystal from the mother solution is much easier compared with the suspension crystallization method (15).

In washing columns, the ice-solution mixture is introduced at the bottom of the tower and the solution is drained off. The crystals move toward the top of the column in countercurrent to the wash liquid, which is obtained by melting part (5–3%) of the washed crystals leaving the column. In this process the loss of dissolved solids with the ice is less than 0.01% and aroma losses are negligible. Washing columns are preferred in freeze-concentration of low viscosity liquids such as beer and wine (1, 12, 13).

C. Influence of Process Parameters

Crystallization is the main step in freeze-concentration, therefore, it is very important to obtain large and symmetrical crystals. Large crystals can be more easily separated from the concentrated solution. Large crystals also reduce the loss of solutes due to occlusion and adherence to the small crystals (1, 3). During crystallization two kinetic processes take place: the formation of nuclei and the growth of crystals. Nucleation is the association of molecules (at some degree of subcooling) into a small particle which serves as a site for crystal growth. Once nucleus is formed, crystal growth is simply the enlargement of that nucleus. Nucleation and growth of crystals are dependent on solute concentration, bulk supercooling, residence time of the crystals in the crystallizer, freezing rate, molecular diffusion coefficient of water, and heat transfer conditions. These factors should be carefully controlled to regulate crystal formation (2, 16).

1. Solute Concentration

In general an increase in solute concentration produces an increase in nucleation, and a decrease in the growth velocity of the ice crystals and in the mean diameter of the crystal. At critical concentration, solutes may solidify along with ice and are difficult to separate. Practical maximum concentrations for freeze-concentration are between 45–55% range (1, 14, 16).

2. Bulk Supercooling

Supercooling is the driving force responsible for the creation of crystal nuclei and its growth. The nucleation rate is proportional to the square of the bulk supercooling. At high bulk supercooling values the nucleation rate decrease due to the inhibition of molecular mobility.

Crystal growth exhibits a first order dependence of the bulk supercooling (1, 14, 16).

3. Residence Time of the Crystals in the Crystallizer

At constant bulk supercooling and solute concentration the crystal size is proportional to the crystal residence time. At short residence time the crystals produced are very small (1, 16).

4. Freezing Rate

A high freezing rate results in a strong local supercooling near the heat-removing interface, thus leading to high nucleation rates and to small crystals. A decrease in freezing rate results in large, uniform crystals with small surface area (1, 16).

5. Molecular Diffusion Coefficient of Water

A decrease in the value of the molecular diffusion coefficient of water results in a decrease in diameter of the crystals (1).

6. Heat Transfer Conditions

The growth rate of ice crystals increases greatly as the rate of heat removal is increased until some very low sample temperature at which mass transfer difficulties (at high viscosity) causing the growth rate to decline. Very large uniform crystals require large exchange surface at relatively high temperatures (1, 2, 14).

7. Viscosity of the Liquid

Viscosity increases markedly as concentration increases, ice crystals grow very slowly at high viscosity, and large crystals become difficult to separate. The maximum concentration obtainable in freeze-concentration depends on the liquid viscosity. Generally, concentration can be carried out to the point where the slurry becomes too viscous to be pumped. For essentially all liquids this viscosity limit is encountered before eutectic point formation occurs (Figure 106.1). The viscosity of cold concentrated liquid and ice is very high and agitation, which is necessary for proper crystal growth, becomes more difficult (9, 16).

In all ice separators, capacity is inversely proportional to the viscosity of the concentrate and directly proportional to the square of the mean diameter of the crystals as expressed by the equation:

$$Q = \frac{\Delta P\, g\, d_e^2}{0.2\,\mu l} * \frac{\varepsilon^3}{(1-\varepsilon)^2} \qquad (106.1)$$

where Q is the draining rate from the crystal bed (cm^3/cm^2s); ΔP is the pressure difference exerted over the bed by compression, centrifugal or pressure drop of the filtrate (kg/cm^2); d_e is the diameter of the crystals (cm); μ is the viscosity of liquid (poise); l is the thickness of the bed (cm); g is the gravity acceleration (cm/s^2); and ε is the volume fraction in the bed filled by the liquid phase (1).

II. FREEZE-DRYING

A. Introduction

Freeze-drying, or lyophilization, is the process of removing water from a product by sublimation and desorption (17). Sublimation is the transformation of ice directly into a gas without passing through a liquid phase. Sublimation occurs when the vapor pressure and the temperature of the ice surface are below those of the triple point (4.58 mm Hg, 0°C), as shown in the pressure-temperature phase diagram of pure water (Figure 106.3) (18). This technique is a widespread dehydration process in which the quality of final products is very high in comparison with that of products dehydrated using other techniques due the prevention of heat damage. Freeze-dried products have high structural rigidity, high re-hydration capacity, low density, and retain the initial raw material properties such as appearance, shape, taste, and flavor. This process is generally used for the dehydration of products of high added value and sensitive to heat treatments, produced by pharmaceutical, biotechnological and food industries.

The phase diagram of Figure 106.3 is separated by lines into three regions, which represent the solid, liquid, and gaseous states of water in a closed system. The points along the separating lines represent the combinations of temperature and pressure at which two states are in equilibrium: liquid-gas equilibrium (DB line), liquid-solid equilibrium (DA line), and solid-gas equilibrium (DC

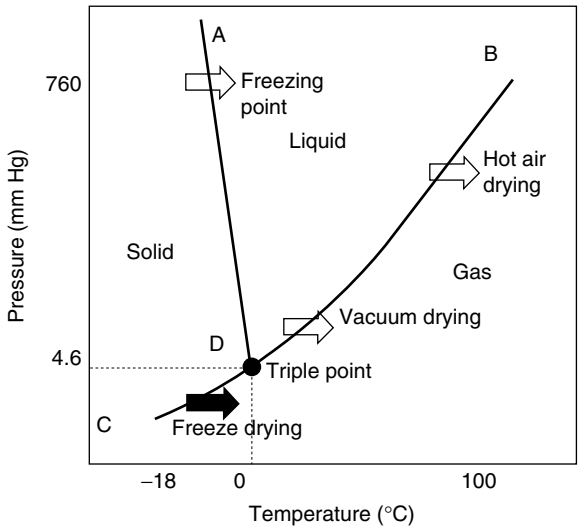

FIGURE 106.3 Pressure-temperature phase diagram of pure water.

line), which is of main concern in freeze-drying. Point D represents the only combination of temperature and pressure at which all three states of water are simultaneously in equilibrium, and it is called the triple point (4, 18).

Freeze-drying can also be conducted at moderated pressures and even at atmospheric pressure. The principle of this process is to produce a vapor pressure difference as large as possible by blowing dry air over the frozen material. In practice, the process is very long because of the low mass and energy transfer rates, but problems related to the application of vacuum do not exist, resulting in an important reduction of operation costs (19, 20).

Compared to air drying processes, which remove water in a single stage, freeze-drying is an expensive process since it takes large operation times and consumes large amounts of energy. Energy is required to freeze the product, heat the frozen product to sublimate ice, condense water vapor, and maintain the vacuum pressure in the system (21, 22). Despite of many advantages, freeze-drying has always been recognized as the most expensive process for manufacturing a dehydrated product (23).

B. Basic Components of a Freeze-Dryer

The typical freeze dryer consists of a drying chamber, a condenser, a vacuum pump, and a heat source (Figure 106.4).

The drying chamber, in which the sample is placed and heating/cooling take place, must be vacuum tight and with temperature controlled shelves. The condenser must have sufficient condensing surface and cooling capacity to collect water vapor released by the product. As vapors contact the condensing surface, they give up their heat energy and turn into ice crystals that will be removed from the system. A condenser temperature of −65°C is typical for most commercial freeze dryers. The vacuum pump removes non-condensable gases to achieve high vacuum levels (below 4 mm Hg) in the chamber and condenser. The heating source provides the latent heat of sublimation, and its temperature may vary from −30 to 150°C (19, 24).

Nowadays different variants of freeze-drying are studied like microwave-freeze-drying and fluidized atmospheric freeze-drier. Neverthless the first has technical problems in food industry and in the second drying times are higher and quality of product is not good due to the use of atmospheric pressure (23). Microwave can speed up the conventional freeze-drying because microwave energy augments the convection heating and drying rates can be increased by as much as an order of magnitude (25). The cost of freeze-drying process depends on the type of raw material, products, packaging, capacity of the plant, duration of the cycle, etc. Freeze-drying not be regarded as a prohibitively expensive preservation process if it gives a reasonable added value to the product (23). Freeze-drying is a method which can be used only for high value vegetables like mushrooms and capsicum or used for products that can be sold at a premium or can withstand only a small amount of sensory deterioration (25, 26).

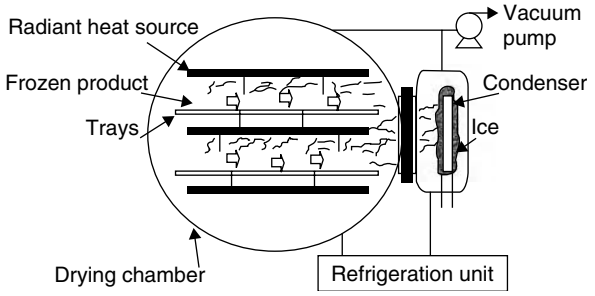

FIGURE 106.4 Simple schematic representation of a freeze dryer system.

C. Freeze-Drying Stages

Freeze-drying involves three essential stages: initial freezing, primary drying, and secondary drying. The objective of the freezing stage is to freeze the mobile water of the product. The product must be cooled to a temperature below its eutectic point, which is the temperature and composition combination that produces the lowest point at which a product will freeze. Freezing has an important influence on the shape, size, and distribution of the ice crystals and thus, on the final structure of the freeze-dried product. In the primary drying, the frozen product is heated under vacuum conditions to remove frozen water by sublimation, while the frozen product is held below the eutectic temperature. During the primary drying, approximately 90% of the total water in the product, mainly all the free water and some of the bound water, is removed by sublimation (27, 28). In the secondary drying, bound water (unfrozen) is removed by desorption from the dried layer of the product, achieving a product that should contain less than 1–3% residual water. This final stage is performed by increasing the temperature and by reducing the partial pressure of water vapor in the dryer (18, 28).

The secondary drying stage requires 30 to 50% of the time needed for primary drying due to the lower pressure of the remaining bound water than free water at the same temperature, yielding a slow process. Freeze-drying is complete when all the free and bound water has been removed, resulting in a residual moisture level that ensures desired structural integrity and stability of the product (18, 22).

D. Heat and Mass Transfer in Freeze-Drying

During the freeze-drying operation, a coupled heat and mass transfer process occurs within the product: energy is transported to the sublimation zone and water vapor is generated. In contrast with mass transfer, which always flows through the dry layer, heat transfer can take place by

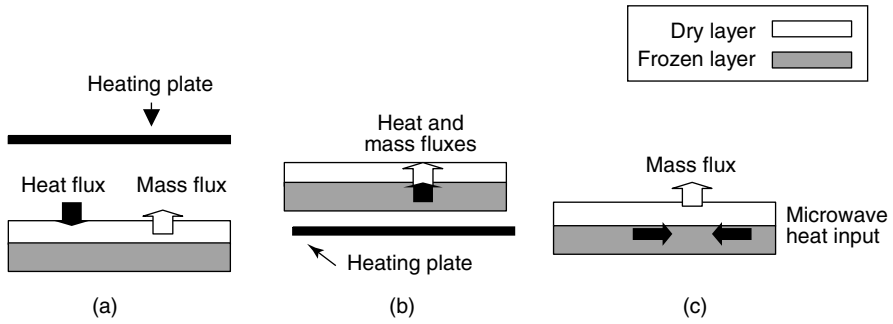

FIGURE 106.5 Basic types of freeze-drying.

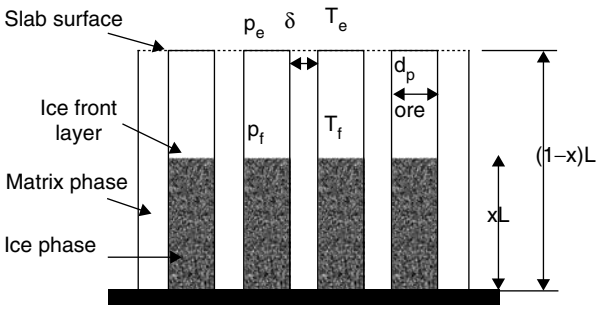

FIGURE 106.6 Schematic representation of freeze-drying of a slab.

conduction through the dry layer (Figure 106.5a) or through the frozen layer (Figure 106.5b), and by heat generation within the frozen layer by microwaves (Figure 106.5c) (12, 20). Microwaves are used as a heat source for drying because they are able to penetrate deeply into product, giving a more effective and uniform heating (29, 30).

Figure 106.6 illustrates a frozen food sample in the form of a slab, with a frozen and a dried porous layer, undergoing one-dimensional freeze-drying (18, 31). The interface between the dried and the frozen layers is referred to as the sublimation or ice front, and it is assumed to move at a uniform rate. The vapor flows through the pores and channels.

In case heat is supplied through the dry layer, the heat flux to the ice front is given by

$$q = k_d \frac{(T_e - T_f)}{(1 - x)L} \tag{106.2}$$

where q is heat flux (J/m^2 s), k_d is the thermal conductivity of dry layer (W/m K), T_e is the temperature at slab surface (°C), T_f is the temperature of sublimation front (°C), L is the thickness of slab (m), and x is the relative height of ice front.

If heat is transferred through the frozen layer,

$$q = k_f \frac{(T_p - T_f)}{xL} \tag{106.3}$$

where k_f is the thermal conductivity of frozen layer (W/m K) and T_p is the heating plate temperature (°C).

If vapor flows in the pores mainly by Knudsen diffusion, the collisions with the dry walls are numerous compared with collisions between water molecules, then the rate of ice sublimation (N_W, kg/s m^2) is given by

$$N_w = \varepsilon D_K \frac{M_w}{RT} \frac{p_f - p_e}{(1 - x)L} \tag{106.4}$$

where ε is the volume fraction of ice, D_K is the Knudsen diffusion coefficient of water vapor (m^2/s), M_w is the molecular mass of water (kg/mol), R is the gas constant (J/mol K), T is the absolute temperature (K), p_f is the vapor pressure at the ice front, and p_e is the vapor pressure at the slab surface (Pa).

The Knudsen diffusion coefficient is related to pore diameter (d_p) and temperature by

$$D_k = \frac{2}{3} d_p \left(\frac{2RT}{\pi M_w} \right)^{0.5} \tag{106.5}$$

At the ice front, T_f represents the sublimation temperature, and by assuming it to be in equilibrium, it is related to vapor pressure (p_w) by the Clausius-Clapeyron equation,

$$\ln(p_w) = 28.9 - \frac{6138}{T_f} \tag{106.6}$$

From a mass balance for water vapor around the drying slab:

$$N_w = \varepsilon \rho_{ice} \frac{d(xL)}{dt} \tag{106.7}$$

where ρ_{ice} is the density of ice (kg/m^3).

Assuming that all supplied heat is used for sublimation of ice, the enthalpy balance gives:

$$q = \Delta H_s N_w \tag{106.8}$$

where ΔH_s is the latent heat of sublimation (J/kg).

For temperature differences not too large, the Clausius-Clapeyron equation can be linearized and the above equations can be solved analytically. The following expressions can be derived for the total drying time

$$t = \frac{\alpha L^2}{D_k}(1 + \beta D_k) \quad (106.9)$$

in which

$$\alpha = \frac{1}{2}\rho_{ice}\frac{RT_f}{M_w}\frac{1}{(p_f - p_e)} \quad (106.10)$$

If heat transfer takes place through the dry layer, then $\beta = 0$; and if heat transfer occurs through the frozen layer,

$$\beta = \varepsilon\frac{M_w^2 \Delta H_s^2 p_f}{R^2 T_f^3 k_{ice}} \quad (106.11)$$

where k_{ice} is the thermal conductivity of ice (W/m K).

Several mathematical equations describing mass and energy transfer have been developed for modeling the freeze-drying process. Such models account for the removal of frozen water only (sublimation model) or the removal of frozen and bound water (sorption sublimation model), examine the methods of supplying heat and the diffusion mechanisms, describe steady or non-steady state processes, or analyze both transfers under various processing conditions. Some models have been found to describe accurately experimental drying rates and freezing times. However, a major problem in the application of some models is the requirement of reliable data on thermal and mass transport properties of food materials such as diffusivity within the porous medium, Knudsen diffusion, water vapor concentration in the dry layer, porosity, effective thermal conductivity, permeability, etc. (21, 27, 29, 32).

E. Influence of Parameters

A number of operation variables influence the performance of the freeze-drying process and the characteristics of the final product.

1. Freezing

The freezing rate has an important influence on the ice configuration and thus on the final structure of the freeze-dried product. Slow freezing rates allow the growth of large ice crystals leading to larger pores, higher mass flow, and thus to shorter freeze drying time (18, 31).

2. Heat Flux

Heat flux that reaches the product is an important factor to reduce drying rate. However, if the drying proceeds too rapidly (high heat flux), the product may melt, collapse, or can be blown out of the container (24). This may cause degradation of the product, and will change the physical characteristics of the dried material. Excessive heat may cause the dry cake to char or shrink. Heating rate can be optimized during operation modifying conveniently product temperatures in the dried zone and at the sublimation front (21, 33).

3. Chamber Pressure

The most important operation variable in the freeze-drying process is chamber pressure. Pressure has a combined effect as controlling mean of sublimation temperature and for modifying the transport parameters that influence the kinetics of vapor removing. At a given temperature, a decrease of the pressure in the drying chamber reduces the vapor pressure at the product's external surface (p_e), thus the driving force ($p_f - p_e$) for drying is enlarged and the total drying time is reduced. Nevertheless, at low pressures, sublimation rate may be limited by the transport of water vapor through the product, if the transport of water vapor falls in the free molecular flow regime (29, 33, 34).

Chamber pressure affects the transport properties, thermal conductivity and water vapor diffusivity. Thermal conductivity of the dry layer is higher at higher chamber pressures, within the range of freeze-drying operation, resulting in high heat transfer rates from the surface to the ice front. Water vapor diffusivity through the dry layer is, however, less at higher chamber pressures, producing low mass transfer rates. So, when pressure is low (low sublimation temperature) freeze-drying is often a heat-controlled process, but at relatively high pressures, freeze-drying becomes a mass-controlled process. In most situations the drying rate is limited by the rate of heat transfer through the dry layer (33–35).

4. Temperature

Aroma diffusivities are very similar to that of water when water content is still high, therefore, maintaining low temperatures during primary drying will reduce aroma losses. The melting point of products has a significant effect on the selection of operation pressures since this is a fundamental factor for the sublimation temperature. Normally, vacuum must be kept so high that no melting occurs in the product during the process, and a true freeze-drying or sublimation takes place. If the temperature of ice in the condenser is higher than product's temperature, water vapor will tend to move toward the product, and drying will stop (34, 35).

When freeze-drying temperature is high enough, the product cake suffers a drastic loss of its structure and is said to have suffered collapse. This phenomenon occurs when the solid matrix can no longer support its own weight, leading to drastic structural changes shown as a marked decreased volume, increase in stickiness of dry powders, loss of porosity, etc. (31). Collapse affects aroma retention, caking and stickiness, rehydration capacity, and final moisture of the product (36). A collapse temperature (T_c) is related to the glass transition temperature (T_g), which in turn depends on temperature and moisture content (Figure 106.1). At temperatures higher than T_g, the viscosity of the amorphous matrix decreases drastically, this decrease being a function of (T−Tg). As the viscosity decreases to a level that facilitates deformation, the matrix can flow, and structural collapse can

occur. A critical viscosity in the range of 10^5–10^8 Pas has been reported to observe collapse (28, 37).

III. CONCLUSIONS AND RECOMMENDATIONS

Despite the reduced use at industrial level of freeze-concentration and freeze-drying processes within food area, both are important to obtain high quality products. Deep knowledge of the thermodynamic fundamentals of phase changes of water in foods and of the effect of the variables on the processes' effectiveness and cost, can open new opportunities for the application of both processes to obtain high quality preserved foods. In the same way and with the development of new ideas about minimal processing and longer storage life for food products, industrial applications of freeze-concentration and freeze-drying could be increased in the near future.

Thermal Processing

107 Thermal Processing of Foods: Principles and Applications

Bradley P. Marks
Department of Food Science, Michigan State University

CONTENTS

I. INTRODUCTION

A. Purpose and Goals

A variety of "non-traditional" processing technologies, such as high-pressure processing or pulsed electric fields, are gaining significant attention in the food industry; however, the application of heat (i.e., thermal processing) remains the dominant means for processing most manufactured food products. Given the practical constraints of cost, throughput, and traditional practice, thermal processing will likely continue as the dominant means for processing value-added food products. Therefore, it is important for practicing food engineers to understand the fundamental principles that underlie the various processing operations that employ heat to achieve the desired purposes.

Thermal processing systems for food products are designed to achieve at least one, but usually several, of the following goals: (i) To destroy undesirable microorganisms that either cause spoilage of the product or are human pathogens, (ii) To inactivate native enzyme systems within the product, which would otherwise affect product quality, and (iii) To impart some desirable quality characteristics to the product, including flavor, color, and textural attributes. For example, heat is the means by which the toxin-producing *Clostridium botulinum* is inactivated in

canned foods. In that same canned product, heat inactivates pectin methylesterase, an enzyme that softens many vegetable products by attacking pectin in the cell wall. In terms of positive quality factors, heat helps create the desired crust and crumb features during baking of bread. In the case of ready-to-eat meat products, heat is used both to inactivate pathogenic bacteria (e.g., *Salmonella*) and to simultaneously create a desirable texture via protein denaturation during cooking. Table 107.1 lists several other examples of how heat plays a positive (+) and negative (−) role in achieving various processing goals.

Often, the best opportunities for improving these types of thermal process occur when operational experience melds with a sound understanding of the fundamental principles behind the process of interest. Operational experience is a valuable asset in food processing; however, without an understanding of the basic principles of heat and mass transfer, attempts at process improvement can result in a haphazard series of hit-and-miss adjustments to a given process. For example, an oven operator might observe that an increase in air velocity in an air impingement oven increases product temperature and therefore enables an increase in product throughput; however, that same operator might not recognize that this increase in velocity also increases mass transfer (via convection), which might have an undesirable effect on product quality, yield, and/or safety. In fact, Deming (1), the "father" of many of the principles embodied in total quality management and continuous quality improvement paradigms, noted that experience alone cannot ensure continuous process improvement. Deming calls for a "system of profound knowledge," in which one must first seek to understand the fundamental characteristics/properties/behaviors of a process or system before attempting to improve that process. In the case of thermal processing of food products, the primary foundation of that "profound knowledge" is comprised of the principles of heat and mass transfer. Only when these fundamental principles are well understood can the food engineer help ensure that any changes in process design or operation are directed toward improvements in the process outcome, whether that is in product safety, quality, or yield.

Therefore the overall goal of this chapter is to outline the general principles of heat and mass transfer that are essential background for a wide range of specific thermal operations that are detailed in subsequent chapters. This introduction is focused on principles most relevant to thermal processing of foods, and therefore cannot cover every aspect of heat and mass transfer. For comprehensive treatment of heat and mass transfer principles, the reader is directed to any of several good monographs or textbooks on the subject (2–5).

TABLE 107.1

B. Categorizing Products

Before outlining the underlying principles of thermal processing, it is necessary to define the domain of interest and application. There are a variety of schemes for categorizing food processing operations. With respect to heat and mass transfer, there are two different categorizations that are important — one based on the product and one based on how the product is exposed to the environment within the operation of interest.

In terms of the physical state of the food product, almost every product is actually comprised of matter in a mixture of phases: solid, liquid, and gas. For example, baked bread is a solid matrix containing a gaseous phase in the crumb. At −5°C, a raw meat product is comprised of an aqueous solution, solid water (ice), and insoluble solids (i.e., fats and certain proteins). The physicochemical complexity of such food products can make a detailed, rigorous analysis of heat and mass transfer during processing a very challenging task. Therefore, it is common to describe these products in a simplified manner, in order to make the heat and mass transfer analysis feasible and practical. Therefore, we can presume to place all food products into three distinct categories, according to physical state: (1) *fluid foods* (e.g., milk, ketchup, applesauce), (2) *solid foods* (e.g., meat patties, breakfast cereals, dried pasta), and (3) *mixed phase foods* (e.g., soups with particulates, canned beans in water). The third category (mixed phase) will be reserved to describe those products that have *macroscopically* distinct phases (i.e., "chunks and pieces"), rather than the cellular level mixture of phases that is common to many food ingredients and products.

It is also important to categorize food products according to how they are exposed to the processing environment. The two categories are: (1) *packaged products* and

(2) *unpackaged products*. Although the distinction is simple, the impact on thermal processing is significant. An impervious package (e.g., can, jar, bag) containing a product has the critically important effect of essentially stopping mass transfer in and out of the product during processing. Of course, some types of packaging, such as plastics, have various degrees of permeability to gases, with oxygen and water vapor being the most important. However, because these permeabilities are relatively low, the time scale for gas movement through the packaging is relevant to product transportation and storage (days to months), rather than to thermal processing operations, which are generally relatively short events (on the order of minutes). Thermal processing of packaged products is therefore primarily a *heat transfer* operation.

In contrast, unpackaged products are exposed to the heating medium, such as air, water, or oil. Consequently, thermal processing of unpackaged products is *both* a heat transfer and mass transfer operation. This adds an additional degree of complexity to the analysis of such operations, as heat transfer and mass transfer are rarely independent processes. For example, mass transfer can create a heat transfer effect when water diffusing to the surface of a product evaporates and creates a cooling effect on the product surface, due to the latent heat of vaporization. Also, oil diffusing into a product in an immersion fryer will carry heat energy into the product. Heat transfer can also create a mass transfer effect when, for example, the heating of a product changes the solid-vapor equilibrium for water in the product and in the surrounding air, and thereby affects drying operations.

Given the limitless combinations of product state, packaging, and processing operations, it would be impractical to describe and analyze heat and mass transfer for every application. Therefore, this chapter focuses on the fundamental principles of heat and mass transfer that underlie every thermal process. After the basic principles are covered, a variety of product/process applications will be examined to illustrate how heat and mass transfer principles are relevant to process design and operation.

II. HEAT TRANSFER PRINCIPLES

A. General Concepts

If a system is in thermal equilibrium, then the temperature is the same at every point in the system. In this state, there is no driving force for heat to flow. If the system is not in thermal equilibrium, then a temperature differential becomes the driving force for heat energy to flow through the system. As is the case in most energy transport phenomena, it can be stated, in the most general terms, that:

$$\text{energy flux} = \frac{\text{driving force}}{\text{resistance}} \qquad (107.1)$$

In heat transfer, the driving force is related to the temperature differential mentioned above, and the resistance is a property of the system.

With respect to the thermal processing of foods, the "system" might be the food product itself, some element of the processing equipment, or the walls surrounding the processing facility. In all of these cases, a temperature differential will cause heat to flow. There are three basic mechanisms by which this occurs: *conduction, convection,* and *radiation*. The subsequent sections describe these mechanisms, outline rate laws for each, and illustrate simple analysis methods applicable to thermal processing of foods.

B. Conduction

1. Fourier's Law

Temperature is a measure of the mean kinetic molecular energy of matter. As molecules with higher energy collide with or interact with nearby molecules of lower energy, energy is transferred from the higher energy molecule to the lower energy molecule. This molecule-to-molecule interaction is the basis of heat conduction.

If we consider a simplified slab of solid material that has a higher temperature (T_1) on one face than on the other (T_2), the molecule-to-molecule energy transfer described above will result in a net heat flow (q) from the hotter to colder surface (Figure 107.1). This conduction heat transfer is described by *Fourier's Law*:

$$\frac{q}{A} = -k\frac{dT}{dx} \qquad (107.2)$$

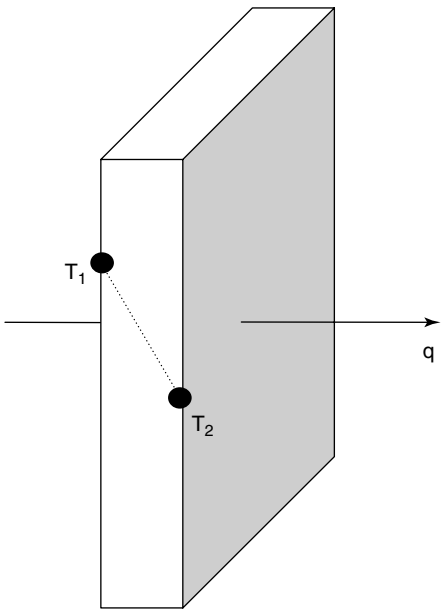

FIGURE 107.1 One-dimensional heat conduction through a slab, from higher temperature to lower temperature.

Where q is the heat flow due to conduction (Watts or Btu/h), A is the cross-sectional area of the slab, q/A is the heat flux (W/m^2), dT/dx is the temperature gradient across the slab, $(T_2 - T_1)/\Delta x$, and k is the thermal conductivity of the material (e.g., W/mK).

In order to illustrate the general principle of heat transfer stated earlier (Equation 107.1), we can rearrange Equation 107.2 to show that:

$$\frac{q}{A} = \frac{\Delta T}{\Delta x/k} \Rightarrow flux = \frac{\text{driving force}}{\text{resistance}} \qquad (107.3)$$

Therefore, in conduction, the driving force for energy transfer is the temperature differential (ΔT) across a finite distance, and the resistance is determined by the thickness (Δx) and thermal conductivity (k) of the material. This resistance term (Δx/k) is commonly referred to as the "R value" for building and construction materials. The concept of thermal resistance in food processing will be further illustrated and applied in subsequent sections.

Within the resistance term, thermal conductivity is an intrinsic property of a given material. From Equation 107.2, it can be seen that a material with a large thermal conductivity conducts heat well, whereas a material with a lower thermal conductivity conducts heat relatively poorly. Table 107.2 lists values of k for a variety of relevant materials. Obviously, metals have a thermal conductivity several orders of magnitude above those of food materials. In fact, the relatively low thermal conductivity of most food materials presents the food engineer with the special challenge of designing thermal processes that optimally match equipment capacities with product characteristics and the particular processing goals (e.g., heating time).

Additionally, there is a wide range of k values among food materials, which depends on chemical composition, physical structure, and temperature. In particular, k is 2–4 times higher for frozen foods than for the same foods in the unfrozen state. Additionally, k increases with moisture content of the food material.

Acquiring accurate k values (and other thermophysical properties) can be one of the most significant challenges in conducting heat transfer analyses of thermal processes for foods. There are essentially three choices for getting k values: (i) finding appropriate values in published sources, such as research articles or handbooks (6), (ii) using predictive equations, usually based on composition and temperature (6,7), or (iii) making experimental measurements with the product of interest, using a thermal conductivity probe (8). The choice of method depends on the application and required accuracy. Using published values is convenient, and suitable estimates can typically be found this way for preliminary or rough analyses involving relatively common, unprocessed food products (e.g., raw meat or vegetables). However, it is difficult to find published values for most processed food products. In contrast, general predictive equations are relatively straight forward, and account for the composition and temperature of the product of interest (assuming these are known); however, most of these general equations were developed for liquid or semi-liquid foods, so any degree of physical structure (e.g., porosity) within a food product can create appreciable errors from the equation-predicted values of k (9). Lastly, thermal conductivity probes can be constructed or purchased commercially, and allow for direct measurement of k for the product of interest. The downside is that the cost and time required for high quality measurements are quite high, and therefore must be weighed against the goal of the analysis and the importance of accuracy.

TABLE 107.2
Typical Thermal Conductivities of Various Example Materials

Material	k (W/mK)
Aluminum	200
Stainless steel	16
Plywood	0.12
Expanded polyurethane	0.02
Chicken breast (unfrozen)	0.41
Chicken breast (frozen)	1.50
Butter	0.20

2. Governing Equation

Fourier's Law (Equation 107.2) describes heat flux at an instant in time and a point in space. If Fourier's Law and the first law of thermodynamics (i.e., conservation of energy) are applied to a control volume, a general governing equation can be derived to describe one-dimensional heat transfer in a system, under any condition:

$$\underbrace{\rho c_p \frac{\partial T}{\partial t}}_{storage} + \underbrace{\rho c_p \frac{\partial}{\partial x}(uT)}_{bulk\ flow} = \underbrace{\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right)}_{conduction} + \underbrace{Q}_{generation} \qquad (107.4)$$

Where ρ is the material density, c_p is the material specific heat, u is the bulk movement/velocity of the material through the control volume, and Q is a heat generation term (W/m^3).

Each of the four terms in Equation 107.4 represent a different aspect of thermal analysis. Therefore, this general equation is the starting point for all subsequent analyses of conduction heat transfer in food materials. However, solution of the complete equation is rarely needed, because one or more of the terms can usually be neglected for a given analysis. The *storage term* represents the net change in thermal energy in the control volume over time. For a steady-state problem (discussed in the next section), temperature

varies with location but not time; therefore, the storage term can be ignored for that case. The *bulk flow term* represents energy moving in or out of the control volume due to mass flow. This is relevant to problems with fluid foods or materials; however, this term can generally be ignored for analysis of heat flow in solid materials. The *conduction term* describes the change in conductive flux across the control volume, and can rarely be ignored in food processing applications (see next section). Lastly, the *heat generation term* represents heat that might result from biological activity (e.g., respiration of microorganisms) in a food material or from exothermic chemical reactions occurring during processing. In most cases, heat from biological activity is more relevant to food storage applications than to thermal processing applications, where the thermal energy applied by the system (e.g., ovens, retorts, fryers) is orders of magnitude greater than energy resulting from biological activity within the food product. The next few sections detail the general solution methods for each of these specific cases, as relevant to thermal processing of foods.

3. Steady-State Conduction

If the temperatures in a system are constant, but unequal (e.g., Figure 107.1), then the flow of heat is constant, and this case is called *steady-state* conduction. Given that the purpose of thermal processing operations is to change the temperature of the food product, steady-state analysis is not directly relevant to heat transfer in food products, and therefore will not be addressed in detail. Such analysis would, however, be relevant if analyzing heat loss or gain through the walls of a piece of equipment, where the exterior and interior surfaces would be at different, but relatively constant, temperatures. In that case, the steady-state heat flux through the equipment wall could be estimated by:

$$\frac{q}{A} = \frac{\Delta T}{\Sigma R} \tag{107.5}$$

Where ΣR is the sum of the R-values for each "layer" comprising the wall of the equipment (e.g., a layer of insulation material sandwiched between two layers of stainless steel sheet).

4. Unsteady-State Conduction

Most thermal processing applications entail unsteady-state conduction of heat through the food material. In these cases, the goal of heat transfer analysis is generally to estimate the product temperature at a given time or to estimate the time required to achieve a target product temperature. For a rigorous analysis of any such process, Equation 107.4 (or the relevant 2-D or 3-D version of the governing equation) needs to be solved, given the boundary conditions for that analysis. For irregular shapes or non-homogeneous materials, this analysis typically requires numerical solutions methods, such as finite element methods or finite difference methods. However, in some applications (e.g., with a solid, packaged product), it is feasible to conduct a simplified analysis to estimate the desired quantities and/or to evaluate the effects of various product or process parameters (e.g., product thickness) on the process outcome. The next few sections briefly present several of these methods.

In all of these cases, the boundary conditions around the product are necessary to solve for the product temperature or processing time. There are three possible boundary conditions:

Type 1: Fixed surface temperature

$$T = T_{surface} = \text{constant} \tag{107.6}$$

Type 2: Fixed surface heat flux

$$\frac{q_{surface}}{A} = -k\frac{dT}{dx}\bigg|_{surface} = \text{constant} \tag{107.7}$$

Type 3: Convection at the surface

$$-k\frac{dT}{dx}\bigg|_{surface} = h(T_{surface} - T_{\infty}) \tag{107.8}$$

Where T_{∞} is the bulk temperature of a fluid (air, water, or oil) surrounding the product, and h is the convective heat transfer coefficient (W/m^2K). This parameter is a function of the fluid properties, velocity, and product/flow geometry, and will be discussed in more detail in a subsequent section. In analyzing a thermal process, values of h are generally: (i) provided by an equipment manufacturer, (ii) estimated by predictive correlations (see Section II.4.c), or (iii) experimentally determined. In the third boundary condition, note that $T_{surface}$ is not a constant, but instead varies with time. If h is large enough, then $T_{surface}$ approaches T_{∞}, and thereby approximates the first type of boundary condition, which simplifies several of the solutions presented in the following sections.

a. Conduction with negligible internal resistance

As previously mentioned, in rare cases, the conduction term in Equation 107.4 can be neglected in the analysis, which leads to a simplified solution to the conduction problem. For a solid product, this condition can be tested via a dimensionless number called the Biot number (Bi). The Biot number reflects the ratio of the internal to external resistance to heat flow:

$$Bi = \frac{\text{internal (conductive) resistance}}{\text{external (convective) resistance}} = \frac{\frac{L}{kA}}{\frac{1}{hA}} \tag{107.9}$$

Where L is a characteristic dimension of the product, calculated as the ratio of volume V to surface area A. Therefore, Equation 107.9 can be rewritten as:

$$Bi = \frac{h\left(\frac{V}{A}\right)}{k} \tag{107.10}$$

For cases where the internal resistance is more than an order of magnitude less than the external resistance (Bi < 0.1), then the following simplified solution of Equation 107.4, known as the *lumped parameter method*, can be used with solution errors typically less than 5%:

$$\frac{T - T_\infty}{T_i - T_\infty} = e^{\left[\left(\frac{-hA}{mc_p}\right)t\right]} \tag{107.11}$$

Where A, m, and c_p are the surface area, mass, and specific heat of the product, respectively, T_i is the initial temperature, t is time, and T is the product temperature at that time. This solution is typically valid only for very conductive materials, such as metals. However, the Bi < 0.1 condition can also be satisfied for very low airflows around an object, which corresponds to higher external resistances (i.e., less effective convective heat transfer at the surface).

Example

An apple (diameter = 8.5 cm; assuming a sphere) is being cooled with low velocity air. The thermal conductivity of the apple is 0.42 W/mK. How low must the air velocity be to satisfy the Bi < 0.1 criterion and thereby make Equation 107.11 a valid solution method?

$$\text{Want } Bi = \frac{h\left(\frac{V}{A}\right)}{k} < 0.1$$

$$\frac{h\left(\frac{\frac{4}{3}\pi r^3}{4\pi r^2}\right)}{k} = \frac{h\left(\frac{r}{3}\right)}{k} < 0.1$$

$$\therefore h < \frac{(0.1)(k)}{\left(\frac{r}{3}\right)} = \frac{(0.1)(0.42\ \text{W/mK})}{\left(\frac{0.0425\ \text{m}}{3}\right)}$$

$$h < 3.0\ \text{W/m}^2\text{K}$$

Although this is a very small value of h, it is a feasible number at *very* low airflow (~5 cm/s for the given geometry), which is on the order of natural convection conditions. Therefore, in such a case, the lumped parameter method (Equation 107.11) could be used to solve for the product temperature. However, this would be very unusual for any thermal processing applications.

b. Conduction for very thick materials or very short times

This special case is typically referred to as the solution for a *semi-infinite geometry*. In this case, the object/body is so thick, relative to the processing time of interest, that it can be assumed to have only one surface, and to extend to an infinite depth below that surface. This assumption is valid if the following is true:

$$L \geqslant 4\sqrt{\alpha t} \tag{107.12}$$

Where L is the thickness of the object (half-thickness if the object is symmetrically exposed to the boundary condition), α is the thermal diffusivity of the object ($\alpha = k/\rho c_p$), and t is the time of interest. If Equation 107.12 is true for any given case, then the following solutions can be applied for each of the three boundary condition types (2), where x is the distance below the surface:

$$\text{Type 1:} \quad \frac{T - T_\infty}{T_i - T_\infty} = erf\left[\frac{x}{2\sqrt{\alpha t}}\right] \tag{107.13}$$

$$\text{Type 2:} \quad T - T_i = \left(\frac{2}{k}\right)\left(\frac{q_{surface}}{A}\right)\left(\frac{\alpha t}{\pi}\right)^{1/2} \exp\left(\frac{-x^2}{4\alpha t}\right) - \left(\frac{q_{surface}x}{kA}\right)\left[1 - erf\left(\frac{x}{2\sqrt{\alpha t}}\right)\right] \tag{107.14}$$

$$\text{Type 3:} \quad \frac{T - T_\infty}{T_i - T_\infty} = erf\left[\frac{x}{2\sqrt{\alpha t}}\right] + \exp\left(\frac{hx}{k} + \frac{h^2\alpha t}{k^2}\right) \times \left[1 - erf\left(\frac{x}{2\sqrt{\alpha t}} + \frac{h\sqrt{\alpha t}}{k}\right)\right] \tag{107.15}$$

Where the error function is defined as:

$$erf(\phi) = \frac{2}{\sqrt{\pi}} \int_0^\phi e^{-\phi^2}\, d\phi \tag{107.16}$$

for which tabular values can be found in most heat transfer books (2,3,4) or engineering handbooks.

Clearly no food product is infinite in thickness. Therefore, this solution method becomes relevant for very short process times. In these cases, the goal might be to evaluate the surface temperature, or the temperature just under the surface, given a short-time heating process.

Example

A ham steak (2.5 cm thick) is packaged after slicing and subjected to a post-process, surface pasteurization treatment

in a saturated steam environment. The package film is 1 mm thick and has the same thermal diffusivity as the ham (1.05×10^{-7} m²/s). The ham is initially at 7°C, and it is exposed to the condensing steam (100°C) for 30 seconds. The condensing condition results in a very high effective h (and therefore a very low external resistance), so that we will assume that $T_{surface} \sim T_\infty = 100°C$. We want to determine the product temperature at the surface between the ham and the package (i.e., 1 mm depth) after 30 s.

To determine whether the semi-infinite solution is valid for this case, we test the condition from Equation 107.12:

$$4\sqrt{\alpha t} = 4\sqrt{(1.05 \times 10^{-7}\,\text{m}^2/\text{s})(30\text{s})} = 0.007\,\text{m}$$

which is less than the half-thickness of the ham slice (0.0125 m). This test implies that for the given conditions and time, the center temperature of the ham slice does not change appreciably. Therefore, given an assumption of a type 1 boundary condition, Equation 107.13 can be used to solve for T(x = 0.001 m; t = 30 s):

$$\frac{T - 100°C}{7 - 100°C} = erf\left[\frac{0.001\,\text{m}}{2\sqrt{(1.05 \times 10^{-7}\,\text{m}^2/\text{s})(30\text{s})}}\right]$$

$$\frac{T - 100°C}{7 - 100°C} = erf[0.281] = 0.3085$$

(where *erf*[0.281] was taken from table values (2))

$\therefore$ T(x = 0.001 m; t = 30 s) = 71.3°C

It should be noted that the above solution method requires a uniform initial temperature within the product. For this case, however, the solution for a semi-infinite solid can be a relatively useful solution technique to estimate short-time/surface heating processes.

c. *Conduction with non-negligible internal resistance and long times*

When the test criteria for the lumped parameter method and the semi-infinite method are not valid, Equation 107.4 can be solved as an infinite series solution (2), where, for the case of an infinite slab (of thickness 2L, with type 1 boundary condition):

$$\frac{T - T_{surface}}{T_i - T_{surface}} = \sum_{n=0}^{\infty} \frac{4(-1)^n}{(2n+1)\pi} \cos\left[\frac{(2n+1)\pi x}{2L}\right] \times e^{-\alpha\left[\frac{(2n+1)\pi}{2L}\right]^2 t} \quad (107.17)$$

Fortunately, graphical representations of Equation 107.17 (truncated) are often employed for the simplified case of 1-D conduction in an infinite slab, an infinite cylinder, or a sphere, given uniform initial temperature, constant boundary conditions, no internal heat generation, and constant thermal properties (2–4). A portion of such a graph is shown in Figure 107.2 to illustrate how these graphs are used. Whereas the solution for a semi-infinite solid was valid for very short times, the graphical solutions (known as the Heisler charts) are valid for longer times, because they represent the truncated (single term) version of Equation 107.17. Therefore, in order to use the charts, the following condition must be true:

$$Fo = \frac{\alpha t}{L^2} > 0.2 \quad (107.18)$$

where Fo is the Fourier number, which is a dimensionless time parameter, and L is the half thickness of a symmetrical, infinite slab. For the cases of infinite cylinders or spheres, L is the radius.

The Heisler charts involve four dimensionless parameters, as follows:

$$m = \frac{k}{hL} \text{ (ratio of external to internal resistance)} \quad (107.19)$$

$$n = \frac{x}{L} \text{ (n = 0 for center and 1 for surface)} \quad (107.20)$$

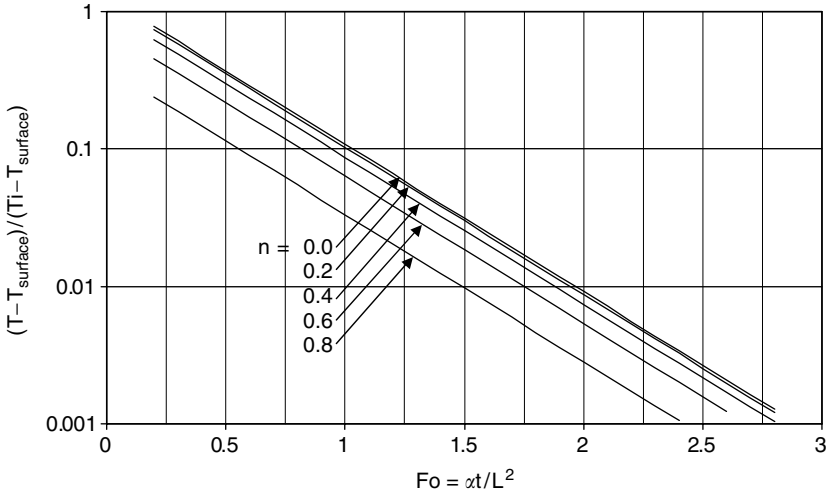

FIGURE 107.2 Example of Heisler-type chart (truncated series) solution for unsteady-state conduction in an infinite slab, for the special case of m ~ 0.

$$Fo = \frac{\alpha t}{L^2} \tag{107.21}$$

$$\frac{\Theta}{\Theta_0} = \frac{T - T_\infty}{T_i - T_\infty} \tag{107.22}$$

where T_i is the initial temperature, T_∞ is the medium (air, water, or oil) temperature, x is the distance from the center line of symmetry in the slab, and the thermal properties (k, α) are those of the product (not the heating medium). In applying graphical solutions, the user can solve for any of the above four parameters, given the other three. For example, one can solve for the product center temperature at a specific time, if the process conditions (h, T_∞, t) and product properties (k, α, R) are known. Conversely, one could estimate the time required to achieve a certain T_{center} if the product properties and process conditions (h, T_∞) were known. As an aside, in many thermal processing operations, which involve very high convective coefficients, m becomes sufficiently small (<0.1) to be assumed to be ~0 when using the graphs.

Example

Consider the packaged ham steak from the previous example (2.5 cm thick), which is now to be fully cooked in flowing hot water. The initial product temperature is 5°C. The thermal conductivity of the product is 0.41 W/mK, and the thermal diffusivity is 1.05×10^{-7} m²/s (assumed to be constant). The water temperature is 95°C, and the convective coefficient (h) is 430 W/m²K. We want to know the center temperature of the product after 8 minutes (480 s) of cooking.

First, assuming that the diameter of the slice is large enough to treat it as an infinite slab (i.e., d >> L), we test whether the graphical solution method is valid by testing whether Fo > 0.2:

$$Fo = \frac{\alpha t}{L^2} = \frac{(1.05 \times 10^{-7}\,\text{m}^2/\text{s})(480\,\text{s})}{\left(\frac{0.025\,\text{m}}{2}\right)^2} = 0.322$$

which indicates that the truncated series (graphical) solution method is acceptable. Now, we calculate the other two dimensionless parameters:

$$m = \frac{0.41\,\text{W/mK}}{(430\,\text{W/m}^2\text{K})(0.0125\,\text{m})} = 0.076 \sim 0$$

$$n = \frac{0}{0.0125\,\text{m}} = 0$$

Now, given Fo = 0.322, m ~ 0, and n = 0, we can estimate (from Figure 107.2) that:

$$\frac{\Theta}{\Theta_0} \approx 0.6 = \frac{T - T_\infty}{T_i - T_\infty} = \frac{T - 95°\text{C}}{5 - 95°\text{C}}$$

$$\therefore T(x = 0;\, t = 480\,\text{s}) = 41°\text{C}$$

It is important to reiterate that the graphical solutions are only valid for uniform initial temperature, constant boundary conditions, and for cases where significant mass transfer (e.g., evaporation) is not affecting the energy balance at the product surface.

d. Multi-dimensional conduction

The graphical solution introduced above for infinite slabs, infinite cylinders, or spheres can also be used to estimate the temperature in a 2-D or 3-D object. For example, a typical cylindrical metal can of food (diameter D and height H) is not sufficiently long to be treated as an infinite cylinder. At any point within the product, the temperature is obviously affected by heat flow through both the side and the ends of the can. Therefore, both dimensions must be considered in the analysis. In order to accomplish via the graphical solutions, the can is treated as the intersection of an infinite cylinder (diameter D) and an infinite slab (thickness H), so that

$$\frac{T(r, z, t) - T_\infty}{T_i - T_\infty} = \left[\frac{T(r, t) - T_\infty}{T_i - T_\infty}\right]_{\text{infinite cylinder}} \times \left[\frac{T(z, t) - T_\infty}{T_i - T_\infty}\right]_{\text{infinite slab}} \tag{107.23}$$

where the dimensionless temperature terms for the infinite cylinder and infinite slab are estimated independently, using the appropriate Heisler charts. The same principle would hold for a rectangular solid, which would be treated as the intersection of three infinite slabs.

C. Convection

In the previous section, the solution of various heat conduction problems required an h value to describe the convective boundary condition, and these coefficients were given as known values. Convective heat transfer coefficients vary widely, depending on fluid properties, flow conditions, and flow geometry (Table 107.3). However, actually determining h values for a thermal processing operation can be a significant challenge, depending on the complexity of the product and process. This section briefly describes the principles behind the convective heat transfer coefficient, general concepts for predicting h, and a basic technique for experimentally determining h.

TABLE 107.3
Typical Values for Convective Heat Transfer Coefficients

Flow Type	h (W/m²K)
Natural air	10
Forced air (fan)	30
Air impingement (dry)	100+
Moving water	~1,000

1. Newton's Law of Cooling and Boundary Layer Concepts

Newton's Law of Cooling describes heat flux between a solid surface and a fluid passing over the surface (Figure 107.3), so that:

$$\frac{q}{A} = h(T_{surface} - T_{\infty}) \tag{107.24}$$

where h is the convective heat transfer coefficient (W/m^2K). As we did for conduction, we can rearrange Equation 107.24 to yield:

$$\frac{q}{A} = \frac{T_{surface} - T_{\infty}}{1/h} \Rightarrow flux = \frac{\text{driving force}}{\text{resistance}} \tag{107.25}$$

Therefore, the driving force for convective heat transfer is the difference between the bulk fluid temperature (T_∞) and the surface temperature, and the resistance is 1/h.

Physically, the convective resistance to heat flow results from the formation of a *boundary layer* near the surface past, which the fluid is flowing (Figure 107.3). Assuming that $T_{fluid,surface}$ equals $T_{solid,surface}$ and a no-slip condition for the fluid at the surface (i.e., $v_{surface} = 0$), then profiles for temperature and velocity are found near the surface (Figure 107.3). The boundary layer thicknesses (δ_T and δ_v) are defined as the point where:

$$\frac{T_s - T_{\delta}}{T_s - T_{\infty}} = 0.99 \text{ (for the temperature boundary layer)} \tag{107.26}$$

$$v_{\delta} = 0.99 v_{\infty} \text{ (for the velocity boundary layer)} \tag{107.27}$$

Equating conductive flux through the boundary layer with convective flux at the surface yields correlations that relate h to the fluid properties, flow conditions, and flow geometry. These correlations are different for forced and natural convection conditions, and they include several dimensionless parameters, as follows:

$$\text{Nusselt Number} = Nu = \frac{hL}{k_{fluid}} \tag{107.28}$$

$$\text{Reynolds Number} = \text{Re} = \frac{v_{\infty}\rho_{fluid}L}{\mu_{fluid}} \tag{107.29}$$

$$\text{Prandtl Number} = \text{Pr} = \frac{\mu_{\text{fluid}}/\rho_{fluid}}{\alpha_{fluid}} \tag{107.30}$$

$$\text{Grashof Number} = \text{Gr} = \frac{\beta_{fluid}\, g\, \rho_{fluid}^2 L^3 \Delta T}{\mu_{fluid}^2} \tag{107.31}$$

$$\text{Rayleigh Number} = \text{Ra} = \text{Gr} \times \text{Pr} \tag{107.32}$$

where μ_{fluid} is the fluid viscosity, β_{fluid} is the coefficient of thermal expansion of the fluid (=1/T for an ideal gas), and g is the gravitation constant.

2. Forced Convection

a. *Predictive correlations*

When a fluid is forced over a surface, the correlations to predict h follow the general form:

$$Nu = f(\text{Re}, \text{Pr}) \tag{107.33}$$

where each geometric case yields a different correlation. These have been determined for various common geometries, such as the following for flow over a flat plate:

$$\text{Local: } \text{Nu}_x = 0.332\ \text{Re}_x^{1/2}\ \text{Pr}^{1/3} \tag{107.34}$$

$$\text{Average: } \text{Nu}_L = 0.664\ \text{Re}_L^{1/2}\ \text{Pr}^{1/3} \tag{107.35}$$

$$\text{where Re} < 200{,}000$$

or for the case of forced flow over a spherical object:

$$Nu_D = 2 + (0.4\ \text{Re}_D^{1/2} + 0.06\ \text{Re}_D^{2/3})\ \text{Pr}^{0.4} \tag{107.36}$$

$$\text{where } 3.5 < \text{Re}_D < 7.6 \times 10^4 \text{ and } 0.71 < \text{Pr} < 380$$

Additionally, the general form of Equation 107.33 has been used to develop a variety of product specific correlations (6),

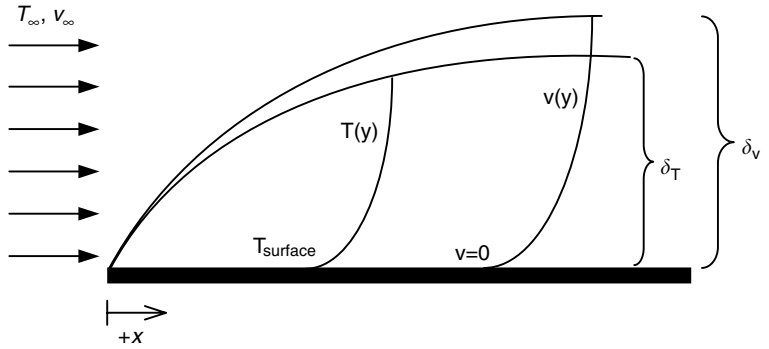

FIGURE 107.3 Temperature and velocity profiles in the boundary layer for laminar flow over a flat plate.

such as the following for airflow over an egg (10), which was developed for an equivalent diameter of 3.4 cm and air velocity from 2 to 8 m/s:

$$Nu = 0.46\ \mathrm{Re}^{0.56} \tag{107.37}$$

Example

Calculate the convective heat transfer coefficient for hot air (220°C) blowing over a pea (T_i = 14°C; 0.85 cm diameter) at a velocity of 3.5 m/s.

In calculating the relevant dimensionless parameters, the fluid properties need to be determined, generally from table values. Because fluid properties can be quite temperature dependent, they should be evaluated at an average temperature called the film temperature: $T_{film} = (T_\infty + T_{surface})/2$. So, for the case of the pea, at the start of the process, $T_{film} = (220 + 14°C)/2 = 117°C$. Therefore, from tables, the following property values were found: $\rho = 0.9050\ kg/m^3$; $\mu = 2.2447 \times 10^{-5}$ kg·m/s; $k_f = 0.03295$ W/mK; $\alpha = 3.5942 \times 10^{-5}\ m^2/s$; and Pr = 0.690. Now,

$$\mathrm{Re} = \frac{\rho v D}{\mu} = \frac{(0.9050\ kg/m^3)(3.5\ m/s)(0.0085\ m)}{2.2447 \times 10^{-5}\ kg \cdot m/s}$$

$$= 1{,}199$$

which is within the acceptable range for Equation 107.36. Although the Pr value (0.690) is slightly below the range for Equation 107.36, we will go ahead and use that equation (lacking any better option and assuming the slight deviation to have a very minor effect on the correlation validity).

$$Nu_D = \frac{hD}{k_{fluid}} = \frac{h(0.0085\ m)}{0.03295\ W/mK}$$

$$= 2 + (0.4(1{,}199)^{1/2} + 0.06(1{,}199)^{2/3})0.690^{0.4}$$

$$\therefore h = 76.7\ W/m^2K$$

Obviously, many real factors, such as the surface characteristics of the food product, would affect the accuracy of these Nu correlations when predicting h values for forced convection. However, the correlations are useful for generating order of magnitude estimates and for estimating the effects that would result from changing product or process parameters (e.g., increasing fluid velocity).

b. Experimental determination

For irregular product or flow geometries, the basic Nu correlations will not work; however, it is reasonably simple to conduct experiments to determine h for a given case (assuming that the processing system/equipment is available). The first step is to create a metal replica of the food product of interest. With aluminum, almost any food product geometry is sufficiently small to meet the $Bi < 0.1$ criterion and thereby make the lumped parameter method (Equation 107.11) an appropriate solution. Therefore, Equation 107.11 can be rewritten as:

$$\ln\left(\frac{T - T_\infty}{T_i - T_\infty}\right) = \left(\frac{-hA}{mc_p}\right)t \tag{107.38}$$

Now, a temperature sensor should be placed in the center of the model (metal) food product, and temperature data should be collected as the metal model is exposed to the processing environment, as if it were being processed like the food product of interest. Given known properties of the metal and known fluid temperature, a linear regression of the time-temperature data (in the form of Equation 107.38) will yield an estimate for h. Depending on the process, one should be cautious that the resulting data indicate a relatively constant h, and that the data are not strongly influenced by mass transfer (e.g., via evaporation of condensation at the surface). Otherwise, the regression will not yield a true h value for the process. Continuously varying boundary conditions create a special challenge for analysis of convective coefficients, which is beyond the scope of this chapter; however, one needs to be aware if this case is encountered.

Natural convection

Even when a fluid is not being mechanically forced past a food product, it is possible for convection to occur. This phenomenon, known as natural convection, is driven by buoyancy differences in the boundary layer near a product surface that is at a different temperature than the surrounding fluid. Analogous to the Nu = f(Re, Pr) correlations for forced convection, correlations for natural convection are typically of the form:

$$Nu = f\,(Ra, \mathrm{Pr}) \tag{107.39}$$

Obviously, h values for natural convection are much lower than those for forced convection, and thermal processes for food products are rarely designed for natural convection conditions. Therefore, correlations for these cases are not presented here, but can be found in most heat transfer texts (2–4).

D. Radiation

In contrast to conduction and convection, radiation heat transfer does not require a transfer medium or directly physical contact. In radiation heat transfer, thermal energy is transferred via electromagnetic waves. Every object emits thermal energy in this way, with hotter objects emitting more energy, as described by the Stefan-Bolzmann Law:

$$\frac{q}{A} = \varepsilon\sigma T^4 \tag{107.40}$$

where ε is the emissivity of the object, T is the absolute temperature (K) of the object, and σ is the Stefan-Bolzmann constant ($5.676 \times 10^{-8}\ W/m^2K^4$).

The emissivity of a material is a function of its composition and surface characteristics, and can range from 0 to 1. For an ideal "black body," which is a perfect emitter, $\varepsilon = 1$. For a perfect reflector, $\varepsilon = 0$. Most food materials (and most biological materials, in general) have relatively high emissivities, in the range of 0.90 to 0.95.

While Equation 107.40 describes the *total* thermal energy radiated by an object, it is generally of more practical interest to evaluate the *net* radiative flux between two objects. For the most general case, with object 1 and object 2:

$$q_{1-2} = \frac{\sigma(T_1^4 - T_2^4)}{\frac{1-\varepsilon_1}{\varepsilon_1 A_1} + \frac{1}{A_1 F_{1-2}} + \frac{1-\varepsilon_2}{\varepsilon_2 A_{12}}} \qquad (107.41)$$

where F_{1-2} is a dimensionless view factor that quantifies (0 to 1) the fraction of total radiation emitted that is exchanged between two objects, given their geometry and orientation.

For the special case when one of the two objects (object 1) is completely enclosed inside the other (Figure 107.4), Equation 107.41 can be simplified to yield:

$$\frac{q_{1-2}}{A_1} = \varepsilon_1 \sigma (T_1^4 - T_2^4) \qquad (107.42)$$

where A_1, ε_1, and T_1 are the properties of the enclosed object. Keeping with our general concept of driving forces and resistances, it can be seen in Equation 107.42 that the driving force for radiation heat transfer is the difference between T^4 values, and the resistance is $1/\varepsilon$, a property of the product.

Example

An infrared/radiative tunnel oven is being proposed to brown the surface of a meat roast before it is cooked in a moist-air oven. The initial temperature of the roast is 6°C (~279 K), and it has an emissivity of ~0.93. The surface temperature inside the oven is 815°C (~1,088 K). What is the initial radiative flux to the surface of the roast when it enters the oven?

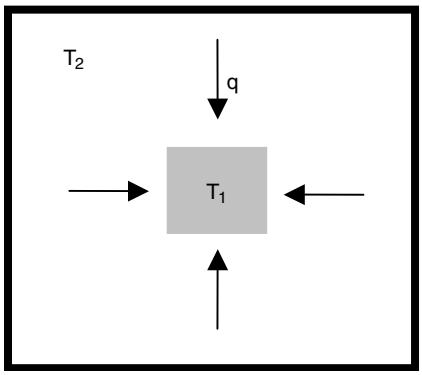

FIGURE 107.4 Radiative flux when one object (1) is completely enclosed by a much larger surface (2).

Using Equation 107.42:

$$\frac{q_{1-2}}{A_1} = (0.93)(5.676 \times 10^{-8}\,\mathrm{W/m^2K^4})(279^4 - 1{,}088^4\,\mathrm{K^4})$$
$$= -73.6\,\mathrm{kW/m^2}\ \text{(The negative sign reflects energy into the roast.)}$$

III. MASS TRANSFER PRINCIPLES

A. General Concepts

As was the case with heat transfer, mass transfer occurs when a system is not equilibrium, so that an analogous generalized transport equation for mass transfer can be stated as:

$$\text{mass flux} = \frac{\text{driving force}}{\text{resistance}} \qquad (107.43)$$

where the mass flux describes the movement of a single species (e.g., water or oil) through a system (e.g., a food product). The distinction between heat transfer analyses and mass transfer analyses is primarily related to the characterization of equilibrium state. In heat transfer, equilibrium is characterized by equal temperature throughout the system. However, in mass transfer, equilibrium is not necessarily characterized by equal concentration throughout the system.

Rather, specific relationships define the equilibrium states at gas-liquid, gas-solid, and liquid-solid interfaces. For a gas-liquid interface, the equilibrium state is defined by *Henry's Law*:

$$p_A = Hx_A \qquad (107.44)$$

where p_A is the partial pressure of component A in the gas, x_A is the molar concentration of A in the liquid, and H is Henry's constant, which is specific for a given liquid, gas, and temperature. For a gas-solid interface, the equilibrium state is defined by *equilibrium (sorption) isotherms* that relate (for example) the moisture content of a food material to the humidity in the surrounding air. These isotherms are product specific and very dependent on product composition. Therefore, they are typically determined experimentally for each food product. Lastly, at liquid-solid interfaces, equilibrium isotherms also describe the relationship between the concentration of A in the liquid and in the solid. In small ranges of concentration, this relationship is often characterized for a given case by a *partition coefficient* (K^*), where:

$$K^* = \frac{C_{A,solid}}{C_{A,liquid}} \qquad (107.45)$$

The next sections will show that the mass transfer rate laws are directly analogous to those for heat transfer. However, it is important to note that accurate mass transfer analyses are highly dependent on good information regarding the equilibrium relationships. Although in-depth analysis of these relationships are beyond the scope of this chapter, the food engineer generally is left to seek out product specific, empirical data for the particular application being analyzes.

B. Diffusion

Transport of a species (e.g., water) through a real food product can result from the combined effect of several mechanisms, including capillary forces, gravitational forces, osmotic potential, and molecular diffusion, making a detailed analysis of a complete mass transfer problem fairly complex for most food products. Transport of a liquid through a porous medium is often described by *Darcy's Law*:

$$n = -K\frac{\partial H}{\partial x} \tag{107.46}$$

where n is the volumetric flux (m^3/m^2s), K is the hydraulic conductivity (m/s), and H is the hydraulic potential (m), which is the sum of the various potential differences driving flow. Many food products are, in fact, porous media, with several of the above flow potentials present. However, it is fairly difficult to isolate and independently describe each of these potential terms.

In contrast, concentration-driven flow of one species (e.g., water) through another (e.g., fruit to be dried) can be described by *Fick's Law*:

$$j_A = -D_{AB}\frac{dc_A}{dx} \tag{107.47}$$

where j_A is the diffusive flux (kg/m^2s) of species A, D_{AB} (m^2/s) is the mass diffusivity of A in B (e.g., water in fruit), and c_A (kg/m^3) is the concentration of A in B. Unlike thermal properties (e.g., k), which are relatively easy to find in the literature, to predict, or to measure, mass diffusivity is experimentally more difficult to measure and therefore far more scarce in the literature. Therefore, it is often necessary to make use of estimates based on data found in the literature for similar food products.

C. Convection Mass Transfer

Convection mass transfer at a surface can be described via an analogy to Newton's Law of Cooling, so that:

$$\frac{j_A}{A} = h_m(c_{A,fluid,surface} - c_{A,fluild,\infty}) \tag{107.48}$$

As with heat transfer, h_m can be predicted by correlations analogous to the Nu = f(Re, Pr) relationships. In fact, the same correlations can be used simply by substituting two of the dimensionless numbers. The Sherwood number (Sh) replaces the Nusselt number, and the Schmidt number (Sc) replaces the Prandtl number, where:

$$Sh = \frac{h_m L}{D_{AB}} \tag{107.49}$$

$$Sc = \frac{\mu_{fluid}/\rho_{fluid}}{D_{AB}} \tag{107.50}$$

where D_{AB} is now the diffusivity of A in the fluid (not the solid).

It is also important to point out that $c_{A,fluid,surface}$ in Equation 107.48 is the concentration of A in the fluid at the surface, rather than the concentration of A in the solid at the surface. As mentioned earlier, $c_{A,fluid,surface}$ and $c_{A,solid,surface}$ are two distinct quantities, which are directly related via equilibrium (sorption) isotherms.

D. Condensation and Evaporation

Condensation and evaporation are often treated as distinct mechanisms of heat transfer; however, both are actually mass transfer phenomena that can create a significant heat transfer effect. In the case of moist air, condensation to a food product surface occurs when $c_{A,air,\infty} > c_{A,air,surface}$, which also corresponds to the state when $T_{air,dewpoint} > T_{product,surface}$. In fact, in condensing conditions, $c_{A,air,surface}$ can be assumed to be the saturation vapor concentration in the air at the surface temperature. Evaporation is simply the opposite phenomenon, which occurs when the converse of the above inequalities are true.

Condensation can be a particularly important mechanism in thermal processing, as condensing steam can transfer significant energy to a product surface. When a condensing-convective boundary condition occurs, the heat flux at the surface becomes:

$$\frac{q}{A} = \underbrace{h(T_{surface} - T_\infty)}_{\text{convection}} + \underbrace{\lambda_v h_m(c_{air,surface} - c_{air,\infty})}_{\text{condensation}} \tag{107.51}$$

where λ_v is the latent heat of vaporization (2,070 kJ/kg for water). Along the course of a dynamic thermal processing operation (e.g., in a continuous, moist-air oven), the driving forces (ΔT and Δc) would vary, while the resistances (1/h and $1/h_m$) would typically remain relatively constant. From the perspective of fundamental principles, this is an important point to consider when designing systems that appropriately match product objectives with process capabilities.

IV. APPLICATION CONCEPTS

The purpose of this section is to illustrate how the various principles introduced in this chapter can be used to evaluate the relative importance of heat transfer mechanisms on thermal processes or to evaluate the impact of changing one or more product/process parameters.

Example

In a dry air impingement oven, with a very large convection coefficient (~110 W/m^2K), which mechanism (convection or conduction) presents the largest resistance to increasing the product core temperature at the beginning stages of baking a cookie (0.8 cm thick, with an estimated k of ~0.39 W/mK)?

The conductive (internal) resistance is calculated as L/k, where L is the half-thickness (assuming symmetrical boundary conditions on the top and bottom). Therefore L/k = (0.004 m)/(0.32 W/mK) = 0.012 Km^2/W. In comparison, the convective (external) resistance is 1/h = 1/(110 W/m^2K) = 0.009 Km^2/W. (Recall that the Biot number, Bi, is a dimensionless measure of the ratio of these resistances.) Although the conductive resistance is slightly larger in this case, the two resistances are of the same order of magnitude. From an equipment or process design perspective, this is a fairly reasonable place to be. If the internal resistance were significantly larger than the external resistance, then we are probably putting too much energy (i.e., via fan size) into achieving a very high convection coefficient, when the internal resistance is the rate-limiting factor. Conversely, if the external resistance were much larger than the internal resistance, then we may have under-engineered our processing system, assuming that rapid heating is a desirable outcome. Even without conducting a complete analysis of the heat transfer in this process, this example illustrates that the basic principles of heat transfer can be used to evaluate various aspects of the process and product design.

Example

In the impingement oven mentioned above, can radiation be ignored in the heat transfer analysis, if the oven air temperature is 205°C (~478 K), the product surface temperature is 10°C (~283 K), and the product emissivity is 0.9?

For the convection component:

$$q_{conv}/A = h(T_\infty - T_{surface}) = (110\ W/m^2K)(205 - 10°C) = 21{,}450\ W/m^2$$

For the radiation component, assuming that the walls in the oven are the same temperature as the air:

$$q_{rad}/A = \varepsilon\sigma[(T_\infty)^4 - (T_{surface})^4] = (0.9)(5.676 \times 10^{-8}\ W/m^2K^4)(478^4 - 283^4\ K^4) = 2{,}339\ W/m^2$$

The convection component is approximately 10 times greater than the radiation component, so that the radiation component can probably be neglected for most simple analyses of this process. However, keep in mind that both of these components of the flux will decrease as the process continues, thereby affecting their relative importance to the process outcome.

Example

In a moist-air, convection oven, which contributes more energy to the product, convection or condensation?

Consider the following set of conditions, which were taken as a "snapshot" from actual experimental trials in a commercial-scale oven: $T_\infty = 127°C$; $c_\infty = 0.45\ kg/m^3$ (corresponds to 83% moisture by volume in the air); $T_{surface} = 30°C$; $c_{surface} = 0.0296\ kg/m^3$ (based on the saturation vapor concentration at $T_{surface}$); $h = 100\ W/m^2K$; and $h_m = 120$ mm/s. Now, from Equation 107.51, we can calculate the instantaneous convective and condensing fluxes:

For the convection component:

$$q_{conv}/A = h(T_\infty - T_{surface}) = (100\ W/m^2K)(127 - 30°C) = 9{,}700\ W/m^2$$

For the condensing component:

$$q_{condensing}/A = \lambda_v h_m(c_\infty - c_{surface}) = (2{,}070 \times 10^3\ J/kg)(0.120\ m/s) \times (0.45 - 0.0296\ kg/m^3) = 104{,}427\ W/m^2$$

Clearly, at the instant in time presented, condensation is responsible for more than 90% of the heat flux into the product. However, as the product temperature rises, eventually $c_{surface}$ will approach and exceed c_∞, thereby eliminating condensation and potentially causing evaporation, depending on the product.

Example

How does doubling the air velocity affect the heating time for any thermal process? Does it cut it in half?

The principles of convection and unsteady-state conduction have shown that the heat transfer mechanisms are non-linear, so that a one-to-one relationship should not be expected between process parameters and product outcomes. In this case, the Nu = f(Re, Pr) correlations show that doubling of the fluid velocity will double Re, but will result in something less than doubling of h, given Re^n, where $n < 1$. Additionally, depending on the processing goal, and therefore the solution method used, the relationship between h and processing time is also non-linear. However, for any specific case, the basic principles introduced in this chapter could be used to evaluate the relative impact that any process or product change would have on the outcome.

System Solutions for the Food Industry

CONTENTS

DEFINITION OF VARIABLES

A = cross-sectional area (m^2)
a = variable power
b = variable power

$$\text{Bi} = \text{Biot number} = \frac{internal\_resistance}{external\_resistance} = \frac{hL}{k} = \frac{UL}{k} \text{ (dimensionless)}$$

C = a constant

Cp = heat capacity (kJ/kg°C)

D = diameter of the pipe (m),

D = (in section 4 on unsteady-state heat transfer), D refers to the critical dimension of a geometry, as defined in the text. This is in general useage.

D_h = hydraulic diameter (m)

E = electromagnetic energy

F_{1-2} = shape factor for radiation absorption

Fo = Fourier number

$$= \frac{\text{rate of heat conduction across D in volume } D^3}{\text{rate of heat storage in volume } D^3}$$

$$= \frac{\alpha t}{D^2} \text{(dimensionless)}$$

f = friction factor

h = the convective heat transfer coefficient (W/m²°C)

k = thermal conductivity (W/m°C)

l = characteristic length

L = length of the cylinder (m)

Nu = Nusselt number

$$= \frac{diffusivity\_by\_convection}{diffusivity\_by\_conduction}$$

$$= \frac{hl}{k} \text{(dimensionless)}$$

Pr = Prandtl Number

$$= \frac{diffusivity\_of\_momentum}{diffusivity\_of\_energy}$$

$$= \frac{C_p \mu}{k} \text{(dimensionless)}$$

q_r = rate of heat or energy flow in radial direction (W) or (kJ/s)

q_x = rate of heat or energy flow in x direction (W) or (kJ/s)

q_{1-2} = heat radiated by surface 1 to surface 2

R_t = total thermal resistance

R_{mi} = resistance of the metal on the inside

R_{ins} = resistance of the insulation

R_{mo} = resistance of the metal on the outside

Re = Reynolds number

$$= \frac{inertial\_forces}{viscous\_forces} = \frac{Dv\rho}{\mu} \text{(dimensionless)}$$

r_o = outside radius (m)

r_i = inside radius (m)

T = Temperature in °C or °K

T_1 at x_1 = temperature at point x_1 (°C or °K)

T_2 at x_2 = temperature at point x_2 (°C or °K)

T_i = temperature on inside surface (°C or °K)

T_o = temperature on outside surface (°C or °K)

T_s = temperature of the solid surface (°C or °K)

T_∞ = temperature of the bulk fluid (°C or °K)

ΔT_{lm} = log mean temperature difference (°C or °K)

U = overall heat transfer coefficient (W/m²°C).

v = fluid velocity in m/s

w = mass flow rate (kg/s)

x = lineal distance (m)

Symbols

α = thermal diffusivity units of m²/s

Δ = difference

ε = represents the emissivity

ρ = density (kg/m³)

δ = thickness of the boundary layer

σ = Stephan-Boltzman constant = 5.669 $(10)^{-8}$ W/m²K⁴

ζ_{1-2} = accounts for both the shape factor and the emissivity of both surfaces 1 and 2

μ = fluid viscosity (Pa · s)

μ_b = bulk fluid viscosity

μ_w = viscosity of the fluid at the hot wall

Subscripts

CF = cool fluid

HF = hot fluid

Heat transfer refers to the rate or speed at which the temperature changes with time and across a distance. Heat transfer applies to processes of cooking, pasteurization, blanching, commercial sterilization, baking, and evaporation, to name a few. In this chapter heat processing equipment and mathematical models of various types of heat transfer are presented. Because this short chapter covers an extensive area, the author recommends several excellent textbooks, which give a detailed coverage of specific areas.

Several mathematical expressions will be given without derivations. For additional background material the reader is referred to the following texts by Holman (1), Bird *et al*. (2), and Chapman (3). In addition, specific examples of heat transfer theory, as it applies to the food processing industry, can be found in some excellent general food engineering texts, Singh and Heldman (4), and Hallström *et al.* (5). These texts also give the reader thermal property data for a variety of foods and some good examples of the various principles. Finally, Perry's chemical engineer's handbooks (6, 7) have a great deal of general thermal property data and design factors

for heat exchangers, as well as good references for difficult-to-find information.

This chapter will broadly cover heat transfer, as it applies to common food processing operations. First, the various heat processing equipment for food products will be addressed. Section II covers thermal properties of food that are necessary for heat transfer estimations, with references to tabulated thermal property data. Three major types of heat transfer will be discussed and methods for estimating each type will be reviewed in section three. This includes methods to estimate heat conduction in a solid, as well as methods to estimate convection in fluids, and radiative heat transfer from hot surfaces. Also a brief section on simple heat exchanger design is included. Finally, two more areas will be addressed, steady-state and unsteady-state heat transfer.

I. HEAT PROCESSING OF FOOD PRODUCTS

Heat is used to process food in a variety of forms: liquids and slurries, semi-solids, and solids. Sometimes the form changes with heating, for example, water evaporates, fat melts, starches gelatinize, a thin fluid may change into a viscous one with different heating characteristics. The process and the equipment chosen depend, among other things, on the physical properties of the food both before and after heating. This section will cover descriptions of methods of heat processing and equipment used.

A. Liquids and Semi-Solids

Liquids, slurries, and semi-solids are most efficiently heat processed in continuous heat exchangers, although stirred, jacketed kettles are still used in smaller operations. Types of heat exchangers include plate, tubular (also called shell-in-tube), and scraped-surface heat exchangers. Swept-surface, jacketed kettles are similar, theoretically, to scraped-surface heat exchangers. These heat exchangers keep the heating medium (for example, hot water or steam) separate from the food and are sometimes referred to as indirect heat exchangers. Heat exchangers that allow direct contact of the heating fluid, usually steam, with the food product are in a separate category from the above. The one type of heat exchanger that will be discussed in this category is termed a steam injection heat exchanger. For further, more detailed information on heat exchanger design and useage conditions, see the following general texts: Hallström *et al*. (5), Singh and Heldman (4), or find information directly from heat exchanger manufacturers on the Internet.

1. Heating Medium

The heating medium is usually treated water or pressurized, treated steam. However, significant energy savings can be realized if heat regeneration can be used. In this case, the already-heated product is cooled by preheating the incoming product stream. This will be discussed further in the plate heat exchanger section and is addressed well in Singh and Heldman (4).

As a heating medium, pressurized steam provides the most efficient heat transfer due to its high temperature and release of latent heat of condensation as it changes state. However, especially in viscous fluid applications, hot water is often a more popular heating medium than steam. This is because it provides for finer temperature control at the heating metal surface. Poor temperature control can lead to under-processed or over-processed product, as well as product deposition (fouling), or sometimes burn-on, which can decrease heat transfer. The disadvantage of hot water is that heating rates are not as efficient as steam.

2. Fouling

No matter what heating medium is used with indirect heat exchangers, deposition, also referred to as surface fouling, will decrease the heat transfer rate from the heating medium to the product. For example, during pasteurization, milk proteins will deposit onto the hot metal surfaces, and as the deposition increases with time, the heat transfer rate will decrease. This will increase the time needed for heat penetration. Over a long period of time, the flow rate will be constricted and the pressure drop will increase. Eventually the process is stopped and the fouled surfaces are cleaned.

The fouling on the food product side should be minimized because time required for cleaning is lost processing time. For dairy products that require ultra-high temperature processing, the operational time of a heat exchanger may be limited to 3 or 4 hours before the heat exchanger surfaces must be cleaned, see Petermeier *et al*. (8).

Fouling also occurs on the heating medium surface side. The fouling on the heating medium side is minimized by treatment of steam and hot water with anti-fouling chemicals, such as treatment for water hardness and also by addition of corrosion inhibitors. This surface should be checked at least yearly.

3. Plate, Tubular, Shell-in-Tube, and Scraped-Surface Heat Exchangers

a. Plate heat exchangers

These units consist of a series of parallel, closely spaced stainless-steel rectangular plates pressed together in a frame, see Figure 108.1. Gaskets made of natural or synthetic rubber, which can be chosen to fit the specific needs of the fluids to be processed, are used to seal the plates together to prevent leakage. These gaskets are also used around the ports for inflow and outflow and this prevents intermixing of the heating fluid and the product stream. The flow through the plates can be arranged for co-current flow (also called parallel flow, where the heating stream and the

FIGURE 108.1 The gasketed, sanitary plate heat exchanger is specially designed for pasteurizing and general heating or cooling of beverages, dairy products, brewery products and other viscous products. (Photo courtesy of Alfa Laval, Inc.)

product stream flow in the same direction) or countercurrent flow, (where the respective streams flow in opposite directions). The plates are corrugated to induce turbulence at low lineal flow rates in the flowing liquid and therefore to increase the heat transfer rate for particular viscosities. Corrugation also increases heat transfer by preventing channeling across the plates. A variety of corrugation patterns is available for these purposes. The food product flows over the plate heat transfer area in a thin film, therefore the retention time is designed to be short. This may reduce thermal damage to the food product, see Kim *et al.* (9).

Plate heat exchangers are designed for low viscosity fluids (Cherry-Burrel Inc. suggest viscosities less than 5 Pa · s) with no particulates, or very small particles (less than 3 mm), depending on the corrugate pattern pressed into the heat exchanger plate. Larger particles can get caught between the plate contact points and burn on, making it difficult to remove using automatic cleaning procedures.

These units provide fast, efficient heat exchange. The plates can be configured for energy savings by using a flow pattern that will take advantage of waste heat by heat regeneration. In the example of pasteurization of juice or milk, the heat given up for cooling can be used to preheat the product for significant energy savings. Plate heat exchangers also have the advantage that they can be easily disassembled and re-assembled for cleaning or inspection. This provides for a sanitary design and is particularly important with heating fluids that cause surface fouling, such as UHT milk. Although, disassembly and re-assembly

FIGURE 108.2 ViscoLine™ sanitary corrugated tubular heat exchangers are designed for food products with a viscosity range between that of Plate-and-Frame Heat Exchangers and that of Scraped-Surface Heat Exchangers such as juices, tomato sauces, puddings, icings, soups and high-acid foods, the production of hot water with steam and heating of CIP solutions with steam. (Photo courtesy of Alfa Laval, Inc.)

is a comparatively fast and efficient process compared with other heat exchangers, this time should be minimized. Also, they offer excellent temperature control for comparably low capital investment and their capacity can easily be increased by adding more plates to the frame.

b. Tubular heat exchangers

Tubular exchangers are a simple, less expensive type of heat exchanger. This heat exchanger consists of a pipe located concentrically inside another pipe and the two streams flow in the annular space and the inner pipe, respectively (see Figure 108.2). These two streams may flow in the same direction (co-current flow) or in opposite directions (counter-current flow). Shell-and-tube heat exchangers are a variation of the tubular unit, where one of the streams flows inside many small tubes, while the other stream is pumped over the tubes through the shell. Baffles are often present in the shell making the flow pattern over the tubes to be more similar to cross-flow. This allows high rates of heat transfer.

Tubular and shell-and-tube heat exchangers are preferred for their low capital cost and also the smaller heat exchanger surface required per unit length of tube, although they are less commonly used in food contact. Examples include preheating and then cooling juices to below ambient temperatures, prior to freezing.

Cleaning such a heat exchanger is similar to cleaning pipes in a manufacturing facility, the automatic CIP (clean-in-place) system is used. Especially with this unit, it is important to avoid heating situations where fouling on the food surface can occur. Compared to the plate heat exchanger, cleaning is time consuming and it is difficult to disassemble by hand to examine for problems such as build up of bio-films or plugging of some of the small tubes.

In contrast to usual uses of this heat exchanger, Satyanarayana *et al.* (10) found a simple triple-tube heat exchanger, to be useful for short runs of UHT milk production for rural, tropical co-operatives. Its low investment cost and high heat transfer per unit length was thought to be better suited to small-scale operations. The triple-tube unit was used to produce UHT milk, using steam in the

innermost and outermost tubes, with the product flowing in the annular space between the two heating fluids. Although the investment costs are attractive, it is apparent that the application will require further examination, especially given an application where milk-side fouling rates are high.

c. *Scraped-surface heat exchanger*

Scraped-surface heat exchangers are good for heat processing viscous fluids and slurries, including fluids that may have high surface deposition. Although these units have higher capital costs than the previous units discussed, they are chosen because previously discussed units would not address the special needs of the food product. See Figure 108.3. This heat exchanger consists of a cylindrical tube with a rotator shaft mounted in the center. Scraper blades are mounted on the center rotator shaft so that they are pushed against the inside of the cylindrical surface when the shaft is rotated. Food material is pumped into the annular space between the heated wall and the rotator shaft. The general public may identify this type of heat exchanger as an ice cream freezer, because originally, it was developed for this purpose. The rotating blades on the center shaft were meant to physically scrape frozen cream particles off the chilled surface of the freezer, resulting in smaller-sized ice crystals and a smoother-textured ice cream. These units continue to be used in the ice cream making industry, but in this chapter, the designs for heating purposes are described.

FIGURE 108.3 The Contherm™ Scraped-Surface Heat Exchanger is particularly suitable for viscous and sticky products including those that contain particulate matter such as fruit or vegetable pieces. (Photo courtesy of Alfa Laval, Inc.)

The scraping-action of the rotator blade against the wall results from centrifugal force of the shaft rotation. In modern units, the blades may not actually contact the inside of the wall, although this depends on the design of the blades and the material of construction. Some blades are made from stainless steel and are meant to physically scrape the processed food from the heated wall, while others are made of fiberglass and are designed to more gently (but more efficiently) process a viscous or particulate-laden fluid by creating turbulence at the fluid boundary with the heated surface. In this way the thickness of the fluid boundary at the wall is decreased, resulting in higher efficiency heat transfer.

In general, scraped-surface heat exchangers increase the fluid turbulence at the tubular wall. However, the rotator blades will not prevent fouling, they will only minimize it. The rotation speed of the blade-mounted shaft varies between 150 and 500 rpm. The higher rotational speed allows for better heat transfer, especially at high viscosities, and the mechanical action provides a whipping action that may impart desirable attributes for some products. However, the mechanical action may also cause mashing of particulates and, in some cases, may significantly reduce product viscosity of some starch-based sauces.

The heat transfer in the scraped-surface heat exchanger is controlled by three major steps.

1. The rate at which the heat is conducted from the heating medium to the metal wall and the rate of conduction through the metal wall.
2. The rate of heat transfer (conductive) from the metal wall into the thin product, surface-boundary layer.
3. The rate at which the thin product layer is removed by turbulence or direct scraping and then mixed in to the bulk fluid.

The rotation speed controls radial mixing, and the overall product flow rate controls axial mixing and some radial mixing. Both flow mechanisms influence the rate at which the thin boundary layer at the wall is mixed into the bulk fluid. Often there may be one optimum rotator speed for heat transfer and a different optimum rotator speed for product qualities such as viscosity, and particulate integrity.

It is important to note that a certain amount of axial back-mixing may occur over the length of the heat transfer cylinder. This can contribute to a lower temperature driving force and therefore, poorer heat transfer. Harrod (11) reviewed both the flow mixing mechanisms as well

as the heat transfer in scraped-surface heat exchangers. Results from experimental studies are summarized as well as theoretical and empirical correlations. It is important to remember that many of the theoretical correlations developed over-predict the heat transfer in these units because of the assumption of complete equalization of temperature in the liquid film at the surface.

4. Steam Injection Heat Exchangers

Steam injection or so-called direct contact heat exchangers are specialized units that may be higher in capital cost than other heat exchangers on a per liter processed basis. One of the major reasons for this is that high quality, food-grade steam is needed for direct contact with the product in the injection process. This special steam must be available as a plant utility or the unit must make its own. This special food-grade steam is termed culinary steam because any steam additives, such as anti-corrosives or anti-foulants must be food-grade chemicals. The advantage of this direct steam injection is that processors may take advantage of the latent heat of condensing steam. This allows for large amounts of heat to be transferred directly to the product. Although the viscosity of the product determines the application, this type of heat process works best when the liquid or slurry is applied through a spreader in a chamber as a thin sheet or in droplets. The process is very efficient, but care must be taken in the application so that over-heating does not occur. This type of heat exchanger has been used in cooking or sterilizing a variety of products including puddings, concentrated soups, and milk.

B. Solids

Heat processing of solids includes such operations as blanching vegetables and fruit in water or steam, frying potato chips or chicken, retort canning, cooking items such as steaks and hamburgers for process-prepared frozen meals, baking, and surface cleaning (steam or hot water) of fruits and vegetables for fresh market, as well as surface cleaning of meat carcasses, or seed for sprouting.

Surface cleaning of fresh fruits and vegetables for the fresh produce market has become more important as more virulent strains of pathogenic microorganisms evolve (12, 13). Surface cleaning of fresh fruits and vegetables with steam or hot water prior to cutting may be one weapon in the arsenal to prevent pathogenic food-borne contamination (see Figure 108.4). Similar high-temperature, short time surface heat treatments are being investigated for sanitizing fresh food items from alfalfa sprout seeds to beef carcasses.

Steam blanching is generally carried out on a stainless steel mesh belt in a steam tunnel for a prescribed amount of time to deactivate enzymes, remove tissue air for further packing, and preserve color. Because the blanch end-point is determined by the needs of the specific fruit or vegetable (that is, the temperature at which appropriate enzymes are activated or deactivated), heat treatment is usually determined for each specific instance in the laboratory. Factored into this treatment is the largest piece size, as well as the needs of the process.

FIGURE 108.4 The Thermosafe™ process uses steam to reduce the microbial load on the outside surface of cleaned, fresh fruits and vegetables by at least 5 logs. (Photo courtesy of Biosteam Technologies, Inc.)

Fluidized beds are used for large volume, continuous heat processing situations. They would commonly be used in the freezing of, for example, green peas, but they are also used in such large-scale operations as roasting coffee beans. They provide uniformity of product and good process control. However, when particles are large (in some cases large might be >5 mm) or unevenly shaped, unstable fluidization patterns (slugging or sticking) can occur which result in poor process control.

The retort canning process is an example of unsteady-state heat transfer. Heat transfer is greater if the can is rolling in a retort rather than stationary. In either case, the center can temperature must be tested to meet time-temperature regulations. If the can contents are liquid with solid pieces, such as green beans or consumé, the faster heat transfer mechanism of convection will predominate inside the can. If, however, the contents are very thick and almost solid, such as thick, chunky beef stew, the slower heat transfer mechanism of conduction will predominate. Therefore, attaining the objective of commercial sterilization in the canning retort will be achieved faster in the can with liquid contents.

II. THERMAL PROPERTIES OF FOOD

The rate of heat transfer depends not just on the equipment or process being used but also on the properties of the food being heated. Estimating the heating rate of pure substances such as water or oil is a relatively easy exercise compared to estimating the heating rate of chili or of a steak. Not only is chili a compound mixture with a non-Newtonian viscosity, but it is also heterogeneous, and many of the solid particles in it are non-isotropic.

Furthermore, on heating, the many components respond to latent heats of fusion and evaporation at a variety of temperatures, depending on composition (14, 15). A change of state can complicate an otherwise straightforward estimate of temperature profile in a substance. Not only does steak have some of the same change of state issues as chili, but also moisture and fat vary with each slice, as does the fiber orientation. This makes estimation of heat transfer properties and rates in food materials more challenging to estimate, but also more fascinating.

Specific heat, thermal conductivity, and thermal diffusivity are important parameters that are discussed in this section, however, other properties impact thermal estimates and are not covered here. These material properties include density, enthalpy, latent heat, dielectric properties, and viscosity. These are discussed in detail in previous sections of this reference volume as well as in Hallström *et al.* (5).

A. Specific Heat

Specific heat of a food is a measure of the amount of energy required to raise the temperature of a unit mass of the food by one degree of temperature. The property is generally represented by the symbol, "Cp," and the units for this value are kiloJoules per kilogram per degree of absolute temperature difference, kJ/(kg°K) or, in this case, equivalently, kJ/(kg°C). Specific heat, also called the mass heat capacity, has been determined experimentally by several methods including the method of mixtures, method of the guard plate, and using a differential scanning calorimeter (16).

Specific heat is a material property that is relatively constant with changing temperature but that varies with food composition (for example, moisture), and that varies with change of state. Therefore, the specific heat of ice at −2°C is 2.09 kJ/kg°C and steam at 110°C and atmospheric pressure is 2.01 kJ/kg°C, while the specific heat of water at room temperature is 4.18 kJ/kg°C (see Table 108.1). Furthermore, the specific heat of a raw food compared to the specific heat after a cooking process may also be markedly different because the composition of the food may have changed. For example, when meat cooks the fat melts and may flow away, the moisture evaporates, and the proteins denature.

TABLE 108.1
Thermal Properties of Food Constituents at Approximately 20°C

Component	Spec. Heat (kJ/kg°C)	Thermal Conductivity (W/m°C)
Water	4.18	0.60
Carbohydrate	1.42*	0.58*
Protein	1.55*	0.20*
Fat	1.67*	0.18*
Air	0.96	0.025
Ice	2.09 (at −2°C)	~2.4 (below zero °C)**
Inorganic minerals	~0.84*	
Metals	0.05–1.0	50–400

* Hallström *et al.* (5).
** Singh and Heldman (4).

The specific heat of a food depends on the composition of the food. For example, the specific heat of fat is 1.67 kJ/kg°C, while the specific heat of water is 4.18 kJ/kg°C. See Table 108.1. A number of correlations to predict specific heat have been developed by Siebel (17) for high moisture foods above the freezing point, and by Charm (18), and Choi and Okos (16) for liquid foods, based on food composition. The food composition includes moisture and fat, the two most critical parameters, as well as protein, fiber, carbohydrate, and ash. Food composition values can be found in Agriculture Handbook No. 8 (19) and selected values may be found in Singh and Heldman (4).

B. Thermal Conductivity

Thermal conductivity is the rate at which heat will be conducted through a unit thickness of material if a unit temperature gradient exists across that thickness. This property is generally represented in mathematical formulae as the symbol, k, and the units for this value are Joules per second per meter per degree of temperature gradient, (J/sm°C), or equivalently, Watts per meter per degree of temperature gradient, (W/m°C). The conduction heat transfer equation relating this constant to the rate of heat conduction is equation 108.2 in Section III. The relative thermal conductivities for a variety of food constituents and materials are shown in Table 108.1. Note that metals, which are good conductors of electricity, are also good conductors of thermal energy.

Similar to specific heat, the thermal conductivity varies with food composition but, unlike the property of specific heat, it varies more with temperature; see Singh and Heldman (4) for graphs of these properties as a function of temperature. Thermal conductivity in heterogeneous, non-isotropic food materials, particularly fibrous foods such as meat, also varies with the heat flow direction in relation to the orientation of the fibers. Tabulated values that have been determined experimentally are available in Singh and Heldman (4) and Sweat (20, 21). In

addition, both these references have regression equations to estimate this constant based on food composition.

C. Thermal Diffusivity

Thermal diffusivity, α, is a property of a material incorporating previously defined properties of thermal conductivity, k, density, ρ, and the heat capacity, Cp. It is represented by the symbol, "α," and has the units of m^2/s. It is defined as follows:

$$\alpha = \frac{k}{\rho C_p} \tag{108.1}$$

and is more often encountered in complex solutions to steady-state and unsteady-state problems. This material property constant was developed prior to computational analysis of differential equations, as a way to conceptualize and solve complex thermal relationships. For example, thermal diffusivity is linked intimately to both density, and moisture during the process of bread baking. See Zanoni *et al*. (22) for an example of the estimation of this continually changing property for the process of baking bread. This is a fascinating example because density and moisture both change appreciably during the baking process. Therefore heat capacity, thermal conductivity, and of course, thermal diffusivity change as well. In addition, because of crust formation, those changes are not homogeneous.

III. STEADY-STATE HEAT TRANSFER

Three types of heat transfer will be discussed in this section: conduction, convection and radiation in the steady-state case. Heat is transferred conductively in a solid when there is only molecular vibrational movement from the cold end to the hot end. Heat is transferred convectively from a solid to a liquid (or vice versa) when, for example, a cool liquid flows over a hot pipe surface. Finally, heat is transferred radiatively when, for example, meat is baked in an oven (neglecting the heat transferred convectively from the moving air).

Furthermore, these types of heat transfer will be discussed in the idealized case, that of steady-state. Steady-state conditions are defined such that the energy going into a system or an object is equivalent to the energy going out of the system or object. This implies that time has no influence on the temperature distribution within the system or object. An example of steady-state heat transfer is taken from Section I of this chapter, the plate heat exchanger that might be used to pasteurize milk. If we look at a short section of the heat exchanger at the entrance, where the temperature of the hot water going into the heat exchanger is constant, at 98°C, and the temperature of the milk coming into the heat exchanger is constant, at 4°C, then the heat transfer through the metal wall separating the two streams is at steady state. The temperature of the metal between the two surfaces will vary with thickness of the metal wall, but, as long as the system is at steady-state, it will not vary with time.

However, in real life, the system may be at steady-state for only brief periods of time. For example, during the start-up phase the equipment must heat up. Also, the hot water will vary around a set point, perhaps between 95°C and 99°C, and the incoming milk will vary with the bulk temperature of the milk coming in, for example, if a fresh batch of milk from a tanker truck, at 10°C, were added to a steady-state system where the initial bulk milk temperature was 4°C. When the temperature of the incoming hot water is changing or the temperature of the incoming milk is changing, the temperature profile through the metal wall changes with time as well as location.

A. Conductive Heat Transfer

In conductive heat transfer there is no physical movement of the material. It is the common mode of heat transfer in heating of solid media. Conduction is the mode of heat transfer in which the transfer of energy takes place at the molecular level. As a molecule gains thermal energy it vibrates in its own location. As the level of thermal energy increases, so does the amplitude of the vibration. These vibrations are then transmitted from one molecule to another.

1. Fourier's Law

Conductive heat transfer takes place in a solid body when a temperature gradient exists, that is, heat will flow from the high temperature region to the low temperature region. This heat flux, q/A (or energy per unit area), is proportional to the temperature gradient. The constant of proportionality required to make the proportion an equation is k, the thermal conductivity. If the heat, q, is flowing perpendicularly through a cross-sectional area, A, and T is the temperature and x is the lineal distance through the cross-sectional area that the heat traverses, then the heat flux is defined mathematically as:

$$\frac{q_x}{A} = -k\frac{dT}{dx} \tag{108.2}$$

Equation 108.2 is known as Fourier's law for heat conduction. The negative sign in equation 108.2 indicates that the heat will flow from the higher temperature to the lower temperature, dT/dx representing a negative gradient. If there were no negative sign, then the negative differential would result in a negative heat flux.

Fourier's law can be solved for many scenarios including rectangular, cylindrical, and spherical geometries and both steady and unsteady-state. It can even be solved for heat transfer situations where there is heat generation, such as cool storage for respiring fruits or vegetables.

a. Fourier's Law for rectangular co-ordinates

If one assumes steady-state conductive flux in a rectangular slab of cross-sectional area, A, and the temperature is

T_1, at x_1 and T_2 at x_2, then, integrating equation 108.2 for those boundary conditions, the solution is:

$$\frac{q_x}{A} = -\frac{k(T_1 - T_2)}{(x_1 - x_2)} \tag{108.3}$$

Equation 108.3 refers to Figure 108.5 where the heat energy is shown flowing from the hot side of a rectangle through the thickness of the rectangle, to the cool side. This rectangle could represent a cross-section of the insulated stainless-steel wall of a hot water vegetable blancher.

In this heat transfer estimate we will neglect the resistance due to the inside and outside layers of metal skin of the blancher. We will also assume that the system is at steady-state. This means that the hot water inside the blancher is boiling at 100°C and the heat flux is constant, flowing through the wall so that heat is given off to the outside surface as fast as it is supplied by conduction through the wall. When the blancher is started at the beginning of the day, the metal walls will have to warm up; this is the unsteady-state time period, which we will not evaluate here. For this example the following conditions hold: wall thickness = 0.075 m, inside blancher temperature, T_1 = 100°C, ambient outside temperature, T_2 = 27°C, thermal conductivity of insulating material is approximately 0.0360 W/m°C for insulation.

Therefore,

$$\frac{q_x}{A} = -\frac{0.036(W/m°C)[100°C - 27°C]}{[0\,m - 0.075\,m]} \tag{108.4}$$

and the estimated heat flux through the insulated blancher wall is equivalent to 35.04 W/m^2. If the sides and the top of the blancher walls were the same thickness and had uniform inside temperatures and uniform outside temperatures and if the total area was 48 m^2, then the total conductive heat flux would be 1685 W. Conversely, if the heat flux could be measured, this equation may also be used to predict the temperature profile through the wall of the blancher. In this case, that temperature profile would be linear.

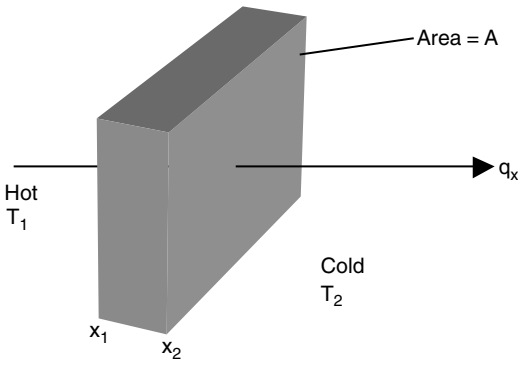

FIGURE 108.5 Heat conduction through a section of wall. Heat flows from the hot side of a section of wall at temperature T_1 to the cold side at temperature T_2. The thickness of the wall is equivalent to the difference between x_1 and x_2.

b. Fourier's Law for other geometries

Solutions to Fourier's Law for other geometries such as the cylindrical case for cans, pipes, and tubular heat exchangers (or even baking bread) and the spherical case for roasts are available in the basic texts noted at the beginning of the chapter. The solution to Fourier's equation in radial coordinates for a hollow tube is:

$$q_r = \frac{2\pi Lk(T_i - T_o)}{\ln\left(\frac{r_o}{r_i}\right)} \tag{108.5}$$

Where the boundary conditions are $T = T_i$ at $r = r_i$ and $T = T_o$ at $r = r_o$ where "i" refers to the inside and "o" refers to the outside. Also, L, refers to the length of the cylinder, r_o refers to the outside radius, r_i refers to the inside radius, so that the heat flux area is defined by $2\pi rL$, and in the process of integration becomes a logarithmic term.

2. Heat Conduction in Multi-Layered Systems

In order to discuss conduction in multi-layered systems, we will go back to the example in Section III.A.1, regarding one dimensional heat conduction in the rectangular coordinates of the insulated walls of a vegetable blancher. In this example, for reasons of simplicity, we neglected heat conduction in the metal layer on the inside of the blancher, next to the hot water and vegetables and we neglected heat conduction in the metal layer on the outside of the blancher next to the ambient air. In order to estimate the amount of heat conduction through several materials of different thicknesses and of different conductivities (and sometimes at different temperatures) one must first estimate the total resistance from the composite materials. Firstly, we must assume that the materials are in complete and full contact with no gaps. Estimating this total resis-tance to heat transfer is similar in theory to estimating the total resistance of several resistors in a series circuit. Therefore, Singh and Heldman (4) show the more detailed derivation from Ohm's law and from equation 108.3:

$$q_x = \frac{T_2 - T_1}{R_t} \quad \text{where } R_t = \left(\frac{x_2 - x_1}{kA}\right) \tag{108.6}$$

such that R_t represents the thermal resistance. Thermal resistance is additive, so that the heat conduction, q_x, through the composite blancher wall would be written:

$$q_x = \frac{T_2 - T_1}{R_{mi} + R_{ins} + R_{mo}} \tag{108.7}$$

Where R_{mi} is the resistance of the metal on the inside of the blancher, R_{ins} is the resistance of the layer of insulation, and R_{mo} is the resistance of the metal on the outside:

$$R_{mi} = \frac{\Delta x_{mi}}{k_{mi}A} \quad \text{and} \quad R_i = \frac{\Delta x_{ins}}{k_{ins}A} \quad \text{and} \quad R_{mo} = \frac{\Delta x_{mo}}{k_{mo}A} \tag{108.8}$$

The x_{mi} refers to the lineal distance, in the cross section that the heat flows through the inside metal skin, the insulation, and so on. Therefore, the heat loss for one square meter of a blancher wall, where the metal on the inside and outside surface is stainless steel (k = 19 W/m°C) and assuming metal thickness of 0.005 m:

$$q_x = \frac{[100°C - 27°C]}{\frac{0.005\,m}{(19W/m°C)(1m^2)} + \frac{0.075\,m}{0.036(W/m°C)(1m^2)} + \frac{0.005\,m}{(19W/m°C)(1\,m^2)}} \tag{108.9}$$

$$q_x = \frac{73°C}{(0.00026 + 2.083 + 0.00026)°C/W}$$

$$= \frac{73}{2.08352} = 35.037\,W \tag{108.10}$$

Therefore the conductive heat flux is 35.037 W for one square meter of surface area. This compares closely to equation 108.4 where the heat flux was estimated at 35.040 W/m^2. In this case, the initial assumption to neglect the resistance of the stainless steel skin was justified.

B. Convective Heat Transfer

1. General Theory

Convective heat transfer occurs when a fluid, such as a liquid or a gas, flows over a solid, such as pipe wall, or a solid food item. Heat will be transferred between the solid surface and the liquid when there is a temperature difference between the two. The rate of heat transferred convectively is not only dependent on the temperature gradient, but also on the properties of the fluid and the fluid flow characteristics. The resistance to heat transfer between the solid and the fluid is thought to be localized in a boundary layer within the fluid, between the flowing fluid and the solid surface. This concept was hypothesized for an ideal system by Prandtl (3), but has been widely used in studying many types of non-ideal systems.

2. Boundary Layer Theory

The boundary layer concept for the rate of convective heat transfer, q, through an area, A, may be written as

$$\frac{q}{A} = \frac{k}{\delta}(T_s - T_\infty) \tag{108.11}$$

where k is the thermal conductivity, δ is the thickness of the boundary layer, T_s is the temperature of the solid surface (and hence also the temperature of the infinitesimally thin layer of fluid on the surface), and T_∞ is the temperature of the bulk fluid, far away from the hot surface. The thickness of the boundary layer is not readily measurable and so the coefficient k/δ is expressed as "h," the convective heat transfer coefficient (also referred to as the surface heat transfer coefficient). This coefficient is expressed in units of W/m^2°C and has been measured by a number of researchers for a variety of conditions. Some approximate ranges of values are shown in Table 108.2. The higher the heat transfer coefficient, h, the faster the heat transfer.

There are two types of convective heat transfer: 1) forced convection, where the fluid is pumped or blown over the hot surface, and 2) natural (or free) convection, where the fluid rises from the surface due to localized heating and the resulting density differences induced by the temperature gradients. Natural convection is slower and therefore is less often used in food processing and will not be addressed in this chapter; see Hallström *et al.* (5) or any other basic heat transfer text.

The flow rate of the fluid affects the rate of heat transferred and therefore, a slow flow rate (characterized by the laminar flow regime) or fast flow rate (characterized by the turbulent flow regime) will affect the thickness of the boundary layer and also how fast the moving fluid can remove heat from the hot surface.

An example of convective heat transfer that is easy to visualize is how air (the fluid) will cool the surface of a hot spoonful of soup (the "solid" in this example). The heat from the liquid surface and the vapor will naturally rise in a curling fashion from the hot surface of the soup into the cooler ambient air. The air at the soup/air interface is much warmer than the air several inches above and therefore, the warmer air will be more buoyant than the cooler air and so it will rise. The liquid in the spoonful of soup will cool by natural convection.

However, if we blow gently across the surface of the hot liquid, the warm air interface directly above the hot liquid will be disturbed and cooler air will be forced to flow past

TABLE 108.2
Ranges of Values of the Convective Heat Transfer Coefficient

Fluid and Mechanism	h, Convective Heat Transfer Coef. (W/m^2°K)
Air – Natural convection	5–50
Air – Forced convection	25–500
Water – Natural convection*	20–100*
Water – Forced convection	250–15,000
Boiling water	2,500–25,000
Condensing water vapor	5,000–100,000

* Singh and Heldman (4).
Source: Holman (1).

the hot liquid. In this way, the air boundary-layer will become thinner when we blow on the liquid and the spoon of hot liquid will cool more quickly through forced convection than if it is allowed to cool via natural convection.

Convective heating is the dominant heat transfer mechanism in heating of liquids, such as milk and juice pasteurization, and often may be important in the heating of solids, such as frying and blanching. See Martens *et al.* (23) for an example of convective heat transfer to a broccoli stem in a blancher, then conductive heat transfer inside the stem. A mathematical model was used and correlated with experimental results so that the blanch time and temperature could be estimated for appropriate enzyme inactivation. Convective heating mechanisms are also used for modeling the drying of food pieces (or drops of milk) when a current of dry air is blown across the surface (spray drying).

3. Estimating the Convective Heat Transfer Coefficient

Estimation of the convective heat transfer coefficient involves an understanding of the rate and quality of fluid flow over the hot surface. Neglecting entrance effects of the fluid and unsteady state heating of the surface, let us look directly at the steady-state case.

The convective heat transfer coefficient is dependent on properties of the fluid, such as the thermal conductivity, density, heat capacity, and viscosity, as well as the temperature difference, the velocity of flow, and the geometrical shape of the solid giving up the heat. Researchers have developed a variety of correlations, based on these parameters, to predict the convective heat transfer coefficient for a specific situation. The correlations are both theoretical and empirical, see Bird *et al*. (2) and Perry *et al*. (6). The parameters are generally grouped for analysis into dimensionless numbers.

a. A word about dimensional analysis

Dimensional analysis is also referred to in terms of dimensionless numbers. Long before CFD (computational fluid dynamics), equations of momentum were used to theoretically model situations were a fluid flowed over a hot surface. The so-called Equations of Change in Bird *et al*. (2) were partial differential equations used to represent the mechanisms of all possible operations within a fluid. Occasionally these equations were able to be simplified enough so that they could be solved analytically. But few interesting problems could be simplified enough to be solved analytically. Finally, when computers came into more common usage, it became easier to solve the more complex equations using numerical techniques.

However, before it became routine to numerically solve these partial differential equations, engineers found alternative ways to solve practical problems using empirical methods based on theory. Certain groups of key variables and constants seemed to appear again and again in the solutions and equation set-ups. Therefore, these resourceful engineers concluded that any theoretical analytical solution must somehow incorporate these key variables and constants. Hence, such dimensionless groups for heat transfer as the Reynolds number, the Prandtl number and the Nusselt number were born. These dimensionless groups are essentially ratios of critical quantities of fluid and heat flow, which effect the boundary layer for the fluid and the boundary layer for the thermal transfer. Notice that the groups are dimensionless. That is, the units of meters and watts and so on, cancel each other out. This made it easier to find mistakes when long, complex manual calculations were made.

$$\text{Reynolds Number: Re} = \frac{inertial\_forces}{viscous\_forces} = \frac{Dv\rho}{\mu} \tag{108.12}$$

$$\text{Prandtl Number: Pr} = \frac{diffusivity\_of\_momentum}{diffusivity\_of\_energy} = \frac{C_p\mu}{k} \tag{108.13}$$

$$\text{Nusselt Number: } Nu = \frac{diffusivity\_by\_convection}{diffusivity\_by\_conduction} = \frac{hl}{k} \tag{108.14}$$

In the Reynolds number, D is a critical dimension, usually the diameter of the pipe in meters, v is the fluid velocity in m/s, ρ is the density of the fluid in kg/m^3, and μ is the fluid viscosity in Pa · s.

In the Prandtl number, Cp is the heat capacity of the fluid in kJ/kg°C, μ is the fluid viscosity in Pa · s, and k, is the thermal conductivity, in W/m°C.

The Nusselt number, in effect, represents the boundary layer heat transfer coefficient, h, in dimensionless form in units of W/m^2°C. This number also uses two other values, "l," a characteristic length in meters (such as the pipe diameter if the heat transfer is occurring inside a pipe), and, k, the fluid thermal conductivity in W/m°C.

The relationships that use these dimensionless groups are empirical, experimentally based correlations developed for specific ranges of fluid flow rate and geometry (among other variables that will not be discussed here). The relations are not the elegant, analytically derived theoretical equations, similar to the Fourier equation, but they are useful in practice and they really work; indeed, commercial heat exchanger design is based on them. Although a great deal of experimental data must be generated in order to predict film coefficients for the variety of flow rates, geometries, viscosities, etc., the dimensionless groups greatly simplify the organization of the data.

In order to estimate a heat transfer coefficient, h, dimensionless numbers are used in the following way.

The experimenter is looking for a relationship that is in the form of the following expression:

$$Nu = C\,\mathrm{Re}^{a}\,\mathrm{Pr}^{b} \qquad (108.15)$$

Where "C" is a constant, and "a" and "b" are powers for the Reynolds number and the Prandtl numbers. The data from a specified range of flow rates and geometries is plotted on log-log paper with the Nusselt number plotted as a function of the Reynolds number for a variety of Prandtl numbers. If the data fall into relatively straight lines, the coefficients are determined for the best fit and hence the constant "C" and powers "a" and "b" are determined.

b. *Estimation of the convective heat transfer coefficient using empirical correlations*

In previous sections and in basic textbooks in fluid mechanics, the velocity profile is estimated and modeled for a variety of channels, pipes, vortices in stirred vessels, and flow around, for example, cylindrical objects. Understanding the velocity profile is critical for estimation of the convective heat transfer coefficient.

The velocity profile

A velocity profile develops in the fluid when it flows over a surface because of the viscous properties of the fluid material. Similarly, a boundary layer develops in the flowing fluid and the thickness of the boundary layer will depend on the viscosity of the fluid (and whether the viscosity is a function of temperature, and shear force), as well as the flow rate, or in effect, the flow regime of the moving fluid.

In the case of fluid flow in a pipe at the lower flow rates, the velocity profile of the fluid will be parabolic so that the highest velocities will be found in the center of the pipe. This regime of fluid flow is referred to as the laminar regime and this regime exists for $\mathrm{Re} < 2100$ for pipe flow.

As fluid velocities increase, the flow enters the so-called transition region where flow patterns are too variable to predict and the charts in Perry and Chilton (7) should be consulted. Even so, the uncertainty of estimation in this regime is greater than the other two regimes. Reynolds numbers for this regime are between 2100 and 10,000 for flow in pipes.

The regime for the highest liquid flow velocities is the turbulent regime, (see charts for flow in pipes in Perry and Chilton (7)). In the turbulent regime, the thin film next to the hot surface is thinner than in the laminar regime, but the velocity profile is no longer parabolic in a pipe. Instead, the fluid above the surface film is filled with eddies and swirls and the velocity profile in this regime is considered to be relatively flat. Good mixing occurs in flows of high turbulence.

Approach to determine the convective heat transfer coefficient, "h"

An experimental approach was described in Section III.B.3.a to determine the coefficients for an empirical correlation for finding the convective heat transfer coefficient, "h." But we may not want to do an experiment every time we need to estimate this number. We would like to look up values in tables and estimate these coefficients using similar scenarios. Therefore, correlations already developed and published may be used. Care must be taken to use this published experimental work judiciously, for the specific conditions, ranges of flow, and assumptions used in the referenced heat transfer work. The following guidelines can be used to check the similarity of correlations to specific needs.

a) Identify the geometry of the flow situation and the characteristic dimension.
   The shape and dimension of the solid surface in contact with the fluid must be identified. Flow in pipes is the classic example, but flow in non-circular ducts, such as plate heat exchangers is also common. The characteristic dimension required for the various dimensionless numbers is the diameter or the equivalent diameter. For flow in pipes this is the pipe diameter, D, but for a non-circular duct, this is referred to as the hydraulic diameter, D_h and is defined:

$$D_h = \frac{4(\mathit{flow\_area})}{(\mathit{wetted\_perimeter})} \qquad (108.16)$$

   Flow around immersed objects has, in the past, concentrated on flow around single spheres or cylinders oriented in a specific way to the flow. However, these models simulate many food processing situations poorly. Multiple pieces vary in orientation to the flow, for example, roasting coffee beans in hot air, blanching broccoli stems, or aseptic processing of green peas. In such situations where the suspension of particles is 15 to 30% of a flow, Chakrabandhu and Singh (24) suggest use of the packed bed flow geometry, where the hydraulic radius of the duct is the important geometry. They found this better represented the characteristic dimension.

   Ghisalberti and Kondjoyan (25) investigated forced air-flow around a variety of geometries including cylinders, truncated cones, and square-sectioned bars. The characteristic dimension was the height to diameter ratio for these objects, depending on flow direction. They found that the fluid flow properties were more significant predictors of the heat transfer coefficient than the geometries for the forms studied in the turbulent regime. Because heat processing situations vary considerably, this important characteristic dimension should be checked with the heat exchanger manufacturer,

the published literature, or in Perry and Chilton (7) for the exact situation.

b) Identify the fluid and determine property data. The fluid may be water, air, or a liquid food product. The bulk fluid temperature (far from the heating surface) or the average temperature between the inlet and outlet should be the temperature at which to obtain the physical and thermal properties of the fluid. Examples are density, viscosity, and thermal conductivity. If these properties vary substantially with temperature between the inlet and outlet temperatures, then two possibilities exist: 1) an overall convective heat transfer coefficient may be calculated based on average properties, or 2) if, for example, the linear average does a poor job of representing the exponential increase of density and viscosity with temperature, then calculate the convective heat transfer coefficient for several short sections of the exchanger.

If the fluid is non-Newtonian, as is common in fluid food product applications, the viscosity must be handled in a slightly different manner and special empirical correlations are available to treat this special case, see Heldman and Singh (26) or Bird *et al*. (2).

In some cases, the ratio of the bulk fluid viscosity to the viscosity of the fluid at the hot wall (μ_b/μ_w), is important and the viscosities should be evaluated at these appropriate temperatures.

c) Calculate the Reynolds number. Using the characteristic dimension, the fluid properties and the fluid velocity, calculate the Reynolds number. The Reynolds number is necessary to determine the flow regime (laminar, transition, or turbulent). This is critical to selection of the appropriate empirical correlation.

d) Select the appropriate empirical correlation. Use the calculations from guidelines a) to c) to choose a correlation that will fit the scenario of the heat process. Calculate the Nusselt number and then finally the convective heat transfer coefficient.

Examples of empirical relations for simple cases three flow regimes

Laminar Regime

For Newtonian fluid flow, Reynolds numbers less than 2100, and flow in a horizontal pipe of diameter, D, and length, L, and for conditions where

$$(\mathrm{Re})(\mathrm{Pr})\left(\frac{D}{L}\right) \geq 100, \text{ then} \qquad (108.17)$$

$$Nu = 1.86\left(\mathrm{Re}\,\mathrm{Pr}\frac{D}{L}\right)^{0.33}\left(\frac{\mu_b}{\mu_w}\right)^{0.14} \qquad (108.18)$$

Therefore, the convective heat transfer coefficient between the hot pipe wall and the Newtonian fluid in the pipe is equivalent to h. This is found by solving the Nusselt number so that

$$h = \frac{Nuk}{D} \qquad (108.19)$$

where k is the thermal conductivity of the fluid in the pipe.

Transition Regime

For Newtonian fluid flow in a pipe at Reynolds numbers greater than 2100 and less than 10,000:

$$Nu = \frac{(f/8)(\mathrm{Re}-1000)\mathrm{Pr}}{1+12.7(f/8)^{0.5}(\mathrm{Pr}^{0.67}-1)} \qquad (108.20)$$

Where, similar to the laminar correlation for pipes, the fluid properties are evaluated at the average fluid temperature. The variable, f, is the friction factor and is estimated for smooth pipes in charts in Perry and Chilton (7) or by using the following correlation:

$$f = \frac{1}{(0.790\ln\mathrm{Re}-1.64)^2} \qquad (108.21)$$

Turbulent Regime

The following correlation for the convective heat transfer coefficient is used for Reynolds numbers greater than 10,000 in pipes for Newtonian fluids:

$$Nu = 0.023\mathrm{Re}^{0.8}\,\mathrm{Pr}^{0.33}\left(\frac{\mu_b}{\mu_w}\right)^{0.14} \qquad (108.22)$$

Kim *et al.* (9) found good correlation of experimental values with the following expression for the convective heat transfer coefficient of orange juice in turbulent flow conditions in a specific plate heat exchanger:

$$Nu = 1.12(10)^{-5}\,\mathrm{Re}^{1.39}\,\mathrm{Pr}^{1.63} \qquad (108.23)$$

This holds true for Re between 156 and 567 and Pr between 41 and 98.

4. The Overall Heat Transfer Coefficient

In common heating situations convective and conductive heat transfer occur at the same time. For example, in the plate heat exchanger, the hot water from the plant boiler transfers its heat to the plate metal wall by means of convection, then the heat conducts through the metal wall, and finally the metal wall heats the food product by means of convection. The method to combine these series thermal resistances is similar to that used previously in Section III.A.2, combining resistances in series in heat

conduction. Therefore the total resistance R_t is equivalent to:

$$R_t = R_{HW} + R_M + R_P = \frac{1}{UA} = \frac{1}{h_{HW}A} + \frac{\Delta x}{k_M A} + \frac{1}{h_P A} \quad (108.24)$$

Where R_{HW} is the resistance due to convective heat transfer from the hot water to the metal plate wall in this example, R_M is the resistance due to the conductive heat transfer through the metal wall, and R_P is the resistance due to convective transfer from the hot metal to the product.

Summing the resistances for rectangular coordinates, where areas are equivalent, yields:

$$q = \frac{(T_{hw} - T_{hotm})}{\frac{1}{h_{HW}A}} + \frac{(T_{hotm} - T_{prodm})}{\frac{\Delta x}{k_M A}} + \frac{(T_{prodm} - T_p)}{\frac{1}{h_P A}} \quad (108.25)$$

In this equation, h_{HW} is the convective heat transfer coefficient on the hot water side of the plate, and T_{HW} and T_{hotm} are the temperatures of the hot water and hot metal respectively. In addition, k_m is the thermal conductivity of the metal, Δx is the thickness of the metal, and T_{hotm} and T_{prodm} is the temperature driving force (the temperature of the water and product sides of the metal, respectively). In addition, h_p is the convective heat transfer coefficient on the product side of the plate and T_{prodm} and T_p provide the temperature boundary layer gradient, the temperatures of the metal on the product side, and the temperature of the bulk product, respectively.

The two convective heat transfer coefficients and the conduction term are often combined into an overall heat transfer coefficient, noted as "U," as in equation 108.24. This is a more useful term because the temperature driving force for the overall coefficient, that is, the bulk hot water and the bulk product temperature, is easier to measure than the film temperatures at the metal wall. Usually the manufacturer will suggest a range of overall heat transfer coefficients, U, based on their own experimentation with the heat exchanger and for the conditions and the product in the range of flow rates that are expected to be used. Therefore, equation 108.25 has been rewritten using the overall heat transfer coefficient and the overall temperature gradient for the specific heat flux area:

$$q = U_{PlateHE} A_{plateHE} (T_{HW} - T_p) \quad (108.26)$$

This example used rectangular coordinates, where area is a constant, but cylindrical coordinates, used with pipes, tubular, and swept-surface heat exchangers, are significantly different because the radius, hence the area of each heat transfer surface, varies with each thickness considered, hence:

$$q = U_i A_i (T_{HW} - T_p) \quad (108.27)$$

Where U_i and A_i are the overall heat transfer coefficient and areas based on the inside area of the tube and T_{HW} is the outside temperature of the bulk heating medium and T_P is the inside temperature of the bulk heated product. The definition of the term U_iA_i, which incorporates the three thermal resistances, based on each area is:

$$\frac{1}{U_i A_i} = \frac{1}{h_i A_i} + \frac{\ln\left(\frac{r_o}{r_i}\right)}{2\pi L k} + \frac{1}{h_o A_o} \quad (108.28)$$

The subscript "i" refers to the dimensions of the inside of the pipe, while the dimension "o" refers to the outside dimensions of the pipe. An example of the estimation of the overall heat transfer coefficient and the resulting heat loss is an insulated hot water pipe, see Heldman and Singh (26).

5. Design of a Tubular Heat Exchanger

In Section I of this chapter a variety of heat exchange equipment was discussed. An objective of this chapter was to determine the capacity or the size of the process unit needed to provide the necessary heat based on the rate at which the heat can be transferred. This section will address the calculations necessary to design a simple tubular heat exchanger to meet those needs.

In order to determine the required capacity of a heat exchanger for a given application, the needed heat transfer area must be estimated. The following assumptions will be used:

a) Heat transfer is under steady-state conditions.
b) The overall heat transfer coefficient is constant over the length of the pipe.
c) There is no longitudinal or axial conduction of heat in the metal pipe.
d) The heat exchanger is well insulated so that heat is only transferred between the two liquid streams in the exchanger. There is negligible loss to the surroundings.

First, the change in the heat energy, q, of a liquid stream, flowing at a mass flow rate of "w" kg/sec is estimated by the change in the temperature from T_1 to T_2:

$$q = wC_p(T_1 - T_2) \quad (108.29)$$

where Cp is the heat capacity (kJ/kg°C) of the liquid stream. In this example, T_1 is the inlet temperature and T_2 is the outlet temperature.

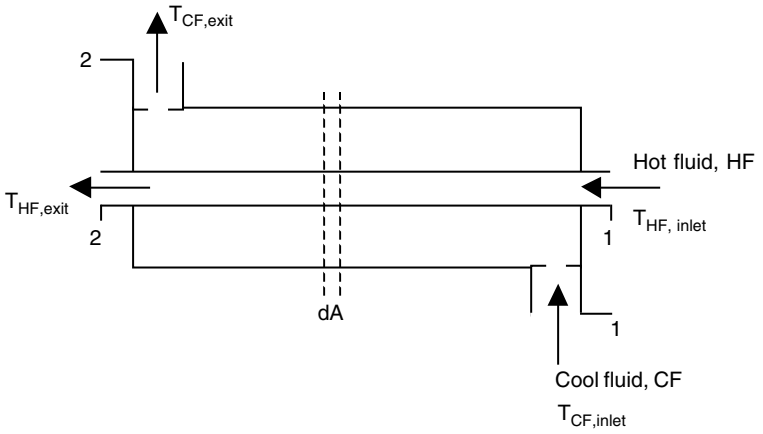

FIGURE 108.6 Tubular heat exchanger showing co-flow of hot and cold liquids for purposes of heat exchanger design.

Figure 108.6 shows an example tubular heat exchanger. In this example the hot fluid could be either water or product and will be noted as HF. It enters the inner tube of the heat exchanger at point 1 and exits at point 2. Its temperature decreases from $T_{HF,inlet}$ to $T_{HF,\ exit}$. Similarly the second fluid, CF, is the cool fluid that enters the annulus, between the inner tube and the outer tube, at point 1 and exits at point 2. Its temperature increases from $T_{CF,inlet}$ to $T_{CF,exit}$. Because there is perfect insulation around the exchanger and because the unit is operating at steady-state conditions, all the heat given up by the hot fluid must be taken up by the cold fluid. Therefore, an energy balance for the rate of heat transferred between the two fluids is:

$$\begin{aligned} q &= w_{HF}Cp_{HF}(T_{HF,inlet} - T_{HF,exit}) \\ &= w_{CF}Cp_{CF}(T_{CF,exit} - T_{CF,inlet}) \end{aligned} \quad (108.30)$$

Where w_{HF} and w_{CF} are mass flow rates of the hot and cold fluids, respectively, in units of kg/s, and Cp_{HF} and Cp_{CF} are the heat capacities of the hot and cold fluids, respectively, in units of kJ/kg°C. This equation determines the needed rate of heat transfer, or heat flux, q, in units of kJ/s or W for the heat process to be successful. This equation is the place to include any phase change information, such as, for example, the heat of condensation for steam, or the heat of fusion for melting fat. However, phase changes will not be considered in this example.

The next step is to determine the heat transfer perpendicular to the direction of flow. The estimation of the convective transfer coefficients and conduction through the metal wall are used here. A simple differential equation can be used to describe the situation. For a thin slice of heat exchanger, dA, perpendicular to the stream flow, the amount of heat, dq, from the hot fluid to the cold fluid will be estimated. The quantity, ΔT, is the difference in temperature between the hot and cold streams for every step, dA, from inlet to exit. Therefore,

$$dq = U\Delta T dA \quad (108.31)$$

where U is the overall heat transfer coefficient for every step, dA, from inlet to exit. In this example, one of the assumptions was that the overall heat transfer coefficient, U, would be constant over the length of the heat exchanger. The term, ΔT, is not assumed to be constant over the length of the heat exchanger. In fact, we already know that this term at point 1 ($T_{HF,inlet} - T_{CF,inlet}$) is different from the term at point 2 ($T_{HF,exit} - T_{CF,exit}$).

In order to easily solve equation 108.31 the term, ΔT, must be constant. In addition, we do not know the temperature at every point along the fluid flow stream, so we must use something similar to the average value, a value, preferably, that is easily measured. Using an arithmetic average temperature would imply that the temperatures are linear along the fluid flow stream and this is not true. Therefore, another method will be used to develop ΔT.

If we were to slice through the tubular exchanger perpendicular to the stream flow we would have two concentric rings. A small differential ring element, using the energy balance for the hot stream would yield:

$$dq = -w_{HF}Cp_{HF}dT_{HF} \quad (108.32)$$

and similarly for the cold stream. Solving for dT_{HF} and dT_{CF}:

$$dT_{HF} = -\frac{dq}{w_{HF}Cp_{HF}} \quad \text{and} \quad dT_{CF} = \frac{dq}{w_{CF}Cp_{CF}} \quad (108.33)$$

Then, subtracting these two equations:

$$dT_{HF} - dT_{CF} = -dq\left(\frac{1}{w_{HF}Cp_{HF}} + \frac{1}{w_{CF}Cp_{CF}}\right) \quad (108.34)$$

Using equation 108.34 above, to substitute into equation 108.31:

$$\frac{d(T_{HF}-T_{CF})}{(T_{HF}-T_{CF})}=-U\left(\frac{1}{w_{HF}Cp_{HF}}+\frac{1}{w_{CF}Cp_{CF}}\right)dA \tag{108.35}$$

Then integrating equation 108.35 from points 1 to 2:

$$\ln\frac{(T_{HF,exit}-T_{CF,exit})}{(T_{HF,inlet}-T_{CF,inlet})}=-UA\left(\frac{1}{w_{HF}Cp_{HF}}+\frac{1}{w_{CF}Cp_{CF}}\right) \tag{108.36}$$

At point 1, $T_{HF,inlet} - T_{CF,inlet} = \Delta T_1$ and at point 2, $T_{HF,exit} - T_{CF,exit} = \Delta T_2$. Substituting these expressions into equation 108.36 and then substituting equation 108.30 into equation 108.36 gives

$$\ln\left(\frac{\Delta T_2}{\Delta T_1}\right)=-\frac{UA}{q}\left[\left(T_{HF,inlet}-T_{HF,exit}\right)-\left(T_{CF,exit}-T_{CF,exit}\right)\right] \tag{108.37}$$

Substituting in the difference equations at points 1 and 2 and rearranging gives the equation for determining heat exchanger design, area and overall resistance:

$$q = UA\frac{\Delta T_2-\Delta T_1}{\ln\frac{\Delta T_2}{\Delta T_1}} \tag{108.38}$$

which is also seen in the form:

$$q = UA(\Delta T_{lm}), \tag{108.39}$$

where ΔT_{lm} is the log mean temperature difference. This equation is commonly used to calculate unknown exit temperatures, as well as necessary area for heat exchange purposes. Equation 108.39 was developed for a simplistic example of a tubular heat exchanger, but this type of exchanger is less common in the food industry. Consult the general references of Hallström *et al*. (5) and Perry *et al*. (6) for specific help in this area or check the Internet.

C. Radiative Heat Transfer

Radiative heat transfer is very different from conduction and convection. Radiative heat transfer has an electromagnetic mechanism, which allows energy to be transported at the speed of light through regions of space that are a complete vacuum. In comparison, for heat conduction to occur there must be a temperature differential at neighboring points in a material. For heat convection to occur there must be a fluid that is free to move and transport energy with it. Radiative heat transfer depends on the emissivity and the absorptivity of the radiating surface as well as the receiving surface, and the rate of heat transferred is also a function of the temperature difference between the surfaces as well as the shape of the object.

Too often the radiative heat transfer in an operation is neglected because it is considered too difficult to estimate or assumed to be negligible in comparison to the other forms of heat transfer. Radiative heat loss from the uninsulated hot surface of a boiler or kettle can be substantial, as can the heat load on the roof of a structure on a clear, sunny day. In addition, radiative heat transfer in a cooking operation, especially one such as grilling or baking in a continuous indirect gas-fired oven is significant; see Broyart and Trystam (15). Utilization of solar radiative energy is important in a variety of operations including drying, and water and air heating. Furthermore, infrared ovens are gaining in popularity because of three basic characteristics: high heat transfer capacity, heat penetration directly into the product, and fast regulation response; see Hallstrom *et al*. (5), Shilton *et al*. (14), and Sheridan and Shilton (27).

1. Radiative Flux

The rate of radiative energy transport between two fully absorptive bodies in a vacuum is proportional to the difference of the fourth powers of their absolute temperatures. The energy radiated from a surface is also dependent on the surface characteristics of the body that is emitting the radiation. A so-called "black body" has a perfect emissivity, that is, emissivity is equivalent to 1. The symbol, ε, for emissivity, represents the degree to which the surface is similar to a black body. The heat flux emitted or radiated from a surface is expressed with the following equation:

$$\frac{q}{A} = \sigma\varepsilon T_A^4 \tag{108.40}$$

In this equation, q/A represents the heat flux in W/m^2, σ, represents the Stephan-Boltzman constant, equal to 5.669 $(10)^{-8}$ $W/m^{2\circ}K^4$, ε, represents the emissivity, and T_A is the temperature of the emitting body in the absolute temperature scale, Kelvin. At a temperature of 0° Kelvin the emission of radiation stops.

The wavelength, in the electromagnetic spectrum, gets smaller as the temperature increases, for example, the radiation emitted by the sun has a much smaller wavelength than the radiation emitted by the element in an electric oven. The infrared part of the electromagnetic spectrum covers the wavelengths between visible light (including solar) and radiowaves (0.6–1000 μm). Infrared energy is naturally emitted by all objects as a result of the thermal vibrations of the molecules and this increases as the temperature is raised. For more discussion of wavelength in radiative heat transfer, as well as the general theory, see Watson and Harper (28).

2. Radiative Heat Transfer Between Two Objects

In order to estimate how much heat is received from the mechanism of radiation, one must consider both the amount

of radiation emitted as well as the incoming radiation. The difference between these two streams is the net exchange and this must always be in the direction of higher to lower temperature.

When electromagnetic energy, E, of a certain wavelength falls on matter, part of it will be absorbed, E_A, to cause heating, part will be reflected, E_R, and part will be transmitted, E_T.

$$E = E_A + E_R + E_T \tag{108.41}$$

In addition, in an isothermal system, Kirchoff's law states that the emissivity of a body surface is equal to its absorptivity for the same wavelength. Emissivity is a property of the material of a surface and tables of emissivities for various material surfaces are available in many heat transfer references including Watson and Harper (28), as well as Singh and Heldman (4). In general, emissivities (and absorptivities) of common surfaces are close to the maximum, so-called, blackbody value of 1, although polished (and even unpolished) metal surfaces have low emissivities. See Table 108.3 for selected examples of emissivities for two temperatures and wavelengths.

The heat transferred by radiation between two surfaces is dependent on the emissivity as well as the absorptivity of the radiating surface. The expression used to describe and estimate the heat, q_{1-2}, radiated by surface 1 and fully absorbed by surface 2, is as follows:

$$q_{1-2} = A\sigma(\varepsilon_1 T_{A1}^4 - E_{A(1-2)} T_{A2}^4) \tag{108.42}$$

where A is the area of the emitting surface (assuming full absorption), σ represents the Stephan-Boltzman constant, ε_1 and T_{A1} represent the emissivity and temperature, respectively, of surface 1, and $E_{A(1-2)}$ represents the absorptivity of surface 2 for radiation emitted from surface 1, at the surface 2 temperature of T_{A2}. It is important to point out that the caveat in equation 108.42 is the assumption that *all* the heat radiated by surface 1 is absorbed by surface 2. This is generally a poor assumption because the geometry as well as the angle of the receiving surface determines how much radiation is absorbed. So in order to account for the variety of shapes, including disks, squares, and rectangles at various incident angles to each other, a shape factor, F_{1-2}, is introduced:

$$q_{1-2} = \sigma F_{1-2} A_1 (T_{A1}^4 - T_{A2}^4) \tag{108.43}$$

This shape factor represents the fraction of the total radiation leaving the surface A_1 that is intercepted by the surface A_2. Singh and Heldman (4) and also Bird *et al*. (2) have some figures of shape factors (also termed view factors) for various dimension ratios. More comprehensive view factors may be found in Hottel (29).

An alternative to using a shape factor is to use Lambert's law, derived in Bird *et al*. (2), for the incidence at angle θ from the normal to the surface. The example illustrating this is the radiant heat flux entering the earth's atmosphere from the sun, also termed the solar constant. This radiant energy is important in solar energy utilization, in particular, and solar food drying operations. Bird *et al*. (2) solve the radiant heat transfer equation using black body assumptions for the sun and the receiving surface on earth and estimate the radiant heat flux to be 1355 W/m^2.

The shape factor in equation 108.43, however, assumes perfect emissivity and absorptivity, i.e., blackbodies and avoids derivations using Lambert's law. In order to account for both shape and emissivity the expression becomes:

$$q_{1-2} = \sigma \zeta_{1-2} A_1 (T_{A1}^4 - T_{A2}^4) \tag{108.44}$$

where ζ_{1-2} accounts for both the shape factor as well as the emissivity of both surfaces 1 and 2 and is defined as such:

$$\zeta_{1-2} = \frac{1}{\dfrac{1}{F_{1-2}} + \left(\dfrac{1}{\varepsilon_1} - 1\right) + \dfrac{A_1}{A_2}\left(\dfrac{1}{\varepsilon_2} - 1\right)} \tag{108.45}$$

Therefore, equations 108.44 and 108.45 may be used to compute the net radiant heat transfer between two gray bodies, each at their own uniform temperature. For further discussion of this useful mode of heat processing see Chapman (3). Hallström *et al*. (5) give some interesting examples of this type of heating in industrial use.

TABLE 108.3

IV. UNSTEADY-STATE HEAT TRANSFER

Unsteady-state heat transfer conditions mean the temperature changes not only with location, but also with time. Steady-state conditions, in comparison, mean the temperature varies only with location. In spite of the fact that transient operating conditions are common, and steady-state conditions are uncommon, steady-state is more often an assumption made in a mathematical analysis because it is simpler than unsteady-state.

However, during the unsteady-state period many important reactions take place. Furthermore, in some operations the unsteady-state period is the major component of

the process. This is especially the case with heating cans for commercial sterilization or cooking, cooling, or freezing solid foods. We cannot use steady-state conditions because the time frame of interest is when the temperature is changing with time and, in the case of canning, microbes are being killed.

A. Use of the Fourier Relationship

In order to mathematically model unsteady-state conductive heating in one dimension, we will use equation 108.2, Fourier's law, and a basic energy equation to result in equation 108.46. For a detailed derivation see Myers (30), Holman (1), Bird *et al.* (2), or Chapman (3).

$$\frac{\partial T}{\partial t} = \frac{k}{\rho C_p}\left(\frac{\partial^2 T}{\partial x^2}\right) \tag{108.46}$$

Therefore, the time evolution of temperature is a function of the combination of material properties, k/ρCp (also defined as the thermal diffusivity, α, from equation 108.1), and the second derivative of the temperature as it varies with distance in the x direction. (This partial differential equation is also the diffusion equation.)

Equation 108.46 has been solved analytically for simplified geometrical shapes (see Myers (30)) such as the sphere (possibly a roast), an infinite cylinder (perhaps a can), and an infinite slab (possibly cooking a hamburger or a box of spinach to be plate-frozen). Take care when using these simplified geometries for real situations that end effects are not significant. For most interesting problems, analytical solutions are not available and advanced computational techniques are generally required to solve the equation.

For reasons similar to those discussed in the dimensional analysis, Section III.B.3.a, food processors found alternative ways to solve practical unsteady-state problems using empirical methods based on theory. In the development of these empirical methods certain groups of key variables and constants seemed to appear again and again in the solutions and equation set-ups. In unsteady-state heat transfer these groups include the Nusselt number, Nu, thermal diffusivity, α, the Fourier number, Fo, and the Biot number, Bi. The Nusselt number and the thermal diffusivity were defined previously and the Biot and Fourier numbers will be discussed below.

B. External and Internal Resistance to Heat Transfer

If an object, say a pineapple at ambient temperature, were placed in a retort of pressurized steam, the pineapple temperature would start to increase, as a function of material properties, time, and of the steam temperature. The temperature profile from the outside surface to the center or pineapple core would change for each second that the whole pineapple was in the retort until the temperature within the pineapple reached equilibrium with the retort (something that might not be desirable). The heat flowing into the pineapple will encounter two major resistances: 1) the convective resistance outside the pineapple of the steam flowing across the surface of the pineapple, and 2) the conductive resistance inside the pineapple of the heat moving from the pineapple surface toward the core.

The Biot number is another dimensionless number and is the ratio of the internal resistance to heat transfer in the solid pineapple to the external resistance to heat transfer from the fluid to the pineapple surface:

$$Bi = \frac{internal\_resistance}{external\_resistance} = \frac{L/k}{1/h} = \frac{hL}{k} = \frac{UL}{k} \tag{108.47}$$

In this equation, L is the characteristic dimension of the object (the diameter for a cylinder or the thickness for a slab), h (or U) defines the surface conductance, and k is the internal conductance of the object.

For Biot numbers greater than about 40, there is generally negligible surface resistance to heat transfer, that is, the "h" value is much greater than "k" value. An example of this might be a metal can of salmon in a steam retort where there is very efficient heat transfer from the flowing, and condensing steam to the metal and also fast heat transfer across the metal can surface, but relatively slow heat transfer from the salmon touching the can through to the center of the can. The heat transfer inside the can is almost 100% conduction in meat, which has a relatively small conductivity.

For Biot numbers less than about 0.1, there is a negligible internal resistance to heat transfer, that is, the "k" value is much greater than the "h" value. Examples of this might occur in the heating of a block of solid metal where the k value, thermal conductivity, is relatively high, 2 to 3 orders of magnitude (see Table 108.1), compared to foods. A more realistic example of this case for the food industry might be a well-stirred liquid in a hot water–jacketed kettle, where the temperature profile is uniform across the container due to the agitation. No temperature gradient with location occurs because the heat transfer is immediate to the bulk liquid.

Between Biot numbers of 0.1 and 40 there is a finite internal and external resistance to heat transfer.

C. Finite Internal and External Resistance to Heat Transfer

The empirical solution to equation 108.46 when the Biot number is between 0.1 and 40 has been simplified to temperature-time charts for the three main geometrical shapes. See time-temperature charts in (4) and (28). In these charts,

a dimensionless unaccomplished temperature is plotted as a function of the thermal diffusivity for several Fourier numbers. The dimensionless unaccomplished temperature is defined as $(T_o - T)/(T_o - T_i)$, where T_o is the outside temperature (also referred to as the temperature of the surrounding medium), T_i is the initial temperature, and T is the variable temperature changing with time. This temperature ratio indicates the change of temperature with time compared to the maximum possible temperature difference. It is not initially obvious that the dimensionless unaccomplished temperature change should be useful for both infinite and finite objects of a slab, as well as a cylinder. Myers (30) provides convincing mathematical derivations.

The dimensionless Fourier number, Fo, is the ratio of the rate of heat conduction across D in volume D^3 (in Watts per degree C) to the rate of heat storage in volume D^3 (in Watts per degree C) and is defined by:

$$Fo = \frac{k\left(\frac{1}{D}\right)D^2}{\rho C_p \frac{D^3}{t}} = \frac{\alpha t}{D^2} \qquad (108.48)$$

where D is a characteristic dimension that might be the shortest distance from the heated surface to the center of the object. For the purposes of this relationship, the characteristic dimension, D, refers to half of the thickness of an infinite slab, the radius of an infinite cylinder and the radius of a sphere. Heldman and Singh (26) suggest another way to think about this parameter: Fo is a measure of the rate of heat conduction per unit of heat storage for a given volume element. Therefore, a larger Fo number indicates a deeper heat penetration into the solid in a given time period.

D. Use of the Temperature-Time Charts for Unsteady-State Heat Transfer in Finite Objects

In order to use the temperature-time charts for estimation of heat transfer rates in appropriately shaped geometries the following steps may be used:

1. Calculate the Fo number using the radius of the cylinder (or half of the height of a slab, or the radius of a sphere) as the characteristic dimension, D.
2. Calculate the Bi number using the radius of the cylinder (or half of the height of a slab, or the radius of a sphere) as the characteristic dimension, D.
3. Use the appropriate temperature-time chart to estimate the unaccomplished temperature ratio, above. From this ratio the center temperature may be calculated providing the initial temperature, T_i and the outside temperature T_o are known.

Be aware that the assumptions within this method are for infinite geometric shapes so that end effects can be quite significant. For example, if the height of a can is smaller than its diameter, then it might be appropriate to treat the short cylinder as a slab in the initial analysis.

For further discussion of unsteady-state heat transfer and use of Schmidt plot, Gurney-Lurie charts and thermal processing examples (1, 4, 5, 30, 31).

CONTENTS

I. INTRODUCTION

The principles of heat processing discussed in the chapters in the heat processing section, and in particular those that refer to the heat resistance of the microorganisms and the mechanisms and rates of heat transfer, are among the absolutely necessary information in establishing a heat treatment for a particular product. No matter if one is interested in establishing a process for steam sterilization or thermal pasteurization, or is aiming in enzyme inactivation through a water blanching procedure, or is simply heating the product as an intermediate step during a particular process, the basic principles are the same. Thus, the concepts that will be presented in this chapter, although they will be, most of the time, focused and referred to thermal processes used for commercial sterilization, they are of general applicability, independently of the severity or the goals of a particular heat treatment.

Products with different characteristics will, most probably, require processing at different *temperature–time combinations* in order to accomplish the objectives set in a particular process. Any change in product or process characteristics requires reevaluation of the necessary time–temperature treatment. It is somewhat intuitive that what could be achieved by heating the product at a given process temperature for a given process time, it can be also achieved by heating the product at a higher temperature for less time. Quantifying this idea will be the task of this chapter.

By introducing more than one objective during a heat treatment, it is usually possible to optimize the process.

Product safety coupled with quality is the basis for proper thermal process design. The required theoretical background and the mathematical procedures, with example calculations, used in designing and evaluating a thermal process will be presented in the remainder of this chapter.

II. BASIC PRINCIPLES

The extent of thermal destruction of a heat labile substance during thermal processing is a function of the sensitivity (or the "thermal resistance") of the particular substance to the various temperatures at which it is exposed and the time that the substance remains at each one of these temperatures during the process. Substances with different thermal resistances will be affected differently, even if they are processed under identical time–temperature conditions. Thus, the severity of a thermal process relates to a particular substance or food attribute and it can be assessed by measuring or evaluating the degree of destruction of that substance or attribute after the process (*e.g.,* remaining microbial spores per can).

The heat labile nature of the microorganisms and the other agents of spoilage makes preservation of foods by heat treatment possible. However, the same destructive effect of a heat treatment on quality factors requires precise and accurate design and control of a thermal process. Differences in thermal sensitivities between the various undesirable and quality agents [1, 2] are in fact what make a thermal process effective.

To facilitate our presentation, in the remainder of this chapter, we will assume (unless otherwise explicitly stated) that the target (undesirable) heat labile substances that we refer to are heat resistant microbial spores. With this note, and before attempting to fully quantify the ideas behind the design of a thermal process, let us introduce and define the term *equivalent processes*. Two thermal processes are considered equivalent only if they produce the same destructive effect on a microbial population, that is, if the number of spores surviving after each process is the same, providing that the two processes are applied to the same type and initial load of spores with all conditions, except the time-temperature exposure of the spores, being the same for the two processes [3].

So, let us assume that by holding a sample of spore suspension at a lethal constant temperature, T_1, for a time period, t_1, we reduce its initial number of spores by 90%. The same 90% reduction can be presumably achieved by heating the sample at a different, higher temperature, T_2, for a shorter time period, t_2. One must very precisely estimate (by experimentation or calculation) this new, t_2, processing time in order to achieve exactly the desired amount of 90% destruction. Obviously, one might choose any appropriate temperature and estimate the required, for 90% destruction, processing time, or, in a similar way, find equivalent processes for any given degree of microbial destruction. If the temperature of a food sample going through a thermal treatment is not constant throughout the process (the usual scenario), there still exists an equivalent process at any desired constant reference temperature.

With the above introductory remarks, we can now approach the subject in quantitative terms. Assuming that thermal destruction of microbial spores follows first order kinetics [4], then the rate of spore destruction (*e.g.,* concentration change, C, over time) during processing at a constant temperature T, is given by Equation (109.1).

$$-\frac{dC}{dt} = k_T C \tag{109.1}$$

The subscript T in the reaction rate constant, k_T, denotes its temperature dependence. Integration of Equation (109.1) between the beginning, t_a, of the process (where spore concentration is C_a) and the end, t_b, of the process (where spore concentration is C_b) gives:

$$\int_{C_a}^{C_b} -\frac{dC}{C} = \int_{t_a}^{t_b} k_T\, dt \equiv f(C_a,C_b) \tag{109.2}$$

or

$$\ln(C_a) - \ln(C_b) = \int_{t_a}^{t_b} k_T\, dt \tag{109.3}$$

The type of the $f(C_a,C_b)$ function defined by Equation (109.2) is determined by the kinetics the thermal destruction obeys. For first order reactions, comparison of Equations (109.2) and (109.3) reveals:

$$f(C_a,C_b) = \ln(C_a) - \ln(C_b) \tag{109.4}$$

Different reaction kinetics give rise to different types of $f(C_a,C_b)$ functions. Thus, for zero and for nth order reactions ($n \neq 1$) the $f(C_a,C_b)$ functions (also referred to as quality functions when the change — destruction — of a quality attribute is examined) are given by Equations (109.5) and (109.6) respectively [5].

$$f(C_a,C_b) = C_a - C_b \tag{109.5}$$

$$f(C_a,C_b) = \frac{1}{n-1}(C_b^{1-n} - C_a^{1-n}) \tag{109.6}$$

As it can be inferred from the right hand side of Equation (109.2), the value of $f(C_a,C_b)$ depends upon the time temperature process conditions (beyond the destruction kinetics). Note that k_T, is a function of temperature while time explicitly appears in Equation (109.2). Furthermore, from the definition of equivalent processes, it is inferred that the $f(C_a,C_b)$ value must be the same for two processes to be equivalent. We must clarify here that it is not necessary that the values of the initial and final concentrations of two processes be the same, in order for the values of the $f(C_a,C_b)$ function of the two processes to be

equal. For example, for inactivation following first order kinetics, the value of $\ln(C_a) - \ln(C_b)$ or $\ln(C_a/C_b)$ or finally the value of C_a/C_b, that is, the ratio of the initial over the final concentration must be equal for the values of the $f(C_a,C_b)$ to be equal, and, therefore, for the two processes to be equivalent. Thus, a process with $C_a = 10^9$ spores/can and $C_b = 10^3$ spores/can is equivalent to a process with $C_a = 10^6$ spores/can and $C_b = 1$ spore/can under the earlier mentioned assumptions.

A thermal process at time varying temperature conditions resulting in an $f(C_a,C_b)$ value, as it is calculated from the right hand side of Equation (109.2) for a particular heat induced change, has an equivalent process at any constant, reference, temperature T_{ref}. The required process time at T_{ref}, in order for the two processes to be equivalent, can be estimated by evaluating the last integral in Equation (109.2). This, for the process at constant temperature ($k_T = k_{T_{ref}}$ = constant, and for t_1 being the beginning and t_2 the end of the process) gives:

$$f(C_a,C_b) = k_{T_{ref}}\,(t_2 - t_1) \tag{109.7}$$

where $(t_2 - t_1)$ is the total (required) processing time at the constant reference temperature. Note that we assumed that processing at the reference temperature starts at t_1 and ends at t_2 to explicitly indicate that processing time at T_{ref}, *i.e.*, $t_2 - t_1$, does not have to be equal to the processing time $t_b - t_a$ of the process with the variable temperature. It is customary to denote that time with $F_{T_{ref}}$ (the index T_{ref} in the "F" symbol denotes the reference temperature used in calculating the required time) that is,

$$F_{T_{ref}} = t_2 - t_1 \tag{109.8}$$

and through Equations (109.2), (109.7) and (109.8), we obtain

$$F_{T_{ref}} = \frac{1}{k_{T_{ref}}} \int_{t_a}^{t_b} k_T\,dt \tag{109.9}$$

With the presentation so far we arrived to the fundamental concept in thermal process design and evaluation, the *F value*. The F value of a process is the equivalent processing time of a hypothetical thermal process at a constant, reference, temperature that produces the same effect (in terms of spore destruction) as the actual thermal process. Note that the mathematical definition of the F value through Equation (109.9) is independent of the order of the thermal destruction kinetics.

The reaction rate constant depends upon a variety of factors, but in the context of the present issue we will only focus upon the temperature dependence of the k_T value. Using the Arrhenius equation to express the effect of temperature on k_T, that is, in one representation [6]

$$k_T = k_{T_{ref}}\,10^{-\frac{E_a}{\ln(10)\cdot R_g}\frac{(T_{ref}-T)}{T_{ref}T}} \tag{109.10}$$

Equation (109.9) reduces to:

$$F_{T_{ref}} = \int_{t_a}^{t_b} 10^{-\frac{E_a}{\ln(10)\cdot R_g}\frac{(T_{ref}-T)}{T_{ref}T}}\,dt \tag{109.11}$$

Note that the parameters T ant T_{ref} in Equations (109.10) and (109.11) are representing absolute temperatures (*i.e.,* expressed in K).

In the classical thermobacteriological approach [7–9] but also in the majority of the recent thermal processing literature, the D_T and z values are used in place of the k_T and the E_a (or better E_a/R_g) parameters. The D_T value (*decimal reduction time*) is defined as the time, at a constant temperature T, required to reduce by 90% the initial spore load. The same definition applies for any heat labile substance. Traditionally, D_T is estimated from a semilogarithmic plot of the number of (surviving) spores, N, *vs* processing time, t, as they are experimentally measured during treatment at constant temperature T. A "straight line" fit of the experimental data (according to the first order destruction kinetics) can be drawn (*Thermal Death Rate Curve* or *Survivor Curve* of Figure 109.1) and the D_T value can be measured directly on the graph, as the time required for the straight line to traverse a logarithmic cycle (a logarithmic cycle corresponds to 90% reduction).

Alternatively, the D_T value can be calculated from the slope of the *Thermal Death Rate Curve*. The slope of the straight line, the *Thermal Death Rate Curve* (Figure 109.1), is given as:

$$\text{slope} = \frac{d(\log(N))}{dt} = \frac{\log(N_2) - \log(N_1)}{t_2 - t_1} \tag{109.12}$$

(for 1 and 2 representing any two points on the straight line). For $N_2 = 0.1 \cdot N_1$ we are referring to 90% destruction, where, by definition, $t_2 - t_1 = D_T$. Under these conditions Equation (109.12) reduces to:

$$\text{slope} = \frac{\log(0.1N_1) - \log(N_1)}{D_T} \quad \text{or} \quad D_T = -\frac{1}{\text{slope}} \tag{109.13}$$

Thus, a statistical linear least square regression can be applied to the experimental log(N) *vs* t data, and D_T can be calculated from the slope of the line through Equation (109.13).

Referring to isothermal conditions, Equation (109.1) suggests a linear relationship, with slope equal to $-k_T$, between ln(C) (or equivalently ln(N)) and t. Going from natural to base 10 logarithms, the following relationship is obtained between D_T and k_T:

$$D_T = \frac{\ln(10)}{k_T} \tag{109.14}$$

As already said, the activation energy, through the Arrhenius equation, is used to express the effect of temperature on k_T. In a similar way, in thermobacteriological

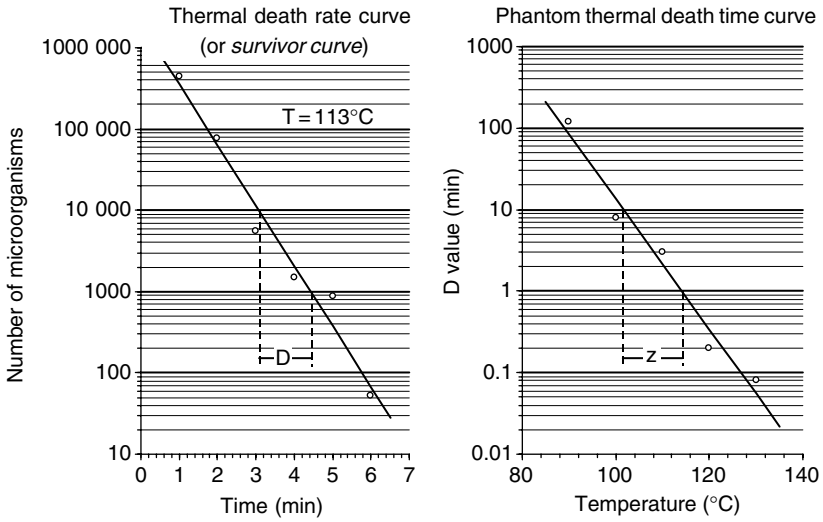

FIGURE 109.1 Graphical determination of the thermal inactivation kinetic parameters D and z through the thermal death rate and the phantom thermal death time curves, respectively.

terms, the z value is used to express, through Equation (109.15), the effect of temperature on the decimal reduction time, D_T.

$$D_T = D_{T_{ref}} 10^{\frac{T_{ref}-T}{z}} \qquad (109.15)$$

The z value is defined as the temperature difference required to achieve a decimal change of the D_T value. In converting z values from one system of units to another, we must remember that z represents a temperature difference. Thus a z value of 10°C is equivalent to a z of 10 K or a z of 18°F. Equation (109.15) is an empirical equation resulted from the observed linear relationship between $\log(D_T)$ and T values. In an analogous way as for the D_T value, the z value can be measured directly on $\log(D_T)$ *vs* T plots (*Phantom Thermal Death Time Curve*, Figure 109.1), as the temperature interval required for the straight line to traverse a logarithmic cycle. Obviously, estimation of the z value requires kinetic (destruction) experiments at different temperatures.

Comparison between Equations (109.10), (109.14) and (109.15) allows for a relation between E_a and z to be determined:

$$z = \frac{\ln(10) \cdot R_g \cdot T_{ref} \cdot T}{E_a} \qquad (109.16)$$

Note that in Equation (109.16) the temperatures T and T_{ref} are representing absolute temperatures (*i.e.,* expressed in K) while the z value is either in °C or K. Furthermore note that although both E_a and z are assumed independent of temperature (it is inherent in the nature of Equations (109.10) and (109.15)) Equation (109.16) suggests the opposite. The contradictory nature of the two models (Equations (109.10) and (109.15)) is given [10]. However, as long as we are not extrapolating beyond the experimental temperature range used for collecting thermal destruction data, both models are considered satisfactory for microbial destruction calculations [11–13]. At this point we should mention that although deviations of microbial thermal destruction from first order kinetics do exist, the "straight-line semilogarithmic model" presented so far (Figure 109.1) is considered as an appropriate engineering tool for thermal process design [14].

As mentioned earlier, the classical thermobacteriological analysis is still followed in the thermal processing literature and industry [2]. From the equations presented so far following the k_T, E_a approach, by appropriate substitutions (through Equations (109.14) and (109.16)), one can obtain the fundamental equations that govern thermal processing in the D, z notation. Nevertheless, for better comprehension, we will, at the risk of being redundant, in brief derive them based on the new nomenclature. Thus, from Equations (109.12) and (109.13) we obtain:

$$\frac{d(\log(N))}{dt} \quad \text{or} \quad \frac{d(\log(C))}{dt} = -\frac{1}{D_T} \qquad (109.17)$$

Upon integration, between t_a (where spore concentration is C_a) and t_b (where spore concentration is C_b) Equation (109.17) gives

$$\int_{C_a}^{C_b} d\log(C) = \int_{t_a}^{t_b} -\frac{1}{D_T} dt$$

$$\Rightarrow \quad \log(C_a) - \log(C_b) = \int_{t_a}^{t_b} \frac{1}{D_T} dt \qquad (109.18)$$

For equivalent processing at constant temperature, T_{ref}, ($D_T = D_{T_{ref}}$ = constant, and for $t_a = t_1$, $t_b = t_2$, where by definition $F_{T_{ref}} = t_2 - t_1$) integration of Equation (109.17) gives:

$$\log(C_a) - \log(C_b) = \frac{t_2 - t_1}{D_{T_{ref}}}$$

$$\Rightarrow \quad \log(C_a) - \log(C_b) = \frac{F_{T_{ref}}}{D_{T_{ref}}} \qquad (109.19)$$

Comparison between Equations (109.18) and (109.19) results to (note the analogy between Equations (109.9) and (109.20)):

$$F_{T_{ref}} = D_{T_{ref}} \int_{t_a}^{t_b} \frac{1}{D_T}\, dt \qquad (109.20)$$

Finally, for variable T, substitution of D_T from Equation (109.15) into Equation (109.20) gives:

$$F_{T_{ref}} = D_{T_{ref}} \int_{t_a}^{t_b} \frac{1}{D_{T_{ref}}\, 10^{\frac{T_{ref}-T}{z}}}\, dt$$

$$\Rightarrow \quad F_{T_{ref}} = \int_{t_a}^{t_b} 10^{\frac{T-T_{ref}}{z}}\, dt \qquad (109.21)$$

By putting together Equations (109.19) and (109.21) we have:

$$F^z_{T_{ref}} = D_{T_{ref}} (\log(C_a) - \log(C_b)) = \int_{t_a}^{t_b} 10^{\frac{T-T_{ref}}{z}}\, dt \quad (109.22)$$

Note that a superscript z is introduced in the notation of the F value. This is to indicate that, as suggested by the right hand side of Equation (109.22), heat induced changes to attributes with different z values correspond to different F values, even if they occur during the same time–temperature conditions. (The symbol F_o is uniquely used for a reference temperature of 250°F and a z value of 18°F.) Equation (109.22) represents the *fundamental equation* in thermal processing. It uniquely indicates the methodologies to be used for thermal process design and evaluation.

There are a few points that must be noted before going further. While different thermal processes can be compared based on their corresponding F values, the accomplishment of the objectives of a process (*e.g.,* commercial sterilization) can be assessed by comparing the F value of the process (which we will term $F_{process}$) with an F value corresponding to a process known to meet our objectives (which we will term $F_{required}$). Given the relationship between concentration and F value (left hand side of Equation (109.22)) the $F_{required}$ value can be defined as the time, at a constant temperature, required to destroy a given percentage of microorganisms whose thermal resistance is characterized by a particular z value.

Furthermore, unless the temperature of the sample is uniform during processing, something that is not the usual case (see the chapter on heat transfer), Equation (109.22) can be used to calculate the F value of a process at a single "point" in the sample where temperatures or concentrations are known throughout the thermal process (termed *point F value*). The objectives of a process have been met throughout the whole product, if they have been met at the *critical point* of the product, that is, the point that receives the least effects, in terms of spore destruction, of the heat treatment (the F value at the critical point is noted as F_c). Integration of the effect of the heat treatment for each of the volume elements of the sample must be performed if equivalent processes in terms of remaining concentration for the total volume of the food sample have to be defined. This (second) integration enables calculation of *integrated F values* (F_s). The significance in calculating F_s values is obvious when we are interesting in quality retention calculations. In microbial destruction calculations, according to Hayakawa [15] the two procedures (F_c *vs* F_s calculations) produce similar results. A further discussion on this matter is given by Stoforos [16]. The relative simplicity in calculating point F values compared to integrated ones gives an advantage to the former procedures, and most of the discussion in the remainder of this chapter will be devoted to them.

The integrated time-temperature effect of a thermal process on a heat labile substance can be evaluated using *in situ*, time-temperature integrators (TTI), or physical-mathematical procedures [17]. The *in situ* measurements as well as the use of TTIs involve direct monitoring of the concentration, before and after processing, of either the heat labile substance of interest itself (*in situ* method) or of another heat labile substance, chosen so as to mimic the original substance as far as its response to thermal treatments is concerned (TTI approach). F value calculations associated with these two methods involve use of the left hand side of Equation (109.22). The basic requirement in using TTIs in thermal process calculations is that the activation energies, or the z values, of the TTI and the substance of interest should be the same [5, 17]. When this is not attainable, the use of multi-component TTIs (with each component having its own activation energy or z value), and correlation of the responses of these multi-TTI systems with the thermal degradation of the substance of interest has been proposed as an alternative [17–20].

Physical-mathematical procedures rely on temperature data, of the product undergoing a thermal process, which together with appropriate thermal destruction kinetics can be used to evaluate the lethal effects of the process. F values by these physical-mathematical procedures are calculated through the evaluation of the integral in Equation (109.22). While the *in situ* or the TTI approach can be the only choice in several cases where time temperature data are not available (*e.g.*, during aseptic processing of liquid/particulate foods) due to inherent difficulties in working with these two procedures [21] physical-mathematical methods are considered to be the most appropriate procedures when product temperature data can become available [22].

III. MATHEMATICAL PROCEDURES FOR THERMAL PROCESS CALCULATIONS

There is a large number of publications dealing with the issue of thermal process calculations through mathematical methods. The core of all these procedures is the right hand side of Equation (109.22). Methodologies have been reported for calculation of point F values from discrete (usually experimental) product temperatures (General

Methods) or from time-temperature curves obtained through appropriate models (Formula Methods). Critical reviews of these methodologies have been presented in the literature [3, 15, 23]. Procedures for evaluating the effects of a thermal process through calculation of integrated F values are also available and have been reviewed [15, 23, 24].

The objectives of any methodology on thermal process calculations consist of:

1. Process evaluation (first type of problem): This refers to the evaluation of the F value of a given process (that is, calculation of $F_{process}$ value). Information on the process (in particular processing time and processing (retort) temperature, etc.) and on the product is available. This is a rather straightforward step.

2. Process design (second type of problem): This step involves the estimation of the proper processing time in order to achieve a particular required F value. A variety of parameters needed for the calculations (*e.g.,* retort temperature, initial product temperature, cooling medium temperature, speed of rotation (if any), can size, headspace volume, etc.) can become available. Obviously this step needs some "predictive" work. Before answering this question we must notice that a cooling cycle always follows the heating cycle in a thermal process in order to control and cease the destructive effects of the elevated temperatures. So, in the design problem we are in fact interested in calculating the time needed to end the heating cycle, *i.e.,* the steam-off time. (The exact duration of the cooling cycle, provided that it is long enough to allow for the food temperature to fall below lethal temperatures, is not important as far as microbial thermal destruction is concerned.) In terms of mathematical representation of this step, dividing the thermal process into the two cycles, Equation (109.22) can be written as:

$$F^{z}_{T_{ref}} = \int_0^{t_g} 10^{(T-T_{ref})/z}\, dt_h + \int_0^{t_{c_b}} 10^{(T-T_{ref})/z}\, dt_c \qquad (109.23)$$

where the first integral is associated with the heating and the second integral with the cooling cycle of the thermal process. What we are in fact looking for, is the value of t_g (steam-off time) — upper limit of first integral — in order for the whole process to result in a given $F_{required}$ value.

Equation (109.23) gives the desired F *vs* t_g relationship. The ultimate objective of all thermal process calculation procedures is to express the F value as an explicit function of the total heating time (and vice versa). An analytical solution of Equation (109.23) can be obtained for only a few product temperature profiles. Given the complexity of product temperature profiles encountered, in most practical cases, during thermal processing of foods, the methodologies developed for thermal process calculation rely on numerical or graphical procedures and/or make use of appropriate graphs and tables. In the remainder of this chapter we will mainly present two of the methodologies used for thermal process calculations: the General Method and Ball's Formula Method.

A. General Method

The first ever scientific procedure for thermal process calculations was the General Method introduced by Bigelow and his coworkers at the National Canners Association over 80 years ago [25]. In approaching the first type of problem, that is, calculation of the F value of a given process, the method, in its original application, calculates the integral appearing in Equation (109.22) graphically (that is why it is also referred to as the *Graphical Method*) from discrete data (usually experimental product temperature values at the critical point *vs* time). It does not make any assumptions about process or product characteristics (termed for this *General Method*) and it calculates an exact (depending on the accuracy of the graphical integration) $F_{process}$ value.

Several complementary works were introduced to make the General Method less laborious, consisting of the use of a special coordinate paper [26–29], or of some numerical integration scheme, such as trapezoidal rule [30], Simpson's rule [31], and Gaussian integration [32]. In fact, a numerical integration scheme is nowadays incorporated to any method that uses a computerized model for product temperature predictions.

In attacking the second type of problem, that is, estimation of the required processing time in order to achieve a particular $F_{required}$ value, any method, including the General Method, has to make some reasonable assumptions in extrapolating time–temperature data to different conditions. The problem, in its simplest form, can be stated as: Given experimental time–temperature data for a particular product during a specific heat treatment (*i.e.*, with specified retort temperature during both heating and cooling cycles of the process, given initial product temperature and steam-off time, specific product characteristics and container type and size, etc.), determine the steam-off time required to achieve a particular $F_{required}$ value for all conditions being the same with those used to obtain the experimental time–temperature curve. General Method approaches this problem using a "geometrical similarity," that is, by assuming that the shape of the integrant in

Equation (109.22) *vs* time curve, after steam-off time, is geometrically the same irrespectively of the total heating time. This is an approximation. With the exception for the case where the product temperature had approached equilibrium with the heating medium temperature, the shape of the lethal rate curve during the cooling phase is a function of the difference between the product and the heating medium temperature at the steam-off time. In the next paragraphs, we will illustrate the application of the General Method in process calculations by the following example.

1. Example Problem

Experimental time–temperature data during processing of canned fish in a still retort at 240°F are given in Table 109.1. Determine the steam-off time for a required F_o value of 6 min.

2. General Method Approach

In one of its applications, General Method uses the lethality of process, that is, the ratio of $F_{process}/F_{required}$ as the design variable.

TABLE 109.1
Heat Penetration Data

Product:	Diced fish in sauce
Can size:	308 × 113

*Steam is turned off after 60 min of heating. Therefore, the 61st minute is the end of the first minute of cooling.

$$\text{lethality} = \frac{F^z_{T_{ref}}\big|_{process}}{F^z_{T_{ref}}\big|_{required}} \tag{109.24}$$

For a process that meets our objectives, $F_{process}$ must be equal to $F_{required}$, or, in other words, lethality must be unity. That is,

$$\text{lethality} = 1 \tag{109.25}$$

Using the right hand side of Equation (109.22) we obtain:

$$\text{lethality} = \frac{1}{F^z_{T_{ref}}\big|_{required}} \int_{t_a}^{t_b} 10^{\frac{T-T_{ref}}{z}}\, dt \tag{109.26}$$

or, by defining TDT (thermal death time) as

$$TDT = F_{required}\, 10^{\frac{T_{ref}-T}{z}} \tag{109.27}$$

Equation (109.26) can be written as

$$\text{lethality} = \int_{t_a}^{t_b} \frac{1}{TDT}\, dt \tag{109.28}$$

Note that the TDT (thermal death time) is the equivalent to the required $F_{T_{ref}}$ time at a constant temperature T (one can check this by evaluating the integral in Equation (109.22) for constant temperature T and letting $TDT = t_b - t_a$) and that the variable 1/TDT is called *lethal rate*.

Based on Equation (109.27) and the experimental data from Table 109.1, the lethal rate (1/TDT) *vs* time curve is plotted in Figure 109.2. The area under this curve (corrected appropriately for the time and the lethal rate scales used) gives the lethality of the process. In the particular example, the area under the original (steam-off time = 60 min) lethal rate curve is equal to 663.7 small (dxdy) squares. This area multiplied by the time scale and the lethal rate scale used is converted to process lethality. Specifically, for the example (Figure 109.2) we have:

$$\text{lethality} = 663.7 dxdy \cdot \frac{1\text{min}}{dx} \cdot \frac{0.010\ \text{min}^{-1}}{5dy}$$

$$\Rightarrow \quad \textbf{lethality = 1.33} \tag{109.29}$$

(From the above value one can calculate, through Equation (109.24), the F value of the process, as: $F_{process} = 1.33 \cdot 6 \Rightarrow F_{process} = 8$ min. If one seeks the $F_{process}$ value without knowing the value of $F_{required}$ — or is not interested in steam-off time calculation — one can assume an $F_{required}$ value of unity. In this case, the area under the lethal curve will give directly the $F_{process}$ value.)

The area under the curve that corresponds to unit lethality (our goal) is called Unit Sterilization Area (USA) and is calculated based on the particular time and lethal rate scales used in constructing the lethal rate curve. That is,

$$USA = \frac{1}{\text{time scale}} \cdot \frac{1}{\text{lethal rate scale}} \tag{109.30}$$

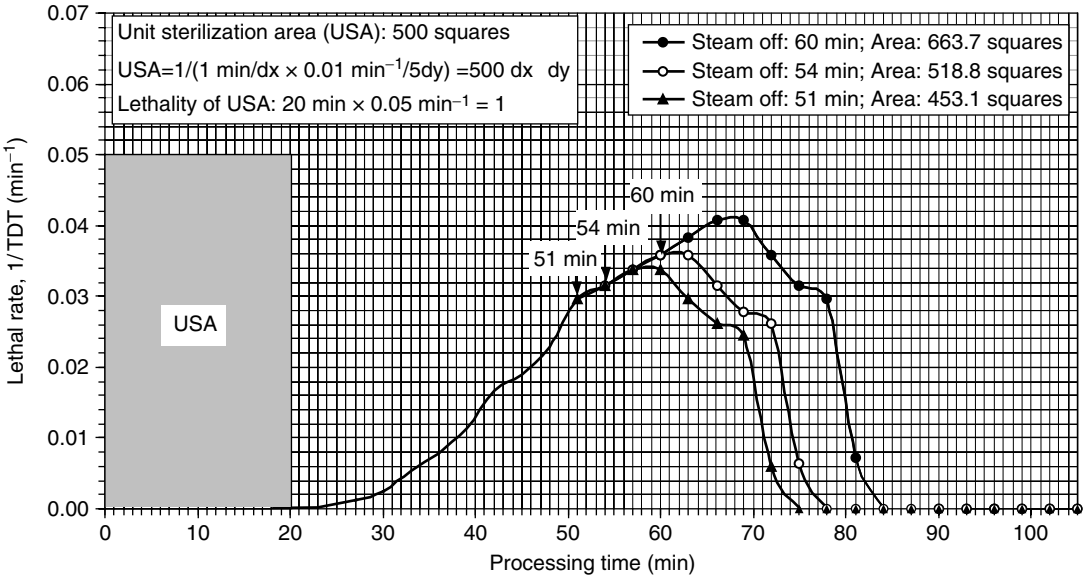

FIGURE 109.2 Graphical determination of process lethality, by trial and error, through the evaluation of the area under the lethal rate curve.

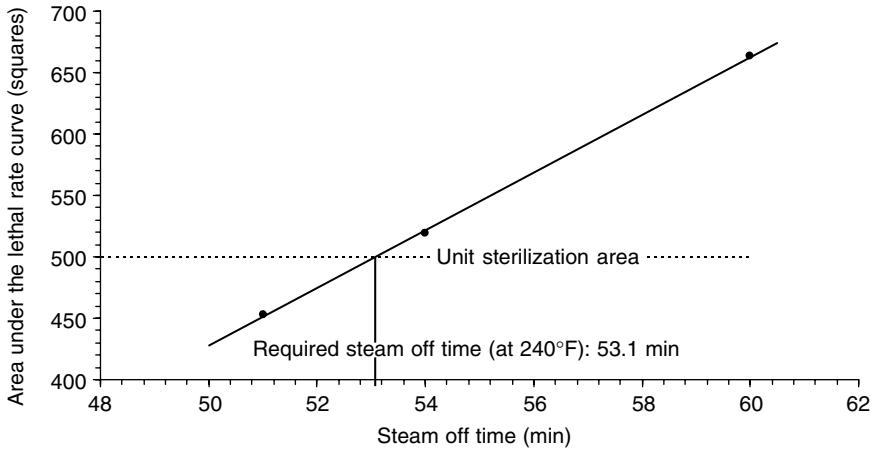

FIGURE 109.3 Graphical interpolation between trials for steam-off time determination.

and for our example,

$$\text{USA} = \frac{1}{\frac{1\,\text{min}}{\text{dx}}} \cdot \frac{1}{\frac{0.010\,\text{min}^{-1}}{5\,\text{dy}}} \Rightarrow \mathbf{USA = 500\,dx\,dy} \tag{109.31}$$

A surface with area equal to USA (*i.e.*, of 500 dx dy squares) is pictured in Figure 109.2 corresponding to a total processing time of 20 min at a temperature resulting to a lethal rate (1/TDT) value of 0.050 min^{-1} (one can calculate from Equation (109.27) that temperature to be equal to 240.59°F).

Thus, so far we calculated the lethality of the original process (data from Table 109.1, steam-off time at 60 min). Proceeding with our goal in finding the steam-off time that gives the unit lethality, we will assume (following a trial and error procedure) a steam-off time of 54 min (based on the early calculations, it should be less than 60 min). We do not know what the product temperature profile will be when the steam will be turned off at 54 min (the only data we have are the ones for 60 min steam-off time), but we will assume, as the General Method dictates, that the new lethal rate curve will follow the shape of the initial lethal rate curve after steam-off time. Such a curve is presented in Figure 109.2. The area under the new curve can be estimated as being equal to 518.8 small (dxdy) squares. This slightly exceeds our target value of 500 dxdy squares.

Repeating the procedure for a new steam-off time of 51 min we find an area under the new lethal rate curve of 453.1 dx dy squares. By interpolation between the three values calculated so far, we obtain the steam-off time corresponding to the Unit Sterilization Area of 500 squares, that is (Figure 109.3), 53.1 min.

The problem we solved, as stated, was in its simplest form. Going to different processing conditions, including, for example, changes in retort temperature, calculations by the General Method become more elaborated. To account for variations in retort and initial temperatures beyond the experimentally obtained values, the use of the dimensionless temperature differences, in the form of $(T_{RT} - T)/(T_{RT} - T_{IT})$, as a function of time only, based on pure conduction or ideal, perfect mixing, models (and for constant T_{RT} and uniform T_{IT}), was suggested [26]. Based on the analytical solution to the heat conduction equation, a procedure to further convert heat penetration data from one can size to another, during the heating cycle only, for conduction heating products, was also suggested [33]. Recently, Simpson *et al.* [34] extended the idea of dimensionless temperature ratios to include linear changing retort temperature profiles, and expanded the applicability of General Method to alternative processing conditions, different than those used in collecting the experimental heat penetration data.

Ending the presentation on General Method, we should mention that the graphical approach followed here was basically chosen for illustration purposes in an attempt to underline some of the basic principles involved. In the reality, the calculations shown here can be done (and were done) in a computer environment following the General Method principles. In the past, area estimations required by the method were done by counting squares, approximating the area with regular geometrical figures of known areas, use of planimeters, weight comparisons (with known areas), etc. This made the method laborious and difficult to use. Formula methods originated, at least in part, in an attempt to make calculations simpler.

B. Ball's Formula Method

Ball, in 1923 [35], introduced a new method for thermal process calculations, named Formula Method from the approach that he used in attacking the problem. He used an equation, a formula, to describe the temperature as a function of time at the critical point of a can, and then he substituted the equation into Equation (109.22) (or better into Equation (109.23)) and performed the integration.

Ball [35] introduced, basically, two empirical parameters, the f and j values, to describe the time-temperature curves of any product during thermal processing. Ball's basic assumption (and simplification) was that any heating or cooling curve when appropriately plotted (as shown in Figure 109.4 and Figure 109.5, respectively) after an initial lag was asymptote to one (*straight-line curve*) or more (*broken-line curve*) straight lines. Therefore, after that initial lag, the curve could be approximated by its asymptote. So, for a straight-line heating curve, the following equation has been suggested:

$$T = T_{RT} - j_h(T_{RT} - T_{IT})10^{-t_h/f_h} \qquad (109.32)$$

Both the f_h and j_h values can be determined from the "heating curve," an "inverted," semi-logarithmic plot of the difference between retort and product temperature (at the critical point) *vs* time, as illustrated in Figure 109.4 (for the data presented in Table 109.1). The j_h value, a dimensionless correction factor, is defined as

$$j_h = \frac{T_{RT} - T_A}{T_{RT} - T_{IT}} \qquad (109.33)$$

for T_A being an extrapolated pseudo-initial product temperature at the beginning of heating defined as the intercept, with the temperature axis at time zero, of the straight line that describes the late, straight, portion of the experimental heating curve plotted as shown in Figure 109.4.

The f_h value is related to the slope of the heating curve. It is defined as time required for the difference between the medium and the product temperature to change by a factor of 10, that is, in relation to Figure 109.4, as the time needed for the straight line heating curve to traverse through a logarithmic cycle.

With these definitions, it becomes clear that Equation (109.32) is the "Exponential Equation" curve shown in Figure 109.4, that is, the straight line that fits the portion of the experimental data after an initial lag period. Although Equation (109.32) approximates the experimental heating curve only after some initial time lag, Ball used this equation for the entire heating curve, reasoning that the thermal destruction taking place at the beginning of a thermal process is negligible since, under common commercial practices, the temperature of the product has not yet reached the lethal temperature range.

Nevertheless, during the initial cooling phase, the product experiences lethal temperatures, and an accurate description of the product temperature during this stage is necessary. Thus, Ball used a hyperbola (Equation (109.34)) to describe the initial part of the cooling phase for $0 \leq t_c \leq f_c \log(j_c/0.657)$,

$$T = T_g + 0.3(T_g - T_{CW}) \left[1 - \sqrt{1 + \left(\frac{1}{0.5275\log(j_c/0.657)}\right)^2 \left(\frac{t_c}{f_c}\right)^2}\right] \qquad (109.34)$$

and another, exponential equation — as for the heating cycle — for the final, the "straight-line," portion of the cooling curve, *i.e.*, for $f_c\log(j_c/0.657) \leq t_c$,

$$T = T_{CW} + j_c(T_g - T_{CW})10^{-t_c/f_c} \qquad (109.35)$$

Note that cooling time t_c counts from the beginning of the cooling cycle ($t_c = 0$ at steam-off) and the f_c and j_c parameters are determined from the cooling curve

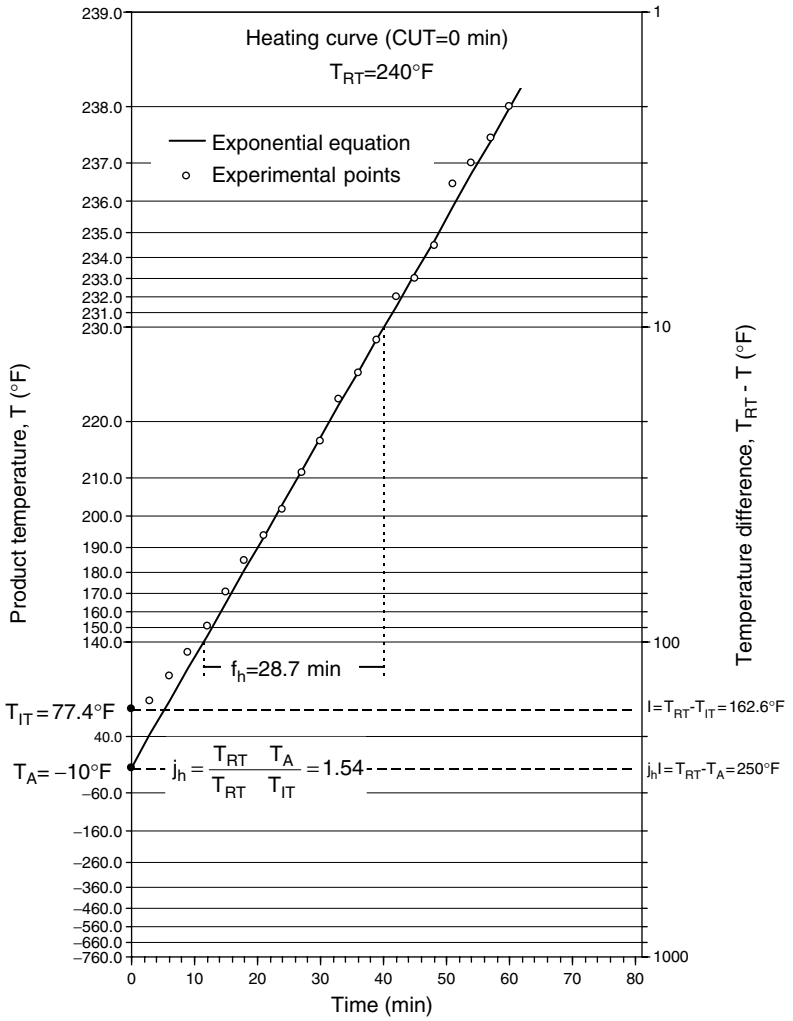

FIGURE 109.4 Experimental *straight-line* heating curve (CUT = 0 min).

(Figure 109.5) in the same way as the f_h and j_h values are determined from the Heating Curve. In particular, j_c is defined as:

$$j_c = \frac{T_B - T_{CW}}{T_h - T_{CW}} \tag{109.36}$$

Before substituting Equations (109.32), (109.34) and (109.35) into Equation (109.23) and proceeding in obtaining a relationship between F and t_g, Ball, based on experimental observations and conservative assumptions, fixed the j_c value at 1.41 and he further considered $f_c = f_h$. After this, Ball proceeded with the substitution into Equation (109.23) and thereafter he solved Equation (109.25) (seeking unity lethality) for the lethality given by Equation (109.24). He ended up with an equation [36] that could not be integrated analytically. So, he graphically evaluated the resulting integrals and he presented the results of the integration in tabular or graphical forms. This step involved some additional (usually minor) assumptions (*e.g.*, that there is no microbial destruction after product center temperature falls 80°F below heating medium temperature).

Ball's final results correlated, graphically, the f_h/U values *vs* log(g) having only the z and the m + g values as parameters. The parameter U is the F value at retort temperature, T_{RT}, that is,

$$U = F^z_{T_{ref}} F_i \tag{109.37}$$

for

$$F_i = 10^{\frac{T_{ref} - T_{RT}}{z}} \tag{109.38}$$

U was used as the depended variable (instead of the $F_{T_{ref}}$ value). The parameter "g" is the difference between retort and product temperature (at the critical point) at steam-off time and was used as the independent variable. Steam-off time, B (in Ball's notation), was related to g

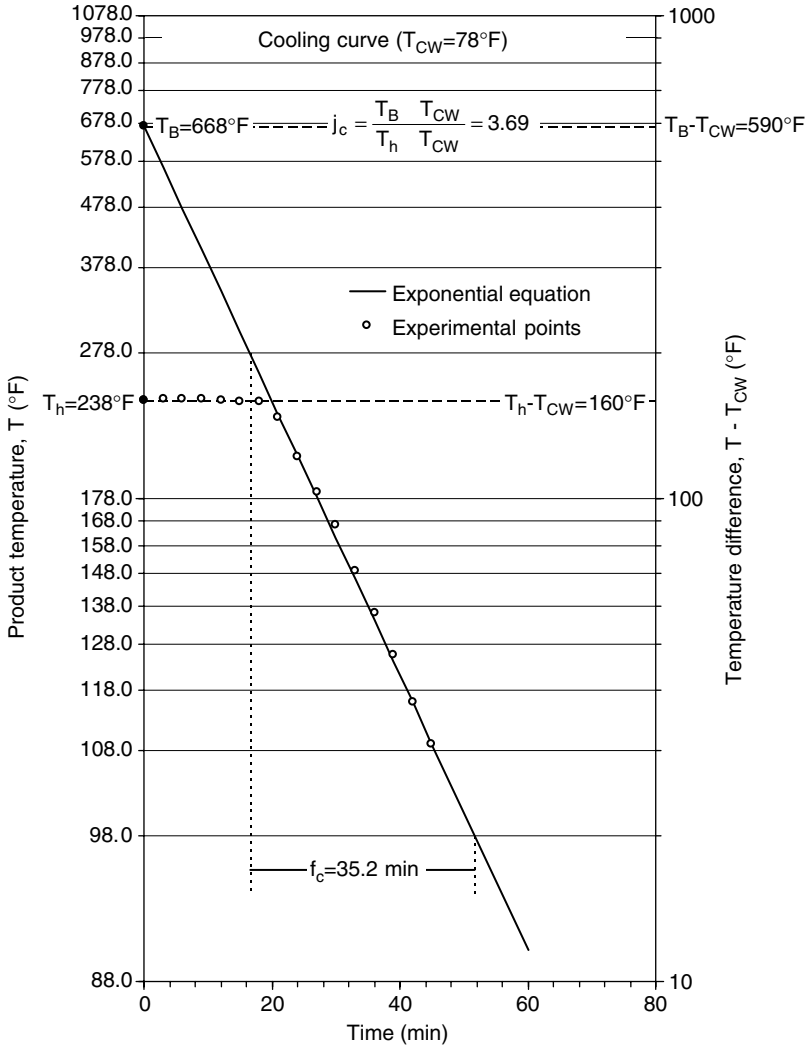

FIGURE 109.5 Experimental cooling curve.

through the following *formula* (originated from Equation (109.32)):

$$B = f_h(\log(j_h I) - \log(g)) \tag{109.39}$$

for

$$I = T_{RT} - T_{IT} \tag{109.40}$$

The parameter "m" was defined as the difference between product temperature at steam-off and retort temperature during cooling, resulting in the following expression for m + g:

$$m + g = T_{RT} - T_{CW} \tag{109.41}$$

In expanding the range of applicability of his Formula Method, Ball further addressed some issues concerning thermal process calculations. By providing additional tables (and working equations) he allowed calculations for *broken-line* (heating) curves, that is, heating curves that could not be adequately described by a single straight line but needed a set of straight lines (for practical purposes two lines), each one with different slope, to be described. In the same context, corrections for the case where $f_c \neq f_h$ were suggested. Finally, Ball accounted for the contribution of the time period needed for the retort to achieve the constant operating temperature during the heating phase, the coming-up time (CUT). For this, based on experimental observations, he concluded that a process at constant retort temperature of duration equal to 42% of the CUT was equivalent to the process at the variable retort temperature profile during the CUT. So he suggested to correct the heating time, by shifting the zero heating time axis by 0.58 · CUT and apply his method, as for a process with CUT = 0, based on this *corrected "zero" axis*.

In brief, the use of Ball's method for determining the F value of a given process involves the following steps:

1. Determination of the f_h and j_h values from the experimental heating curve
2. Calculation of log(g) from Equation (109.39) and the experimental steam-off time, B
3. Finding the f_h/U value, for the log(g) value calculated in step 2, from Ball's graphs [7, 8, 35, etc.]
4. Calculation of F value (from the f_h/U value found in step 3) through the following equation (originated from Equation (109.37) (the definition of U):

$$F^{z}_{T_{ref}} = \frac{f_h}{(f_h/U)F_i} \qquad (109.42)$$

The second type of problem, that is, estimation of the required processing (steam-off) time in order to achieve a particular $F_{required}$ value follows the same steps (in reverse order) and will be illustrated for the problem solved earlier with the General Method, that is, for the data given in Table 109.1.

1. Ball's Formula Method in Calculating Process Time for the Example Data of Table 109.1

Since the data refer to a process at a still retort with 10 min of come up time, the heating curve is replotted on Figure 109.6 to illustrate the correction for the zero time that must be made. From Figure 109.6 we can estimate the heat penetration parameters f_h and j_h as: $f_h = 28.7$ min and $j_h = 0.96$.

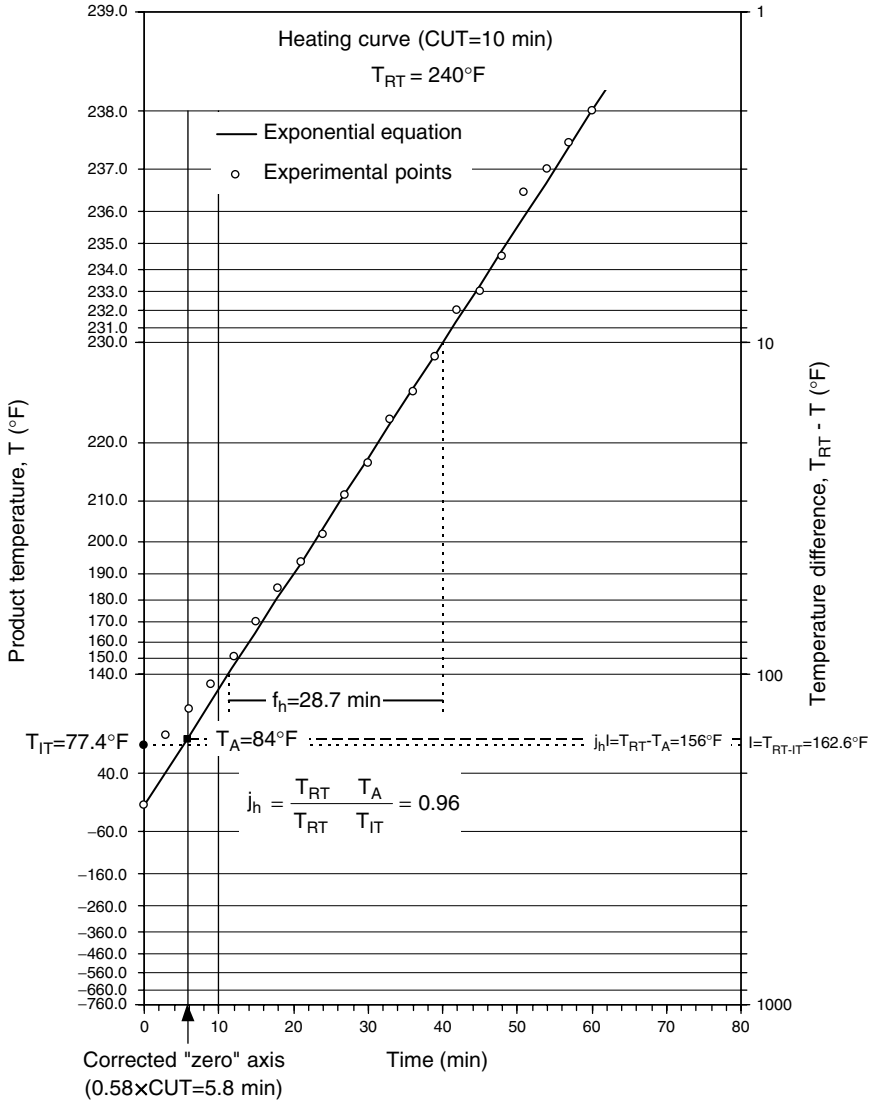

FIGURE 109.6 Experimental *straight-line* heating curve (CUT = 10 min).

For

$$F_i = 10^{\frac{T_{ref}-T_{RT}}{z}} \Rightarrow F_i = 10^{\frac{250-240}{18}} \Rightarrow F_i = 3.5938$$

and Equation (109.37) for U, the value of the parameter f_h/U becomes:

$$f_h/U = \frac{f_h}{F^z_{T_{ref}} \cdot F_i} \Rightarrow f_h/U = \frac{28.7}{6 \cdot 3.5938}$$

$$\Rightarrow f_h/U = 1.33$$

From the f_h/U *vs* log(g) diagrams [8], and specifically for $m + g = 160°F$ (the exact value being: $m + g = T_{RT} - T_{CW}$, *i.e.,* $m + g = 240 - 78 = 162°F$), $z = 18°F$ and for $f_h/U = 1.33$, we find the value of the log(g) equal to: $\log(g) = 0.0$. Hence, for $I = T_{RT} - T_{IT}$ (Equation (109.40)), that is, $I = 240 - 77.4 \Rightarrow I = 162.6°F$ from Equation (109.39), we have: $B = 28.7 \cdot (\log(0.96 \cdot 162.6) - 0.0) \Rightarrow B = 62.95$ min.

Therefore, the time from steam-on to steam-off, t_g, is

$$t_g = B + 0.58 \cdot CUT = 62.95 + 0.58 \cdot 10$$
$$\Rightarrow \mathbf{t_g = 68.8\,min}$$

Comparing this time with the corresponding time found using the General Method, *i.e.*, the 53.1 min found earlier, we conclude that in this particular example, Ball's method overestimates processing time (assuming the General Method's answer as the basis) by about 30%. This must be mainly due to the value of j_c. Ball fixed that value to 1.41. However, for our data (Figure 109.5) this value was equal to 3.69. Ball's assumption about a smaller j_c value means faster cooling than the actual, thus Ball's Formula Method has to allow for longer heating time. The extensive lag period during the cooling cycle observed for the experimental data used can be due to the retort cool down period, that is the time needed for the retort to reach, after steam-off, the cooling temperature (T_{CW}). This is not taken into consideration by any of the thermal process calculation procedures (it can be viewed though as an additional safety factor).

The importance of the j_c value was recognised by Stumbo and his co-workers who in a series of publications [37–39] developed and published [9] a new set of tables for thermal process calculations. The procedure in calculating lethality or process time, through this new set of tables, was identical as for Ball's original formula method. Nevertheless, Stumbo included j_c as a parameter (ranged in his tables from 0.40 to 2.00) and he presented values for a broader range as far as the z value is concerned. In Ball's graphs the z value lied between 10°F and 24°F, while Stumbo employed z values from 8°F to 200°F. While z values in the range of Ball's graphs are sufficient for microbial inactivation, higher z values characterize quality degradation. Aiming in quality retention calculations Stumbo developed a procedure for integrated F values calculations. Although further discussion on this matter is beyond the scope of this chapter, we must notice that quality retention calculations based on mass average values constitute the basis for process optimization.

Several researchers, following Ball's example, used the empirical heat penetration parameters f and j in different formulas to describe the temperature inside the product during thermal processing [40–46]. Although empirical in nature, the use of these parameters resulted in simple, flexible, and of wide applicability, independently of the mode of heat transfer involved, methodologies for thermal process evaluation and design. Theoretical values of these parameters for conduction heating foods under various conditions, as well as for perfectly mixed, forced convection heating foods were presented [7, 47–49]. Factors, used to convert f values from one can size to another (for metal cans) or between different types of containers (*e.g.,* between glass jars and metal cans) for pure conduction or perfectly mixed heating products, have been also reported [35, 50, 51]. So, it is possible, to use Ball's Formula Method to design processes for conditions different from those used in obtaining the experimental data (for example, for different retort temperatures and can sizes).

IV. CONCLUDING REMARKS

This chapter focused on the basic principles involved in establishing the necessary time–temperature combination for an appropriate thermal process. Two of the basic mathematical procedures used for thermal process calculations, namely the General Method and Ball's Formula Method were presented in sufficient detail. Both methods have contributed to the success of the canning industry. Representative example calculations, with the above methods, for establishing the necessary processing time for commercial sterilization were given.

It should be noted that in our entire example calculations temperatures were in degrees Fahrenheit and time units in minutes. This is because literature in thermal process calculations, including working graphs and tables, is traditionally and invariably using these particular units.

The analysis in this chapter referred to "in container" processing. However, the principles presented are of general applicability. Caution, though, must be taken with regards to the assumptions involved in the development of each method. Specific critical factors associated with particular processes must be considered. For example, residence time distribution during aseptic processing could make calculations rather complex and should be properly addressed.

V. NOMENCLATURE

A. Latin Letters

B steam-off time (measured from *corrected zero*), s (unless otherwise explicitly stated)

C concentration of a heat labile substance, number of microorganisms/ml, spores per container, g/ml, or any other appropriate unit

CUT duration of retort come-up time, s (unless otherwise explicitly stated)

D_T (noted also as D) *decimal reduction time* or *death rate constant*—time at a constant temperature required to reduce by 90% the initial spore load (or, in general, time required for 90% reduction of a heat labile substance), s (unless otherwise explicitly stated)

dx the unit length of the x axis scale of a lethal rate curve

dy the unit length of the y axis scale of a lethal rate curve

E_a activation energy, J/mol

F_T^Z (or simply F) time at a constant temperature, T, required to destroy a given percentage of microorganisms whose thermal resistance is characterized by z, *or*, the equivalent processing time of a hypothetical thermal process at a constant temperature that produces the same effect (in terms of spore destruction) as the actual thermal process, s (unless otherwise explicitly stated)

F_c critical point F value

F_i factor defined by Equation (109.38), which when multiplied by $F_{T_{ref}}$ gives the F value at the retort temperature, dimensionless

F_o a reference F value for $T_{ref} = 250°F$ and $z = 18°F$

F_s integrated F value

$f(C_a, C_b)$ function of initial and final concentrations and the destruction kinetics, variable units

f time required for the difference between the medium and the product temperature to change by a factor of 10, s (unless otherwise explicitly stated)

g difference between retort and product temperature (at the critical point) at steam-off time, °C (unless otherwise explicitly stated)

I difference between retort and initial product temperature, °C (unless otherwise explicitly stated)

j a correction factor defined by Equations (109.33) and (109.36) for the heating and cooling curve, respectively, based on the intercept, with the temperature axis at time zero, of the straight line that describes the late, straight, portion of the experimental heating or cooling curve plotted in a semi-logarithmic temperature difference scale as shown in Figures 109.4 and 109.5, respectively, dimensionless

k_T reaction rate constant, s^{-1} for first order reactions

lethality ratio of $F_{process}$ over $F_{required}$, dimensionless

m difference between product temperature at steam-off and retort temperature during cooling, °C (unless otherwise explicitly stated)

N spore load, number of spores

n apparent reaction order, dimensionless

R_g universal gas constant, 8.314 J/(mol · K)

T (product) temperature, °C (unless otherwise explicitly stated)

T_A extrapolated pseudo-initial product temperature at the beginning of heating defined as the intercept, with the temperature axis at time zero, of the straight line that describes the late, straight, portion of the experimental heating curve plotted as shown in Figure 109.4, °C (unless otherwise explicitly stated)

T_B extrapolated pseudo-initial product temperature at the beginning of cooling defined as the intercept, with the temperature axis at zero cooling time, of the straight line that describes the late, straight, portion of the experimental cooling curve plotted as shown in Figure 109.5, °C (unless otherwise explicitly stated)

T_h product temperature at the beginning of the cooling cycle, °C (unless otherwise explicitly stated)

t time, s (unless otherwise explicitly stated)

TDT (thermal death time) time at a constant temperature, T, required to destroy a given percentage of microorganisms, s (unless otherwise explicitly stated)

U the F value at T_{RT}, defined by Equation (109.37)

USA (Unit Sterilization Area) area under the lethal rate curve that corresponds to lethality of unity, units of area, depending on the graph scales

z temperature difference required to achieve a decimal change of the D_T value, °C (unless otherwise explicitly stated)

B. Subscripts

1, 2 refers to a particular condition

a initial condition

b final condition

CW (water) cooling medium

c cooling phase

g condition at steam-off time

h heating phase

IT initial condition (for product temperature only)

process referring to process values

RT (retort) heating medium

ref reference value

required referring to required values

110 Modeling of Thermal Processing of Foods

Sean X. Liu
Department of Food Science, Rutgers University

CONTENTS

I. INTRODUCTION

Thermal treatments of foods can be dated back to prehistoric times when cavemen accidentally discovered the wonder of fire (and heat): the sensory quality of roasted animal carcasses was superior to the raw meats, and later the healthful effect of cooked foods was also appreciated. Frenchman Nicholas Appert, is credited as the one who started the canning industry even though he did not understand why canning techniques he invented prevented food spoilage. It took the genius of Louis Pasteur, a half century later, to discover the relationship between thermal processing techniques on a scientific basis. Thermal processes in modern-day food industry are more or less designed to destroy undesirable microorganisms and enzymes that are either harmful to human health or destructive to food quality during storage. Thermal processing of foods in food industry is generally referred to heating of foods packaged in hermetically sealed containers and pasteurization of liquid foods (may contain some particulates). It is carried out either continuously or batchwise in a consecutive process of heating, holding and cooling. Eating quality (which includes sensory quality) of foods is not always improved through thermal processing. Loss of flavors and nutrients, and changes of textures and colors are recognized as the commonest complaints about thermally processed foods. As a result of this recognition, new thermal processes such as high-heat-short-time (HTST) and ultrahigh-temperature (UHT) have been implemented in thermal processing of some foods, and non-thermal processes (electrical pulse field, high-pressure, ultraviolet light, and ultrasound) have also been developed and tested for certain foods for possible replacement of conventional heat processing (1). Aseptic processing and packaging further reduce heat damage to processed foods.

Thermal processes are generally not designed to sterilize foods completely (or bacteriologically). Rather, they are constructed on the objective of destroying microbial pathogens, parasites and deleterious enzymes present in foods, and of minimizing damage of heat on nutritional and sensory profiles in foods by optimizing temperature and heating time based on models of thermal processing. Even in the heat treatment of canned foods, the objective of the sterilization process is to produce a condition of "commercial sterilization" in canned foods. Some thermophilic or heat-loving microorganism spores could survive the thermal treatment of a retort process, but these microorganisms are not pathogenic or poisonous and therefore of no significance regarding public health (2).

In order to determine the extent of thermal processing for a particular food matrix in a particular environment, several fundamental questions have to be answered:

1. The type of microbial flora associated with all raw materials that are to be treated.
2. The pH value of the food.
3. The reaction kinetics that are related to microbial inactivation, enzyme inactivation, chemical change, and physical change subject to heat treatment.
4. The heating temperature and time combination required to inactivate the most heat resistant pathogens and spoilage microorganisms in a particular food.
5. Heat-penetration characteristics in a particular food including the packaging materials.
6. The thermal, surface, and physical properties of the food and the container (for packaged foods in hermetically sealed containers).
7. Heat transfers that produce the optimal conditions (based on thermal death curves and a sufficient margin of safety) that are required by (4) and (5).

The rate at which microorganisms are killed at high temperature is, of course, a very important study critical to thermal processing of foods. Different microorganisms have inherently different resistances to temperature, in that vegetative cells and yeast are generally susceptible while endospores are much more resistant, with virus between these two extremes. The medium that surrounds the microorganisms also has an extremely large influence, especially pH, water activity, concentration, and type of food components (3). The importance of pH is its link to the death of vegetative cells or the ability of spores to germinate and grow. The pH classification is of importance to the canning industry since *Clostridium botulinum*, a highly heat resistant and deadly bacterium, will not grow in foods at pH 4.6 or below. The pH 4.6 is the demarcation line between low-acid foods and acid foods (2).

The type of food to be thermally treated will have associated microorganisms with a high thermal resistance. These microorganisms must be inactivated to ensure the safety of consumers. For example, in canning operations, it is *Clostridium botulinum* that should be targeted to eliminate to the extent that it will not pose a health threat to consumers. Often, the other microorganisms that co-exist with the targeted microorganism are also destroyed, along with deleterious enzymes in the food. In pasteurization of liquid foods or solid-liquid mixtures, the thermal treatment is mild and does not destroy the entire populations of the targeted microorganisms due to the concern with sensory quality of the processed food. It is imperative that pasteurized foods must be refrigerated after thermal processing and preserved with packaging or/and chemical preservatives.

The death of microorganisms at constant elevated temperature follows a first-order reaction kinetic, i.e.,

$$\frac{dN}{dt} = -kN \tag{110.1}$$

which can be integrated to give

$$\mathrm{N/N_0} = 10^{-\mathrm{t/D}} \tag{110.2}$$

Where D is the decimal reduction time, which is defined as the time necessary for a 90% reduction in the microbial population. N_0 is the initial microbial population and k is the rate constant.

Bigelow (4) showed a linear relationship between the logarithm of the decimal reduction time (also called D-value) for spores and their temperatures. Mathematically, Bigelow's model can be expressed as

$$\frac{D_1}{D_2} = 10^{(T_2-T_1)/z} \tag{110.3}$$

where z is a constant over the temperature range for a particular microorganism. This so-called z-value is defined as the increase in temperature necessary to cause a 90% reduction in the decimal reduction time D. Another model, with similar fashion, defines a Q_{10} value as the ratio of decimal reduction time values at a temperature interval of 10°C, i.e.,

$$Q_{10} = \frac{D_T}{D_{T+10}} = 10^{10/z} \tag{110.4}$$

The most commonly used criterion for commercial sterilization is the F value (5). It is defined as

$$\mathrm{F} = \int_0^\infty \mathrm{L}\ \mathrm{dt} = \int_0^\infty 10^{(\mathrm{T}-\mathrm{T_{ref}})/z}\ \mathrm{dt} \tag{110.5}$$

where L is the lethality and T_{ref} is a reference temperature. The reference temperature should always be close to the range of temperatures normally used in that process (3). For commercial thermal processes, the determined F value is always larger than F_0 (reference thermal death time, defined as the time for a given reduction in population of a microbial spore with a z value of 10°C at 121°C).

Once the information with respect to thermal resistance characteristics of the test microorganism (z and F_0) is known, the temperature history of the product going through the process should be obtained before the thermal processing schedule is formulated. This leads to the development of a heat penetration curve. For detailed information regarding heat penetration curves of packaged

foods and F-values related to processing packaged foods, the reader is referred to the chapter titled, "Thermal Processing of Packaged Foods" by Chung, Papadakis and Yam in this handbook.

II. STEADY STATE HEAT CONDUCTION: FOURIER'S FIRST LAW

Thermal processing involves heat transfer between heating sources and foods. Heat transfer is the movement of thermal energy from one point to another driven by a difference in temperature. When heat transfers between adjacent materials due to temperature difference, the heat transfer mode in this case is called heat conduction. Fourier's law of heat conduction prescribes the mechanism of heat conduction. Fourier's first law of heat conduction can be loosely interpreted as follows, the rate of heat flow between point A of temperature T_1 and point B of temperature T_2 under *steady state conditions* over a distance of y is proportional to the area perpendicular to heat flow, and $(T_1 - T_2)$. The constant of proportionality is termed thermal conductivity of the medium between points A and B, k. It can be mathematically expressed as

$$Q = k\,A\,\frac{T_1 - T_2}{y} \quad \text{or} \quad q = \frac{Q}{A} = -k\frac{\Delta T}{y} \tag{110.6}$$

where q is the heat flux (unit: kJ/m^2 s). However, strictly speaking, a one-dimensional form of Fourier's first law of heat conduction should be

$$q = -k\frac{dT}{dy} \tag{110.7}$$

This equation often serves as the definition of k (6). If the temperature varies in all directions, Fourier's first law of heat conduction in a Cartesian coordinate system would be expressed as

$$q_y = -k_y\frac{\partial T}{\partial y}, \quad q_x = -k_x\frac{\partial T}{\partial x}, \quad q_z = -k_z\frac{\partial T}{\partial z} \tag{110.8}$$

In an isotropic media of heat transport, $k_x = k_y = k_z = k$. For a cylindrical coordinate system (r, θ, z), Fourier's first law of heat conduction may be expressed as

$$q_z = -k\,\frac{\partial T}{\partial z}, q_r = -k\frac{\partial T}{\partial r}, q_z = -k\frac{1}{r}\frac{\partial T}{\partial \theta} \tag{110.9}$$

While in a spherical coordinates (r, θ, φ), the equations would look like

$$q_\phi = -k\frac{1}{r\sin\theta}\,\frac{\partial T}{\partial \phi}, \quad q_r = -k\frac{\partial T}{\partial r}, \quad q_z = -k\frac{1}{r}\frac{\partial T}{\partial \theta} \tag{110.10}$$

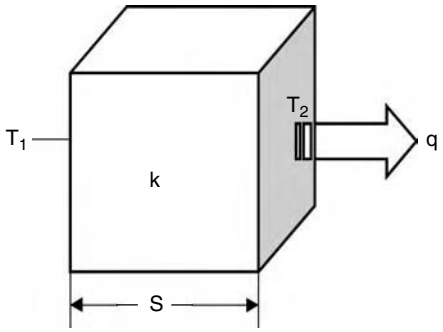

FIGURE 110.1 Schematic diagram of conductive heat transfer in a rectangular slab under steady state conditions.

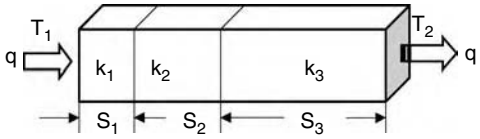

FIGURE 110.2 Schematic diagram of conductive heat transfer in a multilayered rectangular composite slab under steady state conditions.

The heat conduction across a slab under steady state conditions in a Cartesian coordinate system is expressed as (see Figure 110.1)

$$q = k\frac{T_1 - T_2}{S} \tag{110.11}$$

where S is the distance in the direction of heat conduction. The term, k/y, in Equation (110.6) is actually a heat transfer coefficient for heat conduction; the temperature difference $(T_1 - T_2)$ is the driving force. Analogous to an electrical circuit or mass transfer from the bulk of one phase across the interface into the other phase, the reciprocal of the heat transfer coefficient would be the heat conduction resistance. For the case of steady-state conductive heat transfer through a composite system made of several materials of different thermal conductivities and thickness as shown in Figure 110.2, the following resistance-in-series relationship should hold:

$$\frac{S}{k} = \frac{S_1}{k_1} + \frac{S_2}{k_2} + \frac{S_3}{k_3} + \cdots + \frac{S_n}{k_n} \tag{110.12}$$

or

$$R = R_1 + R_2 + R_3 + \cdots + R_n \tag{110.13}$$

where R signifies "resistance." The heat flux through a multiply-layer system (e.g., packaged food or composite wall of a cold room) may be expressed as

$$q = (T_1 - T_2)/R \tag{110.14}$$

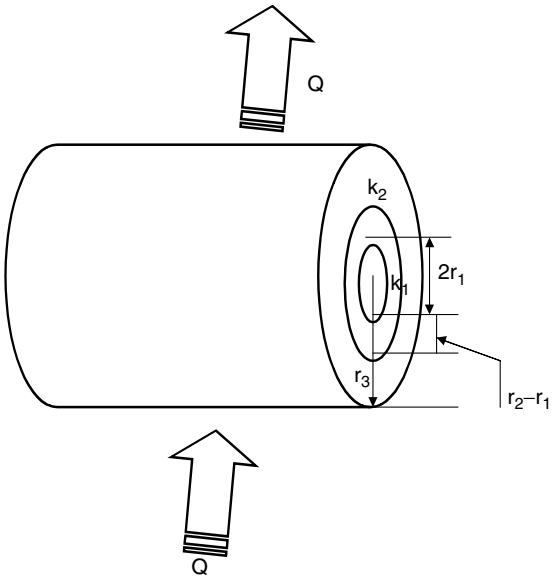

FIGURE 110.3 Schematic diagram of conductive heat transfer in a multilayered composite cylindrical object under steady state conditions.

For composite cylindrical tubes (Figure 110.3) made of multiple layers of different materials, the conductive heat transfer rate (not flux) in the radial direction under steady state conditions can be expressed as

$$Q = (T_1 - T_2)/R \tag{110.15}$$

Where

$$R = R_1 + R_2 + R_3 + \cdots + R_n = \frac{\ln(r_2/r_1)}{2\pi L k_1} + \frac{\ln(r_3/r_2)}{2\pi L k_2} + \frac{\ln(r_4/r_3)}{2\pi L k_3} + \cdots + \frac{\ln(r_{n+1}/r_n)}{2\pi L k_n} \tag{110.16}$$

Heat conduction in a multilayered sphere with spherical hollow core (Figure 110.4) can be written as

$$Q = (T_1 - T_2)/R \tag{110.17}$$

Where

$$R = R_1 + R_2 + R_3 + \cdots + R_n = \frac{r_2 - r_1}{4\pi k r_1 r_2} + \frac{r_3 - r_2}{4\pi k r_3 r_2} + \frac{r_4 - r_3}{4\pi k r_3 r_4} + \cdots + \frac{r_{n+1} - r_n}{4\pi k r_n r_{n+1}} \tag{110.18}$$

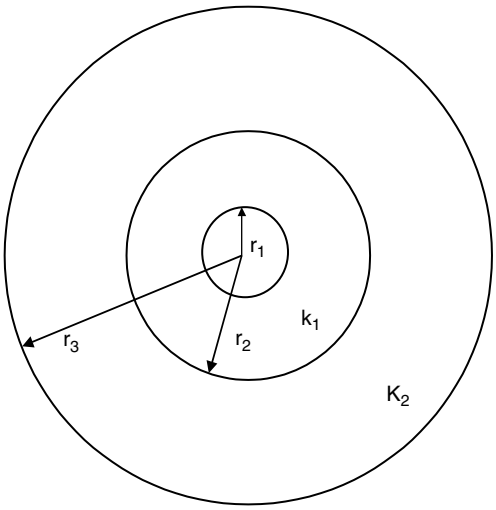

FIGURE 110.4 Schematic diagram of conductive heat transfer in a multilayered composite sphere under steady state conditions.

The values of heat conductivities commonly encountered vary considerably in magnitude. For example, thermal conductivities of metals range from 50 to 400 W/(m°C); alloys 10–120 W/(m°C); water 0.597 W/(m°C) at 20°C; air 0.0251 W/(m°C) at 20°C; insulating materials 0.035–0.173 W/(m°C) (Singh and Heldman, 2001). Many high-moisture food products have thermal conductivities close to that of water and the thermal conductivity values of dried, porous foods are highly affected by the presence of air with its low value (similar to the case of insulating materials). Several publications (7–9) provide tabulated thermal conductivity values of a number of common foods. Alternatively, empirical correlations of thermal conductivities may also be used to estimate the values in heat transfer process calculations where temperature is not constant and/or the values of the temperature entry cannot be found in the tables. Sweat (10) proposed a predictive equation of thermal conductivity for fruits and vegetables (little or no proteins) with moisture content exceeding 60%:

$$k = 0.148 + 0.493X_w \tag{110.19}$$

where X_w is water content expressed as a mass fraction. This equation is able to predict thermal conductivity values within ±15% of experimental data. It is not suitable for foods with low density or/and void spaces such as apples since the values of thermal conductivity of these types of foods would be underestimated using the equation. The reader is referred to the published experimental data on these foods (7–9). Sweat (11) also proposed a predictive equation for meats and fishes

TABLE 110.1
Coefficients of k_i and ρ_i in Equation (110.22) (Ref. 13)

Thermal Conductivity (W/m K)	Density (kg/m^3)
$k_w = 0.57109 + 0.0017625T - 6.7306 \times 10^{-6} T^2$	$\rho_w = 997.18 + 0.0031439T - 0.0037574T^2$
$k_{ic} = 2.2196 - 0.0062489T + 1.0154 \times 10^{-4} T^2$	$\rho_{ic} = 916.89 - 0.13071T$
$k_p = 0.1788 + 0.0011958T - 2.7178 \times 10^{-6} T^2$	$\rho_p = 1329.9 - 0.51814T$
$k_f = 0.1807 - 0.0027604T - 1.7749 \times 10^{-7} T^2$	$\rho_f = 925.59 - 0.41757T$
$k_c = 0.2014 + 0.0013874T - 4.3312 \times 10^{-6} T^2$	$\rho_c = 1599.1 - 0.31046T$
$k_{fi} = 0.18331 + 0.0012497T - 3.1683 \times 10^{-6} T^2$	$\rho_{fi} = 1311.5 - 0.36589T$
$k_a = 0.3296 + 0.001401T - 2.9069 \times 10^{-6} T^2$	$\rho_a = 2423.8 - 0.28063T$

(no carbohydrates) with moisture content ranging from 60–80% between 0–60°C:

$$k = 0.08 + 0.52X_w \tag{110.20}$$

Equations (110.19) and (110.20) ignore the factor of composition of food solids in estimating thermal conductivities, thus limiting their usefulness to high moisture content foods where food solids have much lower values of thermal conductivities. The compositions of most foods in food industry are more complex and therefore an empirical equation of predicting thermal conductivities that accounts for food composition is desirable. Sweat (12) developed the following equation for calculating thermal conductivities of foods at 25°C:

$$k = 0.25X_c + 0.155X_p + 0.16X_f + 0.135X_a + 0.58X_w \tag{110.21}$$

where X is the mass fraction and subscripts c, p, f, a, and w stand for carbohydrate, protein, fat, ash, and water, respectively. The coefficients in Equation (110.21) are the values of the thermal conductivities for carbohydrate, protein, fat, ash, and water. The thermal conductivity of pure water at 25°C is actually 0.606 W/(m°C). The value of 0.58 W/(m°C) betrays the fact that not all water in a food matrix is free water. Notice Equation (110.21) does not include a term for contribution from the thermal conductivity of fiber.

The equations proposed by Sweat (10–12) do not address the issue of change in thermal conductivity due to temperature change. Choi and Okos (13) have postulated the following expression for liquid foods based on the food composition and temperature:

$$k = \sum_{i=1}^{n} k_i Y_i \tag{110.22}$$

The volume fraction Y_i of each component is calculated from the mass fraction, X_i, and the individual densities, ρ_i:

$$Y_i = \frac{X_i/\rho_i}{\sum_{i=1}^{n} (X_i/\rho_i)} \tag{110.23}$$

TABLE 110.2
Temperature Functions of c_{pi} in Equation (110.28) (Ref. 13)

Major Components	Temperature Functions (kJ/kg °C)
Fat	$c_p = 1.9842 + 1.4733 \times 10^{-3}T - 4.8008 \times 10^{-6}T^2$
Carbohydrate	$c_p = 1.5488 + 1.9625 \times 10^{-3}T - 5.9399 \times 10^{-6}T^2$
Fiber	$c_p = 1.8459 + 1.8306 \times 10^{-3}T - 4.6509 \times 10^{-6}T^2$
Ash	$c_p = 1.0926 + 1.8896 \times 10^{-3}T - 3.6817 \times 10^{-6}T^2$
Protein	$c_p = 2.0082 + 1.2089 \times 10^{-3}T - 1.3129 \times 10^{-6}T^2$

where X_i is the mass fraction and ρ_i is the density of *i*th component.

The thermal conductivities in W/(m °C) and individual densities in kg/m^3 of water, ice, protein, fat, carbohydrate, fiber, and ash are computed as functions of temperature in °C and with first letter of each component name as subscript, shown in Tables 110.1 and 110.2.

While thermal conductivity, the rate of heat conduction through a unit cross-sectional area when a unit temperature difference is maintained over a unit distance, describes how fast heat can penetrate through foods and packaging materials, it does not directly give out information on thermal energy requirement for heating certain amounts of foods to prescribed temperature levels. For that aspect of thermal calculations and analyses, a thermodynamic property, specific heat, defined as a measure of energy required by a unit mass of food to raise a unit degree temperature without a change in state, is more practical. Specific heat values of foods can be experimentally obtained through several methods (13). They can also be estimated by several correlations. Dickerson (14) developed the following equation for calculating specific heat of high-moisture content foods in which the influence of the food composition and temperature on c_p is not strong is:

$$c_p = 1.675 + 0.025X_w \tag{110.24}$$

where X_w is the water content expressed as water mass fraction. If the food composition has to be taken into

account for calculations of specific heat, the expression from Charm (15) is used in the following form:

$$c_p = 2.093X_f + 1.256X_s + 4.187X_w \qquad (110.25)$$

The X is the mass fraction of each component. The subscripts, f, s, and w, represent fat, non-fat solids, and water respectively. The coefficients of Equation (110.25) are actually the specific heat values for fat, solids, and water at 70°C. Heldman and Singh (16) expanded the approach used by Charm (15) to include specific heat values of more basic components into the following equation:

$$c_p = 1.424X_c + 1.549X_p + 1.675X_f + 0.837X_a + 4.187X_w \qquad (110.26)$$

where new subscripts, c and a, stand for carbohydrate and ash, respectively. Notice the specific heat value for solid fat is 1.675 kJ/kg°C while the specific heat value for liquid fat is 2.093 kJ/kg°C.

Further expanding Equation (110.26) leads to the following expression:

$$c_p = 1.424X_c + 1.549X_p + 1.675X_f + 0.837X_a + 1.9776X_{fi} + 4.187X_w \qquad (110.27)$$

where X_{fi} is the mass fraction of fiber in the food.

If the temperature dependence of specific heat values is needed, the comprehensive mode proposed by Choi and Okos (13) should be used. Their model is expressed as follows:

$$c_p = \sum_{i=1}^{n} c_{pi} X_i \qquad (110.28)$$

where X_i is the mass fraction of the *i*th component, n is total number of components in a food, and c_{pi} is the specific heat of the *i*th component.

III. CONVECTIVE HEAT TRANSFER

Convective heat transfer is the result of bulk fluid movement in which a temperature gradient exists between the solid surface and surrounding fluid. In any convective heat transfer situation, heat conduction between the bulk fluid and the solid does exist simultaneously but the magnitude of heat conduction is far less than that of convective heat transfer. There is no reason to analyze heat conduction in a convective heat transfer situation. Instead, a heat conduction effect that is associated with convective heat transfer is automatically included in the convective heat transfer analysis in the form of part of a lumped heat transfer parameter called heat transfer coefficient.

It is widely believed that convective heat transfer resistance comes from a thermal boundary layer near the solid surface. The thickness of this "film" epitomizes the resistance to heat transfer as is shown in the equation based on Newton's law of cooling (or heating) as follows:

$$q = \frac{k}{\delta}(T_s - T) = h(T_s - T) \qquad (110.29)$$

where δ is the thickness of the boundary layer or film and T_s is the temperature of the surrounding fluid. Since the thickness of the film is not measurable, the use of the heat transfer coefficient is the commonly preferred method. The heat transfer coefficient, h, however, is not a material property. It depends on physical properties of fluid and solid as well as the hydrodynamic situation in the region where heat transfer takes place. In general, boiling liquids and condensing vapors have very high values of h and gases are poor heat transfer fluids. Steams are often the choice of heating media and the presence of air will reduce the effectiveness of heat transfer of steams (17). Although analytical or numerical treatment of continuity equation, equation of motion and energy equation under steady state, constant density conditions to get temperature profile in the thermal boundary layer (as well as velocity profile in the hydrodynamic boundary layer) is theoretically possible, it is generally neither recommended nor needed. Some classic literature provides some case studies of very simple convective heat transfer situations in the boundary layer (6, 19). Most convective heat transfer calculations involving food thermal processing are carried out using an empirical approach that is based on experimental data in the form of dimensionless number correlations.

There are two modes of convective heat transfer depending on the fluid flow characteristics. Natural (or free) convective heat transfer is due to fluid motion caused by difference in density resulting from temperature difference. If the fluid flow is caused by artificial means such as agitation, pumping, or blowing, the convective heat transfer is named as forced convective heat transfer.

A. Dimensionless Quantities

Nusselt number (N_{Nu}) = hd_c/k = ratio of external convective heat transfer to internal heat conduction.

Prandtl number (N_{Pr}) = $\mu c_p/k$ = ratio of kinematic viscosity to thermal diffusivity.

Reynolds number (N_{Re}) = $\rho uD/\mu$ = ratio of inertial force to viscous force, where D is diameter and u is velocity.

Grashof number (N_{Gr}) = $\frac{(d_c^3 \rho^2 g \beta \Delta T)}{\mu^2}$, where d_c is characteristic length, β is the coefficient of volumetric expansion; ΔT is temperature difference between a solid surface and the surrounding fluid.

Graetz number (N_{Gz}) = $0.25\pi[N_{Re}N_{Pr}(d_c/L)] = \frac{\dot{m}c_p}{kL}$.

B. Dimensionless Number Correlations

Equations for calculating heat transfer coefficients usually take the form of

$$N_{Nu} = f\left(N_{\mathrm{Re}}, N_{\mathrm{Pr}}, \left(\frac{L}{d_c}\right), N_{Gr}, \left(\frac{\mu}{\mu_w}\right)\right) \qquad (110.30)$$

The Grashof number is associated with natural convection and (L/d_c) is related to laminar flow. When calculating these dimensionless numbers, the thermophysical properties of fluids at the arithmetic mean temperature at the entrance and the exit are used. The viscosity of the fluid at the wall (μ_w) is included in the equations to account for the heating process since it affects convective heat transfer. The correlations for forced convective heat transfer can be expressed as a general equation:

$$N_{Nu} = \alpha(N_{\mathrm{Re}})^{\beta}(N_{\mathrm{Pr}})^{\gamma}\left[\frac{L}{d_c}\right]^{\delta} \qquad (110.31)$$

where α, β, γ, and δ are constants from correlation analysis of experimental data and d_c is characteristic diameter (19).

For Newtonian fluids in laminar-flow inside circular pipes, the following equation is used:

$$N_{Nu} = 1.86\left(N_{\mathrm{Re}}N_{\mathrm{Pr}}\frac{d}{L}\right)^{1/3}\left(\frac{\mu}{\mu_w}\right)^{0.14} \qquad (110.32)$$

The characteristic diameter, d_c is the inside diameter of the pipe, d. For fluids flowing outside of but parallel to the pipes, substitute d_e for d in the Reynolds number calculation. The equivalent diameter is defined as

$$d_e = 4\left(\frac{\text{flow area}}{\text{heated perimeter}}\right) \qquad (110.33)$$

This equation can also be used to calculate d_c for noncircular ducts.

For Newtonian fluids in turbulent-flow inside circular pipes and $N_{Re} > 10^5$, $0.7 < N_{Pr} < 700$, and $L/d > 60$, the correlation of N_{Nu} (known as Sieder-Tate equation) is

$$N_{Nu} = 0.023(N_{\mathrm{Re}})^{0.8}(N_{\mathrm{Pr}})^{1/3}\left(\frac{\mu}{\mu_w}\right)^{0.14} \qquad (110.34)$$

For Newtonian fluids flowing around a sphere, the following equation is used:

$$N_{Nu} = 2 + 0.60(N_{\mathrm{Re}})^{0.5}(N_{\mathrm{Pr}})^{1/3} \qquad (110.35)$$

This correlation is useful in predicting convective heat transfer to or from droplets or bubbles. Another correlation that has been proven useful is

$$N_{Nu} = 2 + (0.4(N_{\mathrm{Re}})^{0.5} + 0.06N_{\mathrm{Re}}^{2/3})(N_{\mathrm{Pr}})^{0.4}\left(\frac{\mu}{\mu_w}\right)^{1/4} \qquad (110.36)$$

where the physical properties appearing in N_{Nu} and N_{Re}, and N_{Pr} are evaluated at the approaching stream temperature (20). This correlation is recommended for $3.5 < N_{Re} < 7.6 \times 10^4$, $0.71 < N_{Pr} < 380$, and $1.0 < \mu/\mu_w < 3.2$.

For Newtonian fluids flowing along a flat plate with a sharp edge, oriented parallel to the flow, the local Nusselt number correlation in the laminar region near the leading edge, the following equation is used (18):

$$N_{Nu} = 2\sqrt{\frac{37}{1260}}\,(N_{\mathrm{Re}\,x})^{0.5}(N_{\mathrm{Pr}})^{1/3} \qquad (110.37)$$

in which $N_{Re\,x}$ is the Reynolds number at the point that has a distance of x from the leading edge.

For Newtonian fluids flowing around irregular shaped objects

$$N_{Nu} - N_{Nu,0} = 0.60(N_{\mathrm{Re}})^{0.5}(N_{\mathrm{Pr}})^{1/3} \qquad (110.38)$$

in which $N_{Nu,0}$ is the mean Nusselt number at zero Reynolds number.

The Nusselt correlations for natural convection is more complicated than those for forced convection. In general, these correlations can be expressed as

$$N_{Nu} = \alpha(N_{Gr}N_{Pr})^{\beta} \qquad (110.39)$$

where α and β can be evaluated using the table provided by Singh (8). Alternatively, simplified equations for natural convection to air or water in several geometrical shapes and arrangements is formulated by Toledo (19) based on the data from McAdams (21). A similar set of simplified

equations can also be found in Özisik's (22) book. They all have the following form:

$$h = C(\Delta T)^{0.25} \quad \text{or} \quad h = C(\Delta T/L)^{0.25} \qquad (110.40)$$

for laminar flows, and

$$h = C(\Delta T)^{1/3} \quad \text{or} \quad h = C(\Delta T/L)^{1/3} \qquad (110.41)$$

for turbulent flows where L is replaced by d for cylinders.

More heat transfer coefficient correlations can be found in several books (6, 19). For correlations for non-Newtonian fluids, the textbooks by Heldman and Singh (16) and Toledo (19) are recommended.

C. Overall Heat Transfer Resistance

In most heat transfer processes, particularly those involving indirect heating devices such as heat exchangers, there will be more than one resistance to heat transfer. For a simple heat exchanger, there are two convective heat transfers: one inside and one outside, and one conduction: heat transfer across the walls of the tubes in the heat exchanger. Often in situations like that, an overall heat-transfer coefficient, U, is used and can be calculated as:

$$\frac{1}{U} = \frac{1}{h_1} + \frac{1}{h_2} + \frac{S}{K} \qquad (110.42)$$

IV. UNSTEADY STATE HEAT TRANSFER: FOURIER'S SECOND LAW

When heat transfer across a solid is not uniform, i.e., there is a rate of change in temperature with time; this condition is called unsteady state heat transfer. For example, in sterilization processes, temperature histories of heating and cooling are vital to process operators determining the lethal effect of the thermal processing on microbial populations. Fourier's second law of heat transfer guides unsteady state heat transfer and is mathematically expressed as

$$\frac{\partial T}{\partial t} = \frac{k}{\rho c_p}\left[\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}\right] = \alpha\left[\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}\right] \qquad (110.43)$$

Equation (110.43) is derived in a Cartesian coordinate system. For cylindrical objects with temperature symmetry in the circumferential direction, Fourier's second law of heat transfer takes the following form:

$$\frac{\partial T}{\partial t} = \alpha\left[\frac{\partial^2 T}{\partial r^2} + \frac{\partial^2 T}{r\partial r^2} + \frac{\partial^2 T}{\partial z^2}\right] \qquad (110.44)$$

For sphere with symmetrical temperature profile, the governing equation becomes

$$\frac{\partial T}{\partial t} = \alpha\left[\frac{\partial^2 (rT)}{r\partial r^2} + \frac{1}{r^2 \sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\,\frac{\partial T}{\partial\theta}\right)\right] \qquad (110.45)$$

In order to solve Equations (110.43), (110.44), and (110.45) to obtain temperature histories of foods, it is important to know the relative importance of heat transfer at the surface and the interior of an object submerging in a heating environment. In many unsteady state heating processes, the food often initially has a uniform low temperature. Upon immersing in the heating fluid, the heat transfer to the food object from the fluid will experience two types of resistances: convective heat resistance and conductive resistance. The ratio of these two resistances, called Biot number, is defined as

$$N_{Bi} = \frac{\text{internal conductive resistance within } \textit{the} \text{ body}}{\text{external convective resistance at the surface}} = \frac{hd_c}{k} \qquad (110.46)$$

For the case of negligible internal resistance to heat transfer ($N_{Bi} < 0.1$) where the shape and size of food object are irrelevant, the temperature history is expressed as

$$\frac{T - T_m}{T_i - T_m} = \exp\left(\frac{-hA}{\rho c_p V}\right)t = \exp(-N_{Bi}N_{Fo}) \qquad (110.47)$$

where T_m is the temperature of the heating fluid. T_i is the initial temperature of the food object. N_{Fo} is Fourier number, a dimensionless number that is equal to $\alpha t/d_c^2$.

For the case of negligible internal resistance to heat transfer ($N_{Bi} > 40$) where the shape and size of food object are relevant, the temperature history of an infinite slab is expressed as

$$\frac{T - T_m}{T_i - T_m} = \sum_{n=1}^{\infty}\frac{2}{C_n}(-1)^{n+1}\cos\frac{C_n x}{d_c}\exp\left(-C_n^2\frac{\alpha t}{d_c^2}\right) \qquad (110.48)$$

where x is the variable distance from the central axis, d_c is the half-thickness of the slab, and C_n is $(2n - 1)\pi/2$. Note that Equation (110.48) is obtained by solving Equation (110.43) for an infinite slab (one-dimensional conduction through the thickness of the slab).

In cylindrical coordinates,

$$\frac{T - T_m}{T_i - T_m} = \sum_{n=1}^{\infty}\frac{2}{C_n J_1(C_n)}J_0\left(\frac{C_n r}{d_c}\right)\exp\left(-C_n^2\frac{\alpha t}{d_c^2}\right) \qquad (110.49)$$

where r is the variable distance from the central axis and d_c is the radius of a cylinder.

$$J_0(C_n) = 0 \tag{110.50}$$

Note that Equation (110.49) is obtained by solving Equation (110.44) for an infinite cylinder (one-dimensional conduction in the radial direction).

In spherical coordinates,

$$\frac{T - T_m}{T_i - T_m} = \sum_{n=1}^{\infty} 2(-1)^{n+1} \frac{d_c}{rC_n} \sin\frac{C_n x}{d_c} \exp\left(-C_n^2 \frac{\alpha t}{d_c^2}\right) \tag{110.51}$$

where d_c is the radius of a sphere and r is the variable distance from the central axis. $C_n = n\pi$.

Note that Equation (110.52) is obtained by solving Equation (110.45) for a sphere (one-dimensional conduction in the radial direction).

For the case of finite internal and external resistances to heat transfer ($0.1 < N_{Bi} < 40$) where the shape and size of food object are relevant, the temperature history of an infinite slab is expressed as

$$\frac{T - T_m}{T_i - T_m} = \sum_{n=1}^{\infty} \frac{2\sin C_n}{C_n + \sin C_n \cos C_n} \cos\frac{C_n x}{d_c} \times \exp\left(-C_n^2 \frac{\alpha t}{d_c^2}\right) \tag{110.52}$$

where d_c is the half-thickness of an infinite slab and x is the variable distance from the central axis.

$$C_n \tan C_n = hd_c/k \tag{110.53}$$

In cylindrical coordinates,

$$\frac{T - T_m}{T_i - T_m} = \sum_{n=1}^{\infty} \frac{2}{C_n J_1(C_n)} J_0\left(\frac{C_n r}{d_c}\right) \exp\left(-C_n^2 \frac{\alpha t}{d_c^2}\right) \tag{110.54}$$

This expression is identical to Equation (110.49).

In spherical coordinates,

$$\frac{T - T_m}{T_i - T_m} = \sum_{n=1}^{\infty} \frac{2\sin C_n - C_n \cos C_n}{C_n - \sin C_n \cos C_n} \frac{d_c}{rC_n} \times \sin\frac{C_n x}{d_c} \exp\left(-C_n^2 \frac{\alpha t}{d_c^2}\right) \tag{110.55}$$

where

$$C_n \cot C_n = 1 - hd_c/kT \tag{110.56}$$

The analytical solutions to the governing equations in Cartesian, cylindrical, and spherical coordinate systems are not difficult to use to obtain temperature histories in this age of super fast computer hardware and sophisticated software. For example, a programmed spreadsheet (such as MS Excel®) will crunch these numbers easily. However, for someone who is uncomfortable with using computer programs, there are simple temperature-time charts available (8, 9, 23, 24). These charts are semi-log plots of temperature distribution vs. Fourier number. The charts in Singh and Heldman (9) cover a wide range of Fourier numbers; however, the transient temperatures in the charts are those in the geometrical centers of infinite slab, infinite cylinder, and sphere. Although the other charts mentioned above cover much narrower range of Fourier numbers, the temperatures in those charts are not limited to the geometrical centers. The general procedure for using these charts is very simple. First one calculates Fourier number and Biot number, then locate these numbers on the chart that is designated for the shape of an object similar to one you are interested in (Fourier number is on the abscissas and Biot number is the slope of the straight lines in the chart). Finally, one finds the corresponding temperature distribution on the coordinate axis.

V. THERMAL PROCESSES

Thermal processes vary greatly in their severity ranging from mild treatment of pasteurization to more severe such as retort processes involving foods packaged in hermetically sealed containers. Commercial sterilization processes can be categorized into two basic modes: conventional canning in retorts and aseptic canning where foods and containers are sterilized separately and assembled later in a sterile environment. A wide range of food products, ranging from less viscous fluids to high-viscosity fluids, can be heat treated. The presence of particles (up to 25 mm in diameter) poses a challenging problem for engineers involved in multiphase heat transfer, as it becomes necessary to at least heat both liquid and solids adequately and, if possible, equally. Alternative technologies, such as ohmic heating and microwave heating may help alleviate some of the problems associated with heating of solid-liquid mixture (25–29). The presence of air in either of phases becomes a problem in thermal processing as it escapes from the fluids when temperature increases. Also air is a very poor heating fluid.

A. RETORT

Retort is a closed vessel or other equipment that is used for thermal sterilization of packaged foods. The heating medium is usually pure saturated steam. Canned foods are not the only type of foods that can be treated to commercial sterility. Retort pouches are also widely processed in retorts.

The type of retort equipment includes discontinuous (batch), non-agitating (still), and vertical or horizontal retorts.

Many factors contributing to the conditions necessary to produce commercially sterile packaged foods, include [1] pH, [2] the storage conditions after thermal treatment and expected shelf-life, [3] the heat resistance of the targeted microorganism(s), [4] the heat transfer characteristics of the food, its container, and the heating medium, and [5] the initial load of microorganisms. For packaged low-acid foods, it is *C. botulinum* spores that cause the greatest concern and should be the target for destruction. The modes of heat transfer in thermal processing of foods in retorts could be heat conduction, convective heat transfer, or both, depending on the viscosity of foods in the package and the retort equipment (still or agitating), although conductive heat transfer is probably the predominating heat transfer mode. For low-viscosity foods such as juices, natural convection could arise due to temperature differences in different locations of the package. Many retorts can rotate and therefore forced convection is induced in the package. In the rotating retort, the headspace of the package (such as a can) becomes an important factor to consider when one evaluates the combined effect of natural convection and forced convection. It is common to insert the thermocouple probe in the location that is not the geometrical center of the package but slightly below the center in the retort for measurement of the heat penetration curve since this location is believed to be the coldest spot in the package for low-viscosity foods. The drawback with the thermocouple probe approach is that the probe will disturb the flow patterns, which, in turn, distort the measurement of temperature distribution in the package. Various alternatives were considered and tested. Among them are temperature time integrators (TTI). TTI is designed to replace thermocouple probes and to validate overall process of thermal processing of foods, especially for those containing particulates. A marker is an alternative temperature probe used in TTI, be it a microorganism, or a spore, or an enzyme, or a chemical or a physical marker whose degradation kinetics are first-order, which is stable and has been accurately measured. Markers may be intrinsic (already present in the food) or extrinsic (added to the food) and are immobilized in solid particulates (30). The advent of nanotechnology could revolutionize the TTI approach with chemical markers. Computer simulations of food sterilization in packaged foods are also thriving as the computing power goes up and the cost of computing declines. Many papers have been published in this field (31–35). Commercial computational fluid dynamics (CFD) software package such as FLUENT and PHOENICS is a useful tool available to food engineers and technologists to conduct complex computer simulations (36, 37). The latest approach to predicting temperature histories in retorts is the use of artificial neural network (ANN) coupled with genetic algorithms (GA) based on seminal works by Goldberg (38) and Holland (39). Ramaswamy group of McGill University in Canada has several publications in this area (40).

B. Continuous Heat Processing

Conventional continuous thermal processing of liquid or liquid-particulate foods is intended to pasteurize the foods while minimizes the thermal damage to food quality. Steam or hot water is the common heating medium and the thermal energy is delivered to foods through two means: direct steam heating and indirect heating with steam or hot water using one of several types of heat exchangers.

With direct steam heating, the food is heated to sterilization temperature by mixing it with steam. In the process, some of steam may condense and release latent heat of vaporization. Direct steam heating of foods is fast but the processed product is dilute. The extra water sometimes has to be removed. Regardless the way of direct heating is carried out, either the food is injected to steam or steam is injected to the food; the mathematical modeling is not easy. A thermodynamics approach may be used in calculating energy requirement.

Indirect heating involves using plate or tubular or scraped surface heat exchangers. Each of these types of heat exchangers has their own advantages and disadvantages. Although designs of heat exchangers are many, in principle the only significant difference between them is the direction of flows of the two fluids. In general, there are two designs of heat exchangers commonly used in food industry: cross flow and parallel flow. Parallel flow can be subdivided into concurrent flow and counter-current flow exchangers. Under comparable conditions, more heat is transferred in counter-current exchangers than in

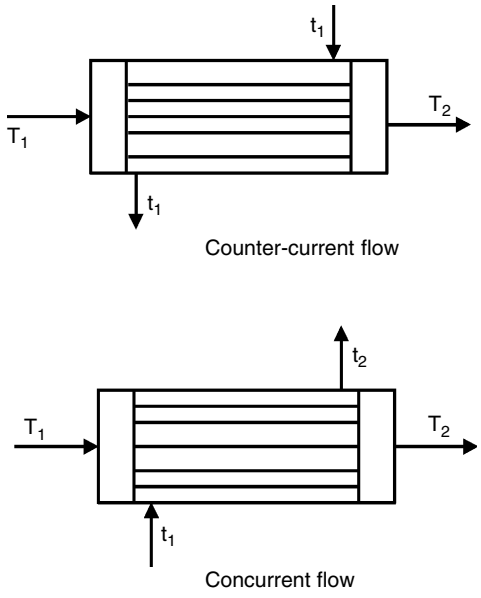

FIGURE 110.5 Schematic diagram of parallel heat exchangers.

concurrent exchangers. Figure 110.5 illustrates the flow arrangement for parallel flow exchangers. There are situations where cross flow exchangers may transfer more heat than counter-current heat exchangers. Parallel flow heat exchangers carry two fluids: one hot and one cold. Heat is transferred to the cool fluid primarily through forced convection.

The rate of heat transfer between the two fluids is

$$Q = UA(\Delta T)_{lm} \tag{110.57}$$

where

$$(\Delta T)_{lm} = \frac{(\Delta T)_2 - (\Delta T)_1}{\ln(\Delta T)_2 - \ln(\Delta T)_1} \tag{110.58}$$

where (ΔT) is the temperature difference at each end of the exchanger and $(\Delta T)_{lm}$ is called the log mean temperature difference.

Scraped surface heat exchangers are often used in heating high-viscous foods or foods containing large particulates (often non-Newtonian fluids). Singh (8) provided the following Nusselt number equation based on Higbie's penetration theory for calculating convective heat transfer coefficient:

$$N_{Nu} = 2\pi^{-0.5}(N_{Re}\,N_{Pr}\,n)^{1/2} \tag{110.59}$$

where n is the fluid behavior index for non-Newtonian fluids.

Plate heat exchangers are commonly used in heating applications in the dairy and food beverage industry. It consists of a series of plates clamped together on a frame. Channels are formed between the plates. The food product and heat transfer medium flow through alternate channels. Because of the narrow channels, plate heat exchangers can be designed to give a high level of induced turbulence in the flowing streams of the food and heating medium. This arrangement along with the small channel size between the plates gives high heat transfer coefficients (3). The plate heat exchangers are compact for any given heating loads. The downside of the design is the narrow channels preclude the flow of high-viscous fluids and liquids containing particulates.

Tubular heat exchangers can be divided into two groups: concentric tubes and shell-and-tube exchangers. Concentric tube type of heat exchangers consists of one pipe inside another. The walls of the inner pipe form the heat transfer surface. Shell-and-tube heat exchangers consist of a bundle of tubes enclosed by a shell. The arrangement allows for one tube pass or multiple passes for the food. In a one-pass arrangement, the product stream enters at one end and exits at the opposite end. In a multiple-pass arrangement, the product stream may flow back and forth through different tubes with each pass before finally exiting the heat exchanger. Tubular heat exchangers can do the jobs that plate heat exchangers cannot. Relatively large tubes of tubular heat exchangers can handle highly viscous fluids or solid-liquid mixtures with ease. But the heat transfer area per unit volume of tubular heat exchangers is smaller than that of the plate exchangers and therefore the heat transfer rate is slower.

111 The Engineering Aspects of Deep-Fat Frying

Rosana G. Moreira
Department of Biological and Agricultural Engineering, Texas A&M University

CONTENTS

I. INTRODUCTION

Deep-fat frying is one of the oldest processes of food preparation. For decades, consumers have desired deep-fat fried products because of their unique flavor-texture combination, ranging from potato chips, French fries, doughnuts, extruded snacks, fish sticks, and the traditional fried chicken products.

Frying is the process of cooking foods using oil as the heating medium. In deep-fat frying, the food is immersed in the oil, which should be enough to cover the food by at least 2 cm. The objective of deep-fat frying is to seal the food by immersing it in hot oil so that all the flavors and juices are retained in a crisp crust.

A. Deep-Fat Frying Systems

The processes used to fry food products can be divided into two broad categories: (1) those that are static and smaller (whose capacity can range from 8 L–28 L of oil), classified as batch fryers used in the catering restaurants; and (2) those that fry large amounts of products in a moving bed, used in the food industry, classified as continuous fryers (having a throughput that varies from 250 kg product hr^{-1} – 25,000 kg product hr^{-1}). These fryers can operate at atmospheric and vacuum and high pressure conditions.

Deep-fat frying of foods is usually performed at high temperature (around 190°C) under atmospheric pressure. Excessive darkening or scorching of the product may occur even before the product is completely cooked. In addition, some of the oil decomposition products have been implicated in producing adverse health effects when fried oils degraded with continued use (Taylor et al., 1983).

High-pressure is another way of producing deep-fat products. Pressure fryers were developed primarily to be used in the food service industry for chicken frying. The time required to fry chicken parts is faster in a pressure fryer than in atmospheric (open) fryers and the food is more moist and uniform in color and appearance. The process increases the boiling points of frying oil and moisture in the food, thus increasing the rate of heat transfer to the

interior of the food and reducing the frying time. The result is a moist and flavorful food product. Pressure batch fryers can be electric or gas fired and are available in many sizes. Oil capacity can range from 11 L to 25 L and food capacity from 5.6 kg to 10.9 kg. The operating temperature of pressure fryers can vary from 160°C to 177°C and the frying time from 7 to 10 min. Two pressure ranges are used, some fryers employ 9–14 psi and others 28–32 psi (Moreira et al., 1999). Some disadvantages of pressure fryers are that the frying oil will degrade faster because steam from the food is retained within the fryers thus increasing buildup of free fatty acids. The oil must be filtered more frequently because bread and crumbs can burn or oxidize causing off flavors (Lawson, 1985).

In vacuum frying operations, food is heated under reduced pressure (<60 Torr) in a closed system. In these systems, the boiling point of the oil and the moisture in the foods are lowered. Some of the advantages include: (1) water in the product can be rapidly removed; (2) natural color and flavors of the product can be preserved due to the low temperature and oxygen content during the process; and (3) vacuum frying has less adverse effects on oil quality (Shyu et al., 1998). In addition, under vacuum, food products can be fried at much lower temperature (around 110°C) and yield products with lower oil content (e.g., potato chips) and same texture and less darkness than those fried at traditional atmospheric fryers (170–190°C) (Garayo and Moreira, 2002).

Continuous vacuum frying was a concept developed by Florigo (H&H Industry Systems B.V., The Netherlands) in the early 1970s to produce high quality French fries. Due to the improvement in quality of the raw materials and blanching techniques, the use of vacuum fryers almost died out with the exception of one or two production companies who still insist in producing a non-blanched product. Today, the Florigo automatic continuous vacuum fryers are used mainly to produce fruit-chips and very delicate snack products.

French fries processed in a vacuum fryer can achieve the necessary degree of dehydration without excessive darkening or scorching of the product. With the natural preoccupation with lowering the fat contents of diets, vacuum frying can be an efficient way of reducing the oil content in fried snacks. In addition, vacuum fryer can be an alternative to produce dehydrated fruits and vegetables with high quality in a short time.

II. FRYING OIL CHARACTERISTICS

During deep-frying, fats and oils are repeatedly used at elevated temperatures in the presence of atmospheric oxygen and receive maximum oxidative and thermal abuse. Heating in the presence of air causes partial conversion of fats and oils to volatile chain-scission products, nonvolatile oxidized derivatives, and dimeric, polymeric, or cyclic substances. By affecting the properties of the heat transfer medium (cooking oil), deep-fat frying in turn affects the quality of the fried food. Chemical and physical changes in the oil can prolong the process time, increase the total amount of oil in the product, induce toxicity, and lower food nutritional value.

The term *fat* is used to refer to animal-origin fat while *oil* is used for plant-origin fat. Fat is one of the body's basic nutrients, providing energy by furnishing calories. It is composed primarily of triglycerides, which are three fatty acid molecules joined by a *glycerol* backbone (Stockwell, 1988). There are several fatty acids, but only about eleven are common.

Glycerol can combine with these fatty acids through esterification to form mono-, di-, and *triglycerides.* The characteristics of a particular fat or oil and therefore its frying properties are dictated by the actual fatty acids that are present in the individual triglyceride molecules. Some of these component fatty acids are longer or shorter in chain length than others.

The various fatty acids are placed in groups to reflect their functionality in products (and in the human body). If a fatty acid is composed of a chain of carbon atoms with no double bonds, it is said to be *saturated*. These fatty acids are generally solid at room temperature. It is possible for the double bonds to occur in different places. In the case of fatty acid with two double bonds, they can be sited close to each other or far apart. The closer they are together, the more unstable the molecule will be. The position of the double bonds seems to be more important than the number of them. A molecule with two double bonds close to each other is likely to be more unstable than one with three positioned well apart from each other (Stockwell, 1988).

From these descriptions, it should be clear that even with only a few types of fatty acids, a larger number of different triglycerides are possible. With eleven distinct fatty acids that occur commonly in nature, over 1300 different triglycerides can be formed.

Unsaturated fats are derived primarily from plants and are liquid (in the form of an oil) at room temperature. Generally speaking, oils are composed (in varying percentages) of both monounsaturated and polyunsaturated fats. In general, the more double bonds in a fatty acid and the longer its carbon chain length, the lower the temperature at which an oil remains liquid. Also, the more double bonds, the more unstable the oil is and the more likely it is to undergo various forms of degradation (Stockwell, 1988). Thus, there is a chemical basis for the trade off between stability (polyunsaturated oils are less stable) and health benefits (polyunsaturated oils are considered to be more healthy).

The three most widely used oils that are high in monounsaturates are olive oil, canola oil, and peanut oil. Polyunsaturated fats are also considered relatively healthy and include the following, ranked in order, most to least, of polyunsaturates: safflower oil, soybean oil, corn oil,

and sesame oil (Stockwell, 1988). Soybean, safflower, sunflower, and canola oils are always partially hydrogenated before being used for frying to increase their stability. Cottonseed, corn, peanut, and olive oils are used as a stable source of polyunsaturated fatty acids because of their low linolenic acid content (Pavel, 1985). Other oils such as jojoba oil have also been tested for frying (Clarke and Yermanos, 1980; Saguy et al., 1996).

III. PRODUCT CHANGES DURING DEEP-FAT FRYING

Fried products absorb oil during frying and as they cool which contributes to a high fat and high calorie product (Moreira et al., 1999). Oil content in fried foods has been related to initial moisture content (Gamble et al., 1987; Moreira et al., 1995), pre-frying treatment (Gamble et al., 1987; Moreira et al., 1997), structural changes during baking (Lee, 1991; McDonough et al., 1993; Rock-Dudley, 1993), and cooling time (Sun and Moreira, 1994). Bulk density decreases, and porosity and oil uptake increase with frying time during frying of tortilla chips (Kawas and Moreira, 2000).

A. Shrinkage, Porosity, and Texture Changes

In general, fried products will shrink during frying, becoming more porous and crispy after frying.

Tortilla chips, for example, decrease in diameter by about 9%, expand in thickness by 10%, and puff by 100% by the end of frying. The chips become more porous by the end of frying due to the decrease in bulk density caused by the water loss during the process. As frying time increases, the amount of large pores increases filling out the entire chips' structure in a normal distribution. Tortilla chips become harder up to 30 s of frying, and then crunchy until the end of frying (60 s). The chips' crunchiness increases during frying (Kawas and Moreira, 2000).

B. Degree of Starch Gelatinization and Oil Absorption

The degree of starch gelatinization (and therefore the structure) of the product prior frying can affect the mechanism of oil absorption during the process. Starch goes through a series of transformations when heated. Gelatinization is typically defined as a physicochemical phenomenon of swelling of starch granules as they imbibe water. It occurs as the starch system is heated above a gelatinization temperature. Gelatinization is both a physical and a chemical process. The physical process happens when the granules hydrate and swell, and leach of amylose and amylopectin molecules into the solution. The chemical process is performed by water breaking molecular bonds and replacing them with water-polysaccharide hydrogen bonds.

Experiments performed with tortillas prepared with different levels of starch gelatinization before frying showed that the higher the amount of starch gelatinized the lower the oil content after frying (Kawas and Moreira, 2001).

The structure of the chips formed during frying also play an important role in the mechanism of oil absorption (Kawas and Moreira, 2001). Tortillas chips that show higher number of small pores uniformly distributed all over absorb more oil during frying. Little diameter shrinkage and no puffiness contribute to the chips higher oil content, which in turn results in low porosity. These chips tend to be crunchy.

Tortilla chips that produce a structure during frying with few large pores distributed all over the surface tend to shrink and puff significantly resulting in higher oil content at the surface and low at the core. These chips are also less crunchy and very hard.

IV. FACTORS THAT AFFECT OIL ABSORPTION

Several factors affect oil absorption in fried foods, including process conditions (temperature and residence time), initial moisture content of product, raw material composition, slice thickness, pre-frying treatment, degree of starch gelatinization prior to frying, and oil quality.

A. Oil Temperature Effect

During frying, the rapid drying is critical for ensuring the desirable quality of the final product. However, the loss of water results in a substantial absorption of oil by the product. Higher oil temperatures lead to a faster crust formation thus favoring the conditions for oil absorption. As the moisture is reduced with frying time, the ratio of oil content to the amount of water removed becomes independent of the oil temperature indicating that the oil content is not directly related to the oil temperature but to the remaining moisture present in the product.

B. Specific Gravity

Potatoes with high specific gravity ($>$1.10) and dry matter ($>$24.0%) produce chips with lower oil content (Lulai and Orr, 1979). French fries made from high dry matter content raw potatoes (around 24.0%) contain 9% less oil content than those made from potatoes containing lower dry matter content (around 19.5%). Thickness of potato slices is another factor that affects oil uptake in chips. The thicker the potato slice, and thus the smaller surface area relative to the chip volume, the lower will be the chip's volume oil content (Gamble and Rice, 1987).

C. Pre-Frying Treatment

Oil uptake varies with the product pretreatment before frying. In producing French fries, blanching alone does not

reduce significantly oil absorption in these products. Blanching makes the fries' color more uniform, reduces oil uptake by gelatinizing the surface starch, shortens frying time, and improves the fries' texture.

The amount of water in the raw material before frying can affect the oil content of the fried product. Removing some of the water prior to frying can help reduce oil uptake after frying. However, depending on the drying process used, the final product will develop a pore structure that will affect how the absorbed oil will be distributed after frying. Microwave dried potato slices can produce chips with lower oil content than chips that are only fried. This drying process provides chips with heterogeneous moisture distribution structure and with large oil-free zones. In hot-air dried chips, the structure of the fried product shows oil more uniformly distributed around the surface than the fried only chips (which have most of the oil concentrated at the edges). Hot-air dried chips also have less oil content than the microwaved potato chips. On the other hand, freeze-drying will produce oily potato chips after frying. Freeze-dried potato slices have shown no major change in the product's structure during freeze-drying, thus resulting in an even distribution of oil all over its surface after frying (Gamble and Rice, 1988).

Baking is used in the manufacturing of tortilla chips, for example. The objective of baking is to reduce the raw tortilla moisture content from about 55% wet basis (w.b.) to around 40%–38% w.b., to strengthen the product structure and to develop its flavor. During baking, the raw tortilla is exposed to high temperatures (320–420°C) resulting in severe starch gelatinization (>40%) (Gomez et al., 1992). Baking time can produce tortillas with different moisture contents and consequently different degree of starch gelatinization before frying.

D. Particle Size Distribution

Another important factor in oil uptake in fried products is the level of particle size distribution in the dry mass flour. Tortilla chips prepared from finely ground masa showed excessive puffing and pillowing, resulting higher oil absorption and lower porosity; tortilla chips made from coarse particles presented the lowest oil content and no puffing; and intermediate masa produced tortilla chips with final oil content closer to the control sample. The function of the coarse particles is to produce fissures in the product that allow water to escape during frying and reduce oil absorption, and to reduce the extent pillowing during baking and frying (Gomez at al., 1987).

E. Degree of Starch Gelatinized

The degree of starch gelatinization in the product before frying can significantly affect oil absorption after frying. Tortillas containing a high degree of starch gelatinized (80%) before frying yielded chips with lower oil content (14% w.b.) than tortilla chips made with tortillas containing 45% degree of starch gelatinized (23% w.b.) and those made with tortillas having 5% degree of starch gelatinized (35% w.b.). The degree of starch gelatinization affects the oil distribution. The higher the degree starch gelatinized the more oil will be at the chip's surface than at the core. Starch gelatinization and subsequent swelling of the starch granules inhibits oil uptake in these products (Kawas and Moreira, 2001).

F. Oil Quality

Used or poor quality frying oil will make the product look oilier although the total oil content will be the same as those fried in fresh oil. Most of the oil absorbed by chips fried in degraded oil is concentrated on the surface. The higher viscosity of the degraded oil could cause the oil to adhere to the product's surfaces thus making it more difficult for the oil to be drained off from the chip's surface during cooling (Tseng et al., 1996).

V. HEAT TRANSFER AND THE MECHANISM OF OIL ABSORPTION

Heat transfer in deep-fat frying of foods is coupled to the transport of mass. Heat is transferred from the hot oil to the product surface by convection and from the surface to the center of the chip by conduction. The liquid water moves from the inside of the chips to the evaporation zone, leaving the surface as vapor. The simultaneous aspect of both heat and mass transfer in addition to the fact that the physical properties of the material vary with changing temperature and moisture content make theoretical treatment more complicated. Many models have been developed to predict the frying process, and the reader is referred to Moreira et al. (1999) and Yamsaengsung and Moreira (2002a,b) for detail descriptions of these models.

Moreira et al. (1997) showed that, during frying, only a small amount of oil is absorbed (20 percent of the total final oil content) during the first 0–5 s and remains constant until the end of the process (60 s). It was shown that for tortilla chips (Moreira et al., 1995) starch gelatinizes, moisture evaporates, the crust develops, and the capillary pores expand during frying. During the post-frying period, the interfacial tension between oil and gas increases as temperature decreases resulting in an increasing capillary pressure which causes the surface oil to imbibe into the porous chip, thus increasing its internal oil content.

Therefore, the frying process of potato or tortilla chips, for example, can be divided into three distinct stages:

1. **Pre-Frying**: This stage is characterized by the raw material conditions before frying. Oil content is zero at this stage. The product physical

properties of importance are the initial moisture content, initial porosity, and density of each component of the product (solid, water, air, oil).

2. **Frying**: The product's properties change during this stage. Moisture content is reduced, the physical properties such as thermal conductivity, specific heat, and bulk density decrease, porosity increases as a result of water evaporation, and the product's thickness increases as a result of puffing. Only 20 percent of the total oil is absorbed during this stage.
3. **Post-Frying (Cooling)**: This period starts immediately after frying, when the product is removed from the fryer. The temperature inside the chip decreases until it reaches the ambient (or cooling) temperature. The water content is constant, and the physical properties, with exception of the bulk density, remain essentially the same. Most of the oil is absorbed during this period.

The most important oil absorption process conditions are product initial moisture content and cooling air temperature. Surface tension and pore radius are also important but their effects on final oil content of fried products are minor.

In conclusion, we can say that deep-fat frying is a complex process that involves heat and mass transfer mechanisms and a variety of physical and chemical changes in both food and frying oil. Understanding the mechanism of oil uptake is crucial to product quality control since oil content is one of the most important quality factors of fried foods in deep-fat frying processes.

Freezing

112 Principles of Food Refrigeration and Freezing

Stephen J. James
Food Refrigeration and Process Engineering Research Center, University of Bristol

CONTENTS

I. INTRODUCTION

Developments in frozen storage in the 18th century established the international food market. Further developments in temperature control for chilled products have led to the rapid expansion of the "fresh" food market. Refrigeration is the most common form of food preservation and has considerable further potential. The International Institute of Refrigeration (IIR) estimates that 240MT of food is refrigerated throughout the world. They believe that at least a further 1800MT of food would benefit from refrigeration in its production and distribution.

Refrigeration stops or reduces the rate at which changes occur in food. These changes can be biochemical (growth of micro-organisms), physiological (e.g. ripening, senescence and respiration), chemical and enzymatic reactions (e.g. browning reactions, lipid oxidation and pigment degradation) and physical (such as moisture loss). Effective refrigeration produces safe food with a long high quality shelf life.

A. Safety and Shelf Life

The American Food and Drug Administration (FDA) reckons — 'conservatively,' according to one official — that there may be anywhere between 24 and 81 million cases and 10,000 'needless deaths' from food poisoning in the US every year. In England and Wales reported cases of food poisoning have increased nearly five-fold over the last decade. In addition to the human cost the economic loss in terms of working days and medical treatment in the US is between $5 billion and $6 billion. A study of one outbreak of *Salmonella enteritidis* in the UK calculated that it cost the country between £224 and £321 million. Even a superficial examination of the problem reveals that temperature control is the prime factor that determines the safe distribution life of most foods.

Temperature is one of the major factors affecting microbiological growth. Microbiological growth is described in terms of the lag phase and the generation time. When a microorganism is introduced to a particular environment there is a time (the lag phase) in which no increase in numbers is apparent followed by a period when growth occurs. The generation time is a measure of the rate of growth in the latter stage. Microorganisms have an optimum growth temperature at which a particular strain grows most rapidly, i.e. the lag phase and generation time are both at a minimum. They also have a maximum growth temperature above which growth no longer occurs. Above this temperature, one or more of the enzymes essential for growth are inactivated and the cell is considered to be heat-injured. However, in general, unless the temperature is raised to a point substantially above the maximum growth temperature then the injury is not lethal and growth will recommence as the temperature is reduced. Attaining temperatures substantially above the maximum growth temperature are therefore critical during cooking and re-heating operations.

Of most concern during storage, distribution and retail display of food is a third temperature, the minimum growth temperature for a microorganism. As the temperature of an organism is reduced below that for optimum growth then the lag phase and generation time both increase. The minimum growth temperature can be considered to be the highest temperature at which either of the growth criteria, i.e. lag phase and generation time, becomes infinitely long. The minimum growth temperature is not only a function of the particular organism but also the type of food or growth media that is used for the incubation. Although some pathogens can grow at 0°C, or even slightly lower (Table 112.1), from a practical point of view the risks to food safety are considerably reduced if food is maintained below 5°C.

TABLE 112.1
Minimum Growth Temperatures for Pathogens Associated with Red Meats

	Minimum Temperature (°C)
Campylobacter spp.	30
Clostridia perfringens	12
Pathogenic *Escherichia coli* strains	7
Salmonella spp.	5
Listeria monocytogenes	0
Yersinia enterocolitica	−2

Food may also become microbiologically unacceptable as a result of the growth of spoilage microorganisms. Their growth can produce unacceptable changes in the sensory quality of many foods and their rate of growth is also very temperature dependent. The development of off odours is usually the first sign of putrefaction and in meat it occurs when bacterial levels reach approximately $10^7\,cm^{-2}$ of surface area (1). When bacterial levels have increased a further 10 fold slime begins to appear on the surface and meat received in this condition is usually condemned out of hand. At 0°C beef with average initial contamination levels can be kept for at least 15 days before any off odours can be detected. Every 5°C rise in the storage temperature above 0°C will approximately half the storage time that can be achieved. So from a spoilage point of view, and the underlying economic consequences of extended storage/distribution life, temperature is again a very important factor in food production.

B. Quality Aspects

Microbial safety and spoilage are not the only aspects of food quality that are temperature dependent. The rate of loss of vitamins from fruit and vegetables during storage also depends upon the storage temperature. It is of interest to note that it is not always a case of the lower the better, especially with citrus and tropical fruits. The optimum temperature for oranges is approximately 12°C with the rate of loss increasing at temperatures warmer or colder than this value.

Some foods exhibit particular quality advantages as a result of rapid cooling. In meat the pH starts to fall immediately after slaughter and protein denaturation begins. The result of this denaturation is a pink proteinaceous fluid, commonly called 'drip,' often seen in prepackaged joints. The rate of denaturation is directly related to temperature and it therefore follows that the faster the chilling rate the less the drip. Investigations using pork and beef muscles have shown that rapid rates of chilling can halve the amount

of drip loss (2). Fish passing through rigor mortis above 17°C are to a great extent unusable because the fillets shrink and become tough (3). A relatively short delay of an hour or two before chilling can demonstrably reduce shelf life.

However, chilling has serious effects on the texture of meat if it is carried out rapidly when the meat is still in the pre-rigor condition, that is, before the meat pH has fallen below about 6.2 (4). A phenomenon known as cold shortening occurs, which results in the production of very tough meat after cooking. As 'rules of thumb' cooling to temperatures not below 10°C in 10 hours for beef and lamb (5) and in 5 hours for pork (6) can avoid cold shortening.

The rate of sugar loss (sweetness) in freshly harvested sweet corn is very temperature dependent. After 20 h at 30°C almost 60% of the sweetness is lost compared with 16% at 10°C and less than 4% at 0°C. Prompt cooling is clearly required if this vegetable is to retain its desirable sweetness. Similarly, the ripening of fruit can be controlled by rapid cooling, the rate of ripening declining as temperature is reduced and ceasing below about 4°C (7).

For several fruits and vegetables, exposure to temperatures below a critical limit, but above the initial freezing temperature, may result in chilling injury. Typical symptoms of chilling injury are internal or external browning, superficial spots, failure to ripen, development of off-flavour and off-taste, etc. It is primarily fruits and vegetables from the tropical and subtropical zones that are susceptible to chilling injury; several Mediterranean products are also susceptible (7).

The extent of damage depends on the temperature, duration of exposure and the sensitivity of the fruit and vegetable. Some commodities have high sensitivity, while others have moderate or low sensitivity. For each commodity the critical temperature depends on species and/or variety. In some cases, unripe fruits are more sensitive than ripe fruits.

A final, but important, quality and economic advantage of temperature control is a reduction in weight loss, which results in a higher yield of saleable material. Meat for example, has a high water content and the rate of evaporation depends on the vapour pressure at the surface. Vapour pressure increases with temperature and thus any reduction in the surface temperature will reduce the rate of evaporation. The use of very rapid chilling systems for pork carcasses has been shown to reduce weight by at least 1% when compared with conventional systems (8).

II. REFRIGERATION COLD CHAIN

The complete refrigeration cold chain for a food will contain many of the following unit operations: prechilling preparation, primary or secondary chilling, freezing, thawing, tempering, storage, transportation and display. Storage, transport and display are temperature maintenance operations. Chilling and freezing produce substantial decreases in the mean temperature of the product. Thawing and tempering produce substantial increases. Whilst during the preparatory treatment there can be a range of temperature responses from a large gain to a small decrease in the temperature of the foodstuff.

The initial and final temperatures, and the maximum and minimum desirable rates of temperature reduction during chilling, depend on the food being processed. In all cases the final product temperature must be above the initial freezing point of the food, but in a number of products biological factors dictate higher storage temperatures.

The same fundamental modes of heat transfer govern processes that change and those that maintain food temperatures throughout the cold chain.

A. Fundamental of Heat Transfer

The principle factors, which control the rate of heat and mass transfer during cooling, are independent of the foodstuff. Heat can be lost from the surface of a body by four basic mechanisms: radiation, conduction, evaporation or convection.

To determine the rate of heat transfer (Q_r) by radiation from food the following approximation may be applied:

$$Q_r = \varepsilon A \sigma (T_s^4 - T_e^4), \tag{112.1}$$

where ε is the emissivity and A is the surface area of the food, σ the Stefan-Boltzman constant and T_s and T_e the temperature of the surface and the enclosure respectively. To achieve substantial rates of heat loss by radiation large temperature differences between the product and the enclosure are required. Such differences are not normally present during food cooling operations except in the initial chilling of bakery products.

The rate of one dimensional heat transfer (Q_{cd}) by conduction is given by:

$$Q_{cd} = kA\frac{\partial T}{\partial x}, \tag{112.2}$$

where k is the thermal conductivity of the medium through which the heat is passing and $\partial T/\partial x$ the temperature gradient.

Physical contact between the product and a cooler surface is required to extract heat by conduction. The irregular shape of most foodstuffs precludes this mechanism in many applications. Plate coolers are routinely used to freeze fish and offal, which have soft pliable surfaces. Belt freezers are used for steaks, fish fillets and other thin products. However, the rate at which heat can be conducted away from the surface is not the sole criterion that governs the time taken to cool a product. Heat must also be conducted from within the product to its surface before it can be removed. Most foodstuffs are poor

conductors of heat and this imposes a severe limitation on attainable chilling times for either large individual items or small items cooled in bulk.

The rate of mass transfer (M) from the surface of an unwrapped food is described by the equation:

$$M = mA(P_s a_w - P_m), \quad (112.3)$$

where m is the mass transfer coefficient, A the area, P_s the saturated vapour pressure at the surface, a_w the water activity and P_m the vapour pressure above the food surface. Q_e, the heat loss due to evaporation, can be obtained by multiplying M by the appropriate latent heat. The heat lost in the evaporation of water from the surface of the product is a minor component of the total heat loss for most foodstuffs. In spray cooling systems, the rate of heat removal is enhanced by evaporation from the surface. However, the main advantage of spray cooling is a reduction in weight loss. In a number of specific cases i.e. vacuum cooling, evaporation is the primary cooling agent.

Most food chilling systems rely on convection as the principal means of heat removal. The rate of one dimensional heat transfer (Q_c) by convection is given by:

$$Q_c = h_c A(T_s - T_a), \quad (112.4)$$

where h_c is the convection or film heat transfer coefficient and T_a the temperature of the cooling medium. The most common media are air or water, although salt solutions, sugar brines and other refrigerants have been used. Each combination of product and cooling system can be characterized by a specific surface heat transfer coefficient. The value of the coefficient depends on the shape and surface roughness of the foodstuff and to a much greater degree on the thermophysical properties and velocity of the medium. Values range from 7 for still air to over $500\,W\,m^{-2}\,K^{-1}$ for agitated water.

B. Primary Chilling

1. Chilling Methods for Solid Foodstuffs

a. *Moving air*

This is the most widely used method as it is economical, hygienic and relatively non-corrosive to equipment. Systems range from the most basic in which a fan blows the cooled air around an insulated room, to products on conveyors passing through blast chilling tunnels or spirals. Low rates of heat transfer are attained in air cooling systems, but this is not important if conduction within the product is the rate-controlling factor. A major disadvantage is excessive dehydration from the surface of any unwrapped product, whilst the need to avoid surface freezing limits the lowest air temperature that can be used in a single stage system. In practice, air distribution is a major, often overlooked, problem.

A batch system where warm food is placed in refrigerated rooms is the most common method of chilling. Individual items such as carcasses, tuna or bunches of bananas are hung from rails, smaller products are placed on racks or pallets, and bulk fruits and vegetables in large bins.

Conveying products overcomes problems of uneven air distribution since each item is subjected to the same velocity/time profile. In the simplest continuous systems the food is suspended from an overhead conveyer and moved through a refrigerated room. This process is often used in air chilling of poultry or in the prechilling of pork carcasses. Some small cooked products are continuously chilled on racks of trays, which are pulled or pushed through a chilling tunnel using a simple mechanical system. In more sophisticated plants the racks are conveyed through a chilling tunnel in which the refrigeration capacity and air conditions can be varied throughout the length of the tunnel.

In larger operations, it is more satisfactory to convey the cooked products through a linear tunnel or spiral chiller. Linear tunnels are far simpler constructions than spirals but require more space.

b. *Hydrocooling/immersion cooling*

Hydrocooling is probably the least expensive method of achieving rapid cooling in small products. The product is immersed in, or sprayed with, cool water, either at ambient or near 0°C. Practical systems vary from simple unstirred tanks to plants where the product is conveyed through agitated tanks or under banks of sprays. Such systems are typically used for celery, asparagus, peas, sweet corn, carrots, peaches etc.

Immersion chilling also has application with larger products. Most poultry to be frozen is initially cooled by immersion in chilled water or an ice/water mixture. The procedure is very fast and the birds gain weight during the process. The maximum weight gain is controlled by legislation.

An alternative system to air or immersion is spray chilling. Practical spray chilling systems use a combination of air and sprays for the initial part of the chilling period and then air only for the rest of the chilling cycle. The sprays of cold water at 2–3°C are not applied continuously but in short bursts. The main advantage claimed for these systems is reduced weight loss.

c. *Plate cooling*

With thinner materials a plate cooling system has the potential to halve the cooling time required in an air blast system. Continuous horizontal and rotary plate freezing systems have been produced commercially and could be modified to operate at higher temperatures. They tend to be expensive, especially if automatic loading and unloading is required, but have low running costs. Designs have been produced for continuous belt coolers similar to those used for belt freezing.

d. Ice or ice/water chilling

Chilling with crushed ice or an ice/water mixture is simple, effective and commonly used for fish cooling. The individual fish are packed in boxes between layers of crushed ice, which extract heat from the fish and consequently melt. The temperature of the 'coolant' remains at a constant 0°C until all the ice has turned into water. The process is labour intensive although automatic filling systems have been developed. Cabbage and root crops are also cooled with crushed ice.

e. Vacuum cooling

Solid products having a large surface area to volume ratio and an ability to release internal water are amenable to vacuum cooling. The products are placed in a vacuum chamber and the resultant evaporative cooling removes heat from the food. In general terms, a 5°C reduction in product temperature is achieved for every 1% of water that is evaporated. Pre-wetting is commonly applied to facilitate cooling without loss of weight.

Vacuum cooling is rapid and economical to operate because of low labour costs, but the capital cost of the large vacuum vessels is high. Large amounts of lettuce, celery, cauliflower, green peas and sweet corn are vacuum cooled.

f. Cryogenic cooling

Avoiding surface freezing of the product is the main problem in using liquid nitrogen or solid carbon dioxide for chilling. Continuous chilling systems using liquid nitrogen either immerse the product in the liquid, spray the nitrogen onto the surface or vaporize the nitrogen in a forced draught and pass it over the surface of the foodstuff.

Direct spraying of liquid nitrogen onto a food product, whilst it is conveyed through an insulated tunnel, is the most common method. Surface freezing is still a problem but an extra refrigeration effect is obtained by precooling the food with the cold gas produced by the vaporization.

2. Chilling Methods for Liquid Foodstuffs

The majority of liquid foodstuffs require cooling after a heat processing operation such as cooking, pasteurisation or sterilization. Milk is cooled at the point of collection to maintain its quality; unpasteurized fruit juices are cooled immediately after production, whilst fermented beverages are often cooled during primary and secondary fermentation, and before storage.

In simple or small scale processes containers of hot liquids are allowed to cool in ambient air or placed inside chill rooms. Other cooling systems for liquid foods rely on direct expansion refrigeration, the use of a secondary refrigerant, which is passed through or around the foodstuff, vacuum cooling, or a combination of liquid and vacuum.

Batch coolers for liquid foods range in capacity from 100 to 10,000 litres with the foodstuff contained in a stainless steel vessel. The cooling medium may circulate through the jacket of the vessel, through a coil immersed in the liquid, or both. Most vessels are provided with agitators to improve convective heat transfer and stop temperature stratification. One common method used to decrease cooling times in a closed vessel is to apply a vacuum to produce evaporative cooling.

Continuous cooling used to be achieved in falling film or surface coolers in which the hot liquid was pumped over the top of a horizontal bank of refrigerated coils and flowed down over the cooled surfaces. Totally enclosed coolers have now replaced these systems. Double pipe coolers have also been employed in specialized applications but have a limited heat transfer surface. Multiplate coolers are extensively used for liquid foods. They have the highest available heat transfer surface, lowest material requirements, maximum efficiency, are very flexible in operation and easy to clean. In certain applications, such as beer and wine cooling, multitube coolers that have a much higher resistance to pressure and can use primary refrigerants have advantages over multiplate coolers.

Scraped surface heat exchangers can have advantages in the cooling of very viscous liquid foods and where surface fouling is a potential problem. Currently there is interest in the use of pumpable ice in the form of an ice 'pig' to clean heat exchangers and pipeline systems for liquid foods.

C. Freezing

The main aim of freezing is to extend the storage life of the raw material or food product beyond that achieved at temperatures above the initial freezing point of the material. In a number of cases freezing is used to produce a product i.e. ice cream, sorbet, ice-lollies, etc. that cannot be produced in any other way.

1. Freezing Rate

The need for fast freezing to maximise the quality of frozen food is increasingly open to argument. The clear message from a recent international food refrigeration conference (9) was that 'fast freezing does not equate to high eating quality.' Fast freezing may well be the most economical practical process and it is very likely to reduce weight loss from unwrapped food. However, papers from food researchers and refrigeration equipment manufacturers failed to show any eating quality advantages of fast freezing. These papers covered meat, fish, fruit and vegetable products. Fast freezing produced more smaller ice crystals than the slower processes. However, the differences in crystal make up did not translate to effects that could be detected by taste panels or qualitative sensory measurements.

For example with hamburgers the effects of three different freezing methods — spiral freezing, cryogenic freezing (liquid nitrogen) and impingement freezing — have

been compared. The parameters studied were appearance, dehydration during freezing, cooking losses, meat-structure by microscopically analysis and sensory properties by sensory analysis.

The times required to freeze a 10 mm thick 80 g hamburger from +4°C to −18°C ranged from under 3 to over 22 minutes. Weight loss in the slow process was over three times that in the fast. Ice crystals were significantly larger in hamburgers frozen in 22 compared with 3 minutes. However, no significant difference could be seen in cooking losses. Sensory analysis revealed no difference in eating quality between the three freezing methods, even after 2 months storage.

Freezing always tends to decrease water-holding capacity and hence increase drip. When meat is frozen quickly the water, released by the fibrils as the meat has gone into rigor, and that which is still held are frozen simultaneously. Consequently, there is no change in their relative positions or amounts. At slower freezing rates, however, the water balance is altered, the extra-cellular water freezing first. As freezing continues, the existing ice crystals grow at the expense of water from the intra-fibrillar space. This can result in salt crystallization and pH changes that potentially cause protein denaturation. It has been well documented for frozen fish, which is much more susceptible to freezing damage than meat.

A number of scientific investigations have defined the effect of freezing rate on drip production in meat (10). These state that the optimal conditions for freezing portioned meat are those that achieve freezing rates between 2 and 5 cm h^{-1} to −7°C. 'Slow freezing' up to 0.39 cm.h^{-1} resulted in decreased solubility of myofibrillar proteins, increase in weight loss during freezing, thawing and cooking, lower water binding capacity and tougher cooked meat. 'Very quickly frozen' meat (>4.9 cm h^{-1}) had a somewhat lower solubility of myofibrillar proteins, lower water binding capacity and somewhat tougher and drier meat. In the studies samples were thawed after storage times of 2 to 3 days at −20°C so the relationship between freezing rates and storage life was not investigated.

The results on freezing rate are scientifically very interesting however, in industrial practice most meat is air frozen in the form of large individual pieces or cartons of smaller portions. In commercial situations, freezing rates of 0.5 cm h^{-1} in the deeper sections would be considered 'fast' and there would be considerable variation in freezing time within the meat. In laboratory studies samples are often much smaller than most commercial products i.e. 77.6 g in one study (11). Even with such small samples there was no significant difference in drip after 48 hours between cryogenic freezing at −90°C and a walk in freezer operating at −21°C.

Rapid freezing of products such as poultry joints results in very small reflective ice crystal at the surface. These give the product a very light appearance that is very desirable in some markets. Poor temperature control during storage will cause the small crystals to grow, merge and loose their lightness.

2. Freezing Systems

Many of the chilling systems already described (air, immersion, plate and cryogenic) can be used to freeze food when operated at a lower temperature. Since freezing is the object not something to avoid then with most foods there is no lower limit to the temperature that can be used in a freezing system. In practice the temperature used is based on availability of equipment, capital and running costs, throughput achieved and with unwrapped products weight loss.

Few mechanical refrigeration systems operate at temperatures below −45°C. Most food is frozen in air blast systems, operating typically at −35°C and an air speed of 3 m s^{-1}. Cryogenic systems using liquid nitrogen can produce temperatures down to −170°C and those using carbon dioxide −78°C.

D. Chilled Storage

Theoretically, there are clear differences between the environmental conditions required for chilling, which is a heat removal/temperature reduction process, and storage where the aim is to maintain temperature. However, in many air based systems chilling and storage take place in the same chamber and even where two separate facilities are used, in many cases not all the required heat is removed in the chilling phase. With some fruits and vegetables the rate of respiration during storage is sufficient to require heat removal if product quality is to be maintained.

1. Bulk Storage Rooms

Most unwrapped meat and poultry and all types of wrapped foods are stored in large air circulated rooms. To minimize weight loss, air movement around the unwrapped product should be the minimum required to maintain a constant temperature. With wrapped products low air velocities are also desirable to minimize energy consumption. However, many storage rooms are designed and constructed with little regard to air distribution and the maintenance of low localised velocities over products. Horizontal throw refrigeration coils are often mounted in the free space above the racks or rails of product and no attempt is made to distribute the air around the products. Using air socks it is claimed that an even air distribution can be maintained with localised velocities not exceeding 0.2 m s^{-1}.

2. Controlled Atmosphere Storage Rooms

Controlled atmosphere storage rooms were developed for specialized fruit stores, especially those for apples. Interest

is growing in the application of this technique to other commodities including meat and fish. In addition to the normal temperature control plant these stores also include special gas-tight seals to maintain an atmosphere which is normally lower in oxygen and higher in nitrogen and carbon dioxide than air. Additional plant is required to control the CO_2 concentration, generate nitrogen and consume oxygen.

There is growing interest in the use of controlled atmosphere retail packs to extend the chilled storage and display life of meat and meat products. Since the packs insulate the products efficient precooling before packaging is important.

E. Frozen Storage

If the temperature of the food is reduced to below −10°C within a few hours and maintained below that temperature then microorganisms, bacteria, moulds or yeasts will not grow. Microbially, the food will always remain as safe to eat as it was before freezing, irrespective of the length of frozen storage. Some microbiologists consider −5°C to be a practical maximum temperature to prevent the growth of microorganisms on food.

The textural quality of the food will change with time and conditions of storage. More importantly, the flavor will deteriorate with time. Ultimately these changes will result in an unacceptable product.

1. Textural Changes

Most of the textural changes that occur due to freezing and frozen storage only become apparent when the food is thawed. A few changes can be observed while the food is still frozen. The most noticeable of these are 'freezer burn' and in package frosting.

a. Freezer burn

Moisture is lost from the surface of a food when the vapour pressure at its surface is higher than that in the surrounding environment. Freezing considerably reduces the vapour pressure at the surface of a food but it is still likely to be higher than that in a frozen storage room or display cabinet. Ice from the exposed surface of unwrapped frozen food will sublimate directly into the surrounding environment. The rate of the subsequent desiccation will depend mainly on the rate of air movement over the surface and its humidity. Extreme desiccation will result in a layer of spongy, dry dark material developing on the surface. This is known as 'freezer burn.'

b. In package frosting

Tight packaging in heavyweight, moisture-resistant wrap will prevent freezer burn. Loose packaging will reduce freezer burn but can allow another problem 'in package frosting' to develop. In package frosting occurs when moisture from the surface of the food freezes on the inner surface of the package. Its main cause is poor temperature control in the store or cabinet.

c. Changes apparent on thawing

However, most of the textural changes caused by freezing are not noticeable until thawing. During the freezing process as the water turns to ice, it expands and the ice crystals formed cause the cell walls to rupture. Consequently, the texture of the product will be much softer when the product thaws.

These textural changes are more noticeable in fruits and vegetables that have a higher water content and especially those that are eaten raw. For example, when a frozen tomato is thawed, it turns into mush and liquid. This explains why celery, lettuce and tomatoes are not usually frozen. It is also the reason that frozen fruit are best served before they have completely thawed. In the partially thawed state, the effect of freezing on the fruit tissue is less noticeable.

In the case of vegetables the normal blanch treatment has a marked softening effect but further changes during freezing or frozen storage are comparatively small. However, if the vegetable is frozen in the raw state or is not correctly blanched then the enzymic action on pectic substances may lead to unacceptable changes in texture.

Textural changes due to freezing are not as apparent in products which are cooked before eating because cooking also softens cell walls. These changes are less noticeable in high starch vegetables, such as peas, corn and lima beans.

Consumers expect to purchase frozen meat at a lower unit price than a similar chilled product. This price differential is due to a belief that the quality of frozen meat is inferior to that of chilled. There is little in the published scientific literature to substantiate this view. Some publications show that freezing, frozen storage and thawing produce beneficial effects on the textural properties of pork loins. The taste panel used found the meat slightly tenderer with improved juiciness and an easier breakdown of particles. This was evidenced by the samples being less cohesive, easier to chew and releasing more moisture during mastication.

Meat frozen quickly after slaughter before the rigor process is complete and thawed rapidly contracts vigorously and exudes much drip. The resulting meat is very tough and this toughness does not disappear with extended cooking. The phenomenon is called 'thaw rigor' or 'thaw shortening' and can be avoided by holding meat prior to freezing. A long thawing process, where the meat remains in the −5 to −2°C range for a long period will alleviate the effect. A similar phenomenon is observed in fish filleted pre-rigor and frozen individually.

2. Storage Life

Three factors during storage — 1. storage temperature, 2. degree of fluctuation in the storage temperature and 3.

type of wrapping/packaging in which the food is stored — are commonly believed to have the main influences on frozen storage life.

Storage temperature has a marked effect on the behaviour of ice crystals that could be detrimental to the ultimate quality of the food. It has been demonstrated that frozen tissue stored for 180 days at −20°C has small ice crystal formations of irregular shape in the extracellular spaces. Storage for the same period at −3°C results in the development of large rounded ice formations with a concomitant compression of the muscle fibres. It is thus desirable that frozen meat should be stored at a sufficiently low temperature to prevent growth of ice crystals in the extracellular spaces.

Generally fluctuating temperatures in storage are considered to be detrimental to the product. Statements have been made that "temperature fluctuations produced during storage and transport of frozen food lead to activation of the recrystallization processes, causing enlargement of the ice crystals and diminishing advantages obtained in quick freezing of products." However it has been reported that repeated freeze-thaw cycles do not cause any essential change in the muscle ultrastructure and that several freeze-thaw cycles during a product's life cause only small quality damage (in terms of juice loss) or possibly no damage at all (12). A slight but significant improvement has been found in samples that have been frozen and unfrozen several times when tested by a taste panel.

If the temperature cycles were so severe that the surface temperature of the food rose above 3°C during the process then this could create a potential microbiological hazard.

Minor temperature fluctuations in a stored product are generally considered to be unimportant, especially if they are below −18°C and are only of the magnitude of 1 to 2°C. Well packed products and those that are tightly packed in palletized cartons are also less likely to show quality loss. When ground pork and beef were placed under fluctuating conditions of between −18°C and −23°C for a 6 month period the well packed samples showed no deterioration. However poorly packed samples were severely affected by the temperature swings.

The proteins of fish differ from those of meat in their higher susceptibility to damage in frozen storage. Frozen storage results in an increasing tendency to lose moisture on thawing and an increased firmness leading to toughness and dryness on cooking. These changes are the result of denaturation and cross linking reactions predominantly of the myofibrillar proteins.

3. Drip

Drip loss in frozen storage has been shown to increase with storage time and increase in storage temperature (13). After approximately 42 and 63 days drip from beef stored at −10 or −15°C had reached 80% and 90% respectively of its maximum. At −25°C, it required over 120 days to reach the 80% value.

Drip loss during thawing from ground beef patties was also found to increase with the length of time the patties had been in frozen storage (14). For higher fat content samples, drip loss increased from 1.8% in fresh samples to 12.5% after 20 weeks in storage. Higher drip losses in thawing were obtained from samples stored at −12.2°C than lower temperatures. However, there was no difference between storage temperatures of −23.3 and −34.4°C.

4. Flavour Changes

No marked changes in the flavour of fruit occur on freezing except after an extended process at elevated temperatures. Changes in flavour constituents of frozen fruit are generated during prolonged storage and increase as storage temperature is increased. The first significant change in stored frozen fruits is a loss of fresh aroma. After this some off flavours may develop that are dependent on the type of fruit. It is known that some fruits are more stable than others but the exact reason is not known.

Enzymes in fruits and vegetables are slowed down, but not destroyed during freezing. If not inactivated, these enzymes can cause colour and flavour changes as well as loss of nutrients.

Blanching inactivates enzymes in vegetables. Blanching is the exposure of the vegetable to boiling water or steam for a brief period of time. The vegetable must then be rapidly cooled in ice water to prevent cooking. Blanching is essential for top quality frozen vegetables.

Another type of chemical change that can take place in frozen products is the development of rancid off flavours. This can occur when fat, such as in meat, is exposed to air over a period.

Species has an influence on rancidity development. Investigations have been carried out on rancidity development in cooked and uncooked ground meat patties made from chicken, beef and pork. Initially TBA values in uncooked patties were higher in beef than in those made from either pork or chicken (Figure 112.1). Levels in chicken patties did not change appreciably during 150 d storage at −20°C. After 150 days TBA values in beef were approximately 7 times higher than those in chicken. Values in pork were 4 to 5.5 times as high as those in chicken. Cooked chicken patties had higher lipid oxidation potential than cooked beef or pork patties.

Other studies found a temperature and species interaction for pork and beef. In experiments the practical storage life (PSL) and high quality life (HQL) of pork were superior to beef at −5°C but at −10 and −20°C the storage life of beef was much longer. In other trials where more than one species was compared storage times were not fully presented or direct comparisons were not possible.

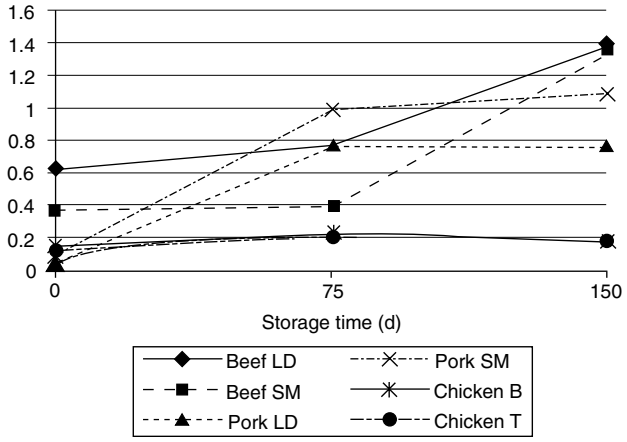

FIGURE 112.1 TBA values during storage at −20°C.

It seems fair to conclude that most work points towards a difference in frozen storage life between species. However, we currently lack the understanding to use data on the frozen storage life of one species under a given condition to predict the likely storage life of other species at that condition.

Animal to animal variation is believed to cause wide variations in storage times. Investigations in New Zealand found that animal to animal variation can lead to storage life differences as great as 50% in lamb, but does not give any definite reason for this variation. Two trials were carried out where lamb was stored at −5°C. In the first trial the lamb was judged rancid after 20 weeks and in a duplicate trial using identical temperature, processing and packaging conditions the lamb was found to store for 40 weeks. The only variation that could be determined was that different animals were used in the two trials.

Processing of meat prior to freezing generally results in a lengthened storage time. It has been found that the amount of TBA-reactive substances, in pre-rigor cooked boar, did not change during 3 months storage at −20°C. Heating prior to freezing can result in a 50% longer PSL for sausages and is thought to be due mainly to an inactivation of some enzymes present. Alternatively, it could be due to the inactivation of the catalytic activity of haemoglobin. However the heating process could be critical since muscles cooked to higher temperatures are most susceptible to oxidative changes during storage. Investigations have also found that pressure-cooking chicken breast at 0.36 kg cm^{-2} produced higher TBA values than cooking at atmospheric pressure.

Smoking is generally advantageous due to the antioxidant properties of the smoke. It has been suggested that wood smoke may not only aid frozen storage due to its antioxidant properties, but that the smoke may also mask off flavors. Smoked broilers were found to store well for over a year without serious quality change. Smoked ham was also found to store well for one year at −18°C without loss of flavour or weight.

Studies on chicken breast and salmon showed that fast and slow freezing, at undefined rates, had no effect on the rate of development of lipid oxidation during storage. Slightly higher levels were found in the fast frozen muscle. In studies on buffalo meat plate frozen meat was scored higher for colour, texture and overall quality than blast frozen samples. Tests were carried out after 3 months storage at −15°C and freezing times, for 500 to 600 g pieces, from 4 to −30°C were 280 and 140 minutes respectively for the plate and blast freezing operations. After 1 month storage TBA values in plate frozen cuts were significantly higher than in those blast frozen but the difference had disappeared after 3 months.

Few would disagree that storage temperature influences frozen storage life and that in general the lower the temperature the longer the PSL. However, few papers have been located where data are presented from experiments on the PSL of food at different storage temperatures. Many of those that have been located are on products that do not meet the lower temperature longer storage rule (normal stability).

It has been shown that rancidity in bacon is increased by higher salt content and that the rates of chemical reactions are accelerated as the temperature is lowered when packed in permeable wrap. Studies have shown that free fatty acids accumulate more readily in bacon stored at −30°C than bacon stored at −12°C. The highest rate of free fatty acid accumulation in bacon was found to be at −62°C. A similar trend was found in trials with liver paste. Cured pork products are known to have an abnormal temperature profile between −5°C and −60°C and store less well between −30°C and −40°C.

Pork chops, Vienna sausage and pork sausages have been found to have straight line quality loss data at lower temperatures but were non linear at higher temperatures. Their storage trials were carried out at −40, −30, −24, −18 and −12°C. Ground veal and pork were also found to have cubic curves at all temperatures.

Improved aroma scores have been found to be only moderately related to lower freezing temperatures, but were not related to flavour. Aroma scores for minced beef improved during 6–12 month storage at −12.2, −17.8 or −23.3°C, although a slight increase in rancidity also occurred. Temperature abuse of −6.7°C for 48 hours caused rancidity on the outside of the samples but did not affect the inner portion. After 24 weeks storage at −12, −18 or −23°C no differences due to storage temperature were found in ground beef patties containing mechanically recovered meat. Ground beef patties stored at −7°C were found to be tougher than those stored at −18 or −23°C. Severe quality deterioration was found in patties stored for 6 months at −7°C. Little difference was found between storage temperatures of −18 or −23°C over an 18-month period.

Consumer panels are often not very sensitive to quality changes. When a consumer panel was used, it could not tell the difference between samples of lamb stored at −5 and −35°C. A trained taste panel could differentiate between the two temperatures and scored the samples stored at −5°C as being rancid.

In recent years energy conservation requirements have caused an increased interest in the possibility of using more efficient storage temperatures than have been used to date. Researchers have questioned the wisdom of storage below −20°C and have asked whether there is any real economic advantage in very low temperature preservation. There is a growing realization that storage lives of several foods can be less dependent on temperature than previously thought, and since research has shown that meat and poultry often produce non-linear time-temperature curves there is probably an optimum storage temperature for a particular product. Improved packing and preservation of products can also increase storage life and may allow higher storage temperatures to be used. It has been suggested that foods should be split into high, medium and low stability categories, with −12°C for products with high stability and −28°C for products with low stability. Some believe that based on storage at −18°C, low stability meats such as mechanically recovered meat should be stored for 8 months or less. Medium stability meats such as pork and processed meats should be stored for between 8 and 15 months. High stability meats, which include all meat and poultry except pork, could be stored for more than 15 months.

F. Thawing and Tempering

Thawing has received much less attention in the literature than either chilling or freezing. In commercial practice there are relatively few controlled thawing systems.

Frozen meat, as supplied to the industry, ranges in size and shape from complete hindquarters of beef to small breasts of lamb, although the majority of the material is 'boned-out' and packed in boxes approximately 15 cm thick weighing between 20 and 40 kg. Frozen fish ranges from large plate frozen slabs to individually quick frozen (IQF) prawns in bags or boxes. Thawing is usually regarded as complete when the centre of the block or joint has reached 0°C, the minimum temperature at which the meat or fish can be boned or cut by hand. Lower temperatures (e.g. −5 to −2°C) are acceptable for product that is destined for mechanical chopping, but such product is 'tempered' rather than thawed. The two processes should not be confused because tempering only constitutes the initial phase of a complete thawing process.

Thawing is often considered as simply the reversal of the freezing process. However, inherent in thawing is a major problem that does not occur in the freezing operation. The majority of the bacteria that cause spoilage or food poisoning are found on the surfaces of food. During the freezing operation, surface temperatures are reduced rapidly and bacterial multiplication is severely limited, with bacteria becoming completely dormant below −10°C. In the thawing operation these same surface areas are the first to rise in temperature and bacterial multiplication can recommence. On large objects subjected to long uncontrolled thawing cycles, surface spoilage can occur before the centre regions have fully thawed.

Most systems supply heat to the surface and then rely on conduction to transfer that heat into the centre of the meat. A few use electromagnetic radiation to generate heat within the meat. In selecting a thawing system for industrial use a balance must be struck between thawing time, appearance and bacteriological condition of product, processing problems such as effluent disposal and the capital and operating costs of the respective systems. Of these factors, thawing time is the principal criterion that governs selection of the system. Appearance, bacteriological condition and weight loss are important if the material is to be sold in the thawed condition but are less so if it is for processing.

G. Secondary Chilling

Products are normally chilled immediately after slaughter or harvest. Most of the subsequent operations in the cold chain are designed to maintain the temperature of the food. Cooking is a very common operation in the production of many products and operators appreciate the importance of rapidly cooling the cooked product. However, any handling such as cutting, mixing or tumbling will add heat to the food and increase its temperature. A secondary cooling operation is always required with chilled products to reduce their temperature to approaching 0°C and maintain their storage life.

The aim of any cooking process is to ensure the destruction of vegetative stages of any pathogenic microorganisms. However, there is always the possibility that the cooking process will not kill some microorganisms that produce spores or that the food can become recontaminated. Therefore, microbiologists recommend that the temperature of the meat, for example, should be rapidly reduced, especially from approximately 60 and 5°C, to prevent multiplication of existing or contaminating bacteria. Rapid cooling is also desirable with cooked products to maintain quality by eliminating the overcooking that occurs during slow cooling.

There are specific cooling recommendations for cook-chill and cook-freeze catering systems. However, even with thin products these are difficult to achieve without surface freezing. Cooling large hams and other cooked meat joints is inherently a much slower process and studies have shown that companies often have very poor cooling systems.

The methods available to cool meat joints, pies and other cooked products have been described in detail (15). A review of the use of vacuum cooling in the food industry has been published (16).

The majority of plants rely on air blast cooling systems for the chilling of pre-cooked meat products. In batch systems the products, packs or trays of cooked material are placed directly on racks in the chiller or on trolleys that can be wheeled into the chiller when fully loaded. Continuous systems range from trolleys pulled through tunnels to conveyorized spiral or tunnel air blast chillers.

Some meals and products are chilled using cryogenic tunnels, however care must be taken to avoid surface freezing. Imperviously packed products can be chilled by immersion in cooled water or other suitable liquid. With some cooked products such as large hams in moulds and sausages, chlorinated water sprays can be used in the initial stages of cooling. Increasingly pie fillings are pressure-cooked and vacuum cooled. With many products an initial cooling stage using ambient air can often substantially reduce the cooling load in the cooling system.

H. Transportation

Developments in temperature controlled transportation systems for products have been one of the main factors leading to the rapid expansion of the chilled food market. The sea transportation of chilled meat from Australasia to European and other distant markets, and road transportation of chilled products throughout Europe and the Middle East, is now common practice. Air freighting was initially used for high value perishable products such as strawberries, asparagus and live lobsters. It is now increasingly used to provide consumers with a year round supply of locally out of season products such as green beans, mange tout and green on carrots.

1. Overland Transport

Overland transportation systems range from 12 m refrigerated containers for long distance road or rail movement of bulk chilled product to small uninsulated vans supplying food to local retail outlets. The majority of current road transport vehicles for chilled foods are refrigerated using either mechanical eutectic plates or liquid nitrogen cooling systems. Irrespective of the type of refrigeration equipment used, the product will not be maintained at its desired temperature during transportation unless it is surrounded by air or surfaces at or below that temperature. This is usually achieved by a system that circulates moving air, either forced or by gravity, around the load. Inadequate air distribution is probably the principle cause of product deterioration and loss of shelf life during transport. Conventional forced air units usually discharge air over the stacked or suspended products either directly from the evaporator or through ducts towards the rear cargo doors. Because air takes the path of least resistance it circulates through the channels that have the largest cross sectional area. These tend to be around rather than through the product. If products have been cooled to the correct temperature before loading and do not generate heat then they only have to be isolated from external heat ingress. Many trucks are now being constructed with an inner skin that forms a return air duct along the sidewalls and floor, with the refrigerated air being supplied via a ceiling duct.

2. Sea Transport

Recent developments in temperature control, packaging and controlled atmospheres has increased substantially the range of foods that can be transported around the world in a chilled condition. Control of the oxygen and carbon dioxide levels in shipboard containers have allowed fruits and vegetables such as apples, pears, avocado pears, melons, mangoes, nectarines, blueberries and asparagus to be shipped from Australia and New Zealand to markets in the USA, Europe, Middle East and Japan.

International Standard Organisation (ISO) containers for food transport are 6 or 12 m long, hold up to 26 tonnes of product and can be 'insulated' or 'refrigerated.' The refrigerated containers incorporate insulation and have refrigeration units built into their structure. Insulated containers either utilize plug type refrigeration units or may be connected directly to an air-handling system in a ship's hold or at the docks. Close temperature control is most easily achieved in containers that are placed in insulated holds and connected to the ship's refrigeration system.

3. Air Transport

Although air freighting of foods offers a rapid method of serving distant markets, there are many problems because the product is unprotected by refrigeration for much of its journey. Up to 80% of the total journey time is spent on the tarmac or transport to and from the airport. Perishable cargo is usually carried in standard containers, sometimes with an insulating lining and/or dry ice but is often unprotected on aircraft pallets.

I. Retail Display

The retail display of chilled food is probably still the weakest link in the cold chain. In the UK, the Food Hygiene (Amendment) Regulations 1990 required food retailers to maintain the temperature of certain chilled foods below 5 and others 8°C during storage, transport and display. This legislation, which contained severe financial penalties for temperature infringements, produced a marked improvement in the design, construction and operation of retail display cabinets. However, the leg-

TABLE 112.2
Temperatures Measured in 8 Surveys of Domestic Refrigerators in Homes

Reference	Country	Number of Samples	Measurement	T_{min}	T_{mean}	T_{max}	% > x°C
(17)	Northern Ireland	150	Thermometer (3 levels: T, M, B)	0.8	6.5	12.6	71% > 5°C
(18)	U.K.	252	Data logger (3 levels: T, M, B)	0.9	6.0	11.4	23% > 7°C
(19)	France	102	Thermometer (3 levels: T, M, B)			14	70% > 6°C
(20)	The Netherlands	125	Thermometer				70% > 5°C
(21)	New Zealand	50	Thermometer (2 levels: T, B)	0	4.9	11	60% > 4°C
(22)	Greece	136	Thermometer				50% > 9°C
(23)	France	119	Data logger (3 levels: T, M, B)	0.9	6.6	11.4	80% > 5°C
(24)	Northern Ireland	30	Data logger (1 level M)	−5	4.5	13.0	53% > 5°C

islation has since been relaxed and there is currently less emphasis on the maintenance of food temperatures.

The required retail display life and consequent environmental conditions for wrapped chilled products differ from those for unwrapped products. The desired display life for wrapped meat, fish, vegetables and processed foods ranges from a few days to many weeks and is primarily limited by microbiological considerations. Retailers of unwrapped fish, meat and delicatessen products normally require a display life of one working day.

Display cabinets for delicatessen products are available with gravity or forced convection coils and the glass fronts may be nearly vertical or angled up to 20°. In the gravity cabinet cooled air from the raised rear mounted evaporator coil descends into the display well by natural convection and the warm air rises back to the evaporator. In the forced circulation cabinets air is drawn through an evaporator coil by a fan and then ducted into the rear of the display. It then returns to the coil after passing directly over the products, or forming an air curtain, via a slot in the front of the cabinet and a duct under the display shelf.

Although the same cabinets can be used for wrapped foods, most are sold from multi-deck cabinets with single or twin air curtain systems. It is important that the front edges of the cabinet shelves do not project through the air curtain since the refrigerated air will then be diverted out of the cabinet. On the other hand, if narrow shelves are used the curtain may collapse and ambient air can be drawn into the display well. External factors such as the store ambient temperature, the position of the cabinet and poor pretreatment and placement of products substantially affect cabinet performance. Computational fluid dynamics (CFD) is increasingly being used as a valuable tool to improve air distribution and temperature control in retail display cabinets and retail stores themselves.

J. Domestic Handling

It is well known that unprotected chilled food will warm up during transportation to the home. Survey results showed that consumers took on average 43 minutes to bring meat, fish or dairy items home from the shops and place them in a refrigerator (10). Although insulated bags and boxes are widely sold only a small percentage (12.7%) used them to transport some of their food home. The vast majority (87.3%) of people did not use any means of protecting food from temperature gains during transportation. Some of the meat product temperatures in samples placed in a car boot rose to around 30°C during the one hour car journey whilst most of the samples placed in a insulated box cooled during the car journey except for a few at the top of the box which remained at their initial temperature. The temperature of frozen products (starting at −25°C) placed in both the cold box and ambient rose during the 1-hour journey. Temperatures of chickens and meat pies placed in ambient reached temperatures approaching 10°C. Frozen meat products, in the cold box kept below −10°C for the period of the journey.

In the past decade there have been at least eight surveys of temperatures in domestic refrigerators. The results are very similar (Table 112.2) with overall mean temperatures ranging from 4.5 to 6.6°C and maximum temperatures from 11 to 14°C. These results are very worrying since they imply that the average temperature of at least 50% of domestic refrigerators is above 4.5°C. When we look at the percentage of temperatures measured that were above set points the results are even more worrying. In the last French study 80% of the temperatures were above 5°C and in the Greek work 50% above 9°C. In Jackson's ongoing investigations only 17% operated below and 20% operated above 5°C for the entire week of monitoring.

III. CONCLUSIONS

Refrigeration has a key role in maintaining the safety and eating quality of most foods. However, it is critical that foods are cooled to the optimum temperature after harvest and processing and that temperature is maintained throughout the cold chain.

Due to the introduction of freezing in the early part of the 20th century meat, fish and some vegetables became readily available year round. Now many 'fresh' chilled products are available at all times of the year due to developments in the chill chain especially in refrigerated storage and transportation. Refrigeration is continuing to develop and an increasing range of raw materials and completely finished refrigerated meals are appearing on the market. Due to demographic changes in the developed world these trends are predicted to continue in the future.

113 Microwavable Frozen Food or Meals

CONTENTS

I. INTRODUCTION

The microwave oven was first developed during the 1950s and became a popular household appliance when its penetration level soared during the 1980s—currently, more than 90% of the US households own at least one microwave oven. The major driving forces for the microwave oven are changing lifestyles and development of microwavable food products.

The changing lifestyles in recent years (two income families, single parents, school-age children home alone) are increasingly putting a premium on convenience and quick preparation of food. The microwave oven captures this opportunity by providing a convenient means for the consumer to cook or reheat food quickly and easily. At the same time, the food industry has also developed new products or reformulated existing products for the microwave oven. Microwavable food products are now ubiquitous in the supermarket. In particular, microwavable frozen meals are a major category since they provide a convenient solution to people who do not have time to prepare their own meals. The packaging industry has also contributed to developing new technologies and packages that are compatible to microwave heating. The consumer can quickly microwave a frozen meal in a container and enjoy the meal from the same container.

While microwavable food products have made significant inroads in the past two decades, there still remain many challenges for the developer and manufacturer. Besides convenience, other factors such as taste and texture are also important to the consumer. Quite often, the consumer perceives food heated by the microwave oven do not taste as good as that heated by the conventional oven. This is because the heating mechanisms of food in the microwave oven and conventional oven are indeed quite different. To develop successful microwavable food products, the developer must have a good understanding of the microwave heating of food, as well as careful considerations of the package design and consumer expectation.

II. BASICS OF MICROWAVE HEATING OF FOOD

Microwave heating of food is a complex process that requires a good understanding of several relevant disciplines: electromagnetism, food engineering, food chemistry, food packaging, and food microbiology. It is beyond the scope of this chapter to provide detailed descriptions of the many aspects of this complex process. Instead, this chapter is aimed at acquainting the reader with the basic working knowledge most relevant to the microwave heating of frozen foods. More general information can be found from references in the literature (1–3).

A. Microwaves

Microwaves are short electromagnetic waves located in the portion of electromagnetic wave spectrum between radio waves and visible light. The energy is delivered in the form of propagating sine waves with an electric field and a magnetic field orthogonal to each other. Microwaves are relatively harmless to human because they are a form of non-ionizing radiation, unlike the much more powerful ionizing radiation (such as x-ray or gamma ray) that can damage the cells of living tissue. Microwaves are used in daily applications such as cooking, radar detection, telecommunications, and so on.

Most microwave ovens for food applications operate at two frequencies. The household microwave oven operates at 2450 MHz (2.45×10^9 cycles per second), and the industrial microwave oven operates at 915 MHz (9.15×10^8 cycles per seconds). The wavelengths associated with those frequencies are 0.122 and 0.382 m, respectively, when the microwaves are assumed to travel at the speed of light (3×10^8 m/sec). Microwaves travel at approximately the speed of light in air, but they travel at a lower speed inside a food material. The relationship between frequency and wavelength is expressed by the equation, $v = f\lambda$, where v is velocity (m/sec), f is frequency (Hz), and λ is wavelength (m) of electromagnetic wave.

There are three possible modes of interaction when microwaves impinge upon a material: absorption of microwaves by the material, reflection of microwaves by the material, and transmission of microwaves through the material. The material may be a food or a packaging material. The food must absorb a portion of the microwave energy in order for heating to occur. Most foods do not reflect microwaves, and thus all the remaining unabsorbed microwave energy is transmitted. Some packaging materials, such as susceptors, absorb microwave energy and become hot. Metals, such as aluminum foils, reflect microwaves. Paper, plastics, and glass are transparent to microwaves. To optimize the microwave heating of food, it is necessary to consider the reflection, absorption, and transmission of microwaves by the food and the package.

In the microwave oven, microwaves are generated by an electronic vacuum tube known as magnetron. The microwaves then travel through a hollow metal tube called "waveguide" to the oven cavity. To improve the heating uniformity, the microwave oven is often equipped with a stirrer or a turntable. The stirrer is a fanlike set of spinning metal blades used to scatter the microwaves and disperses them evenly within the oven. The turntable rotates the food during the microwave process. The history, features, standardization, and safety matters relating to the microwave oven are discussed by Decareau (1).

B. Microwave/Heat Conversion

Microwave energy is not heat energy. In order for microwaves to heat food, they must first be converted to heat. There are two mechanisms by which this energy conversion can occur: dipole rotation and ionic polarization. The two mechanisms are quite similar, except the first involves mobile dipoles while the second involves mobile ions. Both dipoles and ions interact only with the electric field, not the magnetic field.

Figure 113.1(a) illustrates the dipole rotation mechanism of a polar molecule. In the presence of an electrical field, the polar molecule behaves like a microscopic magnet, which attempts to align with the field by rotating around its axis. As the polarity of the electric field changes, the direction of rotation also changes. The molecule thus absorbs microwave energy by rotating back and forth billions of times at the frequency of microwaves. Since the molecule is often bound to other molecules, the rotating action also causes it to rub against those other molecules. The rubbing action disrupts the bonds between the molecules, which in turn causes friction and heat dissipation.

Water molecule is the most abundant polar molecule in food. The water molecules in liquid water are quite mobile, and they readily absorb microwave energy and dissipate it as heat through dipolar rotation. In contrast, the water molecules in ice are much less mobile due to the confined crystal structure, and they do not absorb microwave

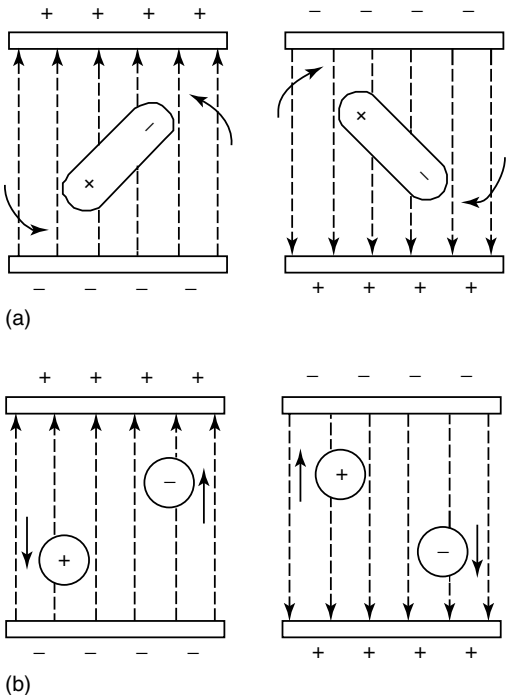

FIGURE 113.1 Microwave/heat conversion mechanisms. The dashed lines denote the alternating electric field at the frequency of microwaves. (a) A dipole rotates back and forth. At high frequencies (such as 2450 MHz), there is not sufficient time for the dipole to rotate 180°, and thus the actual rotation angle is much smaller. (b) A positive ion and a negative ion oscillate in an alternating electric field.

well. The distribution of moisture and the state of water (liquid water or ice) are often two critical factors that determine the behavior of microwave heating of foods.

Figure 113.1(b) illustrates the ionic polarization of a positive ion and a negative ion in solution. In the presence of an electric field, the ions move in the direction of the field. As the polarity of the electric field changes, the ions move in the opposition direction. The ions absorb microwave energy by oscillating themselves at the frequency of microwaves. The oscillating action in turn causes heat dissipation through friction. The common ions in food are those from salts such as sodium chloride. Since ions are less abundant than water molecules in most foods, ionic polarization often plays a less important role than dipole rotation.

C. Dielectric Properties

While dipole rotation and ionic polarization provide a qualitative understanding of the microwave/heat conversion mechanisms, the dielectric properties provide a quantitative characterization of the interactions between microwave electromagnetic energy and food. The dielectric properties, along with thermal and other physical properties, determine the heating behavior of the food in the microwave oven.

TABLE 113.1
Dielectric Constant (ε′), Dielectric Loss Factor (ε″), and Penetration Depth (D_p) of Various Foods at 2450 MHz

	ε′	ε″	D_p (cm)
Ice (−12°C)	3.2	0.0029	1203
Water (1.5°C)	80.5	25.0	0.71
Water (25°C)	78	12.48	1.38
Water (75°C)	60.5	39.93	0.40
0.1 M NaCl (25°C)	75.5	18.1	0.94
Fat and Oil (average)	2.5	0.15	20.6
Raw Beef (−15°C)	5.0	0.75	5.83
Raw Beef (25°C)	40	12	1.04
Roast Beef (23°C)	28	5.6	1.85
Boiled Potatoes (−15°C)	4.5	0.9	4.6
Boiled Potatoes (23°C)	38	11.4	1.07
Boiled Spinach (−15°C)	13	6.5	1.11
Boiled Spinach (23°C)	34	27.2	0.45
Polyethylene	2.3	0.003	986
Paper	2.7	0.15	21.4
Metal	∞	0	0
Free Space	1	0	∞

An important dielectric property is dielectric loss factor (ε″), which indicates the ability of the food to dissipate electrical energy. The term "loss" refers to the loss of energy in the form of heat by the food. It is useful to remember that a material with a high ε″ value (also known as a lossy material) heats well, while a material with a low ε″ value heats poorly in the microwave oven. The dielectric loss factor is related to two other dielectric properties by the equation:

$$\tan \delta = \varepsilon''/\varepsilon' \qquad (113.1)$$

where tan δ is loss tangent and ε′ is dielectric constant.

The dielectric properties (ε′ and ε″) are functions of frequency, temperature, moisture content, and salt content. Values of dielectric properties for foods and other materials can be found in the literature (4–6). Examples of ε″ and ε′ values at 2450 MHz are shown in Table 113.1. Although the literature values can be used as guidelines, actual measurements are often required because of the variability of composition of the materials.

The dielectric properties provide a quick indication of how well a material heats in the microwave oven. For example, the ε″ value of water (12.48) at 25°C is several orders of magnitude higher than that of ice (0.0029) at −12°C. This means water heats far better than ice in the microwave oven. Ice is almost transparent to microwaves because its molecules are tightly bound and do not rotate easily through the mechanism of dipolar rotation. The dramatic increase in ε″ value is also observed, when ice changes to water, during the thawing of frozen foods

including beef, potato, and spinach (Table 113.1). Plastics and paper have low ε'' values because they are almost transparent to microwaves.

D. Penetration Depth

The speed of microwave heating is due to the deep penetration of microwaves into the food, and the dielectric properties can be used to determine the extent of penetration. When microwaves strike a food surface, they arrive with some initial power level. As microwaves penetrate the food, their power is attenuated since some of their energy is absorbed by the food. The term penetration depth (D_p) is defined as the depth at which the microwave power level is reduced to 36.8% (or 1/e) of its initial value, which can be estimated using the equation:

$$D_p = \frac{\lambda_o}{2\pi\sqrt{2\varepsilon'}}\left[\left(1 + \tan^2\delta\right)^{1/2} - 1\right]^{-1/2} \quad (113.2)$$

where λ_o is wavelength in free space. At 2450 MHz, $\lambda_o = 12.24$ cm

$$D_p = 1.38\left\{\varepsilon'\left[\left(1 + \tan^2\delta\right)^{1/2} - 1\right]\right\}^{-1/2} \quad (113.3)$$

where D_p is in cm. The penetration depth is a "visual term" that describes how well a food absorbs microwaves: the shorter is the penetration depth, the more the food absorbs microwaves.

The meaning of penetration depth is further illustrated in Figure 113.2. At the first D_p, 36.8% of the initial power remains, while 63.2% of the power is absorbed. At the second D_p, $(0.368)^2 = 13.5\%$ remains and 86.5% is absorbed. At the third D_p, $(0.368)^3 = 5.0\%$ remains and 95% is absorbed. The penetration depth depends on the composition of material, the frequency of microwaves, and temperature.

Typical values of D_p for various materials at 2450 MHz are also shown in Table 113.1. As mentioned earlier, liquid water absorbs microwaves far better than ice. The D_p of water at 25°C is 1.38 cm, but D_p of ice at −12°C is 1203 cm! Frozen foods have longer penetration depths than unfrozen foods. For example, the D_p values for frozen beef and unfrozen beef are 5.83 cm and 1.04 cm, respectively.

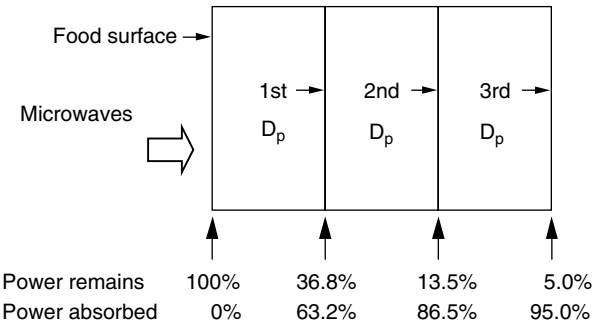

FIGURE 113.2 Power levels at various penetration depths.

E. Mathematical Equations and Models

Besides Equation (113.2), other simple equations can also provide researchers and food product developers a better understanding of the microwave heating process. For example, the microwave power absorption can be estimated using the equation:

$$P = k\,\varepsilon''\,f\,E^2 \quad (113.4)$$

where P is power absorption (watts/cm^3), k is constant (5.56×10^{-13} farads/cm), ε'' is dielectric loss factor of food (dimensionless), f is frequency of microwaves (Hz), and E is electric field strength of microwave (volts/cm). The power absorption is directly proportional to the dielectric loss factor, indicating that a lossy material (which has high ε'' value) is also a good absorber of microwave energy.

The rate of temperature increase of the food can be estimated using the equation:

$$\frac{dT}{dt} = \frac{k\,\varepsilon''\,f\,E^2}{\rho\,C_p} \quad (113.5)$$

where T is average temperature of food (°C), t is time (sec), ρ is density of food (g cm^{-3}), and C_p is specific heat of food (J g^{-1} °C^{-1}). Equation (113.5) is an energy balance equation, which assumes the microwave energy absorbed is balanced by the heat gain of the food. Note that this is a relatively simple equation, and it does not consider the fact that temperature is not evenly distributed within the food.

Mathematical models based on heat-and-mass transfer principles are also available to provide more sophisticated information during the microwave heating of food (7,8). A typical model consists of a set of partial differential equations with the proper initial and boundary conditions. The models can be used to predict the temperature and moisture distribution histories of foods during microwave heating. To use the models, values for dielectric properties, thermal properties, density, electrical field strength, and product dimensions are required. Models for frozen food are more complicated than those for unfrozen food, because the microwave heating behavior changes greatly from the frozen state to unfrozen state.

The models can simulate what-if scenarios and thus can help to minimize the number of experiments and shorten the product development time. However, the models are limited mostly to the predictions of temperature and moisture content, and they do not deal with other important factors such as taste and texture. Most models are also limited to foods that are homogenous and have regular shapes.

III. CHALLENGES IN MICROWAVE HEATING OF FROZEN FOOD

While microwave heating offers the benefits of speed cooking and convenience, it also presents many technical challenges to the food scientist or technologist. Those challenges arise from the need to deal with the many variables relating to the food, package, and microwave oven. For the food, there are variables of food composition, shape, size, specific heat, density, dielectric properties, and thermal conductivity. For the package, there are variables of shape, size, and properties of packaging material. For the microwave oven, there are variables relating to the design of the oven. A related and more important challenge is to solve the problems of the consumer. From the consumer's point of view, the most noticeable problems are those associated with nonuniform heating, lack of browning and crisping, and variation in microwave ovens.

A. Nonuniform Heating

Nonuniform heating is a major problem associated with microwave heating. The problem is especially noticeable for frozen food. It is not uncommon for a frozen food heated in a microwave oven to boil around the edges while the center remains frozen. The problem is caused by the differences in microwave energy absorption of liquid water and ice.

In frozen foods, the water molecules on the surface are relatively free to move compared to the water molecules inside the food. When a frozen food is microwaved, heating begins at the surface where the water molecules are more ready to absorb microwave energy. This causes the adjacent ice crystals to melt and the surface temperature to rise, while the inside temperature is still little affected. As more liquid water is available, the heating of the surface becomes more rapid. This can lead to "runaway heating," in which heating is excessive at the surface while the inside is still frozen. To minimize runaway heating during thawing, microwave energy should be delivered at a slow rate, which allows more time for heat to conduct from the surface to the inside.

Irregular shape of the food can also cause nonuniform heating. The thin parts tend to overcook, while the thick parts tend to undercook. This situation also occurs in conventional cooking but is less pronounced because the cooking is slower. Another cause of non-uniform heating is that different foods have different dielectric and thermal properties. When a microwave meal consists of two or more items, it is possible that the items heat at different rates. For example, when microwave heating a frozen meal consisting of meat and vegetable, the vegetable often becomes overheated and dried out before the meat reaches the serving temperature.

B. Lack of Browning and Crisping

Another problem is that, unlike the conventional oven, the microwave oven is not able to produce foods that are brown and crisp. This is because the heating mechanisms of the conventional oven and the microwave oven are quite different.

In the conventional oven, the food is heated by hot air in the oven, and if the heating element is not shielded, the food is also heated by radiated heat. Heating is concentrated on the food surface by means of heat convection and radiation. The inside of the food is also heated, at a slow rate, by means of heat conduction. The heating causes the moisture on the food surface to evaporate rapidly, and later, browning and crisping to occur. Although the moisture inside the food tends to migrate to the surface, the rate is not sufficiently fast to prevent browning and crisping. As a result, the food surface becomes brown and crispy while its inside remains moist and soft.

In the microwave oven, there is no hot air, and heating is mostly due to the interaction between microwaves and water. Microwave heating is not concentrated on the food surface, but it is distributed within the food depending on the penetration depth. The heating on the food surface is no longer sufficiently intense to cause browning and crisping. Unless the food is microwaved for a long time to remove all or most of the water in the food (which is not desirable because the food quality may no longer be acceptable), browning and crisping either do not occur at all or are inadequate.

Browning formulations have been developed for various meat and dough products (1). Commercial steak sauces, barbecue sauces, soy sauces, and the like are brushed on meat before microwave heating. Reusable browning dishes are also available for browning food surfaces in the microwave oven. Most of the commercial browning dishes are made of glass-ceramic substrate with tin oxide coating on the underside. The packaging industry has also developed a disposable browning and crisping material, known as susceptor, discussed later in this chapter.

C. Variation in Microwave Ovens

Yet another problem is the large variation of performance in different microwave ovens. Microwave ovens are available in different powers, oven cavity sizes, with or without a turntable, with or without a stirrer (to distribute microwaves more evenly in the oven). Consequently, different microwave ovens may produce greatly different results, even if the same cooking instructions are used. To accommodate the differences, the food manufacturer can only place vague microwave heating instructions on their packages. For example, a package may contain vague instructions such as "heat between 4 to 8 minutes, depending on the microwave oven."

D. Meeting the Challenges

There is no easy solution to deal with the complex process of microwave heating. In developing a microwavable food product, the scientist or technologist has to rely on the somewhat useful but incomplete scientific knowledge described in the previous sections, as well as trial-and-error or empirical methods.

From the discipline point of view, there are three approaches to deal with the challenges. The first is the food chemist's approach, in which food ingredients are modified and browning formulations are added to make the food more microwavable. The second is the packaging engineer's approach, in which the package is modified to enhance the performance of microwave heating. The third is the microwave engineer's approach, in which new and useful features are added to the microwave oven. Ideally, these approaches should be integrated into a system to deliver the highest quality of microwavable foods to the consumer.

Many microwavable food products have failed in the past because of lack of performance or high cost. Good technical and marketing tools are essential for developing better tasting microwavable products, without increasing the cost or decreasing the effectiveness of cooking. Although the food manufacturer and the packaging supplier have been working together to develop microwavable products, there has been relatively little collaboration between them and the oven manufacturer. There is a need to have all parties (including also the academia) to work more closely together to bring about innovations that can deliver better microwavable products to the consumer.

IV. MICROWAVABLE PACKAGING

The primary functions of the package are to contain, protect, and sell the product. A general discussion on the packaging of frozen foods is presented in Chapter 133. If the package is used to hold the food during microwave heating (as is the case for many microwavable frozen meals), the interactions between microwave and the package must also be considered. Since the package can transmit, reflect, or absorb microwaves, it can also greatly influence the microwave heating behavior. The package may act "passively" by simply transmitting microwaves. The package may also act "actively" by reflecting and absorbing microwaves in a manner that the power distribution of microwaves and the surface temperature of package are modified. To optimize microwave heating, it is necessary to properly balance these three microwave/package interactions (transmission, reflection, and absorption) to optimize the heating of the food. Microwavable packaging materials may be classified into microwave transparent materials, microwave reflective materials, and microwave absorbent materials.

A. Microwave Transparent Materials

A microwavable package must be wholly or partly transparent to microwaves. The most common microwave transparent materials are paper and plastics. Although glass is also transparent to microwaves, it is seldom used to package frozen food.

Plastic-coated paperboard trays are popular for microwavable frozen meals, mainly because of their low cost. The trays combine the rigidity of the paperboard and the chemical resistance of the plastic. The inside of the trays is either extrusion coated with a resin or adhesive laminated with a plastic film. For microwave-only applications, plastics such as low-density polyethylene (LDPE), high-density polyethylene (HDPE), and polypropylene (PP) are used. For dual oven applications (i.e., usable in both microwave and conventional ovens), polyethylene terephthalate (PET) is used because of its high temperature stability (up to about 200°C).

Molded pulp trays are another common paper product. The containers are dual ovenable and can be molded into several compartments. They are stronger and can carry more load than the paperboard containers.

Thermoformed plastic trays are also common heating containers for microwavable frozen foods. LDPE trays are suitable for light microwave heating because the trays tend to distort at temperatures as low as 75°C. PP trays have a distortion temperature of about 110°C. Homopolymer PP trays are brittle at low temperatures and can crack during distribution and handling at freezer temperatures. Copolymer PP trays have somewhat improved low-temperature durability. Crystallized PET (CPET) trays are the most widely used plastic trays for microwavable frozen meals. The CPET trays are functional in the temperature range from −40 to 220°C. Thus the trays can withstand not only the low temperatures encountered in distribution and handling, but also the temperatures in conventional oven (i.e., the trays are dual ovenable).

B. Microwave Reflective Materials

Aluminum foil, aluminum/plastic laminate, and aluminum/plastic/paperboard laminate are the most common microwave reflective materials. Since these materials do not allow the transmission of microwave, they are also known as microwave shielding materials.

Aluminum is often used to selectively shield microwaves from certain areas of a food (Figure 113.3). For example, a multi-component meal may consist of food items that heat at different rates in the microwave oven. The more microwave sensitive food item(s) can be shielded so that the entire meal can be heated more evenly.

Aluminum is also used as an electromagnetic field modifier to redirect microwave energy in a manner to optimize the heating performance (10). Aluminum can intensify the microwave energy locally or redirect it to places

FIGURE 113.3 Trays with selectively shielded areas. (Courtesy of Graphic Packaging Inc.)

FIGURE 113.4 Metallized film susceptors. (Courtesy of Graphic Packaging Inc.)

in the package that otherwise would receive relatively little direct microwave exposure. This approach has been used to redirect microwave energy from the edges to the center for frozen food products such as lasagna.

When aluminum foils are used in the microwave oven, precautions are necessary to prevent arcing, which can occur between foil packages and the oven walls, between two packages, across tears, wrinkles, and so on. Arcing can be prevented by following several simple design rules (11). For example, any foil components should be receded from the edge of the package to avoid arcing with the oven walls. In additional to following those rules, it is also necessary to thoroughly test the package/product to ensure that the package is safe to use.

C. Microwave Absorbent Materials

Microwave absorbent materials used for food packaging are commonly known as susceptors. The major purpose of susceptors is to generate surface heating to mimic the browning and crisping ability of the conventional oven. Although many types of susceptors have been invented (12), the only commercially available type is the metallized film susceptor (Figure 113.4). This type of susceptor consists of a metallized polyethylene terephthalate film laminated to a thin paperboard. The metal layer is a very thin (less than 100 angstroms), discontinuous layer of aluminum, which is responsible for generating localized resistance heating when exposed to microwaves. The heating can cause the susceptor to reach surface temperatures over 200°C within seconds.

Susceptors have been used for products such as frozen pizza, frozen French fries, frozen waffles, frozen hot pies, and popcorn. Susceptors are available in the forms of flat pads, sleeves, and pouches. The flat pads are suitable for products (such as pizza) that require heating only on one surface. The sleeves and pouches are suitable for heating on multiple surfaces (9). Susceptors are also available in various patterns, in which portions of the metallized layer are deactivated (10). The patterns are designed to provide more control of heating. A company uses a printed checkerboard pattern to generate various levels of heating based on the size of the check.

There is a public concern of migration of mobile compounds from the susceptor to the food, because the susceptor can reach high temperature. The FDA has issued voluntary guidelines regarding the safe use of the susceptor for the packaging company to follow.

V. ADVANCED OVENS

Although the oven manufacturer has made many improvements to the microwave oven, especially during the last two decades, it has also encountered the challenges described earlier. Recently, the oven manufacturer has responded to those challenges by introducing more advanced ovens, such as the high-speed ovens and intelligent ovens described below. These advanced ovens are superior to the microwave oven, and they can provide better heating for frozen food products.

A. High-Speed Ovens

High-speed ovens are essentially multimode ovens equipped with advanced technologies. The move towards using multimode heating instead of single-mode heating to deliver higher speed and food quality is a technically sound one, because any single-mode heating (microwaves or convective heat) has too many inherent limitations. The current commercial high-speed ovens differ from one another in terms of hardware and software.

In hardware, the major difference is in the heating sources: microwaves, convective heat, hot-air impingement, and halogen light. Although it is possible to use more than two heating sources, most ovens are limited to only two heating modes because of the considerations in cost and

power consumption. The high-speed ovens typically use microwaves to provide speed cooking, along with another heating source for browning and crisping. Major oven manufacturers have marketed high-speed ovens using microwave/light and microwave/convective heat. A manufacturer has also developed a vending machine that heats frozen meals using microwave/jet impingement.

In software, the major difference among the ovens is in the ways of controlling the cooking process. Various cooking algorithms have been developed to control the heating sources and heating time. In the future, software development will likely incorporate more food science and technology (to develop cooking instructions, provide nutritional information, etc.), better user interface technology, and the use of fuzzy logic.

B. Intelligent Ovens

In recent years, researchers have also developed the so-called "intelligent ovens," which use information technology to overcome some of the limitations of the microwave oven and enhance the cooking experience of the consumer. An example of the intelligent oven is shown in Figure 113.5.

The intelligent oven is a multimode oven (e.g., microwave/convective heat oven) equipped with a bar code scanner and a microprocessor (13). The oven is connected to an input/output device (such as a touch screen) and the Internet. Below are some advantages of the oven:

1. As mentioned earlier, the heating instructions on food packages are intentionally vague to accommodate the many types of microwave ovens in the market. The intelligent oven can overcome this problem. By scanning the bar code on the food package, its microprocessor is able to generate the precise heating instructions that match the food and the oven.
2. The scanning eliminates the need of entering the heating instructions manually. This is particular convenient when the instructions involve complicated multiple heating sequence, especially for multimode ovens. This feature is also helpful for visual impaired consumers.
3. The Internet connection allows the access of information relating to nutrition, product recall, allergenic ingredients, and so on.

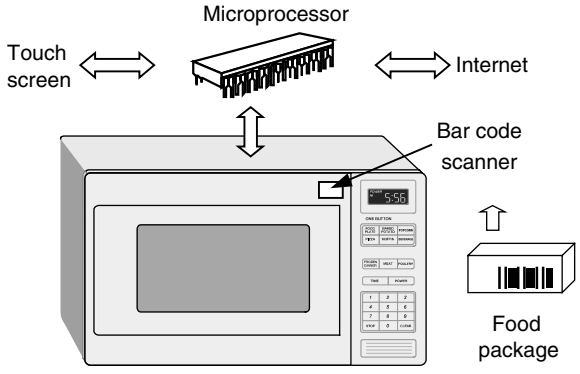

FIGURE 113.5 An intelligent oven.

VI. SUMMARY

While microwavable frozen food and meals have become an integral part of our lifestyle, improvements are still needed to continue to justify their place in the freezer case. Although microwavable frozen products can provide the consumer with convenience, they often fail to impress the consumer with taste and texture. There are many technical and economical challenges for developing new and improved microwavable frozen products. To meet those challenges, the industry (food manufacturer, packaging supplier, and oven manufacturer) and the academia should work more closely together to innovate and develop better microwavable food products that are more tasty, healthy, and convenient to use.

ACKNOWLEDGEMENT

CONTENTS

I. INTRODUCTION

One of the greatest challenges for food technologists is to maintain the quality of food products for an extended period. A decrease in temperature generally decreases the rate of chemical reactions that are responsible for the deterioration in food quality over time; therefore freezing is frequently used to extend the shelf life of food products. However, freezing is not a perfect method of preservation because even at low temperatures deterioration of quality may still occur. The formation of ice may result in textural changes and disruption of cell compartments that cause the release of chemically reactive components. Furthermore, the removal of water during ice formation concentrates the solutes in an unfrozen matrix, which can affect reaction conditions, such as pH and ionic strength. Therefore, in order to extend the shelf life of frozen food products it is crucial to understand the chemical reactions and their kinetics that occur in food components that can lead to quality deterioration.

The effect of freezing on the food components is diverse and some components are affected more than others. For example protein can be irreversibly denatured by freezing whereas carbohydrates are generally more stable. This chapter focuses on chemical and biochemical reactions that affect the quality of frozen food systems. These reactions and specific examples in food are summarized in Table 114.1. Methods for reducing the rate of deterioration are also discussed in this chapter.

II. CHEMICAL AND BIOCHEMICAL REACTIONS IN FROZEN FOOD

A. Protein

Protein may undergo changes during freezing and frozen storage, primarily because of denaturation. Denaturation can be defined as a loss of functionality caused by changes in the protein structure due to the disruption of chemical bonds and by secondary interactions with other constituents [1]. Alterations of the secondary and higher structures of proteins affect the spatial arrangement of the polypeptide chain with respect to other neighboring polypeptide chains [1, 2]. Structural and spatial alterations can cause a range of textural and functional changes, such as the development of toughness, loss of protein solubility, loss of emulsifying capacity and loss of water holding capacity [3–5]. The myofibrillar proteins (mainly myosin and actomyosin) are

TABLE 114.1
Chemical Reactions of Food Components that Affect Food Quality

Food Components	Mechanism of Degradation	Effect on Food Quality	Studies in Food
Protein	Denaturation	Degradation of texture and functional properties	• Toughening and functional changes, particularly loss of protein solubility, in fish [4, 12, 14, 19] • Loss of protein solubility, emulsifying capacity and water holding capacity of meat for processing [3]
Lipid	Hydrolysis	Release of FFA — known to contribute to unpleasant flavors	• Short chain FFA giving rancid odor in dairy product [88] • Medium chain FFA caused a "sweaty" flavor in mutton [89] • Toughening of muscles in frozen Indian oil sardine [8]
	Oxidation • Autoxidation • Enzymatic oxidation	Unstable hydroperoxides break down to reactive compounds and interact with other components to produce off-flavors, discoloration and toughening of muscle protein	• Off-flavors shelled oysters [35] • Detection of rancid flavor in silver pomfret [90]
Carbohydrates	Hydrolysis	Increases the amount of smaller molecular weight components — leads to lower melting temperatures	• Sucrose hydrolysis [47]
		Change of texture	• Firmness of ice cream decreased as hydrolysis progressed [46]
Color Pigments			
(a) Chlorophyll	Pheophytinization	Green chlorophyll forms olive-brown pheophytin in the presence of acid or heat	• Greenness in Brussels sprouts decreased [80] • Stability of green colour in kiwifruit [54, 55] • Frozen blanched spinach had a higher amount of pheophytin than fresh [91]
(b) Anthocyanin	Enzymatic reaction	Glucosidase hydrolyses glycosidic linkages and produces sugars and agylcone compounds	• Loss of anthocyanin in raspberry in the late cultivar was more severe than the early cultivars [59]
	Structure of anthocyanin depends on pH value	Depending on the pH of the food, different forms of anthocyanin exist, usually from red to blue as pH increases	• Red color hue of sour cherry weakens during frozen storage [92]
(c) Carotenoids	Oxidation	The loss of pigments causes fading of color and loss of nutritive value	• Loss of carotenoid in salmon [40]
Flavor Compounds	Enzymatic degradation	Change of flavor profile	• Change in the composition of aromatic compounds of strawberries [67–69] • Change in aroma profile of frozen green peas [70]
	Lipid oxidation	Produces off-flavors	• Green and fatty off-flavor notes in frozen trout due to breakdown products of unsaturated FFA [74]
	Leaching of components during the blanching process	Weakens and changes the sensory perception	• Decrease of organic acids in green beans and Padron peppers [72] • Change in volatile composition of guava [76]
	Effect of heat		• Changes in concentration of odorants during heat treatment [69]
Micronutrients			
(a) Vitamins	Oxidation	Loss of nutritional value because of the loss of vitamins	• Loss of AA and vitamin B6 due to blanching in french fries [81] • Oxidation of AA in peas, lima beans, corn and green beans [82]
(b) Minerals	Generally stable		• Unchanged mineral composition in artichokes, green beans and peas after freezing [87]
	Loss mainly through leaching		• Mineral content of boiled fresh vegetables was not different from frozen vegetables [78]

considered to be the most susceptible to denaturation, while sarcoplasmic proteins have been reported to be more stable [6]. For example, in fresh-water whitefish stored for 16 weeks at −10°C the actomyosin solubility decreased by 50% but the sarcoplasmic proteins were unaffected [4].

In addition to the physical and chemical changes associated with ice formation, loss of protein stability may also be caused by interactions of protein with other components and by enzyme activity. These factors have been reviewed by several authors as causes for denaturation in fish proteins [1, 6, 7]. Lipid oxidation has been shown to be highly correlated with protein denaturation during freezing. For example, the oxidation and hydrolysis of lipids in sardines at −20°C was inversely related to protein solubility and other functional changes [8]. The addition of malonaldehyde, a commonly occurring product of lipid oxidation, to trout myosin solutions during storage at −4°C accelerated protein denaturation [9]. On the other hand, actomyosin in fatty fish, such as halibut and rosefish, is more stable than the actomyosin in lean fish, such as cod and haddock, after one year of frozen storage at −23°C [10]. The actomyosin from fatty fish had little or no denaturation, whereas that from lean fish was almost completely denatured.

Enzymes, particularly trimethylamine oxide demethylase (TMAO demethylase), have been linked to protein denaturation. TMAO demethylase hydrolyses trimethylamine oxide, which is naturally present in some fish and shellfish, into dimethylamine (DMA) and formaldehyde [7]. Formaldehyde is reported to form covalent cross-links with protein and therefore accelerating denaturation [11]. Myofibrillar patterns of hake muscle soaked in formaldehyde had a higher amount of high molecular weight aggregates caused by covalent cross-linking of structural proteins [12]. The effect of the addition of formaldehyde on actomyosin denaturation during frozen storage has also been studied in hake, pork and chicken [13]. The stability of the actomyosin in the presence of formaldehyde differed according to species, with chicken being the most stable to formaldehyde.

Cross-linking of polypeptide chains due to disulfide bond formation may also contribute to protein denaturation in frozen fish, although it may be a secondary factor [14–16]. In minced halibut stored at −10°C, insolubilisation of the myofibrillar proteins was reduced when a disulfide bond reducing agent, such as β-mercaptoethanol, was added [14]. Disulfide bond formation has also been implicated as a factor contributing to the loss of water holding capacity in haddock during frozen storage [12].

Various processing factors may influence protein denaturation during frozen storage. The factors include handling and processing prior to freezing, temperature of storage and the rate of freezing. Mincing has been shown to promote toughening in frozen fish, for example minced hake accumulated formaldehyde at a faster rate than fillets [11]. Depending on the species, aging fish on ice prior to freezing may be advantageous to quality [15]. Aging red hake on ice before processing and frozen storage was shown to produce a more acceptable product than other treatments, such as the removal of dark muscle or dipping in sodium tripolyphosphate or erythorbate [17].

The kinetics of protein denaturation is influenced by temperature. At temperatures just below the freezing point, denaturation is very rapid. For example, the maximum rate of protein denaturation in rabbit and trout myosin solutions was reported to be at approximately −10°C [9]. Lowering the storage temperature generally reduces the degree of protein denaturation [12, 18, 19]. In whiting fillets stored at −20°C and lower, losses in protein extractability, calcium ATPase activity and gel forming ability were reduced [19]. However, there was no significant improvement in the quality of the whiting fillets when stored lower than −20°C. Similar results were observed in halibut [5]. The differences in the development of toughness and off-flavors were insufficient to justify lowering the temperature below −20°C.

Protein stability is also affected by freezing rate. In general, faster freezing rates result in less damage because smaller ice crystals are formed. However, fluctuating temperatures during frozen storage, due to overloading, power failures and equipment breakdowns, can lead to growth of ice crystals, which could counteract the benefit of using fast initial freezing rates [20]. Storage temperature is therefore believed to be a more critical factor than freezing rate.

B. Lipids

Lipids can degrade in frozen systems by means of two well known chemical processes: hydrolysis and oxidation [21]. These processes lead to undesirable changes in the nutritional and sensory quality of foods, such as the production of rancid flavors and discoloration. The hydrolysis of lipids, also known as lipolysis, results in the release of free fatty acids, which can alter the flavor of frozen products. The rate of hydrolysis depends on storage temperature and time, and the type of food product [22–24]. In frozen foods, lipid hydrolysis is generally catalyzed by enzymes. Both phospholipase A and lipases from muscle tissues are responsible for the hydrolysis of phospholipids and neutral lipids in frozen fish [24].

Lipid oxidation is a free radical reaction involving three major steps: initiation, propagation and termination. Oxidation is frequently initiated by a spontaneous reaction with oxygen (autoxidation) or by an enzymatic reaction [25]. Hydroperoxides are the initial products of lipid oxidation. These compounds are unstable and subsequently enter into numerous complex reactions that involve further degradation and interaction with other food components, causing off-flavors, discoloration, loss of nutrients and toughening of protein [8, 21, 26]. The rate of reaction increases with degree of lipid unsaturation, therefore lipid oxidation is particularly a problem in high fat fish [27].

Lipid degradation can be reduced in frozen foods by lowering of the storage temperature, excluding oxygen, adding antioxidants and supplementation of antioxidants in the diet of animals. The effect of lowering the storage temperature from −10°C to −30°C on lipid oxidation and hydrolysis was studied in cod and haddock [28]. At −30°C lipid degradation in both species was reduced to the same extent but at −10°C the haddock was more susceptible to lipid degradation than the cod. Since oxygen is a key component in lipid oxidation, limiting its presence by modified atmosphere packaging can be beneficial to the shelf-life of food, as shown in frozen pork [29], chicken and turkey [30, 31], shrimp [32] and pulverised niboshi (boiled and dried sardines) [33]. The quality of processed fish fingers stored at −20°C was shown to be influenced by the thickness of the packaging and the composition of the packaging material. The control, which was kept without packaging, was discarded after four weeks of storage due to rancid odors, a tough texture and undesirable color changes. Fish fingers packed in 62.5 μm thick low-density polyethylene/high-density polyethylene (LD/HDPE) remained in a satisfactory condition for 28 weeks. The same product packaged with 100 μm thick low-density polyethylene/Nylon-Primacore (LDPE/NY/PC) was stable for 32 weeks [34].

Adding antioxidants, such as butylated hydroxytoluene (BHT) and natural vitamin E reduced lipid oxidation in shelled oysters during storage at −20°C [35]. Frozen rock oysters glazed with 1% sodium ascorbate alone or with 1% monosodium glutamate was efficient in extending their shelf life [36]. Similar results were observed in frozen processed turkey meat treated with antioxidants (a mixture of BHT, propyl gallate and citric acid) where the degree of lipid oxidation was reduced [37]. In addition, supplementing the diet of farm animals with vitamin E was shown to reduce lipid oxidation in meat [38, 39]. Antioxidants may also occur naturally in food. The naturally occurring color pigment astaxanthin has been shown to reduce rancidity in farmed trout [40].

Other factors influencing lipid degradation include handling prior to freezing and the rate of freezing. Precooking of meat prior to freezing can increase lipid degradation during frozen storage, because the denatured heme proteins and ferritin release free iron that catalyse oxidation [41]. It was shown that rancid flavors and thiobarbituric acid (TBA) values increased in precooked chicken meat during two to four months of frozen storage [42]. Rapid freezing of chicken meat in liquid nitrogen produced a product with a lower degree of rancidity than air-blast freezing [42]. Similar results have been observed in pork sausage [43].

C. Carbohydrates

Carbohydrates are susceptible to hydrolysis during frozen storage, as observed in frozen papaya [44]. Starch hydrolysis can be extensive in frozen green beans even when stored at −18°C; almost all of the starch was enzymatically hydrolyzed into reducing sugars, leading to an increase in sweetness and softening [45]. Sugar hydrolysis increases the number of moles of solutes in the food matrix, thus depressing the freezing temperature. This leads to a reduction in the amount of ice in the product, which may alter certain physical properties, for example the firmness of ice cream was inversely related to the degree of hydrolysis [46]. In a model system, the rate of sucrose hydrolysis, by enzymes and under acidic conditions, was investigated at low temperatures [47]. The results indicated that even at temperatures as low as −22°C, hydrolysis still takes place.

D. Color Pigments

The color of raw red meat tissues is mainly attributed to myoglobin. Carotenoid compounds, including astaxanthin, canthaxanthin and β-carotene, contribute to the color of some marine products and poultry [48]. Most of the color in fruit and vegetables is provided by chlorophylls (green leafy vegetables), carotenoids (orange, yellow and red fruits and vegetables) and anthocyanins (majority of berries and red to purplish vegetables).

The stability of color pigments during frozen storage is affected by treatment prior to processing, processing and storage conditions (light, oxygen, heavy metals, temperature, water activity, pH, oxidizing and reducing agents). Furthermore, oxidoreductase enzymes, such as lipoxygenase, catalase, peroxidase, polyphenol oxidase and lipases can cause bleaching of pigments and browning discoloration in fruits and vegetables [49, 50]. Other chemical reactions within the food, particularly lipid oxidation, can also lead to changes in color.

Carotenoids are relatively stable during frozen storage. Sweet potato [51], tomato pulp [52], green beans and broccoli [53] have shown minimal loss of β-carotene during the freezing process. The stability of meat colors, metmyoglobin in meat and carotenoids in fish and poultry, is generally decreased by lipid oxidation [26].

Chlorophyll and anthocyanins are considered to be less stable than carotenoids and can degrade through a variety of mechanisms. In the presence of heat and acid, chlorophyll changes from green to an olive-brown colored pheophytin when the magnesium atom in chlorophyll is displaced by two hydrogen ions [47]. Cultivar type and maturity have been shown to influence the stability of chlorophyll in kiwifruit during frozen storage [54, 55]. This may be because changes in total acidity and pH cause pheophytinization of chlorophyll [54, 55]. However, it was pointed out that at low temperature storage (<-18°C), color of green beans was stable and was probably because of the formation of metal-chlorophyll compounds, which is different from change in color attributing to pheophytisation when stored at high storage temperatures [56]. It was observed in some studies that there was no perceptible

change in greenness of parsley during storage at −20°C for three years [57].

Anthocyanins are relatively unstable during frozen storage and are greatly affected by pH, organic acid content, sugar concentration, enzyme reactions, initial anthocyanin composition and anthocyanin content. Anthocyanins are more stable under acidic conditions [48]. In blackberries, maturity rather than cultivar was found to be more important for preventing blackberries from turning red during storage because the change in color was correlated with lower soluble solids, total anthocyanins and higher titratible acidity [58]. Glycosidases and polyphenolases are two classes of enzymes that promote loss of anthocyanin color intensity [48]. Glycosidases hydrolyze cyanidin 3-glucoside thus contributing to color loss in raspberries [59].

The choice of processing method can affect the stability of color pigments during frozen storage. Light and oxygen have been shown to accelerate color loss in tomato sauce [52], possibly by solubilisation, isomerization and degradation of lycopene [60]. The lycopene content of tomato sauces prepared in an open kettle decreased faster during frozen storage than samples prepared in a tubular pasteurizer [60]. If the tomato product is carefully processed in the absence of oxygen, it can exhibit excellent lycopene stability throughout the normal frozen storage shelf life [61]. The effect of still air freezing versus air-blast freezing on the color of pineapple slices was evaluated [62]. The results showed that the freezing rate did not have any affect on the subsequent frozen storage stability of the pineapple color.

Various methods, such as blanching, modified storage atmosphere, and addition of antioxidants, have been used to enhance the stability of the color pigments in frozen foods. The main purpose of blanching prior to freezing is to inactivate enzymes that degrade color pigments. For example, lipoxygenase is known to degrade β-carotene and lutein [53]. However, blanching can also lead to color losses. Heating can cause the development of an undesirable olive-green color in green vegetables because of chlorophyll degradation [53]. Therefore, minimization of blanching time is generally recommended [49]. Modified atmospheres can be used to reduce color changes. For example, boiled shrimp flushed with nitrogen and sealed in a bag with low oxygen transmission reduced color fading and improved the overall quality of the shrimp [32]. Furthermore, flushing precooked crabmeat with carbon dioxide was shown to prevent blue discoloration [63].

Color can also be stabilized using chemical additives such as antioxidants, applied either as a dip or added directly to the food product or even to the diet of the animal. Natural antioxidants, including ground tomato seeds and spices (rosemary and marjoram) have proved successful for color retention when added to tomato sauce to stabilize carotenoid pigments during frozen storage [52]. Frozen avocado purees can be prevented from browning by adding sodium bisulfite and ascorbate prior to freezing [26]. Browning in frozen crabmeat was reduced by a citric acid dip but no significant reduction in the browning was observed with dips of sodium nitrite, ascorbic acid, sodium acid pyrophosphate, and brine with sodium citrate or tripolyphosphate [63]. Sulfite can inhibit melonosis (blackspot) on crustaceans [64]. However, if it is used in excess (2% for ten minutes), it can cause decomposition of TMAO, thus initiating a chain of lipid and protein degradation reactions [64].

Dietary vitamin E supplementation for Holstein steers increased the color stability of the meat during storage at −20°C [65]. The color and carotenoid content salmon fed with diets supplemented with astaxanthin was stable during frozen storage for up to 12 weeks at −20°C, but salmon fed with cathaxanthin had significant loss in color scores and carotenoid content [66]. In contrast, smoking of the fish significantly reduced the carotenoid content of astaxanthin-fed salmon, but did not cause any decrease in color in canthaxanthin-fed Atlantic salmon during frozen storage [66].

E. Flavor Compounds

Food flavors are composed of volatile aroma compounds and taste components, such as organic acids and sugars. The effect of freezing and frozen storage on flavor compounds in food is variable with flavor changes being affected mainly by enzymatic activities and lipid oxidation. Freezing and thawing processes have been shown to change and weaken the flavor profile of fresh strawberries [67–69] and peas [70], but minimal changes were observed in the aroma volatile composition of raspberries studied under similar conditions [59]. The flavor of fruit and vegetables may also be modified by the decrease in organic acids as observed in frozen kiwifruits, pineapples and blanched green beans [55, 71, 72]. In seafood, the development of off flavors has been associated with the enzymatic degradation of TMAO that produces trimethylamine and dimethylamine [73]. Another type of off-flavor in fish is caused by autoxidation of long chain ω-3-unsaturated fatty acids, which produce carbonyl compounds characterized by an "oxidized fish oil" aroma [73, 74].

Blanching of vegetables prior to freezing can be used to inactivate the enzymes that cause changes to the flavor. The flavor of carrot, cauliflower and beans during frozen storage has been stabilized by blanching [78]. However, complete inactivation of enzymes may not be necessary as it was shown that 5% residual peroxidase activity did not affect the quality of these blanched vegetables during storage [75]. In contrast, the flavors of unblanched leek, onion and swede did not change appreciably during frozen storage and were preferred to blanched products. The disadvantages of blanching with regard to flavor preservation are the loss of flavor compounds through leaching [72] and creation of a different flavor profile through heating [76]. Therefore, it is important to identify and specifically target enzymes such

as lipoxygenases, lipases, lyases and proteases for adequate blanching, rather than to utilize excessive blanching regimes for peroxidase destruction, which is commonly used as an indicator enzyme for vegetables [49]. Foods, such as white truffle, that are unsuitable for blanching, are susceptible to deterioration. These, along with the loss of other volatile compounds were responsible for the typical truffle flavor [77].

Pasteurization is another heat pretreatment frequently used for frozen foods. Changes in the volatile composition of a pasteurized guava puree product were investigated during four months of storage at −10°C and −20°C [76]. Pasteurized guava puree had increased levels of aldehydes and hydrocarbons and decreased levels of esters compared to unpasteurized guava puree. There was only a slight decrease in the concentration of alcohols and hydrocarbons in pasteurized guava puree stored at −20°C.

F. Vitamins

Freezing is considered as one of the best processing methods for preserving nutrients in food. In a comparison of different storage methods, the nutrient content of frozen beans, sweet corn and peas was similar to fresh vegetables that had been cooked by boiling. Frozen vegetables were higher in vitamin C, riboflavin and thiamin content than canned vegetables [78]. Processing foods prior to freezing can result in vitamin losses through oxidation and leaching, with heat being a secondary factor [79]. Generally, vitamin C has been used as a nutritional and quality marker for monitoring the effect of manufacturing processes on nutrient losses, therefore it has been the focus of many studies in food [81]. Vitamin C usually refers to the sum of both ascorbic acid and dehydroascorbic acid, since both are active forms of the vitamin [79], although studies have shown that ascorbic acid has been shown to have faster degradation rate than dyhydroascorbic acid [45]. Beta-carotene is also commonly used to monitor the effect of processing on nutrient losses.

Blanching of foods prior to freezing can contribute to vitamin loss. The loss of 47% ascorbic acid and 10% vitamin B6 in commercially processed french fries during freezing was attributed mainly to the blanching process; the decrease caused by other unit operations was insignificant [81]. Steam blanching is generally better for maintaining vitamin activity than hot water blanching. Large-size cut french fries had better vitamin retention than small-size french fries because leaching was reduced. The effect of alternate freezing and thawing of peas, lima beans, corn and green beans increased the destruction of ascorbic acid. This may have been due to an increase in the concentration of ascorbic acid and oxidative catalysts in the fluid of the tissue matrix [82].

The use of blanching to preserve nutrients depends largely on the type of food. Red peppers and kiwifruit, usually frozen without blanching, showed no significant loss of ascorbic acid during freezing [83]. In contrast, the ascorbic acid content of unblanched okra and beans decreased by about 50% during freezing, while after blanching there was no significant change in the ascorbic acid content. The maximum decrease in ascorbic acid content in this study was observed at −1°C to −8°C [83]. Another study showed that even though blanching reduced the vitamin C content of beans by 28%, it reduced further losses during twelve months of frozen storage [84]. Unblanched beans and peppers lost more than 97% of their vitamin C content within one month of freezing, strongly indicating the need for blanching of vegetables before frozen storage in order to preserve nutrients. Similar results were obtained for broccoli and green beans [85]. Vitamin C could be the shelf life limiting factor, where it was shown that beyond the 45th day of storage, even when the sensory parameters are well retained, the nutritional parameter were at diminished levels [45].

G. Minerals

Minerals in food matrices may be present in many different forms such as chemical compounds, molecular complexes and even as free ions. Minerals present in any form can dramatically affect the color, texture, flavor and stability of foods [86]. Minerals cannot be easily destroyed by exposure to heat, light, oxidizing agents or extremes in pH, but they can be lost through leaching or by physical separation of components. Even so, there were no changes observed in six mineral elements (Ca, Cu, Mg, Mn, Ni and Zn) between fresh and frozen artichokes, green beans and peas [87]. Furthermore, the mineral content of boiled fresh vegetables was shown to be similar to boiled frozen vegetables [78].

III. CRYOPRESERVATION OF FROZEN FOOD

In the previous section different techniques were discussed for reducing the rate of chemical reactions in foods, such as lowering the temperature, blanching and modified atmosphere packaging. In conjunction with these techniques, further reductions in the rate of these reactions can be achieved by cryopreservatives, which can be natural components of the food or added as a pre-freezing treatment. Cryopreservatives can be classified as cryostabilisers or cryoprotective agents. Cryostabilisers are added to increase the viscosity of the frozen system while cryoprotective additives are used to change or stabilize the structure of components that are susceptible to undesirable changes caused by freezing. The variety of frozen products may require special “cocktails” of cryopreservatives to be developed for each individual product [93].

The underlying principle of cryostabilization is based on increasing the viscosity of the frozen system, which

controls the diffusion of solutes and therefore the rate of quality deterioration [94, 95]. When food is frozen, ice is formed and the solutes are concentrated in an unfrozen matrix. At the temperature of maximum freeze-concentration, where no more ice is formed, the unfrozen matrix undergoes a transition from viscous rubbery to a highly viscous glassy state. This temperature is called the glass transition temperature (Tg′) [96]. The extremely high viscosity associated with the glassy state limits the mobility of solutes and therefore, reduces the rate of diffusion-controlled reactions.

Various types of reactions respond differently to this change in viscosity. Simple diffusion-controlled reactions, which have low activation energies (8 to 25 kJ/mol), are especially sensitive to changes in the viscosity [97, 98]. The rate of lipolysis, lipid oxidation and diffusion of ^{14}C-fructose were studied in mackerel mince at temperatures between −5°C and −20°C [99]. The results indicated that the diffusion of ^{14}C-fructose and the production of thiobarbituric acid–related substances (TBARS) in mackerel mince decreased dramatically when the temperature was just below the Tg′ of mackerel. Similar results were observed in reformulated kumara (sweet potato) frozen paste products [100]. However, the rate of lipolysis and accumulation of peroxides were only moderately influenced when stored below the Tg′ of mackerel. Other studies have shown that ice recrystallization is reduced at temperatures below the Tg′ of the unfrozen matrix [95, 101].

The rate of diffusion-controlled reactions has been studied in frozen systems by adding maltodextrins with high Tg′ values (Tg′ ranged from −10°C to −18°C) and carboxymethylcellulose (CMC, Tg′ of −12°C) [102]. It was shown that in frozen systems containing maltodextrins the diffusion-controlled reaction rates were reduced at temperatures below their corresponding Tg′, but frozen systems containing CMC were not reduced. These results showed that even though the adding of selective compounds with a high Tg′ may reduce the rate of diffusion controlled reactions but may not always be true for all.

Typical cryostabilisers are high MW compounds, such as starch and starch hydrolysates, which elevate the Tg′ of the product [94, 95]. In general, low molecular weight components have a lower Tg′ than high molecular weight components [95]. The glass transition temperature is also affected by structural variation, such as polymer branching or linking of monomers [95]. For instance, the Tg′ for various disaccharides with a MW of 342 g/mol can differ by up to 7 K [95]. Table 114.2 summarizes the Tg′ and dextrose equivalent (DE) values for starch hydrolysates.

Cryoprotective agents are widely used to protect protein from denaturation [93, 104]. The additives interact with the surrounding water of the protein and create a preferential hydration of the protein and thus protects functional groups in protein from dehydration [104, 105]. The structure of cryoprotective compounds is diverse. Several small sugars, polyols, amino acids, nucleotides, salts and even surfactants have been shown to stabilize protein at sub-ambient temperature [93]. Researchers have carried out extensive studies to evaluate the effect of different cryoprotective agents and freezing conditions on the preservation of gamates of different origin [106–108]. Such studies could be considered in the future for freezing preservation of food products.

TABLE 114.2
Tg′ and DE Values for Sugars and Polysaccharides [103]

Solute	Tg′ (°C)	Dextrose Equivalent (DE)
Glucose	−43	100
Maltose	−31	53
Star Dri 42F[a]	−27	42
Maltotriose	−24	35
Maltoheptose	−13	16
Star Dri 20[a]	−13	22
Star Dri 5[a]	−10	5

[a] Star Dri 5–42 corresponds to the dextrose equivalent, that is, the higher the number the smaller the average molecular weight.

ACKNOWLEDGEMENT

CONTENTS

I. INTRODUCTION

The main objective of freezing is to prolong shelf life of foods. On this basis, freezing is considered an excellent means of maintaining acceptable quality in red meats for months and even years.

Currently consumers prefer chilled to frozen red meat, probably because of a desire on the part of the purchaser to assess several meat quality attributes, such as ratio of bone to muscle, presence of fat, and the like (49). Such an assessment is difficult when meat is frozen. Despite this, freezing and frozen storage of red meat are gradually increasing. Frozen storage is regarded as a useful technological aid because it makes possible the supply of large amounts of meat for catering and supermarkets, extends the storage life of meat when supply exceeds demand, and represents a flexible tool for sellers.

The quality of red meat brings together sensory (i.e., texture, flavor and color), microbial, nutritional and functional characteristics. In most cases, freezing does not modify quality in any considerable way. However, frozen meat may present defects in quality and naturally can suffer deterioration in quality during storage. Colour, flavour and texture defects, together with moisture losses, are the principal factors to which due regard must be paid.

Colour and flavour can become altered during storage, with lipid and myoglobin oxidation being the main adverse changes affecting the eating quality of frozen red meats.

With respect to texture, there are two circumstances having detrimental effects on the quality of frozen meat, both related to a significant decrease of temperature in prerigor meats. These are cold shortening and thaw rigor, which lead to toughness. In order to avoid these processes the advice has generally been to freeze post-rigor, instead of pre-rigor, meat. Nevertheless, pre-rigor freezing is also possible, provided that preventive measures are brought into play, such as electrical stimulation and tempering during thawing.

In addition, frozen meat production implies some profit losses related to the reductions in weight resulting from freezing. Generally, in comparison with rapid freezing, slow freezing produces greater damage to the muscle structure, resulting in a decrease in myofibrillar protein solubility and water holding capacity (WHC) and an increase in weight losses on defrosting or thawing (44).

The principal factors affecting frozen meat quality include the intrinsic quality of the meat, chilling and freezing conditions, and protection and storage conditions throughout the cold chain (17, 20, 38) (Table 115.1). These

TABLE 115.1
Main Considerations Influencing Frozen Red Meat Quality

Pre-Freezing:	species, genetic, livestock, feeding — lipids, vitamin E –, transport and slaughtering, postmorten processes — electric stimulation, chilling, hot deboning, freezing pre or post-rigor, ageing –, quality of raw materials including microbial status, type of muscle, processing of meat — cutting, cooking, packaging.
Freezing:	freezing rate, freezing technology.
Frozen Storage:	temperature, time, temperature fluctuations.
Thawing:	rate, technology, tempering or cooking of frozen meat.
Culinary Elaboration:	technology, temperature, time.

Adapted from Genot (17).

factors are not independent of one other. The effects on the eating quality of red meats of ageing time of meat before freezing, the freezing rate and the cooking method used, and also on thawing and cooking losses, showed a large number of significant interactions (28).

In relation to the effect of storage temperature on the quality of frozen foods, glass transition temperature under conditions of maximal freeze concentration (with a slow-frozen sample), Tg', is a potential means of assessing the stability of foods that deteriorate as a result of diffusion-limited events. In the case of beef, apparent Tg' values were approximately $-12°C$ (6). This temperature seems also to be the lower limit for microbial growth in meat.

In this chapter, the topics reviewed are the structure, moisture losses, microbiology, organoleptic properties, nutritional value and shelf life of frozen red meat.

II. STRUCTURAL DAMAGE IN FROZEN MEAT (EFFECTS OF FREEZING RATE AND FREEZER TEMPERATURE)

Muscle cells are flexible and elongated, share their alignment, have minimal air spaces and are separated by a matrix rich in glycoproteins. Although muscle cells are difficult to rupture by freezing and thawing, freezing and frozen storage can produce marked effects on the structural properties of red meat tissues, with cell-cell separation being the most evident structural change.

The freezing point in lean red meats is approximately $-1.5°C$, depending on meat composition. After this point, as temperature decreases a higher proportion of water turns into ice crystals. At temperatures below $-7°C$ more than 80% of the water is frozen. Water outside the muscle fibres freezes first, thus intracellular water tends to be drawn out of the fibres by osmotic effects, increasing the intracellular concentration of solutes. The consequences of this cryoconcentration (i.e., changes in osmotic pressure, pH, ionic force, viscosity, *Aw*) trigger the denaturing of and damage to muscle (i.e., myofibrillar and sarcoplasmic) protein, which progress with longer time and lower temperature of frozen storage (23). These changes in the functional properties of proteins may be responsible for changes in texture, colour and flavour. Finally, as solutes reach saturation point two outcomes are possible: the formation of eutectics or of a supersaturated metastable rubbery phase (glass transition). According to Brake and Fennema (6) the formation of eutectics during the freezing of meat is uncommon.

Freezing rate has an important influence on crystal size, location (intra- or extra-cellular) and morphology. Slow freezing rates (i.e., a rate of advance of the frozen front below the range 0.1–0.2 centimetres per hour) in matured meats produce large and, according to Grujic et al. (21), for the most part extracellular crystals, which damage muscle proteins and cell membranes, causing considerable distortions in tissue microstructure. Thus, the WHC of the meat decreases and the exudate produced during thawing increases. At intermediate freezing rates (from 0.2 to 1.0 cm/h) medium-sized ice crystals are formed both inside and outside cells. In this case cellular damage and drip losses are also high. By contrast, fast freezing rates (1.0 to 10.0 cm/h) bring about the formation of numerous small crystals, mainly intracellular, uniformly distributed. In this case, there is a minimum of physical harm to cells and of chemical changes to proteins (15). However ultra-fast freezing (in excess of 10.0 cm/h) may cause freeze-cracking in joints of frozen meat, due to sudden changes of volume. The full effects of fast and slow freezing on the eating quality of frozen meat are still unclear. In general, it is considered that freezing rate has only limited effects (17).

As storage times get longer ice crystals undergo gradual growth (39). Temperature fluctuation is considered a major stimulator of crystal growth through inducing recrystallization. Crystal growth is associated with a decrease in the WHC of meat protein, an increase in tissue damage, and a subsequent increase in drip losses from thawing meat.

In order to reduce structural damage during freezing, a number of cryoprotectants have been used in meat, including aspartate, cystine and β-alanine, sugars, dicarboxylic acids, phosphates and starch hydrolysis products. Unfortunately, the use of cryoprotectants has sometimes been associated with a sweet taste or lipid oxidation defects in meat. Nonetheless, these substances are used in cut, minced and restructured meat, and some of them have even been incorporated into meat by injection in live animals before slaughtering (14). Hence, a topic of great research interest is the application of antifreeze glycoproteins found naturally in cold-water fish or similar substances, incorporated in meat by brining or injection. These substances have the ability to make crystals smaller in size, to inhibit recrystallization and so to reduce drip loss.

III. MOISTURE LOSSES

During freezing, storage and thawing, meat loses water by evaporation, sublimation and exudation, respectively; moisture is also lost during cooking. Moisture losses are of great monetary importance. Although moisture losses make meat less attractive, they do not significantly influence its eating quality after cooking, except in the case of very large losses, which could affect juiciness and tenderness (17).

Evaporation losses depend on freezing conditions, as relative humidity (RH) and temperature, and meat characteristics, as the size and area-to-volume ratio of pieces, fat covering, and the presence of skin or packaging. Moisture losses by evaporation during freezing of non-packed carcasses or joints normally amount to between 0.5 and 1.2% of the total weight (17).

Sublimation during storage is another important cause of moisture loss. Greater weight losses occur when there is a higher air speed, more surface of lean exposed, longer storage or a higher temperature. Monthly losses of 0.15% to 0.7% were found in traditional stockinette-wrapped meat stored at −30°C and −10°C, respectively (9). In general, moisture loss increases when temperature fluctuates, that is, when it rises and falls by more than 2°C. In the extreme case, a severe local loss of water through sublimation may cause freezer burn.

The exudate formed during thawing (purge or drip loss) generally accounts for between 1% and 5% weight of meat pieces (17). Drip loss has a negative financial impact on processors, makes the meat visually unattractive, and also involves loss of soluble nutrients. Amounts of drip loss from frozen meat are determined by two main factors: the volume of the exudate generated during defrosting and its migration speed.

The former depends on the freezing and thawing conditions and features intrinsic to the meat itself (4, 33, 41), the water-binding capacity of proteins being involved in both. The latter depends on the size and shape of the pieces of meat, the myofibrillar orientation and geometry, the presence of large blood vessels and the intensity of physical cellular or macroscopic damage (freeze-cracks) produced during freezing, that is, with fast freeze rates.

As previously mentioned, drip loss has been associated with cellular damage caused by large crystals and extracellular crystal presence, these crystals being formed at slow and intermediate freezing rates. Furthermore, the water from the extracellular crystals formed seems not to be reabsorbed on thawing, thus producing drip loss. Hence, intermediate and slow freezing rates (those in which the time taken for the temperature to fall from −1°C to −7°C exceeds 10 minutes) show greater drip loss than faster rates (4). Within this range, these authors found a peak in drip losses in defrosting at a rate of 15–20 min. In the light of the effect of freeze rates on drip loss, several authors recommend freezing rates in the range 2.0 to 5.0 cm/h (17, 21).

When industrial freezing methods based on thermal gradient are used, large volume carcasses and joints undergo different freezing rates depending on depth, so that the thermal centre shows larger and more numerous extracellular ice crystals, which would lead to a poorer quality product (34, 47). New methods like high-pressure-assisted freezing (for example at a pressure of 200 MPa) would be necessary to overcome these difficulties (39). Pressure brings the freezing point of water down to a minimum of −22°C at 207.5 MPa (8). Thus, meat would be cooled to −20°C under pressure, so included water remains in its liquid state, and then pressure would be released, so that an instantaneous and homogeneous micro-crystallization would occur.

In addition, high and fluctuating temperatures and long storage favour large crystal formation and hence increased drip loss. Drip losses in vacuum packed pork, beef and veal are reported as 1.2%, 4.2% and 2.2%, respectively, after four months of storage (17). However when storage was 16 months the losses were 4.7% for pork and more than 8% for beef and veal. In other work, it has been reported that drip losses from fast-frozen and stored meat increase with storage time, reaching the same level as the drip losses observed from meat frozen at a slow rate but not stored for any length of time (42).

Packaging also shows an influence on drip loss, vacuum and oxygen-impermeable packaging being the most effective. For instance, the volume of exudate from cut pork kept frozen for 13 weeks at −17°C was between 2.5% and 5.0%, in accordance with the packaging characteristics (7).

Moreover, thawing time seems to be correlated with extracellular water re-absorption, which is a slow process. This might be the reason that faster thawing rates (defined as involving a time of under 50 min. for the temperature to rise from −5°C to −1°C) produced more drip loss in frozen beef (19). In contrast, other authors found fast thawing rates resulted in smaller drip losses (41, 42). The most recent suggestion has been that slow thawing causes more structural damage through recrystallization (2) and more protein denaturation. These authors recognized that fast freeze rates were more suited to fast thaw rates and vice versa.

Several intrinsic factors have been noted as affecting drip loss: species, type of muscle, pH, which has an inverse correlation with drip loss (33), pre-rigor and post-rigor freezing (the latter presenting more exudate in the case that thaw rigor is avoided) or ageing time (matured meat gives less drip loss).

To sum up, under industrial freezing conditions, storage time, temperature fluctuations and the intrinsic characteristics of the meat, rather than freezing rate, seem to have the biggest effects on drip loss.

Finally, cooking loss from frozen meat depend principally on the processing of meat before freezing, especially rigor onset temperature (10), and on the cooking method,

particularly the cooking temperature. Although cooking loss is accepted as being higher when freezing rates are slow (see review of Genot), the effect of freezing rate on cooking loss seems to be slight (13).

IV. MICROBIAL EFFECTS (HYGIENE)

Low freezer temperatures (i.e., below −18°C) bring about a practically total inhibition of the cellular metabolism in animal tissues and substantially decrease the rate of almost all chemical reactions. Microbial development in meat virtually comes to a stop when a temperature of −12°C is reached (33), this being the lowest point reported as allowing growth of moulds on meat. In this way, mould spoilage may be the most substantial problem affecting frozen carcasses that have been subjected to temperature abuse.

In general, a large proportion of the microbiota of a foodstuff will be killed or sublethally damaged by freezing (owing to thermal shock, ice formation, dehydration or solute concentration). In fact, a decrease in aerobic spoilage organisms has commonly been observed in frozen meat (25). Freezing process and animal species involved influence the microbial counts. Faster freezing rates have been demonstrated to have a less injurious effect than slower ones, and in addition, the longer the storage time, the more serious the damage.

Among the various organisms, gram-positive bacteria are generally more resistant to freezing than gram-negative, cocci more than bacilli and yeast and moulds more than bacteria. Bacterial and fungal spores and toxins of *Clostridium botulinum* and *Staphylococcus aureus* are highly resistant to freezing (18). In any case, pathogenic micro-organisms are commonly isolated from thawed frozen meats.

Furthermore, freezing has a sanitizing effect on frozen red meat. Freezing can be used to destroy larvae of *Taenia* spp. and *Trichinella spiralis*. These organisms are killed after 1 to 3 weeks at −18°C or after an ultra-rapid freezing at −29°C (48).

Nonetheless, defrosted meat seems to spoil faster than chilled meat because of the damage to tissues and because the exudate formed enhances microbial growth (17). Thus, the thawing process represents a fundamental phase with respect to the microbiological quality of thawed meat. In this way, increases in bacterial numbers become unacceptable in the air thawing of beef and pork carcasses or quarters if temperatures in excess of 10°C are maintained (20). Also, the time for which meat surfaces are at temperatures in excess of 1°C must be kept short if pathogen development is to be prevented. In this respect, tempering meat pieces during thawing at temperatures between −5°C and −2°C, and processing the meat (undertaking operations such as cutting, mincing and the like) at these temperatures may be really advisable. Apart from thawing, microbial counts in frozen meats depend on the initial level of microbial contamination and contamination during freezing and storage.

Microbiological status of good-quality meat (a satisfactory standard has aerobic plate counts at 25°C from the surface of frozen prime joints of beef under 10^5 colony forming units per square centimetre (cfu cm^2) and coliform counts under 10^3 (26); and in frozen minced beef under 10^5 and under 10^2, respectively (25) is largely due to hygiene in dressing and butchery of the carcasses, short time and low temperature of chilled storage, high freezing rate, proper packaging and so forth.

V. ORGANOLEPTIC PROPERTIES OF FROZEN RED MEAT

A. Texture (Cold Shortening and Thaw Rigor)

In frozen red meat, changes in the main attributes of meat texture, namely tenderness and juiciness, depend principally on changes in myofibrillar and stroma proteins (rigor shortening, denaturation, crosslinking, linking between proteins and free fatty acids or lipid auto-oxidation products and similar). These changes affect the functional properties of proteins (WHC, solubility and enzyme activity) throughout freezing and thawing processes. The severest effects appear at low freezing rate and long-time-high-temperature storage (46, 51). However, the mechanisms of protein denaturation and other changes in frozen muscles are still not fully understood, and their real effects on meat eating quality have not been totally established (37).

The freezing process for post-mortem meat in industrial practice seems to have only a slight effect on tenderness and juiciness. These attributes are more dependent upon the intrinsic factors of meat, specifically maturation before freezing, which improves tenderness. On this point, it has been found (50) that beef frozen after 14 days of ageing was the tenderest.

In any case, there have been several instances in which meat frozen then thawed was found tenderer than chilled meat (30, 50). This may represent an advantage for beef and lamb eating quality. The tenderizing effect of freezing might be explained by tissue damage due to ice formation (16) or an improved ageing process in red meats resulting from a decrease in calpastatin activity (52).

On the other hand, pre-rigor freezing could effectively produce a detrimental effect on meat tenderness, if cold shortening and/or thaw rigor took place. Thaw rigor may account for 40% of myofibrillar shortening (33), which induces toughness. These effects are not frequent in entire carcasses of pork and beef, especially if they are covered by a layer of fat and the freezing rate is not too fast (33), for rigor occurring before the decrease in temperature becomes critical. However, in lamb carcasses and hot-deboned joints

both processes can occur. In these cases, lower freezing rates, i.e., attaining −1°C within 5 hours post-mortem (34), are responsible for cold shortening and higher ones for thaw rigor, which is the case of meat frozen before the onset of rigor mortis.

Nonetheless, cold shortening and thaw rigor can be prevented. Post-mortem electrical stimulation, which accelerates the glycolytic process and hence the onset of rigor mortis, has been used to, and can effectively, prevent cold shortening and also thaw rigor (16, 33). For instance, electrical stimulation of lamb carcasses prevented cold shortening at freezing rates such as those needed to attain −4°C within 12 hours post-mortem (17).

Besides, if meat is frozen before rigor onset, tempering the meat at temperatures between −2°C and −5°C for approximately three days during thawing can prevent thaw rigor. At these temperatures the ATPase activity is enough to trigger rigor in the frozen state, thus preventing shortening. ATPase activity has been observed even at −12°C (33). Another way of preventing thaw rigor consists of adding salt, ca. 1.5–1.8%, to meat pieces (5). Salt inhibits glycolysis and rigor mortis onset, thus the levels of ATP, pH, ionic force and WHC of meat remain high during the freezing and thawing processes.

To conclude, provided that the measures to prevent cold shortening and thaw rigor are brought into play, prerigor frozen meat can be better than post-rigor, that is, prerigor frozen meat has been reported to preserve to a great extent the functional properties of proteins and produce less drip loss during thawing and cooking (11, 53).

B. Flavour and Colour (Lipid Oxidation and Discoloration)

Raw meat has a weak or "flat" flavour, but contains flavour precursors from which more than a thousand volatile substances are generated during cooking by a complex sequence of chemical reactions. It appears that a freezing-thawing process applied to beef loin (50), or to red meats in general, has no significant effect on flavour.

However, during frozen storage the flavour of meat can be somewhat altered. Firstly, flavour seems to decrease and lose balance but does not become unpleasant. In this regard, Lawrie (33) pointed out that there is a gradual loss of the most volatile compounds even at temperatures below freezing. Also, flavour and flavour precursors which are soluble substances (reducing sugars, amino acids, peptides and nucleotides such as IMP and GMP) may be lost or degraded during freezing and, above all, during thawing. Equally, freezing-related protein changes can account for differences in their ability to bind taste and volatile compounds, thus modifying flavour perception.

Finally, after longer storage times unacceptable "off" flavours may be detected, normally rancid flavours, which are produced by numerous volatile compounds coming from lipid oxidation. This process can be avoided in full only if oxygen is completely eliminated and storage temperature is extremely low, i.e., under −60°C (31). Furthermore, flavour may be altered by interactions between several oxidation products and different flavour compounds, or hydrophilic peptides (27). Apart from flavour alteration, lipid oxidation may affect texture and nutritional properties of frozen meat. Lipid oxidation is definitely one of the principal limiting factors for frozen meat shelf life.

Theoretically, factors favouring or inducing meat lipid oxidation are numerous (traces of transition metals, sodium chloride, light, heat, protons, active oxygen species, damage to muscle structures, and enzymes). These enzymes (lipases, lipo-oxigenases and so forth) may remain active at sub-zero temperatures (12, 24). On the contrary, muscle possesses endogenous antioxidant capacity (involving α-tocopherol, carotenoids, ubiquinone, glutathione, carnosine, anserine, ascorbic acid and the enzymes with antioxidant activities, such as glutathione peroxydase, superoxyde dismutase and catalase). Storage of meat may result in a decrease in the activity of the antioxidant enzymes (35).

During freezer storage, when the balance of the factors favouring oxidation and of the antioxidant capacity of muscle foods tilts towards lipid oxidation, the latter is no longer controlled. In these circumstances lipid oxidation begins, first in the highly unsaturated phospholipid fraction in cellular biomembranes, thanks to its amphiphylic nature and proximity to the aqueous medium (20). In addition, triglycerides and cholesterol can be oxidised.

On the other hand, visual attributes such as red bright colour, fat colour, fat content (including perceived marbling and external fat cover) and general appearance serve as the first or only consumer indicators of the quality of chilled, and where possible frozen, red meat quality at the time of purchase.

Browning of meat during frozen storage and thawing is a consequence of myoglobin oxidation, which turns the pigment to metamyoglobin. If the percentage of metamyoglobin on the meat surface reaches a certain point (ca. 40% of total myoglobin), purchasers will reject meat. Accumulation of metamyoglobin depends on the relative rates of oxymyoglobin auto-oxidation and enzymatic or non-enzymatic reduction of metamyoglobin to oxymyoglobin. The rate of auto-oxidation of myoglobin is strongly dependent on temperature and exposure to light. Unlike chilling, where thermal auto-oxidation is predominant, under freezer storage conditions, light-induced processes become increasingly important (3, 36). Oxygen concentration is another important factor for colour stability. According to Lanari et al. (32), vacuum packaging and packaging material with incorporated light adsorber increase frozen red meat shelf life. Furthermore a blooming time (some 6 to 48 hours) in oxygen before freezing is advisable.

TABLE 115.2
Times of Storage (Months) at Which Lipid Rancidity or Browning Are Manifested in Lean Meat

	Storage Temperature			
	−8°C	−15°C	−22°C	−30°C
Beef	3	6	12	—
Pork without skin and fat cover	—	3	6	12

Adapted from Lawrie (33).

Colour instability together with lipid oxidation definitely constitute the principal limitations on frozen meat shelf life (Table 115.2).

Brown discoloration (metamyoglobin formation) and lipid oxidation in frozen red meats seem to be related (1, 40). Thus, Lanari et al. (32) and Guidera et al. (22) claimed that frozen meat colour stability and susceptibility to rancidity indicated the oxidation status of meat. Both processes demonstrate similarities in their progression in meat and meat products. Experimental results support the view that lipid oxidation contributes to oxymyoglobin oxidation and meat discoloration (43). However, in frozen meats, colour losses generally occurred much earlier than lipid oxidation (1, 3), these authors stating that pigment oxidation might be an initiator of lipid oxidation. In fact, the exact mechanism for a possible coupling between pigment oxidation and lipid oxidation is not well understood (20).

The susceptibility of specific frozen red meats to lipid oxidation and discoloration is influenced by intrinsic and extrinsic factors, which are shown in Table 115.3 (17).

Frozen meat colour at the surface may also be affected by excessive dehydration during storage, appearing as greyish-brown leathery spots: freezer burn, which leaves the meat dry and stringy. Moreover, dehydrated surface conditions enhance protein denaturation, lipid and colour oxidation. Freezer burn is not necessarily correlated with moisture loss in a simple manner (45). It tends to happen when meat surfaces are initially wet and freezing is very fast, when the lean meat surface is not protected, air speed in storage chambers is fast, and there are temperature fluctuations. In order to prevent freezer burn the recommendation is to prevent air from reaching the surface of the meat, mainly by using vapour-proof packaging materials.

Other defects in colour and/or aspect of frozen meats are yellow coloration of fat through lipolysis, deformations and freeze-cracks arising from sudden changes of volume during freezing, and mould development caused by temperature abuse.

Finally, meat may show different colours according to the size of ice crystals. When the freezing rate at the surface of the meat is high, crystals are smaller and scatter more light than larger ones, and then meat is more opaque and its colour lighter. In the case of red meats, fast freezing at very low temperatures may yield too pale a colour, thus reducing quality.

VI. NUTRITIONAL VALUE OF FROZEN RED MEAT

Red meats are considered as an important source of high quality food protein, minerals and B vitamins. Although freezing implies some losses in those compounds (specifically a loss of water-soluble nutrients in the exudate during thawing), the losses generally lack nutritional impact. Freezing can preserve the nutritional value of meat better than most other preservation methods. Vitamin loses are variable depending on the process. In general, the decrease in B vitamin content of frozen meats should be less than 25% for vitamin B1, 15% for B2, 10% for niacin and 20–50% for B6 or pyridoxine (17).

VII. SHELF LIFE OF RED FROZEN MEAT (CONCLUSIONS)

In terms of quality, freezing is one of the best technologies for preserving red meats. The main limitations on frozen red meat shelf life are the changes in sensorial attributes, specifically colour and flavour, due to pigment and lipid oxidation, respectively. Sublimation and drip loss during freezing and thawing may mean a considerable financial loss, however their influence on eating quality seems in reality to be slight (17).

In spite of the extensive literature on the shelf life of frozen meat, experimental data to support that body of theory seem to be scarce and rather old, based on freezing conditions that nowadays are old-fashioned. Furthermore, there is a lack of agreement among data on the storage life of industrial frozen meat (20). Nonetheless, general rules have been established. In this respect, it has been stated that the shelf life of red meat normally ranges from 8 months to 3 years (20), and likewise that beef and lamb can be stored at −18°C for at least 6–12 months and pork for 6 months. Moreover, frozen meat shelf-life data, defined as the practical storage life (PSL) recommended by the International Institute of Refrigeration (IIR), are shown in Table 115.4. In general, PSL seems to be two to five times high quality life (HQL) (20).

Quality problems in frozen meats subjected to extended storage are substantially reduced following some technological indications (specialist packaging, low (−18°C) and constant storage temperature). Packing/wrapping has a large direct effect on storage life. It can be effective in reducing oxidation, as packaging material can constitute a light and/or oxygen barrier, and dehydration. Fluctuating temperatures during storage are considered to be detrimental to the product.

Although appropriate freezing technology conditions appear to be more important than intrinsic meat quality in extending shelf life, it is nevertheless true that the best way to improve frozen storage life of red meats consists in an integrated package of measures including production, muscle to meat conversion and freezing technology.

TABLE 115.3
Intrinsic and Extrinsic Factors Influencing Lipid Oxidation and Discoloration in Frozen Meats

Factor	Several Significant Effects	Main Causes
	Intrinsic	
Species differences[a]	Pork is more sensitive than beef.	Pork has more PUFA[b] than beef.
Animal to animal variation: genetic, season, physiology		Not fully understood.
Feeding	The more the PUFA — or linoleic acid contents — in the diet, the more unstability, especially in monogastric. Higher content of antioxidant or prooxidant compounds in the diet represent an increase or decrease in stability, especially vitamin E.[c]	Meat composition: vitamins E and C, β-carotenes, carotenoids, prooxidants such as Cu and Fe, oxidative status of lipids in the feed.
Cuts of meat and muscle type	Red muscles are more unstable than white ones.	Oxidative pattern and composition differences, i.e., pH, % PUFA, antioxidant dipeptides, etc.
	Extrinsic	
Transport and slaughtering conditions	Stressed lambs carcasses with high pH were unstable to rancidity (23).	Variations in pH.
Chilling conditions, time and ageing	Increasing the time in chilling reduces frozen storage life. Hot-deboned frozen meat is more stable (47).	
	Processing of Meat	
Cutting and muscle disintegration,[d] structure damage	It favours the deterioration reactions contributing to reduce shelf life.	Enzyme/substrate contact is facilitated.
Salting	Salt contributes to unstability in frozen red meats, especially with light exposure (1).	Amplifies Fe reactivity in autooxidation, modifies enzymatic activity (35), may be a source of traces of prooxidant compounds.
Pre-cooking[e]	On the one hand, pre-cooking increases the propensity of meat to undergo oxidation during freezer storage. On the other hand, cooking may help to increase shelf life.	Cooking produces a structural change and accounts for liberation of prooxidant compounds.
Antioxidants addition in meat (mainly minced or restructured)	Tri-polyphosphates (TPF), fenolics — i.e. BHT, TBHQ, BHA, propyl gallate–, α-tocopherol, spices — i.e. rosemary, marjoram, cumin, ginger–, carnosine at 0.5–1.5% (w/w).	Antioxidant activity.
Packing/wrapping	Proper packaging[e] increased stability. This stability may represent the same as a decrease in 10°C temperature of storage — from −10 to −20°C (17).	Oxygen and light barriers.
	The Freezing Process	
Freezing rate	Freezing rates have not shown a significant effect.	
Storage temperature	The lower the temperature the higher the stability.	Oxidation reactions are temperature dependent.
Temperature fluctuations[f]	Oxidation is favoured.	
Thawing conditions	Lipid oxidation may suppose a problem in long thawing processes at sub-zero temperatures (33).[g]	

[a] Lipid oxidation has been an important problem in pork as well as comminuted lamb and beef (23, 46).

[b] Unstability of frozen meat to lipid oxidation depends mainly on poly-unsaturated fat acids (PUFA) content.

[c] Supplemented vitamin E in diet — usually α-tocopherol — at supranutritional level, i.e., >100 mg/kg feed during 50 days before slaughtering, accounts for a significant increase of vitamin E content in muscle, reaching levels of 3.5–7 μg/g. At this amount vitamin E appears to delay oxidation processes during frozen storage. This protective effect against oxidation of vitamin E might be reinforced with added antioxidants and vacuum packaging in order to eliminate practically the risk of oxidation of meat. Furthermore additional amounts of vitamin E in diet were responsible for decreased drip loss in pork.

[d] Mechanically deboned meat is especially unstable.

[e] The thumb rule to achieve a long shelf life of cooked-frozen meat consists on oxygen and lights barrier-packaging materials, i.e., aluminium foil, polivinidene chloride and storage below −18°C.

[f] Temperature fluctuations cause the rate of several changes to increase or decrease, especially in the vicinity of the freezing point, the glass transition point, and other phase transition temperatures.

[g] Thawing must be fast enough to delay oxidation reactions but slow enough to permit water re-absorption.

TABLE 115.4
Practical Storage Life Expressed as Months

Product	−12°C	−18°C	−24°C
Beef carcasses	8	15	24
Beef steaks/cuts	8	18 (max. 12)	24
Ground beef	6	10 (max. 10)	15
Veal carcass	6	12	15
Veal steaks/cuts	6	12	15
Lamb carcasses	18	24	>24
Lamb steaks	12	18 (max. 10)	24
Pork carcasses	6	10	15
Pork steaks/cuts	6	10 (max. 6)	15

116 Principles of Frozen Storage

Geneviève Blond, Dominique Champion, and Martine Le Meste
ENSBANA, Université de Bourgogne

CONTENTS

The use of freezing for food preservation has rapidly developed; the fact that products, mainly meat and fish, could be stored for considerable periods and served, after thawing, as fresh products, is at the origin of its development as one of most common methods for food preservation.

Freezing implies two linked processes: a lowering of temperature and a phase change of water from liquid to solid. Both processes tend to reduce rates of physical and chemical changes and might be expected to enhance the shelf life of the products.

At the same time, quality degradation during storage remains the most common problem for manufacturers and for bringing food freezing to the fullest possible extent. So it is vital to understand well the essentials of the technology. Freezing seldom does not improve the quality of food products; the raw material quality is of primordial importance, and this quality must be preserved during processing and storage. There is no single universal rule governing frozen food preservation; just as with optimal freezing rates, which vary from product to product, the storage time depends not only on the temperature but also on the type of product and packaging. Most physical and chemical reactions are slowed with the decrease in temperature, but they are not stopped at common storage temperatures. The product deterioration during cold storage is a slow, continuous, cumulative, and irreversible process.

The physical properties of food products change dramatically depending on water availability and tempera-

ture. The major assumption relating to quality, and thus shelf life, is that stability is maintained in the glassy state. In a glass, the diffusion of solutes and degradation reactions should be strongly limited, and long-time stability during storage expected. The shelf life of frozen food products should be largely controlled by the physical state of the freeze-concentrated fraction produced by the ice separation. It is desirable to better know how this physical state changes with temperature.

I. PHYSICAL STATE AS A FUNCTION OF TEMPERATURE

A. Physical Changes during the Freezing Process

The freezing of pure water takes place at 0°C (freezing point); this temperature is steady as long as the liquid and solid phases coexist because the chemical potentials of two phases are equal. The freezing of food products is more complex, due to the presence of their soluble and dispersed components. The water begins to freeze at lower temperature than 0°C (freezing point depression); the ice formation increases the solute concentration, reducing the chemical potential of water, and therefore requires a decrease in temperature which depends on the product composition.

For practical purposes, the freezing process is considered complete when most of the water at the center of the food product has been converted into ice. At −15°C, more than 80% of total water is transformed into ice [1]. The system is segregated into a crystalline phase of pure water and an amorphous domain, which contains solutes and residual water. As the temperature decreases, the viscosity of the interstitial fluid increases rapidly as a result of both concentration increase and temperature decrease. When the viscosity reaches 10^{11}–10^{12} Pa.s, a solidification (vitrification) occurs, and the concentrated phase surrounding the ice crystals becomes a glass. The temperature at which this transition appears is called Tg′, the glass transition temperature of the maximally freeze-concentrated system [2]. The freezing of water is stopped at this temperature; the water still unfrozen at Tg′ is often called "unfreezable" water.

Since the water content of foods is often close to 80–90%, its behavior during the freezing process can be considered as that of an aqueous solution. The proposed model is often a sucrose solution, which could be representative of the freezing behavior of a wide range of solutions when no solute crystallizes during cooling. That can easily be checked on fruits, fruit juices, vegetables like tomatoes, and ice creams which show very similar thermal changes. The equilibrium temperatures and concentrations vary with the nature and composition of the product. If cooling is slow enough compared to the kinetics of ice formation, the concentration in the liquid phase depends only on the temperature for a given product and is independent of its initial water content. As a consequence, Tg′ is also independent of the initial water content.

B. Determination of Tg′

Differential scanning calorimetry (DSC) is the technique most often used to measure the glass transition temperature; this transition appears as a typical heat capacity jump on the DSC traces and can be characterized by different temperatures (Figure 116.1). In the presence of ice, the glass transition, which is visible just before the ice-melting peak on the heating scans, appears more complex, presenting a larger heat capacity change than predicted from the solid content in macromolecule frozen solutions [3]. For frozen solutions of small solutes (sugars, polyols), the thermograms show a two-step endotherm (Figure 116.2). These features appear to be very similar to those observed with synthetic polymers and are interpreted as a glass transition with associated enthalpy relaxation [4,5]. There is still no agreement on how the DSC data should be interpreted. The

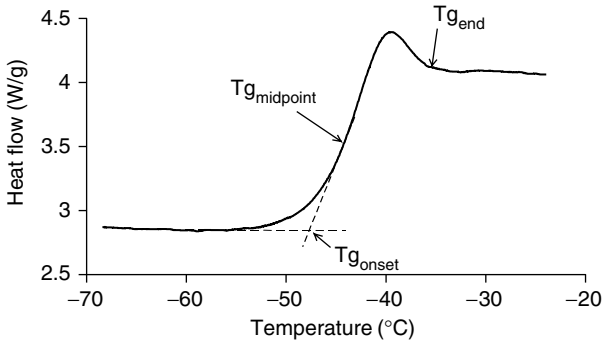

FIGURE 116.1 DSC thermogram of a 80% sucrose solution (cooling and heating rates: 10°C/min).

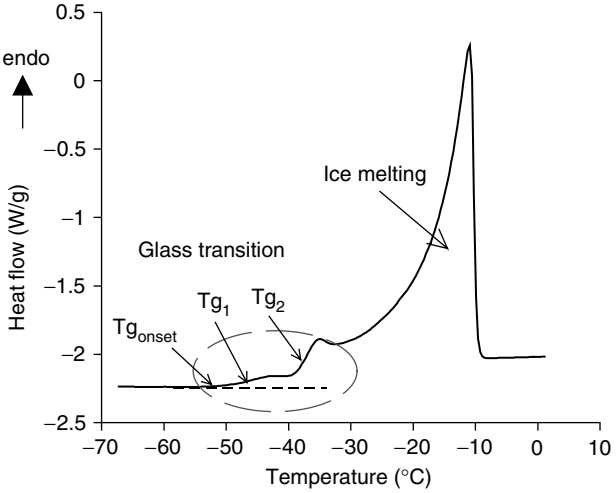

FIGURE 116.2 DSC thermogram of a frozen sucrose solution (50% w/w) (cooling and heating rates: 10°C/min).

reported Tg' value, according to some authors, is the temperature of the midpoint or the onset of the first transition; for others, it is the midpoint of the second step. They are called Tg_{onset}, Tg_1, and Tg_2 respectively, on Figure 116.2. This explains the variations in published Tg' values [6].

Because of the ambiguity of the Tg' determination from simple DSC traces, it was suggested to use simplified state diagrams of solute-water blends, which represent their different physical states in the low-temperature range. The two curves, corresponding, respectively, to the equilibrium liquid/solid or ice melting curve (*Tm* curve), and the kinetically controlled glass transition curve (*Tg* curve), are drawn. The diagram representing the various states of the sucrose-water system as a function of concentration and temperature is appropriate to illustrate the demonstration (Figure 116.3). The curve *Tm* represents the temperature at which ice begins to separate as a function of initial concentration, or the concentration of the freeze-concentrated phase as a function of temperature. For all points on this curve, the freeze-concentrated phase is in equilibrium with ice; its partial water vapor pressure is equal to that of ice at the same temperature. For soluble solutes, the temperature of the glass transition depends on the water content; it decreases when the water content increases. The intersection of the two curves could provide a better estimation of Tg' [7]. The freezing of water is stopped at this temperature; the concentration of the maximally freeze-concentrated phase is called Cg'.

There are obvious problems with the accuracy of the *Tm* and *Tg* curves. The experimental *Tm* values as obtained by DSC for the most concentrated solutions are considered as more or less reliable; an extrapolation of the *Tm* curve can be subjective; therefore the curve represented in Figure 116.3 is derived from excess properties and solid-liquid equilibrium using a UNIQUAC model [8]. For the *Tg* curve, the experimental data taken into account can be the temperature of the beginning Tg_{onset}, or the middle of the transition $Tg_{mid\text{-}point}$ (value most often used) or even of the end of the transition (see Figure 116.1 for sucrose solution). The cooling/heating rates contribute to some changes in *Tg* due to the time dependence of the glass transition feature. The DSC values of Tg_{onset} and Tg_1 of frozen sucrose solutions, in Figure 116.2, were found to be close to the intersection of the *Tm* curve with the Tg_{onset} and Tg_{mp} curves in Figure 116.3. The Tg'-Cg' coordinates vary from −45°C, 82.2% to −41°C, 81.2% [8] depending on the *Tg* value taken into account. Using the method of optimal annealing temperature, Abblet and coauthors have obtained very similar data in considering the mid-point: −40°C, 82% for Tg'-Cg' [9].

The liquid-glass conversion must be considered to occur in a temperature range that is characteristic of the fraction forming the glassy matrix. The coordinates Tg'-Cg' can be far away from the eutectic point predicted by equilibrium thermodynamics; for example, with sucrose-water binary *Te*, *Ce* are −14°C, 64%, respectively.

Thermomechanical spectroscopy (DMTA) studies of frozen sucrose solutions show that the change in mechanical properties, obtained with low sollicatations, becomes perceptible at Tg_{onset} as seen by DSC. A maximum in the loss modulus (E″ or G″) occurs at a temperature between Tg_1 and Tg_2 [10]. Apart from its scientific interest, the sucrose-water phase diagram (Figure 116.3) could be considered as representative for a wide range of products containing low molecular weight solutes; very similar diagrams are reported for some fruits [11].

C. Storage Conditions and Shelf Life of Frozen Foods

The choice of the storage temperature is of considerable practical importance in the frozen food industries. It is

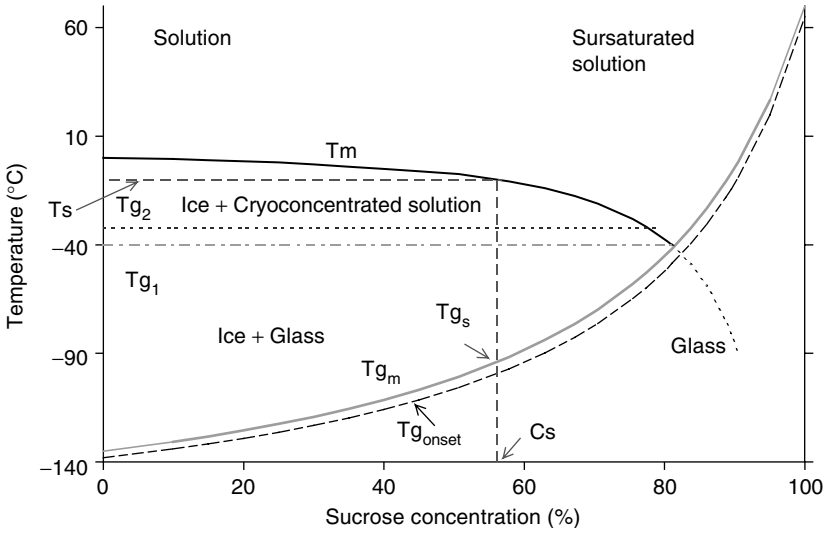

FIGURE 116.3 State diagram of sucrose-water binary, adapted from (8).

the major variable which can affect stability; a product retaining a good quality for months at −20°C can lose it in a few days at −10°C. Moreover, it is well demonstrated that frozen foods stored at fluctuating temperatures have not the same shelf life as products stored at constant temperatures [12–14]. The weakest links of the frozen food chain are handling time, temporary storage, and transport temperatures. The last link of the chain, the retail shops, is often critical. Frozen products delivered to the retail outlets are not always placed in refrigeration immediately; the problem includes temperature increases during defrosting. In Europe, where food stores are not open 24 h per day as in the United States, using night covers and programming the defrosting during the night may help to minimize the temperature fluctuations.

In order to ensure product quality, temperature control is necessary throughout the cold chain, and the required temperature must be maintained from production to consumption. European and international regulations concerning the storage temperature of frozen foods set −18°C as the highest temperature during storage and distribution, although many studies have shown that slow degradation of the product quality may occur even at this temperature. This temperature must be constant and maintained at all points in the product (therefore at the surface); possible brief upward fluctuations of 3°C maximum are admitted during transport, as well as a tolerance of 3°C during local distribution and in retail display cabinets [15,16]. To maintain an optimal quality, the products are generally held at temperatures colder than this in primary cold stores (−25, −30°C).

There is a clear effect of temperature on storage life, with lower temperatures resulting in extended shelf life; but −18°C corresponds to an optimum between the financial costs and the shelf life of frozen foods. As it is the same storage temperature for all frozen products, the marketing shelf life varies from 6 months to 2 years (Table 116.1) [1].

At this temperature frozen foods are neither fully frozen, nor inert, the Tg′ of most products being below −18°C. Table 116.2 shows the Tg' of some food products or more exactly the temperatures corresponding either to the second step of the transition (called Tg_2 on Figure 116. 2) or to the midpoint for a single transition. The Tg' data for solutions of numerous simple ingredients (sugars, polysaccharides, proteins) can be found in an article by Levine and Slade [25]. It must be emphasized that these temperatures, and consequently the glassy state, is readily attained by a very limited number of frozen food products at temperatures commonly employed in the distribution chains. That means that the freeze-concentrated phase is more or less fluid, and solute mobility may be significant. Frozen storage usually continues for long periods, so products undergo deterioration, which can be as important as those due to the freezing and thawing processes. The underlying reason for necessary extensive studies about change of quality during storage is that the causes of deterioration are not known enough to be able to propose efficient predictive models.

TABLE 116.1
Practical Storage Life (PSL) in Months at Several Temperatures

Product	−12°C	−18°C	−24°C
Beef steaks/cuts	8	18	24
Ground beef	6	10	15
Pork steaks/cuts	6	10	15
Fatty fish (glazed)	3	5	>9
Lean fish	4	9	>12
Butter lactic unsalted	15	18	20
Butter, lactic salted	8	12	14

II. CHANGES IN FROZEN FOODS DURING STORAGE

The main factors affecting frozen food quality during storage can be divided into two categories: processing and compositional factors. The quality factors associated with processing parameters are mostly related to the ice phase. Defects associated with compositional factors are related to chemical reactions and affect flavor, texture, appearance, color, and nutritional properties.

A. Physical Changes

1. Water Migration

The main physical change that occurs during storage of frozen foods results from water migration. Solid/liquid and

especially liquid/crystal transformations can occur with temperature fluctuations, but important water motions can take place without temperature changes. There is always, inside a package or a product, some difference of water vapor pressure due to a temperature gradient or a surface energy difference. As water molecules are not completely immobilized by low temperatures [28], a significant redistribution can be observed in frozen products because of the duration usually involved for the storage. The water migration causes either water content changes or changes in ice crystal size called recrystallization. Water migration is highly temperature dependent, and it occurs at any storage temperature, although good conditions (e.g., low temperature, no temperature fluctuations) minimize its importance.

a. Migration with change in water content

Water migration can correspond either to a water loss through surface dehydration or to only a water location change for products with heterogeneous water contents.

The surface dehydration adds to dehydration suffered during the freezing process, which can vary from almost zero for packaged products and cryogenic freezing to 3–4% for naked products and poorly designed freezers [29]. These moisture losses have the same origin, i.e., a temperature difference between the product and the surrounding atmosphere, resulting in a difference of water pressure that produces a water molecular flux from the surface of the frozen product to a colder area. Ice sublimation progresses during storage, and it is more pronounced when the storage temperature is higher. A common example is observed with frozen fruits and vegetables that are not protected by transparent films in close contact with them. The films cool faster than the surface of the product, setting up a water pressure gradient; thus a small amount of vapor water migrates from the product to the inside surface of the package. When the freezer temperature increases, the process is reversed and the water vapor condenses on the product surface. The dehydration must be considered irreversible, reabsorption of water in the product being not possible; this removed water crystallizes and remains inside the package as frost. As this cycle is repeated, the buildup of frost in the package becomes noticeable, this effect being amplified by the frequency and magnitude of temperature fluctuations; more than 2°C fluctuations promote an important sublimation of ice. The consequences are more or less important depending on the products, as the water losses can reduce the weight of the product, thereby reducing the market value for large pieces of meat sold before transformation; overall, the dehydrated surface of a product reduces its appeal to the consumer. Meat appears darker when frozen, since oxygen cannot produce the bright red color of oxymyoglobin (its "natural" color returns on thawing). A surface dehydration on this product leads to the important defect known as freezer burn, particularly for meat carcasses, cuts, and poultry, stored without an adequate packaging. Dehydrated surfaces come in grayish patches, because the disappearance of ice crystals by sublimation forms small cavities on the surface that appear grayish because of the light scattering. Dehydration of unprotected fish can lead to irreversible quality loss when the fish surface becomes dry with a "woody" texture. This dehydration also contributes to increase the rate of rancidity and discoloration. The dehydrated surfaces of vegetables may also appear clearer before thawing, but color changes for these products are predominantly caused by oxidative reactions.

The dehydration effects almost completely disappear on thawing and cooking, except if the product has been stored in bad conditions and dehydration was too severe. But the appearance in the frozen state needs to be taken more into consideration, because it is decisive for the consumer considering whether to buy the product or not. Moreover, the melting of frost during thawing causes an unpleasant appearance when a wet layer appears on the product surface.

Today these defects are more rarely observed, because efficient packaging prevents products from dehydration. Each product to be stored in a freezer over an extended period should be wrapped. Moisture-impermeable films offer considerable protection against moisture loss, but products must be packed with a minimum head space to reduce frost; vacuum packing, which ensures maximum contact of film to product, suppresses all frost and also limits the thermal gradient. Its use is limited because it is more expensive and unsuitable for delicate products. Surface dehydration can also be limited by coating with a continuous film of ice or glaze. Glazing consists in the application of a potable water spray immediately after freezing, a thin layer of ice covering each piece (fish, shellfish, fruit, vegetable) as protective coating; the water amount is normally in the range of 5 to 10%. Ice glaze is considered to be a cheap means of protection for frozen fish. The glaze is also used for giving some mechanical protection to the delicate frozen florets of cauliflower and broccoli. The formulated coatings, which are added-value processing for fish and meat, are also a protection against dehydration.

More difficult to suppress is the water migration in frozen foods containing regions with large water content differences, generally prepared frozen foods that are a combination of several dissimilar components. There is no particular problem if each component contains ice crystals: the water activity is the same in the whole food. But when a part of the food has a low water content, and consequently contains no ice, there is a high water pressure gradient between the "dry" part and the ice of the "frozen" part, irrespective of temperature. The resulting water migration produces moisture redistribution. These local water content changes can be important, and detrimental, for the product quality. They are found in frozen pies, fancy cakes, and desserts. Water migrates from the filling to the crust

of frozen pies and pizzas or from ice cream to the wafer, and the crispy components become moist and soggy. In frozen bread, if a thermal gradient adds to the difference in moisture, water migrates from the center to the region just under the crust and then freezes to form an icy area, which produces trust separation from the crumb at thawing.

As the water vapor pressure is always higher in the part containing ice, edible barriers with low water permeability must be developed, based on hydrophobic substances such as lipids and waxes, to stop or at least slow down the water transfer. The top of the baked trust of pies or pizzas may be sprayed with shortening to keep the sauce moisture from soaking into the crust. Cocoa butter or chocolate coatings are widely used in the ice cream industry for protecting wafer.

b. Migration without water loss: recrystallization

The quality objectives of the frozen food industry are to set a homogeneous ice crystal distribution and to preserve it during storage. The initial freezing process, particularly when occurring rapidly, yields a highly dispersed crystal phase. This initial distribution promotes metastability: small crystals are thermodynamically less stable than large ones, since they have a higher surface/volume ratio and therefore a higher excess surface free energy. The size and consequently ice crystals number must change.

It is not sufficient to produce products with a specified structure through control of the nucleation and crystallization rates. During the storage not only the size and number of ice crystals change but also their shape and orientation. This process is known as recrystallization; it corresponds to water migration as a result of local water motions allowing molecular diffusion from one ice crystal to another, more often without change in ice content. Mazur [30] and then Fennema [31] described several mechanisms of recrystallization; they include migratory, accretive, isomass, and irruptive recrystallizations. Melting and refreezing (regelation) due to temperature fluctuations is also defined as a recrystallization process, which causes the most significant and rapid changes in ice crystal distribution. Except for irruptive crystallization, the mean ice content is not altered by these different mechanisms.

i. Migratory recrystallization

Migratory recrystallization, which is referred to as "grain growth," is also known as the Ostwald ripening. It corresponds to the tendency for the large crystals to grow at the expense of small crystals.

The equilibrium shape of a crystal is the one that minimizes its surface free energy (at constant temperature and volume of crystal); the free energy of a crystal is at a minimum when its structure is perfect and its size infinite. A difference in stability brings about the size difference at constant temperature. The thermodynamic basis is the Kelvin equation, which states that the chemical potential of a curved surface differs from that of a plane one, and relates the vapor pressure over a spherical solid surface to the radius of curvature (r) [30]:

$$\mu_2 - \mu_1 = RT \log p_2/p_1 = 2V\,\sigma\,[1/r_2 - 1/r_1] \quad (116.1)$$

where μ_2 and μ_1 are the chemical potential of the two crystals, p_2 and p_1 their respective vapor pressures, r_2 and r_1 their mean radii, V is the molar volume of ice, and σ the interfacial tension. The relationship between pressure and melting point (Clausius-Clapeyron equation) allows us to calculate the crystal melting point (*Tm*) as a function of its curvature radius. The undercooling due to the curvature radius decreases as the sphere size increases. For a given storage temperature there is one crystal size that is in equilibrium: a solution with small crystals could also be regarded as being undercooled as compared to the one with large crystals. For pure water, *Tm* varies from −0.004 to −3.99°C when the crystal radius decreases from 10 to 10^{-2} μm [32]. Different values can be found in the literature, indeed some parameters are difficult to estimate, particularly the interfacial tension.

ii. Accretion

Accretion, also termed sintering, is the joining together of two crystals or more to form one larger crystal. A neck is formed between two adjacent crystals, and this neck grows until the original crystals are indistinguishable. The chemical potential, and consequently the vapor pressure, of a spherical surface is greater than that of a concave surface (*r* is negative). Reducing the surface concavity can lessen this difference in chemical potential. The vapor pressure difference is always the driving force that explains the neck construction. Kingery (cited by Mazur [30]) found that this growth was strongly dependent on temperature: in pure water the neck growth rate decreased from 3.3 to 0.033 $\mu m \cdot s^{-1}$ when the temperature decreased from −2 to −25°C. When the ice volume is important, this mechanism is certainly dominant, the ice crystal contacts making migration easier. Sutton and coworkers [33] showed that the recrystallization rate was dependent on the ice volume, and the accretion rate decreased as ice phase volume decreased.

iii. Isomass recrystallization

Ice crystals generally tend to become more spherical through isomass rounding during storage even at constant temperature [34]. The driving force is also the water pressure gradient; the Kelvin equation can be used considering different local curvature radii due to the irregular surface. Experimental control has been made in model solutions [35]. In actual foods, the ice crystals are so closely packed that isomass crystallization may not be clearly identified, as water molecules may easily diffuse between different crystals; however, the end results, are identical: all crystals become smoother. It must be emphasized that the

transport processes by which a crystal can change its shape at constant volume may be very slow by comparison with those involved in its growth. Theoretically, recrystallization could occur at a significant rate only for crystals with diameters less than about 2 μm [31]. In frozen foods, the average crystal size is generally much greater than 2 μm, and temperature fluctuations enhance recrystallization.

iv. Melt-refreeze recrystallization

Melt-refreeze recrystallization is observed during temperature oscillations. When the temperature increases, ice crystals partly melt and become smaller; they grow again when the temperature decreases. The smaller ones, which have the highest free energy and the lowest melting point, melt more, grow less, and so gradually decrease in size over time. They can completely disappear; as there is no formation of new nuclei, water refreezes on the surface of remaining crystals, and the total number of crystals decreases and their mean size increases. Fluctuating temperatures stimulate crystal growth; small temperature fluctuations are common during the long life of frozen products, particularly during distribution, but also because of the cyclic nature of refrigeration systems and the need for defrosting. Melt-refreeze recrystallization occurs in combination with other growth modes; most often it is not possible to distinguish which mechanism is the most important. The duration of temperature cycles can also be important for allowing migration of water molecules from one crystal to another; if the temperature fluctuations are fast relative to the diffusion rate of water and/or solute molecules, the crystal changes can be slowed down.

v. Irruptive recrystallization

Additional ice formation may occur during rewarming; this is referred to as irruptive recrystallization or devitrification. These terms could be discussed because (a) they assume that the medium had already been frozen and in fact they are generally used for systems cooled without or with incomplete crystallization and (b) they should imply that a vitreous state was obtained. Cooling may result in products that are not in equilibrium with respect to the freezing point (*Tm* curve). The amount of ice is smaller than predicted; the unfrozen phase is diluted compared to the theoretical equilibrium state. This situation is possible only when ultrarapid freezing can be employed or for products with high viscosity and/or relatively low water content. This state is stable only at temperature below the corresponding glass transition temperature (*Tg*). Above, the product crossing the temperature range where crystal nucleation and growth rates are maximum [36] the equilibrium state is obtained by a sudden appearance of a crystallized state.

Most foods, however, contain large amounts of water, and the freezing rates used in industrial processes are sufficiently low to produce a cryoconcentrated phase in thermodynamic equilibrium. This feature could be found in the high pressure assisted freezing process; after pressure release, the nucleation, in the undercooled product, is instantaneous and the crystallization rate is very fast [37].

c. Consequences of crystal growth

In many frozen food products, large crystals have an important adverse effect on the texture. In ice cream and frozen dairy desserts, a coarse texture results from an increase in the mean size of ice crystals, which become perceptible by consumers. For delicate plant tissues (strawberries) a disruption of cell walls is often observed, which produces a loss of turgidity because of a decrease in the water retention capacity. Meat and fish are a little less sensitive to ice crystal size changes, but crystal growth might enhance shrinkage of muscle fibers and even disrupt the cellular structure, resulting in a greater chance of oxidative catalysts coming into contact with reactive components. In view of the importance of ice crystals in modifying the texture of frozen foods, it is not surprising that there have been considerable efforts to control ice crystal size, and scientific investigations to bring to light the parameters that play on the different recrystallization modes. The higher the storage temperature, the faster is the crystal growth. The influence of the storage temperature is well documented: for example, the mean ice crystal diameter, which was of 10 μm in beef muscle frozen at −40°C, becomes equal to 40 μm after a 150 h storage at −5°C [38]. This crystal growth leads to greater tissue disruption, protein denaturation, and exudate production [39].

Crystal size has considerable importance in ice cream manufacture; ice cream is the only frozen product consumed in the frozen state, and large ice crystals make the product appear colder and sandy. Polysaccharides were reported as efficient stabilizers in several ice cream studies; they alter both initial crystal size and recrystallization rate [40]. In a study on the cryoconcentration process, Smith and Schwartzberg [41] observed that the presence of gelatin resulted in a decrease in ripening rates. The reported effects of polysaccharides on the slowing down of recrystallization are real; but the mechanisms by which they exert such effects are not well understood. Among the potential mechanisms that have been suggested are an effect on viscosity of the cryoconcentrated phase [10], and the polymer adsorption on ice crystals [42]. If the formation of a weak gel slows down the initial crystallization rate [43,44] by a hindering mechanism, the water diffusion that allows the recrystallization is not slowed down by the existence of a network [45].

There is no evidence to support the view that polysaccharides could affect the amount of ice formed, which is in agreement with the thermodynamic properties of solutions. They can even enhance the process of nucleation by the introduction of specks (outside impurities) [46].

2. Solute Crystallization

Many solutes are supersaturated in the unfrozen phase, particularly sugars. After a while, they may crystallize, as

is the case of lactose in ice cream. Even if the lactose crystal size is smaller than that of ice crystals they give a sandy texture because they melt more slowly than ice crystals in the mouth. This effect is limited by polysaccharide addition, but an important lactoprotein content increases its risk if lactose proportion becomes large. Sugars may also crystallize on the surface of high sugar fruit spreads during frozen storage, giving the appearance of mold colonies on the surface. The same effect can be observed with icing or glazes of frozen desserts; the soft texture of these latter must be preserved by a modification in formulation: replacement of sucrose by invert sugar and addition of stabilizers such as polysaccharides. The formulations used must have the greatest degree of tolerance to temperature abuse. While a certain amount of temperature fluctuation is unavoidable, efforts should be made to minimize it.

In most cases, the texture quality of frozen food products is better preserved when their temperature is maintained as low as practicable during storage. The temperatures used to monitor recrystallization rates are generally high compared to the actual storage temperatures. At −18 to −20°C, the recommended temperatures, crystal growth is much slowed, and the main problem remains the temperature oscillations that induce the melt refreeze process. This leads to adopting lower storage temperatures (around −30°C for ice creams) for long-term storage of frozen products awaiting distribution.

B. Chemical Changes

An abundance of chemical and biochemical reactions may take place in animal and plant tissues, even in dead cells. If during the freezing process most reactions are stopped, some may be only reduced. As a frozen product is typically available after several months in storage, some changes can be observed thus far, but they are minimal if optimal conditions of storage are respected, i.e., low and stable storage temperature. Chemical reactions are slowed down by the temperature effect, but small solutes retain some mobility in the unfrozen phase. Because of freeze-concentration, reactants are in close proximity, and reactions rates may increase. It has been shown that freeze-concentration is likely to increase reaction rates over the subzero temperatures, the temperature range depending on substrate composition [47,48]. At lower temperatures, reactions may become diffusion-controlled and the rates decrease as the maximal freeze-concentration, i.e., Tg', is approached.

Evaluation of the chemical changes during frozen storage is a difficult task: (a) because of the duration of the experiments; at −18°C, they have to spread over one or two years; (b) the difficulty for dissociating storage influence from other process effects: blanching, freezing, and thawing; and (c) because of the diverse nature of the sensitive compounds, the chemical heterogeneity should require experiments for each vitamin, lipid, and protein.

Apart from the general problem of analysis methods, there are many possible sources of variations in product quality: for animals, breed, age, diet, preslaughter treatment; for plants, cultivar, maturity, harvesting practice; and recipes for prepared foods. The complexity, variability, and diversity of interactions between different ingredients, and thus the physical laws that control their reactions, are unknown. This may also result from incomplete destruction of enzymes during blanching or cooking, or to oxidations permitted by packaging materials permeable to oxygen.

The analyses done at different temperatures allow the determination of the reactions Q_{10}, i.e., the ratio of deterioration rates at two temperatures separated by a 10°C interval; it indicates how much longer the product quality will be retained when the temperature is decreased by 10°C. The Q_{10} values can be high for frozen products, varying from 2 to 30, while for temperatures above 0°C they are generally between 2 and 3.5.

This complexity can be illustrated by a comparison of chlorophyll degradation in frozen green beans either blanched or unblanched [49]. The rate of color degradation was faster in blanched than in unblanched green beans at −6°C, while the opposite was observed at −18°C. This study well demonstrated that comparison at only one temperature can be misleading; this can be explained by the difference in Q_{10} values, respectively equal to 7.8 and 2.8 at the studied temperature range (Figure 116.4). The degradation ways are different: in unblanched green beans, the degradation is associated with the peroxidation of some fatty acids by lipoxygenase, which gives uncolored substances; in blanched green beans, the bright green chlorophyll is converted to olive

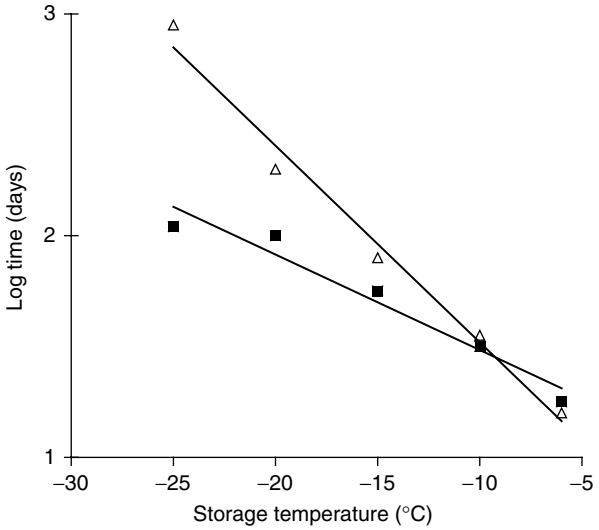

FIGURE 116.4 Days of storage required for a 10% decrease in chlorophyll of blanched (Δ: r = −0.99; Q_{10} = 7.8) and unblanched (▪ r = −0.97; Q_{10} = 2.8) frozen green beans (var. Koba) as a function of temperature, redrawn from Ref. (49).

green pheophytins, independently of enzymes and oxygen presence.

The difficulty of analysis and of interpretation is also demonstrated by the review by James and Evans [50] on the storage life of beef, pork, and lamb at different temperatures. Experimental data from many publications show there is agreement that storage temperature influences frozen state life, and that in general the lower the temperature the longer the shelf life. But considerable scatter between results at any one temperature is observed. Moreover, few papers present data at different storage temperatures, and many experiments are realized at too high a temperature compared to storage common practice.

Different types of chemical changes are particularly troublesome: oxidative processes and protein degradation, denaturation/aggregation, result in texture, flavor, and color degradations, and vitamins losses, i.e., decreases in sensory and nutritional qualities.

1. Oxidative Deterioration

Lipid oxidation corresponds to the most important chemical reactions associated with quality change during frozen storage. In foods, lipids can be oxidized by both enzymatic and nonenzymatic mechanisms. It is generally agreed that autoxidation, that is, the reaction with molecular oxygen, is the main reaction involved in oxidative deterioration of lipids. The major pathway for oxidation involves a self-catalytic free radical mechanism, which can be shown as a three-step simplified scheme: (a) initiation in which free radicals R° are formed from unsaturated lipid molecules RH by their interaction with oxygen in the presence of catalysts; (b) propagation in which the free radicals continue to be generated, and (c) termination when an antioxidant, an oxygen or free radical scavenger, reacts with free radicals. Lipases and phospholipases are enzymes, which hydrolyze lipids, the release of fatty acids can lead to rancid flavor. Lipoxygenases have also proved to be active in frozen foods and to cause changes in lipid constituents. This does not only hold for animal tissues, rich in lipids, but also for plant products. Lipoxygenase is mainly responsible for the deterioration of flavor occurring in frozen unblanched vegetables.

Lipid oxidation most commonly occurs in fatty meats and is considered as the main cause of frozen shelf life reduction compared to lean meat species. The importance of lipid oxidation varies with the quantity and the nature of the lipids; highly unsaturated lipids are less stable than saturated ones. Polyunsaturated fatty acids are autoxidized in the presence of oxygen to hydroperoxides that decompose into volatile compounds, forming flavor and aroma compounds characteristic of rancid foods. Fatty acids formed during autoxidation may produce indirect effects on textural degradation by promoting protein denaturation [51].

Color degradation is also related to oxidation during storage. For example, the discoloration of tuna is due to the oxidation of myoglobin to metamyoglobin; for salmon, the pink color, given by carotenoids, can disappear by oxidation after a long storage.

For animal tissues, the stability studies focus on lipid oxidation. Clearly, composition has an appreciable effect on the storage stability of frozen products. Fish products are the best example, their shelf life being related to their fat content: fatty fishes have a shelf life of 4–6 months at −18°C, whereas the lean ones can be preserved 7–12 months [52]. Pork meat fat contains a higher proportion of unsaturated fatty acids than other meat fats such as beef, lamb, and chicken; consequently pork has a shorter storage life (Table 116.1). Antioxidants are regularly used to stabilize the flavor of composed foods; they delay the development of rancidity by interfering with the initial step of the free radical reactions or by interrupting propagation of the free radical chain [53]. Antioxidants are of little effect in intact muscle; they are more effective when mixed with ground meats; their efficiency appears better when used as nutritional supplements. Also, the very undesirable effect of salt in flesh products is well noticed [54].

For vegetables and fruits, color changes are predominantly caused by oxidative reactions. Enzymatic browning is due to polyphenoloxidase promoting the direct reaction of polyphenolic substances with air oxygen. This problem can be overcome by blanching, but fruits generally are not blanched, because this process gives them a cooked flavor and a soft texture. Color stability is improved by the presence of ascorbic acid or the addition of citric acid, which preserve the phenolic substances in a reduced colorless state. Sugar or syrups added to fruits before freezing also help to limit browning by slowing down the enzymes' action and by protecting against oxygen. The stability studies focus on vitamin changes over time. Vitamin C (ascorbic acid) is the vitamin most readily associated with vegetables; it is also the most labile vitamin. It is oxidized by oxygen, the phenomenon being enhanced by active oxidizes (ascorbases, catecholoxidases) and metallic elements (Fe, Cu). Vitamin C content varies considerably between different vegetables, but also in a vegetable, depending upon variety, maturity, and agronomy. The level of vitamin C is not an indicator per se, but this latter is generally used as the most appropriate "marker" for monitoring quality changes during processes. Favell [55] compared the vitamin C content in some commercially quick- frozen vegetables stored for up to 12 months with the same fresh vegetables at various stages of distribution. For frozen products the major loss was attributed to pretreatments; changes, observed after storage at −18°C for 12 months, were minimal, and the frozen products presented the best nutritional qualities among products usually available to the consumer. This report confirms that for all frozen vegetables, nutritional quality is equal to and even

better than that of fresh vegetables bought in supermarkets; frozen vegetables are also "fresher" than those preserved by other thermal processes.

2. Protein Denaturation

The conformation of protein derives from its secondary and tertiary structure. As a result, every treatment of proteins with concentrated saline solutions, organic solvent, heat, and cold may modify this conformation. Denaturation is an elaborated phenomenon during which new conformations appear. The effects of protein denaturation are numerous: decreased solubility, altered water binding capacity, loss of biological activity, particularly enzymatic, and increased susceptibility to attack by proteases due to the unmasking of peptide bonds in unfolded structures. The sensitivity of a protein to denaturation is related to the readiness with which the denaturing agent breaks the stabilizing interactions. Since the latter vary according to the protein, the resulting effect of the same treatment is variable. Freezing concentrates solutes, including salts and small organic molecules. Changes in ionic strength and possibly pH [56] in the remaining unfrozen aqueous phase ensue, leading to the denaturation of proteins. Aggregation and precipitation may occur. The toughening and poor water retention observed in some species of fish, the precipitation of casein micelles in milk, and the gelation of egg yolk lipoproteins result from a decrease in protein-water hydrogen bonding and an increase in protein-protein interactions in the frozen product. The myofibrillar proteins, which aggregate during frozen storage, are probably linked by secondary interactions and disulfide bonds. As these aggregates tend to grow in number and size, the proteins lose more or less of their water-binding capacity.

The most popular tests to determine the denaturation during storage of frozen meat or fish, for example, are the determination of the loss in solubility or extractability of proteins and the measurement of the water-retention properties of the muscle system. The use of cryoprotectants in cured and processed meats can stabilize the functional properties of myofibrillar proteins; for example, addition of polyhydroxy compounds such as sorbitol and sugar in comminuted fish flesh allows one to preserve the gel-forming ability essential to obtain a surimi pasta.

Even at the low temperatures used for storage, most enzyme systems are still active. Quality deterioration is most commonly observed in meat and fish products because they are raw materials, whereas vegetables are generally subject to blanching, which destroys most enzymes, before freezing. However, the high concentration of the unfrozen phase increases the possibility of contacts between residual enzymes and substrates. Since some proteins also act as enzymes, attempts have been made to assess denaturation from the angle of enzyme inactivation. The loss of protein activity is more reflected by enzymatic activities than by extractability or solubility. It is possible that enzymatic reactions are accelerated during freezing because of the cofactors' concentration and because of membrane disruption, which allows easier enzyme-substrate interaction than in intact cells.

C. Microbial Processes

Frozen food products and particularly fish products are far from sterile and cannot be considered as microbial safe products. Many microorganisms are not destroyed by the freezing process and may survive even if they remain inactive during storage.

The effects of frozen storage on microorganisms are variable, depending upon the organism considered. The lower limit for bacterial growth in food is about −10°C and for yeasts it is about 5°C lower. However, it is not possible to store food for long periods at temperatures slightly below the growth limits of microorganisms. Foods thus stored show noticeable signs of deterioration that should be also due to the activity of microorganism enzymes, adding to that of the product specific enzymes. Whereas a heat treatment used before freezing decreases the number of surviving microorganisms, the enzymes secreted into the food, such as lipases and proteases, are much less affected by heat.

At −18°C no growth of microorganisms will occur. The reduction in number owing to storage is possible but not of practical importance. Therefore the quality of raw products and a good hygiene during the production are most important.

In the practical application of freezing technology, microbial processes are essentially limited to the effects of microbial enzymes; frozen products with a maximum shelf life can only be produced when raw materials of initially outstanding quality are used [57].

III. STABILITY AND SHELF LIFE

A. Which Model for Stability Studies in Frozen Foods?

The principal factors affecting the quality of frozen foods during their storage are (a) storage temperature and time, (b) nature and quality of the product at the time of freezing, (c) preparation and freezing processes, and (d) packaging.

The first two are referred to as TTT factors (time-temperature tolerance). They have been widely analyzed during the 1950s and 1960s and have allowed important progress in frozen food quality [58]. The two following decades have considered the PPP factors (product, process, packaging) [54]; it has been clearly proved that frozen product quality is directly related to the quality of the raw material used and to the optimization of preparation processes (heat treatment); moreover good packaging may often more than double their storage life.

Today the studies' objectives are to elaborate predictive models based on a more accurate knowledge of physical state and molecular mobility in the frozen product as a function of the storage temperature. Levine and Slade [2] have promoted the idea that the transition of a liquid to a glassy state for the maximally freeze-concentrated fraction, and consequently the temperature at which this glass transition takes place (Tg'), was the threshold of instability, and that the kinetics above this temperature were controlled by the difference between the storage temperature and Tg'.

It is essential, however, to define a shelf life for each frozen food product put on the market. Product shelf life can be estimated by (a) objective measurements of properties or characteristic changes related to food quality, *e.g.*, the ascorbic acid content of frozen fruits, and (b) shelf life failure criteria based on some noticeable quality difference between experimental and control samples.

Around 1960, it was suggested that in regulations pertaining to the keeping quality of a frozen product one should use the concept of time first to *just noticeable difference* (JND). In IIR-IIF publications [1] this is referred to as a product's *high quality life* (HQL). HQL is defined as the elapsed time between the freezing of a high-quality product and the storage time when 70% of an experienced taste panel is able to distinguish, by triangle tests, the product from the control stored at a very low temperature ($<-40°C$) [58]. Sensory quality can also be estimated using an hedonic scale method. But obviously consumers are not as sensitive to a small change as is a taste panel, and an acceptability time has been introduced that corresponds to the concept of *practical storage life* (PSL). It corresponds to the consensus of opinions about the useful "storage life" to be reasonably expected for the product.

There are many occasions for frozen products to suffer heat shock abuse during distribution and to reach an unacceptable level of quality. Since there is no way of identifying the conditions under which frozen products will be handled once they leave the manufacturer's control, it is problematic to predict an exact shelf life for any frozen product. A practical approach can be based on the profile of received consumer complaints, combined with the evaluation of products purchased at or near the sell by date. The level of complaints involving chosen quality attributes in most aged products would support a decision to extend or reduce the sell by date.

Thus the shelf life of a product essentially becomes a measure of the suitability (or lack of suitability) of a product for consumption.

No precise relationship has been demonstrated between HQL and PSL, the time gap measured between the two varying with the product. The TTT relationships are deduced from experimental studies, and the data can only be compared so long as the PPP factors are the same. Moreover, the TTT relationships are not mathematical functions. The books by Van Arsdel and coauthors [59], Jul [54], and IIR-IIF [1] reported numerous results of storage investigations on the keeping quality of frozen foods and PSL and HQL data.

B. Glass Transition and Stability Prediction

1. Vitreous State in Frozen Materials

As described before, all physical, chemical, and biochemical changes occurring during the storage of frozen foods are strongly affected by temperature, and also by water availability; the temperature effect is associated with the increasing concentration of the liquid phase as the temperature is lowered. Comprehensive procedures have been searched for accurately predicting stability. Temperature is of little value; the shelf life of different products is not the same at a given temperature. Water activity (Aw) is also not effective as a predicting parameter. The freeze-concentrated phase is in equilibrium with ice, so its partial water vapor pressure is equal to that of ice at the same temperature. Thus for all frozen foods the same water activity would be expected at the same temperature; the water activity in frozen foods only depends on temperature (Figure 116.5). Levine and Slade [2] proposed that the changes in amorphous concentrated systems should be controlled by kinetic rather than thermodynamic constraints. Consequently, the viscosity and other relaxation properties would be appropriate to predict the rate of reactions when molecular mobility is reduced.

When temperature decreases, diffusion-controlled processes slow down with the increase in viscosity due to the combined effects of concentration and temperature. The shelf life of frozen food products should be largely controlled by the physical state of their freeze-concentrated fraction. In the glassy state, i.e., below Tg', chemical reactions should be strongly limited, and a long time stability expected. In practice, foods are rarely maintained at storage temperatures below Tg'; as described before, they become

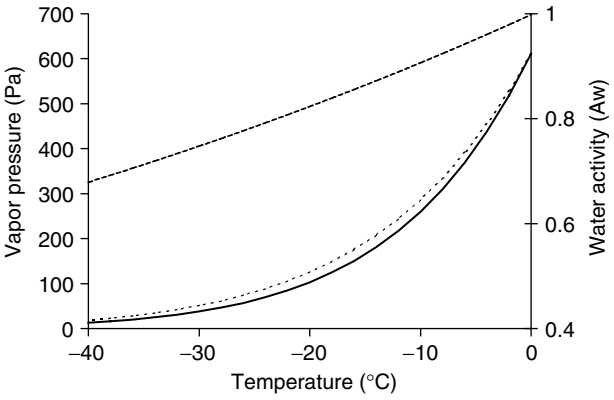

FIGURE 116.5 Water activity (Aw) of ice as a function of temperature; vapor pressure of ice: full line, of liquid water: dotted line, Aw: dashed line.

vulnerable to crystal ripening and chemical changes. Then, the properties and behavior of the unfrozen phase appear to be the key factor for understanding and improving the stability of frozen foods and their shelf life.

The glass-liquid transition is characterized by a rather abrupt change in many physical properties of the material. The main observable phenomenon is a change in the mechanical properties: the glassy brittle solid is changed into a "rubber" in the case of a polymeric material, or in a viscous liquid the viscosity of which strongly decreases as the temperature increases. The most important implication of the glass transition concept in frozen foods, and foods in general, is that translational motions of molecules, especially larger ones, do not occur in the glassy state during a practical time frame. Storage at a temperature above this characteristic temperature range would result in pronounced changes in mobility of solutes and an increase of degradation rates. There should be two possibilities for improving the stability of a frozen product: to lower the storage temperature below its Tg' and to modify this latter by a recipe change, a possibility for manufactured foods.

However, experimental data that analyze quantitatively the relationship between the stability of actual frozen foods and the glass transition are very scarce, and the few tests [27,60,61] are not always conclusive. This scarcity cannot be attributed to a lack of interest in this parameter but rather to the credibility of data as found in the literature. The published Tg' values for sucrose frozen solutions, as collected by Sahagian and Goff [6], vary from −32 to −46°C, and even their designation is different: Tg', $T'm$, Tg_2, and also Tg_{r2}; for fish the values vary from −70 [24] to −13°C [62]. There is general agreement on the concept, but it is necessary to clarify the important discrepancies as regards its practice. The question is not so much what is the true value of Tg' but more about the molecular mobility changes in that temperature range. Two aspects must be considered: (a) to have reliable information on the glass transition temperature of the maximally freeze-concentrated phase (Tg'), and (b) to know in which conditions Tg' is the reference temperature.

2. Influence of Composition on Tg'

For a series of homologous polymers it is well known that the temperature of the glass transition is increasing with the molecular weight; the same is shown to be true for sugars [63]. Other molecular properties such as branching [64] and cross-linking [65], play a lesser role. For a mixture, the glass transition temperature can be predicted from the characteristics of each component by means of expressions such as the semitheoretical Couchman and Karasz expression [66]:

$$\ln \mathrm{Tg} = \frac{\Sigma_1^n(\mathrm{C_i}\Delta \mathrm{Cp_i} \ln \mathrm{Tg_i})}{\Sigma_1^n(\mathrm{C_i}\Delta \mathrm{Cp_i})} \qquad (116.2)$$

where C_i is the mass fraction, Tg_i the glass transition temperature, and ΔCp_i the increment in heat capacity at Tg_i for each component.

However, given the uncertainties in the Tg_i and Cp_i values for biopolymers, and the poor agreement with experimental data when one component is water, the more empirical Gordon-Taylor equation is preferred [67]:

$$\mathrm{Tg} = \frac{\mathrm{C_s Tg_s} + \mathrm{kC_w Tg_w}}{\mathrm{C_s} + \mathrm{kC_w}} \qquad (116.3)$$

where C_S and C_w, are the mass fractions of solid and water, Tg_s and Tg_w their Tg values, and k a fitting parameter.

The thermodynamic properties of solutions depend on the size and nature of the solute; thus composition changes modify both the Tm and Tg curves, and consequently the Tg' value. Tg' will be influenced mainly by the molecular weight (MW) of the solute and to a lesser extent by its conformation and structure; for example, Tg′ is around −40°C for sucrose solutions and −46°C for glucose solutions.

The presence of high MW solutes could increase the Tg' and could be expected to improve stability. Hydrocolloids (polysaccharides or gelatin) must be added at a rather high concentration to a solution of low MW solutes, to have a significant impact on Tg'. In fact, they essentially alter the second step (Tg_2) of the transition; Tg_{onset} and Tg_l do not increase (Figure 116.6) [68]. This may indicate that the temperature at which some mobility appears is not raised upon the addition of the polymer. At the opposite, low MW solutes have a plasticizing effect and thus lower the Tg' of multicomponent samples. The addition of mineral salts largely decreases Tg'. For frozen saline sucrose solution containing 26% sucrose + 6% NaCI, Tg' decreases to −75°C [69]; with $CaC1_2$ in the same ratio, Tg' equals −90°C [66]. The Tg' of fish at −70°C can be explained by the presence of salts in the flesh composition [24]; this low-temperature transition is confirmed by

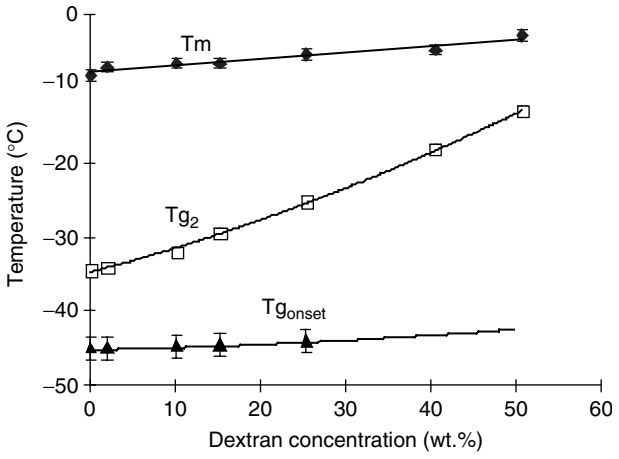

FIGURE 116.6 DSC transition temperatures as function of composition for frozen sucrose dextran solutions (50% w/w).

mechanical measurements [70]. Chang and Randall [71] showed that if for frozen pure protein solutions the Tg' is high (−10, −12°C), it decreases with the addition of small solutes (sugars, polyols). It is a common observation that in mixed materials, the glass transition range broadens; for instance, with a mixture of salts, the transition may spread over a range of nearly 30°C [72]. The presence of ice may promote this broadening, amplifying the Tg_2 feature supposed to be due to enthalpy relaxation associated with the beginning of ice melting. Low Tg' values are not always reported for actual frozen food products (meat, fish) because experimental works may not extend to a low enough temperature range for observing the beginning of the glass transition feature.

The addition of hydrocolloids greatly increases the viscoelastic modulus of the freeze-concentrated phase just above Tg′. Mechanical measurements show a tendency toward the development of a rubbery plateau (Figure 116.7); this effect increases in the order of increasing shear thinning behavior of polysaccharides [10]. These properties are certainly more representative of the macroscopic properties than of the molecular ones. They depend, moreover, on the behavior of both coexisting phases: the ice crystals and the freeze-concentrated phase. In the latter, the freeze-concentrated polymers are above their critical concentration for entanglement.

3. Molecular Mobility Around the Glass Transition and Consequence for Stability

The stability of frozen foods strongly depends upon the storage temperature. This temperature dependence is due to the dramatic decrease in viscosity at $T > Tg'$. It was tempting to explain the drastic effect of temperature by Williams, Landel, and Ferry kinetics [73], the WLF equation [Equation (116.4)] specifying a much greater temperature dependence of molecular viscosity and viscosity-dependent properties than the Arrhenius equation [Equation (116.5)].

$$\log(\eta_T/\eta_{Tg}) = C_{1g}(T - Tg)/(C_{2g} + (T - Tg)) \quad (116.4)$$

$$\eta_T = \eta_0 \exp(-Ea/RT) \quad (116.5)$$

where η_T and η_{Tg} are viscosity at T and Tg, respectively, Ea activation energy, R gas constant, η_0, C_{1g} and C_{2g} are phenomenological coefficients.

Note that the evolution of molecular mobility above the glass transition temperature may be different depending on the material, as shown by the strong/fragile classification of Angell and coworkers [74,75]. Strong liquids are those with Arrhenius or near-Arrhenius behavior above glass transition, in contrast, fragile liquids show an important increase in mobility with increasing temperature.

The major complication of the WLF theory as applied to frozen systems is that the composition of the unfrozen fraction changes as the temperature increases owing to ice melting [60]. Thus dilution of the unfrozen phase results in an even greater decrease in mobility than predicted by the WLF equation where Tg' is taken as the glass transition temperature (Figure 116.8).

In a glass, long range motions are restricted; motions (reorientation of small groups of atoms) are mainly local. The temperature dependence of dynamic properties is generally considered to obey the Arrhenius law [79]. In maximally frozen systems, ice seems to promote structural relaxations in the glass over a broad temperature range below Tg', which may explain the complex features that are observed with frozen sugar solutions by DSC analysis; a

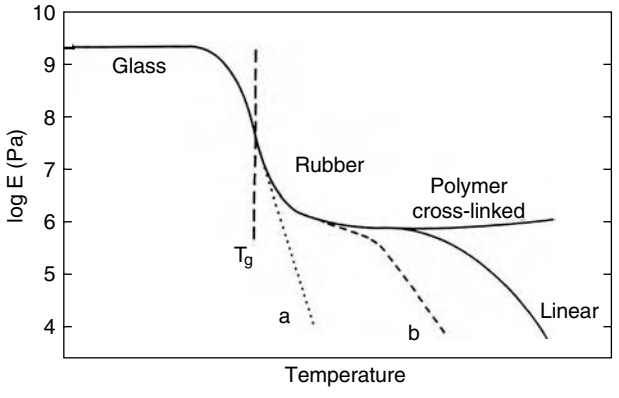

FIGURE 116.7 Theoretical thermomechanical spectra (storage modulus E′) versus temperature for different molecular weight components in the glass transition range (a = frozen sugar solution, b = frozen sucrose + polymer solution).

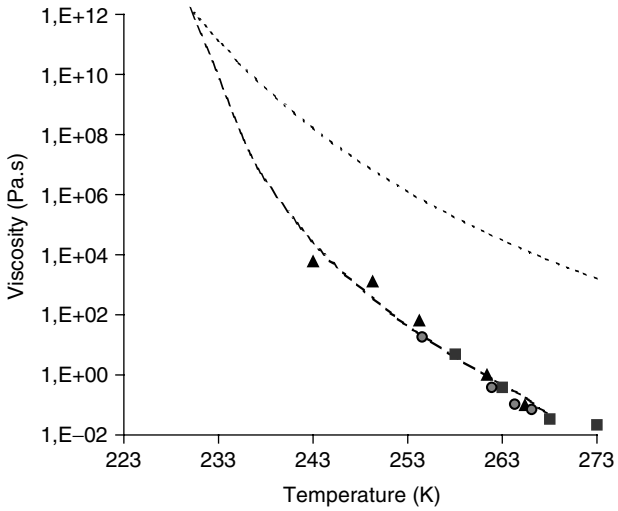

FIGURE 116.8 Viscosity of freeze-concentrated sucrose solutions as function of temperature. Symbols are experimental values: ■ (76), ▲ (77), ● (78) and dashed line represents the WLF prediction of viscosity, dotted line the viscosity predicted for a 82% sucrose solution (maximum cryoconcentration admitted as constant).

slowing down of enthalpy relaxation processes is induced by polymer addition [10].

C. Storage Temperature (*Ts*) and Stability

For products stored at a temperature $Ts < Tg'$, long-term stability may be expected. Translational molecular motions of glass-forming molecules are effectively inhibited; the diffusion-controlled processes cannot be observed on a practical time scale. By contrast, in the product stored at *Ts* between Tg' and *Tm,* the mobility of reactive solutes is higher, resulting in losses of nutrients and quality.

The relevance of Tg' as a reference temperature, for predicting the rate of physical and chemical changes during storage in the frozen state, presents no clear bases, although it has often been mentioned. Different experimental data, essentially the rate of ice crystal growth and some enzymatic reactions, have been analyzed with WLF kinetic equation. Sutton and coworkers [80] showed that ice crystallization rates in fructose solutions increased exponentially with increasing temperatures and followed WLF rather than Arrhenius kinetics, but the authors stressed the point that the range and the number of tested temperatures were too small for exact determination of the best model of temperature dependence. The possibility of inhibiting the recrystallization in ice creams by raising Tg' through the addition of high MW compounds was explored in many studies. There was a general trend where the recrystallization rate increased with increasing $(Ts - Tg')$, but the data did not fit WLF kinetics well [25]. For these models, the reference temperature was taken as constant (Tg'), although the composition of the amorphous phase was variable in the tested temperature range. From a practical point of view, the high MW solutes used as stabilizers in ice creams are added at too low levels (0.1–0.3%) for having significant impact on Tg' of ice cream mix [27], but they certainly slow down the ice recrystallization.

The main mechanism of the beneficial effect of the stabilizer addition to ice cream texture should be related to the perception in the mouth [81].

Manzocco and coworkers studied polyphenoloxidase and peroxidase activity in media with marked differences in viscosity at equal subfreezing temperatures; the rate values for the catalyzed reactions were within the same order of magnitude, in spite of the large differences in viscosity; and Arrhenius kinetics gave a fit at least as good as WLF kinetics over the temperature range of −30 to −5°C [82]. Biliaderis and coworkers [83] presented similar results for the temperature dependence of the oxidation rate of ascorbic acid in the presence of starch hydrolyzates.

More generally, the temperature dependence of many deterioration processes is much too weak to be correlated with the drastic decrease in viscosity above Tg' resulting from ice melting associated with the WLF effect when the latter is calculated using a constant Tg' [84].

For the glass transition concept to be relevant for predicting the rate of diffusion-controlled reactions, several requirements have to be met: diffusion and viscosity should be linked according to the Stokes-Einstein relation, and viscosity should have a WLF temperature dependence; for frozen products, an appropriate glass transition temperature has to be considered, taking into account the varying concentrations in the prevailing storage conditions.

Appropriate WLF parameters C_{1g} and C_{2g} have to be used [85], and *Tg* values much lower than Tg' have to be considered. For frozen food stored above Tg' (Table 116.2), the freeze-concentrated phase is more diluted than at Tg'; this latter parameter cannot be used as a reference temperature [86]. For example, in ice creams, the Tg' value is close to −34°C; if the storage temperature is −20°C (*Ts*), the freeze-concentrated fraction is liquid. Because its state diagram can be compared with that of sucrose-water binary, the reference *Tg* to consider in the WLF equation to predict the influence of temperature can be estimated at around −75°C, i.e., the temperature at which the liquid phase would turn into a glass if it could be cooled without further crystallization. The mobility and the resulting stability in the matrix would be related to the difference between *Ts* and *Tgs* and not between *Ts* and Tg' (see Figure 116.3).

Figure 116.9 shows that a good correlation can be found between the experimental and the calculated data for the rate constant of the hydrolysis of disodium *p*-nitrophenol catalyzed by alkaline phosphatase in sucrose solutions in the [+20, −24°C] temperature interval [76]. The prediction assumes that the reaction rate is viscosity dependent; in the studied temperature range, translational

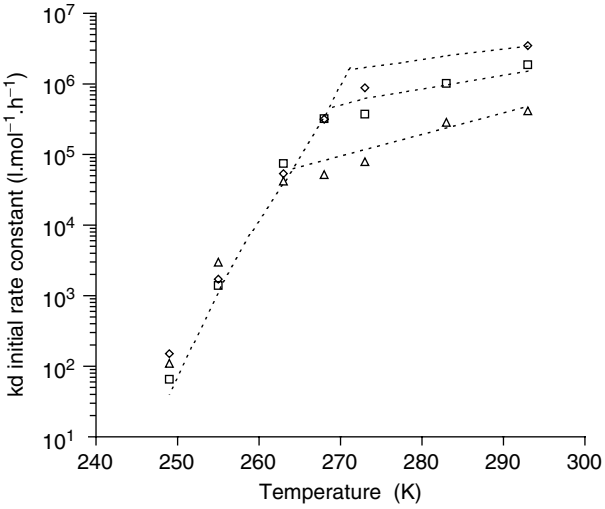

FIGURE 116.9 Initial reaction rate constant kd of alkaline phosphatase as a function of temperature in sucrose solutions (◇ 30% sucrose, □ 40%, Δ 57.5%). Dotted lines: k_d predicted from the measured viscosity (samples without ice) or from the predicted viscosity for the freeze-concentrated phases. (From Ref. 76.)

diffusion *(D)* of reactants and viscosity *(η)* were found to be linked by the Stokes-Einstein relation [87]:

$$D = KT/6\pi r\eta \quad (116.6)$$

where r = hydrodynamic radius of the diffusing molecule.

The prediction is based on the measured and calculated viscosity; the WLF equation was used to predict the medium viscosity taking as temperature reference the glass transition temperature *Tgs* corresponding to the concentration at the storage temperature *Ts* (Figure 116.3).

Even if reaction rates are viscosity dependent, this parameter is not the only one that should be taken into account to predict the complex changes during low temperature storage [82]. A simple relationship: stability = $f(Ts - Tgs)$, cannot be expected; the kinetics of physical and chemical processes taking place in frozen products stored above Tg' may be controlled by many factors depending or not on the concentration changes: solute concentration, pH, ionic strength. In structured products cell membranes limiting the solute diffusion, aggregation, and conformational change of protein or enzyme with temperature must also be taken into account. Sometimes enzyme activity is better preserved in model solutions than in the food product [88].

The discrepancy between theory and experiment can also be explained by the difficulty of knowing if, in the temperature range considered, the reactions are diffusion controlled or still activation-controlled or even in a transition region where activation and diffusion constraints coexist. A more important point is that the molecular diffusion of some components might be influenced by temperature and water content in a way very different from macroscopic properties. When the size of diffusing molecules is very small compared with the matrix molecules, the macroscopic viscosity may not reflect the "local" viscosity and be the parameter that controls diffusion.

Despite the limitation of the glass transition concept with regard to quantitative prediction of reaction kinetics, the Tg' value of a food product is of practical significance because it should provide a guideline to the industry in the formulation of manufactured foods.

A good stability being related to the possibility of maintaining the product below Tg', the formulation change could be a possible improvement. Attention must be given to the presence of small solutes, which contribute to provide some mobility at low temperatures. For example, the experiments of Wang and Jane [89] show that the addition of sugar increases the starch degradation, even for storage temperatures below the apparent Tg'.

It should also be remembered that storage in the glassy state does not guarantee long-term stability, as this state appears to have only a weak direct impact on the diffusivity of small molecules such as oxygen and water. The relatively high mobility of oxygen in glassy matrixes is often responsible for the oxidation in frozen foods stored below their Tg', and thus for their limited shelf life.

Tg' has been proposed and remains as the temperature of critical importance. This parameter represents a interesting limit to characterize the product stability, but it cannot be reliably used as a reference temperature for evolution kinetics above Tg'. The relevant temperature is then the glass transition temperature *Tgs* of the analyzed medium at the storage temperature.

IV. CONDITIONS OF BETTER FROZEN STORAGE

How long can a food be maintained in a state of satisfactory quality during frozen storage depends on the type of food, how it is processed and packaged before freezing, and on the storage temperature and how it is handled during the storage time.

Exposure to high temperature and/or fluctuations of storage temperature produces cumulative adverse effects on the quality of stored foods, which are the primary cause of damage to food marketed through retail channels. The rate of quality deterioration increases with increase in storage temperature, and such changes (reactions) are irreversible. If microorganisms will not grow in frozen foods, chemical and physical changes occur at rates that are of commercial significance during insufficiently controlled storage. Violations of recommended storage conditions should be detected and corrections instituted.

Many investigations have been made to control temperature rise in the logistic frozen food chain; these studies show large variations of product temperature even after a short exposition to ambient conditions. The temperature of the most exposed packaged product in a pallet can exceed −15°C at core for an ambient temperature of 21°C over a 25 min period; the surface temperature was 3 to 5°C higher than the core temperature. Today mathematical models are more precise and allow us to calculate the consequence of this temperature rise; it should be possible to specify what the initial temperature of the product must be maintained at −18°C throughout the distribution chain [90].

Time-temperature indicators (TTI) applied to cases or pallets could be of great help in this regard; but they are very little used yet.

A. Time-Temperature Indicators

Considerable research has been conducted to develop and design reliable systems to monitor temperature abuses. There exist different indicator kinds: temperature indicators showing only exposure above a reference temperature and temperature-time indicators taking into account the cumulative effects of time and temperature above a reference temperature; the latter would be preferred because

both temperature and time are important for quality control of frozen foods during storage and transportation.

Various types of time-temperature indicators have been developed that are based on mechanical, chemical, microbial, or enzymatic irreversible reactions for visualization of the degree of food quality change [91–93]. The problem is that for accurately monitoring changes in frozen food quality the TTI activation energy should be closely matched to that of the food quality factor. To meet such a requirement is a difficult but possible challenge [94]; moreover, an important limit is the cost of such indicators, which should be placed on the outside of each package.

Temperature management requires monitoring devices; today, many recording thermometers are available and must be used to monitor distribution conditions.

Samples must also be protected against light for preserving the color stability. Exposure to the levels of light found in some retail frozen food display areas can cause appreciable color changes within days. Products kept in dark or opaque packaging may be expected to retain color longer than those exposed to light.

Realizing the importance of creating quality reserve for the consumers, most large food industries in Europe are demanding much lower temperatures in the first links of the chain. Two main challenges for the years to come will be to improve consumer education for proper handling of frozen foods throughout the whole frozen chain and to find simple and inexpensive ways for control and checking.

V. CONCLUSION

Appropriate freezing and thawing processes and optimized temperature stability during storage preserve the quality and characteristics of fresh foods in the frozen product to a degree that is scarcely reached by any other preservation method. Since the glassy state is only readily attained by a very limited number of frozen food products, product deterioration in frozen storage is a continuous irreversible process. Physical and biochemical activities continue at −18°C, but the reaction rates at this temperature have only a limited practical significance during the commercial life.

It must be borne in mind that raw material characteristics are the most important factors to final frozen food quality. No process improves the intrinsic qualities of a food product, but a most efficient way to preserve them over time always exists. The challenge of the freezing process is to reduce the rate of physicochemical deterioration through improved storage, particularly its temperature stability and packaging material and also through the quality of the raw material.

ACKNOWLEDGEMENT

The information in this chapter has been modified from "Principles of frozen storage," by G. Blond, D. Champion and M. Le Meste. In *Handbook of frozen foods*, Editors: Y. H. Hui et al., 2004, Marcel Dekker, NY.

CONTENTS

Some modifications involving several constituents of bread formulation take place during preparation and baking of bread from frozen dough. This work analyzes the effect of freezing on the several ingredients, regardless of the processes and formulations used.

I. FLOURS

As in any baking process, flour quality is essential for obtaining a good product. In this case, the freezing process, transportation, possible temperature variations and thawing are all factors demanding flours of better quality than those used for traditional baking.

In breadmaking, the proteins play a key role. After water addition, a cohesive dough is formed which is structured by gluten. Gluten proteins associated with lipids are responsible for dough cohesive and viscoelastic properties. These properties make the dough capable of retaining the gases produced by yeast action, leading, after baking, to a spongy product bearing elastic crumb. Processes that affect the proteins will also affect the quality obtained.

In the USA, flours recommended for breadmaking should have a protein content between 12 and 14% (1), though classical baking is carried out with flours containing 11% of protein (2). European recommendations suggest flours with 12.5% of protein with about 30% of wet gluten (3). Nevertheless, the quality of these proteins might be as important as the amount shown by Inoue and Bushuk (4). These authors studied the effect of freezing on baking performance with bread made of selected flours. These flours were quite similar in protein content (between 13.7 and 14.4%) but quite different in quality. Extensigraph results (maxima resistance and extension) showed that dough strength and loaf volume were decreasing after freezing and thawing and during frozen storage. Some experiments were realized with constant yeast activity (same level as in non-frozen doughs) and showed that loss of dough strength on freezing, thawing and during frozen storage was the main reason for the decline in bread loaf volume. Inoue and Bushuk (4) showed that protein content, in the range covered, appeared to be less important than protein quality. Doughs made from extremely strong flours resulted in firmer crumb texture (5).

During frozen dough processing, dough weakening occurs which, together with yeast damage, are the main causes of the shortcomings of this methodology. This is evidenced by the production of bread loaves with lower volume, by the increase in fermentation times, and by alterations in textural properties (4,6–9).

The decrease of dough strength during freezing and the freezing-thawing cycles has been attributed to several factors. Ice crystals formation in non-fermented doughs stored for 24 weeks was found to cause rupture of the gluten network as observed in previous works by scanning electron microscopy (SEM) (10).

Freezing process causes yeast death and the release of reducing substances; these effects were investigated. Some authors (11–12) have proposed that owing to the reducing nature of these substances (mainly glutathione), disulfide bridges could be broken, thus leading to dough weakening. However, it has been suggested in other works that structural changes induced in frozen and thawed doughs are unrelated to the release of reducing substances (8,13–14).

It was observed that, during dough storage at −18°C, glutenin aggregates of molecular weight 129,100 and 88,700 experience depolymerization, which becomes more noticeable for longer storage times (15). This confirms that long-term frozen storage of doughs causes gluten depolymerization.

The release of reducing substances from dead yeasts added to the rupture of gluten network caused by ice crystals may explain the decrease of strength in frozen doughs, the loss of CO_2 retention capacity and the corresponding volume loss in bread loaves prepared with this technology.

Perron et al. (16) have not found a clear correlation between the quality of breads obtained from frozen dough and protein content. However, it is known that the shortcoming of quality in this type of product is more noticeable when weak flours are used. In the USA it was reported that vital gluten supplementation improves product quality, lessening the difficulties mentioned above (9,15).

The effect of freeze damage on the crumb grain was studied using Scanning Electron Microscopy (SEM) (18–19). Figure 117.1 clearly show the structural damage caused on dough ultra structure by frozen storage.

Starch is another important component of flour. This storage polysaccharide participates in breadmaking process by absorbing water. For this reason, it is recommended for breadmaking from frozen dough that the flour used does not have more than 7% damaged starch (2), since excessively high levels of damaged starch increase the water absorption capacity of flours, creating problems during dough handling and fermentation (19).

From the technological point of view, the role of starch is more important in bread firming. Despite the nature of physico-chemical modifications that explain bread hardening that are still widely discussed, a key role is assigned to starch in all hypotheses.

The mechanism causing bread firming has been studied for many years; its elucidation will allow the appropriate selection of methods to lessen this process. At first, the popular belief was that bread hardens with time only because of the moisture loss, but Boussinggault in 1852 (20) stored hermetically packaged bread and also observed firming (21).

A century later it was postulated that starch was responsible for hardening (22). Later, several works contributed with elements to relate bread firming with starch retrogradation (23–27). However, other results were in conflict with the hypothesis explaining bread firming as a consequence of amylopectin retrogradation: (i) the rate of bread hardening is linear up to day 5 while amylopectin retrogradation rate increases linearly up to day 3 (28). (ii) Breads with low moisture content harden faster while starch retrogradation rate keeps unaltered (29); (iii) breads added with α-amylase as additive harden more slowly but they show increased crystallinity studied by X-ray (30).

Upon these results Martin et al. (31) have proposed a bread firming mechanism based on the increase in interactions between starch molecules and gluten proteins. However, later works have shown that gluten addition in model systems did not affect firming rate (32–33).

León et al. (27) have developed a new technique aimed for studying the changes occurring during bread storage, which is based on direct observation of the transformations in progress. To this end, bread dough is baked in a differential scanning calorimeter capsule, following the temperature profile at the crumb center, to test samples by new calorimetric runs after different storage times. By applying this methodology to frozen dough, greater retrogradation rates were found in samples kept frozen for more than 30 days compared with control samples.

By deepening this research, it was found in frozen samples stored for 60 days and then baked in the DSC capsules that amylopectin retrogradation was faster than in fresh doughs. When stored both at 4 and 20°C, though in the former temperature, the effect of freezing was more noticeable (Table 117.1) (34).

II. YEASTS

Freezing induces stress to microorganisms. Five major factors might affect the cell during freezing (35): (i) low temperature, (ii) extracellular ice formation, (iii) intracellular ice formation, (iv) concentration of the extracellular solute and (v) concentration of intracellular ice. (iv) and (v) can be due to ice formation (intra or extra cellular) or to water/solute diffusion through the cell membrane. Factors (i) and (ii) cannot cause *per se* cell damage (35). Most microorganisms can support cell dehydration. Factors (iii) and (iv) are most likely to be the major phenomena involved in cell damage. Intracellular freezing is very difficult to achieve in most conventional industrial

168	−3.12 ± 0.24	−3.68 ± 0.03	−2.18 ± 0.06	−2.16 ± 0.21

freezing processes. Freezing rate in excess of 10°C/min to 100°C/min can produce intracellular ice formation for yeast and bacteria, respectively (35). The lower the size of the cell, the higher the freezing rate should be; this is due to the cell volume and to the thermodynamics associated to ice crystallization. It has been demonstrated that a critical ice nuclei radius exists below which the nuclei is not stable and cannot exist or grow (36). Conventional freezing process as the one used to freeze bread dough has limited possibilities in term of freezing rate. Yeast is a quite resistant microorganism but the activity of yeast is affected by freezing.

Higher yeast proportions are thus recommended in frozen dough formulations to compensate for the activity loss which is due to freezing *per se* but also during the storage periods, leading to lower gas production capacity (37). This is provoked by the changes induced during freezing, which can cause yeast death. The cells exposed

TABLE 117.2
Dead Yeasts Percentage during Freezing Dough and Yeasts for Several Storage Times

	%Dead Yeasts			
Time (days)	0	40	60	90
Frozen dough	2.7	7.5	20.2	27.7
Frozen yeast	1.4	1.7	2.5	5.2

to temperatures below 0°C are damaged in different ways depending on the temperatures reached and cooling rate. Besides, higher yeast content formulations produced bread with a higher specific volume; whereas during storage, the specific volume decreased, probably because the ice crystallization caused damage to the bread structure (38).

Although freezing point of the cytoplasmic content of cells is about −1°C, it can remain unfrozen even in the presence of ice crystals in the external medium (39). The higher water vapor pressure in the cell interior compared with that of the external ice causes water loss. This dehydration equilibrates vapor pressures at both sides of the membrane, leading to solutes concentration in the cytoplasm (40).

It has been suggested that the optimum cooling rate for destroying as few yeast cells as possible is 7°C/min. For rates below the optimum, the proportion of deaths increase by 'solution effect' (increase in concentration) while rates above recommended values increase the damage by intracellular ice formation (40). Besides, ice crystals recrystallization leads to cells death by causing damage inside the cell and on the plasmatic membrane.

The solution effect is explained by four stages occurring during freezing: a) water is transferred towards the ice, b) solutes become concentrated, c) cell volume decreases, d) some solutes precipitate (41).

The results of Mazur (40) were obtained with cell suspension and cannot be directly applied to the case of frozen dough. When incorporated in the bread dough yeast does not behave the same as yeast alone. The relationship between freezing and yeast activity becomes more complex. The proportion of dead cells caused by freezing is higher in yeast incorporated to the dough than in freezing yeasts (37,42) (Table 117.2).

This phenomenon can be explained by considering that active cells (as those found in the dough) have their plasmatic membranes thinner than in dormant cells, and therefore less resistant to damage. Besides, molecules produced by fermentation such as ethanol, acetic acid and lactic acid concentrate in the unfrozen region of the aqueous phase. This concentrated solution of organic substances can produce autolysis of yeast cells, as it is known that active cells are more sensitive to this autolytic action (12).

The decrease in yeast yield exceeds cell death since CO_2 production losses of 13.2% are found in ready frozen dough; this loss increases to 37.7% at 45 days and 52.4% at 60 days of frozen storage. Therefore, freezing causes yeast death and impairs CO_2 production capacity of surviving yeast. By adding frozen yeast extract to bread formulation, it was observed that the longer the yeast remained in frozen state before extraction, the lower the specific volume of bread obtained with that extract (42).

The dissimilar sensitivity of yeasts from different origins is related to lipid composition, mainly the sterols/phospholipids ratio, which affects plasmatic membrane fluidity (43). In recent years work is being carried out to obtain yeast strains of improved resistance to freezing, in order to use them in breadmaking via frozen dough (44–49).

Other substances were used to protect yeasts, such as trehalose (50–51). This carbohydrate is known to be an efficient protective agent to keep membrane integrity and intracellular structure in a wide range of physiological and room conditions (52). Meric et al. (51) showed that a 5% minimum trehalose content was necessary to achieve a significant improvement of yeast resistance to freezing. No real benefit was observed above this limit. For this reason, in new yeast strains, efforts are directed to make trehalose synthesis more active and to lessen the effect of catabolic routes (41).

III. OXIDIZING AGENTS

The role of these oxidizing agents is essential in breadmaking because they increase gluten strength and allow breads of higher volume to be obtained. In breadmaking via frozen dough, oxidant addition is particularly necessary due to protein matrix weakening caused by the mechanical action of ice and by the effect of reducing substances released by yeasts.

In the USA, flour for breadmaking via frozen dough was usually added with 45 ppm potassium bromide combined with 100 ppm ascorbic acid (1). After potassium bromide prohibition as breadmaking additive in almost all the world, azodicarbonamide was proposed as a substitute, to be used in combination with ascorbic acid and enzymes such as lipoxygenase, or else enzymatic complexes contained in active soy flours.

The comparative analysis of potassium bromide and ascorbic acid actions showed that both improve product quality and that the quality of bread added with ascorbic acid is higher than that added with potassium bromide (53).

Azodicarbonamide is a 'quick action' oxidant, very sensitive to glutathione and to other substances released on yeast death (54). Thus, it is best used, according to recommendations, when combined with benzoyl peroxide (55). Concerning fermentation time, Dubois and Blockolsky (6) showed that potassium bromide, used in low concentrations shortens fermentation time compared to that obtained with ascorbic acid.

If potassium bromide is used in high concentrations, it is found that from 20 weeks of frozen storage on,

TABLE 117.3
Principal Additives Used in the Formulation of Frozen Dough

Additive	Effect	Reference
Gluten 2%	Increase dough strength	Wang and Ponte, 1994 (57)
SSL 0.5%	Decrease the freezing effect on bread volume	Abd El-Hady et al. 1999 (53)
DATEM 0.6%	Increase bread volume	Sahlstrom et al. 1999 (56)
Mix of sucrose, fatty acid ester, DATEM, fatty acid monoglycerides and sugar	Avoid the harmful effects of freezing on the quality of baking products	Nakamura et al. 1996 (61)
Mix of gums, tensioactive agents and forming film proteins	Avoid the harmful effects of freezing on the quality of baking products	Larson et al. 1983 (62)
Mix of gluten, emulsifier and polymeric substances	Inhibit the deterioration of dough eliminating the damage produced by big ice crystals	Yamaguchi and Watanabe 1987 (63)
Hidroxy propyl methyl cellulose (HPMC)	Reduce the hardness and increase the specific volume of bread	Barcenas et al. 2004 (64)
Enzymes that produce maltotrioses and glucose oxidase and/or hemicelulase	Prevent volume reduction due to the freezing	Tanaka et al. 1997 (65)
Glycerol 0.75–1.0%	Improve the structure of the crumb	Dubois and Blockolski 1986 (6)
Ethanol-water 5–20%	Decrease the water melting point and to diminish the thawing time previous to fermentation	Lidstrom and Slade 1987 (66)
Sucroglycerides	Protect the yeast against the harmful effect of freezing on baking products	Le Duff 1987 (67–68)
Lecithin 0.2–0.3%	Flour strength	Grandvoinnet et al. 1986 (69)
Alfa-amylase 0.05–0.1%	Produce fermentable carbohydrates	Larsen 1991 (70)
Skim milk-whey protein 2.2%	Provide humidity in baking products, avoiding the use of gluten that alters the organoleptic properties	Seneau 1989 (71)
Carboxy methyl cellulose (CMC), bean gum, gum arabic	Improve the dough and bread characteristics	Sharadanant and Khan 2003 (72–73)
Guar gum 0.5%, DATEM 0.5%	Improve volume and texture of bread	Ribotta et al. 2004 (18)

fermentation times become longer than those obtained with ascorbic acid, potassium iodide and, specially, than that found when using azodicarbonamide (54).

IV. ADDITIVES

Emulsifiers are increasingly used in those bakery products including fat in its formulation, since they improve dough stability and retention capacity of the gases produced by fermentation, improve loaf volume and crumb freshness with longer shelf-life.

For frozen doughs, effective additives have been proposed to improve product quality such as SSL and DATEM (8). By adding SSL, freezing-induced quality losses can be alleviated (53). DATEM addition significantly increased volume, shape ratio and bread quality (56).

Glycerol used at 0.75–1.5% (on flour basis) causes little effect on the volume obtained via frozen doughs, though crumb structure is improved. In turn, xanthan gum addition does not improve volume and reduces crumb quality (6).

In order to have a flour bearing the required 'strength,' a gluten additivation percentage of 2% has been proposed as the optimum level to improve bread quality, gas retention capacity and fermentation time (57). Apart from improving protein quality, a cryoprotectant effect on yeast is obtained since, on increasing glass transition temperature, the free water proportion is decreased (58). Other additives capable of reducing, at least partially, the shortcomings caused by dough freezing have been described. Among them, we find egg yolk and sugar esters (59), and addition of vegetal fats to form water/oil emulsions at different proportions (60).

A summary of the principal additives and their effects on the characteristics of frozen bread are shown in Table 117.3.

V. CONCLUSIONS

Over frozen dough processing, dough weakening occur which, together with yeast damage, are the main causes of the shortcomings brought about by this technology. The increase in fermentation times, the production of bread

loaves with lower volume and alterations in textural properties are detected.

The success in the expanding use of frozen dough for the production of bread and bakery products depends of the resolution of these problems.

The fact that the freezing process affects the viability of yeast cells and the CO_2 and the reducing substance production by yeast opens an important technological and research field. In this sense, the obtainment of new strains of yeasts and the searching of additives and variables of process that help the cryoresistance of the microorganisms are essential.

Another important phenomenon that deserves attention is the protein depolymerization during the frozen storage, which may partially reduce using different additives.

In the production of bread from frozen dough complex formulations must be used for reducing the harmful effects of freezing. These formulations include lipids, high percentages of yeast and oxidizing agents, as well as mixes of different oxidizing agents, surfactants or emulsifiers that improve the bread matrix, gluten, soy flour, sugars and enzymes. For this reason the freezing process is more profitable for the bakery products with a high added value.

118 Minimal Processing: Fundamentals and Applications

Stella Maris Alzamora and Daniela Marisol Salvatori
Facultad de Ciencias Exactas y Naturales,
Universidad de Buenos Aires

CONTENTS

I. INTRODUCTION

Consumer's wants, needs and desires have driven the greatest advances and the most significant changes in food processing in the last two decades (Exhibit 118.1). Consumers are increasingly aware of the health benefits and risks associated with consumption of food. At a time when they are requiring less extreme treatments (less heat and chill damage), with lower levels of salts, fats, acids and sugars and/or the complete or the partial removal of chemically synthesized additives, there is also an increased demand for convenience foods with fresh attributes and long shelf-lives.

Food trends towards fresh image on one side and convenience on the other side often conflict. In most cases the fresh quality is negatively affected by the processing procedure. The most crucial current and future challenge is to retain the natural functional properties and the sensory and nutritional quality with the appropriate shelf-life and safety.

To meet these expectations, the food industry and the researchers have developed in the last years a range of strategies and minimal processing (MP) techniques for food preservation that allow better retention of product

Exhibit 118.1

CONSUMER REQUIREMENTS AND DEMANDS

High quality standards with acceptable price levels
High safety standards
Convenience of distribution and preparation
Nutritional concepts and healthy appeal to a broad age group
Satisfaction of cultural and ethnic local habits
Suitable to modern lifestyles
Variety of choice

Adapted from Jiménez-Laguna et al. (1).

flavour, texture, colour and nutrient content than comparable conventional treatments. The MP concept includes a series of products and processes that may be grouped in diverse food categories such as: minimally processed, with invisible processing, carefully processed, partially processed, and high moisture shelf-stable (2). These terms are not exactly equivalent but reflect the great diversity of alternatives for high quality products.

In this chapter, the fundamentals of the main minimal techniques (already used industrially or still in development or testing) are considered, a number of recent achievements are highlighted and some safety and quality considerations for a successful design of minimally processed products are presented.

II. DEFINITION OF MINIMAL PROCESSING

The MP concept has evolved, giving a wider approach than those terms used earlier by Rolle and Chism (3), Shewfelt (4), Huxsoll and Bolin (5), Wiley (6), and Ohlsson (7) (2). According to Rolle and Chism, the manipulation and basic preparation of foods, as well as life permanence in the biological tissue, are the elements that distinguish the minimal processing. Shewfelt added to the definition the possible use of low level irradiation and individual packaging as preservation factors that allow safety and high quality. Examples of minimally processed products presented by Shewfelt included vegetable stick snacks, packaged tossed salads, chilled peach halves, peeled and cored whole pineapple, shelled fresh legumes, microwaveable fresh vegetable trays, gourmet chilled dinners, among others. The use of refrigeration appears as a fundamental preservation factor for this type of foods. Huxsoll and Bolin included those foods whose tissues could be not alive, but freshness should be kept as an important objective of preservation. These authors also expressed that minimally processed foods (MPF) are not necessarily for direct consumption, but can be considered as preserved foods that maintain their freshness characteristics and can be later transformed into processed products using conventional techniques.

Wiley presented a very important alternative to the use of refrigeration alone: the modification and control of atmospheres in food packages as other preservation factor to be employed during the MPF elaboration. Ohlsson mentioned, as an important element, the necessity that this processing should be enough and adequate to keep the product quality during the storage period that goes from preservation to consumption. Manvell (8), more recently, situated MP methods within the broader objective of food processing to extend the shelf-life of foods. He defined that MP must be a safe balance between desired and adverse effects of preservation processes and accordingly, a minimal process is "the least possible treatment" to achieve a purpose. Thus, he considered as minimal processes available traditional techniques that have been improved to obtain safe and high quality products (i.e., aseptic packaging, ohmic heating, radio frequency heating, microfiltration, etc) as well as techniques based on emerging preserving factors (i.e., high pressure, ultrasound, pulsed electric field, etc.). In the same trend, Ohlsson (9) stated that developments in thermal technologies are considered "minimal" when they minimized quality losses in foods compared to conventional thermal techniques. Lastly, and in partial agreement with these terms, Snyder (10), taking into account that there was no regulatory definition for MPF, gave an operating definition of them as "foods in which the biological, chemical, and physical hazards are at tolerable level." He divided them into three groups according to the type and severity of treatment: those foods that need no cook intervention (i.e., raw foods, nuts, grains and eggs); foods with a mild disinfection or reduction by 10^{-2} to 10^{-5} of pathogenic substances, chemicals and microorganisms by blanching, washing without or with chemicals, etc. (i.e., cut fresh fruit and vegetables, berries); and pasteurized foods with a 10^{-5} to 10^{-7} reduction of pathogens by applying irradiation, heat, pulsed light, ultraviolet light, high pressure, etc. (i.e., *sous-vide* products, pasteurized and refrigerated products, tomato sauces and salad dressings with preservatives), and also foods that are formulated to be safe by fermentation, drying, salting or acidification.

The expansion of MP concept has been reflected in new, renewed, and improved products and processes formulated and designed to produce a greater diversity of MPF. The reviews and/or books of Ahvenainen et al. (11–13), Singh and Oliveira (14), Wiley (15), Oliveira and Oliveira (16), Alzamora et al. (17) and Ohlsson and Bengtsson (18) on minimal processing could be used as further reference on the subject.

III. USE OF MULTITARGET PRESERVATION IN THE DESIGN OF MINIMALLY PROCESSED FOODS

Homeostasis or internal media stability (composition and volume of fluids) is vital for survival and growth of microorganisms. Preservation procedures are effective when they overcome, temporally or permanently, the various homeostatic reactions that microorganisms have evolved in order to resist stresses (19). Table 118.1 shows, as mode of example, the mechanisms of action of some environmental stresses in foods or during processing and the microbial homeostatic reactions produced by their application.

Homeostatic mechanisms that vegetative cells have evolved in order to survive extreme environmental stresses are energy dependent and allow microorganisms to keep functioning. In contrast, homeostasis in spores is passive, acting to keep the central protoplast in a constant low-water-level environment, this being the prime reason for the extreme metabolic inertness or dormancy and resistance

TABLE 118.1
Modes of Action of Selected Preserving Factors and Homeostatic Response in Microorganisms (19–22)

Stress Factor	Principal Effects	Homeostatic Mechanisms
Vegetative Cells		
Low water activity	Loss of water and consequent reduction or prevention of metabolism.	Accumulation by synthesis or active transport of compatible cytoplasmic solutes to balance external osmolality avoiding excessive loss of water from cell and of membrane turgor, changes in membrane lipids.
Low pH		
Strong acids	Denaturation of enzymes on cell surface and lowering of cytoplasmic pH due to proton permeation through membrane in response to the increased pH gradient.	Control of the activity of ion transport systems that facilitate proton entry to maintain the intracellular pH within a narrowed range.
Lipophilic weak acids	Lowering of citoplasmic pH due to undissociated acid passage through the membrane; specific effects of acid anion on metabolism; extensive protein denaturation and DNA damage in some organisms.	Increase of ATPase activity, synthesis of new proteins and synthesis of positively charged aminophospholipids that impart to the membrane surface a net positive charge that acts as a barrier to protons, etc.
Low temperature	Reduction or inhibition of growth rate; alteration of metabolic activity and substrate uptake (i.e., permeases unable to combine with substrates due to changes in the molecular architecture of lipid bilayer of the cytoplasmic membrane and arrest of active transport of solute across membrane due to insufficient energy in mesophilic organisms).	Depending on the organisms involved, alterations in fatty acid and phospholipid composition of membrane so as to obtain lipids with a lowered-gel-to-liquid-crystalline state transition temperature maintaining the membrane fluidity; increased enzyme synthesis in psychrophiles to compensate for reduced enzyme activity.
Thermal treatment	Single- and double-strand breaks in DNA, inactivation of specific enzymes, RNA degradation, leakiness of membranes and heat-induced damage of the various chemiosmotic and transport functions of the cell.	Repair of DNA; synthesis of "heat-shock" proteins leading to a rise in heat resistance when long, slow heating is involved.
Ionizing radiation	Damage to DNA	Development of enzymic mechanisms for repairing ionizing radiation–induced lesions in DNA.
Nisin	Pore formation in cytoplasmic membrane, leakage of ATP from target cells.	Synthesis of nisinase. Changes in the bacterial membrane structure to decrease membrane fluidity.
Spores		
Thermal treatment	Depurination and depyrimidation of spore DNA; enzyme attack on apurinic DNA after germination; destruction of the activity of the enzyme(s) on the germination pathway.	Resistance/dormancy mechanisms comprise low core water content by some osmotic and/or pressure-generating function of the cortex and "mineralization" and immobilization of ions in the core of the spore.

of these cells. It seems likely that the structural arrangement of the cortex of the spore is responsible for the dehydration of the protoplast (23, 24).

In foods preserved by combined methods (so called "hurdle technology" or "multitarget preservation"), the active homeostasis of vegetative microorganisms and the passive refractory homeostasis of spores are disturbed by a combination of gentle antimicrobial factors at a number of sites or in a cooperative manner (19, 25, 26). For example, for vegetative cells (where homeostasis is energy dependent), the goal is to reduce the availability of energy (removing O_2, limiting nutrients and reducing the temperature) and/or to increase the demand for energy (reducing water activity (a_w), reducing pH and adding membrane active compounds). Placing a number of sublethal stresses (i.e., preserving factors) on a microbial cell potentially results in metabolic exhaustion and death. For spores (where homeostasis is non-energetic and depends on the structures of the organism), the goal is to damage key structures (by chemical, enzymic, or physical attack on coats, cortex, etc.) or to release spores from dormancy (initiating germination with natural germinants or with false triggers, or applying high pressures).

Antimicrobial preservation of foods by combined methods should be considered not only as interference of the homeostasis by additive or synergistic hurdles on the same microorganism, but also as the selective application of preservation factors that may be effective against a specific organism or group of organisms, while not against others.

In the last fifteen years, the popularity of the hurdle concept has dramatically increased and numerous publications have now indicated its potential for the development of minimally processed foods.

As it will be discussed, combined technology can be applied in the design of the preservation system of MP

foods in many ways: (i) at various stages of the food distribution chain, in storage, in processing and/or in packaging as a "back-up" measure in existing MP products with short shelf-life, in order to diminish the risks and/or increase their shelf-life (26); (ii) as an important tool for improving quality of long shelf-life products without sacrificing their microbiological stability; or (iii) as a new preservation procedure deliberately intended for obtaining novel MP foods.

IV. GENERAL OVERVIEW OF MP TECHNIQUES

According to previous definitions, MP focuses on preservation while keeping food quality attributes, following the principle "as little as possible, but much as necessary" (8, 27). As said before, this concept involves a wide variety of processes with a correspondingly large variety of products. Three major initiatives are currently being purposed by the research community and the industry to make MPF with improved quality (28, 29):

1. Optimization of traditional preservation methods to enhance sensorial, nutritional and microbiological quality of foods, yield and energy efficiency.
2. Development of mild processes by novel combinations of traditional physical and chemical preserving factors, each one applied at low intensity, to obtain products with quality attributes reminiscent of the fresh or native state of a given food but with longer shelf-life.
3. Development of new techniques to obtain novel foods with fresh quality attributes by using combinations of emerging preservation factors or combinations of emerging factors with traditional ones, all of them applied at low doses.

These approaches to obtain foods products of higher perceived quality face different limitations and possibilities for the design, optimization and experimental assessment as well as validation of process conditions. Table 118.2 lists selected examples for each approach.

TABLE 118.2
Selected Existing and Novel MP Technologies

Enhanced Traditional Techniques
Aseptic packaging of thermally processed foods (tube in tube heat exchangers, etc.)
Semi-aseptic processes (high heat infusion, vacuum steam + vacuum cooling, etc.)
Ohmic heating
Radiofrequency heating
Microwave heating
Inductive electrical heating
Infrared heating
Microfiltration
Osmotic dehydration
Vacuum dehydration
Microwave and dielectric drying
Cryogenic freezing
Freezing in dynamic dispersion medium
New Mild Techniques Based on Novel Combinations of Traditional Preserving Factors
Sous vide and cook-chilled processing
Modified/controlled atmosphere packaging (MAP/CAP)
Active packaging techniques
"Ready-to-eat foods"
New Techniques Based on Combinations of Emerging Preserving Factors
Emerging Factors:
- High hydrostatic pressure
- Ionizing radiation
- High electric field pulses
- Ultraviolet light
- Light pulses
- Natural antimicrobials
- Ultrasound
- Biopreservation

A. Improved Traditional Technologies

The first category refers to the many advances in invention and improvements of equipment and techniques connected to traditional methods of food preservation — canning, aseptic packaging, dehydration, a_w reduction, freezing, distribution, storage, analytical devices, new packaging materials, etc. over the past 30 years. Before that, the traditional food industry was, in general, technically unsophisticated compared to several other industries. These above engineering advances, which have had broad economic and quality product impact, have been also accompanied by replacing empirical fashion for establishing processing parameters and formulations with sound knowledge and skills, many times taken over from different science branches (i.e., biomaterial and colloid sciences) and adopted to foods. Attention has been particularly focused on research that aims at maximising the product quality, since mechanisms of microbial inactivation/inhibition under these improved techniques are in general the same as under the conventional processes.

These significant developments were accompanied by: 1) the application of statistical quality control to all phases of food operations; 2) the growing safety regulations and recommendations of governments and international organisms (FDA, USDA, FAO, WHO, Codex Alimentarius, etc.); 3) the adoption of automatic inspection devices and many computer-driven process controllers; and 4) the advances in mathematical modelling of the phenomena. In the following, some of them are commented.

Thermal processing affects the quality of foods significantly (loss of vitamins and minerals, loss of fresh appearance, flavour and texture, etc.). Quality optimization greatly depends on the ability to process foods under the high temperature–short time (HTST) concept, since activation energies for inactivation of microorganisms are higher (and hence the rate is more temperature-dependent) than those for many undesirable quality changes. These HTST processes are currently done for packaged liquid foods and liquids with particles, but for large solid products the food in contact with the hot surfaces will be overheated during the time needed to heat the coldest spot of the food. Suitable industrial systems to overcome this problem are based on heating unpackaged foods followed by aseptic packaging, or on the use of new heating technologies, such as the so called "volumetric electric heating" (30).

Electric heating is done by applying electromagnetic energy to increase food temperature. These methods directly heat the whole volume of the food, without heating up heat transfer surfaces and requiring less time to come up to the desired temperature. According to the frequency of the electromagnetic spectrum, we can distinguish three types of processes:

- electric resistance/ohmic heating (50/60 Hz) (application in the food industry: pasteurization and sterilization of fruit juices, with or without particulates; blanching of vegetables; cooking of foods in catering sector and in preparing low-acid-ready-to-eat meals);
- high frequency/radio frequency heating (10–60 MHz) (application in the food industry: post-baking of biscuits and cereals; drying, bulk defrosting of meat and fish);
- microwave heating (1–3 GHz) (application in the food industry: baking bread, cakes and pastry; tempering of foods; drying, pasteurization of pumpable foods).

In ohmic heating, the food itself acts as a conductor between the ground and a charged electrode, or it can be immersed in a conducting liquid. The resistivity of the food will determine the current that will flow between the ground and the electrode (voltages up to 5000 V) according to Ohm's law. Main advantages of ohmic heating are: 1) the food is heated by internal heat generation and so does not exhibits large temperature gradients during process; 2) particulates in liquid-particulate mixtures achieve higher temperatures over liquids; 3) high energy efficiency (≅90%); and 4) reduced maintenance cost and ease of process control.

Microwave and radio frequency heating generate heat in the material by primarily two mechanisms: dielectric and ionic (31). In dielectric heating, water molecules, due to their dipolar characteristic, try to follow the electric field associated with electromagnetic radiation, oscillating at the very high frequencies and producing heat. In ionic mechanism, the oscillatory migration of ions under the influence of the oscillating electric field results in heating. Microwave and radio frequency heating may be relatively more uniform than conventional treatment but heating uniformity is hard to predict. The product may be turned on or off instantly, and can be pasteurized after being packaged.

For all these electric processes, the thermal effect is presumably the principal lethal mechanism and the most heat-resistant pathogens of concern as well as their thermal inactivation kinetics are already well known. The influence on chemical constituents is also the same than in conventional heating methods. So, time-temperature history at the coldest location will determine the safety of the process. But the application of electric heating in the food industry is limited at present by a number of reasons: 1) for ohmic heating, the lack of quantification of the heat generation rate and the electrical field distribution as affected by the electrical heterogeneity of particles and the different conductivity between solid and liquid phases; scarcity of data about critical factors affecting heating, such as residence time, loading levels, etc., and the difficulty in localization of hot/cold spots (30); 2) for microwaves, the high energy costs, the non-uniformity of heating and the inability to ensure sterilization of the entire package (31); and 3) for radiofrequency heating, equipment and operating costs are higher than for conventional or ohmic heating techniques (30).

In the freezing area, the attention had been aimed at maximising the product quality during storage. Frozen foods are not stable and deteriorate at commercially significant rates during frozen storage due to chemical and physical changes. The improvement of quality had been focused with an integrated approach:

- firstly, by selecting adequate processing conditions, product characteristics and formulation for conventional freezing processes;
- in second place; by considering new techniques;
- on the other hand, by application of the fundamentals of bio-materials sciences to the formulation of frozen products with cryoprotectants and other additives for improving their keeping quality. Important advances had been made in the understanding of glass transition and of crystallization/recrystalization phenomena in the frozen matrix (32).

B. Techniques Based on Novel Combinations of Traditional Preserving Factors

An important sector of the MP foods market is formed by chilled foods, e.g., foods that rely either exclusively or

primarily on cold storage for preservation. These foods may contain entirely raw foods; low-risk raw and uncooked ingredients ("prepared chilled" or "ready-to-eat-foods," typical shelf-life ≅10–14 days) such as salad or cheese components; entirely cooked or baked ingredients ("cooked ready-to-eat-foods," typical shelf-life ⩾ two weeks) or they can be in-pack pasteurized and stored for extended periods ("ready-to-eat products for extended durability" or REPFED, typical shelf-life >40 days) (28, 33, 34).

Major concerns over the microbiological safety of chilled foods have been extensively detailed in the literature (33–35). The principal situation that affects safety is improper refrigeration (accidental due to mechanical failure or intentional to save energy costs) during manufacture, distribution, retail sale and at home. Chilled foods are not free from abuse. Refrigeration temperatures are not standardized. In the real world conditions, during distribution and retail presentation and storage of perishable foods, temperatures often cycle between low and high temperatures (36). In addition, refrigerated foods can be stored by the consumer for a longer time than intended because sensory quality is still good. The main concern is that spoilage bacteria are inhibited sufficiently to allow toxin formation, toxigenesis preceding organoleptic spoilage.

Although modified atmosphere packaging (MAP) extends shelf-life and visual appearance of food, its use continues to be questionable because of the possible growth of anaerobic and psychrotrophic pathogens. Microbial safety is affected in three ways: (i) the stimulatory effect of CO_2 on spore germination; (ii) the inhibition of the spoilage microorganisms, which are indicators of incipient spoilage; and (iii) the potential for temperature abuse (37).

Storage at chilled temperatures cannot prevent all pathogenic growth, but can inhibit the growth of some types of microorganisms and decrease the growth rate of others (Table 118.3). Therefore, the shelf-life of chilled foods depends on a balance between the minimum temperature for growth, the growth rate at chilled temperatures and the storage time and temperatures. As temperature control is one of the key issues with regard to chilled foods to control the survival or growth of any microorganisms that remain in the food or that enter food after processing, and there are many opportunities for temperature abuse to occur, authorities in different countries are increasingly suggesting the use of others factors in combination with refrigeration.

For instance, many possible additional hurdles have been proposed for being used in combination with *sous vide* process (i.e., cooking a food product inside a hermetically sealed vacuum package, rapid chilling and chilled storage of end product) (38). As these products usually have a pH > 4, $a_w > 0.93$ and contain no preservatives, abuse temperatures can lead to germination and outgrowth of spore-forming pathogenic (i.e., *Clostridium botulinum*) as well as to repairing thermally injured cells. Thus, as soon as the food is purchased by the consumer, it is outside of any of the legislative requirements. The UK Advisory Committee on the Microbiological Safety of Food (1992) has recommended, in addition to chill storage, the following preservation factors to be used singly or in combination: 1) heat treatment at 90°C for 10 minutes or equivalent process; 2) a pH < 5.0 throughout all components of complex foods; 3) a minimum salt concentration of 3.5% in the aqueous phase of all components; 4) an $a_w < 0.97$ throughout all components of complex foods; and 5) a combination of heat and preservative factors that have been shown to prevent growth of and production of toxin by psychrotrophic *C. botulinum*. Biopreservation, the use of sodium lactate, a combination of a slight reduction in a_w and pH and irradiation have also been proposed by many authors as promising potential "back up" hurdles when temperature is out of control (38).

TABLE 118.3
Pathogenic Microorganisms of Concern in Chilled Foods and their Minimum Growth Temperature, pH and a_w (Adapted from Alzamora (38))

Critical Hazard	Microorganisms	T (°C)	pH	a_w
Infectious pathogens	*Salmonella* species	5.1	3.8–4.0	0.92–0.95
	Listeria monocytogenes	−0.1	4.4	0.90–0.92
	Vibrio parahaemolyticus	5	4.8	0.94–0.96
	Aeromonas hydrophila	0	4.0	0.94
	Campylobacter jejuni and *coli*	25–30	5.3	0.985
	Escherichia coli	4–7.1	4.4	0.935–0.95
Toxigenic pathogens	*Staphylococcus aureus*	7.7	4.0	0.86
Toxigenic spore-forming pathogens	*Clostridium botulinum* type E and non proteolytic strains B & F	3.3	5.0	0.96
	Bacillus cereus	<4	4.4–4.9	0.90–0.93
	Clostridium perfringens	5	5.5	0.93–0.95
	Clostridium botulinum (proteolytic strains)	10–12	4.6	0.94

C. Techniques Based on Combinations with Emerging Preserving Factors

There is a wide range of modern preserving factors, developed in the last few years and decades, that cause physical inactivation of microorganisms at ambient or sublethal temperatures (i.e., high hydrostatic pressure, pulsed electric fields, ultrasound, pulsed light, ultraviolet light, etc.), avoiding the deleterious effects that severe heating has on flavour, texture and nutritional quality of foods. Table 118.4 lists some new physical food preservation techniques, the mechanisms of action on the microorganisms and the factors of the technique itself that influence the efficacy of the preservation. Some of these processes are still under

TABLE 118.4
Main Emerging "Non-Thermal" Preserving Factors (27, 31, 39)

Factor	Mechanism of Inactivation	Critical Factors	Potential Application/ Products on the Market
High Pressure Processing (HPP)			
Subjecting liquid and solid foods, with/without packaging, to 100–800 MPa, below 0°C to 100°C, from seconds to about 20 min, instantaneously and uniformly throughout food, independent of size, shape and food composition	Membrane damage, protein denaturation, leakage of cell contents	Temperature, pressure magnitude, rate of compression and decompression, and holding time at pressure, time to achieve treatment pressure, composition, pH and a_w of the food, product initial temperature; and critical factors of other constraints in combination	Jam, jellies, fruit juices, oysters, guacamole, ham, fruit yogurts, dairy-based fruit smoothie, processed meat products, pressure-treated ready-to-eat rice, sauces (in use since 1990)
Pulsed Electric Field (PEF)			
Pulses of high voltage (≅ 20–80 kV/cm) to foods between two electrodes, in the form of exponentially decaying, square wave, bipolar or oscillatory pulses at ambient, sub-ambient or slightly above ambient temperature, for less than 15 seconds	Electrical breakdown and electroporation of cell membranes	Electric field intensity, pulse width, treatment time and temperature, and pulse waveshapes, pH, ionic compounds, conductivity and medium ionic strength, and critical factors of other constraints in combination	Only two industrial-scale PEF systems recently available. Fluid foods (fruit juices, liquid, eggs, milk, sauces, beverages)
Ultraviolet Light			
Radiation from the ultraviolet region of the electromagnetic spectrum (UVC 200–280 nm), at least 400 J/m^2	DNA mutations induced by UV light absorption	Transmissivity of the material, homogeneity of the flow pattern and the radiation field, UV wavelength, thickness of the radiation path through the food (geometric configuration of the system); product composition, solids content, and starches	Pasteurization of apple and clear juices. Surface and air decontamination
Pulse Light			
Few flashes applied in a fraction of a second of intense pulses of broad spectrum "white light" (ultraviolet to the near infrared region)	Chemical modifications and cleavage of the DNA and destruction of cellular components by the high peak power and the broad-spectrum of the flash	Light characteristics (wavelength, intensity, duration and number of pulses); packaging and type, transparency and color of food are considered to be critical process parameters	Sterilization or reduction of microbial load on surfaces and transparent products
Ultrasound			
Energy generated by sound waves of 20 kHz or more	Disruption of cellular structure and functional components and cell lysis attributed to cavitation	Power and amplitude of ultrasonic waves, exposure time, volume and composition of the food to be processed, temperature of treatment and the critical factors of procedures used in combination	No commercial food products. Limited to product modification and process efficiency improvements (enhancement of mass and heat transfer, degassing of liquids, cleaning of surfaces)

development but have commercial potential. Others have completed development and are waiting to be licensed or transferred to industry. Others are commercially applied.

The usefulness of many of these techniques is limited due to the following aspects. Most of these emerging factors are effective in inactivating vegetative cells of most microorganisms but spores are far more tolerant, and very high treatment intensities are required to achieve spore destruction in low acid foods. These big doses may significantly affect the sensory and/or functional properties of foods. So, these alternative factors for inactivating microorganisms are analogous to thermal pasteurization and their potential use for the sterilization of low acid foods is not yet possible.

The scheduled process for traditional thermal processes is based on the knowledge of the thermal inactivation kinetics of the most heat-resistant pathogen of concern for each specific product and of the heat transfer rate. The validity of the established process is often confirmed using an inoculated test pack study (under actual plant conditions) (31). As the mechanism of microbial inactivation for electric heating is basically the same as under conventional thermal treatment, the indicator microorganisms to validate the processes are the same used for conventional heating. But alternative non-thermal techniques involve different mechanism for microbial destruction and the organisms of concern are not the same, and neither are the inactivation kinetics that follow the exponential relationship that is usually the basis of the thermal process design. The most resistant pathogens and the corresponding surrogate organisms for alternative preservation processes are yet to be clearly defined. Moreover, limited information is available about the mechanisms of inactivation of microorganisms by alternative factors and survivor plots commonly exhibit a shoulder and/or a tail (44). A highly resistant subpopulation remains usually viable over a long period of treatment time, causing a substantial decrease in the efficacy of the processes.

Antimicrobial systems naturally present in plants (e.g., phenolics, essential oils, phytoalexins), animals (e.g., lisozyme, lactoperoxidase system, lactoferrin, chitosan), or microorganisms (e.g., nisin, pediocin and other bacteriocins, pimaricin and others antibiotics) have potential, in the context of "natural preservatives," to replace or reduce reliance on synthetic food preservatives (28, 40, 41). Because of interactions with food components (proteins, lipids, aldehydes and many macromolecules), natural antimicrobial concentrations required for microbial inhibition in real foods are considerable higher than in laboratory media and frequently above tolerable thresholds, limiting their industrial application (42).

However, a multifactorial preserving approach can minimize sensory changes in foods with natural antimicrobials, or enhance inactivation of highly resistant microbial subpopulations by alternative non-thermal factors, so that lower factor intensities can be used (42). Combining emerging factors with conventional preserving ones or with other novel techniques has been explored in the last years with promising results (42–45). Some successful additive or synergistic combinations are the following:

- High hydrostatic pressure and lowered pH: this combination prevents microbial growth and the germination of spores that can survive HHP treatment at acidic pH.
- High hydrostatic pressure and antimicrobial agents: sublethal injured cells by HHP become more susceptible to antimicrobials.
- Pulsed electric fields and heat: high temperatures increase the fluidity and the thickness of membranes, increasing the lethality of PEF treatment.
- Pulsed electric fields and antimicrobials: antimicrobials that act on the cell membrane may increase the susceptibility of membranes to dielectric breakdown and/or PEF may facilitate the access of antimicrobials that cross the membrane and acts in the cytoplasm.
- Ultrasound and natural antimicrobials (i.e., cinnamon): the lipophilic antimicrobial could accumulate in the lipid bilayer of the membrane, sensitizing this structure to the action of ultrasonic waves.

V. STRATEGIES TOWARDS MICROBIAL SAFETY OF MINIMALLY PROCESSED FOODS

The primary concern of the approach to the management of food from raw material to a consumed item is safety. Many MPF are good media for growth of microorganisms and represent a potential health risk. Because of the reduced microbiological safety margins, work is now being focused not only on the application of strict hygiene and good manufacturing practices, and implementation of hazard analysis and critical control points principles, but also on the design of the preservation system with additional hurdles so that an imperfect processing and/or packaging, distribution and storage can still guarantee safe products.

An analysis of the voluminous literature on the subject serves to highlight various important points to take into account to design effective MP techniques.

A. Formulation of the Combined MP Preservation System

– Most work has been focused on studying the response to the stress factors of key microorganisms in laboratory media and in model system, and few studies have been undertaken using actual foods. Moreover, when actual foods were

assayed, in most cases the native flora had been previously inactivated. The ecology of pathogens and non pathogens in foods is very complex and their interactions are difficult to predict.
- In many cases, intensity of the hurdles is detrimental to the food quality (e.g., flavour) and should be lowered, keeping in mind that hurdles levels must not only consider safety, but also desired total quality.
- The success of the hurdle technology used to design and/or to increase the safety of MP foods can be compromised in many ways. Two phenomena that appear to be significantly affecting the efficiency of the combined approach are next addressed.

1. Adaptation of Microorganisms to Sublethal Stresses

Spore-forming and non-spore-forming microorganisms sometimes react or adapt to mild stress factors by developing some mechanisms to repair the damages and to become even more resistant, surviving more severe homologous or heterologous stresses (46). Much of the research on the so-called "global stress response" has only been focused on the heat stress response and on acid adaptation, with the physiological bases involved not yet being fully understood. For example, bacteria that have been exposed to mildly acidic conditions acquire the ability to survive not only normally lethal pH values but also other stresses that microorganisms may meet in foods (47).

After adaptation to mild stresses, cells behave differently from unadapted ones and can grow at values outside the traditionally known ranges of temperature, water activity and pH determined under nearly optimal conditions (47). Therefore, microbiological challenge testing to assess the risk of food poisoning or to establish MP product stability needs careful design, and stressed known or potential pathogens would be also selected to validate the process.

Another point to be considered is that in certain instances, subinhibitory levels of additives, preservatives or chemicals may stimulate mold growth and/or toxin accumulation (28). The use of additives or preservatives at subinhibitory levels can not only stimulate toxin production but also eliminate other indigenous microflora that might be competitive with the growth of the mold favouring mold growth and toxin production (28).

2. Interactions between Stress Factors and Food Matrix

The intensity of the hurdles may change along product storage. Alternatively, the initial intensity of the hurdle may be less than the level applied. It is well known that sorbates, commonly used as preservatives in many food products, can be destroyed through an autoxidation mechanism, its destruction affecting food product safety (28).

Many natural antimicrobials (e.g., bacteriocins, some phenolics and essential oils) are less effective inhibitors in food matrix than *in vitro* (41). For instance, vanillin activity against *L. monocytogenes* in fluid milk decreases with increasing fat concentration. The preservatives probably bind to the fat, which thereby reduces their availability to inhibit microorganisms. The presence of di- and trivalent ions (such as Mg^{2+}, Ca^{2+}) has been reported to reduce the efficiency of nisin against Gram-positive bacteria due to inhibition of electrostatic interactions between positive charges on the bacteriocins and the negatively charged headgroups of the phospholipid molecules of the cytoplasmic membrane (21).

These and other phenomena that can reduce the intensity of the barriers are summarized as follows: binding to food components such as proteins and fats; chemical degradation; inactivation and/or biological destabilization by other ingredients or components; pH and temperature effects on hurdles stability and activity; physical losses by mass transport from the food to the environment; poor solubility and uneven distribution in the food (21, 48).

The interaction of antimicrobial factors can be additive, synergistic or antagonistic. It is not easy to anticipate the type of the interaction resulting of the combination of many factors. Moreover, the characteristics of the interaction can change along storage time or with minimal alterations in the food formulation (42).

Based on the facts cited above, much remains to be done regarding the contribution of the hurdles approach to minimal food preservation. In addition, Gould et al. (49, 50) pointed out that, although much progress on the physiology of the most important target microorganisms relevant to factors affecting growth and survival has been made, this has not yet been sufficiently exploited in the control of food poisoning microflora in a practical way of commercial interest.

B. Design of Minimally Processed Foods and Predictive Microbiology

Until recently, combined factors techniques were designed through observations of cardinal parameters for growth or decay as well as trial and error. In the last 20 years, a number of models to mathematically describe the growth or inactivation/decline of microorganisms under specific environmental conditions have been developed. Within this frame of risks, hazards and consumer trends, predictive microbiology emerges as a powerful tool to quickly explore the microbiological impact of varying conditions within MPF formulation, processing and/or distribution and retail conditions.

Information provided by the models can be used advantageously in the design of combined technologies for obtaining MPF in many ways (51):

- Although most of these MPF are preserved by more than one hurdle, there is a lack of quantitative data available to allow predicting the adequate and necessary levels of each hurdle. Thus, if we can predict with accuracy the growth kinetics (lag phase duration, growth rate), or the interface between microbial growth and no growth, or the decay kinetics for an identified target microorganism under several combinations of factors, the selection of such factors can be made on sound basis, and the selected hurdles can be kept at their minimum doses.
- Modelling has application in products where the perceived "naturalness" prevents the use of large intensities of chemical preservation and/or solutes and/or acids or/and heating or/and other non-thermal factors. Sensory selection of hurdles and their levels may be done between several "safe" equivalent combinations of interactive effects determined by the models.
- While much relevant information is available in the scientific literature concerning factors/interaction of factors that influence microbial activities in foods, it is seldom usable in formulating combined techniques. Many times, information involves only data from traditional challenge testing in particular food conditions, microbial presence or absence tests, or growth or no growth determination. These isolated results do not allow us to compare quantitatively what happens in a food system when the levels of the independent preservation variables are changed. Neither can the sensitivity of the key microorganisms to the different factors be inferred.
- Rather than inactivating the microorganisms, many MP techniques inhibit their growth through the manipulation of various growth-controlling factors. Thus, microbiological safety and stability margins are being reduced, and improved control in manufacture and distribution are required to ensure the recommended shelf lives. Temperature abuse, emergent pathogens, induced tolerance of microorganisms to stress factors and food matrix-stress factor interactions have caused concern about the safety of some of these nonsterile products. In this type of product, end-product testing is useless, and mathematical modelling can help developing qualitative and quantitative information to describe microbial behaviour, allowing a better control and prediction of the shelf-life.

VI. STRATEGIES TOWARDS SENSORY QUALITY OPTIMIZATION OF MINIMALLY PROCESSED FOODS

The concept of hurdle technology has been usually used to improve the microbial stability and safety of foods but the preservation of other food attributes is of additional concern. The combined technology concept refers not only to microbiological stability, but also to total quality of foods, comprising the application of preservation factors to inhibit or delay physicochemical and biochemical reaction deleterious to colour, texture, flavour and nutritive value of foods (22). Somehow, the application of combined processes for the enhancement of sensory or nutritional properties is not still sufficiently studied (51, 52).

Next, some examples of the application of combined techniques for enhancing quality retention are addressed.

A key quality problem in minimally processed vegetables and fruits, such as peeled and sliced apple and potato, is enzymatic browning by polyphenol oxidase (PPO). The prevention of browning reactions in this kind of product has been traditionally studied, but the effect of browning inhibitors on the sensory quality has not been examined. Sensory attributes such as appearance, flavour, odour and texture are also important factors affecting consumer acceptability and must be taken into account when a browning prevention method is selected (53). Enzymatic browning requires four different components: oxygen, an enzyme, copper and a substrate. At least one component must be removed from the system to inhibit browning (52). Historically, enzymatic browning has been controlled by heat inactivation of the enzyme or by the application of sulphites. In addition to the adverse health effects on asthmatics, sulphites may produce tissue softening and off-flavours. Some potential alternatives to sulphites include: 1) ascorbic acid (AA), that reduces quinones back to phenolic compounds before they can undergo further reaction to form pigments, chelates copper and acts as a competitive inhibitor of PPO; 2) citric acid (CA), which acts as chelating agent and acidulant; 3) 4-hexilresorcinol (HR), that interacts with PPO, avoiding its participation in the browning reaction; 4) EDTA, that acts as complexing agent; 5) sulphydril-containing amino acids like cisteine, which prevent brown pigment formation by reacting with quinine intermediates; and 6) MAP, which reduces the oxygen concentration in the atmosphere surrounding a product (52). Hurdle approaches for inhibiting browning can be formulated by using some of these alternatives in combination. For instance, AA or AA derivatives, like AA-2-phosphate and AA-2-triphosphate, have been used in combination with CA, Ca_2Cl, phosphoric acid and sodium acid pyrophosphate (SAPP) in potatoes (54, 55); with HR in apples (56) and with CA in potatoes (57). Digestion with hot ascorbic acid/citric acid solutions also improved the shelf-life of pre-peeled potatoes (55). However, high

concentrations of ascorbic acid (0.75%) may impose an unpleasant taste on fruits (58). Apple pieces treated with 0.01% HR, 0.5 & AA and 0.2% Ca_2Cl and packed under partial vacuum could be stored at 0.5% for 50 days with acceptable colour (58). A natural combined system is pineapple juice, which has been found to be an effective browning inhibitor in fresh as well as in dried apples (59). Pineapple juice compounds which may have potential as PPO inhibitors include organic acids, proteins, amino acids, certain metals and sulfhydryl compounds. Dipping potatoes into solutions of L-cisteine and CA followed by packing and flushing with N_2 also allowed to obtain an extended shelf-life (60).

Texture is another quality determinant in fruits and vegetables. Calcium has widely been reported to play an important role in preserving structural integrity and mechanical strength of cell walls (61, 62). Depending on the impregnation method and on the pretreatment (blanching), it has been successfully used as a texture enhancer when added in infusion solutions as calcium lactate in minimally processed kiwi, strawberry and melon (63). However, applied as calcium chloride during osmotic adjustment of a_w and pH in apple preserved in a similar way, it was not able to prevent softening, probably due to the high calcium concentration employed and solubilization of pectin substances (64). Calcium (as 1% $CaCl_2$) and ascorbic acid dips have also been employed as firming agents to extend postharvest shelf life in sliced pears and strawberry stored in controlled atmosphere (65). The combined effects of heat treatment (20, 40, 60°C) and calcium dips (2–5% $CaCl_2$) on the firmness of fresh-cut cantaloupe melons was studied by Luna-Guzmán et al. (66). A dip in 2.5% $CaCl_2$ solution at 60°C for 1 min not only resulted in a great improvement in firmness but the fruit seemed to hold firmness over 10 days of storage samples (Figure 118.1). This effect in calcium and heat treated melon was attributed to PE activation, allowing more calcium complexing following PE-activated and middle lamella, and/or to a membrane or turgor pressure effect.

The impact of processing and the vegetable stress reactions that often take place during storage may be minimized by refrigeration and suitable modified atmosphere packaging. MAP fresh produce requires that a narrow range of concentrations be maintained in a package, typically 2–5% O_2, 2–5% CO_2 and the rest nitrogen (67). This is achieved by means of a dynamic interaction between the respiring produce, the gas permeability of the packaging film and environmental conditions such as storage temperature. High O_2 MAP treatment has been found to be particularly effective at inhibiting enzymatic browning, preventing anaerobic fermentation reactions and inhibiting aerobic and anaerobic microbial growth. It is hypothesized that high O_2 levels may cause substrate inhibition of PPO or alternatively high levels of colourless quinones subsequently formed may cause feedback production of PPO (53). When

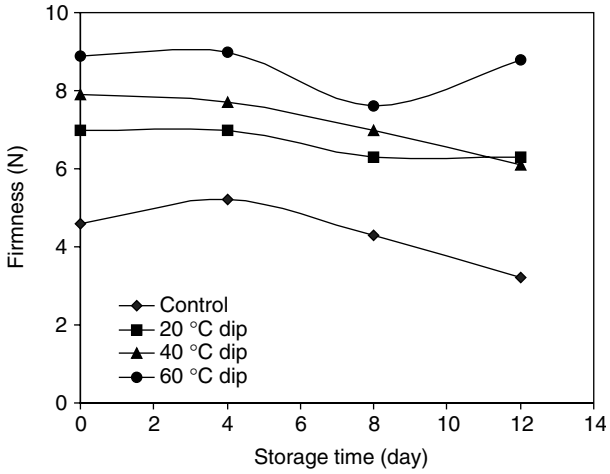

FIGURE 118.1 Firmness of fresh-cut cantaloupe melon during storage at 5°C and 95% RH for 12 days after being dipped in 2.5% calcium chloride solution for 1 min at different temperatures. Adapted from Luna-Guzmán et al. (66).

the packaging material is not sufficiently permeable and the produce has high respiration, microholes of defined sizes and a defined quantity can be made in the material in order to avoid anaerobiosis (68). Barry-Ryan et al. (69) showed by using different films and storage temperatures (3 and 8°C) that deterioration in shredded carrots (slime production, loss of firmness and the development of off-odours) occurred more rapidly with the depletion of O_2 than by the rise in CO_2 and that a film with similar permeability to O_2 and CO_2 was the most suitable for the storage. Packaged perforation significantly improved, for example, the shelf-life of grated carrots (52), but it was not needed in shredded Iceberg lettuce dipped in betaine solutions (70). According to Gil et al. (71), the colour preservation (anthocyanin content) of pomegranate seeds was similar after storage at 1°C in perforated polypropylene (air atmosphere) or in unperforated polypropylene (MAP). The potential benefits of controlled atmospheres and heat treatment to maintain high quality and to extend shelf-life of green onions were reported by Hong et al. (72). Atmospheres of 0.1–0.2% O_2 or 0.1–0.2% O_2 containing 7.5–9% CO_2 were the conditions that best maintained the visual appearance in both intact and cut onions, and in combination with a pre-storage treatment (55°C for 2 min), provided a shelf-life of more than 2 weeks at 5°C. This combination of factors did not reduce the soluble sugar and thiosulfinate concentration of produce. A controlled atmosphere (air + 15% CO_2) at 5°C greatly reduced development of macroscopic decay, translucency and off-odours in pieces of honeydew melons (73). Controlled atmospheres reduced colour changes, but not firmness loss; soluble solids concentration was maintained during storage in air or controlled atmospheres. Edible coatings are an alternative packaging method for extending the post-harvest storage of minimally processed

fruit and vegetables, because they have the potential to reduce moisture loss, restrict oxygen entrance, lower respiration, retard ethylene production, seal in flavour volatiles and carry additives (such as antioxidants) that retard discoloration and microbial growth (52).

The control of nutritive value (i.e., vitamin, sugar, amino acid, fat and fibre content) of minimally processed produce is an area that needs more research. The steps often involved during processing and storage conditions usually have an effect on nutrients and these changes must be taken into account. Important components of vegetables include vitamins, particularly those which act as antioxidants, such as ascorbic acid and β-carotene. Loss of these nutrients is one of the main limiting factors of nutritional quality (15). Recently, the importance of changes of the total antioxidant activity as an indicator of overall quality of any processed product has also been highlighted (74, 75). Barry-Ryan and O'Beirne (76) analyzed the effects of slicing method, packaging atmosphere and storage temperature on ascorbic acid retention and quality of shredded lettuce. Modified atmosphere packaging, nitrogen flushing, manual tearing or slicing and low temperatures were effective postharvest storage treatments for conserving ascorbic acid and visual quality. Kaur and Kapoor (75) studied the effect of different dip treatments and storage period on the antioxidant activity and ascorbic acid and carotenoids contents of Indian cabbage. Incorporation of ascorbic and citric acids in dip water improved the overall appearance and retained the maximum antioxidant activity, ascorbic acid and total carotenoids (Figure 118.2).

Emerging non-thermal factors, such as ultrasound, electric pulses, light pulses and high pressure are promising procedures, from the point of view of both shelf-life and product modification. The impact of cell membrane permeabilizing features of non-thermal processes to introduce modifications in plant foods, such as the retention and availability of nutritionally relevant metabolites from plant materials, as well as the improvement of mass transfer of functional ingredients during drying processes, was highlighted by Rastogi et al. (77) and Knorr (78). Pulse electric fields have been applied successfully prior to osmotic dehydration to enhance mass transfer of water and sugar in carrots (79), and pineapple (80). Ade-Omowaye

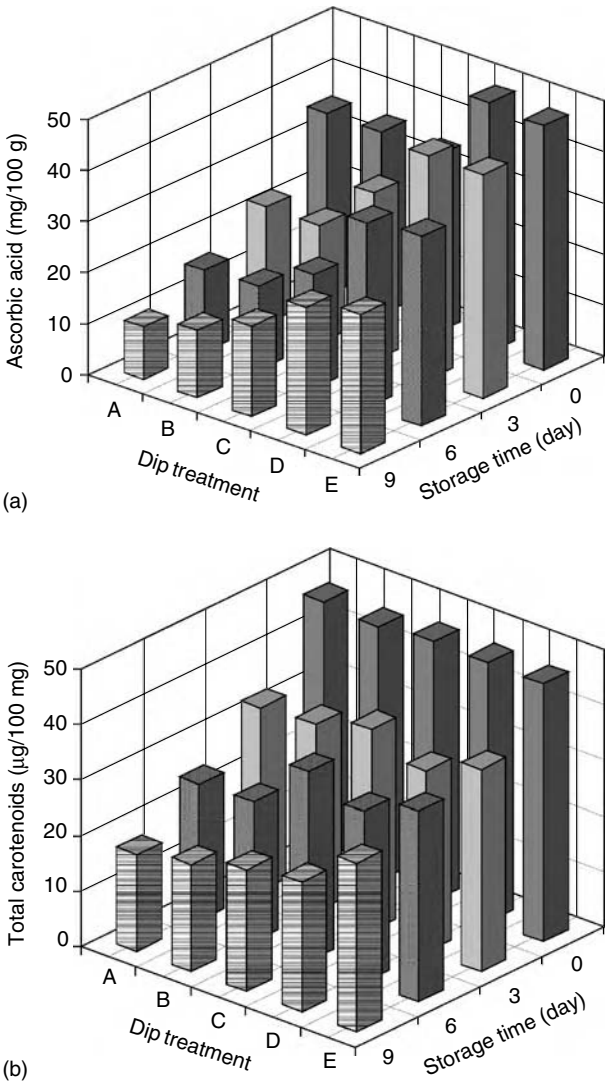

FIGURE 118.2 Effect of different dip treatments (A = water at 4°C, B = chlorinated water at 4°C, C = chlorinated water + citric acid (10 g/l) at 4°C, D = chlorinated water + ascorbic acid (10 g/l) at 4°C, E = chlorinated water + citric acid (10 g/l) + ascorbic acid (10 g/l) at 4°C) on: a) ascorbic acid content, and b) carotenoids content of minimally processed cabbage (var. Golden Acre) throughout the storage time. Adapted from Kaur and Kapoor (75).

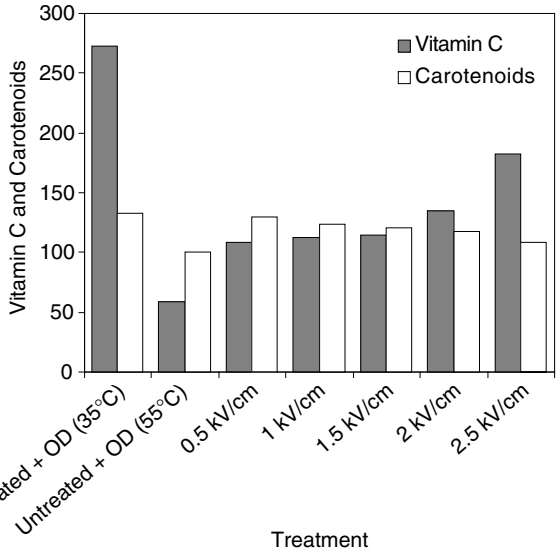

FIGURE 118.3 Vitamin C and carotenoids contents of dried osmosed bell pepper treated at different temperatures (35°C and 55°C) and high intensity electric field pulses at different field strengths (E = 0.5–2.5 kV/cm). Adapted from Ade-Omowaye et al. (81).

et al. (81) evaluated the influence of high intensity electric pulses field at varying field strengths (E = 0.5–2.5 kV/cm), osmotic agent (sucrose or sodium chloride) and moderate thermal treatment (25–55°C) on selected quality parameters (vitamin C and carotenoids) of bell peppers. Increasing temperature resulted in water loss from 32% to 48% and increasing field strength resulted in water loss from 36% to 50% of initial moisture content. But combination of high intensity electric pulses (2.5 kV/cm) with subsequent osmotic dehydration at 35°C gave products higher in vitamin C and carotenoids than osmotic treatment alone at 55°C, suggesting high intensity electric pulses as an alternative to thermal processing to improve mass transfer (Figure 118.3). A combination of high pressure treatment, in conjunction with subsequent freezing prior to fluidized bed drying of green beans, carrots and potatoes appeared to improve mass transfer and enhance product quality regarding to texture and colour of rehydrated product (Figure 118.4) (82). Simal et al. (83) also reported the applicability of sonication to increase water loss and solute gain during osmotic dehydration of apple cubes.

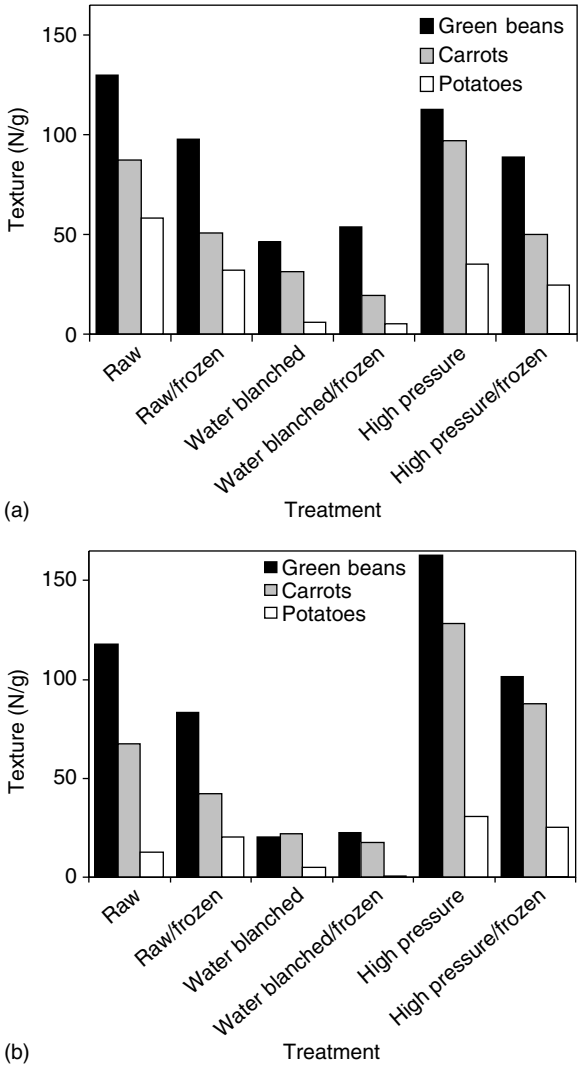

FIGURE 118.4 Texture measurements of green beans, carrots and potatoes: a) prior fluidized bed drying, and b) after rehydration. Adapted from Estiaghi et al. (82).

VII. FINAL REMARKS

Minimally processed foods are becoming an important component of the food supply. The older methods of food preservation continue to be used extensively and technological advances to enhance their efficiency and effectiveness are being developed at a high rate. The adoption of newer techniques for industrial application, in spite of the enormous advancement in technological and fundamental knowledge made in the last decade, is slow. More research is needed. Most minimal processing technologies need to be considered as combined techniques. So, it is imperative that reactions that are responsible of microbial, sensory, nutritional, physical and chemical quality be understood and quantified as a function of the hurdles involved in the combined preservation system. In addition, food safety and quality aspects have to be integrated along the entire food chain, from "farm to table." The production of MPF should include: scrutinizing materials entering the food chain; inhibiting microbial, biochemical and physicochemical deleterious reactions (i.e., refrigerated storage and distribution); and decreasing or eliminating the microbial load by processing and preventing post-processing contamination as well as decreasing quality changes. That is, the safety and quality of food should be based on controlling all steps in the food production process.

CONTENTS

A. NOMENCLATURE

A = Area, m^2
A_F = Area of film, m^2
A_H = Total area of holes, m^2
D_{CO_2} = Diffusivity of CO_2 in air, $m^2.sec^{-1}$
D_{O_2} = Diffusivity of O_2 in air, $m^2.sec^{-1}$
D_P = Diameter of perforation, m
e = Thickness of film, m
E_{CO_2} = Activation energy of permeability for CO_2, $kJ.mol^{-1}$
E_{O_2} = Activation energy of permeability for O_2, $kJ.mol^{-1}$
H_T = Height of package, m
I_F = Intercept of film line, atm
I_N = Intercept of a line perpendicular to film line, atm
L_P = Length of perforation, m
L_T = Length of package, m

M = Weight of commodity, kg
m_M = Molar mass
N_H = Number of holes
N_{ap} = Number of perforations
$P^*_{CO_2}$ = Permeability pre-exponential factor for CO_2, $ml.mil.m^{-2}.hr^{-1}.atm^{-1}$
$P^*_{O_2}$ = Permeability pre-exponential factor for O_2, $ml.mil.m^{-2}.hr^{-1}.atm^{-1}$
P_{CO_2} = Permeability for CO_2, $ml.mil.m^{-2}.day^{-1}.atm^{-1}$
P_{O_2} = Permeability for O_2, $ml.mil.m^{-2}.day^{-1}.atm^{-1}$
P_T = Total pressure, Pa
R_{CO_2} = Rate of CO_2 production rate, $ml.kg^{-1}.h^{-1}$
R_{O_2} = Rate of O_2 consumption rate, $ml.kg^{-1}.h^{-1}$
$R^A_{CO_2}$ = Rate of CO_2 production at the $y^{min}_{O_2}$ and $y^{min}_{CO_2}$, $ml.kg^{-1}.h^{-1}$
$R^A_{O_2}$ = Rate of O_2 consumption at the $y^{min}_{O_2}$ and $y^{min}_{CO_2}$, $ml.kg^{-1}.h^{-1}$
$R^B_{CO_2}$ = Rate of CO_2 production at the $y^{max}_{O_2}$ and $y^{max}_{CO_2}$, $ml.kg^{-1}.h^{-1}$
$R^B_{O_2}$ = Rate of O_2 consumption at the $y^{max}_{O_2}$ and $y^{max}_{CO_2}$, $ml.kg^{-1}.h^{-1}$
$R^{best}_{CO_2}$ = Rate of CO_2 production at the intersection point, $ml.kg^{-1}.h^{-1}$
$R^{best}_{O_2}$ = Rate of O_2 consumption at the intersection point, $ml.kg^{-1}.h^{-1}$
$R^{mean}_{CO_2}$ = Rate of CO_2 production at average of optimum window, $ml.kg^{-1}.h^{-1}$
$R^{mean}_{O_2}$ = Rate of O_2 consumption at average of optimum window, $ml.kg^{-1}.h^{-1}$
R = Gas constant ($0.008314\,kJ.mol^{-1}.K^{-1}$)
R_H = Radius of hole, m
RQ_A = Respiratory quotient at the $y^{min}_{O_2}$ and $y^{min}_{CO_2}$
RQ_B = Respiratory quotient at the $y^{max}_{O_2}$ and $y^{max}_{CO_2}$
RQ_{mean} = Respiratory quotient at average of optimum window
S_F = Slope of film line
S_N = Slope of a line perpendicular to film line
T = Storage temperature, °C
t_{O_2} = Equilibrium time, sec
$t^{eq}_{CO_2}$ = Equilibrium time for CO_2, sec
$t^{eq}_{O_2}$ = Equilibrium time for O_2, sec
y_{CO_2} = CO_2 concentration, atm
y_{O_2} = O_2 concentration, atm
$y^{best}_{CO_2}$ = CO_2 concentration at the intersection point, atm
$y^{best}_{O_2}$ = O_2 concentration at the intersection point, atm
$y^{eq}_{CO_2}$ = Equilibrium CO_2 concentration, atm
$y^{eq}_{O_2}$ = Equilibrium O_2 concentration, atm
$y^{e}_{CO_2}$ = External CO_2 concentration, atm
$y^{e}_{O_2}$ = External O_2 concentration, atm
$y^{i}_{CO_2}$ = Initial CO_2 concentration, atm
$y^{i}_{O_2}$ = Initial O_2 concentration, atm
$y^{min}_{CO_2}$ = Minimum CO_2 of optimum window, atm
$y^{min}_{O_2}$ = Minimum O_2 of optimum window, atm

I. INTRODUCTION

There has been an increasing interest in using polymeric films for packaging of fresh and fresh-cut horticultural commodities to provide several benefits such as protection against physical injuries, improved sanitation, control of light conditions, and more importantly modification of atmospheric composition. There is a wealth of published information on Modified Atmosphere Packaging (MAP), yet no systematic theoretical study has been conducted to establish which commercially available plastic films would be most suitable for MAP of a particular produce. Such analysis could provide an initial screening of polymeric films, point out potential limitations, and help minimise the number of experimental trials.

The objective of MAP design is to define conditions that will create the atmosphere best suited for the extended storage of a given produce and to minimise the period of time to achieve this atmosphere. A MAP system not properly designed may be ineffective or even shorten the storage life of a product. If the desired atmosphere is not established rapidly, the package has no benefit. For example, high perishable products may deteriorate before the recommended atmosphere is attained. If O_2 and/or CO_2 levels are not within the recommended ranges of O_2 and CO_2 concentrations the product may experience serious alterations and its storage life is shortened. It may

even induce anaerobiosis, with the possible growth of pathogens and concomitant effects on product safety.

The success of MAP depends largely on the selected package material and thickness, as well as on the package surface area and the free volume inside the package. These depend on the respiration rate of the product, weight to be packed and temperature of the distribution chain. Design criteria for modified atmosphere packaging of respiring products have been widely reported in literature. Yet, their industrial application is limited, owing to the numerical complexity of the design equations, the lack of relevant data and the non-availability of user-friendly simulator tools.

Simulation of a MAP system is the most appropriate method to allow a correct MAP design and consequently obtain a successful commercial product. The "pack and pray" procedure may have economic and safety hazard consequences and the "trial and error" approach is an extremely time consuming procedure. The Department of Process Engineering, University College, Cork, Ireland has developed user-friendly software, called PACKinMAP, for designing MAP for fresh produce. PACKinMAP can be used as a tool to ensure the proper equilibrium modified atmosphere for each packaged fresh whole/fresh cut product. To reach this optimal atmosphere inside the package, PACKinMAP simulates O_2 and CO_2 concentrations for different combinations of films, area, and weight, avoiding time-consuming experiments to determine the best film to be used in packaging each type of product. The resulting PACKinMAP solution takes into account factors such as respiration rate, temperature, packaging film and its area, produce weight, package geometry and its volume.

II. DESIGN METHODOLOGY

Figure 119.1 schematically shows respiring produce stored in a package comprised of a plastic film. The simplest concept is to let the plastic film serve as the regulator of O_2 flow into the package and the flow of CO_2 out. Assuming that there is no gas stratification inside the package and that the total pressure is constant, the differential

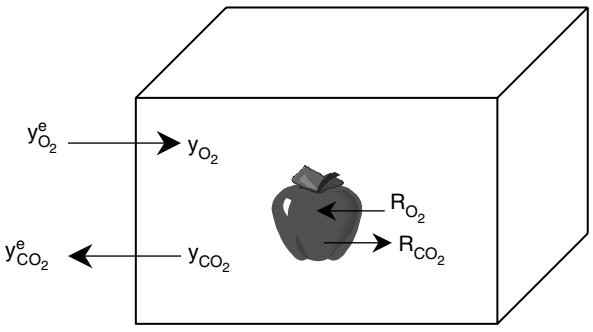

FIGURE 119.1 Gas exchange mechanism in MA package containing fresh produce.

equations of mass balance for O_2 and CO_2 in MAP containing a respiring product are (balance with N_2):

$$V_f \times \frac{d(y_{O_2})}{dt} = \frac{P_{O_2}}{e} \times A \times (y^e_{O_2} - y_{O_2}) - R_{O_2} \times M \quad (119.1)$$

$$V_f \times \frac{d(y_{CO_2})}{dt} = \frac{P_{CO_2}}{e} \times A \times (y^e_{CO_2} - y_{CO_2}) + R_{CO_2} \times M \quad (119.2)$$

Equations 119.1 and 119.2 are first-order linear differential equations, which are useful for describing the unsteady state behaviour of MAP system during the process of passive modification. When the accumulated term is zero, Equations 119.1 and 119.2 are reduced to the steady state as:

$$y^e_{O_2} = y_{O_2} + \frac{R_{O_2} \times e \times M}{P_{O_2} \times A} \quad (119.3)$$

$$y^e_{CO_2} = y_{CO_2} - \frac{R_{CO_2} \times e \times M}{P_{CO_2} \times A} \quad (119.4)$$

The above equations describe the dynamic equilibrium behaviour of the MAP system, when the CO_2 evolution rate equals the efflux rate of CO_2 through the package and the O_2 consumption rate equals the influx rate of O_2 through the package. In most commercial package situations, steady state or dynamic equilibrium is approached within two days. For long storage of the product, the dynamic equilibrium behaviour is more important than the unsteady state behaviour. To use Equations 119.3 and 119.4 as design equations, it is necessary to keep track of how many independent or design variables are available. As per Table 119.1 there are a total of 11 variables: R_{O_2}, R_{CO_2} and M are associated with the product; P_{O_2}, P_{CO_2}, e and A are associated with the package; $y^e_{O_2}$, y_{O_2}, $y^e_{CO_2}$ and y_{CO_2} are associated with the environment. Once the product and the temperature are selected, six out of the 11 variables are already decided: R_{O_2} and R_{CO_2} from the respiration rate model as reported in the literature; y_{O_2} and y_{CO_2} are assumed to be the optimum O_2 and CO_2 concentrations and $y^e_{O_2}$ and $y^e_{CO_2}$ are constant, i.e., 0.21 atm and 0.0003 atm, respectively. With six variables fixed and two equations to satisfy, there are only $(11-6-2) = 3$ design variables. That is, only

TABLE 119.1
Variables Used in MAP Design

Input variables	Surrounding-related	$y^e_{O_2}$, $y^e_{CO_2}$
	Package-related	A, e
	Commodity-related	M
Calculated variables	Package-related	P_{O_2}, P_{CO_2}
	Commodity-related	R_{O_2}, R_{CO_2}
Response variables	System-related	y_{O_2}, y_{CO_2}

three out of the remaining five variables (M, e, A, P_{O_2} and P_{CO_2}) can be specified arbitrarily. Combining Equations 119.3 and 119.4 we get:

$$\frac{y^e_{CO_2} - y_{CO_2}}{y^e_{O_2} - y_{O_2}} = -\frac{RQ}{\beta} \qquad (119.5)$$

Where, RQ is the respiratory quotient and β is the permeability ratio, defined as R_{CO_2}/R_{O_2} and P_{CO_2}/P_{O_2}, respectively.

III. COMMODITY RELATED ASPECTS

For any packaging design, the product characteristics such as its weight, respiration rate, density and the optimum conditions for the best shelf life are needed for the mathematical calculations. Such data is widely available in literature. For the present software a database is prepared which includes all these parameters. This database is flexible as users can change it as per their requirements.

A. Respiration Rate

Control of respiration is an important effect of atmosphere modification on post harvest life of fruits and vegetables (1). High respiration rates are associated with rapid deterioration of the product. Design of a MAP system that will prolong the storage or shelf life of fresh product requires the mathematical equation for predicting the respiration rate at the various influencing factors. Thus, the respiration rate model is central to the design of MAP for fresh fruits and vegetables.

B. Mathematical Modelling of Respiration Rate

There are a number of limitations to the development of predictive models. Potentially large experimental errors and time consuming experiments for the determination of respiration rates for MAP design as well as the complex nature of the process are limitations to the development of predictive models. Thus, a constant respiration rate is sometimes considered in MAP modelling reported in the literature (2). However, this approach can only be accepted as a simplified model, as, in fact, MAP relies on the ability to control the respiration rate by changing the atmospheric composition. Hence, the design should take into consideration not only steady-state conditions, but also the dynamic process, because if the product is exposed for a long time to unsuitable gas composition before reaching the adequate atmosphere, the package may have no benefit. Moreover, the success of MAP greatly depends on the accuracy of the predictive respiration rate models. Table 119.2 presents the factors for conversion of the different units used in the published works to the International System (SI) of units.

The fruits and vegetables listed in Table 119.3 have been selected based on the availability of respiration rate models in the published literature. These models are function of O_2, CO_2, temperature and time or combinations thereof. All the models were modified to yield uniform units of respiration rate, i.e., $m^3.kg^{-1}.s^{-1}$. The respiration rate of each selected fruit and vegetable is calculated at 5°C with air and is shown in Table 119.3.

TABLE 119.2
Conversion Factors to SI Units

Units to be Converted	Conversion Factor	Units Obtained
$mg.kg^{-1}.h^{-1}$	$2.778 \times 10^{-7}/m_M$	$mol.kg^{-1}.s^{-1}$
$ml.kg^{-1}.h^{-1}$	$3.341 \times 10^{-11} \times \frac{p_T}{R \times T}$	$mol.kg^{-1}.s^{-1}$

C. Commodities and their Optimum Conditions

The best atmosphere to extend product shelf life varies from product to product and depends on temperature. Recommended concentrations also depend on the quality parameter under evaluation. Criteria include lowering of C_2H_4 production or action, lowering of the number and extent of physiological disorders, retention of quality and better colour, flavour or texture. Normally the most important one is selected, that is, the one that limits shelf life. Usually, the recommendations for CA storage are also applied to MA. However, optimum MA concentrations may be more severe (lower O_2 and higher CO_2 concentrations) than long CA conditions because the product is submitted to the atmosphere over a much shorter period of time.

The first commercial recommendations for the CA storage of apples were formulated over 80 years ago by Kidd and West in England (34). CA/MA requirements and recommendations on the optimum atmospheric conditions for selected whole and cut vegetables and fruits are periodically presented in the International Controlled Atmosphere Research Conference. The recommendations are updated over the years when research introduces new data. The range of gas composition that best extends product shelf life is often called the "window" of recommended atmosphere. However, the extension of product shelf life by use of low O_2 and high CO_2 is not convenient for all products. Some vegetables, such as asparagus and okra, do not benefit from low O_2 levels. There are great differences in tolerance to CO_2 levels. While most fruits may tolerate up to 5% CO_2, some fruits may show CO_2 injury at this level and others may even tolerate 15–20% CO_2. The recommended atmospheres for fruits and vegetables are shown in Figures 119.2 through 119.4.

D. Calculation of Limiting β Values

Selection of a film having optimal β is necessary to achieve the optimum atmosphere in the package. Use of a polymeric film with a high β (e.g., >4–6) results in an equilibrium atmosphere that is low in CO_2, and films with low β (e.g., <2) tend to accumulate high levels of CO_2 without regard to absolute permeability rates. Equation 119.5 implies that, for a product with a given RQ, a given packaging can only yield a limited combination of O_2 and CO_2 concentrations, which is controlled by the relative transfer rate of CO_2 to O_2. Thus, the selection of packaging material basically relies on the choice of a material with a permeability ratio that will allow it to reach the desired atmosphere composition at steady state. This requires computation of the extreme β values adequate for the chosen commodity and can be calculated by solving Equation 119.5 at the maximum and minimum values of O_2 and CO_2 concentration as:

$$\beta_{min} = RQ_B \left(\frac{y_{O_2}^{e} - y_{O_2}^{max}}{y_{CO_2}^{max} - y_{CO_2}^{e}} \right) \tag{119.6}$$

$$\beta_{max} = RQ_A \left(\frac{y_{O_2}^{e} - y_{O_2}^{min}}{y_{CO_2}^{min} - y_{CO_2}^{e}} \right) \tag{119.7}$$

$$\beta_{mean} = \frac{\beta_{min} + \beta_{max}}{2} \tag{119.8}$$

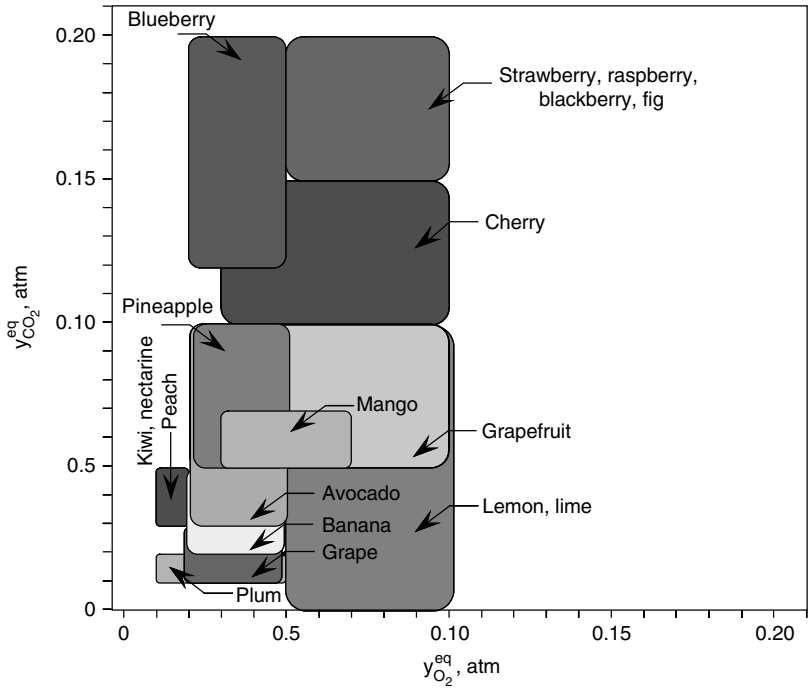

FIGURE 119.2 Recommended atmospheres for fresh fruits (boxes show the recommended atmosphere for each product).

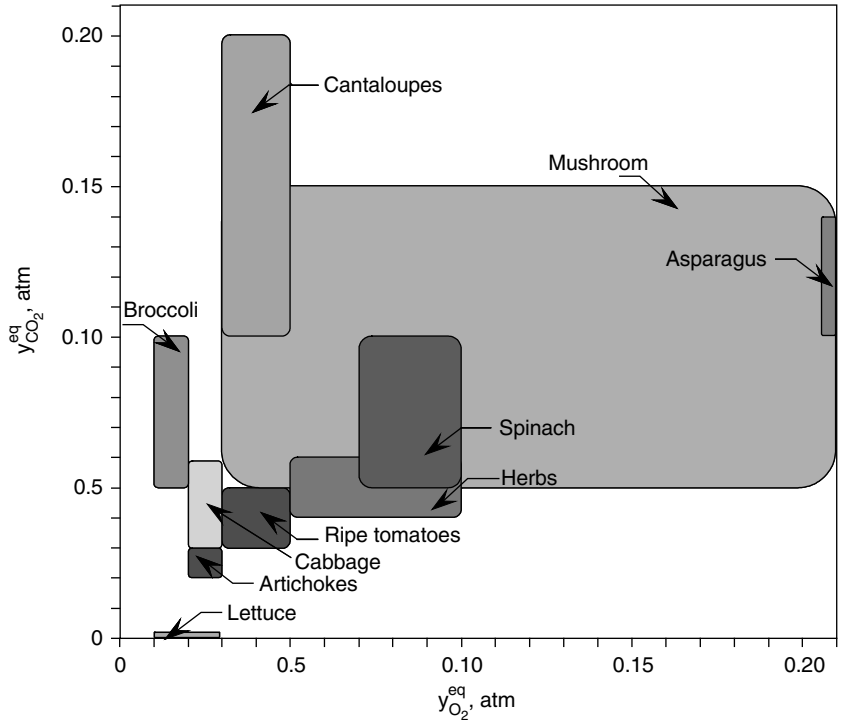

FIGURE 119.3 Recommended atmospheres for fresh vegetables (boxes show the recommended atmosphere for each product).

The Respiratory Quotients (RQs) are calculated at the bottom-left (A) and top-right (B) corners of the "Optimum Window" of recommend gas composition, i.e., for lowest O_2 and CO_2 concentrations and for highest O_2 and CO_2 concentration. These calculations are done for the temperature specified by the user. The model is selected based on the commodity chosen. In order to set the limit of RQ by Equations 119.6 and 119.7, the

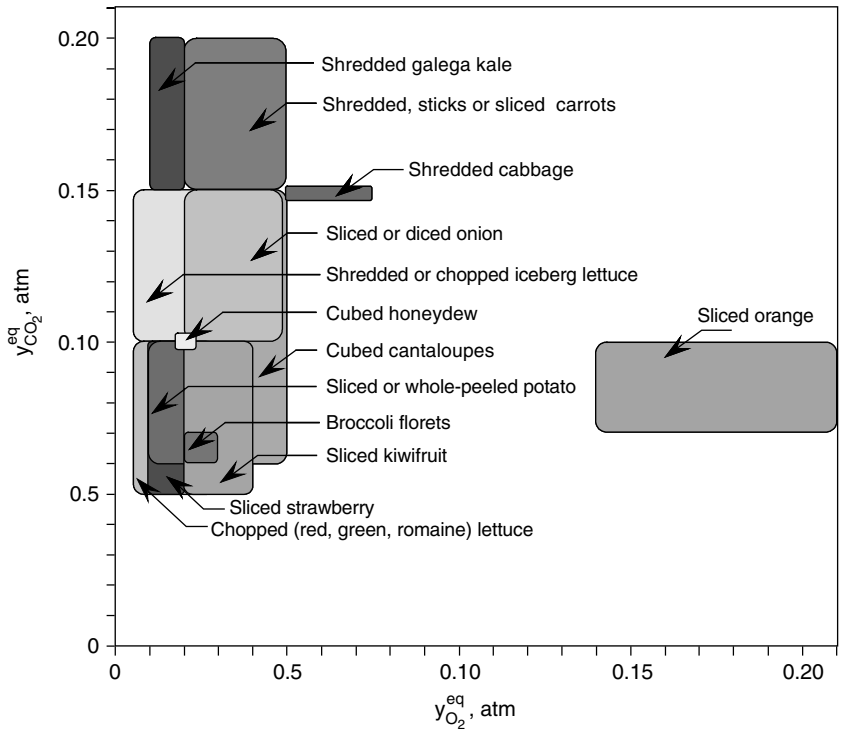

FIGURE 119.4 Recommended atmospheres for minimally processed produce (boxes show the recommended atmosphere for each product).

program calculates the respiration rate at the bottom-left and top-right corners of the "Optimum Window" as shown below.

$$R^{A}_{O_2} = \text{model}(y^{min}_{O_2}, y^{min}_{CO_2}, T) \quad (119.9)$$

$$R^{A}_{CO_2} = \text{model}(y^{min}_{O_2}, y^{min}_{CO_2}, T) \quad (119.10)$$

$$R^{B}_{O_2} = \text{model}(y^{max}_{O_2}, y^{max}_{CO_2}, T) \quad (119.11)$$

$$R^{B}_{CO_2} = \text{model}(y^{max}_{O_2}, y^{max}_{CO_2}, T) \quad (119.12)$$

$$RQ_B = \frac{R^{B}_{CO_2}}{R^{B}_{O_2}} \quad (119.13)$$

$$RQ_A = \frac{R^{A}_{CO_2}}{R^{A}_{O_2}} \quad (119.14)$$

IV. PACKAGING SYSTEM

Since there are many varieties of produce, a wide range of permeabilities is required. High permeabilities are needed for rapidly respiring produce, low permeabilities for slowly respiring produce. The required permeability may be achieved by three different types of packaging systems:

i. Polymeric films without perforations;
ii. Macroperforated polymeric films;
iii. Perforation-mediated packaging systems.

The details of each system are shown in Figure 119.5. Non-perforated polymeric films yield low O_2 and low CO_2 concentrations because the CO_2 permeability of these materials is generally 3 to 6 times that of O_2 permeability. These materials are suitable for less CO_2 tolerant commodities such as mango, banana, grapes and apples. Perforated films have higher permeability rates, but the ratio of CO_2 and O_2 permeability is much lower, approaching one. Such films are, therefore, of great interest for commodities tolerating simultaneously low O_2 and high CO_2 levels such as fresh-cut products, strawberry and mushroom. Perforation-mediated packaging is a system where tubes, which may be packed with an inert filling, are inserted in an otherwise airtight package. This system is also adequate for products requiring high CO_2/low O_2 concentrations and minimises water accumulation inside the package; because the package is rigid, it is suitable for bulk products and for products sensitive to mechanical damage.

V. MAP USING POLYMERIC FILMS

Permeable polymeric films are the most popular among available barriers to create modified atmospheres. These materials present different properties depending on the chemical structure, production process and additives.

A. Available Polymeric Films

The permeability coefficient of most commercially available films may be obtained from the company data.

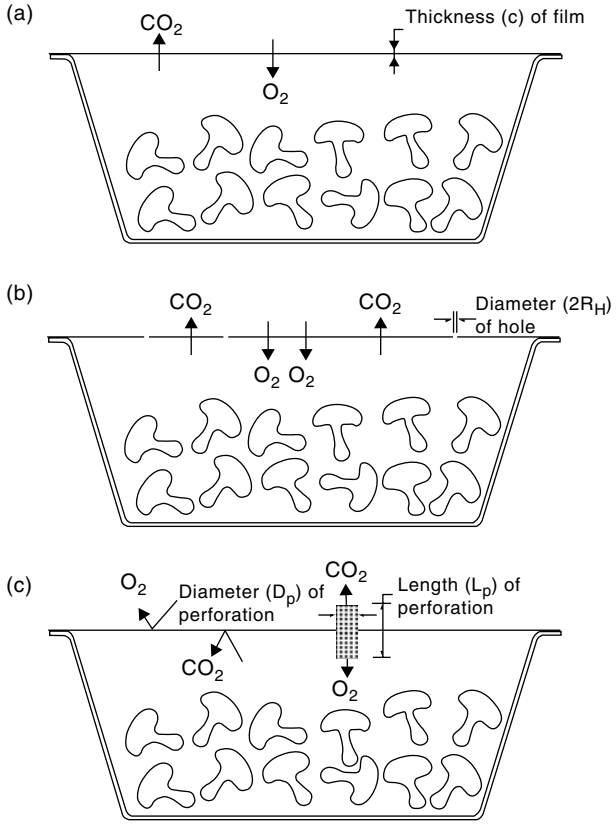

FIGURE 119.5 Schematic representation of three packaging systems (a) MAP with polymeric film (b) MAP with macroperforated polymeric film (c) perforation-mediated MAP.

However, these values were determined at some fixed temperature, usually in the ambient temperature range, 20–25°C. Most packaging films used for fresh fruits and vegetables are exposed to much lower temperatures. Moreover, the permeability for O_2 and CO_2 of a packaging film is temperature dependent; hence, data on the film permeability must be converted to the exact storage temperature of the produce. For this purpose the following Arrhenius model can be used:

$$P_{O_2} = P^*_{O_2} \exp\left[\frac{-E_{O_2}}{R \times T}\right] \quad (119.15)$$

$$P_{CO_2} = P^*_{CO_2} \exp\left[\frac{-E_{CO_2}}{R \times T}\right] \quad (119.16)$$

As per the above equations, permeability increases with temperature. If this increase were in the same magnitude as the increase in respiration due to temperature, then the net effect of temperature would be negligible, as far as the gas composition inside the package is concerned. In most cases however, the rates of increase of permeability and respiration due to temperature are not the same. Usually, the respiration rate tends to increase faster than the permeability. As the respiration rate is increased, less O_2 is available, and that, in turn, causes anaerobic respiration of packed products. This indicates that temperature, O_2 and CO_2 are the prime parameters to be considered while calculating film permeability and produce respiration rate. Using the pre-exponential factor and activation energy as specified in Table 119.4, P_{O_2} and P_{CO_2} are calculated at 5°C and are shown in Figure 119.6. The film permeability of each film is calculated as per the given values of activation energy and pre-exponential factor and accordingly the functions are written in Matlab (Version 13.1, The Mathworks Inc., Natick, US) programming language. Three parameters, i.e., A_F, e and T, are required to solve these functions giving the values of P_{O_2} and P_{CO_2}.

$$P_{O_2} = \text{film}\ (A_F, e, T) \quad (119.17)$$

$$P_{CO_2} = \text{film}\ (A_F, e, T) \quad (119.18)$$

A fortunate situation occurs when the desired permeability requirements are met by one or more existing commercial films. If this is the case, a good chance exists for a successful design. Unfortunately, this is not often the case because the choices of suitable polymeric films are rather limited. The problem can be appreciated by examining Figure 119.6, which reveals that the β values for most films fall within a rather narrow range between 3 and 6; however, Figures 119.2 to 119.4 show that many fruits and vegetables require β values outside this narrow range. It should be noted that there is a great deal of variation in measured and published permeability values due to variation in film thickness and its structure and measurement methods. Hence, it is advised to verify the gas permeability values of the selected film, if precision is required. In addition, it is necessary to study the feasibility of the package containing produce before actually putting them in the market.

B. Film Selection

The polymeric material with β within the set interval of β_{min} and β_{max} is considered as the best one for the product under study. The film selection steps are described in Figure 119.7. Matlab programming language was used to solve these steps. If the number of selected films is more than one, then the film having β value close to the β_{mean} would be selected. If there is an option left, a film having minimum equilibrium time is selected. Then this selected film is used to calculate equilibrium modified atmosphere parameters and gas kinetics. The rest of the films are displayed as the alternative optimal films for the given commodity.

C. Calculation of the Equilibrium Modified Atmosphere (EMA)

The program calculates the equilibrium gas composition, commodity weight, film area and equilibrium time that is

[b] Yam (36).

achievable by the selected film(s) as described in the following steps.

It calculates the average of O_2 and CO_2 composition in the recommended range and corresponding respiration rates:

$$y_{O_2}^{mean} = \left(\frac{y_{O_2}^{max} + y_{O_2}^{min}}{2} \right) \quad (119.19)$$

$$y_{CO_2}^{mean} = \left(\frac{y_{CO_2}^{max} + y_{CO_2}^{min}}{2} \right) \quad (119.20)$$

$$R_{O_2}^{mean} = \text{model}\ (y_{O_2}^{mean}, y_{CO_2}^{mean}, T) \quad (119.21)$$

$$R_{CO_2}^{mean} = \text{model}\ (y_{O_2}^{mean}, y_{CO_2}^{mean}, T) \quad (119.22)$$

$$RQ_{mean} = \frac{R_{CO_2}^{mean}}{R_{O_2}^{mean}} \quad (119.23)$$

i. It calculates the slope (S_F) of the line corresponding to the selected film(s):

$$S_F = \frac{-RQ_{mean}}{\beta} \quad (119.24)$$

ii. It calculates the slope (S_N) of the line that passes thorough the average gas composition and is perpendicular to the line corresponding to the film selected, i.e., the line that passes through 0.0003 atm CO_2 and 0.21 atm O_2 and has a slope equal to S_F as shown in Figure 119.8.

$$S_N = \frac{\beta}{RQ_{mean}} \quad (119.25)$$

iii. It finds the intercept of the line corresponding to the film:

$$I_F = y_{CO_2}^e + \frac{RQ_{mean} \times y_{O_2}^e}{\beta} \quad (119.26)$$

iv. It finds the intercept of the line perpendicular to the line of the film:

$$I_N = y_{CO_2}^{mean} - \frac{\beta}{RQ_{mean}} \times y_{O_2}^{mean} \quad (119.27)$$

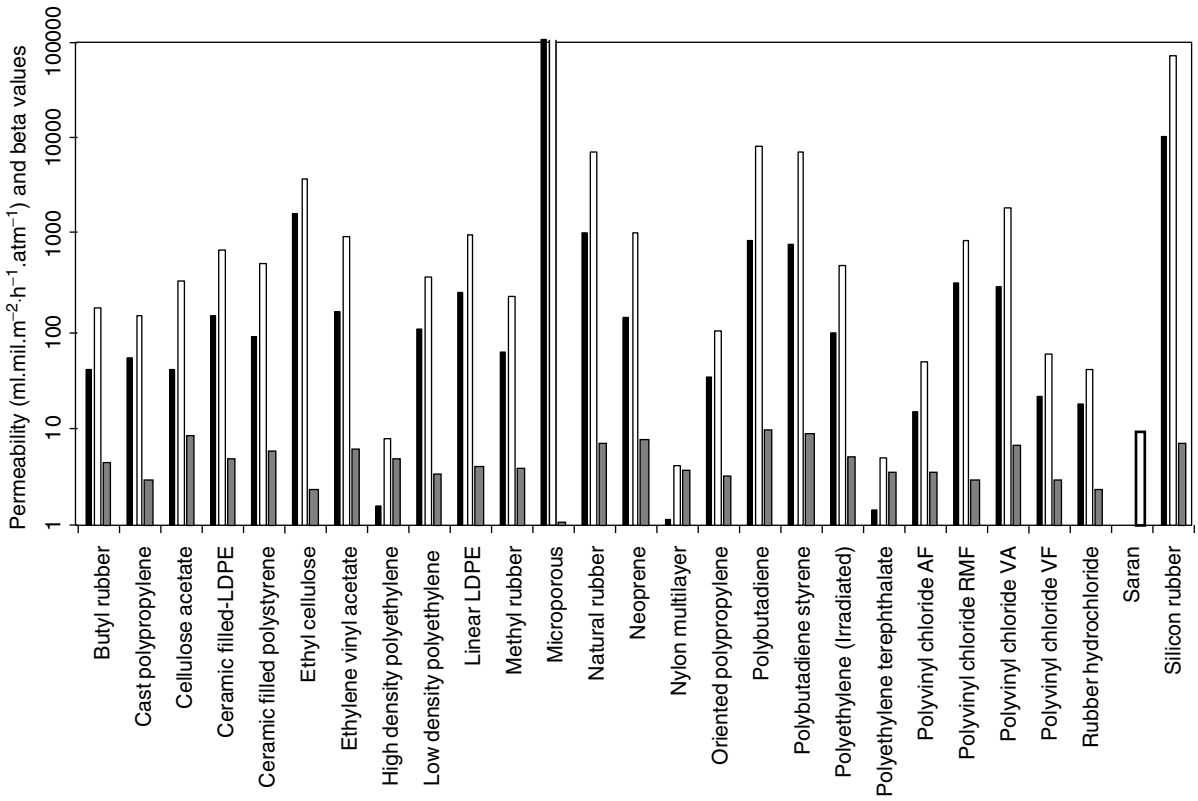

FIGURE 119.6 Permeability and β values of different polymeric films at 5°C (solid square: P_{O_2}; empty square: P_{CO_2}; lined square: β).

v. It finds the co-ordinates of a point (equilibrium gas composition) where the two lines intersect:

$$y_{O_2}^{best} = \frac{I_F - I_N}{S_N - S_F} \tag{119.28}$$

$$y_{CO_2}^{best} = \frac{RQ_{mean}}{\beta}(y_{O_2}^{e} - y_{O_2}^{best}) + y_{CO_2}^{e} \tag{119.29}$$

$$R_{O_2}^{best} = \text{model}(y_{O_2}^{best}, y_{CO_2}^{best}, T) \tag{119.30}$$

$$R_{CO_2}^{best} = \text{model}(y_{O_2}^{best}, y_{CO_2}^{best}, T) \tag{119.31}$$

vi. It calculates the area of film and weight of commodity by combining Equations 119.1 and 119.2 at equilibrium. We get Equation 119.32 from this which we can use to predict the film area required to achieve the desired gas composition at given weight of commodity or predict the weight of commodity to achieve the desired gas composition at given film area.

$$A_F = \left[\frac{M(R_{CO_2}^{best} + R_{O_2}^{best})}{\frac{P_{O_2}}{e}(y_{O_2}^{e} - y_{O_2}^{best}) - \frac{P_{CO_2}}{e}(y_{CO_2}^{e} - y_{CO_2}^{best})}\right] \tag{119.32}$$

vii. Approximate volume of the package can be calculated by multiplying the produce volume by the factor 1.8 to account for typical headspace found in retail packages (35). By using this volume, the dimensions of the package are decided. Finally, these dimensions are used to calculate the actual total volume of the package. The free volume inside the package containing produce is calculated using Equation 119.34.

$$V_t = W_B \times H_T \times L_T + \frac{(W_T - W_B) \times H_T \times L_T}{2} \tag{119.33}$$

$$V_f = V_t - \frac{M}{\rho} \tag{119.34}$$

viii. In order to know if the atmosphere inside the package may achieve the gas concentrations desired to preserve the produce in a reasonable period of time, a simplified model can be developed in order to simulate the process. This simplified model considers a constant respiration rate, a constant temperature and uniform concentrations inside the package. With these assumptions, Equations 119.1 and 119.2 can be integrated, yielding the history of concentrations

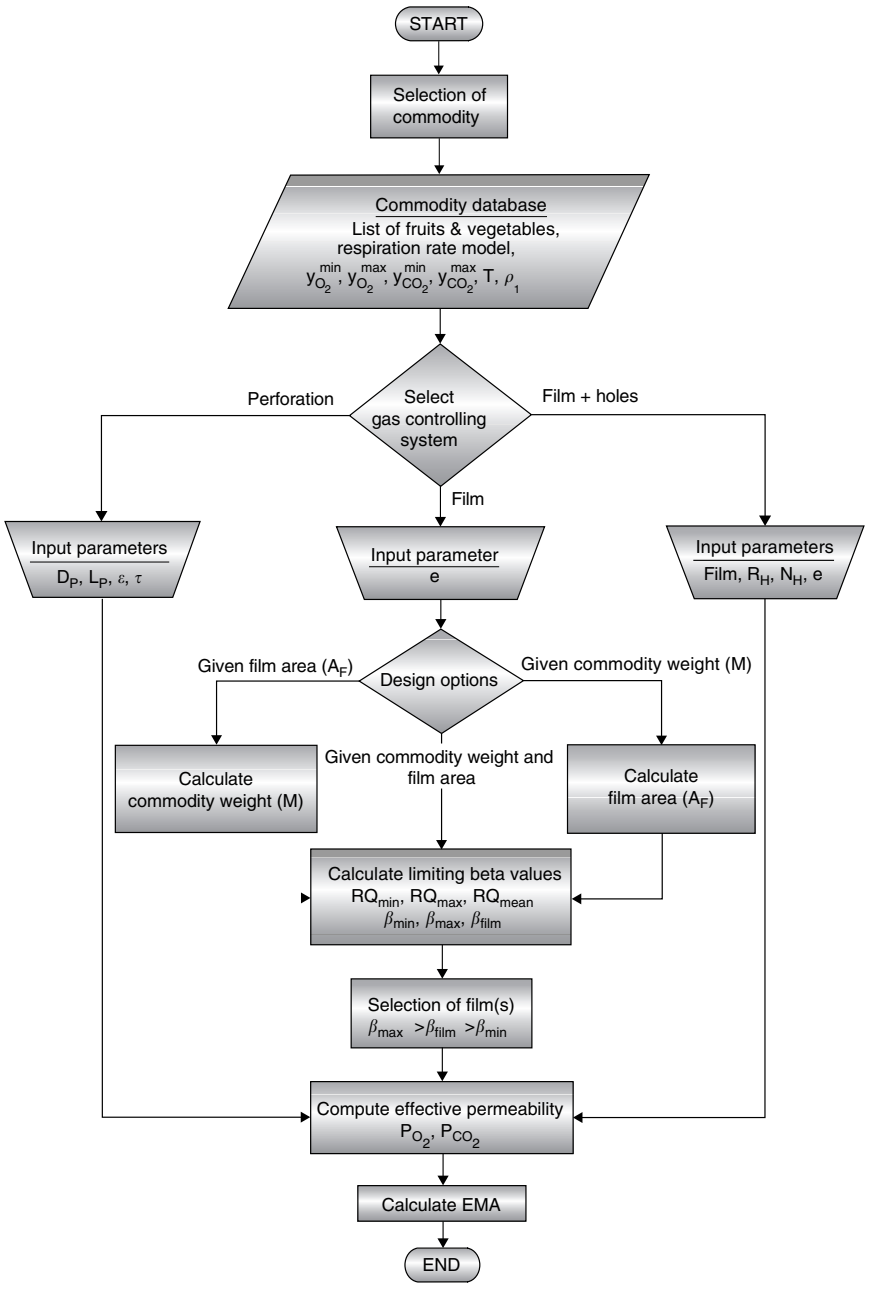

FIGURE 119.7 Description of steps involved in MAP design.

of both gases in the package from which the equilibrium time can be calculated as follows:

$$t_{O_2}^{eq} = \frac{-V_f \times e}{24 \times 3600 \times P_{O_2} \times A} \times \ln \left| \frac{\left(y_{O_2}^{eq} - y_{O_2}^{e}\right) + \dfrac{R_{O_2} \times M \times e}{P_{O_2} \times A}}{\left(y_{O_2}^{i} - y_{O_2}^{e}\right) + \dfrac{R_{O_2} \times M \times e}{P_{O_2} \times A}} \right| \quad (119.35)$$

$$t_{CO_2}^{eq} = \frac{-V_f \times e}{24 \times 3600 \times P_{CO_2} \times A} \times \ln \left| \frac{\left(y_{CO_2}^{i} - y_{CO_2}^{e}\right) + \dfrac{R_{CO_2} \times M \times e}{P_{CO_2} \times A}}{\left(y_{CO_2}^{eq} - y_{CO_2}^{e}\right) + \dfrac{R_{CO_2} \times M \times e}{P_{CO_2} \times A}} \right| \quad (119.36)$$

Equations 119.35 and 119.36 show that the variables that affect the time required to reach the

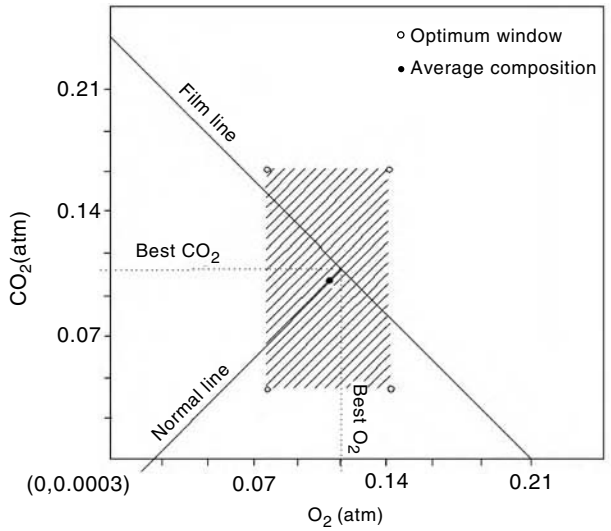

FIGURE 119.8 Determination of equilibrium gas composition to be achieved by the selected film.

equilibrium are O_2 and CO_2 permeability of film, free volume inside the package, the concentrations of O_2 and CO_2 at the beginning and at equilibrium and the product weight, A and e. The highest time of t_{O_2} and t_{CO_2} is the one considered for simulation of gas composition inside the package. Usually the initial concentrations are those in atmospheric air and the concentrations at equilibrium are the ones for optimal preservation of the produce. But in passive MAP the gas composition changes with time due to which respiration rate also changes and achieves constant rate at the once equilibrium gas composition reaches. Hence, it is necessary to consider the effect of change in gas composition on the respiration rate and thereby on the equilibrium time.

ix. The last step consists of the calculation of the changes in package gas composition with time. The program uses an optimisation routine named fsolve to solve the two ordinary differential Equations 119.1 and 119.2 for O_2 and CO_2 concentrations, respectively. The program calculates the O_2 and CO_2 concentrations at every minute. The respiration rate is re-calculated at new gas composition, i.e., composition after one minute and is used to calculate the next O_2 and CO_2. In this way gas composition is predicted until the equilibrium time t^{eq} ($=t^{eq}_{O_2}$ or $t^{eq}_{CO_2}$, whichever is higher) is reached.

VI. PERFORATION-MEDIATED MAP

A major challenge is to develop films that have greater permeability and have a wider range of β values than existing types. Films of enhanced permeability are necessary for packaging high respiration rate products and for preventing the development of anaerobiosis. A wider range of β values, especially those below 3, is necessary to better match the respiration behaviour of many products. The use of either perforation systems or microporous films is a possible solution to meet these two requirements. These systems and films have permeabilities many orders of magnitude higher than those of non-perforated polymeric films, as well as β values between 0.8 and 1. The use of perforations in MAP has been recently reported by Fonseca et al. (36), Silva (37) and Emond (38). The gas transfer coefficients through perforations can be described by Equations 119.37 and 119.38 characteristics (36). This model has a functional form similar to the one that would be expected by dimensionless analysis and has the advantage of having less number of parameters than those suggested by Emond (38) and Silva (37). Γ is the tortuosity of the path through which the pores pass and is equal to 1.14. The other parameters are shown in Table 119.5.

$$P_{O_2} = N_P \times \frac{\varepsilon}{\Gamma^2} \times a \times D_p^b \times L_p^c \qquad (119.37)$$

$$P_{CO_2} = N_P \times \beta \times \frac{\varepsilon}{\Gamma^2} \times a \times D_p^b \times L_p^c \qquad (119.38)$$

VII. MACROSCOPIC HOLES IN COMBINATION WITH POLYMERIC FILM

Since β value of polymeric films is much larger than the respiratory quotient, RQ, there will be more CO_2 leaving the package than O_2 entering. Nitrogen cannot make up the volumetric difference, so the package free volume tends to shrink during storage. This volume shrinkage can be eliminated by introducing a very small hole that allows a convective influx of air to balance the total pressure inside the bag with the air outside. This, of course, alters the composition of the gas in the package relative to what it would have been in the absence of the hole. For some products, it is necessary to have a lower CO_2/O_2 permeability ratio than available polymer choices permit in

TABLE 119.5
Parameters of the Mathematical Model Shown in Equations 119.37 and 119.38

Parameter	Value
a	6.42×10^{-6}
b	1.45
c	−0.598
Γ	1.14
D_{O_2}	$16.4 \times 10^{-6}\,m^2.sec^{-1}$
D_{CO_2}	$20.6 \times 10^{-6}\,m^2.sec^{-1}$

order to achieve the CO_2/O_2 composition for optimal extension of shelf life. This can be solved by making the area of the holes large enough to provide non-selective permeation in parallel with the film; thus reducing the net CO_2/O_2 permeability ratio.

The macroscopic perforation in the polymeric film represents an alternate route for gas transport, which is in parallel to the barrier formed by the plastic material. The total flow through polymeric film having N_H number of holes is

$$\text{Total permeation} = \left\{\begin{matrix}\text{Permeation}\\ \text{through film}\end{matrix}\right\} + \left\{\begin{matrix}\text{Permeation through}\\ \text{one hole} \times N_H\end{matrix}\right\} \quad (119.39)$$

The macroscopic perforations in polymeric films have diameters of the order of 10^{-4} m or greater, whereas the mean-free path of gas molecules at atmospheric pressure is much less, being about $(1 \text{ or } 2) \times 10^{-7}$ m (25). Therefore, transport through the perforation may be treated as macroscopic diffusion in a cylindrical pathway filled with air. If the distance between perforations is much greater than their radius, the diffusive pass length becomes the length of cylindrical pore plus the radius of the hole. Diffusive flux in this case obeys Fick's law:

$$P_{O_2} = \left[P_{O_2}^{film} + \frac{\pi R_H^2 \times D_{O_2}}{(e + R_H)} \times N_H\right] \quad (119.40)$$

$$P_{CO_2} = \left[P_{CO_2}^{film} + \frac{\pi R_H^2 \times D_{CO_2}}{(e + R_H)} \times N_H\right] \quad (119.41)$$

VIII. DEVELOPMENT OF SOFTWARE

The graphical user interface of the software was built in Matlab programming language. The same tool was used to solve the design steps as explained in Figure 119.7.

IX. CASE STUDY

A case study is presented to illustrate the use of the software to design MAP for whole mango. In this case study, the design procedure is explained for two kinds of package: permeable polymeric film and microscopic perforation (hole) with permeable polymeric film. A tray type package as shown in Figure 119.5 is selected for the present case study. The product and package characteristics are shown in Table 119.6.

For the selected commodity and at given optimum conditions β_{min} and β_{max} were found to be 1.71 and 3.84, respectively. As in Figure 119.9, the thick rectangle indicates the limits, inside which lines must run so that the corresponding films are eligible for selection. As can been seen, there are 11 films selected from the database of 27 films. These films will modify the package atmosphere leading to the optimum level for the selected commodity provided that the area of film is kept as shown in Table 119.7. The equilibrium modified atmosphere parameters such as $y_{O_2}^{eq}$, $y_{CO_2}^{eq}$, A_F and t^{eq} are calculated and are shown in Table 119.7. All the 11 films were found to give the optimum atmosphere, but the area of film required is different for all of them. Moreover, the film area required to achieve equilibrium is different from the possible area

* Thickness = 1 mil; ¢ Not suitable for mango.

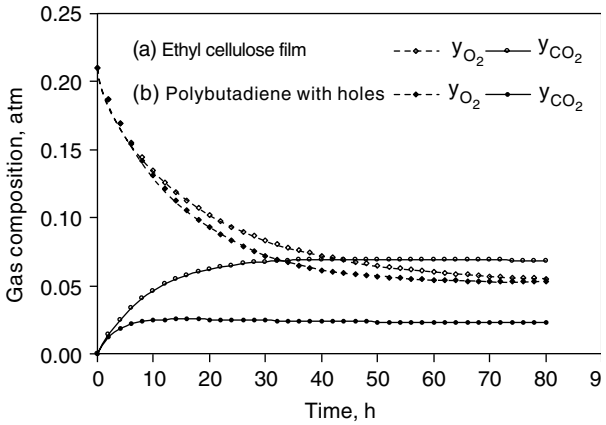

FIGURE 119.10 Steady-state establishment of O_2 and CO_2 in MAP with (a) Ethyl cellulose film having thickness = 1 mil, area = 0.0146 m^2; (b) Polybutadiene film having thickness = 1 mil, area = 0.0224 m^2, number of holes = 2, diameter of each hole = 0.0001 m.

($A_F^{Tray} = 0.16 \times 0.14 = 0.0224\ m^2$) for the selected tray type of package. For the present case, ethyl cellulose film is selected because it presents the minimum difference between A_F^{Tray} and A_F. If the area of any other chosen film is kept 0.0224 m^2, the package will not achieve the optimum levels. The change in O_2 and CO_2 in MAP with ethyl cellulose film is shown in Figure 119.10 (a).

The rest of the films are not suitable due to their high β values. Nevertheless, these films could be used for MAP of mango after making certain number of holes to increase the gas transfer across the film (Figure 119.10(b)). Table 119.8 shows the results of microperforations with polymeric films having β value more than β_{max}. It is necessary to decrease the β value of the film in order to produce the atmosphere within the optimum range of mango, by making tiny holes in polymeric film. The number of holes and diameter depends on the permeability and area of the film as shown in Table 119.8.

Although the polymeric films are the most useful packaging material, they are unable to produce the optimum atmosphere for the high respiration and transpiration rates and higher CO_2 tolerance commodities. The perforation-mediated package is one such alternative, where the regulation of the gas exchange is achieved by single or multiple perforations or tubes that perforate an otherwise impermeable covering. This perforation-mediated MAP has special interest in fresh-cut products, e.g., cut Galega kale (21). Table 119.9 shows the design output for the perforation-mediated MAP for cut Galega kale at 20 and 5°C. The resultant steady state establishment of O_2 and CO_2 in perforation-mediated MAP is shown in Figure 119.11.

120 Ohmic and Inductive Heating

Rhonda Bengtson, Emily Birdsall, Stuart Feilden, Sireesha Bhattiprolu, Sandeep Bhale, and Marybeth Lima
The Department of Biological & Agricultural Engineering, Louisiana State University

CONTENTS

I. OVERVIEW

Ohmic and inductive heating are alternative methods of heating to conventional heating techniques. Ohmic heating, also known as Joule heating, electric resistance heating, direct electric resistance heating, electro heating, and electro conductive heating, is a process in which alternating electric current is passed through food material; heat is internally generated within the material due to its resistance to the applied electrical current. Inductive heating is a technique that uses electric coils to generate oscillating electric fields that send currents through the food.

Ohmic heating is not a new technology; it was used as a commercial process in the early 20th century for the pasteurization of milk (1). However, the "Electropure Process" was discontinued between the late 1930s and 1960s, ostensibly due to the prohibitive cost of electricity. Interest in ohmic heating was rekindled in the 1980s, when investigators were searching for viable methods to effectively sterilize liquid-large particle mixtures, a scenario for which aseptic processing alone was unsatisfactory. Very little information exists on inductive heating because its development in food processing is so recent.

The purpose of this chapter is to present general information regarding ohmic heating, and to identify areas of study which will add to the knowledge base of this subject. This chapter is separated into several sections: (1) general information on ohmic heating, (2) modeling of

ohmic heating processes, (3) novel uses of ohmic heating, and (4) future research directions.

II. GENERAL INFORMATION ON OHMIC HEATING

A. Advantages

Ohmic heating exhibits several advantages with respect to conventional food processing technologies, as follows:

- Particulate foods up to 1 in^3 are suitable for ohmic heating; the flow of a liquid-particle mixture approaches plug flow when the solids content is considerable (20–70%).
- Liquid-particle mixtures can heat uniformly under some circumstances (for example, if liquids and particles possess similar electrical conductivities, or if properties such as solids concentration, viscosity, conductivity, specific heat, and flow rate are manipulated appropriately).
- Temperatures sufficient for UHT processing can be rapidly achieved.
- There are no hot surfaces for heat transfer, resulting in a low risk of product damage from burning or overprocessing.
- Energy conversion efficiencies are very high.
- Relatively low capital cost.

B. Applications

Ohmic heating can be applied to a wide variety of foods, including liquids, solids, and fluid-solid mixtures. Ohmic heating is being used commercially to produce liquid egg product in the United States. It is also being used in the United Kingdom and Japan for the processing of whole fruits such as strawberries. Additionally, ohmic heating has been successfully applied to a wide variety of foods in the laboratory, including fruits and vegetables, juices, sauces, stews, meats, seafood, pasta, and soups.

Widespread commercial adoption of ohmic heating in the United States is dependent on regulatory approval by the FDA, a scenario that requires full understanding of the ohmic heating process with regard to heat transfer (temperature distributions), mass transfer (concentration distributions, which are influenced by electricity), momentum transfer (fluid flow), and kinetic phenomena (thermal and possibly electrothermal death kinetics, and nutrient degradation).

Larkin and Spinak (2) examined safety considerations for ohmically heated, aseptically processing, multiphase low acid food products, and discussed the need for providing information on equipment design, product specification, process design, and process validation for regulators. Full knowledge of these areas is critical to ensure that the food product receives adequate thermal treatment. Significant research strides toward widespread commercial use have been made, though more work remains to be done.

FIGURE 120.2 APV ohmic heater used for industrial applications. (Courtesy of Dr. Sudhir Sastry, Ohio State University.)

C. Design

Ohmic heating devices consist of electrodes, a power source, and a means of confining the food sample (for example, a tube or vessel). Appropriate instrumentation, safety features, and connections to other process unit operations (pumps, heat exchangers, holding tubes, etc.) may also be important. Ohmic heaters can be static (batch) or continuous. Figure 120.1 contains a graphic of a static ohmic heating apparatus, while Figures 120.2 and 120.3 represent an early[1] continuous ohmic heater used by APV Baker, a U.K. company using ohmic heating for food processing, and a more recent continuous ohmic heating system developed by S. Sastry, respectively.

Important design considerations include electrode configuration (current flows across product flow path or parallel to product flow path), the distance between electrodes, electrolysis (metal dissolution of electrodes, particularly at low frequencies), heater geometry, frequency of alternating

[1] 1980s and 1990s.

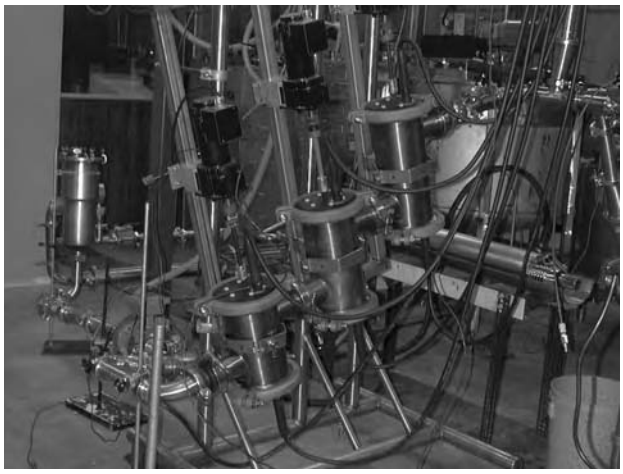

FIGURE 120.3 Ohmic heater developed by Dr. Sudhir Sastry. (Courtsey of Dr. Sudhir Sastry, Ohio State University.)

current, power requirements, current density, applied voltage, and product velocity and velocity profile. Additional factors regarding the food system used in an ohmic heater include the type of product and its properties, especially electrical conductivity and heating rate; others include percent solids, acidity, product viscosity, specific heat, and density, and solid particle size, shape, and orientation to the electric field. Substantial literature has been devoted to these topics; see, for example, references (3–10).

Coated electrodes can minimize or eliminate electrolytic reactions; temperature measurement remains an area of concern, as many measurement methods influence the electric field during ohmic heating. Some success has been seen with thermocouples that are coated with material such as Teflon, however, non-invasive temperature measurements that do not interfere with the electric field remain a challenge, particularly with regard to temperature measurement inside particles.

D. Cost

Investigators (11) conducted an economic engineering analysis of ohmic food processing for low and high acid foods. They found that ohmic heating is an economically viable technology for processing low acid foods. Though ohmic heating was found to be more costly than conventional methods for processing high acid foods, the authors believed that ohmic heating was still viable in these cases because of its potential to produce superior product quality.

III. PARAMETERS OF IMPORTANCE IN OHMIC HEATING

A. Product Properties

The most important parameter of interest in ohmic heating is the electrical conductivity of the food and/or food mixture. Substantial research was conducted on this property in the early 1990s because of the importance of electrical conductivity with regard to heat transfer rate and temperature distribution.

The electrical conductivity is determined using the following Equation (120.1):

$$\sigma = \frac{L}{AR}$$

where
σ = specific electrical conductivity (Siemens/m)
A = area of cross section of the sample (m^2)
L = length of the sample (m)
R = resistance of the sample (ohm)

General[2] findings of numerous electrical conductivity studies are as follows:

- The electrical conductivity is a function of food components; ionic components (salt), acid, and moisture mobility increase electrical conductivity, while fats, lipids, and alcohol decrease it.

Electrical conductivity is linearly correlated with temperature when the electrical field is sufficiently high (at least 60 V/cm). Non-linearities (sigmoidal curves) are observed with lower electrical field strength (3, 12).

- Electrical conductivity increases as temperature and applied voltage increases, and decreases as solids content increases.
- Lowering the frequency of alternating current during ohmic heating increases the electrical conductivity.
- The waveform can influence the electrical conductivity; though alternating current is usually delivered in sine waves, sawtooth waves increased the electrical conductivity in some cases, while square waves decreased it (12).
- Electrical conductivity increases by heating cycle; preheated samples showed increased electrical conductivity as opposed to raw samples when both were subsequently subjected to ohmic heating (13).

The electrical conductivity of solids and liquids during ohmic heating of multiphase mixtures is also critically important. In an ideal situation, liquid and solid phases possess essentially equal electrical conductivities, and would thus (generally) heat at the same rate. When there are differences in the electrical conductivity between

[2] These findings are true in general; some exceptions may exist depending on the situation.

a fluid and solid particles, the particles heat faster than the fluid when their conductivities are lower than the fluid. Also, solid particulates heat more slowly than a fluid when the electrical conductivity of the solid is higher than that of the fluid. Fluid motion (convective heat transfer) is also an important consideration when there are electrical conductivity differences between fluids and particles.

Other product properties that may affect temperature distribution include the density and specific heat of the food product. When solid particles and a fluid medium have similar electrical conductivities, the component with the lower heat capacity will tend to heat faster. High densities and specific heats are conducive to slower heating. Fluid viscosity also influences ohmic heating; higher viscosity fluids tend to result in faster ohmic heating than lower viscosity fluids.

B. Texture Analysis

Sensory evaluation is critically important to any viable food process. Numerous publications have cited the superior product quality that can be obtained through decreased process time, though few published studies specifically quantify sensory and texture issues. Six stew formulations sterilized using ohmic heating before and after three years of storage were analyzed; the color, appearance, flavor, texture, and overall food quality ratings were excellent, "indicating that ohmic heating technology has the potential to provide shelf-stable foods closely equivalent to those prepared from scratch" (14).

C. Gelatinization

Starch gelatinization is an important parameter in food processing, and can be either advantageous or disadvantageous depending on the desired product formulation. The electrical conductivity of a food product is influenced significantly by starch gelatinization (13). These investigators found that electrical conductivity decreased with the degree of gelatinization, and suggest that ohmic heating can be used in the development of a sensor to detect starch gelatinization.

Ohmic heating was used to maximize the gel functionality of a seafood product (15). The ohmic heating process was superior to the conventional heating process due to rapid heating that deactivated enzymes, which in turn enabled strong gel formation.

IV. MODELING OF OHMIC HEATING PROCESSES

A. Basic Equations

Considerable effort has been expended to model the heat transfer mechanisms and microbial death kinetics involved during ohmic heating. Models are of interest in the analysis and design of ohmic heating processes to provide information about the temperature distribution throughout the process, especially "the cold spot," and to provide accurate predictions of the minimum lethal processing time. Complexities in modeling heat transfer processes during ohmic heating arise when the liquid and particle possess different electrical conductivities, and because electrical conductivity is a (sometimes non-linear) function of temperature and frequency of alternating current. Basic equations regarding ohmic heating are included below.

The temperature distribution in a fluid during ohmic heating is based on an energy balance as follows:

$$\rho C_p v_z \frac{\partial T_f}{\partial z} = \nabla \cdot (k_f \nabla T_f) - n_p A_p h_{fp} (T_f - T_{ps}) + \dot{u}_f$$

where
ρ = density
C_p = specific heat
T = temperature
z = distance
v_z = fluid velocity
f = fluid
p = particle
ps = particle surface
k = thermal conductivity
n_p = number of particles
A = surface area of particles
h_{fp} = fluid to particle heat transfer coefficient
$\dot{u}_f$ = internal energy generation rate of the fluid

The temperature distribution in a particle during ohmic heating can be predicted with the conduction heat transfer equation with internal energy generation:

$$\nabla \cdot (k \nabla T) + \dot{u} = \rho C_p \frac{\partial T}{\partial t}$$

where k = thermal conductivity

The internal energy generation is:

$$\dot{u} = |\nabla V|^2 \sigma$$

where
V = voltage
σ = electrical conductivity
$\dot{u}$ = energy generation rate per unit volume

The voltage field is determined by solving:

$$\nabla \cdot (\sigma \nabla V) = 0$$

Numerous models have been developed based on numerical solution of these equations with appropriate boundary conditions and assumptions, and also from

dimensional groupings. Though these models have contributed significantly to the understanding of heat transfer in ohmic heating, none have completely described the ohmic heating process to date.

The voltage field (Laplace) equation for a single solid particle in a static heater has been solved (16). Numerical solutions and experimental simulations to more complex ohmic heating situations have been developed (17–22) using magnetic resonance imaging to rapidly map the temperature of food particles during ohmic heating.

B. Microbial Death Kinetics

In terms of microbial death kinetics, considerable attention has been paid to the following question: does electricity result in microbial death, or is microbial death due only to heat treatment? The challenge in modeling microbial death kinetics is precise matching of time-temperature histories between ohmic processes and conventional processes. The FDA has published a comprehensive review of microbial death kinetics data regarding ohmic heating (23).

Initial studies in this area showed mixed results, though the experimental details were judged insufficient to draw meaningful conclusions (1). Researchers compared death kinetics of yeast cells under time-temperature histories as identical as possible and found no difference between conventional and ohmic heating (24).

More recent work in this area has indicated that decimal reduction times of *Bacillus subtilis* spores were significantly reduced when using ohmic heating at identical temperatures (25). These investigators also used a two step treatment process involving ohmic heating, followed by holding, followed by heat treatment, which accelerated microbial death kinetics; they hypothesized that electroporation may positively influence microbial death kinetics.

The inactivation of yeast cells in phosphate buffer by low-amperage direct current electrical treatment and conventional heating at isothermal temperatures was examined (26). These researchers concluded that a synergistic effect of temperature and electrolysis was observed when the temperature became lethal for yeast.

Further research regarding microbial death kinetics, survivor counts subsequent to treatment, and the influence of electricity on cell death kinetics are necessary to address regulatory issues. At the present time, assuming that microbial death is only a function of temperature (heat) results in an appropriately conservative design assumption.

C. Vitamin Degradation Kinetics

Limited information exists regarding product degradation kinetics during ohmic heating. Researchers measured vitamin C degradation in orange juice during ohmic and conventional heating under nearly identical time-temperature histories, and concluded that electricity did not influence vitamin C degradation kinetics (27). This study was conducted at one electrical field strength (E = 23.9 V/cm). Others found that the ascorbic acid degradation rate in buffer solution during ohmic heating was a function of power, temperature, NaCl concentration, and products of electrolysis (10). Further research in this area could include the influence of electrical field strength, endpoint temperature, and frequency of alternating current on the degradation of food components during ohmic heating. The characterization of electrolysis is also a critical need in this area.

V. NOVEL USES OF OHMIC HEATING

A. Background

Early research on ohmic heating was conducted on heat transfer and sterilization of liquid-particle mixtures. In executing such studies, investigators observed unanticipated phenomena. For example, ohmically heating beetroot resulted in enhanced diffusion of betanin from the beetroot tissue when compared to beetroot tissue heated conventionally (28). These investigators hypothesized that the enhanced mass transfer could be due to electroosmosis.

Investigators expanded on the aforementioned work and found that diffusion of beet dye from beetroot into a carrier solution from was enhanced as much as 40% during heating from 20°C to 80°C, and that the concentration of diffused dye was proportional to particle surface area, and a linear function of electric field strength (29). Other researchers ohmically heated Japanese white radish and found that the ohmic heating rate was influenced by frequency; as the frequency of alternating current decreased, the heating rate increased (30). These investigators used H-NMR analysis and hypothesized that at low frequency (50 Hz), rapid heating is due to electroporation of radish tissue membrane, which resulted in a decrease of electrical impedance. Subsequent studies (9, 31) have concluded that electroporation is the most likely mechanism for enhanced mass transfer effects during ohmic heating.

Electroporation is defined as the formation of holes in a cell membrane resulting from local pressure of ions, which cannot initially permeate the cell membrane, but are forced against it by the electric field (32). The relatively low alternating frequencies employed during ohmic heating enable this charge build up to occur on the cell wall, resulting in the formation of pores. This also suggests that the lower the frequency of ohmic heating, the more pronounced the mass transfer effect; this concept has been demonstrated in the literature (31, 33–34). It was found that direct current resulted in less mass transfer enhancement than low AC frequency ohmic heating (at 15 V/cm, 250 Hz $<$ DC $<$ 50 Hz). Kulshrestha and

Sastry postulated that a monopolar electric charge (DC) is not as effective as a bipolar electric charge at creating stress on the cell membrane, thus yielding less of an effect than low frequency alternating current (31).

Electrically heating foods influences their mass transfer properties. This phenomenon has important implications for food processing operations that involve mass transfer. In 2001, the FDA reported that "A large number of potential future applications exist for ohmic heating, including its use in blanching, evaporation, dehydration, fermentation, and extraction" (23). In this section, we will report on some of the research regarding these novel uses.

B. Blanching

Because blanching requires large volumes of water during processing, and often requires dicing vegetables, studies to increase the efficiency of blanching using ohmic heating are important. Wigerstrom (35) found that electric fields enhanced moisture loss during the blanching of potato slices. Mizrahi (36) determined that ohmic heating was an effective method for blanching because the rapid, uniform heating exhibited by ohmic heating eliminated the need for dicing vegetables. The quick process time and reduction in surface area (no dicing) reduced solute losses by an order of magnitude during blanching. Sensoy, Sastry, and Beelman (37) found that using ohmic heating during the blanching of mushrooms resulted in the shrinking of mushrooms at a lower temperature and with less water use as compared to conventional blanching. Lakkakula, Lima, and Walker (34) showed significant lipase deactivation in rice bran during ohmic heating, with and without a corresponding temperature increase. Taken collectively, these studies show that ohmic heating can increase process efficiency in blanching.

C. Evaporation

Wang and Chu (38) studied the effect of ohmic heating on the vacuum evaporation of orange juice, and found that the evaporation rate could be increased as much as three times using ohmic heating, and resulted in enhanced product quality. The authors conclude that ohmic heating has potential as a fast evaporation method and recommend further development in this area.

D. Dehydration

Ohmic heating has also been used to enhance the drying rate of vegetable tissue. Wang and Sastry (39) showed that ohmically treating sweet potato prior to dehydration accelerated the hot-air drying rate significantly compared to raw, conventionally treated, and microwaved samples. Lima and Sastry (33) found that the lower the frequency of alternating current used in ohmic heating, the faster the hot-air drying rate. Maximum drying benefits were seen when drying to initial or intermediate moisture contents. Zhong and Lima (40) showed that ohmic pretreatment accelerated the vacuum drying rate of sweet potato as much as 24%; these investigators also demonstrated that minimal ohmic treatment (electrical field strength of 50 V/cm and an endpoint temperature of 40°C) resulted in the maximal or near maximal acceleration of drying rate. These investigators suggested that because ohmic heating enhances drying rates and enhances extraction yields, the process could be ideal for the recovery of high value, heat labile components from biological materials using unit operations such as supercritical fluid extraction.

E. Fermentation

Cho, Sastry, and Yousef (41) found that mild electrical treatment significantly decreased the lag time of *Lactobacillus acidophilus*, possibly due to electroporation, which could enhance the transport of substrates across the cell membrane. These investigators also found that electricity applied later in the microbial growth cycle proved detrimental, possibly due to the enhanced transport of inhibitory substances across the cell membrane.

F. Extraction

Ohmic heating has been used to enhance the extraction of components from foods. Katrokha, Matvienko, Vorona, Kupchik, and Zaets (42) used an electric field to extract sugar from sugar beets. Kim and Pyun (43) extracted soymilk from soybeans. Lima and Sastry (33) and Wang and Sastry (44) found that ohmically heating apple tissue prior to mechanical juice extraction significantly increased apple juice yields with respect to non-treated apple tissue, and that the lower the frequency of alternating current, the greater the extraction yield.

Several studies have examined the diffusion of beet dye from beetroot. In addition to the pioneering work mentioned above, Lima, Heskitt, and Sastry (45) found that the diffusion enhancement beet dye due to ohmic heating was especially pronounced at lower temperatures (42°C vs. 58°C and 72°C), and could be related to the difference in electrical conductivity of beet tissue between conventional and ohmic cases at the same temperature. Kulshrestha and Sastry (46) showed that significant leaching of beet dye occurs with temperature increases of 1–2°C in ohmic heating. Lakkakula, Lima, and Walker (34) used ohmic heating to significantly increase the extraction of rice bran oil from rice bran (with moisture addition), especially at low (1 Hz) frequency.

G. Summary of Novel Processes

There exists a strong potential to enhance mass transfer operations using ohmic heating, particularly because mild ohmic treatment has been shown to significantly increase

dehydration and extraction efficiencies. Future work in these areas includes establishing a more complete body of knowledge regarding the mechanisms for mass transfer effects, and process design to establish industrial processes that take advantage of this technology.

VI. FUTURE RESEARCH DIRECTIONS

Though there has been a proliferation of published research on ohmic heating during the past fifteen years, there exist many opportunities for contributing to the body of knowledge regarding ohmic and inductive heating.

In terms of inductive heating, so little information exists that substantial contributions can be made in all areas of research, including equipment design and instrumentation, process characterization, properties of importance in inductive heating, and modeling process transport phenomena and kinetics (microbial death and food degradation).

In terms of ohmic heating, areas of future work include the following:

- Developing temperature measurement methods that are (preferably) non-invasive and that do not interfere with the electrical field for the internal monitoring of solid particles during ohmic heating.
- Developing models that correlate process parameters and process design with properties of the product (physical, electrical, chemical, biological, microbial) in order to standardize ohmic heating design and analysis, and to accurately quantify changes in process or product.
- Determining the influence of temperature and electrical field on the degradation kinetics of key pathogenic microorganisms.
- Developing the knowledge necessary to quantify the effects of electrical field on mass transfer properties in order to optimize promising applications of ohmic heating, including drying, extraction, blanching, fermentation, evaporation, and gelatinization.
- Quantifying electrolytic effects during ohmic heating, particularly the minimization of electrolysis at low frequencies, where several novel process options exist.

CONTENTS

I. INTRODUCTION

Sound waves are mechanical vibrations that travel through solids in the form of transverse waves, and through liquids and gases in the form of longitudinal waves. Ultrasound refers to sound waves having a frequency higher than the range audible to humans. The lowest ultrasonic frequency is commonly taken as 20 kHz (1 Hertz = 1 cycle per second). The upper limit of ultrasound frequencies is not clearly defined but is usually taken to be 5 MHz for gases and 500 MHz for liquids and solids (1). Applications of ultrasound can be divided broadly into two categories: low- and high-power ultrasound (Figure 121.1).

The first category involves low amplitude sound waves and is also referred to as "low intensity," "diagnostic," or "high frequency" ultrasound. Low power ultrasound uses very high frequencies of 2 MHz to 20 MHz with low sound intensities of 100 mW/cm^2 to 1 W/cm^2. It measures the velocity and attenuation of the wave in a medium and utilizes such information in medical imaging (e.g., scanning an unborn fetus), chemical analysis, food quality assessment, and non-destructive testing (e.g., regular crack testing for aircraft structures). A low-power ultrasound measurement system is composed of a transducer, a signal generator, a digitizer, and a measurement cell. Possible applications of low-power ultrasound in food

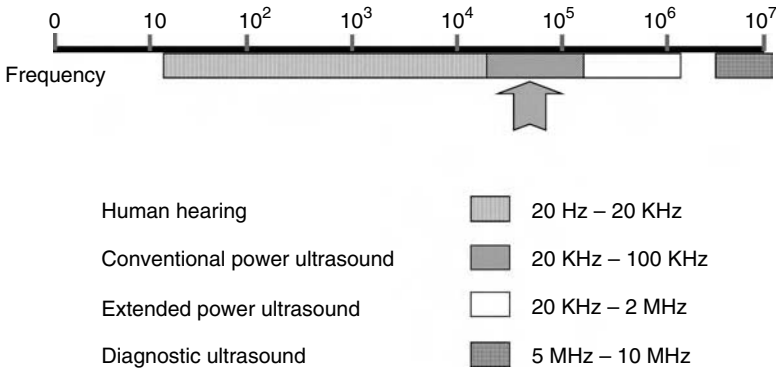

FIGURE 121.1 Sound wave spectrum (from ref. (1)).

processing and quality determination include measurement of temperature and flowrate, determination of composition, determination of particle size, determination of creaming and sedimentation profiles, monitoring of phase transitions, study of gelation, ultrasonic imaging, fouling detection, and the study of molecular properties.

The second category in often known as "power ultrasound" or "high intensity ultrasound." Power ultrasound uses lower frequencies (typically 20 kHz to 100 kHz) and produces sound intensities of 10 to 1,000 W/cm^2 with amplitudes ranging from about 5 to 50 microns. It finds applications in food processing operations such as emulsion generation, dispersion of aggregated materials, drying, inactivation of microbes and enzymes, heat and mass transfer enhancement, biological components separation, and modification and control of crystallization process (2).

The purpose of this chapter is to provide an insight into the general principles of power ultrasound, as well as to review recent progress in the research and development of power ultrasound and its applications in the food processing industry. Readers who are interested in low-power ultrasound applications can refer to the comprehensive review articles of McClements (3, 4) for detailed information.

II. GENERATION OF ULTRASOUND AND ULTRASOUND SYSTEMS

A. Ultrasound Generation

Ultrasound is generated via an ultrasonic transducer — a device by which mechanical or electrical energy can be converted into sound energy. There are two fundamental transducer designs used for power ultrasonic applications today, magnetostrictive and piezoelectric, both powered by electricity.

1. Magnetostrictive Transducers

Magnetostrictive transducers consist of a large number of nickel plates or laminations arranged in parallel with one edge of each laminate attached to the bottom of a process tank or other surfaces to be vibrated. A coil of wire is placed around the magnetostrictive material. When a flow of electrical current is supplied through the coil of wire, a magnetic field is created. This magnetic field causes the magnetostrictive material to contract or elongate, thereby introducing a sound wave into a sonicating fluid.

2. Piezoelectric Transducers

The heart of a piezoelectric transducer is a single or double thick disc of piezoelectric ceramic material, such as barium titanate, lead metaniobate, or lead zirconate titanate (PZT), sandwiched between electrodes that provide the attachment points for electrical contact. The ceramic assembly is compressed between metal blocks (one aluminum and one steel) to a known compression with a high strength bolt. When a voltage is applied across the ceramic through the electrodes, the ceramic expands or contracts, depending on polarity, due to changes in its lattice structure. This physical displacement causes a sound wave to propagate into a treatment solution.

3. Comparison between Magnetostrictive and Piezoelectric Transducers

Piezoelectric transducers utilize the piezoelectric property of a material to convert electrical energy directly into mechanical energy. Magnetostrictive transducers utilize the magnetostrictive property of a material to convert the energy in a magnetic field into mechanical energy. Both types of transducers have advantages and disadvantages. A comparison between two types of transducers is given in Table 121.1.

B. Power Ultrasound Systems

A typical ultrasonic system comprises three essential parts (2): a generator that converts electricity into required high frequency alternating current, a transducer that converts the high-frequency alternating current into

TABLE 121.1
A Comparison between Piezoelectric Transducers and Magnetostrictive Transducers

Transducer	Frequency Range (kHz)	Noise	Reliability	Sweeping	Aging	Energy Efficiency
Piezoelectric	Wide range	Less noisy	Improving reliability	Not easy	Noticeable	>70%
Magnetostrictive	18–30	Noisy	Reliable	Easy	NA	35–40%

mechanical vibrations, and a delivery system to convey the vibration into a food system, such as the tank of the ultrasonic bath and the horn of the ultrasonic probe system.

1. Conventional Power Ultrasound Systems (1)

In practice, ultrasound can be introduced into a food system to perform various applications in two ways: direct and indirect contacting. With the direct contacting method, a food is in direct contact with an ultrasonic element, which can be a thin metal blade in the case of a liquid whistle apparatus or a sonic horn for probe type designs. Transducer arrays can also be arranged with sonic horns attached to them inserting into a treatment chamber or flow cell of different geometry to facilitate various sonication treatments. The advantage of this arrangement is that ultrasound can be directly transmitted into a food system with less energy loss. It can be used to design a high surface power density (W/cm^2) system or a high volumetric acoustic energy (W/cm^3) system by controlling the treatment chamber volume. The disadvantages may include difficulty of temperature control, and the possibility of generating free radicals on the contacting surfaces when surface power density is high. Another direct contacting design is a sonic vibrating bar developed by a Canadian company (5). The metallic bar is driven by three magnets and vibrates at the audible frequencies. It can operate at power as high as 75 kW and is effective as a mixer and grinder.

In an indirect contacting system, the ultrasound transducer is usually mounted onto a large surface to perform sonication treatments. The widely used ultrasonic baths are a good example of this design. In this category, ultrasound has to be transferred through a wall to reach the food system under treatment and thereby both the ultrasound power intensity (W/cm^2) and the volumetric acoustic energy density (W/cm^3) are low. It also has the problems of poor temperature control and difficulty in quantifying power delivered into the food system during sonication. Systems developed based on this design are widely used owing to their simplicity and ease of operation. The most successful application of the indirect contacting system is surface cleaning of jewelry and gun parts. In recent years, various food surface decontamination applications have been explored.

2. Variable Frequency Systems

Due to the ultrasound generation mechanism, traditional ultrasound systems are inherently single frequency units. In recent years, the concept of using more than one transducer each with different frequencies to enhance cavitation has been explored. Researchers have demonstrated several-fold increases in cavitation activities in lab testing in a dual or multi-frequency ultrasound system (6). Ultrasound units using this concept have to use more than one transducer, each with its own generator. This will complicate the design and operation, and will increase the cost of the unit. A new concept, the multi-frequency, multimode, modulated (MMM) technology was recently developed to facilitate variable frequency sonication applications. In a MMM unit (Figure 121.2), the ultrasonic power supply is able to produce variable frequency-sweeping oscillations around a central operating frequency, and has an amplitude-modulated output signal (where the frequency of amplitude modulation follows sub-harmonic low frequency vibrating modes of the mechanical system). The MMM technology can utilize the coupled vibrating modes in a mechanical system by applying advanced digital signal processing to create driving wave forms that synchronously excite many vibrating modes (harmonics and sub-harmonics) of an acoustic load. It will help to produce uniform distribution of high-intensity acoustical activity to make the entire available vibrating domain acoustically active while eliminating the creation of potentially harmful and problematic stationary and standing wave structures (7).

C. Cavitation

Most power ultrasound applications are based on the activity of cavitation, which refers to the formation, growth, and implosion of gas- or vapor-filled cavities in liquids when large acoustic pressure differences are applied. When sound waves travel through a liquid in the form of longitudinal waves comprising a series of compression and rarefaction portions, negative pressures are generated at the rarefaction portions. It is believed that nucleation is initiated at sites where the tensile strength of the liquid is dramatically lowered. One generally accepted nucleation mechanism states that gas entrapped in small-angle crevices, when subjected to negative

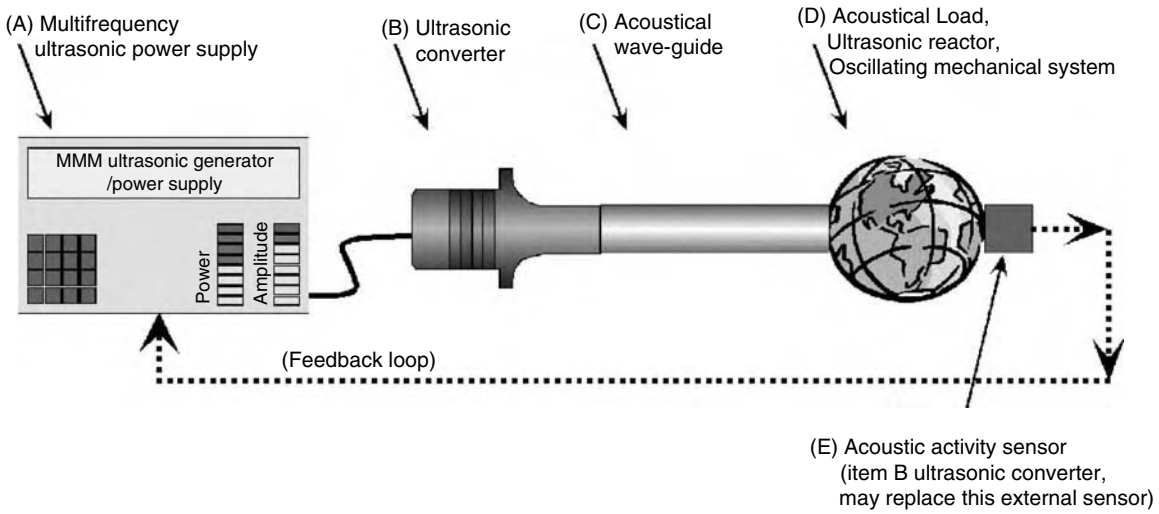

FIGURE 121.2 A multifrequency, multimode, modulated (MMM) ultrasound system (courtesy of MP Interconsulting).

acoustic pressure, undergoes expansion and forms small free bubbles (8). The behavior of the bubbles in a sonicating liquid determines the cavitation dynamics. Transient cavitation bubbles are generated when sound intensity is greater than 10 W/cm^2. These bubbles, with effective residence time of $<$100 nano-seconds, will experience large expansion in size in a few acoustic cycles and terminate in a violent collapse. The collapse of transient micro-bubbles can create extreme physical conditions, such as temperatures and pressures as high as 5,000 K and 1,000 atmospheres (8). It is believed that the localized high temperatures and pressures are responsible for most of the sonochemical and bactericidal effects. The release of the high pressure results in the formation of shock waves that often provide mechanical cleavage of large biopolymers. Stable cavitation is produced at fairly low sound intensities (1–3 W/cm^2). Stable bubbles have a much longer residence time so that the mass transfer of gas into them will result in growth of bubble sizes. As bubble sizes increase, stable bubbles can transform into transient bubbles and undergo collapse. They can also float to the surface and be expelled. Stable bubbles oscillating in resonance with the applied acoustic field can generate intense local strains in the bubbles' vicinity, which are the cause of many of the disruptive mechanical effects of sound (1).

There are several parameters affecting cavitation activity in a sonicating liquid. Increasing frequency decreases the intensity of cavitation because, at high frequencies, the rarefaction cycle is too small to permit a bubble to grow to a size sufficient to cause implosion. Since the prerequisite for micro-bubble formation in a liquid is that the negative pressure must overcome the cohesive forces, it is more difficult to generate cavitation in viscous and high surface tension liquids. Cavitation intensity increases with temperature when the acoustic power density is a constant. Increased vapor pressure makes it easier to surpass the crushing force, the difference between the hydrostatic pressure and the acoustic pressure, to generate cavitation. The effect of applied external pressure is two-fold. Higher external pressure will result in a higher cavitation threshold, as well as an increase in the intensity of bubble collapse.

III. SELECTED POWER ULTRASOUND APPLICATIONS

A. EMULSIFICATION

Emulsification is one of the earliest applications of power ultrasound. When a bubble collapses in the vicinity of the phase boundary of two immiscible fluids, the resulting shock wave can provide a very efficient mixing of layers (9, 10). Stable emulsions generated with ultrasound have been used in the textile, cosmetic, pharmaceutical, and food industries. The emulsions obtained by mechanical oscillations at ultrasound frequencies are known to have a number of advantages, including stable emulsions even without the addition of surfactant, and narrow mean droplet size distribution compared to other methods (11). Mongenot et al. (11) reported that encapsulations spray-dried from ultrasound-generated emulsions of maltodextrin better retained cheese aroma. In milk homogenization tests with ultrasound, shorter fermentation time of yogurt was found. Ultrasound treatment also altered the physico-chemical properties of the milk (12).

The mechanical device used to acoustically generate emulsification can be a sonicator with a piezoelectric or magnetostrictive transducer, or a "liquid whistle" that is

widely used for homogenization and emulsification applications in the manufacture of fruit juices, tomato ketchup, and mayonnaise (9).

B. Cutting

Ultrasonic knives made of titanium have been used in slicing or slitting of different food products. An ultrasonic cutting machine consists of a specially designed horn, used as a knife, driven by an ultrasound transducer, usually through a booster, and a precision positioning mechanism. The reciprocating vibration of the blades at ultrasonic frequency greatly reduces friction between the knife and the product, which ensures straight and clean cuts and results in products with uniform size, shape, and density. Ultrasonic knives can be used to cut sticky and brittle products. Nuts, raisins, and other hard fruits are cut cleanly without plowing or displacement, and peanuts are cut with minimum waste. Production costs and downtime associated with conventional cutting methods are minimized. With greatly reduced friction, there is minimal knife abrasion and blades stay sharper longer, which reduces annual maintenance costs. An ultrasonic cutting unit can be easily incorporated into an existing production line. It can also be a complete custom-built combined ultrasonic slitting and guillotine cutting station.

C. Inactivation of Microorganisms

The bactericidal effect of ultrasonic waves has long been observed (13). At that time, the effect was attributed to the compression that ultrasound would generate in a liquid. However, the relatively low inactivation rate of sound waves compared with other methods prevented ultrasound from being used as a food preservation method. In the early years, the low inactivation capacity of ultrasound was related to the low power density used.

A few studies have examined the use of ultrasound in conjunction with other preservation methods for the destruction of microorganisms. Neppiras and Hughes (14) reported that static pressure helped to increase the inactivation capacity of sound waves. Burgos et al. (15) showed that the heat resistance of bacteria spores decreased under sonication. Ultrasound has been combined with ozone (16) and H_2O_2 (17) to inactivate bacteria and spores and a synergistic effect was observed. When combining heat with power ultrasound (20 kHz) (thermosonication), the microbial inactivation rate was greater than the addition of the inactivating effect of heat to that of ultrasound when acting independently (18). Pagán et al. (19,20) and Mañas et al. (21) documented in their studies inactivation of *L. monocytogenes* with ultrasonic waves under pressure at sublethal (manosonication) and lethal (manothermosonication) temperatures and reported a significant increase in inactivation due to pressurization.

Several theories have been proposed to describe the inactivation mechanism of ultrasound. When ultrasonic waves pass through a liquid, bubbles or cavities can be formed if the amplitude of the waves is high enough. This phenomenon is known as cavitation. Cavitation can affect a biological system by virtue of a highly localized temperature rise and mechanical stress (22), which cause double-strand DNA breaks, enzyme inactivation, and damage to liposomes. Application of ultrasound to a liquid also leads to the formation of OH^- and H^+ species and hydrogen peroxide (23). These species also have important bactericidal properties. When ultrasound is combined with heat and pressure, the synergistic effect was attributed to the disruption of the bacterial spore cortex, which resulted in protoplast rehydration and loss of heat resistance (24). In the case of sonication assisted by elevated pressures, the increase in inactivation rate was probably due to an increase in bubble implosion intensity, as postulated by Pagán et al. (19). For certain microorganisms, such as *L. monocytogenes*, *S. enteridis*, and *A. hydrophila,* only additive effects were observed under the conditions tested by Pagán et al. (19).

Ultrasound has also been tested for its efficacy on surface decontamination of poultry (25) and fresh produce (26), as well as on removal of biofilm (27). The use of ultrasound in microbial inactivation for a food system is still in the stage of laboratory testing. No commercial applications of food microbial reduction have been documented.

D. Enzyme Activity Control

Ultrasonic energy has been used either to increase or inhibit enzyme activity, depending upon the ultrasound intensity. At low ultrasound intensities, Ishimori et al. (28) achieved a two-fold increase in α-chymotrypsin activity in a casein substrate. Enzyme activity inhibition at high ultrasound intensity levels has long been observed. Inactivating enzymes with ultrasound, however, usually requires long treatment times and the presence of oxygen (29). To increase the effectiveness of ultrasound treatment, different combined processes have been used to inactivate food enzymes. The most recent development includes treatments using a combination of heat, low pressure and ultrasound to increase the inactivation rate (manothermosonication). Lopez et al. (30) studied tomato pectinmethylesterase (PME) and polygalacturonase (PG) inactivation kinetics using manothermosonication (MTS) in a buffer and reported D values of 0.85 min for PME, and 1.46 and 0.24 min for PG1 and PG2, respectively. Vercet et al. (31) applied MTS to inactivate enzymes in a tomato paste at 200 MPa and 70°C for 1 min. They found that PME residual activity in treated samples was undetectable and PG residual activity was 38%. As observed with microorganisms, enzyme inactivation by a combination of heat and ultrasound under pressure exhibited a synergistic effect. The enzyme inactivation efficacy of

heat is increased by a factor that is dependent on the nature of the enzyme and the working conditions (29). In laboratory tests, MTS has been proven to be an effective means to inhibit enzyme activity. An advantage of using MTS is that both microbial inactivation and enzyme activity inhibition can be achieved in one processing step.

E. Modification of Biopolymers

Jackson et al. (32) used ultrasound to dissolve corn and sorghum starch granules after heating. They reported that ultrasonic vibrations disrupted swollen granules, thereby releasing amylose and amylopectin from the granules, which resulted in an increase in water solubility of the starch. Chung et al. (33) used power ultrasound to treat mung bean, potato, and rice starches with heating followed by ultrasound and reported that the average degree of polymerization did not change after sonication. They postulated that the changes in starch properties were induced by the disruption of swollen granules rather than the breakage of glucosidic linkages. In a study to examine the effect of ultrasound treatment on starch at different pH (2.0, 4.5, 7.0, 9.5, and 12.0), Zhang et al. (34) found that starches treated with power ultrasound had lower peak viscosity (PV) and higher pasting stability than did native starch. Ultrasound treated starches exhibited a decrease in the gelatinization enthalpy (ΔH) and an increase in the gelatinization onset (T_o). Ultrasound also significantly increased the in vitro digestibility of starches in the earlier stage.

F. Separation of Bio-Polymers and Bio-Components

Studies utilizing the mechanical action of sonication have been performed in recent years to realize various bioseparation operations. Mason (35) reported a study using ultrasound to treat rice grains in which surface erosion and particle size reduction resulted in shorter cooking and gel times. In a study on rice starch isolation, Wang et al. (36) found that high-intensity ultrasound treatment resulted in a high starch recovery but a slightly higher residual protein content. Zhang et al. (37) tested power ultrasound as a means to recover starch from degermed corn flour and hominy feed, which are reasonably high in starch and may be a source of non-sulfate treated starch. They used five treatments to produce starch from degermed corn flour and hominy feed slurries (10% solid): control, ultrasound only, ultrasound followed by fine grinding, fine grinding followed by ultrasound, and fine grinding only. The total starch recovery data are listed in Table 121.2. The starch yield from the corn flour was 37.1% for the control, and those by ultrasound treatments were 65.5 to 67.0%, a 28.4 to 29.9% increase compared to the control. Similarly, starch yields from the hominy feed by ultrasound treatments were 45.4 to 45.8%, a 16.1 to 16.5% increase compared to the control (Table 121.2). Comparing with the total starch contents in the two products, ultrasound treatments recovered 97.3 to 99.5% starch from the degermed corn flour and 97.8 to 98.9% from the hominy feed. Obviously, ultrasound treatment is a very effective method to recover starch from low value degermed corn flour and hominy feed.

TABLE 121.2
Starch Yields from Corn Flour and Hominy Feed Treated with Different Methods

Product	Treatment	Fractions (%)			Starch Recovery (%)
		Starch	Gluten	Fiber	
Corn flour	Ultrasound	66.8	15.7	16.7	99.1
	Ultrasound-Grind*	65.5	16.3	17.5	97.2
	Grind-Ultrasound	67.0	15.9	15.8	99.4
	Grind	34.7	8.4	55.2	51.5
	Control	37.1	5.9	56.0	55.0
Hominy feed	Ultrasound	45.6	22.5	29.0	98.3
	Ultrasound-Grind	45.4	26.7	24.5	97.8
	Grind-Ultrasound	45.8	27.5	23.1	98.7
	Grind	34.6	21.2	39.9	74.6
	Control	29.3	12.3	54.6	63.1

*Grind = fine grounding.

Power ultrasound was also used to increase starch yield in a novel corn processing method, the quick-germ/quick-fiber process (38). In the experiments, yellow dent corn soaked in deionized water at 52°C for 24 hrs without addition of SO_2 was wet-milled using a 100-g laboratory procedure with some modifications. Ultrasound treatments were performed at different process steps: first grind followed by ultrasound, ultrasound followed by second grind, second grind followed by ultrasound, fine fiber slurry treatment with ultrasound, and milling only (no ultrasound). A conventional wet milling treatment was used for comparison. Starch yield resulting from no ultrasound treatment was 61.7%, ultrasound treatments were 66.9–68.7%, and conventional wet milling was 68.9%. The characteristics of the starches produced with ultrasound treatments are similar to that from a conventional wet milling method as shown by color measurements and RVA curves.

G. Case Study — Power Ultrasound Enhanced Corn Pericarp Separation (39, 40)

Corn pericarp is a main source of dietary fiber. Refined corn pericarp has at least 92% dietary fiber, which places it among the most concentrated sources of edible fiber. It can be used as a supplement in dietary beverages, extruded breakfast cereals and snack foods, and breads and other bakery products. Currently, there are no rapid and effective pericarp separation methods available. It is imperative for

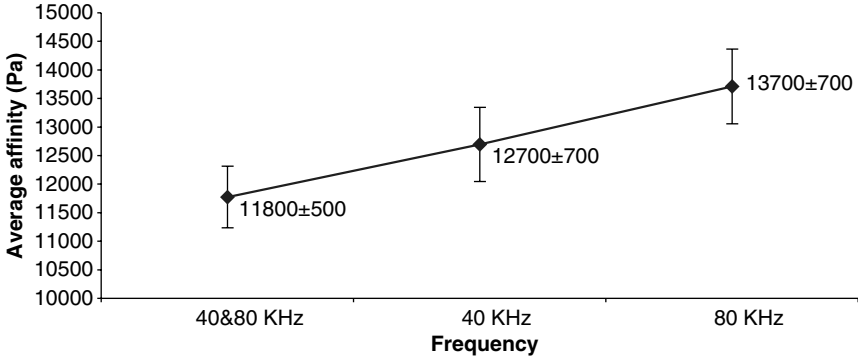

FIGURE 121.3 Pericarp affinity at three sonication frequencies. The samples were sonicated for 1 min at room temperature using the Zenith sonicator with a rating power of 925 W.

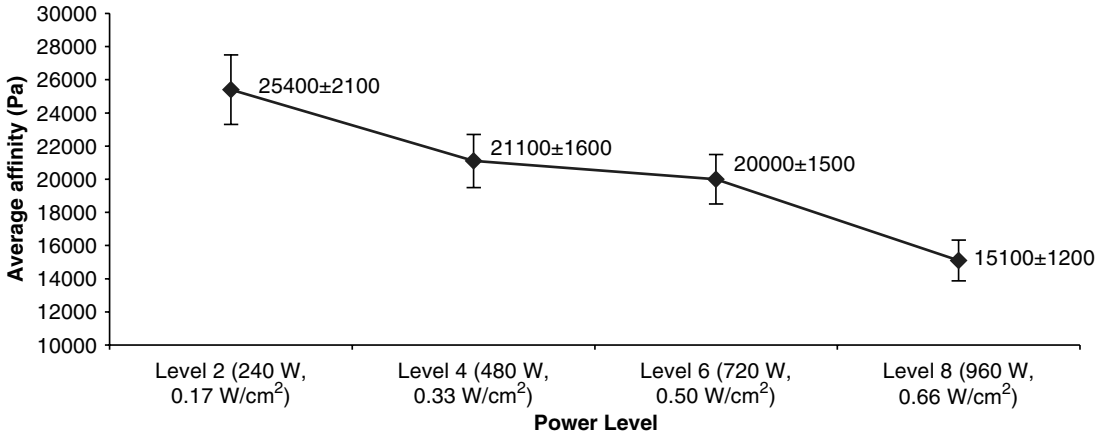

FIGURE 121.4 Pericarp affinity at four ultrasonic power levels. The samples were sonicated for 1 min at room temperature using a VWR sonicator at 40 kHz. The wattage for power levels of 2, 4, 6, and 8 was 240, 480, 720, and 960 W, respectively, and the corresponding power intensities were 0.17, 0.33, 0.50 and 0.66 W/cm^2, respectively.

such methods to be developed to facilitate the lab use for transgenetic research of corn as well as for industrial applications of the corn pericarp and other components.

Yellow dent corn at about 13% moisture content was treated with two ultrasonic baths at different frequencies, treatment times, temperatures, and power levels. Corn sample (50 g) was sealed in a plastic bag containing 200 ml of water and placed in the ultrasonic baths for sonication tests. After sonication, the pericarp can be easily separated by mechanical friction or abrasion. To quantify the separation effect of ultrasound, the affinity of the pericarp (Pa) was measured with an Instron Testing Machine (Instron Corporation, Canton, MA).

Figure 121.3 shows the average pericarp affinity for each of the three frequency conditions tested in the experiments: 40 kHz, 80 kHz, and a combination of 40 and 80 kHz. From Figure 121.3 it can be seen that pericarp sonicated at 40 kHz had a lower affinity (i.e., was easier to separate) than that sonicated at 80 kHz. Compared to the pericarp sonicated at 40 kHz or 80 kHz alone, the pericarp sonicated with a combination of 40 & 80 kHz resulted in the lowest pericarp affinity. Figure 121.4 shows the average pericarp affinity at four power levels. One can see that the pericarp affinity showed a decreasing trend with the power level. The power level had a significant effect ($\alpha = 0.05$) on the pericarp affinity. However, changes in sonication duration and sonication temperature did not show a marked effect on pericarp affinity.

122 Ultraviolet Light

Gilbert Shama
Department of Chemical Engineering, Loughborough University

CONTENTS

I. THE ULTRAVIOLET PORTION OF THE ELECTROMAGNETIC SPECTRUM

Ultraviolet light forms part of the electromagnetic spectrum. The ultraviolet wavelength range is from about 10 to 400 nm, placing it between X rays and the visible part of the spectrum (Figure 122.1).

Ultraviolet is frequently referred to as 'non-ionising' radiation, however the shortest ultraviolet wavelengths do bring about some ionisation. The ultraviolet portion of the spectrum has been sub-divided on a more or less arbitrary basis primarily for convenience. The term 'vacuum ultraviolet' is reserved for wavelengths below 200 nm, because in this region ultraviolet is strongly attenuated by air. It is usual to refer to the region between 200 and 300 nm as 'far ultraviolet' and that between 300 and 400 nm as 'near ultraviolet.' Alternative sub-divisions are often quoted in the scientific literature: thus UV-C is used for wavelengths in the range 100 to 280 nm, UV-B for 280 to 315 nm and UV-A for 315 to 400 nm. In what follows here, the abbreviation 'UV' will be used to denote UV-C.

II. THE EFFECT OF UV ON MICROORGANISMS

The fate of a microbial cell, or a population of such cells, following exposure to UV will depend on a number of factors. The range of wavelengths used to irradiate the cells will be one such factor. All UV sources used for commercial and industrial disinfection are polychromatic but the spectral range emitted will depend on the type of source used.

The most directly lethal wavelengths will be those that are maximally absorbed by the bases of DNA. The precise wavelength for maximum lethal effect varies from species to species because the DNA composition of species differs and because each DNA base has its individual peak absorptivity. Giese and Darby (2) compared the lethality of two UV wavelengths (280 and 301 nm) using a variety of bacteria and a bacteriophage (Table 122.1). There were greater differences in UV susceptibility between species at the highest wavelength (301 nm) but as the lethal effect of wavelengths in this part of the UV spectrum is low, the

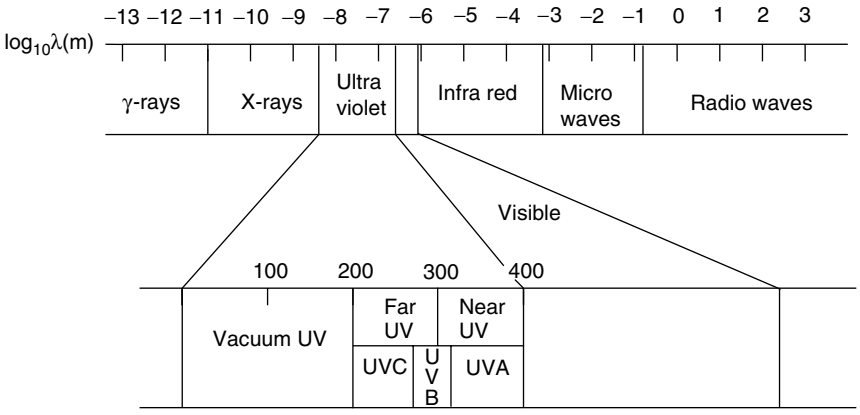

FIGURE 122.1 The electromagnetic spectrum.

TABLE 122.1
Germicidal Efficiencies at 280 and 301 nm

Micro-organism	Mean Germicidal Efficiency* at 280 nm	Mean Germicidal Efficiency* at 301 nm
Citrobacter diversus	0.894	0.025
Citrobacter freundii	0.834	0.017
Klebsiella pneumoniae	0.787	0.043
Bacteriophage ϕX-174	0.899	0.054

* Relative to 254 nm.

Data from (2).

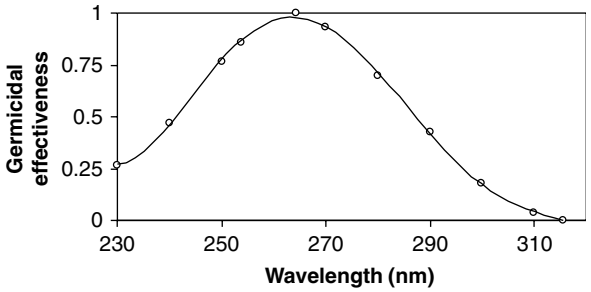

FIGURE 122.2 Relative effectiveness (with reference to 254 nm) of wavelengths of the UV spectrum. Data from ref. (3).

differences are of no real significance and for all practical purposes it appears justifiable to use data that is species-independent (see Figure 122.2). This figure shows that wavelengths in the vicinity of 265 nm are the most effective at inactivating microbial cells.

As the UV penetrates the microbial cell it will be attenuated by the various cellular structures and components. Attenuation effects are wavelength-specific. For example, the cell membrane may absorb 25% of the UV light at 280 nm but only 10% of the UV light at 254 nm, thereby decreasing the germicidal efficiency at 280 nm (2). Some organisms have evolved strategies for surviving irradiation by synthesising various UV-screening compounds (4). However, the majority of these compounds provide protection against UV-A and UV-B. A recent comparison of the sensitivity of a pigmented and a non-pigmented mutant of *Rhodobacter sphaeroides* to short wave UV showed no significant difference between the two cultures (5).

Although UV can bring about changes to a number of cellular components, the most significant reactions in determining cell survival are those that occur between UV and the nucleic acids. If the retroviruses, which contain only RNA, are omitted from further discussion, it becomes possible to concentrate solely on DNA. The interaction between UV and DNA will result in the formation of so-called 'photoproducts.' The most important of these are pyrimidine (i.e., thymine and cytosine) dimers. These are formed between two pyrimidine bases adjacent to one another on the same strand of DNA. Thymine dimers tend to predominate because thymine has a greater absorbance than cytosine in the germicidal wavelength range (6). Thymine (T) occurs in DNA in equal amounts with adenine (A) and it might be thought that species that contained a high proportion of A + T in their DNA might be particularly sensitive to UV, but this is not borne out by existing experimental evidence (5). Another type of photoproduct, 'pyrimidine adducts' are also formed between adjacent pyrimidine bases but at reduced rates of formation compared to dimers. At sufficiently high UV doses DNA-protein cross-links are formed, whilst at higher doses still, DNA strand breakages may be induced. A unique photoproduct — the so-called 'spore photoproduct,' another dipyrimidine — has been found in bacterial spores.

Nearly all living cells possess the ability to reverse the damage caused to their DNA by UV by using one or more repair mechanisms of which there are three principal types. In photoenzymic repair, dipyrimidine dimers are

enzymically monomerized in the presence of light. The second type of repair process, excision-resynthesis repair, involves removing sections of damaged DNA and resynthesising them using the intact strand as template. Whilst in postreplication repair, undamaged sections of DNA are replicated and combined in such a manner that an intact double stranded molecule, identical with the original, is formed.

The physiological state of cells is another factor that determines survival. It has been shown that microorganisms harvested at different stages of growth show differences in susceptibility to UV (7). Moreover, the physical state of cells can also have an effect on cell survival: when cell aggregates are irradiated, the cells on the outside can effectively shield those towards the centre of aggregates. This phenomenon manifests itself as a 'tail' in the so-called 'dose–response curve' for that species of organism. The dose response curve is simply a plot of the reduction in cell viability against dose.

It has generally been accepted that the effect of UV exposure on living cells is solely determined by the dose absorbed. The UV dose is defined as the product of the exposure time and UV intensity (or 'fluence rate'). In other words, a short, high intensity exposure is equivalent to a protracted low intensity one. This is the Bunsen-Roscoe reciprocity law. However, it has been known for some time that experimental data exists which casts doubt on the veracity of this law. Sommer *et al.* (8) compared survival data for three different strains of *E. coli* irradiated at constant doses achieved by varying the UV intensity and time of exposure. In all cases the most lethal effects were achieved at the highest intensities. These findings can be interpreted in mechanistic terms: irradiation of microbial cells will lead to the formation of DNA lesions as explained above, however this process is counteracted by the cells' repair capabilities. As the UV intensity is increased the rate of lesion formation will eventually exceed the capacity of the repair systems. A similar argument has been used to explain the presence of 'shoulders' on the UV dose–response curves of certain microbial species.

The most commonly used method of assessing cell viability following UV irradiation is to plate the cells out onto an agar medium. However, recent work suggests that there may be risks in using this type of assay to definitively define viability. Physical and chemical stresses applied to microbial cells can induce them to enter, what has been termed a 'viable but non-culturable' (VBNC) state. Of particular relevance is work that shows that cells of *E. coli* 'killed' by UV were capable of performing a number of metabolic functions 48 hours after being irradiated. These functions included expression of esterase activity, uptake of glucose and cell elongation (9). In the context of food processing knowledge of whether VBNC cells retain their pathogenicity could be of crucial importance. The evidence accumulated to date is that cells of *Salmonella typhimurium* do not retain their pathogenicity (10) whereas *E. coli* cells do (11).

III. UV DOSE LETHALITY

Compilations of data have been published which show the UV doses necessary to bring about specific reductions in the populations of a variety of microbial species (3). These data are often given in the form of the doses necessary to reduce the population size by one tenth (the 'decimal reduction dose,' D_{10}) or by 1/e, i.e., 37% (D_{37}). The very existence of this data seems to have perpetuated the notion that a single value of D_{10} can be ascribed to a particular species in much the same way as can the density of a solution of sugar of known concentration. Closer comparisons of data published for individual species reveal some quite large discrepancies. To quote just one example for the radioresistant bacterium *Deinococcus radiodurans*, estimates for the D_{37} dose in kJ/m^2 include 0.40 ± 0.13 (12), 0.34 ± 0.05 (5) and 0.55 to 0.60 (13). Moreover, it is generally assumed that taxonomically closely related species have similar UV susceptibilities, whereas some quite large variations have been shown to exist (14). Decimal reduction doses, in common with all other measures of the effects UV on microbial populations, are subject to influence by all of the factors discussed above, i.e., the physiological and physical state of the cells as well as irradiation conditions.

Van Gerwen *et al.* (15) adopted an interesting approach to the treatment of D_{10} doses for ionising radiation which might profitably be applied to existing UV data. These workers analysed over 500 estimates of D_{10} doses from the literature. After eliminating data clusters for unusually tolerant species such as *D. radiodurans* as well as data for particularly sensitive and highly resistant spores, they were able to specify an average D_{10} value for bacterial spores as well as one for vegetative cells. Until such an analysis becomes available of the UV data, the existing D_{10} compilations should be viewed upon as simply providing general guidance.

IV. INACTIVATION OF MICROORGANISMS ON FOODS

Downes is credited in 1886 with discovering that the ultraviolet portion of the solar emission is lethal towards microorganisms (16). The first artificial UV source was patented in 1903 and soon after this UV sources were being used to disinfect water. The first recorded use of an artificial UV source for food disinfection was in 1906, for milk (17). Subsequent applications of UV in the early stages of its development as a method of disinfection are covered in the reviews of Moldovan (18) and Proctor and Goldblith (19).

Decimal reduction doses (D_{10}) are typically obtained by irradiating dilute suspensions microorganisms in water or buffer. The difficulties in interpreting data obtained under these relatively well-defined conditions, as discussed above, are greatly compounded when such data is required for the surfaces of foods.

There are a number of considerations that will influence the nature of the data obtained. Firstly, researchers have a choice of either working with the microflora naturally present on a particular food, or of artificially culturing organisms of interest and then applying them to the food in some way. Whilst the former approach might hold obvious attractions, it presents certain experimental difficulties. Samples of foods, even those taken from a single source, may harbour both different numbers, and different species of microorganisms, a problem made worse if more than a single source is used. This makes replication and statistical evaluation of results difficult. In addition to this, it has been accepted for some time that not all microbial species present on environmental samples — this includes foods — can be cultured under laboratory conditions. Whilst such difficulties may be greatly reduced by working with artificially cultured microorganisms, other complications arise. The association of microorganisms with foods is complex and can take more than one form. Microbial cells coming into contact with the food may adsorb to the food and then go on to multiply at its surface. This may simply lead to greater cell assemblages, however certain species may produce polysaccharides that serve not only to attach the cells more strongly to the food, but which can also protect them from external stresses. Moreover, the physiology of cells embedded in polysaccharide matrices, or 'biofilms,' is known to differ from those of planktonic cells (20). In addition, recent work has shown that certain elements of the natural microflora may offer protection against pathogens (22). In many cases the true state of the association between a particular food and its natural microflora is unknown, and the methods chosen by researchers to apply microorganisms to food surfaces may result in highly artificial associations. Often there are no alternatives to such methods. However, if these inherent experimental limitations are taken into account then the existing experimental data available for a number of different foods can provide a useful guide to assessing whether UV treatment of a particular food is feasible.

Table 122.2 shows a compilation of recent data. The range of foods is quite diverse as are both the targeted microbial species and the dosages applied.

Relatively few evaluations have been made of the effect of UV on the organoleptic characteristics of the foods. Such considerations are far from trivial and deleterious changes could lead to rejection by consumers despite the fact that treatment may have produced a safer product.

When treating solid materials, such as foods, with UV, it is characteristic of the surfaces that are of primary importance, as UV radiation will not penetrate very far beyond the surface layers of the material. On this basis, these surface properties can be expected to influence strongly the chances of microorganisms surviving irradiation. Evidence of the importance of macroscopic surface features is provided by work done on the irradiation of fish fillets by Huang and Toledo (33). These researchers found that UV was more effective in inactivating microorganisms on the surfaces of smooth-fleshed fish, such as mackerel, than on rough-fleshed fish such as mullet. This was because the surface of the mullet provided ridges around which microorganisms were shielded from incident UV light. Microscopic surface characteristics and irregularities may similarly be expected to affect microbial survival: surfaces which might appear smooth to the human eye, may at scales comparable to the dimensions of microorganisms (i.e., of the order of 1 to 10 μm) resemble a topography as rugged as that of the Himalayan foothills.

One approach to account for surface topography and surface–organism interactions is to extend the concept of the decimal reduction dose (D_{10}). A comparison of the D_{10} value for a particular microorganism in conditions where the nature of the medium surrounding the organism does not unduly influence microbial survival with that obtained on the surface of a food can provide some sort of measure of surface-related protective effects. When in dilute aqueous suspensions, microorganisms are essentially fully exposed to incident UV but, presumably for reasons of convenience, many workers have opted instead to irradiate colonies on the surface of agar to obtain 'basal' D_{10} values. Relatively few published studies contain sufficient data to enable this to be done but the data available is presented in Table 122.3.

Implicit in this approach is the assumption that the inactivation data is approximately linear in form. This is the case for most of the data shown in the table, but there are instances where the data deviates significantly from linearity. A case in point is the data of Wong *et al.* (35) for both *E. coli* and *Salmonella senftenberg* on the surface of agar (i.e., the basal D_{10}). In order to obtain D_{10} values under these conditions these workers effectively imposed linearity on their data to enable comparisons to be made with data for the surface of pork which was linear.

Gardner and Shama (40) suggested an alternative approach to the use of decimal reduction factors. Working with model materials (cellulose filter papers), they proposed that the surfaces of foods could be considered as constituting a discrete number of zones each of which contained a certain fraction of the microbial surface population. Each zone was typified by a so-called 'exposure factor.' This quantified the degree of attenuation to incident UV. Thus factors near 1.0 indicated that the zone offered little attenuation, whilst zones with low factors offered high levels of attenuation, and therefore high UV doses were required in order to inactivate the organisms

TABLE 122.2
UV Disinfection of Foods

Food	Microbial Flora	UV Dose kJ/m^2	No. of Log Reductions	Adverse Effects	Other Comments	Reference
Beef (slices)	Cultivated psychrophilic *Pseudomonas* sp. *Thamnidium* sp. *Candida scotii*	77.0	Results highly variable: 0.1 to 2.2 for a dose of 77 kJ/m^2 for *Pseudomonas* sp.	None evaluated.	Effects obtained by continuous long exposure (c. 3.5 days) at low UV intensities. UV irradiation resulted in increased growth lags and decreased growth rates for *Penicillium* sp., *Pseudomonas* sp. and *Thamnidium* sp. but not for *C. scotii*.	21
Beef (muscle and adipose tissue)	Natural microflora	Not measured.	Not stated.	Consumer desirability ratings based on colour were measured. Best results were obtained for samples wrapped immediately after irradiation.	Type of UV source not stated but peak emissivity was at 366 nm with some contribution at 253.7 nm. Shelf life increased by 1.5 to 2 days.	23
Beef	Cultivated *Pseudomonas* spp. *Micrococcus* spp. *Staphylococcus* spp.	0.66	2.0 for the mixed bacterial culture.	No significant differences in odour or appearance between irradiated samples and controls.		24
Bread (Baguette)	Natural microflora	0.14–0.54	Not stated.	None evaluated.	Shelf life extended by approx. 9 days.	25
Chicken (whole)	Natural microflora	0.1	Not stated.	No adverse effect on organoleptic quality.	Although an immediate effect on surface contamination of treated, as opposed to untreated, chickens was observed, the shelf life was not significantly increased.	26
Chicken (halves)	Cultivated *S. typhimurium* and natural psychrotrophic microflora	0.8	0.5 (*circa*) for *S. typhimurium* no significant effect on psychrotrophs.	No significant effects on colour or rancidity.		27
Chicken (skin)	Cultivated *S. typhimurium*	0.16–0.97	80.5% reduction (mean value for all doses).	None evaluated.		28
Chicken (breasts)	Cultivated *S. typhimurium, L. monocytogenes, E. coli* O157:H7	0.015	0.48 for *L. monocytogenes;* 1.02 for *S. typhimurium;* 1.28 for *E. coli*. For chicken with the skin left on.		Number of log reductions for all three bacterial species were decreased when the chicken was treated with the skin left on.	29
Chocolate	Cultivated salmonellae	1.7	5.3 for *S. eastbourne* in a 0.1 mm film of chocolate. No reduction in a 0.5 mm film.	None evaluated.	Photoreactivation was not observed.	30
Cider	Cultivated *E. coli* O157:H7	0.1–0.6	3.81 (mean reduction for all treatments).	None evaluated.	Treatment was affected by the original background microflora. Unable to consistently achieve the 5 log reduction required for the product by the regulatory authorities.	31

(*Continued*)

TABLE 122.2 (*Continued*)

Food	Microbial Flora	UV Dose kJ/m^2	No. of Log Reductions	Adverse Effects	Other Comments	Reference
Cider	Harvested *Cryptosporidium parvum* oocysts	0.14	5	None evaluated.	Oocyst viability was determined using mice.	32
Fish (fillets)	Natural microflora	3.0–75	2.5 for mackerel 0.3 for mullet For low pressure source at a dose of 3.0 kJ/m^2. 2.7 for mackerel 0.4 for mullet For high intensity source at a dose of 60 kJ/m^2	None evaluated.	Both low pressure and high intensity sources used. Poor effect on mullet attributed to the rough surface of the fish. Best results obtained by combining UV irradiation with chlorinated water wash. Shelf life extended by at least 7 days for mackerel.	33
Maple syrup	Natural microflora	Not stated.	Not determined.	The treated sap retained its flavour and colour.	Maple sap was stored in tanks and continuously irradiated. Under these conditions the bacterial count was maintained below 4.0×10^5 per ml for 11 days.	34
Pork (skin and pork muscle)	Cultivated *E. coli* *S. senftenberg*	1.92	3.8 on skin 4.6 on muscle for *S. senftenberg*. 1.6 on skin 1.5 on muscle for *E. coli*.	None evaluated.	D values At 1000 uW/cm^2 *S. senftenberg*: Skin 490 s Muscle 1064 s *E. coli*: Skin 592 s Muscle 1205 s	35
Sausages	Cultivated *E. coli* *B. subtilis*	2	5 for *E. coli* 4 for *B. subtitlis.*	None evaluated.	High intensity source. Sterilisation was not as effective at the ends of the sausages as towards the centre due to shadowing effects.	36
Shell Eggs	Natural microflora	Up to 39	2 at a dose of 10 kJ/m^2. 3 at a dose of 30 kJ/m^2.	None evaluated.	Type of source not stated. Eggs were rotated during treatment.	37
Shell Eggs	Cultivated *S. enteritidis*	Up to 0.5	1.1 at a dose of 0.08 kJ/m^2. 2.5–4.0 at a dose of 0.5 kJ/m^2.	None evaluated.		38
Strawberries	*Botrytis cinerea*	0.25 and 1.0	Not explicitly stated.	Extensive tests performed. At a dose of 2.5 kJ/m^2 fruit had a higher anthocyanin content and were firmer than controls. Suggestion of damage to fruit at the higher dose (10 kJ/m^2) on the basis of electrical conductivity measurements.	Shelf life extended by 4–5 days.	39

TABLE 122.3
Decimal Reduction Doses (D_{10}) for Various Foods

Food	Bacteria	D_{10} Values kJ/m²			UV Intensity W/m²	Reference
Chicken	*Listeria monocytogenes*	Peptone water 0.079	Chicken (with skin) 1.948	Chicken (without skin) 1.911	5	
	Salmonella typhimurium	Peptone water 0.13	Chicken (with skin) 0.888	Chicken (without skin) 2.439	5	29
	E. coli O157:H7	Peptone water 0.061[a]	Chicken (with skin) 0.677	Chicken (without skin) 1.06	5	
Chocolate	*Salmonella eastbourne*	Peptone water 0.18[a]	Chocolate (0.1 mm thickness) 0.797	Chocolate (0.3 mm thickness) 16.28	19	30
Pork	*E. coli*	Agar 1.77	Pork skin 5.92	Pork muscle 12.05	10	35
	Salmonella senftenberg	Agar 0.21	Pork skin 4.90	Pork muscle 10.64	10	

[a] Estimate based on only two data points.

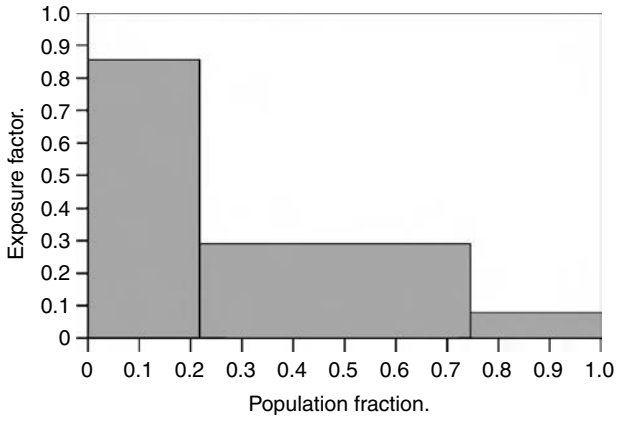

FIGURE 122.3 Zone model for UV inactivation of microorganisms on a solid surface (40).

present. Figure 122.3 shows a typical food surface simulation. In this instance the surface of the food comprises three zones, containing 22, 53 and 25% of the microbial population and with exposure factors of, respectively, 0.85, 0.29 and 0.08.

An extension of this approach to actual food surfaces might go some way to providing data that would enable the UV doses necessary to bring about given reductions in the viability of microbial populations to be predicted.

V. COMBINED TREATMENTS INCORPORATING UV

A. UV AND HYDROGEN PEROXIDE

The germicidal effects of UV can be enhanced by hydrogen peroxide. Hydrogen peroxide possesses antimicrobial properties in its own right, but when combined with UV produces synergistic disinfection effects. This has been demonstrated both for bacterial spores (41) and for vegetative bacteria (42).

TABLE 122.4
Enhancement of UV Disinfection by Hydrogen Peroxide

Medium	Ratio of First Order Inactivation Rate Constants (UV + H_2O_2[a]/UV)	Reference
Coarse cellulose filter paper	3.2	43
Fine cellulose filter paper	5.3	43
Distilled water	4.8	44

[a] H_2O_2 concentration 1% (w/v).

Hydrogen peroxide undergoes photolysis in the presence of UV to yield hydroxy radicals (OH°):

$$H_2O_2 \rightarrow 2OH^\circ$$

These short-lived radicals are highly reactive and will attack microorganisms indiscriminately. The germicidal effect of hydrogen peroxide in aqueous solutions increases with concentration. However, as hydrogen peroxide absorbs UV quite strongly, concentrated solutions of hydrogen peroxide will attenuate incident UV resulting in reduced activity against microorganisms. Therefore, an optimum concentration exists at which the synergistic germicidal effect is at its greatest. This concentration has been shown to be approximately 1% (w/v) for *Bacillus subtilis* spores either in suspension (41) or on solid surfaces (43). Irradiation of hydrogen peroxide solutions at this concentration results in enhanced rates of spore inactivation compared to UV alone as Table 122.4 shows.

Perhaps the most successful commercial application of the combined UV–hydrogen peroxide treatment has

been in the decontamination of beverage cartons (45). Although hydrogen peroxide treatment is currently being evaluated for decontaminating a wide variety of foods, it is somewhat surprising that not more attention has been paid to the combined treatment, particularly as UV can reduce residual hydrogen peroxide levels to those considered acceptable.

B. UV and Ozone

The classification of ozone by the Food and Drugs Administration in the USA as being generally recognised as safe (GRAS) has led to growing interest in its use as a germicide in the food industry (46). In common with hydrogen peroxide, ozone is known to exhibit synergistic disinfection effects under conditions of UV irradiation. The mechanism by which free radicals and other oxidising species are liberated during UV irradiation are quite complex but well established (47).

Despite the advantages that ozone residuals are short-lived, very little work has been published on the combination of ozone and UV of direct relevance to foods. One early study (22) did show that a synergistic inhibitory effect against two species of moulds, (*Thamnidium* sp. and *Penicillium* sp.) was obtained when beef slices were irradiated with UV in the presence of gaseous ozone.

C. Other

An interesting combination involves the use of long wave UV with a class of compounds known as the furanocoumarins. These tricylcic compounds exert their lethality by intercalation within the double helical structure of DNA and cross-linking with DNA bases. One particular attraction in the context of food processing is that furanocoumarins occur naturally in a number of food plant species including lemons, celery and parsley. Bintsis *et al*. (48) showed that the combination of UV and relatively high concentrations of furanocoumarins inactivated both pathogenic bacteria such as *E. coli* O157:H7 and *Listeria monocytogenes*, and the natural brine microflora. Further work in this field, possibly in relation to minimal processing, might yield more positive outcomes.

The anatase crystalline form of titanium dioxide when irradiated by UV light in the presence of water generates free hydroxy radicals. This phenomenon has been widely exploited in environmental applications and some of these are of interest in food processing. One such application is the destruction of ethylene by UV-irradiated titanium dioxide (49, 50). Ethylene is known as the 'ripening hormone' and its accumulation in storage depots of certain horticultural products, i.e., fruit, vegetables and flowers, leads to considerable losses through accelerated senescence resulting in unmarketable produce.

Immobilized titanium dioxide was recently shown to be active in treating the water used in bean sprout cultivation (51).

VI. UV HORMESIS

The uses of UV described so far have related to its direct effects against microorganisms. However, there seems to be a growing interest in the treatment of fruit and vegetables with UV in order to bring about indirect effects in plant tissues that confer resistance to a variety of fungal pathogens.

To date this interest appears to be restricted to that of the research community with little evidence of its adoption by growers or processors. To some extent this is due to the fact that the magnitude of the effects obtained is due to the particular cultivar used or the precise conditions under which it was grown. For example, it is known that there are seasonal variations in susceptibilities of fruits to stresses (52) and such factors would need to be taken into account in commercialising any process based on irradiation with UV. However, as the changes that UV induces in plant materials become better defined and understood, irradiation of agricultural produce might well provide a viable method of reducing postharvest losses in the future.

It has been claimed that postharvest losses of agricultural produce are significant in developed countries, but that in developing countries they can be catastrophic. A number of measures are applied in developed countries to reduce such losses. Principal amongst these is postharvest storage at low temperature. Fewer losses are sustained if in addition to cold storage fungicides are used. These are typically applied to the crops some short while before they are harvested. Interest in the potential use of UV stems from pressures from the regulatory authorities to reduce the dependence on chemical fungicides as primary disease control agents. To these concerns must be added those of consumers who are increasingly demanding food free from chemical additives and produced by methods that cause minimal environmental impact.

The application of UV to the treatment of agricultural produce is termed 'hormesis.' Hormesis may be defined as a beneficial plant response resulting from the application of a low dose of a so-called 'stressor.' A variety of physical treatments, including UV irradiation, may serve as stressors. Although the phenomenon of hormesis was described in the 1940s, it is really in the last 20 years that it has excited interest as a practical method of reducing postharvest losses of crops (53).

Irradiation of fruits and vegetables with UV will result in at least some direct inactivation of microorganisms present at the surface, but hormesis is quite distinct from purely surface disinfection and may even be considered as additive to it. The evidence for hormetic effects is that fungi deliberately inoculated into fruit some distance from

the surface are inhibited following low level irradiation (54). Moreover, hormetic effects have been shown to be reversible by illuminating the plant tissue with visible light following UV irradiation. This would seem to implicate genetic involvement in the response of the plant to UV. Indeed, the isolation of a gene in grapefruit that is activated in response to UV and produces an isoflavone reductase-like protein has recently been announced (55). In addition, it seems that there is a delay after irradiation before the maximum protective effect is achieved; this delay can be as long as 96 hours (56). Table 122.5 reveals that hormesis can be induced in a number of different crops.

The only exception appears to be cactus pears where at best UV treatment resulted in no positive benefits (58). The optimal doses for achieving hormetic effects range from 0.12 to 9.0 kJ/m^2, this is a much narrower range of doses than those used in irradiating foods for obtaining germicidal effects (see Table 122.3). For certain crops the nature of at least one 'hormetin,' the substance produced in response to the application of UV, has been identified. However, it seems likely that the formation of a number of quite different classes of compounds is probably elicited by hormesis. In many cases the exact identity of these compounds have yet to be described. Typically researchers have confined themselves to assaying only one or two previously identified compounds. The enzyme phenylalanine ammonia-lyase (PAL) has been found in a number of different fruits including sweet potato (54). This enzyme is associated with lignin biosynthesis which is a common plant response to fungal attack. There is mounting evidence to suggest that phytoalexins are produced following irradiation. Phytoalexins are low molecular weight compounds that are produced by plants in response to microbial infection or physical damage. The phytoalexin scoparone has been detected in a number of citrus fruits (52, 62), whilst 6-methoxymellein has been found in carrots (59) and resveratrol in grapes (72).

The effects of irradiation with low doses are not restricted to the inhibition of fungal pathogens. A number of workers have shown that ripening of fruit can also be delayed (70). Premature ripening, as may occur for example in storage, is also the cause of postharvest losses as over-ripe produce is not marketable.

There is compelling evidence that even more subtle effects than hormetic ones may be at work and that if these are better understood even greater protection may be given to agricultural produce without resorting to fungicides. The natural epiphytic (i.e., surface-associated) microflora found on certain fruits may inhibit certain fungal pathogens but is itself not affected by low UV doses. This has been demonstrated for the epiphytic yeast *Debaromyces hansenii*, which survives UV doses on the surfaces of peaches which would normally inactivate it on artificial surfaces. This strongly implicates one or more control factors which are imposed by the fruit. *D. hansenii* has been shown to be inhibitory towards the soft rot fungus *Monilinia fructicola* without forming antibiotics. A synergistic protection of peaches against this particular fungus has been demonstrated by the application of the yeast with low UV doses (21).

Of related application to the subject discussed above is the possibility of producing functional foods through UV treatment. Mau *et al*. (73) showed that the vitamin D_2 content of a number of different mushroom species could be increased by irradiating them with UV-B. Cantos *et al*. (74) proposed subjecting grapes to UV-C pulses to increase their resveratrol content.

VII. DELETERIOUS EFFECTS OF UV ON FOODS

Most of the data available on the damaging effects of UV on foods relates to the work done on applying hermetic UV doses to fruits and vegetables. These effects are summarised in Table 122.4. In general, UV doses much above the levels that bring about beneficial hermetic effects, approximately 0.12 to 9.0 kJ/m^2, may result in surface discoloration, accelerated senescence or sprouting. Relatively few adverse effects following UV irradiation were reported in the range of foods listed in Table 122.2, this was mainly because such evaluations were often outside the scope of the work reported. In fact, very few studies have specifically focussed on this aspect of the UV treatment of foods. The extended irradiation of cold liver oil resulted in the formation of toxic aldehydes (75). Studies with artificial food colouring showed that prolonged UV irradiation led to the formation of breakdown products that were DNA damaging (76). However, the UV doses necessary to bring about these effects were not specified.

VIII. UV TECHNOLOGY

A. UV Sources

Despite being published 20 years ago, a very useful source of fundamental information on UV sources remains that of Phillips (1). UV sources are in the main gas discharge sources containing xenon and mercury or xenon and argon. The low vapour pressure mercury source is perhaps the most commonly used method of achieving disinfection. It operates optimally at a temperature of approximately 40°C and is often referred to as 'monochromatic' but actually 90% of its output is emitted at 253.7 nm which is fortuitously close to the maximum absorptivity of DNA. Increasing use is being made of medium and high pressure UV sources in water disinfection and this trend may extend to the food industry. These are not as efficient as the low pressure sources in emitting in the germicidal range but their higher power ratings

TABLE 122.5
UV Hormesis of Horticultural Produce

Crop (Variety)	Targeted Pathogen	UV Dose Range Investigated kJ m^{-2}	Optimal UV Dose kJ m^{-2}	Additional Details	Reference
Apple (Red Delicious)	*Penicillium expansum*	7.5	Not determined	Treated fruit stored at 24°C for 14 days. The earliest application of UV treatment (96 hours) before inoculating with *P. expansum* provided the best defence against disease. Combining UV irradiation with other disease prevention measures, harpin, chitosan and yeast antagonists *Candida saitoana* and *C. oleophilia* offered no advantages.	56
Cabbage seeds (Acc 16 Hybrid)	*Xanthomonas campestris*	1.3–7.5	3.6	Irradiation performed on cabbage seeds which were stored for up to 8 months. Improvements in quality and growth response observed at optimum dose. Disease resistance of treated seeds decreased with storage time.	57
Cactus Pear (Gialla)	Not specified	0.75	Not determined	UV treatment did not reduce the incidence of decay. Skin damage observed following irradiation.	58
Carrot (Caropak)	*Botrytis cinerea*	0.11–0.88	0.44–0.88	Both fresh and aged carrots were studied. Aged carrots had been stored at 1°C for 4 months. After irradiation carrots were stored at 1°C for 25 days. Only carrots that had been surface-wounded responded to UV treatment at 1°C but intact roots responded to treatment at 20°C. Treatment of fresh carrots gave higher resistance to storage rots. Exposure to UV induced 6-methoxymellein production.	59
Grape (Italia)	*Botrytis cinerea*	0.125–4.0	0.125–0.5	Irradiated grapes were stored at either 3°or 21°C. Grapes irradiated 24–48 hours before inoculating with *B. cinerea* showed a lower disease incidence than those inoculated immediately before irradiation. Doses above 1.0 kJ m^{-2} resulted in skin discolouration. Treatment within the optimum range did not significantly reduce the numbers of yeasts antagonistic towards pathogenic moulds.	60
Grapefruit (Star Ruby)	*Penicillium digitatum*	0.5–3.0	0.5	Quality and disease resistance determined after storage at 7°C for 4 weeks followed by 1 week at 20°C. Scoparone and scopoletin levels were increased at all UV doses. Rind browning and tissue necrosis occurred at UV doses >1.5 kJ m^{-2}.	61
Kumquat (Nagami)	*Penicillium digitatum*	0.2–15	1.5	Scoparone levels increased following irradiation at all UV exposures. After 2 weeks of storage at 17°C UV-treated fruit showed signs of damage, however at lower temperatures UV damage was practically absent even at the highest dose used.	62
Lemon (Eureka)	*Penicillium digitatum*	0–15	5	Irradiated fruit was stored in the dark at 17°C. UV was only effective in suppressing decay in fruit that had been irradiated at least 24 h before inoculation with *P. digitatum*. Increased levels of scoparone were found in irradiated fruits.	63
Mango (Tommys Atkins)	Not specified	4.9 and 9.9	4.9	Quality and disease resistance determined after storage at 5°C for 14 days followed by 7 days at 20°C. Treatment at 4.9 kJ m^{-2} resulted in improved appearance and texture of fruit. Irradiation induced spermidine and putrescine. The higher dose induced senescence.	64
Onion (Walla Walla)	*Aspergillus* spp., *Penicillium* spp., *Erwinia* spp.	0.44–19.10	7.33	Quality and disease resistance determined after storage at 20–25°C for four weeks. UV exposure was generally better than gamma or electron beam irradiation at	65

(*Continued*)

TABLE 122.5 (*Continued*)

Crop (Variety)	Targeted Pathogen	UV Dose Range Investigated kJ m^{-2}	Optimal UV Dose kJ m^{-2}	Additional Details	Reference
				reducing the incidence of disease and improvement in marketability and storage life. UV irradiation did not affect texture or flavour. Some UV doses induced sprouting.	
Orange (Biondo Comune, Washington Navel, Tarocco, Valencia Late)	Not specified	0.5–3.0	Not determined	Quality and disease resistance determined after storage at 7°C for 4 weeks followed by 1 week at 20°C. Peel quality was affected in all cultivars with the exception of Valencia L. Percentage of damaged fruit at the higher dosages decreased as the season progressed. UV irradiation at 0.5 kJ m^{-2} was effective in reducing decay development. The higher dose of 1.5 kJ m^{-2} was more effective but only in early harvested fruit. Concentrations of scoparone and scopoletin increased in all varieties with increasing dose.	52
Oranges (Shamouti, Valencia)	*Penicillium digitatum*	0.2–15	9.0	After 2 weeks of storage at 17°C UV-treated fruit showed signs of damage, however at lower temperatures UV damage was practically absent even at the highest dose used. Scoparone levels increased following irradiation at all UV exposures.	62
Peach (Elberta)	*Monilinia fructicola*	0.84–40	7.5	Exposure to UV delayed ripening, suppressed ethylene production and increased phenylalanine ammonia-lyase activity. Doses of 40 kJ m^{-2} increased susceptibility to brown rot. Irradiation resulted in increased numbers of the antagonist yeast *Debaryomyces hansenii* on the surface of the fruit.	66
Pepper (Bell Boy, Delphin)	Natural infections and *Botrytis cinerea*	0.22–2.20	0.88 for *Botrytis cinerea*	Fruit were stored at either 13° or 20°C following irradiation. All doses tested provided protection against natural infection. UV provided protection against *B. cinerea* only when artificial inoculation occurred after irradiation but not before. Two successive exposures at 0.44 kJ m^{-2} were equivalent to a single exposure at 0.88 kJ m^{-2}.	67
Potato (Superior)	*Fusarium solani* *Erwinia carotovora*	7.5–15	Not determined	Potatoes stored at 8°C for 3 months. Disease suppression increased with UV dose. Doses higher than 15 kJ m^{-2} associated with induction of sprouting and were not investigated.	68
Sweet Potato (Jewel)	*Fusarium solani*	1.3–20	3.6	Tubers stored for up to 8 weeks at 25−27°C. All UV exposures resulted in increased phenylalanine ammonia-lyase activity.	54
Tomato (Tuskegee 80–130, Floradade, Better Boy)	*Alternaria alternata* *Botrytis cinerea* *Rhizopus stolonifer*	1.3–40	3.6–7.5	UV doses of 3.6 and 4.8 kJ m^{-2} delayed ripening whilst doses of 40 kJ m^{-2} resulted in skin discolourization.	69
Tomato (Capello)	-	3.7–24.4	3.7	Study aimed at delaying senescence only. Treated fruit were stored at 16°C for 35 days. High UV doses caused abnormal browning of the surface of fruits. Treatment with doses of 3.7 kJ m^{-2} delayed ripening for 7 days. This correlated with increased amounts of putrescine in the fruits.	70
Zucchini Squash (Tigress)	Not specified	0.49–9.86	Not determined	Fruit sliced prior to irradiation and stored at 5° and 10°C for up to 18 days. Doses above 4.9 kJ m^{-2} retarded microbial growth. Treatment at the higher doses resulted in slight discolouration for fruit stored at 10° but not 5°C.	71

mean that greater overall outputs can be obtained. 'Doping' with e.g., metal halides can modify the spectral output of these sources.

Recent advances have led to the development of pulsed UV sources in which the duration of the pulse varies from nano- to milli-seconds. Comparisons with continuous i.e., conventional sources have shown that pulsed sources are more effective at decontaminating surfaces (77, 78). Similarly tunable excimer lasers have been used to disinfect food packaging (79). Plasmas, generated in vacuum or at atmospheric conditions also have potential for use in surface disinfection (80).

B. UV Irradiation Equipment

The history of treating water precedes that of food disinfection and it is therefore not surprising therefore that most innovations relate to the treatment of liquids and water at that. Novel thin film devices have been proposed for disinfecting liquids, such as cider and syrups, that have low UV transmittance (81) but such systems have low liquid throughputs. Solids are generally conveyed on belts past UV sources. These may be mounted on the walls of enclosures to create 'UV tunnels.' Shama *et al*. (82) proposed the hydraulic conveying of particulate matter over UV sources. Some innovative designs have been reviewed in relation to UV curing of inks on curved surfaces which could well have applications to food treatment (83).

123 Aseptic Processing: Basic Principles and Advantages

K.P. Sandeep and Josip Simunovic
Department of Food Science, North Carolina State University

CONTENTS

I. INTRODUCTION

A. Components of an Aseptic Processing System

Aseptic processing consists of pumping, deaeration, heating of the product (also referred to as "pre-sterilization"), passage of the product through a holding tube wherein the product attains the required temperature for the required amount of time (achievement of commercial sterility), cooling of the product, possible holding of the product in an aseptic surge tank, and subsequent packaging of the product in a pre-sterilized container under aseptic conditions. This process results in a high quality shelf-stable product in a hermetically sealed container.

Pumping of the product at a constant rate (also referred to as "timing") is very important to ensure that all parts of the product receive uniform and the required amount of heat treatment. The most common type of pump used for this purpose is the piston type positive displacement pump wherein slippage (back flow of the product) is minimal. This type of pump delivers the product at a constant rate even if the pressure against which it is pumping fluctuates (for example, when fouling in the heat exchanger increases the pressure or when the opening and closing of valves causes changes in pressure). For certain fluid products, homogenization of the product may be required and this is achieved by using a homogenizer, which can also serve as the "timing" device.

Deaeration of the product removes excess air in the product. It is accomplished in a vessel maintained at a certain degree of vacuum by means of a vacuum pump. The product is fed into the vessel at 55–70°C through a nozzle at the center of the vessel. Vacuum is controlled to obtain a product flash of about 5°C. An internal spiral

condenser condenses vapors and other condensable gases. The deaerated product is discharged through the bottom and pumped to the heating section. This serves the purposes of increasing the rate of heat transfer during heating and cooling, maintaining the specific volume of the product in the holding tube (to avoid reduction in holding time due to expansion of product), maintaining a constant fill rate and prevention of foaming during packaging, and minimizing oxidation reactions within the product during storage. The deaerator is placed before pre-heating in cases where loss of volatiles at elevated temperatures is of concern and after pre-heating in other instances since it is easier to remove air at higher temperatures due to its expansion.

The high temperatures required for aseptic processing (125–145°C) are achieved by direct or indirect contact heat exchangers (usually with steam as the heating medium) and a back pressure valve (placed after the cooling unit) that maintains high enough pressure to prevent boiling (or flashing) of the product. The required back pressure for the process can be achieved by using a piston-type air actuated valve, diaphragm valve or pressurized tanks. Heating of the product can be accomplished by direct (steam injection of infusion) or indirect (tubular, shell and tube, plate, scraped surface, microwave, radio frequency, or ohmic) means. The choice of the type of heating and cooling equipment depends on a variety of factors such as type of product (acid or low-acid, viscous or non-viscous, fluid or particulate, heat sensitive or heat stable), potential for fouling, ease of cleaning, and as always the cost of the heat exchanger. An additional useful characteristic of the back pressure valve is that it also provides a dampening effect against the fluctuating or pulsating action of pumps used in aseptic processing.

The holding tube is an important part of the aseptic processing system since this is where the product receives the required time-temperature treatment in order to render the product commercially sterile. The holding tube is always inclined upwards (requirement from regulatory agency) with a vertical rise of at least ¼″ per foot length of the tube. This vertical rise ensures that the product completely fills the holding tube (with no air pockets) and that the product returns to the supply tank when the pump is shut off (thereby minimizing contamination issues).

An aseptic surge tank provides the means for product to be continuously processed even if the packaging system is not operational due to any malfunction. It can also be used to package the sterilized product while the processing section is being re-sterilized.

1. Historical Perspective

Historically, the first aseptic packaging of food (milk in metal cans) was done by Nielsen in Denmark in 1913. In 1917, Dunkley of the U.S. sterilized cans and lids by saturated steam and filled pre-sterilized product in it. In 1923, aseptically packaged milk from S. Africa reached a trade fair in London in perfect condition. The work of Olin Ball and the American Can Research Department laid the foundation of aseptic processing in the U.S. as early as 1927 when the HCF (heat, cool, fill) process was developed. This was followed by the Avoset process in 1942 (steam injection of the product coupled with retort or hot air sterilization of packages such as cans and bottles) and the Dole-Martin aseptic process in 1948 (product sterilization in a tubular heat exchanger, metal container sterilization using superheated steam at temperatures as high as 450°F since dry heat requires higher temperature than wet heat, followed by aseptic filling and sealing of cooled product in a superheated steam environment). The early 1960s was marked with the advent of a form-fill-seal package — tetrahedron package. The late 1960s saw the advent of the Tetra Brick aseptic processing machine and the late 1970s saw the advent of the Combibloc (blank carton) aseptic system. Soon, aseptic filling in drums and bag-in-box fillers were established. One of the major landmarks in the history of aseptic processing is the approval of use of hydrogen peroxide for the sterilization of packaging surfaces by the FDA in 1981. In recent years, a major break-through for the aseptic processing industry was in 1997 when Tetra Pak received a no-objection letter from the FDA for aseptic processing of low-acid foods containing large particulates.

2. Advantages and Disadvantages

Better product quality (nutrients, flavor, color, texture), less energy consumption, fewer operators, less space requirements, eliminating the need for refrigeration, easy adaptability to automation, use of any size package, use of flexible packages, and cheaper packaging costs are some of the advantages of aseptic processing over the conventional canning process. It also does not have the problem of texture changes associated with frozen products and increased permeability of packaging material such as ethylenevinylalcohol (to oxygen) due to the high temperature as in retortable pouches. Some of the reasons for the relatively low number of aseptically processed products include slower filler speeds and higher overall cost. Aseptic processing also requires better quality control of raw products, better trained personnel, and better control of process variables and equipments. It is also subjected to stringent and extensive validation procedures. Some of the disadvantages of aseptic processing include increased shear rates, degradation of some vitamins (some vitamins are stable at pasteurization temperatures but not at sterilization temperatures), separation of solids and fats, precipitation of salts, and change in flavor or texture of the product (steam injection followed by flash cooling may eliminate off-flavors) relative to what consumers are accustomed to.

Though aseptic processing could potentially result in better product quality, one has to keep in mind that several chemical changes take place during temperatures encountered during aseptic processing which do not occur under normal processing conditions. Some of these chemical changes include age gelation, browning reactions, oxidation reactions, and changes in pigments and have been described in detail in references (1, 2).

Due to some of the stringent regulatory requirements of aseptic processing, many processors adopt an aseptic process, but package it in non-aseptic containers. This results in products that are called "extended shelf-life products." Such processes are easier to adopt, require less monitoring (since the resulting product-package combination does not need to be sterile), and are easier to file with regulatory agencies. One such process involves ultra-pasteurization of milk wherein extended shelf-life can be obtained.

Notwithstanding the problems associated in producing aseptically processed foods, several companies have adopted this technology. Some of the products that are aseptically processed include fruit juices, milk, condensed milk, coffee creamers, puddings, soups, butter, gravies, and jelly. Some of the companies that deal with aseptic processing and packaging equipment are International Paper, Tetra Pak, Combibloc, Elopak, Cherry Burrell (tubular: Unitherm; plate: Thermaflex; SSHE: Thermutator; steam injection: Aseptic direct steam incorporation), Alfa Laval (Plate: Steritherm; SSHE: Contherm; steam followed by SSHE: Viscotherm; steam injection: VTIS — Vacu-therm instant sterilizer; corrugated tube: Spiraflo), ASTEC, VRC, APV (Plate: Juicematic; Plate for low-acid: Super ultramatic; steam injection: Uperizer), FranRica, Benco, Scholle, Bosch, and Metal Box.

B. Important Facets of Aseptic Processing

Some of the important facets of aseptic processing include fluid mechanics (residence time and residence time distribution of the fluid elements and particles in the product), kinetics (of microbial destruction, enzymatic inactivation, and nutrient destruction), and heat transfer (transfer of heat from the heating medium to the liquid and particulate portions of the product and accumulation of F_0 or F-value at 121.1°C and z = 10°C, where z is the temperature change required for an order of magnitude change in the decimal reduction time, D).

1. Fluid Mechanics

The Food and Drug Administration (FDA) only credits heat treatment experienced in the holding tube, which makes its design critical. The velocity profile of the fluid in the holding tube is affected by the degree of its deviation from the behavior of a Newtonian fluid. The degree of deviation is characterized by the flow behavior index, n', for Ostwald-de-Waale fluids. For a Newtonian fluid ($n' = 1$) flowing under laminar conditions in a straight tube of circular cross-section, the maximum velocity occurs at the center of the holding tube and its magnitude is twice the average velocity of the fluid. For pseudoplastic fluids ($n' < 1$), differences between the maximum and average velocity becomes smaller as n' decreases. In other words, the velocity profile becomes flatter. For the extreme case ($n' = 0$), the plug flow profile is attained. However, for most cases ($n' > 0$), the maximum velocity occurs at the axis of the tube, which means that the minimum residence time corresponds to the residence time of particles located along the center-line of the tube. Consequently, these particles receive the least amount of heat treatment. Thus, the holding tube length required to achieve the required F_0 value (time-temperature effect) can be calculated based on the knowledge of this minimum residence time, but this will result in an over-processed product. This is where the residence time distribution (RTD) of the particles comes into the picture. To understand RTD, we begin with the following equation, which describes the velocity profile for flow of a Newtonian fluid under laminar conditions in a pipe of circular cross-section:

$$u = 2\,\bar{u}\,[1 - (r^2/R^2)] \qquad (123.1)$$

Where u is fluid velocity in m/s, $\bar{u}$ is average fluid velocity in m/s, r is the radial distance from the center of the tube in m, and R is the radius of the tube in m.

Thus, it can be seen that different fluid elements (at different radial locations) spend different amounts of time in the tube. For instance, a fluid element traveling at the center of the tube will travel twice as fast as the average fluid element. The distribution of times spent by various fluid elements within the tube is referred to as the residence time distribution (RTD) of the fluid elements. Similarly, when different particles are flowing through the tube, they spend different times in the tube, and the distribution of these times is the RTD of the particles. The RTD of the particles depends a great deal on the RTD of the fluid. It also depends on flow rate and viscosity of the carrier medium, and also the size, density, and concentration of particles. Analysis of particle RTD is relatively simple when there is only one type of particle in a system. However, when different types of particles (especially particles of different densities) are present in a product, the flow behavior is quite different from the situation when they are each present as the only particle type in suspension. For instance, in a mixture of two types of particles, denser particles (which traveled slowly at the bottom of the tube when present alone) could be sped up by foreign particles due to collisions, and in turn, the foreign particles could get slowed down. Thus, an analysis has to be performed for each combination of particle types present in a system and direct inferences cannot be made from RTD of each particle type separately.

The existence of a RTD for the particles results in some particles receiving more heat treatment than others in the holding tube. From a safety standpoint, the fastest particle is what is of concern and the holding tube length is based on the fastest particle residence time. Thus, it can be seen that if the particle RTD is narrow, the quality of the product would be high since the difference between the fastest and slowest particle residence time is not very high. The wider the RTD of the particles in the holding tube section, the more non-uniform the process. One of the techniques that can be used to narrow the RTD of the fluid and particles is the use of helical tubes.

When a non-Newtonian (power-law) fluid flows through a straight tube under laminar flow conditions, the velocity profile is given by the following equation.

Non-Newtonian fluids:

$$u = \frac{3n' + 1}{n' + 1}\,\bar{u}\left[1 - \left(\frac{r}{R}\right)^{\frac{n'+1}{n'}}\right] \qquad (123.2)$$

Thus, for a pseudoplastic fluid ($n' < 1$), the maximum fluid velocity is given by:

$$u_{max} = \frac{3n' + 1}{n' + 1}\,\bar{u} \qquad (123.3)$$

Hence it can be seen that the maximum velocity in the case of a pseudoplastic fluid is less than twice the average fluid velocity. Thus, the RTD of the fluid is narrower for a pseudoplastic fluid in comparison with that for a Newtonian fluid. Hence, the RTD of particles is also narrower when the carrier medium is a pseudoplastic fluid. Further details of RTD of fluid elements and particles have been presented by (3).

The average fluid velocity can be calculated once the volumetric flow rate of the product is known. To determine the distribution of fluid residence times, salt injections, dye tracers, and fine particles are used. Magnetic resonance imaging can also be used under certain circumstances to obtain a fluid flow profile. Fluid flow profiles, though important, are usually not the target, since the species of concern are the slow-heating particles. Particle residence times, residence time distributions, and velocities can be determined by using a stop-watch, digital image analysis, LASER-Doppler velocimetry, and also with the aid of magnetically tagged particles.

2. Kinetics

Sufficient heat has to be applied to a food product to inactivate microorganisms that cause food spoilage and food poisoning, and inactivate enzymes. However, the color, texture, flavor, and nutrients within the food must not be destroyed to an unacceptable level. This is where optimization of the process comes into play. Several combinations of time and temperature could be used to destroy the microorganisms of concern. Out of these, the combination that results in the least nutrient destruction would be the desired combination. In order to arrive at this combination, a thorough understanding of the kinetics of microbial and nutrient destruction is essential.

The heat resistance of microorganisms is affected by several factors. Some of these factors include water activity, pH, lipids and oily materials, dielectric constant, ionic species, ionic strength, oxygen level, organic acids, and antibiotics. Methods to measure heat resistance in the temperature range of 60–135°C are the end-point method (a number of replicate containers with a known number of spores are heated successively for longer periods of times until no survivors are obtained by culturing each container) and the multiple-point method (a batch of spores is heated continuously and samples are withdrawn at selected intervals, followed by determination of the number of survivors).

The most general equation representing the kinetics of microbial inactivation, enzymatic inactivation, nutrient destruction, or other chemical reactions is

$$-\frac{dc}{dt} = k_n c^n \qquad (123.4)$$

with c being the concentration of the reacting species at time t, k_n being the specific reaction rate, and n being the order of the reaction. To determine the order of the reaction, the logarithm of the equation is taken on both sides and a graph is plotted between $\ln(-dc/dt)$ versus $\ln(c)$. The intercept of the graph is $\ln(k_n)$ and the slope is the rate of the reaction.

$$\text{Zero order reaction } (n = 0): -\frac{dc}{dt} = k_0 \qquad (123.5)$$

$$\text{Integrating, we get: } c_0 - c = k_0 t \qquad (123.6)$$

Caramelization of sugar and degradation of vitamin C in model meat systems are examples of reactions that fall under this category.

$$\text{First order reaction } (n = 1): -\frac{dc}{dt} = k_1 c \qquad (123.7)$$

$$\text{Integrating, we get: } \ln(c/c_0) = -k_1 t$$

$$\text{This can also be written as: } c/c_0 = e^{-kt} \qquad (123.8)$$

Most reactions, including microbial inactivation, enzymatic inactivation, and nutrient destruction, fall under this category.

$$\text{Second order reaction } (n = 2): -\frac{dc}{dt} = k_2 c^2 \qquad (123.9)$$

$$\text{Integrating, we get: } 1/c - 1/c_0 = k_2 t \qquad (123.10)$$

Destruction of thiamin in milk falls under this category.

Other orders of reaction (fractional): Reactions involving the color ($n = 1.31 \pm 0.18$), texture (1.13 ± 0.20) of peas and the texture (0.36 ± 0.17), and appearance (0.44 ± 0.16) of beans fall under this category.

The more common way of representing the rate of microbial destruction is through the use of decimal reduction time (D). The relationship between the rate of a reaction and decimal reduction time is

$$N/N_0 = e^{-kt} \tag{123.11}$$

$$\log_{10}(N/N_0) = -kt/2.303$$

$$\text{with } D = 2.303/k \tag{123.12}$$

if k is represented in s^{-1} and D in s.

Thus, $N/N_0 = 10^{-t/D}$ where N_0 and N are the initial and final number of microorganisms, respectively, and t is time.

The D value determined at a reference temperature (T_{ref} or T_r) is denoted by D_{ref} or D_r.

The ratio of D_{ref} to D is referred to, as the lethal rate.

The effect of temperature on rate of reaction can be described by one of the following two models:

1. Thermal death time (TDT) method (D-z model): TDT is the time required for total destruction of a microbial population or the time required for destruction of microorganisms to an acceptable level. The plot of D (logarithmic scale) versus T is referred to as the "phantom" TDT curve (or the thermal resistance curve). The slope of this curve is "$-1/z$."

$$\log(D_1/D_2) = (T_2 - T_1)/z \tag{123.13}$$

   The points on this curve correspond to the combination of time and temperature that results in 90% reduction in microbial count. A similar curve with either 100% reduction in microbial count (based on experiments) or acceptable levels of reduction in microbial counts is referred to as the TDT curve and the time on the curve at a given temperature is the TDT at that temperature. Note that the slope of this curve is also "$-1/z$."
2. Arrhenius kinetics method (k-E model): The basic equation is as given below.

$$k = A\, e^{-E/R_gT} \tag{123.14}$$

   where A is a pre-exponential factor, collision number, frequency factor (s^{-1}), E is the activation energy (J/kg-mol), and R_g is the universal gas constant (= 8314 J/kg-mol-K).

Writing the above equation for two different temperatures, yields:

$$\frac{k}{k_{ref}} = e^{-\frac{E}{R_g}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right)} \tag{123.15}$$

The activation energy is the minimum energy which molecules must have for the reaction to occur and the exponential term "e^{-E/R_gT}" is the fraction of molecules that collectively have the minimum energy.

The above equation can be simplified to:

$$E = 2.303\, R_g(T)(T_{ref})/z \tag{123.16}$$

For unimolecular reactions A varies from 10^{14} to $10^{20}\,s^{-1}$, for bimolecular reactions it varies from 10^4 to $10^{11}\,s^{-1}$, and intermediate values for chain reactions. For heat resistant bacterial spores, A is extremely large, of the order of 10^{30}–$10^{60}\,s^{-1}$ and E can be up to 500 kJ/mol. For *Clostridium botulinum* spores, $A = 2 \times 10^{60}\,s^{-1}$ and E = 310.11 kJ/mol-K for the range of temperatures from 100°C to 150°C (4).

It is assumed that A and E are independent of temperature, but this may not be the case always. There are several approaches available to correct this assumption or approximation — absolute reaction rate theory and quotient indicator method are two of them.

Once the time-temperature profile within a product is determined, the degree of lethal treatment delivered is determined by determining the F-value of the process. The F-value of a

$$F = \int_0^t 10^{\frac{T - T_{ref}}{z}}\, dt \tag{123.17}$$

process is the time (in mins) at a reference temperature that would produce the same degree of microbial destruction as in the process under consideration. It is computed as follows.

For a constant temperature process, the above equation reduces to

$$F = 10^{\frac{T - T_{ref}}{z}}\, \Delta t \tag{123.18}$$

In aseptic processing, the reference temperature is usually chosen as 121.1°C (250°F) and the z value chosen is 10°C (or 18°F). The F-value computed with these values of T_{ref} and z is referred to as the F_0 value of the process.

The use of a time-temperature integrator (TTI) as an alternative to temperature measurement or microbiological testing for process evaluation (determination of F-value) is becoming popular. A TTI can be an enzyme such as amylase or peroxidase that denatures (an unwinding of the structure) as it is heated. If the reaction kinetics of the

temperature-induced denaturation match those of the microbial death kinetics for the target species, it is possible to use such TTIs as non-biological markers of a process.

3. Heat Transfer

Heat is transferred from the heating medium (steam or hot water) to the product in the heat exchanger. For liquid foods, the rate of increase of product temperature depends on the overall heat transfer coefficient between the heating medium and the product. For particulate foods, there is an additional factor — heat from the liquid portion of the product has to be transferred to the particulates. This is affected by the convective heat transfer coefficient between the particles and the fluid and also thermal conduction within the particulates (governed by the thermal diffusivity of the particles). Efforts have been geared towards decreasing fouling (deposition of the food material on the heat exchanger) and increasing the rate of heat transfer between the heating medium and the product by not only minimizing fouling but also by new designs of heat exchangers and the change of processing parameters.

During aseptic processing, the FDA does not credit lethality accumulation (accumulation of F-value) within a product in the cooling section. This is because particulates could possibly break up in the cooling section and thus, due to their smaller size, cool rapidly, thereby not accumulating the required F-value. Also, due to the uncertainties in the temperature distribution within the product in the heat exchanger, lethality credit is not given in this section. Lethality credit in the heat exchanger could possibly be included if the time-temperature history within the heat exchanger could be determined or modeled conservatively.

Some of the techniques used to determine the temperature distribution within a product include the use of thermocouples, resistance temperature detectors, data tracers, infrared imaging, thermochromic dyes, magnetic resonance imaging, thermoluminescent markers, and magnetic particles. The non-invasive techniques among these are of more interest in aseptic processing. However, each of those techniques has their limitations in determining the center temperature of particles under unobstructed flow conditions. Thus, researchers are focusing on developing reliable techniques that can be used to non-invasively determine the internal temperature of flowing particles.

Further details of the heat transfer aspects of aseptic processing have been described in detail by (5). This includes discussion of convective heat transfer coefficient, steam quality, dimensionless numbers governing heat transfer, natural (free) and forced convection, transient heat transfer within particles, hydrodynamic and thermal entrance lengths, heat transfer coefficient in straight tubes, heat transfer coefficient in helical tubes, heating media and equipment, co-current and counter-current heat exchangers, governing heat transfer equations and energy balance, fouling and enhancement of heat transfer, and techniques to estimate the temperature history of a product.

C. Processing Details

Some of the important processing and packaging details to be considered during aseptic processing and packaging of liquid and particulate foods are discussed in this section.

1. Issues to be Dealt with for Liquid and Particulate Foods

In aseptic processing, if we ensure that the slowest heating point (critical point) within the product is sufficiently processed, the entire product will be sufficiently processed. The critical point for a fluid product is generally at the center of the product. There are exceptions to this — for example, for flow in a helical tube, the fastest fluid element is located away from the center of the tube (towards the wall of the tube). The critical point with a particulate product is usually the center of the particle that receives the least heat treatment (critical particle). The critical particle in a system containing only one type and size of particle is the fastest particle in the holding tube. In a multi-particle product, the critical particle is the slowest heating particle, which is not necessarily the fastest particle since slower particles may potentially have a lower thermal diffusivity than the fastest particle. Mathematical modeling (with conservative assumptions) of the process would be one way to narrow down the choice of the critical particle.

2. Product Heating and Cooling

Heating of the product is the first step towards delivering the required F-value to the product. For fluid products, a plate, tubular, scraped surface, steam injection/infusion, and volumetric heating mechanisms (ohmic, microwave, and radio frequency) can be used. It has been shown that the use of higher temperatures for shorter times is the generally preferred technique from the standpoint of nutritive value of the product. Thus, techniques to rapidly heat products are being sought.

Product cooling is the final heat exchange operation prior to filling into aseptic packaging containers. Since the product temperatures achieved in aseptic processing are typically higher than in other thermal sterilization methods, and no creditable microbial lethality is accumulated in the cooling section (as opposed to the canning where creditable lethality can also be accumulated during the cooling stage), there is a need for rapid reduction of product temperature during cooling in order to minimize the negative effects of high temperature on various product quality characteristics such as nutrient, color, flavor, and texture retention. This reduction of temperature can be

performed, using appropriate coolant fluids, in the same types of heat exchangers listed for product heating (plate, tubular, and scraped surface heat exchangers), with the exception of steam injector equipment and volumetric heating equipment. For products where water is added through direct steam injection, flash or vacuum cooling can be employed to remove the added water as well as to effect very rapid cooling by boiling off the water under reduced pressure. The removal of the sensitive heat of evaporation causes the product material to cool to ambient or final filling very rapidly, typically within seconds.

Indirect vacuum cooling equipment employs evaporating environment of cooling fluid to surround the flow-through tubes of process material to effect rapid indirect, vacuum-driven cooling of product.

3. Sterilization of Equipment

Sterilization of the processing, packaging, and the airflow system prior to processing are of utmost importance. This is what is referred to as pre-sterilization. Pre-sterilization of the air system is done by high efficiency particulate arresting (HEPA) filtering or incinerated air. For equipment, it is accomplished by steam, hydrogen peroxide, or other disinfectant solutions. For filling lines, pre-sterilization is done with steam or water at high pressure. The recommended heating effect for pre-sterilization (using hot water) of the processing equipment for low-acid foods is the equivalent of 250°F for 30 minutes. The corresponding combination for acid or acidified products is 220°F for 30 minutes. This often involves acidification of the water (to below a pH of 3.5 for acid products) used for sterilization. Pre-sterilization of an aseptic surge tank is usually done by saturated steam and not hot water due to the large volume associated with the surge tank.

Once the product is processed, the system has to undergo a clean in place (CIP) operation. The CIP cycle for low-acid foods involves the use of hot water, alkali, hot water, acid, and hot water sequentially. The CIP cycle for high-acid foods is hot water, alkali, and hot water sequentially. A detailed description of fouling, cleaning, and disinfection has been presented by (6).

Sterilization of the food contact surface of packaging material is the next point of consideration. For non-sterile acidic products ($pH < 4.5$), a 4D process is required. For sterile, neutral, low acid products ($pH > 4.5$), a 6D process is required. However, if there is possibility that *C. botulinum* is able to grow in the product, then a full 12D process is required. It has been suggested that only 3% of the total number of microorganisms on the package surface are spores. An upper value of 1,000 microorganisms per m^2 (30 spores per m^2) has been assumed for plastic films and paperboard laminates on reels, and 3,000 microorganisms per m^2 (90 spores per m^2) for prefabricated cups.

Some of the techniques used for sterilization are listed below.

a. Radiation

UV-C Radiation (250–280 nm)

Optimum effectiveness at 253.7 nm; applicable only to smooth, even surfaces.

Infrared Radiation

Applicable only to smooth, even surfaces (Al lids coated with plastic laquer).

Ionizing Radiation

Co-60 or Cs-139; 25 kGy (2.5 Mrad); 100 keV of electron beam (empty sealed containers such as bag-in-box).

b. Heat

Saturated Steam

165°C and 600 kPa for 1.4 s (cups) and 1.8 s (lids); disadvantages include need for high pressure, removal of air (to promote heat transfer), and possible dilution of product as steam condenses.

Superheated Steam

220–226°C for 36–45 s.

Hot Air

315°C (surface temperature reaches 145°C for ~3 min); suitable only for acidic products.

Hot Air and Steam

Hot air is blown through a nozzle in such a way that the base and walls are uniformly heated; used for cups and lids made of PP which is thermally stable up to 160°C.

Extrusion

During extrusion of plastic granules prior to blow molding of plastic containers, temperatures of 180–230°C are reached for up to 3 min. However, because the temperature distribution inside the extruder is not uniform and the residence time of the plastic granules varies considerably, it is not possible to guarantee that all particles will achieve the minimum sterility. It has been suggested that extrusion results in a 3–4D process. Thus, aseptic filling into extruded containers should be used only for acidic products. For low-acid products, a hydrogen peroxide treatment is usually done.

c. Chemical Treatment

Hydrogen Peroxide

Dipping, spraying, rinsing processes, or combined with UV-C or heat at least 80°C and 30% concentration is required; residual peroxide should be less than 100 ppb at time of filling and must decrease to 1 ppb within 24 hours. Since it is hard to detect peroxide in foods, containers filled with water are run through the machine initially.

Peracetic Acid

Produced by oxidation of acetic acid by hydrogen peroxide; effective even at 20°C (1% solution will eliminate

7–8 logs of the most resistant spores in 5 min at 20°C; maximum usable temperature is 40°C).

Ethylene Oxide

It is a toxic gas and can penetrate porous materials; thus it is used for pre-sterilization of paperboard-based packaging materials (particularly preformed carton blanks which are to be assembled in an aseptic filler).

Verification of sterilization is done by inoculation of the surface of the web, cup, or lid stock with the proper concentration of the test organism and allowing this to dry. The system is then run as in a commercial run and the finished containers are filled with an appropriate growth medium and observed for growth. Two of the most important factors affecting the success of the tests are the choice of the indicator organisms and the physical state of the microorganisms used. The indicator organisms used are: *B. stearothermophillus* strain 1518 (for superheated steam, peroxide + steam, and extrusion), *B. polymyxa* PSO (for dry heat), *B. subtilis* strain A (for peroxide + UV), *C. sporogenes* PA 3679 (for ethylene oxide), and *B. pumilus* (for gamma radiation).

4. Heat Exchange Equipment and their Suppliers

The various types of heat exchangers used in heating and/or cooling products include plate, tubular, scraped surface, microwave, radio frequency, and ohmic heating devices. Each of these devices has their advantages, disadvantages, and range of applicability. Some of the systems that handle the liquid and solid portions of a particulate food separately are the Jupiter system, rotaholder, and the fluidized bed system (7).

a. Plate Heat Exchanger

Numerous companies produce plate heat exchangers. Some of the well-known major suppliers of integrated aseptic processing lines including plate heat exchangers are Tetra Pak Inc (Vernon Hills, IL, USA), Alfa Laval, Inc. (Glen Allen, VA, USA), FMC FoodTech (FranRica, Madera, CA, USA), Waukesha Cherry-Burrell (Delawan, WI, USA), Invensys/APV (New York, NY, USA), and Stork Food and Dairy Systems (Gainesville, GA, USA).

b. Tubular Heat Exchanger

In addition to companies listed above, there are several companies producing Tube in tube and tube in shell heat exchangers. They are Feldmeier Equipment Inc. (Syracuse, NY, USA) and Rossi & Catelli (Parma, Italy).

c. Helical Heat Exchanger

VRC Co. Inc. (Cedar Rapids, IA) and GEA-AG (Bochum, Deutschland).

d. Steam Injection and Steam Infusion Unit

Most of the major heat exchanger producer companies listed under plate heat exchanger also offer steam injection direct heaters in various configurations.

e. Scraped Surface Heat Exchanger (SSHE)

Major suppliers of scraped surface heat exchanger equipment are the same equipment companies providing the integrated aseptic processing systems.

f. Continuous Flow Volumetric Heaters

Radio Frequency Heater

Radio Frequency Co., Inc. Millis, MA.

Continuous Flow Ohmic/Electro Heater

Invensys/APV (New York, NY, USA) and Raztek (Sunnyvale, CA, USA).

Continuous Flow Microwave Heaters

Industrial Microwave Systems (Morrisville, NC, USA), Keam Holdem Associates (Auckland, NZ), and Armfield Limited (Ringwood, England).

D. Packaging Details

1. Types of Packaging Systems

Modern aseptic packaging units for foods cover an extensive range of materials, shapes, and sizes. For individual and family-size packages, traditional paperboard laminate package types are still the dominant form, with reclosable lids and pouring spouts introduced more recently. Some of the well known companies providing the packaging equipment and materials are Tetra, SIG Combibloc and Elopak. These types of packages — thermoformed polymer cups and pots with peel-off laminate layer tops and, depending on package size, re-closable lids are also well known and on the market for a considerable time — the packaging units and materials are provided by Robert Bosch Corporation. Individual serving size bottles with re-closable snap-on or screw-on lids made of high density polyethylene, polyethyleneterepthalate, or other polymers have also been introduced to the market by companies like Sidel, Krones AG, and Stork. Production of fluid products and beverages aseptically packaged into conventional packages such as glass bottles and aluminum cans has also been increasing during the last several years.

Multi-layer laminate bags and pouches in forms from single serving mini-pouches, stand-up pouches and bags fitted with various pouring and dispensing closures and spouts are also on the market. Small 2–3 oz packages to 1–3 gallon bag and bag-in-box package types for institutional use to 50–60 gallon bags in boxes for industrial ingredient and raw material use are provided by Liqui-Box, Rapak, Astepo, Scholle, etc.

Aseptic packaging systems are generally classified into the following categories.

a. Can Systems

Pioneered by Martin in the late 1940s, the first system was commissioned by Dole Corp. (CA) in 1950 for soups. It uses superheated steam at 225°C for up to 40 s to sterilize can and ends, with temperature not to exceed 232°C since

tin flow underneath the enamel can occur, resulting in blister formation during seaming of the lid (the lining compound is still at ~220°C and is plastic; thus, the seamed can should be transported in vertical position for at least 15 s after seaming to allow compound to settle and hermetically seal the can). For composite cans consisting of a spirally wound body made from laminations of foil, plastics, and paper with metal ends, hot air at 143°C for 3 min is used to sterilize the packaging materials as steam would cause swelling of the paper layers. The Dole, Serac, and Remy systems are examples of systems that fall under this category.

b. Bottle Systems

Glass

Saturated steam or dry heat (when dry heat is used, extended cooling by sterile air is required to minimize thermal shock when cool product is filled in it; no commercial unit, yet).

Plastic

Non-sterile bottles: After blowing, the plastic bottles are conveyed into a sterile chamber which is kept at a slight over-pressure of sterile air. The bottles are inverted and sprayed inside with hydrogen peroxide and passed through a hot air tunnel to evaporate the residual peroxide. The bottles are rinsed with sterile water and then filled. A chemically sterilized, heat sealable closure such as a plastic film or cap is then applied.

Sterile Blown Bottles

Bottles are extruded, blown with sterile air, and sealed under conditions that ensure internal sterility of the container. The sealed bottles are introduced into a sterile chamber (maintained at a slight positive pressure) where the outside surfaces are sterilized by hydrogen peroxide sprays. The closed top of the bottle is cut away, the neck trimmed, the bottle filled, and a foil cap or heat sealable sterile closure applied.

Single Station Blowing, Filling, and Sealing

This is a complex system. The separate operations of parison extrusion, blow molding, bottle filling, and sealing all take place in sequence in a single mold. Sterility of the inside surface of the container is ensured by the high temperature (164 to 234°C) of the plastic material during extrusion of the parison, and the use of sterile air for blowing. After filling, the tube projecting from the bottle mold is vacuum-formed or sealed with jaws into a cap which closes the bottle. No special arrangements to ensure sterility are required since the filling and sealing are carried out within the closed mold.

c. Sachet and Pouch Systems

Form-Fill-Seal Systems

A vertical form-fill-seal machine operates in a sterile chamber. The packaging material is passed through hydrogen peroxide and then drained and dried. The Asepak, Impaco, DuPont, Prodo-Pak, and Thimmonier systems fall under this category.

Layflat Tubing

This system uses a blown film polymer in the form of a layflat tubing so that only a transverse seal is required to form the bag. It is assumed that the inside of the tubing is sterile due to the temperature achieved during the extrusion process. The tubing is fed from the reel into a sterile chamber in which an over-pressure of air is maintained. The sachets are sealed at the bottom, cut, and moved into a filling station. After filling, they are sealed at the top and leave the chamber through a water seal.

d. Cup Systems

Preformed Plastic Cups

The cups are fed onto a conveyor which is inside a sterile tunnel supplied with sterile air. The cups are sprayed with hydrogen peroxide and after about 3 s, the solution is removed with compressed hot air at ~400°C with the inside surface of the cups reaching ~70°C which completes the surface sterilization and reduces the peroxide residue to acceptable levels. The cups are then filled and sealed with aluminum foil (sterilized by peroxide with residue removed by heat) with a thin coating of a thermoplastic to provide heat sealability. The Metal Box, Gasti, Crosscheck, Hamba, Ampack, and Remy systems fall under this category.

Form-Fill-Seal Cups

The plastic material (usually polystyrene) in the form of a web is fed from a roll into a thermoformer. Sterilization of the web is done prior to forming using a hydrogen peroxide bath. It then passes through a tunnel where it is heated to 130–150°C to prepare it for thermoforming. Mechanical force and compressed air is used to form the container in a water-cooled mold below the web.

e. Carton Systems

Form-Fill-Seal Cartons

The packaging material is supplied in rolls which have been printed and creased (for ease in the forming process). A polyethylene (PE) strip is sealed to one edge and the packaging material sterilized using a wetting system or a deep bath system. The sterilized packaging material is fed into a machine where it is formed into a tube and closed at the longitudinal seal by a heat sealing element. In this process, the PE which was added prior to sterilization is heat sealed across the inner surface of the longitudinal seal to provide protection of the aluminum and paperboard layers from the product which could corrode or swell the layers if such a strip were absent. Product is then filled into the tube and a transverse seal made below the level of product, thus ensuring that the package is completely filled. The Tetra-Pak and International Paper systems fall under this category.

Prefabricated Cartons

In this method, prefabricated carton blanks are used, the cartons being die-cut, creased, and the longitudinal seam

completed at the factory of origin. The cartons are delivered to the processors in lay-flat form, ready to be finally shaped in the filler and the top and bottom seams formed and bonded. Stacks of blanks are loaded into a magazine from which they are individually removed by suction pads, opened up into a rectangle, and placed on a mandrel. PE at the bottom of the carton is softened by hot air. The bottom is then folded by transverse and longitudinal folders and sealed. The top is then pre-folded. All of this takes place in a non-sterile zone. The inside surface is then sterilized by peroxide in a sterile zone (over-pressure of sterile air). The carton is then filled, closed, and heat sealed.

f. Bulk Packaging Systems

Metal Drum

Two major systems are in use and both use a 55 gallon metal drum constructed from steel with an electrolytically coated tin lining outside. The ends are double-seamed onto the body of the drum during manufacture and filling takes place through a threaded hole in which a cap is swaged after filling. The Scholle, FranRica, and Cherry-Burrell systems fall under this category.

Bag-in-Box

In this system, the product is filled into a plastic bag which when full is put into an outer container such as a drum or a paperboard box. For large containers, filling occurs after the bag is placed in the box. The Scholle, FranRica, Liquibox, and ELPO systems fall under this category.

Further details of aseptic packaging systems are described in reference (8). In addition, details of some of the "FDA-accepted" low-acid packaging systems have been presented in reference (9).

2. Testing of Package Integrity

Testing of the integrity of aseptic packages is usually done by one of the following methods.

a. Destructive Methods

Teardown

The flaps of the package are unfolded and pressure applied to the package to check the tightness of the transverse seals. The quality of the transverse and longitudinal seals is determined by carefully pulling apart the seals — if the seal is good, the PE layers will be removed and the aluminum foil laid bare in the sealing zone.

Electrolytic Test

This test is based on the principle that a tight plastic container is an electrical insulator. By introducing an electric potential across a brine-filled package which is partially immersed in a brine solution, the existence of holes in the package can be determined. Positive tests are generally followed by a dye test for confirmation.

Dye Test

After rinsing with water and drying, a solution of 0.5% Rhodamine B in isopropanol is applied to the critical areas of the package including the longitudinal and transverse seals. The carton is then allowed to develop for 5 minutes and dried in a warm cabinet overnight. The flaps of the package are unfolded and the dye coated paper removed and examined for ink penetration. Any sign of the pink ink indicates the presence of holes in the PE layers.

b. Nondestructive Methods

These include visual inspection, computer-aided video inspection, and automatic profile scanning.

c. Biotest Methods

The package is filled with a nutrient broth, sealed, and placed in contact with a medium infected with a test organism. After contact for a certain period of time, the package is placed in an incubator and microbial growth is assessed after an appropriate period of time.

E. Issues Related to Process Validation

Thermal process validation involves three stages: process establishment, lethality assurance, and record keeping. Process establishment involves considerations related to product formulation and properties, initial temperature, container size and shape, location of thermocouple, critical point, container stacking, retort controls, and steam and water controls. Lethality assurance involves comparison of the actual lethality delivered to that based on the scheduled process. Record keeping involves maintenance of full records of the process history of all production runs which contain the details of all critical factors related to the scheduled process.

In aseptic processing, biological validation tests are performed at various stages of the process — just after start-up, during the middle of the run, and just before shut-down. These tests account for variations during the process and also for factors such as fouling. The validation tests are conducted at different temperatures to document a positive/negative result at the end of the process. This will aid in determining the minimum allowable process temperature that will result in a safe process. Microbiological validation tests are done using PA 3679 inoculated within alginate particles. Care should be taken to ensure that the spores do not leach out into the fluid. If the target for the process was a 5D process, and an initial load of 10^5 spores per particle is used, a final count of <1 would indicate a safe process. The decimal reduction time of the organisms used is determined by means of thermal death time studies. Based on all of these tests, a process is designed and finally verification of the established process has to be conducted. During this process of verification, comparisons are made between actual temperatures and lethalities to the predicted temperatures and lethalities in

order to ensure that the mathematical model developed (details of mathematical models have been provided by (3)) results in a conservative prediction of process lethality.

Once verification is successful, all the process and system parameters are noted down and care should be taken to ensure that these parameters remain within an acceptable range. Some of the parameters include hydration time, mixing/batching time, temperatures at various locations, product flow rate, back pressure, and product properties. The final step in commercialization of the product involves process filing with the FDA using form 2541c. A comprehensive overview of the procedures and processes involved in process filing for a product such as the one discussed above has been given in a report prepared based on the workshops organized by the Center for Advanced Processing and Packaging Studies (CAPPS) and the National Center for Food Safety and Technology (NCFST) — (10) and the detailed discussion of the form has been presented in reference (3).

At pH values below 4.6, processes are aimed at controlling the survival and growth of spore-forming organisms such as *B. coagulans*, *B. polymyxa*, *B. macerans*, and butyric anaerobes such as *C. butyricum* and *C. pasteurianum*, but not *C. botulinum*. An $F_0 = 0.7$ min is generally regarded as adequate for this. NFPA suggests $F^{8.3}_{93.3} = 10$ min when pH is between 4.3 and 4.5; $F^{8.3}_{93.3} = 5$ min when pH is between 4.0 and 4.3. Below a pH of 3.7, processors are concerned with the control of non-sporing bacteria, yeasts, and molds. They can be generally controlled by heat processes with temperatures below 100°C.

Aseptic process validation requirements differ depending on the country of marketing and distribution and product type being marketed. In North American countries, requirements and procedures are regulated by government regulatory agencies like the Food and Drug Administration in the U.S. In most other countries, validation procedures and requirements are typically defined and implemented by the food producers. In either case, the producers need to design and implement a treatment that imparts the degree of sterility to the least treated food segment sufficient to inactivate all microorganisms of public health significance and sufficiently reduce the risk of product spoilage by the more resistant spoilage-related microorganisms.

Unlike in European countries (11, 12) where regulations are based on spoilage tests, the FDA requires microbiological tests to prove the safety of a process with sufficient latitude for variability in process conditions. In the U.S., different regulatory agencies and rules apply to different products. For example, UHT milk processing is covered under title 21 (parts 108, 113, 114) of the code of federal regulations (CFR). The process should also adhere to the pasteurized milk ordinance (PMO). When meat is involved, the regulations are imposed by the USDA. In addition to these regulations, certain states have state regulations imposed on certain processes. During the past few years, HACCP has gained tremendous importance and its implementation has been extended by the FDA to various products after its initial application to certain acidified and low-acid canned foods. The details of the requirements of a HACCP program are described in detailed in 21 CFR 113, 114. In addition, details of the evaluation of a HACCP program for a multiphase food product aseptically produced has been presented in reference (3).

Shelf-stable low-acid food products constitute a special case since the conditions of storage and chemical composition are conducive to the growth and toxin formation by various strains of *Clostridium botulinum*, microorganisms capable of producing one of the most potent toxic substances known, the causing agent of potentially fatal botulism poisoning. Processes for treating these types of products need to be designed and validated to consistently deliver a 12D reduction of spores of the most resistant proteolytic strains of *C. botulinum*. For homogeneous materials like beverages, dairy products, purees, homogenates, and clear and smooth soups, procedures and methodology to establish and validate these types of processes are well known and established.

General FDA Requirements for Establishment of Registration, Thermal Process Filing, and Good Manufacturing Practices for Low-Acid Canned Foods and Acidified Foods are covered in 21 CFR 108, 21 CFR 110, 21 CFR 113, and 21 CFR 114. These and other listed regulations and forms are also accessible through contact with FDA directly or from their web site.

Aseptically processed low-acid particulate products present a formidable challenge to the processor in terms of the ability to design, document, and validate a process that will deliver adequate treatment to the fastest moving, slowest heating particle within a continuously processed system. Three decades of intensive research and development by numerous researchers and engineers have been invested in the development of knowledge methodology and a technology database to perform these documentation and validation studies to meet the regulatory agency requirements. Typical thermal process design for aseptically processed liquid foods, aseptically processed fluid homogeneous foods, and aseptically processed low-acid heterogeneous foods containing discrete particulates have been presented in reference (9).

A series of industry-university-government workshops on aseptic processing of multiphase foods in 1995 and 1996, sponsored by the National Center for Food Safety and Technology in Chicago and the Center for Advanced Processing and Packaging Studies at North Carolina State University in Raleigh, resulted in a publication of the "Case study for condensed cream of potato soup from the aseptic processing of multi-phase foods workshop" (10).

As a result of these workshops, criteria for demonstrating a safe process for aseptic particle-containing foods were established (13). Within one year, Tetra Pak Inc., in

conjunction with the NFPA, developed the necessary data required for a low-acid canned foods filing for cream of potato soup, which was accepted by the FDA in May 1997. After this first successful filing, no further filings are known that were submitted to FDA and no aseptically processed and packaged low-acid products are known to be on the North American market.

This illustrates the still-prevailing hurdle of regulatory requirements and the lack of appropriate validation techniques as one of the major remaining obstacles to wider commercialization of multiphase aseptic products and aseptically processed foods in general.

As a result, there is an abundance and wide variety of fluid and homogeneous semi-fluid aseptically processed products on the market, but low-acid products containing particles, in spite of the obvious advantages of aseptic processing technologies to their quality and distribution, remain limited world-wide and absent on the North American market. Further development of technologically more sophisticated, but easier to implement validation methods and tools is expected to reduce this last remaining obstacle to aseptic technology penetration and implementation into a wider range of processed food products and biomaterials.

124 Food Irradiation Using Electron-Beam Accelerators

Rosana G. Moreira
Department of Biological and Agricultural Engineering, Texas A&M University

CONTENTS

I. INTRODUCTION

Food irradiation involves exposing the food (packaged or in bulk) to controlled amounts of ionizing radiation to achieve certain desirable objectives. The technology has recently been identified by the Food and Drug Administration (FDA) and World Health Organization (WHO) as having significant strategic importance for the future of food safety worldwide.

Food irradiation has been around for over 60 years and can offer a number of potential benefits including inactivation of microorganisms, inhibition of many enzymatic processes (such as those that cause sprouting and ripening), in addition to the fact that it can be used as an alternative to chemical treatment for disinfestations. The recent progress in the development of electron beam accelerators, together with the increased number of illnesses associated with produce-related foodborne disease outbreaks in the last years, provide the incentive for the development of an efficient technique to ensure hygienic quality of food products, especially those to be consumed raw or undercooked, to protect consumer health.

It is estimated that up to 81 million people a year are infected by foodborne illness, and of that number, 10,000 die (1). With an estimated 25% of all food production lost after harvesting to insects, bacteria, molds, and premature germination and the potential for continued rise in food poisoning incidence, irradiation could be used more widely to improve the quality and safety of the food supply in the future.

II. SOURCE OF IONIZING RADIATION

The type of radiation used in processing materials is limited to high energy *gamma-rays*, *X-rays,* and *accelerated electrons*. These radiations are also referred to as *ionizing radiations* because their energy is high enough to dislodge electrons from atoms and molecules and to convert them to electrically charged particles called ions. Gamma-rays and X-rays, like radiowaves, microwaves, ultraviolet, and visible light rays, form part of the electromagnetic spectrum, occurring in the short wave length, high energy region of the spectrum. Their properties and effects on materials are

the same, but their origins are different. In most cases, X-rays with varying energies are generated by machines. Gamma-rays with specific energies come from the spontaneous disintegration of radionuclides. Only certain radiation sources can be used in food irradiation. These are the radionuclides cobalt-60 (^{60}Co) or caesium-137 (^{137}Cs); X-ray machines having a maximum energy of 5 MeV, or electron machines having a maximum energy of 10 MeV. Energies from these radiation sources are too low to induce radioactivity in food.

As shown in Figure 124.1, gamma-rays and X-rays radiation can penetrate distances of a meter or more into the product, depending on the product density, whereas electrons, even with energy as high as 10 MeV, can penetrate only several centimeters.

A. Cobalt-60

Naturally occurring and man-made radionuclides, also called radioactive isotopes or radioisotopes, are unstable, and emit radiation as they spontaneously disintegrate, or decay, to a stable state. The Becquerel (Bq) is the unit of radioactivity and equals one disintegration per second.

The radionuclide used almost exclusively for the irradiation of food by gamma rays is ^{60}Co. Until 1993, food irradiation in the United States occurred exclusively from the use of ^{60}Co (2). It is produced by neutron bombardment, in a nuclear reactor, of the metal ^{59}Co, and then doubly encapsulated in stainless steel "pencils" to prevent any leakage during its use in a radiation plant. ^{60}Co has a half-life of 5.3 years.

The emitted gamma rays are photons with very short wavelengths, similar to ultraviolet light and microwaves but with much higher energies. Because gamma radiation does not elicit neutrons (i.e., the subatomic particles that can make substances radioactive), irradiated foods and their packaging are not made radioactive (3). Since 1960, the worldwide use of ^{60}Co has resulted in the accumulation of a vast and successful record of safety and reliability (4).

One economic factor related to ^{60}Co is the fact that its supply is limited and is practically a monopoly of Nordion Inc. (Ontario, Canada). Prices have increased and a sufficient future supply is questionable. A significant increase in demand would require the development of increased nuclear reactor capabilities.

In a typical gamma radiation facility, the radioactive material (^{137}Cs or ^{60}Co) is placed at the top of an elevator that can be moved up for use or down under water when not in use. Materials that need to be irradiated are placed around the radioactive material at a suitable distance for

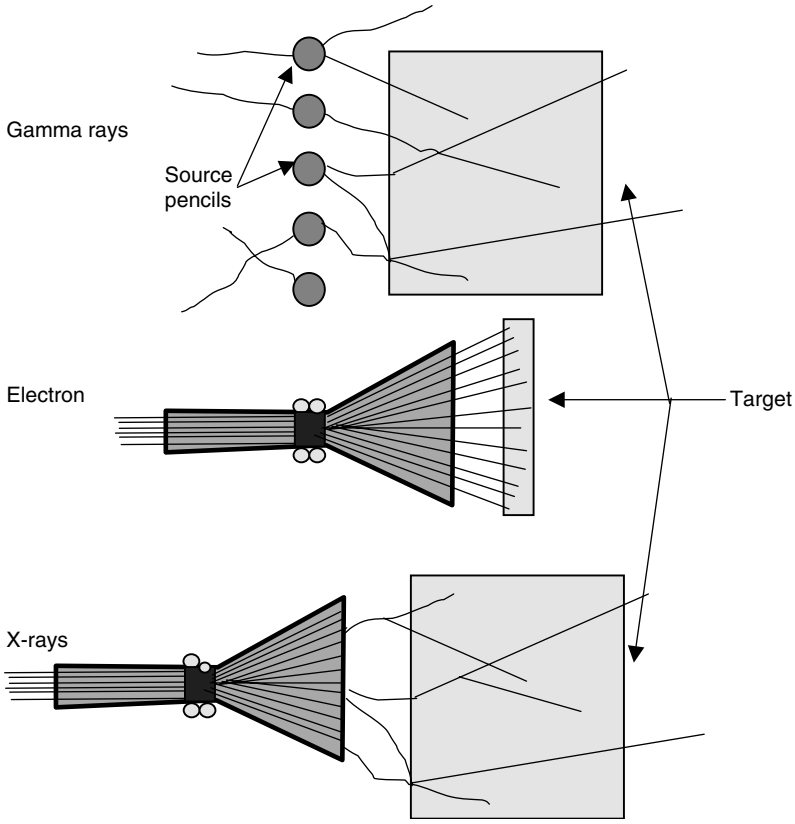

FIGURE 124.1 Typical sources used for food irradiation.

their desired dose. Among the drawbacks to the use of radioactive material is that the isotope source emits rays in all directions and cannot be turned "on" or "off" (4).

B. Cesium-137

^{137}Cs is the only other gamma-emitting radionuclide suitable for industrial processing of materials. It can be obtained by reprocessing spent, or used, nuclear fuel elements and has a half-life of 30 years (6).

The proposed use of ^{137}Cs as a radiation source dates from the early 1970s. It was based on the availability of vast quantities of unprocessed and encapsulated ^{137}Cs from US Government's stock of byproducts from nuclear energy and nuclear weapon production programs. By 1988, the Department of Energy canceled the program and the option of using ^{137}Cs as an ionizing radiation source for food safety was eliminated (5).

C. Electron Beam Accelerators

Some machine sources of radiation are suitable for irradiating certain materials. High energy electron beams can be produced from machines capable of accelerating electrons (accelerators). Electrons cannot penetrate very far into food, compared with gamma radiation or X-rays. However, X-rays can be produced when a beam of accelerated electrons bombards a metallic target. Although X-rays have good penetrability into food, the efficiency of conversion from electrons to X-rays is generally less than 10% (7).

Electron accelerators offer certain advantages over radioactive elements, which make them more attractive for industrialization: (1) The efficiency for direct deposition of energy, (2) the easy variability of electron-beam current and energy to provide flexibility in the choice of surface and depth treatments for a variety of food items, and (3) the ease with which an electron accelerator can be turned off or on.

There are two main differences between gamma rays and accelerated electrons. First, gamma penetration is higher than accelerated electrons, but the penetration capacity of the latter increases with their energy. Electrons at 10 MeV are more penetrating than those at 4 MeV. Second, the gamma dose rate from a typical ^{60}Co irradiator is 1–100 Gy/min, whereas electron beams from an accelerator can produce 10^3–10^6 Gy/sec (5).

A particle accelerator delivers energy to a charged-particle beam by the application of an electric field. Acceleration of charge particles can be divided in two categories: electrostatic and electromagnetic acceleration. An electrostatic accelerator consists basically of two conducting surfaces with a large voltage difference and a particle with charge gains kinetic energy. The peak energy of the beam is limited by the voltage that can be sustained without breakdown (8). The Van de Graaff accelerator is an electrostatic accelerator and will be described below since it is the electron beam source simulated in this work.

Electromagnetic fields are required in order to obtain energies above a few million electron volts. Electromagnetic accelerators can be resonant or nonresonant. Nonresonant are pulsed and are essentially step-up transformers, with the beam acting as a high voltage secondary. Resonant means that electromagnetic oscillations in resonant cavities or waveguides are used to transform input microwave power from low to high voltage. There is also a close coupling between properties of the particle orbits and time variations of the accelerating field. The category of resonance accelerators includes the linac, cyclotron, and synchrotron. Linac is an abbreviation for linear accelerator and the charged particles moves on a linear path and are accelerated by time dependent electromagnetic fields. Likewise, the particle orbit in a cyclotron is a spiral and a circle for a synchrotron (8).

1. Van de Graaff Accelerator

Mechanical transport of electric charges to the inner surface of a hollow electrode underlies the operation of electrostatic generators (Figure 124.2). In this type of accelerator a corona discharge from an array of needles in gas is used as the source of electrons. The electrons drift toward the positive electrode and are deposited in a moving belt. The belt, which is composed of an insulating material with high dielectric strength, is immersed in insulating gas at high pressure. The attached charge is carried mechanically

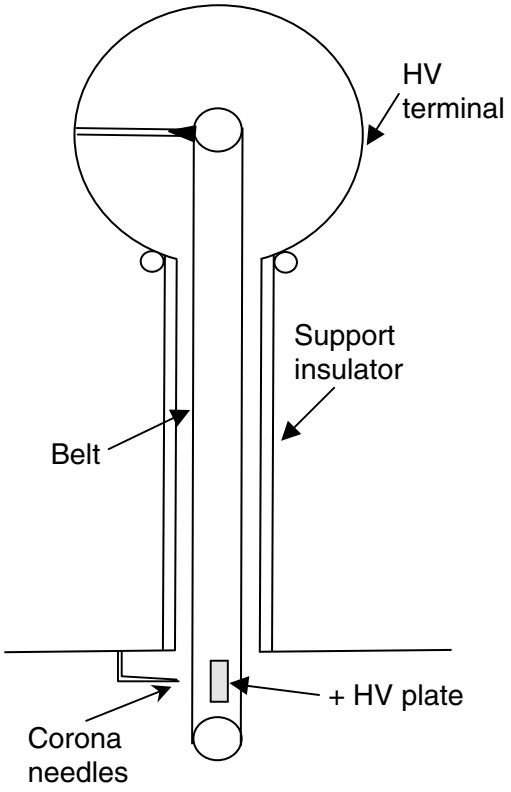

FIGURE 124.2 Schematic of the Van de Graaff accelerator.

against the potential gradient into a high-voltage terminal. The terminal acts as a Faraday cage and there is no electric field inside the terminal other than that from the charge on the belt. The charge flows off the belt when it touches a metal brush and is deposited on the terminal.

The energy to charge the high-voltage terminal is supplied by the belt motor. High-voltage terminals are usually constructed as large, smooth spheres to minimize peak electric field stress. The current available to drive a load (such as an accelerated beam) is controlled by either the corona discharge current or the belt speed. Typical currents are in the range of 10 μA. Van de Graaff accelerators are excellent research tools since they provide a steady-state beam with good energy regulation (8).

Electron beam facilities, widely used to irradiate medical equipment, have been built for food treatment. A conveyor or cart system moves the product to be irradiated under the electron beam at a predetermined speed to obtain the desired dosage. The products move in and out the irradiation area continuously. Energy penetration is about 3.86 cm in food products, so the thickness of items to be treated is limited to about 7.62 cm with double-sided treatment (9).

X-rays are electromagnetic radiation produced when energetic electrons hit a target. In an X-ray machine, the electrons are emitted by a heated cathode whose potential may be the order of 30 to 50 kV above the target (made of a material such as tungsten or molybdenum). For food irradiation electrons from a linear accelerator operating at 5 MeV hit a target to make X-rays and then treat the food.

The early design of accelerator systems provided poor penetration (produced only low energies, −2 MeV), were difficult to control, and were unreliable. So, the irradiation market was taken over by ^{60}Co (gamma).

During the 1970s, several companies, including Varian Associates, Phillips, and Siemens, took a new look at the application of X-ray technology for radiographic and oncology therapy equipment (10). Their involvement in the improvement of durability and reliability of accelerated electron technology raised performance parameters to a new level (11).

Today, industrial e-beam accelerators are characterized by (11):

- Higher energy (10 MeV) and thus better penetration
- High duty cycles (7,000–8,000 hours/year)
- Fully automated electronic control systems featuring programmable logic controllers (PLCs)

The applications of electron beam processing have then increased substantially in the last decades and are still growing.

A comparison among the three basic industrial electron accelerators is shown in Table 124.1 (10): (1) Direct Current machines (DC); (2) Rhodotrons, and (3) Pulsed and Continuous Wave Linear Accelerators (CW LINAC).

TABLE 124.1
Industrial Electron Accelerator Parameters

	Direct Current[1]	Rhodotron[2]	CW LINAC[3]
Energy	10 MeV	10 MeV	10 MeV
Max beam power	50 kW	200 kW	500 kW
Efficiency	<30%	38%	40%
Duty factor	5%	100%	100%
Dimensions	~1.0 × 1.0 × 4.0 m^3	~2.9 × 2.2 m^2	~0.8 × 0.8 × 9.0 m^3
Approximate cost	~$2 M	~$4 M	~$1.5 M

[1] (25) [2] (24) [3] (10).

A Direct Current machine is a linear accelerator that operates at 50 kW to produce up to 10 MeV beams. In a linear accelerator particles move in a linear path and are accelerated by time-dependent electromagnetic fields. The Rodotron technology utilizes a coaxial accelerating cavity of 2 meters in diameter. 10 mA of electrons are sent into the cavity and undergo a first acceleration of 0.5 MeV. Electrons pass through an opening and then emerge into the second part of the cavity, as the electrical field is reversed, they gain once more 0.5 MeV. Around the cavity, window-frame magnets are bending electrons back into the cavity for further acceleration steps. Ten successive crossings would be required to obtain 10 MeV beams (12).

A LINAC may be operated continuously, which is called a continuous-wave (CW) operation or may also be pulsed operated. If the accelerated beam current is small, most of the power in CW operation is not delivered to the beam but is dissipated in the structure walls. If the accelerator is pulsed operated, a larger fractional power is delivered to the beam, and the efficiency is improved (13).

Low-energy applications with electron beams up to ~1 MeV are adequately served by DC machines. These accelerators have high beam power and plug efficiency, but are bulky, thus being difficult and costly to handle. Above ~3 MeV, the CW LINACs have the lowest beam power cost of any commercial accelerator (10).

Electron beam irradiator facilities require shielding and product handling equipment similar to ^{60}Co facilities, although some shielding requirements may be reduced due to the directionality of radiation fields generated by machine sources. In addition, semi permanent facilities may also be developed, because electron beam accelerators can be made transportable (4).

III. EFFECT OF IONIZING ENERGY ON FOOD

Regardless of the source, the effect of ionizing energy on food is identical. Energy penetrates the food and its packaging but with X-rays and gamma-rays most of the energy simply passes through the food, similar to the way

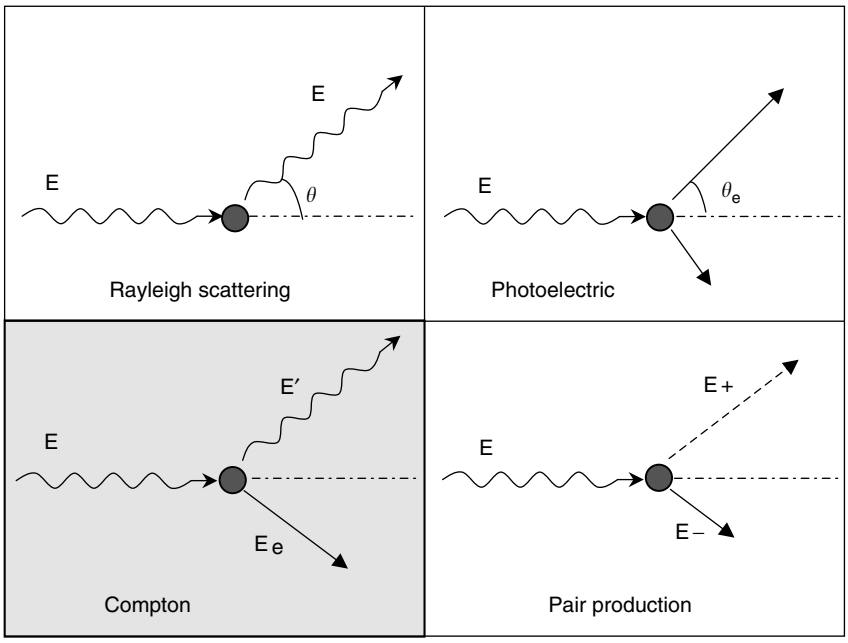

FIGURE 124.3 Basic interaction of photons with matter.

microwaves pass through food, leaving no residue. Most of the energy that does not pass through the food is converted to heat, but some produces DNA strand breaks that inactivate bacteria.

E-beam accelerators work on the same principle as a television tube. Electrons are emitted from a cathode and accelerated by an electric or magnetic field in a vacuum. Instead of being widely dispersed and hitting a phosphorescent screen at low energy levels, the electrons in the accelerator are concentrated and accelerate to higher energy, approximately 99% of the speed of the light. The electrons then pass through a thin metal foil and enter air at normal pressure.

Irradiation efficiency depends on both the accelerator characteristics and irradiation technique, as well as on a number of factors including the type of material, its geometric dimensions, its shape, the packaging material, etc. Processing capacity (kg/h) is directly related to the beam power (kW) and system efficiency, and inversely related to the dose.

The dose unit in the system is the Gray (Gy) — the dose at which 1 Joule of energy is absorbed in each kilogram of substance; the dose rate (D_r) is expressed most often in kGy/s; the total dose absorbed by the irradiated material is directly related to the dose rate and the irradiation time. The dose rate depends on the current (I, mA), the cross-section area (A, m^2) of the irradiation field, over which the electron is scanned, and the energy gradient or the stopping power (T, MeV/g/m^2) of the electrons. In general, the dose rate increases with energy and beam current and decreases as the distance between the accelerator and the irradiated material increases.

The electron range, the distance the electron will penetrate, is inversely proportional to the density of the material being irradiated. The useful range can be increased by 2.5 times by using two-sided irradiation rather than one-sided irradiation (14). In the case of food materials, if radiation is done from one side only a detector can be placed in the back of the material to monitor beam penetration and dose rate.

A. Basic Interaction of Photons and Electrons with Matter

Photons (gamma rays and X-rays) are electrically neutral and do not steadily lose energy as they penetrate food materials. Instead, they can travel some distance before interacting with an atom. Penetration depth of a given photon depends on the specific medium traversed and on the photon energy. When photons interact with matter, they might be absorbed and disappear or be scattered, changing direction of travel, with or without energy loss (Figure 124.3).

By contrast, a charged particle (electron), being surrounding by its Coulomb electric force field, interacts with one or more electrons or with the nucleus of practically every atom it passes (Figure 124.4). Thus, it is convenient to think of the particle as losing kinetic energy gradually in a friction-like process, often referred to as the "continuous slowing-down approximation" (CSDA).

In general, electrons have much less penetration power than gamma and X-rays. Because of the small mass and single negative charge, each time an electron approaches a target, it is deflected from its path by the orbital electrons and the positive atom nuclei. For those reasons, electrons have a poorer penetrability compared to gamma and X-rays.

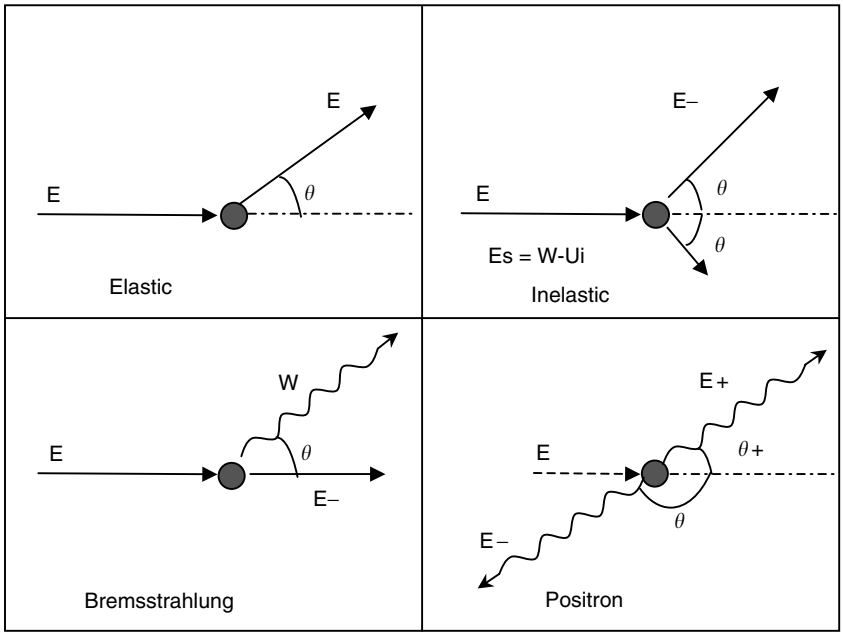

FIGURE 124.4 Basic interaction of electrons with matter.

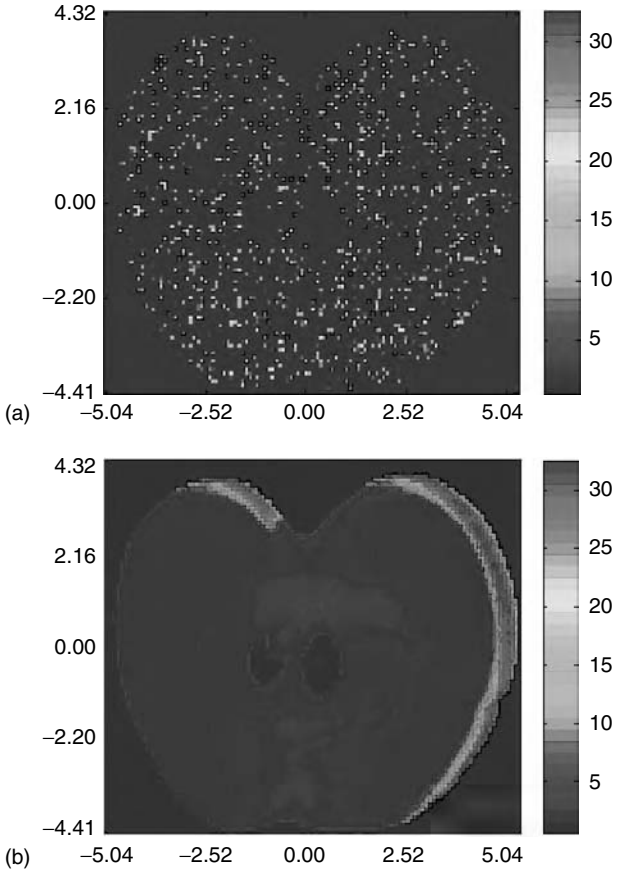

FIGURE 124.5 (a) 1 MeV photons incident in an apple; (b) 1 MeV electrons incident in an apple.

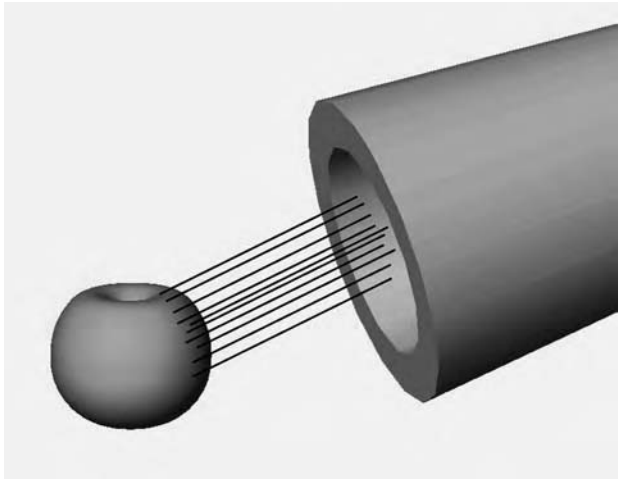

FIGURE 124.6 Source direction in an apple.

Figures 124.5a and 124.5b show the results of a simulation of the energy deposition of 1 MeV photons and electrons, respectively, in an apple with tilted source direction (Figure 124.6). The simulated results clearly show that the absorbed energy is distributed into the entire apple when 1 MeV photons is used as the energy source (Figure 124.5a). However, electrons with the same energy only penetrate about 5 mm of the apple (Figure 124.5b). For surface pasteurization of fruits and vegetables, electrons beams are the preferable source of treatment.

B. The Effect of Ionizing Radiation on Microorganisms

According to the target theory (15), lethality due to ionizing radiation occurs when the irradiated microorganisms are destroyed by the passage of an ionizing particle or quantum of energy through, or in close proximity to, a sensitive portion of the cell. This direct "hit" on the target causes ionization in this sensitive region of the organism or cell and subsequent death.

Bacterial spores are more resistant to ionizing radiation than are vegetative cells. Gram-positive bacteria are more resistant than gram-negative bacteria. The resistance of yeast and molds varies considerably, but some are more resistant than most bacteria.

According to reference (16), the efficacy of a given dose of irradiation to destroy a microbial population depends on the following:

- The kind and species of the organism.
- The numbers of organisms (or spores) originally present. The more organisms there are, the less effective a given dose will be.
- The composition of the food. Proteins, catalase, and reducing substances (nitrites, sulfites, and sulphydryl compounds) may be protective. Compounds that combine with the SH groups would be sensitizing.
- The presence or absence of oxygen. The effect of free oxygen varies with the organism, ranging from no effect to sensitization of the organism. Undesirable "side reactions" are likely to be intensified in the presence of oxygen and to be less frequent in a vacuum.
- The physical state of the food during irradiation. Both moisture content and temperature affect different organisms in different ways.
- The condition of the organisms. Age, temperature of growth and sporulation, and state (vegetative or spore) may affect the sensitivity of the organisms.

C. Chemical and Nutritional Changes in Foods

In general, the irradiation process produces very little chemical change in food. None of the changes known to occur have been found to be harmful or dangerous. Some of the chemical changes produce so-called "radiolytic" products. These products have proven to be familiar ones, such as glucose, formic acid, acetaldehyde, and carbon dioxide that are naturally present in foods or are formed by heat processing. The United States Food and Drug Administration has estimated that the total amount of undetected radiolytic products that might be formed when food is irradiated at a dose of 1 kGy would be less than 3 milligrams per kilogram of food — or less than 3 parts per million (17).

Research has shown that protein, carbohydrates, and fat are relatively stable to radiation doses of up to 10 kGy. Different types of vitamins have varied sensitivity to irradiation and to some other food processing methods. For example, vitamins C and B-l (thiamine) are sensitive to irradiation as well as to heat processing. The evidence suggests that irradiation does not induce special nutritional problems in food (18).

The change in nutritional value caused by irradiation depends on a number of factors including the radiation dose to which the food has been exposed, the type of food, packaging, and processing conditions (temperature during irradiation). Most of these factors are also true for other food preservation technologies.

D. Low Dose Irradiation for Surface Pasteurization of Fresh Produce

Ingestion of raw vegetables and fruits has been linked to outbreaks of food borne illness. Contaminated artichoke, beet leaves, cabbage, carrots, cauliflower, celery, eggplant, endive, fennel, onion, lettuce, mushrooms, potatoes, tomatoes, cantaloupe, watermelon, raspberries, strawberries, apples, etc. have been vehicles for transmission of pathogens (19). The viability of pathogenic organisms on the surface of fresh fruits and vegetables can be significantly reduced by electron beam irradiation. By limiting the irradiation to the surface, changes in the quality of the bulk of the product can be minimized. Electron beams (e-beams) are produced by small accelerators (which do not produce radiation when not in use) and electron energies, which penetrate only a short distance into the tissue, can easily be obtained. The most difficult technical challenge for surface irradiation is the need to achieve a uniform dose over the entire surface. This is particularly difficult if there are deep recesses such as the area of the stem of an apple, or convoluted surfaces such as some type of lettuces.

Most of the investigations in the area of e-beam accelerators to irradiate food have dealt with the effect of this energy source on the inactivation of microorganisms and on the product characteristic changes. No information is available in the literature regarding the development of methods for ensuring reliable quality control of the irradiation process on materials with irregular shapes, for example. Methods to continuously monitor the e-beam characteristics, such as the electron energy, electron current, scanner width, scanner uniformity, penetration depth, and conveyor speed need to be evaluated for these types of product.

IV. DOSE DISTRIBUTION DETERMINATION IN FOOD PRODUCTS

In food irradiation, one way to verify dose distribution in an irradiated product is by using photo luminescent dosimeters (20). This dosimeter is a small plastic wafer that is irradiated with the food. The dosimeter documents the dose received so that the process can be controlled to ensure that the product receives doses within regulatory requirements (dose range). Shining blue light on the irradiated dosimeter induces it to emit a red light (fluorescence). The intensity of the fluorescence is proportional to the dose that the food received.

A chemical dosimeter using a ferrous sulfate (Frike) solution was used by (21) to calibrate e-beam irradiation dose to different foodstuffs. The dosimeter uses the change in ultraviolet absorption caused by dose-dependent oxidation of ferrous to ferric ions. The homogeneity of the dose delivered to the products was verified with an ionizing chamber on a motor-driven scanning system.

The dose can also be predicted by various mathematical methods. Most of the research advances in dose distribution calculations has been in the area of radiation therapy. Although the application and practice of e-beam irradiation techniques vary from one industry to another, engineers tend to learn from each other. Thus, it is worth reviewing some of the radiation applications in the medical industry to learn how to improve the application of this technique to reduce pathogens in the US food chain.

One of the most important steps in radiation treatment planning process is the determination of radiation dose distribution in the body. There are two main methods for calculating the dose in the patient: measurement-based empirical methods and model-based methods (22). The empirical approach relies on experiments with dose measurements in a 'phantom' (a box filled with water). The measured dose is then slightly corrected to account for actual beam shape, patient shape, and density and composition of the body tissue. Measured-based methods are accurate if the beam shape is a simple square, the surface of material to be irradiated is flat and perpendicular to the beam, and the beam travels through homogeneous soft tissue. This method would not be accurate for a more complex 3D structure of foods since it does not adequately account for their inhomogeneity and the lack of secondary electron equilibrium in and around the typical food object.

The model-based methods are then generally used to estimate the dose in a body in radiation treatment planning. Monte Carlo technique is today the most accurate means of dose calculation. Monte Carlo transport simulates the behavior of irradiation particles as they interact with atoms in the body during a typical radiation treatment.

Simulation of radiation transport (electrons and photons) by the Monte Carlo method has been used to simulate radiation treatment machine heads, absorbed dose distribution, energy distributions, and electron-treatment planning (23).

As an example, Figures 124.5a,b show Monte Carlo simulation used to determine the dose distribution at the surface of an apple irradiated with e-beam generated by a Van de Graaff accelerator (1–2 MeV). The dose distribution was used to develop the best irradiation angle while rotating an irregularly shaped food material (the apple) for uniform surface irradiation.

V. CONCLUSIONS

We know that consumption of food contaminated with pathogens (*Salmonella* and *E. coli*, for example) causes serious foodborne illness and even death. Also, foods may be used as vehicles to deliver biological agents to cause disease. The security and safety of our food supply and agricultural production will continue to be topics of widespread international interest in the years to come. Consequently, efforts across the food industry to improve and implement measures to enhance assurances of food safety will always be needed.

Progress in electron beam accelerators will continue to further the development of efficient methods to ensure quality and safety of food products, especially those to be consumed raw or undercooked, to protect consumer health. Satisfactory irradiation of foods will be a common goal for producers, processors, government agencies, and consumers around the world. Advances in dosimetry methods in heterogeneous and irregular shaped materials such as foods will provide accurate, precise, and wide range dosimetry data for effective treatment planning of a wide number of food products.

125 Microwave Heating in Food Processing

Yi-Chung Fu
Department of Food Science, National Chung Hsing University

CONTENTS

I. INTRODUCTION

Microwave heating of food has existed since 1949. Growth in the number of homes with microwave ovens, combined with the industrial use of microwaves, has created a large market for microwave-processed foods and, consequently, has changed food preferences and preparation methods and increased the need for research on the behavior of various types of foods during microwave heating.

Using microwaves as a source of heat in the processing (thawing, heating, drying, etc.) of food materials is advantageous because it offers a potential for rapid heat penetration, reduced processing times, and, hence, increased production rates, more uniform heating, and improved nutrient retention. The use of microwaves represents the use of sophisticated technology in the food industry. Lack of sufficient and unified knowledge of this complex and radically different heating process has been the primary contributor to its unpredictability. Emphasis should be on basic research to better understand the interaction between the microwave energy and product. This chapter will provide fundamentals of microwave heating and description of microwave processes in the food industry.

II. MICROWAVE HEATING

The temperature of a material can be increased either directly or indirectly. The indirect methods are those in

which heat is generated external to the product and is transferred to it by conduction, convection, or radiation. The direct methods are those in which heat is generated within material itself. Dielectric heating is used with electrically non-conducting materials. The material to be heated is placed between two electrodes and forms the dielectric component of a capacitor. Excitation is by means of a high frequency voltage (2 to 100 MHz) applied to the condenser plates. Radio frequency heating, which is at a much lower frequency, has thrived as an industry alongside microwaves over the decades. Radio frequency heating in the United States can be performed at any of three frequencies: 13.56, 27.12, and 40.68 MHz. Microwave heating is a special field of dielectric heating in which very high frequencies (300 MHz to 30 GHz) are applied. Domestic microwave ovens operate at 2450 MHz and industrial processing systems generally use either 2450 MHz or 915 MHz (896 MHz in the UK). A domestic microwave oven is a multimode cavity in which electromagnetic waves form a resonant pattern.

As dielectric materials are poor heat conductors, heat applied from the outside by convection, radiation, or conduction is inefficient. In some cases the heat applied causes a skin or crust to form on the outside which is in itself a thermal barrier. The single most important thing about microwave heating is the unique opportunity to create heat within a material — the volumetric heating effect — not achievable by any other conventional means. No temperature differential is required to force heat into the center of the material. Generation of heat within food products by microwave energy is primarily caused by molecular friction attributed to the breaking of hydrogen bonds associated with water molecules and ionic migration of free salts in an electric field of rapidly changing polarity. Substances that respond to and, therefore, can be processed by microwave energy are composed of polar (e.g., water), ionic, or conductive (e.g., carbon black) compounds. Non-polar substances, e.g., polyethylene and paraffin, are unaffected.

III. DEFINITION OF TERMS AND PROPAGATION OF WAVES

James Clerk Maxwell (1831–1879) developed the classical theory of electromagnetism and correctly predicted that an electromagnetic wave has associated electric field E and magnetic field H. A uniform plane wave characterized by $E = a_x E_x$ propagating in a lossy medium in the +z-direction has associated with it a magnetic field $H = a_y H_y$. The solution to be considered here is that of a plane wave, which for the electric field attains the form

$$E(x) = E_{\max} e^{j\omega t - \gamma z} \tag{125.1}$$

A propagation constant, γ, is defined as

$$\gamma = jk_c = j\omega\sqrt{\mu\varepsilon_c} \tag{125.2}$$

with

$$\varepsilon_c = \varepsilon' - j\varepsilon'' = \varepsilon_0(\varepsilon_r' - j\varepsilon_r'') \tag{125.3}$$

$$\varepsilon_r' \equiv \varepsilon'/\varepsilon_0;\ \ \varepsilon_r'' \equiv \varepsilon''/\varepsilon_0 \tag{125.4}$$

where ε_0 is the permittivity of free space (8.8542E-12 Farad/m). Hence, all the previous equations for nonconducting media will apply to conducting media if ε is replaced by the complex permittivity ε_c. The material's ability to store electrical energy is represented by ε', and ε'' accounts for losses through energy dissipation. ε_r' is often called "relative dielectric constant." This is somewhat inappropriate, as the term "constant" should be used only for true constants. ε_r' varies significantly both with temperature and frequency for many typical workload substances. ε_r'' is called the relative dielectric loss incorporating all of the energy losses due to dielectric relaxation and ionic conduction. The ratio $\varepsilon''/\varepsilon'$ is called a loss tangent because it is a measure of the power loss in the medium:

$$\tan\delta_c = \frac{\varepsilon''}{\varepsilon'} \cong \frac{\sigma}{\omega\varepsilon} \tag{125.5}$$

The quantity δ_c may be called the loss angle.

The propagation factor $e^{-\gamma z}$ can be written as a product of two factors:

$$E(x) = E_{\max} e^{-\alpha z} e^{j(\omega t - \beta z)} \tag{125.6}$$

where α and β are the real and imaginary parts of γ, respectively. Since γ is complex, we write, with the help of Equation (125.3),

$$\gamma = \alpha + j\beta = j\omega\sqrt{\mu\varepsilon}\left(1 + \frac{\sigma}{j\omega\varepsilon}\right)^{1/2} = j\omega\sqrt{\mu\varepsilon'}\left(1 - j\frac{\varepsilon''}{\varepsilon'}\right)^{1/2} \tag{125.7}$$

$$\alpha = \frac{\sqrt{2}\pi f}{c}\sqrt{\varepsilon_r'\left(\sqrt{1 + \tan^2\delta} - 1\right)} \tag{125.8}$$

$$\beta = \frac{\sqrt{2}\pi f}{c}\sqrt{\varepsilon_r'\left(\sqrt{1 + \tan^2\delta} + 1\right)} \tag{125.9}$$

As we shall see, both α and β are positive quantities. The first factor, $e^{-\alpha z}$, decreases as z increase and thus is an attenuation factor, and α is called an attenuation constant. The second factor, $e^{-j\beta z}$, is a phase factor; β is called a phase constant which expresses the shift of phase of the propagating wave and is related to the wavelength of radiation in the medium (λ_m) by $\lambda_m = 2\pi/\beta$ which, in free space, reduces to $\lambda_0 = 2\pi/\beta = c_0/f$.

From Equation (125.6), the first exponential term gives the attenuation of the electric field, and, therefore, the

distribution of the dissipated or absorbed power in the homogeneous lossy material follows the exponential law (Lambert's Law):

$$P_{diss} = P_{trans} e^{-2\alpha z} \tag{125.10}$$

where P_{trans} is the power through the surface in the z direction. Theoretically, the power penetration depth, D_p, is defined as the depth below a large plane surface of the substance where the power density of a perpendicularly impinging, forward propagating plane electromagnetic wave has decayed by $1/e$ from the surface value, $1/e \approx 37\%$ [1]. The absorbed power in the top layer of this thickness in relation to the totally absorbed power (per surface area), is then 63%.

$$D_p = \frac{1}{2\alpha} \tag{125.11}$$

Substitution of Equation (125.8) into Equation (125.11) yields the general expression for the penetration depth:

$$D_p = \frac{c}{4\pi f}\sqrt{\frac{2}{\varepsilon_r'\left(\sqrt{1+\tan^2\delta}-1\right)}} = \frac{\lambda_0}{2\pi\sqrt{2\varepsilon_r'}\left(\sqrt{1+(\varepsilon_r''/\varepsilon_r')^2}-1\right)^{1/2}} \tag{125.12}$$

The skin depth D_s, where the electric field strength is reduced to $1/e$ (and the power density thus to $(1/e)^2$), is twice the power penetration depth, $D_s = 2D_p$.

IV. MICROWAVE POWER DISTRIBUTION

Most practical materials treated by microwave power are nonhomogeneous and very frequently anisotropic; the permittivity of these materials changes with temperature and moisture content (drying process). Thermal losses from the material surface and heat transfer in the bulk of material give additional complications. The generation of heat in food materials is also accompanied by significant moisture migration which, in turn, affects the energy absorption characteristics of food creating a coupling of heat and mass transport that complicates mathematical analysis.

From the physical point of view, microwave heating is a combination of at least four different processes: distribution of power, absorption of power, heat transfer, and mass transfer. The magnitude and uniformity of temperature distribution are affected by both food and oven factors such as:

1. Magnitude and distribution of microwave power where the food is placed;
2. Reflection of waves from the food surface and penetration depth, as characterized by the food geometry and properties;
3. Distribution of absorbed power as well as power dissipated at a particular point (electric field intensity) as functions of the material parameters, temperature, and time (due to drying); and
4. Simultaneous heat and mass transfer.

A. Electric Field Intensity

Electromagnetic waves transport energy through space. The amount of microwave energy absorbed is, in turn, determined by the electric field inside the microwave applicator. It offers an intangible link between the electromagnetic energy and the material to be treated.

For microwave heating, the governing energy equation includes volumetric heat generation that results in a temperature rise in the material:

$$\frac{\partial T}{\partial t} = \alpha\nabla^2 T + \frac{Q_{abs}}{\rho C_p} \tag{125.13}$$

In this equation Q_{abs} (watts/cm^3) corresponds to volumetric rate of internal energy generation due to dissipation of microwave energy. Basically, the apparatus is placed in the oven at the position of interest and the rate of temperature rise, $\partial T/\partial t$, is measured. C_p (cal/g °C) is the heat capacity of the material, and ρ (g/cm^3) is the density of the material. Assuming no temperature gradients in a small mass of dielectric medium, the energy balance can be obtained by simplifying Equation (125.13):

$$Q_{abs} = \frac{P_{abs}}{V} = \rho C_p \frac{\partial T}{\partial t} \tag{125.14}$$

where P_{abs} is the total power absorbed by the dielectric medium (watts). Its relationship to the E-field at the location can be derived from Maxwell's equations of electromagnetic waves [2].

$$Q_{abs} = 2\pi f\, \varepsilon_0 \varepsilon_{eff}'' E_{rms}^2 \tag{125.15}$$

where f is the microwave frequency (2450 MHz), ε_{eff}'' is the dielectric loss factor for the dielectric material being heated, and E_{rms} is the root mean square value of the electric field intensity. By knowing the rate of temperature rise, the heat generation, Q_{abs} can be determined and equated to the electric field, E_{rms}, using Equation (125.15).

$$E_{rms} = \sqrt{\frac{\rho C_p}{2\pi f\, \varepsilon_0 \varepsilon_{eff}''}\frac{\partial T}{\partial t}} \tag{125.16}$$

B. Lambert's Law

In several computational studies of microwave heating, the heat generation has been modeled by Lambert's law, according to which the microwave power is attenuated exponentially as a function of distance of penetration into the sample [3–9]. It must be emphasized that these penetration depth

calculations are valid only for materials undergoing plane wave incidence and for semi-infinite media only and henceforth will be referred to as Lambert's law limit [5, 8]. Although Lambert's law is valid for samples thick enough to be treated as infinitely thick, it is a poor approximation in many practical situations and often does not describe accurately the microwave heating of food in a cavity.

To determine the conditions of the approximate applicability of Lambert's law for finite slabs, Ayappa and others [8, 9] compared it with microwave heating predicted by Maxwell's equation. The critical slab thickness L_{crit} (in cm) above which the Lambert's law limit is valid can be estimated from $L_{crit} = 2.7/D_p - 0.08$. Fu and Metaxas [10] proposed a new definition for the power penetration depth Δ_p, which is the depth at which the power absorbed by the material is reduced to $(1 - 1/e)$ of the total power absorbed. This definition allows a unique value of Δ_p to be found for all thickness and also gives an indication of the validity of assuming exponential decay within the slab. Another approach is used where a spherical dielectric load is assumed to absorb energy from a surrounding radiation field [11]. The power absorption inside of dielectric medium can be estimated in the following way. Assume that the power flux (power per unit area) entering through the surface of the dielectric medium is uniform, and all the waves are transmitted into the medium, i.e., no wave reflection. Then power decays exponentially, $P(x) = P_0 \cdot \exp(-x/D_p)$ where, P_0 is the incident power at the surface. From the Poynting theorem [12], the field energy that dissipates as heat in the enclosed volume is equal to the total power flowing into a closed surface minus the total power flowing out of the same closed surface.

$$\sum P_{eff} = \int \frac{P_0 e^{-x/D_p}}{D_p}\, dx = -P_0\left[\int_0^a \frac{e^{-(a-r)/D_p}}{D_p}\, d(a-r) - \int_0^{-a} \frac{e^{-(a-r)/D_p}}{D_p}\, d(a-r)\right] \quad (125.17)$$

$$P_{abs} = \sum P_{eff} = P_0[1 - e^{-2a/D_p}] \quad (125.18)$$

where a is the radius of the spherical dielectric load, P_{eff} is the effective magnitude of the Poynting vector, and P_{abs} is the total power absorption by the dielectric medium. The use of Lambert's law requires an estimate of the transmitted power intensity P_{trans} (Equation (125.10)), which is obtained from calorimetric measurements [4, 7] or used as an adjustable parameter to match experimental temperature profiles with model predictions [6]. Thus P_{trans} measured by the above methods represents the intensity of transmitted radiation, the accuracy of the estimate depending on the method used. Alternately if P_{trans} is the incident power flux then Lambert's law must be modified to account for the decrease in power, due to reflection at the surface of the sample.

Since Lambert's law does not yield a comprehensive approach, a more accurate estimation of the heating rate based on predicting or measuring the fundamentally nonuniform electric field intensity in a cavity should be the most important subject of current research. How the shape and volume (relative to the microwave oven) of a food material change the rate of heating must be investigated further. The interior electric field, the moisture movement in solid foods, and changes in the dielectric and other properties combined to make designing microwave processes a difficult task.

V. INTERACTION OF MICROWAVE WITH FOOD

Food shape, volume, surface area, and composition are critical factors in microwave heating. These factors can affect the amount and spatial pattern of absorbed energy, leading to effects such as corner and edge overheating, focusing, and resonance. Composition, in particular moisture and salt percentages, has a much greater influence on microwave processing than in conventional processing, due to its influence on dielectric properties. Interference from side effects like surface cooling, interior burning, steam distillation of volatiles, and short cook time alter the extent of interactions.

A. Dielectric Properties

The dielectric properties of foods are very important in describing the way foods are heated by microwaves. The most comprehensive effort on dielectric properties data to date being that of von Hippel [13]. The dielectric properties of foods vary considerably with composition, changing with variation in water, fat, carbohydrate, protein, and mineral content [14]. Dielectric properties also vary with temperature. As indicated earlier, the dielectric properties affect the depth to which microwave energy penetrates into the food to be dissipated as heat. The magnitude of the penetration depth, defined as the depth at which 63% of the energy is dissipated, can be used quantitatively to describe how microwave energy interacts with the food. A large penetration depth indicates that energy is poorly absorbed, whilst a small penetration depth indicates predominantly surface heating.

Dielectric properties data for agricultural products, biological substances, and various materials for microwave processing are widely dispersed in the technical literature [15–18]. Those literature data can provide guidelines, but variability of composition of food products, and other specific conditions for particular applications, often require carefully conducted measurements.

B. Geometrical Heating Effects — Corner, Edge, and Focusing Effects

With conventional cooking methods, heat is transferred from outside to the food product by conduction, convection, or infrared radiation. There is a temperature gradient from the outside to the inside. It is often said that with microwaving, heating takes place from the inside to the outside. This is not true; heating occurs throughout the whole food simultaneously, although it may not be evenly distributed. Probably this misapprehension is due to the fact that surface temperatures tend to be lower than temperatures inside the food (this is because of evaporative cooling and geometrical heating effect). For foods with a high loss factor, most of the microwave energy of a wave impinging on the food will be absorbed near the surface, and penetration and in-depth heating will be limited. In general, the surface will heat more rapidly than the interior, but there are exceptions. Refraction and reflection at interfaces will cause reinforcement of the field pattern near corners and edges of rectangularly shaped foods, resulting in overheating. Core heating effects of the same nature occur in foods of spherical or cylindrical shape at certain dimensions, causing energy concentration and overheating of the central part.

The concentration heating effect means maximum heating occurs in the center for certain spherical and cylindrical geometries [19]. The well-known explosion of eggs during microwave heating is one of the most significant demonstrations of core heating effect. This occurs because center heating cause formation of steam which induces an energy impulse with such high power as to move the surrounding mass parts away from each other. This kind of thermal behavior has already been observed by many people [3, 6, 19, 20] for cylindrical and spherical shaped foods. The maximum heating regions also move slowly from the center towards the surface when the diameter increases. If the diameter is much greater than penetration depth, the temperature profile will be similar to that observed for a "semi-infinite" body. That is, the temperature decreases exponentially from the surface in accordance to Lambert's law which governs the absorption of microwave power. If the diameter is much less than penetration depth, the heating profile will be flat. In between these extremes the focusing effect occurs. Moreover, Mudgett [3] pointed out the effect of salt on drying behavior. With addition of sodium chloride, penetration depth decreases significantly and, therefore, the heating profile could shift from that of focusing and center heating to one of surface heating.

Another reason for uneven heating in lossy products can be traced to the electromagnetic boundary conditions at edges and corners [21]. This is the so called edge and corner effects. In an electric field, where the wavelength is larger than the dimensions of the heated object, field bending will give rise to concentrations at some locations. The convergence of two or more waves at a corner results in a higher volumetric power density than on the flat surface. Higher heating rates will thus be obtained at the corners. If the electric field is strong enough, an arc may emanate from there when the air ionizes [22]. Square containers can cause burning in the corners of the product due to a greater surface area/volume ratio, resulting in more microwave energy absorption. Circular or oval containers help reduce the strong edge and corner effects as energy absorption occurs evenly around the edge but core heating effects may then originate.

C. Microwave Bumping

Another phenomenon during microwave heating is the "bumping" which may occur in microwave cooking. The term, "microwave bumping," also known as microwave popping or microwave splattering, is descriptive of the explosion phenomenon and is characterized by a jostling or shaking of the container, usually accompanied by an audible explosion. When microwave bumping occurs, the explosive sounds which can be heard some distance away are annoying and an unexpected surprise to consumers. Microwave bumping is due to the explosion of food particulates, not localized boiling of the liquid. Increasing the viscosity of the liquid did not result in a significant difference in intensity or frequency of bumping. Degree of microwave bumping is believed to be directly related to local superheating effects. The higher the electric field intensity, the greater the incidence of bumping. Due to edge, corner, and focus heating effects by microwave, container shape influences heating pattern of a food product and location of bumping in the container. Sterilizing vegetable particulates which causes excessive softening and salting food particulates which causes high microwave heating rate are two indispensable conditions to produce microwave bumping [23].

D. Evaporative Cooling and Steam Distillation

During the heating process of foods containing water, the resulting evaporation at the surface causes a depression of the temperature, known as evaporative cooling. The surface of food is seen to be cooler than the region just below the surface and warmer than the surrounding air. This phenomenon is readily seen during the cooking of a meat roast [6, 24].

At the same time, this surface evaporation can cause steam distillation of certain flavor components. Flavor release in microwave cooking is increased by steam distillation. In microwave heating, water vapor (steam) is one of the most important transport mechanisms contributing to movement of flavor compounds within a food matrix.

Individual compounds that make up a flavor which are particularly low molecular weight and water-soluble may be driven off or steam distilled out of the product during microwave heating. Fruit and other "sweet" flavorings are more of a problem. They evaporate easily in foods with high initial water content because they contain a great number of short-chain, volatile flavoring substances. Moreover, they are often of a more hydrophilic character and therefore a great part of the flavoring substances migrates to the aqueous phase of the food, which selectively absorbs the great part of microwave energy [25]. The percent loss may range from less than 10% for high boiling compounds to 95% for very volatile compounds [26]. The latter are the ones that create a strong aroma which is necessary when the flavor is designed to impart a balanced aroma profile in the room during microwave heating [27]. In this case the flavor was added solely for aroma generation and contributed very little to the flavor profile of the microwave product itself. However, this phenomenon, flash-off, often leads to imbalance of flavor concentrations in a finished product with a different character from the flavor that was added before cooking. Formulations that compensate for flash-off may require a highly imbalanced flavor character prior to microwaving. The specific loss is dependent on the types of flavor components used and the food system in which it is incorporated. As the outward migration of water vapor is the most important factor influencing flavor retention in the food product, the flavorings used for microwave application should have low water vapor volatility unless the flavorings are intended to create the "oven aroma" of conventional cooking methods, or to cover undesirable off-notes released during microwave cooking.

E. Lack of Crispness (Texture) and Browning (Color, Flavor) of Microwave Foods

The texture of a microwaveable food may directly affect its acceptance. Toughness or lack of crispness in bread slightly overcooked in a microwave oven may not directly change its flavor, but does influence the consumer's perception of the product. The lack of conventional-styled browning and crisping in microwave ovens is due to the microwave frequency used. At 2450 MHz, the wavelength, 12.2 cm, is too long to create the intense surface heat which occurs at the higher infrared frequencies, limiting the food item to a temperature of approximately 100°C. This is ideal for wet foods like vegetables and stews, but unacceptable for pastry, breaded or batter-coated items, and roast meat. In contrast to the convectively heated food, we have relatively low temperature ambient air (60–75°C) with a rather high relative humidity in most cases during microwave heating. The level of maximum temperature and consequently of maximum water vapor pressure generally lies further below the surface. The main driving force, therefore, is directed towards the surface instead of towards the center [28, 29]. Water vapor generated inside the food continuously migrates to the surface, drawing flavoring substances with it on the way out. As the evaporation rate of water is not high enough to dry out the surface, the evaporated water is continuously replaced by migration of water from the inside [25]. For foods which require a long heating time, e.g., meat joints, the effect can be significant and the resulting moisture loss from the surface of the product can be appreciable. An electromagnetic phenomenon creating "hot" and "cold" spots is inherent in all microwave ovens and is responsible for much of the uneven cooking associated with them. Liquid products quickly dissipate the microwave energy and result in a more uniform product. Solid food products, multiphase systems, or frozen products develop hot and cold spots during heating which further complicate flavor delivery in these systems [27].

During microwave heating the low surface temperature and its much higher water activity (approximately 1.0) and the lack of prolonged baking time have the following consequences: (1) no crust is formed because the necessary physical changes (protein denaturation, starch gelatinization, etc.) are inhibited, and (2) the formation of many flavor compounds and/or pigments (Maillard browning reactions) do not occur to the required extent. Thus, some flavors that typically develop in a conventionally cooked product will not necessarily work in a microwaved product. Van Eijk [25] stated that the differences in flavor generation and the performance of flavoring substances in microwave foods can be explained satisfactorily by the differences in heating pattern, the corresponding differences in water vapor migration, and the resulting physical changes, particularly at the surface of the food. No athermal effects have been observed.

F. Food Ingredients

Some of the ingredients in foods such as water, ionized salts, and fats and oils, in particular, and the distribution of these ingredients in the food product, exert a strong influence on temperature level and distribution. These ingredients interact physically and chemically to an extent dictated by numerous factors including mode of heating.

The dielectric and thermal properties of foods can be modified by adjusting food ingredients and formulations and are manageable within certain limits. Frozen pure water has no microwave dipole relaxation and is therefore microwave transparent. Frozen foods, however, are not microwave transparent since some of the water is still in free liquid form. So when deep-frozen foods are defrosted by microwave energy, particularly difficult problems arise once both ice and water are present. Hot spots and runaway heating may be the consequence in this case. Fats have a low dielectric loss and consequently do not generate as much heat directly from the microwave field. Once

heat has been generated, conduction and convection become the main mechanisms of heat transfer. Fats reach very high temperatures due to their high boiling points, whereas water is limited to a maximum temperature of 100°C. However, since the heat capacity of fats is about half that of water, they heat more quickly in the microwave.

Factors that affect dielectric properties of water, including the presence of other interactive constituents such as hydrogen bonding resulting due to the presence of glycerol and propylene glycol, and sugar and carbohydrate-like polyhydroxy materials will also impact microwave heating [30]. Salts and sugars can be used to modify the browning and crisping of food surface. Heating a sample with higher salt content can change the microwave heating pattern from center heating to surface heating [31]. In addition to direct microwave interactions, lipids, salts, sugar, and polyhydroxy alcohols can also raise the boiling point of water. This allows the food to reach a higher temperature needed for the development of reaction flavors, and Maillard browning reactions.

To obtain useful and meaningful information on the contributions of rates of flavor migration and kinetics of degradation under various conditions, Fu and others [32] designed an apparatus for on-line measurement of flavor concentration, to formulate a thermally stable flavor-dough system and to accomplish isothermal heating. Photoionization detection method [33] and a cold-trap, on-line sampling method [34] were to investigate migration of flavor compounds in a solid food matrix subjected to microwave heating. As the moisture concentration decreased below 0.1 g water/g solid during microwave heating of gelatinized flour dough, a type of encapsulation occurred that prevented flavor from being released. The results of microwave reheating of limonene-formulated dough showed limonene is very stable and no significant limonene concentration profile in the sample and less than 1% overall change in total limonene concentration [35].

VI. MICROWAVE PROCESSING

In the quest for better quality of shelf-stable, low-acid foods, a number of emerging technologies have been considered [36]. Food engineering will continue to evolve. Although alternative processes have been developed over the years, thermally processed food products maintain a clear dominance in the marketplace, primarily as a result of the wealth of theoretical and empirical knowledge that has been developed regarding thermal inactivation of pathogenic microorganisms and their spores [37]. Microwave sterilization is a nontraditional but solely a thermal process and so can be regarded by technologist and regulators as another terminal thermal sterilization technique.

Microwave heating offers numerous advantages in productivity over conventional heating methods such as hot air, steam, etc. These advantages include high speed, selective energy absorption, excellent energy penetration, instantaneous electronic control, high efficiency and speed, and environmentally clean processes [38]. Currently, microwave and radio-frequency both are laboratory or pilot scale and there are no known large operating microwave systems operating in the food industry, except for bacon precooking or tempering. It remains a very exciting processing tool, unmatched by any other technology if attention is paid to their selection.

A. Drying and Dehydration

Microwave drying is rapid, more uniform, and energy efficient compared to conventional hot air drying and sometimes it results in an improvement in product quality. But it is highly unlikely that an economic advantage will be demonstrated if only bulk water removal by microwave heating is desired, such as occurs in the constant-rate region [39]. During the falling-rate period because of the low thermal conductivity and evaporative cooling effect, high product temperatures are not easily obtained using convective drying. Surface hardening and thermal gradients again provide further resistances for moisture transfer. Actually, it has been suggested that microwave energy should be applied in the falling rate period or at low moisture content for finish drying [40–43]. Correspondingly sensory and nutritional damage caused by long drying times or high surface temperatures can be prevented. It is important to understand the dielectric properties of the material with different moisture content during microwave drying. The ability of dielectric heating to heat selectively areas with higher dielectric loss factors and the potential for automatic moisture leveling afford a major advantage for even drying of these types of materials [39].

Because internal microwave heating facilitated a more predominant vapor migration from the interior of the material as compared to that during conventional drying, microwave dried products have been reported to show a higher porosity because of the puffing effect caused by internal vapor generation [44–46]. Similar results are also found for pasta drying. Microwave drying produces a slightly puffed, porous noodle which rehydrates in half the time required for noodles dried by conventional methods [47]. Tong and others [44] investigated temperature and pressure distribution in a dough system with porosity ranging from 0.01 to 0.7 during microwave heating using miniature fiber optic temperature and pressure probes. Pressure build-up to approximately 14 kPa occurred during the initial stages of the heating process when the initial porosity was less than 0.15 and disappeared when the pressure exceeded the rupture strength of the dough. Volume expansion was observed up to the point where the dough sample ruptured, producing visible cracks in the structure. So microwaves produce a pressure gradient that pumps out the moisture [44]. This property can be used to

advantage to speed up the drying process. If the pressure build-up did not exceed the rupture strength of the structure it might be the result of such enhanced porous structure of the samples. So, it is a difficult task for reducing drying time and increasing quality at the same time. Careful studies need to be done by applying the right amount of microwave energy in the process.

Nonuniformities in the microwave electric field and associated heating patterns can lead to high temperature in various regions dried earlier, causing product degradation [48]. Improvement can be achieved by using a fluidized bed dryer, or spouted bed dryers to average the uneven electric field [49, 50]. The combination of microwave and vacuum drying [51–54] or freeze drying [55–59] also has a certain potential. The vacuum process opens the cell structures (puffing) due to the fast evaporation and an open pore structure is generated. Reduced drying time is the primary advantage of using microwaves in the freeze-drying process. But no commercial industrial application can be found, due to high costs and a small market for freeze dried food products.

Pasta and potato chips have been dried successfully. Freeze drying and vacuum drying, in conjunction with microwave energy, have also shown promise and interest from an academic point of view but not meeting the economic criteria. A relative new and successful combination of microwave energy and frying process is used to produce fried goods, such as chips, noodles, and chickens, with 60% reduced time, 50% reduced fat content, and 33–60% energy saving [60].

B. Pasteurization and Sterilization

Pasteurization provides a partial sterilization of substances by inactivating pathogenic microorganisms, notably vegetative cells of bacteria, yeast, or molds. Products have to be refrigerated. Sterilization processes are designed to inactivate microorganisms or their spores. Thermal sterilization is usually done at temperatures in excess of 100°C which means they are usually done under pressure. Industrial microwave pasteurization and sterilization systems have been reported on and off for over 30 years [61–68]. Studies with implications for commercial pasteurization and sterilization have also appeared for many years [69–77]. Early operational systems include batch processing of yogurt in cups [78] and continuous processing of milk [79]. A very significant body of knowledge has been developed related to these processes. As of this writing, two commercial systems worldwide could be located that currently perform microwave pasteurization and/or sterilization of foods [68, 80]. As a specific example, Tops Foods (Belgium) [68] produced over 13 million ready meals in 1998 and have installed a newly designed system in 1999.

Microwave pasteurization can reduce the come-up time, which can shorten to a small fraction of the time used by the conventional process. After this, the microwave heated meals pass into a nonmicrowave hot air tunnel for the hold-time period, and then to the cooler. Microwave is difficult to hold a constant temperature and should not be used. Especially in Europe, food pasteurization by microwave processing has been successfully accomplished for decades. The major advantage of the microwave process is that the product may be pasteurized within a package. A product goes through the line in wrapping continually, package by package, pallet by pallet. Shelf life can be extended from days to over a month without preservatives.

Typical sterilization temperatures in the product may be 121–129°C (250–265°F) with hold times of 20–40 minutes. The come-up time may be significantly reduced by microwaves. This reduced come-up time would provide greater product quality. The enhanced quality retention is due to the fact that quality attributes normally have much lower activation energy (10–40 kcal/mol) than the microbial spores (50–95 kcal/mol). The heat-up time of the microwave process is much faster than that in a retort, so the product's organoleptic (texture, color, and flavor) and nutritional qualities could be considerably improved. Microwave sterilization is more flexible than ohmic heating and aseptic processing. It can sterilize liquids, semi-solid, and solids and it can also sterilize pre-packed food products.

There are several practical concerns and problems that have to be solved before it can be applied at the industrial level. The main issue has been the regulation of process parameters so that commercial sterility can be achieved. For the conventional retort process, by monitoring the time-temperature history at the cold point using a thermocouple thermometer, it is reasonably easy and accurate to determine the microbial lethality through mathematic calculations. But, determining the microbial lethality for a microwave sterilization process is not straightforward. The cold point during microwave sterilization is not always located on the central axis. The problem of providing a uniformly heated product makes it extremely time-consuming and costly to adjust the microwave pattern to produce the quality advantage theoretically possible by using microwaves. Each product could require custom adjustment. The presence of uneven heating (hot and cold spots) makes it very difficult to ensure that all portions of a meal have reached a kill temperature. Microbiological safety is the major reason for the slow acceptance of microwave sterilization. In addition, the technical ability to accurately measure the temperature distribution throughout an entire microwave sterilized product has not been demonstrated. From the engineering point of view, no computer simulation models are available for investigating the feasibility of microwave sterilization. These computer simulation models are not only required by the Food and Drug Administration (FDA) for regulating and

approving microwave sterilization processes, but also highly demanded by the food industry for performing the cost/ benefit analyses. Without the reliable inputs of dielectric properties, thermophysical properties, and boundary conditions, a computer model is completely useless. Unfortunately, literature values on these properties are only available at room temperature to 60°C and not readily available at sterilization temperature.

In Europe, microwave-sterilized foods, primarily pasta dishes such as lasagna and ravioli, are on many grocery shelves with no reported difficulties. Safety regulations are less stringent in Europe. For example, in one implementation [68] the process design consists of microwave tunnels with several launchers in relation to the number of products (ready meals). Microwave-transparent and heat-resistant trays are used with shapes adapted for microwave heating. Exact positioning of the package is made within the tunnel and the package receives a pre-calculated, spatially varying microwave power profile optimized for that package. The process consists of heating, holding, and cooling in pressurized tunnels. The entire operation is highly automated. But, microwave sterilization has not been approved on the use of microwave processing for food sterilization by the Food and Drug Administration in the United States (US-FDA). Today, there continues to be a great deal of interest and some R&D activity in pasteurization and sterilization by microwaves [81–88].

C. Tempering and Thawing

Thawing and tempering of frozen food materials is an important part of some food processes, especially in the meat industry and food service. Reducing thawing time by higher temperatures results in a decrease in product quality such as more dip loss and surface drying in addition to increased risk of microbial growth.

Frozen foods can be considered to be the mixture containing two components: fixed structure of ice and biological material surrounded by monomolecular layer of strongly bound water, and loose liquid water saturated with dissolved salts. Dielectric activity of this mixture is much higher than that of pure ice, but much less than that of the same material at temperatures above zero. The loss factor (ε'') of water is approximately 12; while that of ice is approximately 0.003. The penetration depth in water (1.4 cm) is much lower than in ice (1160 cm) [89]. If the thickness values is much greater than penetration depth, the temperature profile will be similar to that observed for a "semi-infinite" body. That is, the temperature decreases exponentially from the surface in accordance to Lambert's law. Surface layers thus absorb more energy and heat up a little bit faster than the inside of the product. But for thickness values smaller than a certain value, resonance can still not be avoided and inside of a slab can be heated directly at high intensity, resulting in quick thawing. As the loss factor increases with the temperature, the surface heats up faster and faster and the penetration depth continually decreases. Spots of free water and spots that have reached temperature 0°C absorb more energy than crystals of ice, which leads to further acceleration of heating.

Microwave energy penetrates a food material and produces heat internally. The main advantage consists of speed because tempering by microwave takes minutes instead of hours or even dozens of hours. For example, a 20 cm thick piece of beef, frozen to −16°C, thaws more than 10 hours at the surrounding temperature of +4°C. On the other hand, the whole cycle of MW tempering with following slicing, modification, and repeated freezing takes only 30 minutes [90]. There are at least 400 tempering systems operating in the United States alone. Food is heated to just under freezing temperatures, allowing easy chopping, cutting, processing, etc. In the United Kingdom there are several large systems, up to 200 kW, utilized for tempering of frozen beef, as well as butter. The lower frequencies, e.g., 915 MHz band, are used to advantage for MW thawing and tempering of larger blocks of food. For example, when tempering 18 cm thick blocks at 915 MHz frequency, temperature gradient is half of the gradient for 2450 MHz frequency [90]. 915 MHz tempering systems, batch and continuous, are sold worldwide.

Microwave thawing remains a major problem. A main difficulty is formation of wide temperature gradients (run-away heating) within the product. The preferential absorption of microwaves by liquid water over ice is a major cause for run-away heating. Maximum homogeneity is achieved with temperatures slightly above zero. After that the inhomogeneity rises again. Therefore it is advantageous to reduce the thawing process to plain tempering, i.e., to stop the heating at the temperatures −5 to −2°C. Another reason why tempering is preferred is that the progress of energy consumption is dependent on the temperature. With most biological materials and water, the energy consumption starts to rise sharply at temperatures above −5°C; the less fat they contain the higher is the consumption. Since the thawed material has a much higher dielectric loss, microwave penetration depth at the surface is significantly reduced, in effect developing a "shield." Surface cooling helps to reduce the gradient in a frozen food, thus enabling the microwave power to remain on longer to decrease the thawing time. The temperature uniformity during microwave thawing can be improved when appropriate sample thickness, microwave power level, frequency, and/or surface cooling are applied [64, 91–93]. Today, there continues to be a great deal of interest and some R&D activity in thawing and tempering by microwaves [94–97].

D. Baking

Baking, in all cases except unleavened products, involves the creation, expansion, and setting of edible foams through

the use of heat. Proofing is the step of causing the dough to rise and precedes the final baking or frying in the case of donuts. During the baking of raw bread dough significant volume change occurs, and the dough is converted from a viscoelastic material containing airtight gas cells with the ability to expand to a rigid structure which is highly permeable to gas flow. The cell walls are elastic but strong and the increasing gas pressure must cease while the cell walls set. Baking is a complex physicochemical reaction in which all the events must be carefully timed and must occur in a well-defined sequence. All baked products form some sort of crust which acts as a shield, making heat even harder to reach the inside. The heat transfer problems encountered by conventional means can be easily overcome by microwave heating. Pei [98] reviewed heat and mass transfer in the bread baking process and discussed the application of microwave energy. Goedeken [99] investigated microwave baking of bread dough with simultaneous heat and mass transfer. Highly porous products, such as bread, lend themselves well to the use of microwave energy because of greater penetration of microwave energy resulting in more uniform energy distribution within the product. But the microwave application must be carefully controlled or heating and expansion will occur too quickly, and while the cake may look fully expanded and baked, it will collapse to a pancake when the microwave energy is removed.

Bread baking by means of microwave energy was first reported in the literature by Fetty [100]. Decareau [101] noted the possibility of combining microwave energy and hot air to produce typically brown and crusted loaves of bread in a shorter time than by conventional baking methods. One microwave baking process that was quite successful for several years was the microwave frying of doughnuts. Frying times of approximately two-thirds normal time are possible with 20% larger volumes, or 20% less doughnut mix required for standard volume. Fat absorption can be 25% lower than conventional. This proofing system was developed by DCA Food Industries, which operated 2450 MHz and varied in output from 2.5 to 10 kW for production rates of 400–1500 dozen doughnuts per hour [102–104]. One difficulty in the microwave baking process was to find a microwavable baking pan that is sufficiently heat resistant and not too expensive for commercial use. A patent by Schiffmann and others [105] describes microwave proofing and baking of bread in metal pans. This technique utilizes partial proofing in a conventional proofing followed by proofing in a microwave proofer utilizing warm, humidity-controlled air and reduces the proofing time by 30–40%. This was then followed by microwave baking in a separate oven. Four patents by Schiffmann and others [104–107] describe procedures for the baking of bread utilizing metal pans and, in some cases, also provided for partial proofing of the bread in the pans. In the procedure described in the aforementioned patents, the microwave baking process involved the simultaneous application of microwave energy and hot air to both bake and brown the bread, producing thoroughly browned and crusted loaves of comparable volume, gain structure, and organoleptic properties. It was found that the use of either 915 MHz or combinations of 915 and 2450 MHz were quite effective in baking a loaf of bread. The system of microwave frying doughnuts was very successful for quite some time during the 1970s. These doughnuts have longer shelf life, better sugar stability, and excellent eating quality. The larger volume and lower fat absorption provided high profits for the bakery.

To date, some very sophisticated packaging along with advanced susceptor technology has been the predominant solution to the lack of conventional-styled browning and crisping. Susceptors rapidly heat to temperatures where browning readily occurs and thus help produce flavor in the product. However, susceptors solve the flavor-related problems only on the surface. Another possible solution to the lack of browning during microwave cooking is the addition of compounds which give a roasted or toasted reaction flavor. Today, there continues to be a great deal of interest and some R&D activity in baking by microwaves [108–115].

VII. RADIO FREQUENCY PROCESSING

Radio frequency and microwave heating refers to the use of electromagnetic waves of certain frequencies to generate heat in a material [2, 116, 117]. Radio frequency heating, which is at a much lower frequency, has thrived as an industry alongside microwaves over the decades. Radio frequency heating in the United States can be performed at any of three frequencies: 13.56, 27.12, and 40.68 MHz. The heating mechanism of radio frequencies is simply resistance heating which is similar to ohmic heating. This lossy dielectric arises from the electrical conductivity of the food and is different from the resonant dipolar rotation of microwave frequencies.

Unlike microwave sources, one cannot purchase an RF high power source. Due to the high impedance nature of RF coupling, the RF source and applicator normally need to be designed and built together. Manufacturers of RF equipment develop the whole system, rather than only the power source. Therefore, developments in RF processing must involve the commercial RF manufacturers. RF equipment is available commercially at much higher power levels than microwave sources. While commercial microwave sources are available only below 75 kW, RF equipments at hundreds of kW are very common. At these high levels, the price per watt of RF equipment is much cheaper than microwaves. In addition to higher power and lower cost, another advantage of RF equipment over microwaves is in the control area. In high power RF systems, the source and the load are commonly locked together in a feedback circuit. Therefore, variations in the load can be followed by the source without external controls [118].

Microwave or radio frequency? For the same electric field, the higher the frequency, the higher the amount of power into the material. This is the reason why microwaves are a conceptually more effective means of heating. However, RF equipment has several advantages which workers in the field of microwave processing may find more suitable for scale-up of some processes. The microwave fields attenuate within the bulk of conductive materials and materials with high dielectric loss. The penetration depth of microwaves is much lower. This is particularly troublesome for larger scale processes. But, this type of nonuniformities are frequency dependent and become less severe as frequency is lowered. Because of much longer wavelengths of radio frequencies, they have better uniformity. Also, the depth of penetration is much higher. So, in cases where uniformity of heating is a critical issue, use of the radio frequencies and 915 MHz microwave frequency may have potential for the future [119, 120].

Working at radio frequencies allows it to process a large range of material types, from the thin wide webs of the paper industry to large three-dimensional objects like textile packages. In general terms, microwave is better for irregular shapes and small dimensions and RF is better for regular shapes and large dimensions. Microwave is more suitable for hard to heat dielectrics. Actually, many applications can be done by either, but RF is cheaper if it fits. RF equipment is easier to engineer into process lines, and can be made to match the physical dimensions of the up- and down-stream plant. In the case of microwaves, in a continuous process, complex arrangements may be necessary to allow the product to move in and out of the enclosure without giving rise to excessive leakage of energy [121]. This is because the wavelengths at microwave frequencies (e.g., 12.54 cm at 2450 MHz) are very much shorter than those at radio frequencies (e.g., 1100 cm at 27.12 MHz).

An overview of food and chemical processing uses of radio frequency can be seen in Minett and Witt [122] and Kasevich [123]. The industrial applications using radio frequency include textiles (drying of yarn packages, webs, and fabrics), food (bulk-drying of grains; moisture removal and moisture leveling in finished food products), pharmaceutical (moisture removal in tablet and capsule production processes), and woodworking (adhesive curing for wood joinery). Radio frequency heating has been used in the food processing industry for many decades. The post-baking of biscuits, crackers, and snack foods is one of the most accepted and widely used applications of RF heating in the food processing industry. A relative small RF unit can be incorporated directly into a new or existing oven line (a hot air oven or conventional baking line) to increase the line's productivity and its ability to process a greater range of products. The benefits of RF-assisted baking are precise moisture control, reduced checking, improved color control, and increased oven line throughput [124]. RF drying is intrinsically self-leveling, with more energy being dissipated in wetter regions than in drier ones [121]. This RF leveling leads to improvements in product quality and more consistent final products. Recently, RF cooking equipment for pumpable foods has been developed. These devices involve pumping a food through a plastic tube placed between two electrodes, shaped to give a uniform heating [125]. The primary advantage of improved uniformity of heating was also shown for in-package sterilization of foods in large packages using radio frequency at 27.12 MHz, although enhanced edge heating continued to be an issue [120]. Defrosting of frozen food using RF was a major application, but problems of uniformity with foods of mixed composition limited the actual use. The interest in RF defrosting has increased again in the last number of years [125].

Today, the use of a more recent 50 Ω RF heating equipment which allows the RF generator to be placed at a convenient location away from the RF applicator gives the possibility of an advanced process control [126]. Whether conventional or 50 Ω dielectric heating systems are used, the RF applicator has to be designed for the particular product being heated or dried. RF post-baking, RF-assisted baking, and RF meat and fish defrosting systems will continue to benefit both existing and emerging food applications and the availability of low cost RF power sources could lead to a major growth in the use of RF heating in the commercial food sectors.

RF heating is well established in industry and, for many applications, it is the standard method. Its equipment is well proven and also reliable. It is an excellent choice where it fits.

VIII. CONCLUSION

The fundamentals of microwave heating should be studied in depth before spending a great deal of effort and time on trial and errors.

Microwave and radio frequency heating all provide a product that is potentially superior in quality to the product produced by conventional techniques. This point is key to almost all industrial processes. The potential synergistic effects of microwaves combined with steam, forced-air convection, and/or infrared will probably lead the future expansion of microwave processing technology.

Microwaves are an extremely expensive way to evaporate water as compared to frying, high-velocity hot air, or infrared. They can be commercially successful if the products are of high intrinsic economic value and can carry the extra cost burden put on them.

126 Pulsed Electric Field in Food Processing and Preservation

Paul Takhistov
Rutgers University

CONTENTS

Pulsed electric field (PEF) processing is a non-thermal method used to maintain food safety and increase shelf life of foods by inactivating spoilage and pathogenic microorganisms. Many researchers have investigated this problem, including Sale and Hamilton (82, 83), Mizuno and Hori (64), Jayaram *et al.* (36), Qin *et al.* (75), and Pothakmury *et al.* (71). PEF processing is advantageous over other methods because the changes in product color, flavor, and nutritive value during the treatment are minimized (19, 40–42). A high intensity pulsed electric field processing involves the application of pulses of high voltage (typically 20–80 kV/cm) to foods placed between two electrodes. PEF treatment is conducted at ambient, sub-ambient, or slightly above ambient temperatures for less than 1 s, and energy loss due to heating of foods is minimized. For food quality attributes, PEF technology is considered superior to traditional heat treatment of foods because it avoids or greatly reduces the detrimental changes of the sensory and physical properties of foods (78). Although some studies have concluded that PEF preserves the nutritional components of foods, effects of PEF on the chemical and nutritional aspects of foods must be better understood before PEF can be used in food processing (74).

Some important aspects in pulsed electric field technology are the generation of high electric field intensities, the design of chambers that impart uniform treatment to foods with minimum increase in temperature, and the design of electrodes that minimize the effect of electrolysis. The large field intensities are achieved through storing a large amount of energy in a capacitor bank (a series of capacitors) from a DC power supply, which is then discharged in the form of high voltage pulses (108). Studies on energy requirements have concluded that PEF is an energy-efficient process compared to thermal pasteurization, particularly when a continuous system is used (73).

I. TREATMENT CHAMBERS AND EQUIPMENT

Currently, there are only two commercial systems available (one by PurePulse Technologies, Inc. and one by

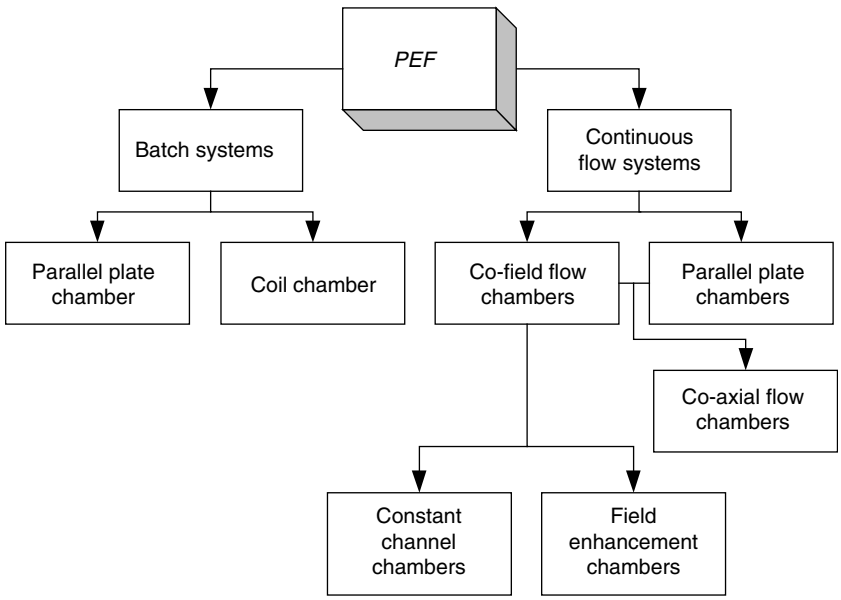

FIGURE 126.1 Classifications of PEF treatment chambers.

Thomson-CSF). Different laboratory- and pilot-scale treatment chambers have been designed and used for PEF treatment of foods. They are classified as static/batch (U-shaped polystyrene and glass coil static chambers) or continuous (chambers with ion conductive membrane, chambers with baffles, enhanced electric field treatment chambers, and coaxial chambers), see Figure 126.1.

A diagram for PEF processing of foods is depicted in Figure 126.2. The test apparatus consists of seven major components (25): a high-voltage power supply, an energy storage capacitor, a treatment chamber(s), a pump to conduct food though the treatment chamber(s), a cooling device, measuring devices (voltage, current, and temperature measurements), and a computer to control operations.

A. Batch Type Processing ("Static") Chambers

1. Parallel Plate Electrode Chambers

This model consists of two carbon electrodes supported on brass blocks placed in a U-shape polystyrene spacer (Figure 126.3a). Different spacers regulate the electrode area and amount of food to be treated. The brass blocks are provided with jackets for water recirculation and controlling temperature of the food during PEF treatment. This chamber could support a maximum electric field of 30 kV/cm. The second chamber model designed by Dunn and Pearlman (19) consists of two stainless steel electrodes and a cylindrical nylon spacer. Another model (3) consists of two round-edged, disk-shaped stainless steel electrodes, with polysulfone used as an insulation material. The effective electrode area is 27 cm^2 and the gap between electrodes can be selected at either 0.95 or 0.5 cm. The chamber can support up to 70 kV/cm. Water circulating at pre-selected temperatures through jackets built into electrodes provides cooling of the chamber.

2. Glass Coil Static Chambers

A model proposed by Lubicki and Jayaram (59) uses a glass coil surrounding the anode. The volume of the chamber is 20 cm^3, which requires filling liquid with high conductivity and similar permittivity to the sample (media — NaCl

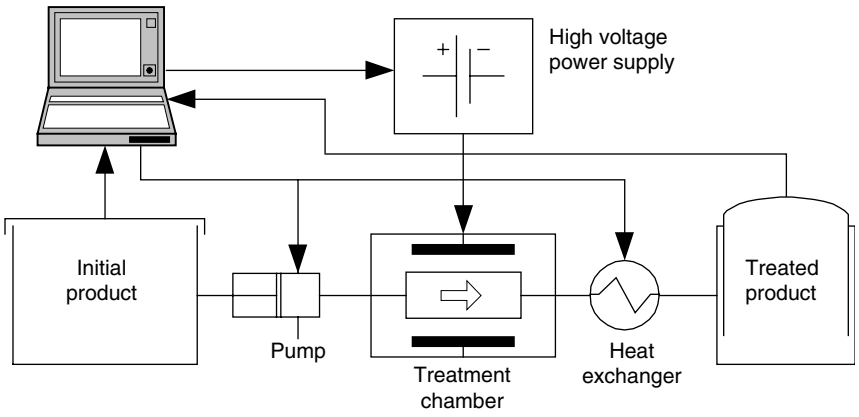

FIGURE 126.2 Flow chart of PEF food processing.

solution, $\sigma = 0.8$ to 1.3 S/m; filling liquid (water) $\sim 10^{-3}$ S/m) to be used because there is no inactivation with a non-conductive medium (silicone oil).

B. Continuous Flow PEF Chambers

Continuous flow PEF treatment chambers (77) are suitable for large-scale operations and are more efficient than the static chambers.

1. Parallel Plate Chambers (Figure 126.3b)

The first experimental chambers were designed to treat a confined, static volume. Some of the first designs incorporated parallel plate geometry using flat electrodes separated by an insulating spacer. The major disadvantage of this type of design is the low productivity of these chambers. Due to the electric field strength limitation it is difficult to increase product load and make this chamber more efficient.

2. Co-Field Flow Chambers

Co-field chambers described by Yin *et al*. (106) have two hollow cylindrical electrodes separated by an insulator to form a tube through which the product flows (Figure 126.3c). Field distribution in a co-field chamber is not expected to be uniform, though some useful advantages may be gained by special shaping of the insulator. The primary advantage of co-field chambers is that they can be designed to operate in PEF systems at lower currents than the coaxial chambers.

3. Coaxial Continuous PEF Chambers

Coaxial chambers are generally composed of an inner cylinder surrounded by an outer annular cylindrical electrode that allows food to flow between them, see Figure 126.3d. A protruded outer electrode surface enhances the electric field within the treatment zones and reduces the field intensity in the remaining portion of the chamber. The electrode configuration was obtained by optimizing the electrode design with a numeric electric field computation. Using the optimized electrode shape, the prescribed field distribution along the fluid path without an electric field enhancement point was determined. This treatment chamber has been used successfully in the inactivation of pathogenic and non-pathogenic bacteria, molds, yeasts, and enzymes present in liquid foods such as fruit juices, milk, and liquid whole eggs (3).

4. Enhanced Electric Field Continuous Treatment Chambers

Yin *et al*. (106) applied the concept of enhanced electric fields in the treatment zones by development of a continuous co-field flow PEF chamber with conical insulator shapes to eliminate gas deposits within the treatment volume (Figure 126.3e). The conical regions were designed so that the voltage across the treatment zone could be almost equal to the supplied voltage.

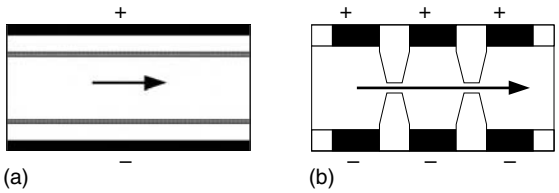

FIGURE 126.4 Special design chambers: a — continuous treatment chamber with ion-conductive membranes separating the electrode and food, b — continuous treatment chamber with electrode reservoir zones.

C. Special Design Flow-Through Chambers

1. Continuous Chamber with Ion Conductive Membrane

One design by Dunn and Pearlman (19) consists of parallel plate electrodes and a dielectric spacer insulator (Figure 126.4a). The electrodes are separated from the food by conductive membranes made of sulfonated polystyrene and acrylic acid copolymers. An electrolyte is used to facilitate electrical conduction between electrodes and ion permeable membranes.

2. Chamber with the Electrode Reservoir Zones

Another continuous chamber described by the same authors (19) is composed of electrode reservoir zones instead of electrode plates (Figure 126.4b). Dielectric spacer insulators have slot-like openings (orifices) between which the electric field enhances. The average residence time in each of these two reservoirs is less than 1 min.

II. MECHANISMS OF MICROBIAL INACTIVATION

The application of electrical fields to biological cells in a medium (for example, water) causes build-up of electrical charges at the cell membrane (84). Membrane disruption in many cellular systems occurs when the induced membrane potential exceeds a critical value of 1 V, which, for example, corresponds to an external electric field of about 10 kV/cm for *E. coli* (15). Several theories have been proposed to explain microbial inactivation by PEF (2, 7, 44, 85, 86, 100, 105). Among them, the most studied (see Figure 126.5) are electrical breakdown and electroporation or disruption of cell membranes (113).

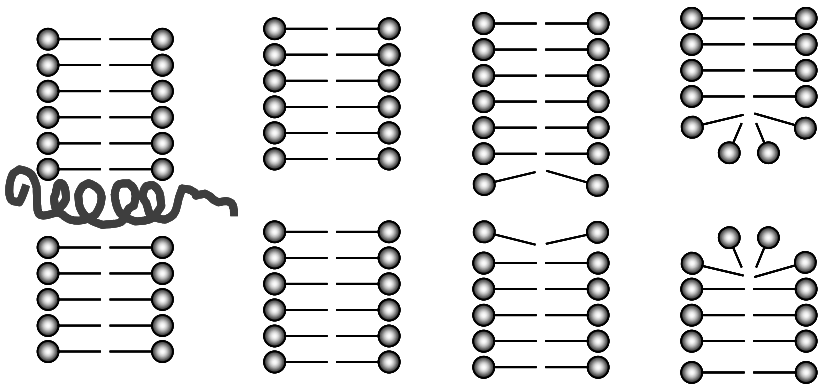

FIGURE 126.5 Schematic diagram of reversible and irreversible breakdown: pore development and cell membrane disruption.

A. Electrical Breakdown

Zimmermann (112) explains what electrical breakdown of cell membrane entails. The membrane can be considered as a capacitor filled with a dielectric (Figure 126.5). The normal resisting potential difference across the membrane V_m is 10 mV and leads to the build-up of a membrane potential difference V due to charge separation across the membrane. V is proportional to the field strength E and radius of the cell. The increase in the membrane potential leads to reduction in the cell membrane thickness. Breakdown of the membrane occurs if the critical breakdown voltage V_c (of the order of 1 V) is reached by a further increase in the external field strength. It is assumed that breakdown causes the formation of transmembrane pores (filled with conductive solution), which leads to immediate discharge at the membrane and thus decomposition of the membrane. Breakdown is reversible if the product pores are small compared to the total membrane surface. With electric field strengths above critical and long exposure times, larger areas of the membrane are subjected to breakdown. If the size and number of pores become large in relation to the total membrane surface, reversible breakdown turns into irreversible breakdown, which is associated with mechanical destruction of the cell membrane.

The corresponding electric field is $E_{critical} = V_{critical}/f_a$, where a is the radius of the cell and f is a form factor that depends on the shape of the cell (84). For spherical cells f is 1.5; for cylindrical cells of length l and hemispheres of diameter d at each end, the form factor is $f = l\,(1 - d)/3$. Typical values of $V_{critical}$ required for the lysing of *E. coli* are of the order of 1 V. The critical field strength for the lysing of bacteria with a dimension of approximately 1 μm and critical voltage of 1 V across the cell membrane is therefore on the order of 10 kV/cm for pulses of 10 microseconds to milliseconds in duration (84).

B. Electroporation

Electroporation is the phenomenon which occurs when a cell exposed to high voltage electric field pulses temporarily destabilizes the lipid bilayer and proteins of cell membranes (15, 43, 45, 87, 114). The plasma membranes of cells become permeable to small molecules after being exposed to the electric field, and permeation then causes swelling and eventual rupture of the cell membrane (46, 88, 91, 92). The main effect of an electric field on a microorganism cell is increasing of the membrane permeability due to membrane compression and poration (31, 79, 103–105). Kinosita and Tsong (50) demonstrated that an electric field of 2.2 kV/cm induced pores in human erythrocytes of approximately 1 nm in diameter. They suggested a 2-step mechanism for pore formation in which the initial perforation is a response to an electrical suprathreshold potential followed by a time-dependent expansion of the pore size (Figure 126.5). Large pores are obtained by increasing the intensity of an electric field and pulse duration or reducing the ionic strength of the medium (26, 43).

III. EVENTS OF ELECTROPORATION AND MICROBIAL LYSIS

A. Electric Field-Induced Transmembrane Potential

We now know that when a cell (radius = R_{cell}) suspended in a medium is exposed to external electric field (direct current of strength E_{appl}), there is a rapid redistribution of cations in the vicinity of the plasma membrane, thus generating a transmembrane potential $\Delta\psi_{membr}$ with a rise time, τ_{membr}:

$$\Delta\psi_{membr} = 1.5R_{cell}E_{appl}\cos\theta\,[1 - \exp(-t/\tau_{membr})] \quad (126.1)$$

$$\tau_{membr} = R_{cell} C_{membr} (r_{\text{int}} + r_{ext}/2) \qquad (126.2)$$

Here θ is an angle between the field line and the normal from the center of the spherical cell to a point of interest on the membrane surface; C_{membr}, r_{int}, and r_{ext} are the membrane capacitance (per unit area), and the resistivities of the cytoplasmic fluid and the external medium respectively (17). For biological cells of micrometers in diameter, $\tau_{membr} < 1\,\mu s$ and the exponential term in equation (126.1) approaches zero within 1 μs. Cells of larger diameters have $\tau_{membr} > 1\,\mu s$ (49). The maximum transmembrane potential generated in a cell with the DC electric pulse a few times longer than τ_{membr} is

$$\Delta\psi_{membr,\,\max} = 1.5 R_{cell} E_{appl} \qquad (126.3)$$

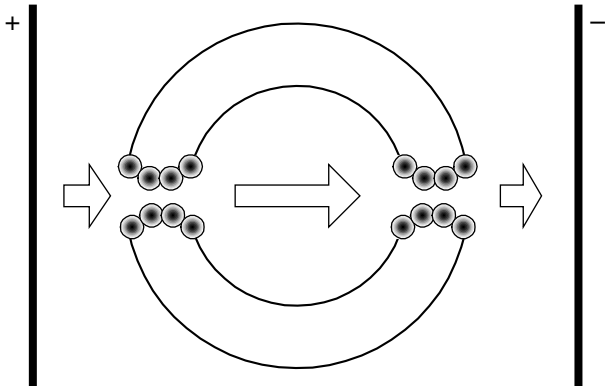

FIGURE 126.6 Electroosmosis-induced hydrodynamic flow toward the negative electrode regardless of whether electropores are in positive-facing or negative-facing hemispheres.

B. Kinetics of Electroporation in Cell Membranes

The plasma membrane of a cell is the first site of the electric interaction. Beside lipids, there are proteins, carbohydrates, and other types of molecules, most of which are either charged or polarizable. Channel proteins are especially sensitive to the $\Delta\psi_{\text{membr}}$, and each type of channel has a range of $\Delta\psi_{\text{membr}}$ in which it becomes conductive. The range of $\Delta\psi_{\text{membr}}$ for opening protein channels is approximately 50 mV, considerably smaller than the dielectric strength of the lipid bilayer, which is in the range of 150–400 mV. Like a lattice defect of the lipid bilayer, once a protein channel is forced to open, a strong current greatly exceeding the normal conductance of the channel will generate local heat sufficient to denature the protein. This denaturation could be reversible or irreversible, depending on the extent of temperature change and the properties of the channel. The time of opening/closing of the protein channel is in the submicrosecond time range (94). Thermal denaturation of a protein takes milliseconds to seconds. Renaturation of a protein occurs in seconds (48). Electropores in lipid domains will reseal within seconds (93). Closing of PEF-perforated protein channels should transpire in milliseconds. However, repairing of a PEF-damaged cell membrane will take minutes to hours (50).

C. Colloid Osmotic Lysis

A major difference between electroporation of lipid vesicles and that of cells is the colloid osmotic lysis of cells (50). A PEF-perforated cell membrane loses its permeation barrier to ions and small molecules but not necessarily to proteins. The electroperforated membrane becomes semipermeable to cytoplasmic macromolecules. The osmotic pressure of these macromolecules causes the cell to swell. This process, known as colloidal swelling, eventually leads to a rupture of the plasma membrane because of the excessive osmotic pressure imposed on the cells.

Colloidal osmotic pressure in the PEF-treated red blood cells was identified as the main cause of the electric field-stimulated hemolysis. Colloidal swelling depends on the osmotic imbalance of the cytoplasm and the suspending medium. When the difference is large, PEF-treated cells will swell in the minute time range. During this swelling phase, electropores in cell membranes also begin to reseal. If the resealing takes place faster than the swelling, cells will shrink again and recover their original volume, thus averting membrane rupture. If, on the other hand, the resealing is slower than the swelling, the plasma membrane of cells will be ruptured. The colloidal osmotic lysis may be prevented by balancing the osmotic pressure of the cytoplasm and the medium.

D. Electroosmosis in Electropores

An electric field parallel to the surface/liquid interface will cause a net hydrodynamic flow in the appropriate direction as long as there is an imbalance in the numbers of the two charges in the layer of liquid adjacent to the charged surface. If electropores, which are expected to be induced closer to the "poles" of the cell that face the electrodes, are viewed as cylinders with an average net negative (from ionized headgroups of phospholipids and ionized amino-acid side chains on integral proteins) charge on this surface and with their axis perpendicular to the plane of the membrane, then a hydrodynamic flow existence would be expected during the electric field pulse (Figure 126.6). It was predicted and experimentally demonstrated that the overall permeabilization difference between both hemispheres would be less than originally thought if an electroporation experiment were conducted to take electroosmosis into account (90).

IV. MICROBIAL INACTIVATION KINETICS

Three types of factors that affect the microbial inactivation with PEF have been identified:

- the process factors (electric field intensity, pulse width, treatment time and temperature, and pulse waveshapes);
- microbial entity factors (type, concentration, and growth stage of microorganisms); and
- treatment media factors (pH, antimicrobial and ionic compounds, conductivity, and medium ionic strength).

Hülsheger and Niemann (32) were the first to propose a mathematical model for inactivation of microorganisms with PEF. Their model was based on the establishing dependence of the survival ratio $S = N/N_o$ (the ratio of living cell count before and after PEF treatment) on the electric field intensity E by the following expression:

$$\ln S = -b_E(E - E_c) \tag{126.4}$$

where b_E is the regression coefficient, E is the applied electric field, and E_c is the the critical electric field value obtained by extrapolating E for 100% survival.

The regression coefficient reflects the gradient of straight survival curves and is a microorganism-media depending constant. The critical electric field was found to be the function of cell size and applied pulse duration. Hülsheger *et al*. (34) proposed an inactivation kinetic model that relates microbial survival fraction (S) with PEF treatment time (t) in the form of

$$\ln S = -b_t \ln \frac{t}{t_c} \tag{126.5}$$

where b_t is the regression coefficient, t is the treatment time, and t_c is the critical treatment time, or extrapolated value of t for 100% survival.

The model proposed by Peleg (69) describes a sigmoid shape of the pathogen survival curves generated by the PEF inactivation. The model represents the percentage of surviving organisms as a function of an electric field and the number of pulses applied. This model is defined by the critical electric field intensity that corresponds to 50% survival (E_d), and the kinetic constant K that is a function of the number of pulses representing the steepness of the sigmoid curve. Generalized equations for both models are combined in Table 126.1.

Small values of the kinetic constants for both models indicate a wide span in the inactivation rate curves and hence lower sensitivity to PEF, whereas large values imply a steep decline or higher susceptibility to PEF.

TABLE 126.1
Inactivation Models

Hülsheger's Model (32)	Peleg's Model (69)
$S = \left(\frac{t}{t_c}\right)^{\frac{-(E-E_c)}{K}}$	$S = \frac{1}{1 + e^{\frac{E-E_d}{K}}}$
E – electric field; t – treatment time; E_c – critical electric field; t_c – critical time; K – kinetic constant.	E_d – electrical field when 50% of population is inactivated; K – kinetic constant.

Lower E_c (or E_d) values indicate lesser resistance of pathogens to the PEF treatment.

A. Microbial Factors in Efficacy of PEF Processing

1. Type of Microorganisms

Among bacteria, gram-positive ones are more resistant to PEF treatment than gram-negative (33). In general, yeasts are more sensitive to electric fields than bacteria due to their larger size, although at low electric fields they seem to be more resistant than gram-negative cells (74, 82). A comparison between the inactivation of two yeast *spp*. of different sizes showed that the electric field intensity needed to achieve the same inactivation level was inversely proportional to cell size. These results are logical but inconsistent with the results obtained by Hülsheger *et al.* (33). Further studies are needed to better understand the effect of microorganism type on microbial inactivation effectiveness.

2. Growth Stage of Microorganisms

Bacterial cells in logarithmic phase are more sensitive to various stresses than cells in lag and stationary phases. Microbial growth in logarithmic phase is characterized by high proportion of cells undergoing division, during which cell membrane is more susceptible to the applied electric field. Gaskova *et al*. (23) reported that the killing effect of PEF for *S. cerevisiae* in the logarithmic phase is 30% greater than for those in stationary phase of growth.

B. PEF Microbial Inactivation

Numerous publications on microbial inactivation present data on vegetative cells, the majority of them from a few genera. Extensive microbial inactivation tests have been conducted to validate the concept of PEF treatment as a non-thermal food pasteurization process (15, 73, 74, 98, 99, 108).

An applied intensive pulsed electric field produces a series of degradative changes in blood, algae, bacteria, and yeast cells (15). The changes include electroporation

TABLE 126.2
Some Bacteria Effectively Inactivated with PEF

Bacillus cereus (70, 81)	*Pseudomonas aeruginosa* (52)
Bacillus subtilis (18)	*Pseudomonas fluorescens* (11, 97)
Bacillus subtilis spores (28)	*Saccaromyces cerevisiae* (111)
Candida famata (102)	*Salmonella* (37, 61)
Escherichia coli (95, 96)	*Staphylococcus aureus (ATCC 25923)* (77)
Listeria innocua (13, 14)	*Yersinia enterocolitica* (60)
Listeria monocytogenes (Scott A) (1, 21, 95, 96)	
Lactobacillus leichmannii (80, 95, 105)	

and disruption of semipermeable membranes, which lead to cell swelling and/or shrinking, and finally to lysis of the cells. The mechanisms for the inactivation of microorganisms include electric breakdown, ionic punch-through effect, and electroporation of cell membranes (75). The inactivation of microorganisms is primarily caused by an increase in membrane permeability due to compression and poration (99).

Castro *et al*. (15) reported a 5-log reduction in bacteria, yeast, and mold counts suspended in milk, yogurt, orange juice and liquid egg treated with PEF. Zhang *et al*. (109) achieved a 9-log reduction in *E. coli* suspended in simulated milk ultrafiltrate (SMUF) and treated with PEF by applying the converged electric field of 70 KV/cm strength, and a short treatment time of 160 μs. These processing conditions and results are adequate for commercial food pasteurization that requires 6- to 7-log reduction cycles. Table 126.2 presents the bacteria reported to be successfully inactivated by the pulsed electric field treatment.

V. PEF PROCESS CALCULATIONS AND VARIABLES

To treat foods with PEF in a continuous system, the liquid food product is pumped through a series of treatment zones in the chamber with high voltage electrodes on one side of each zone and a low voltage electrode on the other side. The PEF process conditions are defined by an applied electric field strength and a treatment time.

A. Electric Field Intensity

It is one of the main factors influencing microbial inactivation (20, 32). The microbial inactivation increases with an increase in the electric field intensity, above the critical transmembrane potential (72). This is consistent with the electroporation theory, in which the induced potential difference across the cell membrane is proportional to the applied electric field. The critical electric field E_c (an electric field intensity below which inactivation does not occur) increases with the transmembrane potential of the cell. Trans-membrane potentials, and consequently E_c, are larger for larger cells (39). Pulse width (duration) also influences the critical electric field; for instance, with pulse widths greater than 50 μs, E_c is 4.9 kV/cm. With pulse widths less than 2 μs, E_c is 40 kV/cm (84).

B. Treatment Time

Treatment time is defined as the product of the number of pulses and the single pulse duration. An increase in any of the two variables improves microbial inactivation (82). As noted above, pulse width influences microbial reduction by affecting E_c. Longer widths decrease E_c, which results in higher inactivation; however, an increase in pulse duration may also result in an undesirable food temperature increase. Optimum processing conditions should therefore be established to obtain the highest inactivation rate with the lowest heating effect (24, 51). The inactivation of microorganisms increases with the treatment time (33). In certain cases, however, the number of pulses that increase inactivation rate reaches saturation. This is the case in *Saccharomyces cerevisiae* inactivation by PEF that reaches saturation with 10 pulses of an electric field at 25 kV/cm (3).

Critical treatment time also depends on the electric field intensity applied (1, 80, 107). At electric field values above E_c, critical treatment time decreases with electric field increase. Barbosa-Cánovas *et al.* (3) reported that for the electric field strength 1.5 times higher than E_c, the critical treatment time would remain constant.

C. Pulse Waveshape

Electric field pulses may be applied in the form of exponentially decaying, square-wave, oscillatory, bipolar, or instant reverse charges (16, 77). Oscillatory pulses are the least efficient for microbial inactivation, and square-wave pulses are more energy and lethally efficient than exponentially decaying pulses (5, 107). Bipolar pulses are more lethal than monopolar pulses, because PEF causes movement of charged molecules in the cell membranes, and reverse in orientation or polarity of the electric field causes a corresponding change in the direction of charged molecules movement (29, 75). The difference between bipolar and monopolar pulses was reported in *Bacillus spp*. (30) and *E. coli* (75) inactivation studies. With bipolar pulses, the alternating changes in the movement of charged molecules cause a stress in the cell membrane and enhance its electric breakdown. Bipolar pulses also offer the advantages of minimum energy utilization, reduced deposition of solids on the electrode surface, and decreased food electrolysis (3).

A study conducted by Zhang *et al.* (110) showed the effect of square-wave, exponentially decaying, and instant-charge-reversal pulses on the shelf life of orange

juice. Square wave pulses were more effective, yielding products with longer shelf lives than those treated with exponentially decaying and charge reverse pulses. In agreement with this study, Love (58) quantitatively demonstrated the stronger inactivation effect of square-wave pulses over all other wave shapes.

D. Treatment Temperature

Experimental results have demonstrated that, in challenge tests, both treatment temperatures and process temperatures impact microbial survival and recovery (8, 107).

PEF treatments at moderate temperatures (50 to 60°C) have been shown to exhibit synergistic effects on the inactivation of microorganisms (19, 36). At the constant electric field strength, pathogen inactivation increases with an increase in treatment temperature (13). Since application of an electric field causes increase in the temperature of the treated foods, proper cooling of treatment chamber is necessary to maintain food temperatures far below those existing during a thermal pasteurization process (10, 57, 68).

Additional effects of high treatment temperatures include changes in cell membrane fluidity and permeability, which increase the susceptibility of the cell to mechanical disruption (34). Also, a low trans-membrane potential decreases E_c and therefore increases inactivation (39).

E. Electrochemistry of a Highly Polarized Electrode/Food Product Interface

Usually, PEF processing is considered as "zero chemistry" treatment with no chemical reactions involved. However, reported changes in the sensory and physical attributes of processed foods are not solely the result of Joule heating and high electric current that passes through the food product. All treatment chambers in existing PEF systems have extremely high electrode surfaces-to-treatment volume ratio due to power supply and electric field strength limitations. Therefore, electrode materials are directly involved in the PEF treatment process. They interact with treated food products by electrochemical reactions that occur at the surface of highly polarized electrodes, and electric double layer assisted reactions of food particulates (solid phase of food product) with the electrode surface. These interactions include (6, 12, 101):

- adsorption of organic and inorganic anions;
- changes in the chamber capacitance due to changes of electric double layer relaxation time;
- electrophoretic deposition of food solids;
- electrocoagulation of solid phase at the electrode surface;
- electrodissolution of electrode material;
- hydrogen/oxygen evolution due to electrode reactions.

Electrode surface interactions with food matrix components have been previously underestimated by the researchers and rarely investigated (5). Due to the importance of the electrode surface properties to the food product behavior in the electrode vicinity and PEF treatment process, electrochemical polarization characteristics of electrode material play the critical role. This is also important because electrical impulses can accelerate electrochemically induced changes in electrode polarization and food properties.

The potential scanning measurements of various food products in the range from 0.5 to 3 V for two widely used electrode materials — aluminum (alloy 2024) and stainless steel — have been performed. Electrochemical potential is the thermodynamic potential that characterizes reaction ability of an electrode in the solution. Increasing of thermodynamic potential by 1 V is equivalent to changing the reaction temperature by 10^3 K. Electrode polarization in the range between 2 and 3 V is considered as extremely high polarization.

Despite the general similarity, both electrodes demonstrate different behavior in acid media (orange juice) (Figure 126.7). In low polarization region aluminum shows the more stable behavior and less corrosive activity. However, to increase electric current through the aluminum electrode one should maintain very high voltage. The stainless steel electrode can support higher current due to lower adsorbance of HO_3 ions at the electrode surface. In the high polarization region both electrodes demonstrate similar volt-ampere characteristics. However, stainless steel has the potential dynamic curve shifted in the direction of higher values of electric current, and therefore is more suitable for PEF applications. For low electric field applications (ohmic heating) aluminum electrodes are more preferred.

The food product composition is a significant factor influencing electrodic processes. Potential dynamic characteristics of stainless steel electrodes in orange juice, whole milk, and tomato soup are depicted in Figure 126.8. Tomato soup has classical corrosion-type characteristics that include Taffel region (adsorption) and electrodissolution (corrosion) of electrode material (12). Orange juice has similar characteristics except the two regions of current-voltage instability, which can be explained with polarized pulp aggregation at the electrode surface. The most unusual potential dynamic curve corresponds to the electrochemical treatment of milk. This type of curve usually corresponds to the passivated metal electrode. At low polarization potentials the behavior of stainless steel electrode in milk does not differ from the other food products. Potential rise leads to the deposition of milk constituents onto the electrode and blockage (passivation) of its surface. In the high polarization regime all three products behave similarly.

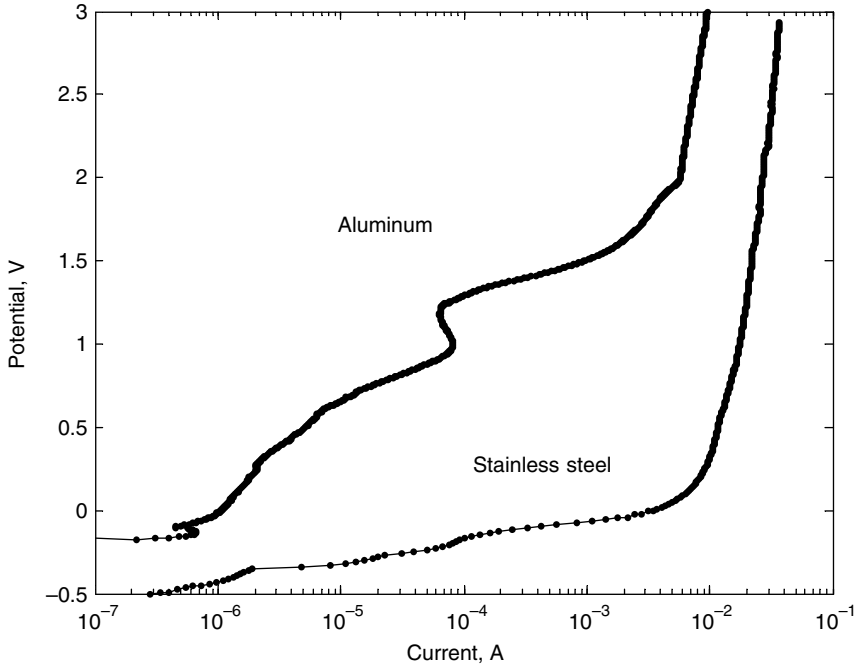

FIGURE 126.7 Polarization of stainless steel and aluminum electrodes in orange juice.

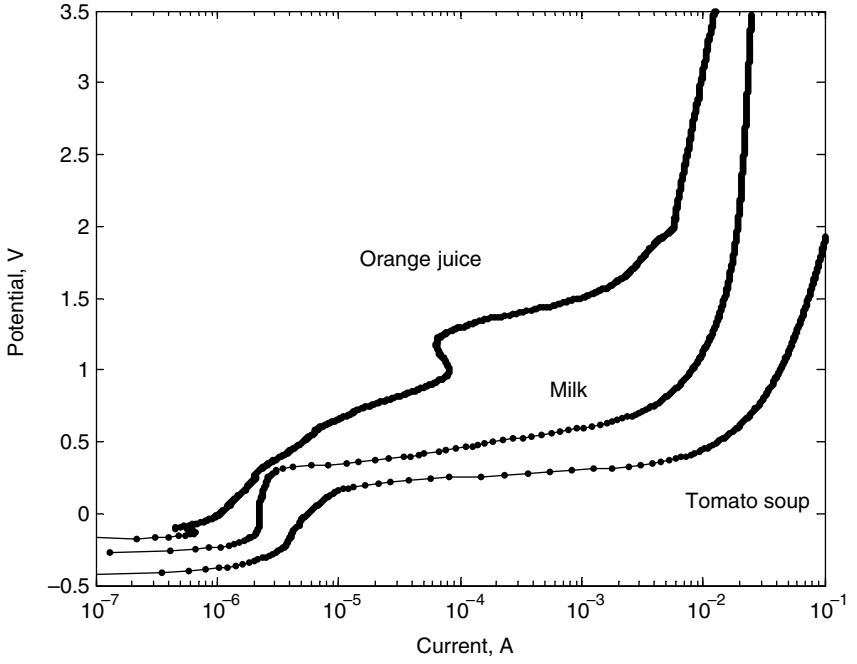

FIGURE 126.8 Potentiodynamic curves of polarized stainless steel electrode for various food products.

V. MATHEMATICAL MODEL OF CONTINUOUS OPERATION (22)

From an engineering point of view, it should be of interest to differentiate between the single pass and recirculation modes of operation of PEF treatment chamber. In both cases, the mathematical model consists of energy and mass balances, kinetic equations, and equilibrium conditions. It is possible to build a large and complicated mathematical model, but that would not be useful. In order to simplify the model, some assumptions may be adopted. Accordingly, plug type flow in the PEF chamber, perfect mixing in the tank, and a first order kinetics for the inactivation of microorganisms were assumed.

A simplified scheme of PEF installation operating in a single pass mode is depicted in Figure 126.2. It can be assumed that the concentration of microorganisms in the feed tank c_T (microorganisms/L) is the same as that at the PEF chamber inlet, and that the rate of microorganism destruction r (microorganisms/(L/s)) follows the first order kinetics with respect to microorganism concentration c (microorganisms/L):

$$r = -kc \tag{126.6}$$

where k (s^{-1}) is the kinetic constant of microorganism inactivation.

Assuming stationary state and plug-type flow in the PEF chamber (56), the microorganism balance gives the following expression:

$$q \ln(c/c_T) = -kV_r t \tag{126.7}$$

where q (L/s) is the fluid flow rate and V_r (L) is the PEF chamber volume.

According to the last equation, the relation between the outlet microorganism concentration c (microorganisms/L) and time t(s) is exponential.

$$c = c_T e^{\frac{-kV_r}{q}} \tag{126.8}$$

The energy balances are more complex. The energy E (J) dissipated during the discharge of the capacitor C (μF) at a voltage V(V) is given by the following equation:

$$E = \frac{1}{2} CV^2 \tag{126.9}$$

Taking into account frequency $f(s^{-1})$ of the pulses, the energy dissipation per second during the liquid flow through the chamber Q (J/s) is:

$$Q = \frac{1}{2} fCV^2 \tag{126.10}$$

However, only one part ϕ of this energy will heat the liquid food (flow q (L/s), density ρ) that passes through the PEF chamber. This ratio ϕ must be less than 1, and strongly depend on the electrical conductivity of the food product. Energy balance for the PEF chamber after the stationary state is reached is represented by:

$$q\rho C_p(T - T_T) = \phi Q \tag{126.11}$$

where q (L/s), ρ (kg/L), and C_p (J/kg°C) are the flow rate, density, and specific heat of the liquid food product, respectively; T_T and T (°C) are the temperature of food sample in the feed tank and in the chamber, respectively. Consequently, the increase in the temperature $T - T_T$ of the liquid food can be estimated as:

$$(T - T_T) = \frac{1}{2} \frac{\phi f CV^2}{q\rho C_p} \tag{126.12}$$

TABLE 126.3
PEF Process Variables

Process Variable	Notation	Dimension
Electric field strength	E	V/m
Total treatment time	t	s
Number of electrode pairs in treatment chamber	n	
Treatment zone diameter	D	m
Mean liquid velocity	μ	m/s
Product electrical conductivity	σ	S m
Product density	ρ	kg/m^3
Product specific heat	C_p	kJ/kg°C

VII. PROCESS CALCULATIONS

The total possible temperature change per pair of electrodes in treatment chamber (ΔT), total energy input during treatment per electrode pair (P), and Reynolds number (N_{Re}) can be calculated using the following equations:

$$\begin{aligned} \Delta T &= (E^2 t\sigma/\rho C_p)/n \\ P &= E^2 t\sigma/n \\ N_{Re} &= \rho D u/\mu \end{aligned} \tag{126.13}$$

The process variables used in the equations are described in Table 126.3.

VIII. PHYSICAL PROPERTIES OF FOOD PRODUCTS FOR PEF PROCESSING

Physical properties of foods that are the most critical for PEF treatment efficacy are the electrical conductivity, density, specific heat, and viscosity of the product. Some useful data can be found in reference (5). Liquid foods contain several ion species that carry an electrical charge and conduct electricity. At a given voltage, the electrical current flow is directly proportional to the electrical conductivity of the food product (108). An increase in the electrical conductivity causes an increase in the overall energy input and change in the product temperature during processing.

The density and specific heat of food product affect the temperature change during PEF treatment. As the density of product decreases, the total temperature change increases (108). Similarly, a decrease in product specific heat also increases the temperature change during PEF processing.

The viscosity of the product determines flow characteristics, which are calculated based on the Reynolds number. For the Reynolds number greater than 5000, the product flow is turbulent, which provides uniform velocity profile in the treatment chamber that, in turn, is likely to provide uniformity of PEF process (8, 57).

A. Conductivity, pH, and Ionic Strength

The electrical conductivity of a medium (σ Ohm^{-1}/m), which is defined as the ability to conduct electric current, is an important variable for PEF processing. Electrical conductivity is the reciprocal of resistivity (r), which is measured in Ohm/m. Foods with large electrical conductivities generate smaller peak electric fields across the treatment chamber, and therefore are not susceptible for PEF treatment (3). Studies on inactivation of *Lactobacillus brevis* with PEF showed that as the conductivity of the fluid increased, the resistance of the treatment chamber was reduced (36), which in turn reduced the pulse width and decreased the rate of inactivation. Since an increase in medium conductivity results from increase of its ionic strength, the latter leads to the decrease in bacteria inactivation rate. Furthermore, increased difference between the conductivities of a medium and microbial cytoplasm weakens the membrane structure due to an increased flow rate of ions across the membrane. Thus, the inactivation rate of microorganisms increases with decreasing conductivity, even at equal input energy (36). Yet another study performed by Dunne *et al.* (20) showed that the resistivity had no influence on *E. coli* and *L. innocua* PEF inactivation effectiveness. These controversial results may be due to the microorganisms or media used.

Vega-Mercado *et al.* (99) studied the effect of pH and ionic strength of the medium (SMFU) during the PEF treatment. The inactivation ratio increased from not detectable (zero) to 2.5-log cycles as ionic strength of the solution was adjusted from 168 to 28 mM. At 55 kV/cm (8 pulses), as the pH was reduced from 6.8 to 5.7, the inactivation ratio increased from 1.45- to 2.22-log cycles. The PEF treatment and ionic strength of the solution were responsible for electroporation and compression of the cell membrane, whereas the pH of the medium affected the cytoplasm when the electroporation was complete. Dunne *et al*. (20) reported that, depending on the microorganism, acidic pH enhanced microbial inactivation, although no specific details were provided (what microorganisms were affected or what range of pH was used).

B. Particulate Foods

Inactivation of microorganisms in liquid-particulate systems has been studied by Dunne *et al.* (20). *E. coli*, *L. innocua*, *Staphyloccocus aureus*, and *Lactobacillus acidophilus* were suspended in a 2 mm diameter alginate beads model system, and the effects of PEF process variables on microbial inactivation were tested. The researchers concluded that the process was effective in killing microorganisms embedded in particulates. However, to achieve more than a 5-log cycle reduction, high energy inputs were needed (70–100 J/ml, depending on the bacteria treated). Qin *et al.* (76) reported that dielectric breakdown occurs when air or liquid vapors are present in the food because of the difference in dielectric constants between liquid and gas.

IX. APPLICATION OF PEF IN FOOD PRESERVATION

PEF has been mainly applied to preserve the quality of foods, such as to improve the shelf life of apple juice (Evrendilek *et al*., 2000a; Simpson *et al*., 1995), cranberry juice (Evrendilek *et al*., 2001a), skim and chocolate milk (Evrendilek *et al*., 2001a), orange juice (Qui *et al*., 1998; Yeom *et al.*, 2000), liquid eggs (Hermawan, 1999), and pea soup (Vega-Mercado *et al*., 1996a).

A. Processing of Apple Juice and Cider

Simpson *et al*. (1995) reported that apple juice from concentrate treated with PEF at 50 kV/cm electric field strength, 10 pulses, 2 μs pulse duration, and maximum processing temperature of 45°C had a shelf-life of 28 days compared to a shelf life of 21 days of fresh-squeezed apple juice. There were no physical or chemical changes in ascorbic acid or sugars in the PEF-treated apple juice, and a sensory panel found no significant differences between untreated and electric field treated juices. Vega Mercado *et al*. (1997) reported that PEF treatment extended the shelf life of fresh apple juice, and apple juice at 22–25°C had a shelf life more than 56 days or 32 days, respectively. There was no apparent change in its physicochemical and sensory properties. Evrendilek *et al*. (2000a) indicated that PEF treatment of apple juice and PEF + mild heat treatment of apple cider improved the shelf life quality of the products compare to control samples at 4, 22, and 37°C without degradation of vitamin C and change in the color measured by L (white if L = 100, black if L = 0), a (−a = green, a = red), and b (−b = blue, +b = yellow) values.

B. Processing of Orange Juice

Sitzmann (1995) reported the reduction of native microbial flora of freshly squeezed orange juice by 3 log cycles with an applied electric field of 15 kV/cm without significantly affecting its quality. The shelf life of reconstituted orange juice treated with an integrated PEF pilot plant system consisted of a series of co-field chambers evaluated by Qui *et al*. (1998) and Zhang *et al*. (1997). It is reported that total aerobic counts were reduced by 3 to 4 log cycles under 32 kV/cm electric field strength. When stored at 4°C, both heat- and PEF-treated juices had a shelf life of more than 5 months. Vitamin C losses were lower and color was generally better preserved in PEF-treated juices compared to the heat-treated ones up to 90 days (storage temperature of 4 or 22°C) or 15 days (storage temperature of 37°C) after processing. In the study of Yeom *et al*. (2000) orange juice was treated by PEF, and with an

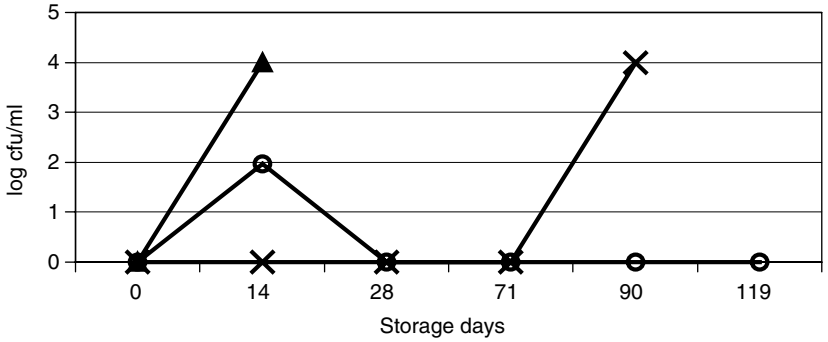

FIGURE 126.9 Total plate count in chocolate milk during storage at 22°C. ○ = PEF + 112°C; X = PEF + 105°C; ▲ = control.

increase in electric field strength longer shelf life is obtained. Compared to heat treatment more flavor components were retained in PEF treated orange juice.

C. Processing of Cranberry Juice

Cranberry juice was treated either by high voltage pulsed electric field at 20 kV/cm and 40 kV/cm for 150 μs, or by thermal treatment at 90°C for 90s. Higher electric field and longer treatment time reduced more viable microbial cells. The overall volatile profile was not affected by PEF treatment, but it was affected by heat treatment. Compared to control samples PEF treatment caused no color change in the samples. When treatment conditions were 40 kV/cm for 150 μs, there was no mold and yeast growth at both 22 and 4°C and no bacterial growth at 4°C (Jin and Zhang, 1999). PEF (32 kV/cm electric field strength, 500 pps frequency, 1.4 μs pulse duration, and 47 μs total treatment time) and PEF + heat (60°C for 32s) processing of cranberry juice revealed that shelf life cranberry juice stored at both 4 and 22°C increased significantly (for 197 days). The PEF and PEF + heat treatments did not cause any significant differences in the color retention of the samples (Evrendilek *et al*., 2001a).

D. Processing of Milk

Inactivation of *Salmonella dublin* and shelf life study with homogenized milk was performed by the electric field strength of 36.7 kV/cm and treatment time of over a 25 min (Dunn and Pearlman, 1987a). *S. dublin* was not detected after PEF treatment or after storage at 7–9°C for 8 days. The naturally occurring milk bacterial population increased to 10^7 cfu/ml in the untreated milk, whereas the treated milk showed approximately 4×10^2 cfu/ml. Further studies by Dunn (1987b) indicated less flavor degradation and no chemical or physical changes in milk quality attributes for cheesemaking.

Fernandez-Molina *et al*. (2001) studied the shelf life of raw skim milk (0.2% milk fat), treated with PEF at 40 kV/cm, 30 pulses, and 2 μs treatment time using exponential decaying pulses. The shelf life of the milk was 2 weeks when it is stored at 4°C; however, treatment of raw skim milk with 80°C for 6 s followed by PEF treatment at 30 kV/cm, 30 pulses, and 2 μs pulse width increased the shelf-life up to 22 days, with a total aerobic plate count of 3.6 log cfu/ml. Reina *et al*. (1998) studied the inactivation of *Listeria monocytogenes* Scott A in pasteurized whole, 2%, and skim milk by PEF. *L. monocytogenes* was reduced 1 to 3 log cycles at 25°C and 4 log cycles at 50°C, with no significant differences being found among the three milks. The lethal effect of PEF was a function of the field intensity and treatment time. Calderon-Miranda (1999) studied the PEF inactivation of *Listeria innocua* suspended in skim milk and its subsequent sensitization to nisin. The microbial population of *L. innocua* was reduced by 2.5 log after PEF treatments at 30, 40, or 50 kV/cm. The same PEF intensities and subsequent exposure to 10 IU nisin/ml achieved 2, 2.7, or 3.4 log reduction cycles of *L. innocua*. Similar to cranberry juice, chocolate milk was processed by PEF (35 kV/cm electric field strength, 600 pps frequency, 1.4 μs pulse duration, and 45 μs total treatment time) and PEF + heat (105 and 112°C for 31.5 s) by pilot plant PEF processing system (Figure 126.4). Compare to control samples, the shelf life of chocolate milk treated by PEF + 105°C and PEF + 112°C increased significantly at 4, 22, and 37°C (Figure 126.9). The PEF + heat treatments did not cause any significant differences in the color retention (Evrendilek *et al*. 2001a).

E. Processing of Eggs

PEF studies in liquid eggs, on heat-pasteurized liquid egg products, and on egg products with potassium sorbate and citric acid (added as preservatives) were conducted by Dunn and Pearlman (1987b). Comparisons were made with regular heat-pasteurized egg products with and without the addition of food preservatives when the eggs were stored at low (4°C) and high (10°C) refrigeration temperatures. The study focused on the importance of the hurdle approach in shelf-life extension. Its effectiveness was even more evident during storage at low temperatures,

where egg products had a final count around 2.7 log cfu/ml stored at both 10°C and 4°C. The samples maintained a low count for 4 and 10 days, respectively, versus a few hours for the heat pasteurized samples.

In addition to color analysis of eggs products, Ma *et al*. (1997) evaluated the density (indicator of egg protein-foaming ability) of fresh and PEF-treated LWE (liquid whole egg) as well as the strength of sponge cake baked with PEF-treated eggs. The stepwise process used did not cause any difference in density or whiteness between the PEF-treated and fresh LWE. The strength of the sponge cakes prepared with PEF-treated eggs was greater than the cake made with non-processed eggs. This difference in strength was attributed to the lower volume obtained after baking with PEF-treated eggs. The statistical analysis of the sensory evaluation revealed no differences between cakes prepared from PEF processed and fresh LWE.

A study reported by Hermawan (1999) indicated that there is a 90% of reduction of *Salmonella enteritidis* inoculated into LWE with circulation mode fluid handling system using 200 pps pulse repetition rate, 2.12 μs pulse duration, and 25 kV/cm electric field strength.

F. Processing of Green Pea Soup

Vega-Mercado *et al*. (1996) exposed pea soup to two steps of 16 pulses at 35 kV/cm to prevent an increase in temperature beyond 55°C during PEF treatment. The shelf life of the PEF-treated pea soup stored at refrigeration temperature (4°C) exceeded 4 weeks, and 22 or 32°C was found inappropriate to store the product. There were no apparent changes in the physical and chemical properties or sensory attributes of the pea soup directly after PEF processing or during the 4 weeks of storage at refrigeration temperatures.

G. Processing of Yogurt Based Product

PEF and mild heat (60°C for 30 s) processing of yogurt based products similar to a dairy pudding dessert and yogurt based drink revealed that the combination of PEF plus mild heat significantly increased the microbial stability of the product at 4 and 22°C without any difference in the sensory attributes. Sensory evaluation of the products indicated that there was no significant difference between control and processed products. Color, pH, and °Brix were not significantly affected by the processing conditions (Evrendilek *et al*. 2001b; Yeom *et al*. 2001).

H. Processing of Rice Pudding

Due to its higher viscosity, rice pudding was preheated to 55°C for 30 s before PEF treatment. Processing conditions were 33 kV/cm electric field strength, 100 L/h flow rate, 1.47 μs pulse duration, and 500 pps frequency. Monopolar negative pulse was applied. Shelf life studies of the product showed that total plate count and a value for color measurement of the PEF treated and control samples were significantly different. PEF treated rice pudding has a shelf life of 94 days, whereas, control samples were spoiled in 10 days (Ratanatriwong *et al*. 2001).

X. PEF AS A HURDLE TECHNOLOGY

In general, controlling the combination of factors (hurdles), such as pH, ionic strength, and antimicrobial compounds of the solution, during PEF treatment can effectively aid in microorganism inactivation. The term *hurdle technology* covers an intelligent use of multiple preservation procedures in combinations specifically relevant to particular types of foods. The concept is pertinent to the control of pathogenic and food spoilage microorganisms, and to almost all food commodities and products. Furthermore, hurdle technologies have been traditionally employed in all countries of the world, although with greatly differing emphasis depending on the history and social characteristics of different cultures (55).

Preservation technologies are based mainly on the inactivation of microorganisms or on the delay or prevention of microbial growth. Consequently, they must operate through those factors that most effectively influence the survival and growth of microorganisms (35). Such factors are not numerous. They include a number of physical factors, some chemical ones, and some that are essentially microbial in that they depend on the nature of microorganisms present in particular products. The most widely quoted classification of those factors derives from the original proposals of Mossel and Ingram (67), updated by Mossel (66). They include:

- *Intrinsic factors*: Physical and chemical factors that exist within a food product, and with which contaminating microorganisms are inextricably in contact.
- *Processing factors*: Procedures that are deliberately applied to foods in order to achieve improved preservation.
- *Extrinsic factors*: Factors that influence microorganisms in foods, but which are applied from or exist outside the food; they also act during storage.
- *Implicit factors*: Factors related to the nature of microorganisms present in food product, and to their interactions among themselves and with the environment during growth.
- *Net effects*: These take into account that many of the factors strongly influence each other, so that the overall effect of combinations of different factors may not be obviously predictable, but may be usefully greater than the perceived effects of the single factors.

Combination (hurdle) effects are the focus of many of the recent developments in the predictive modeling of microbial growth and survival in foods. The limits presented at which these different preservative factors inactivate or inhibit relevant microorganisms must be used to evaluate the effects of these factors on spoilage and food poisoning microorganisms. However, it has to be remembered that the limits listed only apply if all other factors are optimal for the microorganisms in question. But this is hardly the case in any foodstuff. If more than one of the preservative factors (hurdles) is present then an additive or even synergistic effect results, and this is the basis of the hurdle effect and the intentional hurdle technology.

The effective hurdle technologies typically employ multiple hurdles to preserve foods. In the use of such multiple hurdles, a consideration of the stress reactions and adaptations that microorganisms undergo underpins the logic of employing hurdles that affect different targets in the microbial cell. Ideally, the targets should be complementary to gain synergism rather than simply additive effects (55).

If mild heating can be applied to the food, then the injury that would impair the membranes functionality may represent a further sensible target, which should amplify the effects of the previously applied hurdles relying on properly functioning membranes. The potential value of the multitarget approach can therefore be appreciated easily, and perhaps built on more logically in the future. An example of a multitarget novel process is PEF food treatment, which damages the cell membrane, in combination with the application of nisin, so the membrane cannot be repaired due to the membrane-active action of nisin (13, 65). Overall, therefore, homeostasis is interfered with by attacking two distinct targets.

It has been suspected that different hurdles in a food might not just have an additive effect on microbial stability, but could act synergistically (53). A synergistic effect could be achieved if the hurdles in a food hit, at the same time, different targets within the microbial cells and thus disturb the overall homeostasis of microorganisms present in several respects. If so, the repair of homeostasis as well as the activation of "stress shock proteins" in microorganisms becomes more difficult. Therefore, employing simultaneously different hurdles in the preservation of a particular food should lead to optimal stability (54). In practical terms, this could mean that it is more effective to employ different preservative factors (hurdles) of small intensity than one preservative factor of larger intensity, because different preservative factors might have a synergistic effect.

The multitarget preservation of foods is a promising research area, because if small hurdles with different targets are selected, a minimal but most effective preservation of foods could be accomplished. It is anticipated that the targets in microorganisms of different preservative factors will be more fully elucidated, and that hurdles could then be grouped in classes according to their targets. A mild and effective preservation of foods, i.e., a synergistic effect of hurdles, is likely to be achieved if the preservative measures are based on intelligent selection and combination of hurdles taken from different target classes (54). This approach is probably valid not only for the traditional food-preservation procedures, but also for modern processes of food irradiation, ultra-high pressure, or pulsed electric field, or light beam treatments, in combination with conventional hurdles.

a. PEF + hydraulic pressing

Mechanical expression is widely used in the food industry for extraction of fruit juices and vegetable oils, dewatering of fibrous materials, etc. (89). Efficacy of this process can be increased by raw material plasmolysis, cellular damage, or permeabilization prior to its expression. Various methods are traditionally used to increase the degree of raw material plasmolysis: heating, osmotic drying or freezing dehydration, alkaline breakage, enzymatic treatment, etc. (4). Earlier on, the method of electric field treatment (both DC and AC) was also proposed for cellular material plasmolysis. The methods of electro-plasmolysis were shown to be good for juice yield intensification and for improving the product quality in juice production (62), processing of vegetable and plant raw materials (27), foodstuff processing (63), winemaking (47), and sugar production (38). But all these electric field applications are usually restricted by the high and uncontrolled increase in food temperature and product quality deterioration because of electrode material electrolytic reactions, etc.

Bazhal *et al*. (9) investigated the influence of PEF applied simultaneously with pressure treatment on juice expression rate from fine-cut apple raw material. Three main compression phases were observed in the case of mechanical expression. A unified approach was proposed for juice yield data analysis allowing a reduction in data scattering caused by the differences in the quality of samples. PEF application at the moment when the press-cake's specific electrical conductivity reaches the minimum and the pressure achieves its constant value is reported to be the most optimal.

The combination of pressing and PEF treatments significantly enhances the juice yield and improves its quality in comparison with samples untreated by PEF. The PEF treatment intensifies pressing whenever it is applied. The best juice excess yield results at the lowest value of the applied field may be obtained when PEF is applied after some pre-compression period. Such pressure pretreatment before PEF application is necessary for structuring uniformity of the press-cake, removing excess moisture, and decreasing the electrical conductivity of the material. In Bazhal *et al*. (9) the precompression period of 300–400 s and PEF treatment after that period were found

to be optimal for the quality of juice, which was confirmed by its coloration and transmittance. The simultaneous pressure application and PEF treatment reveal the passive form of the PEF-induced cell plasmolysis, which develops very slowly under a low electric field without pressure application. The pressure promotes damage of defective cells, enhances diffusion migration of moisture, and depresses the cell resealing processes.

b. PEF + bacteriocins

Microorganisms in the presence of PEF suffer cell membrane damage, and nisin is a natural antimicrobial known to disrupt cell membrane integrity. Thus the combination of PEF and nisin represents a hurdle for the survival of *Listeria innocua* in the liquid whole egg, which has been investigated by Calderon *et al*. (13). *L. innocua* suspended in liquid egg was subjected to two different treatments: PEF and PEF followed by exposure to nisin. The selected frequency and pulse duration for PEF was 3.5 Hz and 2 ms respectively. Electric field intensities of 30, 40, and 50 kV/cm were used. The number of pulses applied to the liquid whole egg was 10.6, 21.3, and 32. The highest extent of microbial inactivation achieved with PEF was 3.5 log cycles (U) for an electric field intensity of 50 kV/cm and 32 pulses. Treatment of liquid egg by PEF was conducted at relatively low temperatures, 36°C being the highest. Exposure of *L. innocua* to nisin after the PEF treatment exhibited an additive effect on the inactivation of the microorganism. Moreover, a synergistic effect was observed as the electric field intensity, number of pulses and nisin concentration increased. *L. innocua* exposed to 10 IU nisin/ml after PEF exhibited a decrease in population of 4.1 U for an electric field intensity of 50 kV/cm and 32 pulses. Exposure of *L. innocua* to 100 IU nisin/ml following PEF treatment resulted in 5.5 U for an electric field intensity of 50 kV/cm and 32 pulses.

The model developed for the inactivation of *L. innocua* by PEF followed by the exposure to nisin (13) was established to be successful in predicting the extent of microbial inactivation resulting from the combination of PEF and nisin. The combination of these two preservation factors proved to be a hurdle against the survival of *L. innocua* in the liquid whole egg. When energy conservation is a goal, inactivation of *L. innocua* in liquid egg products can be accomplished by selecting the proper combination of PEF intensity and nisin concentration.

Carvacrol was used in another study as a third preservative factor to further enhance the synergy between nisin and pulsed electric field treatment against vegetative cells of *Bacillus cereus* (70). Applied simultaneously with nisin, carvacrol (0.5 mM) enhanced the synergy found between nisin and PEF treatment (16.7 kV/cm, 30 pulses) in potassium-N-2-hydroxy-ethylpiperazine-N-ethanesulfonic acid (HEPES) buffer. The influence of food ingredients on bactericidal activity was tested using skimmed milk that was diluted to 20% with sterile demineralized water. The efficacy of PEF treatment was not affected by the presence of proteins, and the results found in HEPES buffer correlated well with the results obtained in milk. Nisin showed less activity against *B. cereus* in milk, and carvacrol was not able to enhance the synergy between nisin and PEF treatment in milk, unless used in high concentrations (1.2 mM). This concentration in itself did not influence the viable count, but carvacrol did act synergistically with PEF treatment in milk, and not in HEPES buffer. This synergy was not influenced by milk proteins, since 5% milk still allowed synergy between carvacrol and PEF treatment to the same extent as 20% milk.

127 Nanotechnology and Its Applications for the Food Industry

Paul Takhistov
Rutgers University

CONTENTS

I. INTRODUCTION

Nanotechnology — a term introduced in 1974 to describe ultrafine machining of matter — now can be applied to a wide scope of small-scale engineering (133). Nanotechnology research has emerged as one of the most revolutionary scientific topics in decades. Nanotechnology focuses on the physical/biological structures smaller than 100 nm, which result in unique material properties because of their nanosize. Some of these structures can be manipulated and converted into nanomachines able to perform functions previously not possible. Nanotechnology arises from the exploitation of new properties, phenomena, processes, and functionalities that matter exhibits at intermediate sizes between isolated atoms or molecules (~1 nm) and bulk materials (over 100 nm). The reason that nanoscale materials and structures are so interesting is that size constraints often produce qualitatively new behavior. When the sample size, grain size, or domain size becomes comparable with a specific physical length scale such as the mean free path of the molecules, the domain size strongly affects the corresponding physical phenomena. Figure 127.1 represents the fundamental science and engineering disciplines endowing in the nanoscience and nanotechnology development in their current state.

The objective of this chapter is to show the potential of the nanotechnology field to the food science and technology community.

Food manufacturing will benefit greatly from future developments in nanoscale science, engineering, and technology. For instance, nanoscale synthesis and assembly methods are expected to result in significant improvements in energy-efficient food processing; stronger, lighter materials that increase transportation efficacy; greatly improved chemical and biological sensing; use of low-energy chemical pathways to break down toxic substances for environmental remediation and restoration; and better controls that enhance efficacy of manufacturing processes.

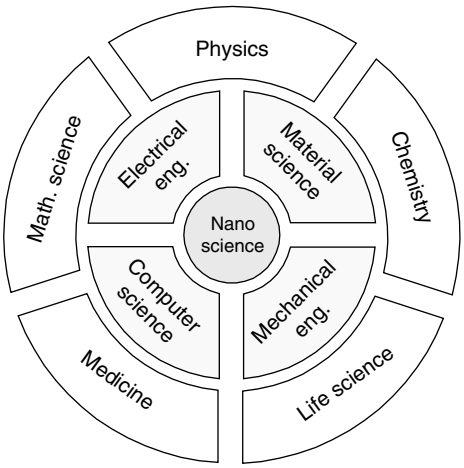

FIGURE 127.1 Nanoscience is the integrative combination of applied and basic sciences.

The study of nanostructures in biological materials of plant and animal origin enables scientists to establish relationships between macroscopic and molecular properties of materials, such as molecular structure, degree of order, and intermolecular forces. Minuscule nanomachines able to circulate through the blood stream and clean out fat deposits from arteries, kill microbes, undo tissue damage, and reverse cancer, could be delivered to the human body through foods. This will put in a new perspective the health promotion role of foods (111). Generation of foods by nonbiological means using advanced nanotechnology could be another future development, meant to ensure enough nutrition for the entire human population with limited resources. In food systems it is possible to envision self-assembling molecules capable of building well-defined food structures; the manipulations of molecular conformation to deliver active compounds precisely to designated sites.

II. NANOTECHNOLOGY IN FOOD SCIENCE

Nanotechnology has the potential to revolutionize world's food system. Agricultural and food systems security, disease treatment delivery methods, new tools for molecular and cellular biology, new materials for pathogen detection, protection of the environment, and education of the public and future workforce are examples of the important links of nanotechnology to the science and engineering of agriculture and food systems. Some overarching examples of nanotechnology as an enabling tool for food industry are:

- Manufacturing, processing, and shipment of food products can be made more secure through the development and implementation of nanosensors for pathogen and contaminants detection.
- The development of nanodevices that will enable maintaining the historical environmental records of a particular product and tracking of individual shipments.
- Systems that provide integration of sensing, localization, reporting, and remote control of food products ("Smart/Intelligent Systems") that can increase efficacy and security of food processing and transportation.

Strategies to apply the achievements of nanoscience to the needs of food industry are quite different from the traditional nanotech applications. Food processing is multitechnology manufacturing with a broad range of raw materials used, high biosafety requirements, and well-regulated technological processes. Four major trust areas in food production can be significantly enhanced by nanotechnology, bringing it to the next technological level: development of new functional materials; micro- and

nanoscale processing; product development; and methods and instrumentation design for improved food safety and biosecurity. Possible nanotechnology applications in food industry, grouped by the target area are depicted in Figure 127.2.

Employing nanoscience in food technology is the complex process not limited to improvement of individual processes and products, but considering the whole food supply chain as a continuous process sequence.

Nanotechnology works at the same scale as a virus or disease-infecting particle, and thus has the potential for very early detection and eradication of pathogens. Nanotechnology holds out the possibility that "smart" treatment delivery systems could be activated long before macro symptoms appear. For example, a smart system could be a miniature device implanted in an animal that samples saliva on a regular basis. Long before an illness develops, the integrated sensing and monitoring system would detect the presence of a disease, and activate a targeted treatment delivery system.

The fundamental processes in agriculture are explored through research in molecular and cellular biology. New tools for molecular and cellular biology that are specifically designed for separation, identification, and quantification of individual molecules are needed. This is possible with nanotechnology and will permit broad advances in agricultural research areas such as reproductive science and technology, conversion of agricultural and food wastes to energy and other useful by-products through enzymatic nanobioprocessing, and disease prevention and treatment in plants and animals.

New materials that have special characteristics at the nanoscale will be a tremendous breakthrough in agriculture and food systems for pathogen and contaminant detection. Materials that have self-assembly and self-healing properties will find a multitude of applications in agriculture. Packaging of food in "antimicrobial" containers would prevent food microbial contamination and facilitate food preservation, storage, and distribution.

Protection of the environment through the reduction and conversion of agricultural materials into valuable products is an exciting potential area of nanotechnology advancement. The design and development of nano-catalysts for the conversion of vegetable oils into biobased fuels and biodegradable industrial solvents is one approach already under scientific examination, and would be greatly enhanced with the addition of nanotechnological abilities.

Management of local and environmental emissions is another area of agriculture that could benefit from nanotechnology. Before reaching the dinner table, the lettuce, baked potato, broccoli, and warm wheat bread have survived a formidable number of challenges from the environment. Agricultural crops must be protected against the invasions of wild animals, weeds, insect pests, fungal pathogens, and the whimsy of the weather. Daily "scouting" of crops for potential problems is one of the most important tasks in the agriculture sector. Preventive monitoring and treatment of crops with nanoscale devices (sensors and delivery systems) can improve the quality of food products and durability of post-harvesting processes.

III. NEW PROPERTIES OF MATERIALS AT NANOSCALE

The area of nanomaterials technology presents an unprecedented opportunity to investigate the new properties of materials at the nanoscale (158), and to exploit this knowledge to our benefit. The tools responsible for this

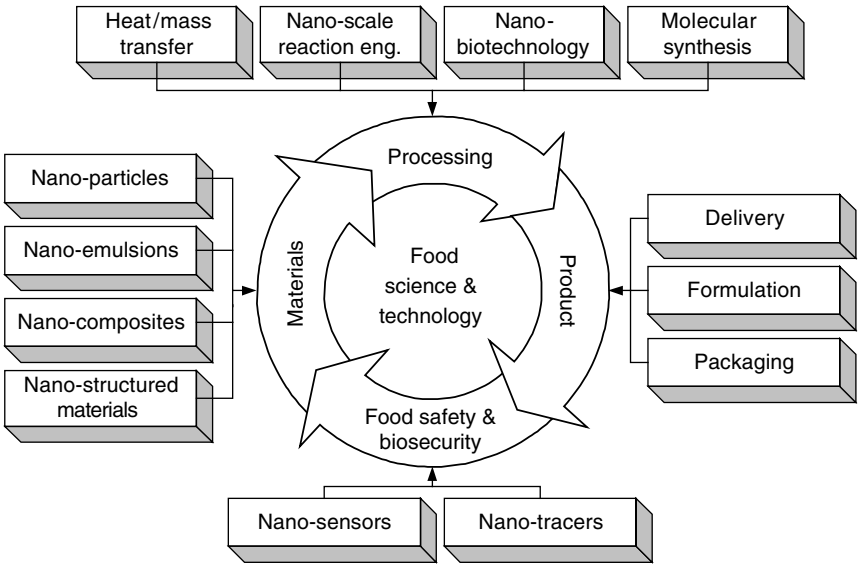

FIGURE 127.2 Application matrix of nanotechnology in food science.

opportunity include synthesis methods that permit atomic and electronic structure of the material to be controlled to the atomic scale, in all three dimensions; instrumental probes that are capable of characterizing nanoscale materials, structures, and their properties on a wide range of length and time scales; and growing computational power which permits theoretical exploration of structures and properties from the atomic to the macroscopic scale.

Nanomaterials can be either created through nanotechnology, or found in nature, such as nanoparticles existing in soil (clays, zeolites, imogolite, iron, and manganese oxides). They provide the potential to manipulate structures at the nanoscale, and to control and catalyze chemical reactions. The shape, structure, and aggregation abilities of individual particles at the nanoscale influence the properties of the material at the macro-level. "Smart fabrics" that can monitor the vital signs of the wearer are an example of the potential new uses envisioned for agricultural fiber products. Nanoparticles are also produced as agricultural by-products: airborne dust and aqueous runoff that cause air and water pollution. Controlling these nanoparticles is in the best interests of cost-effective and environmentally responsible agriculture. Soils are aggregates of nanoparticles, layer particles, organisms, and water. Viewing soil as a nanocomposite, and applying the paradigms and technologies of nanoscale science to it will lead to more efficient and environmentally friendly agriculture.

A. Effects of Size Constraints

Size constraints alone are often responsible for qualitatively new behavior of materials. For example, if the nanoscale structure is smaller than the characteristic lengthscale for scattering of electrons or phonons (the mean free path), qualitatively new modes of electrical current and/or heat transport can arise (49, 148).

Thermodynamic properties, including interface phenomena and phase transitions demonstrate substantial changes when the system size is comparable to the particle size or the coherence length for collective behavior (70). Systems with components sizes ranging from a few tenths to about ten nanometers lie at the fuzzy boundary between the quantum and classical domains. Such systems are also in the size range where thermal energy fluctuations and Brownian motion can have significant effects.

The mechanical properties also change dramatically as the grain size in polycrystalline materials approaches the nanometer scale (3). Changes in the strength of nanoscale structural elements, changes in the nature of friction, and effective modes of fluid flow (hence, of lubrication) all require new design strategies for micromachines (87). Modes of failure also will change, as the size of devices and machines decreases toward the nanoscale. The causes include different mechanical properties that will modify fracture characteristics; the increased importance of surface tension; and, the enhanced role of diffusion and corrosion at the large surface-to-volume ratios that exist in materials at nanoscale (106).

B. Shift of Characteristic Time Scales

Lengthscale change is accompanied by concomitant changes in the characteristic time scale of physical phenomena. In part, this is no more than the increase in characteristic frequencies that follows from the decreased time required to travel shorter distances at a fixed propagation velocity (for phonons, photons, electrons, etc.).

Another time-dependent phenomenon at nanoscale is an increased rate of kinetic processes due to the increased fluctuation rate, as the reduced dimensionality of important structural features (e.g., surface-to-volume ratio) becomes important or dominant. This effect also leads to the increased effectiveness of sensor elements in biological systems.

C. Magnetic Properties

Dramatic quantization and other effects occur in magnetic materials at the nanoscale. The ability to control thin-film growth at the near-atomic level to form epitaxial and heteroepitaxial structures has recently been extended to magnetic nanostructures, including metallic, oxide, and semiconducting phases (51, 116).

D. Thermal Properties

Thermal transport properties of nanostructured materials have received relatively little attention in the past decade. It is well known that polycrystalline materials exhibit lower thermal conductivity than low-defect single crystals of the same material. Investigators have recently realized that this could result in significantly reduced thermal conductivities of nanostructured materials (86, 129), which are expected because of a reduction in the phonon mean free path due to grain boundary scattering (43).

In contrast to the reduced thermal conductivity of nanostructured thin films or coatings, opportunities exist for increasing thermal transport rates in fluids by suspending nanocrystalline particles in them. These "nanofluids" have recently been shown to exhibit substantially increased thermal conductivities and heat transfer rates compared to fluids that do not contain suspended particles (96). Food industry widely employs heat exchangers that require fluids with efficient heat transfer properties. With new "nanofluids" with increased heat transfer rates manufacturers can make heat exchange systems smaller and lighter, and reduce the amount of energy and heat transfer fluid required for the system operation.

E. Energy Conversion and Transport

Energy conversion and transport in nanostructures impacts a variety of fields and applications. Although energy

conversion and transport at macroscales is relatively well understood, it is not at all clear at the nanoscale. For example, it is well known that thermoelectric refrigerators and engines are not as efficient as other energy conversion devices because heat conduction by phonons is too high in thermoelectric materials. There is evidence that nanostructuring can improve electron transport (67–69).

F. Friction Control at Nanoscale

Nano-devices are expected to significantly improve the performance of robots, computers, communication, and other electrical/optical/mechanical devices. However, friction imposes significant limitations on the usage of these tiny devices. As a manifestation of the *nano in the macro*, hundreds of millions of dollars can be lost as a result of wear, friction, breakdowns, and wasted energy at nanoscale. Achievements in the research allowing friction control at the nanoscale will result in highly improved performance in the macro world and can produce significant economic savings (21).

Traditional lubrication methods employ organic substances whose functional groups can adsorb onto polar surfaces to form closed-packed arrangements of almost perpendicularly oriented lubricant chains. Nano-machines lubricant selection is complicated by new considerations. Due to the built-in-place nature of nano-mechanics, lubrication by the conventional means of hidden and contacting surfaces is prohibited. Fluid lubricants may also introduce capillary and viscous shear mechanisms, which would result in energy dissipation. Despite great progress made during the past half century, many basic issues in fundamental tribology such as the origin of friction and the failure of lubrication remained unsolved. Moreover, current reliable knowledge related to friction and lubrication is mainly applicable to macroscopic systems and machinery, and will be of only limited use (if at all) in nano-systems. When the lubrication film thickness is of the same order as the molecular or atomic size, the behavior of the lubricant becomes significantly different (75). Understanding the mechanisms of friction, lubrication, and other interfacial phenomena at atomic and molecular scales can provide designers and engineers with the required tools and capabilities to control friction, reduce unnecessary wear, and predict mechanical faults and failures of lubrication in nano-devices (20, 146).

IV. CONTROLLED SYNTHESIS AND PROCESSING AT NANOSCALE

Nanotechnology is comprised of the large family of phenomena and processes. Only two of them — nanomeasurement and nanomanipulation — are currenty developed and technically proven. Molecular manufacturing is the combination of these two activities. Application of nanotechnology to molecular manufacturing allows that the environmentally clean, inexpensive, and efficient manufacturing of structures, devices, and "smart" products based on the flexible control of architecture and processes at the atomic or molecular scale can be feasible in the near future. The ultimate goal of the molecular manufacturing is to produce complex products on demand from simple raw materials, e.g., inserting basic chemical elements in a molecular assembly factory to yield a common household appliance, perhaps with built-in sensors and actuators to respond to commands or changes in environmental conditions.

A. Nanotechnology: Drawing Inspiration from Nature

Living organisms are not just the collections of nanoscale objects — atoms and molecules; these objects are organized in hierarchical structures and dynamic systems, that are the results of the million years-long Mother Nature's experiments. Tenth-nanometer ions such as potassium and sodium generate our nerve impulses. The size of vital biomolecules, such as sugars, amino acids, hormones, and DNA, is in nanometer's range. Membranes that separate one cell from another, or one subcellular organelle from another, are about five-fold bigger. Proteins can be tens of nanometers across. Every living organism on Earth exists because of the presence, absence, concentration, location, and interaction of these "nano-structures."

The uses of biological molecules are split between two categories:

- Biological molecules can be used in conjunction with other structures to perform just as they do in organisms.
- Biological molecules can be used in conjunction with other structures to perform in a novel manner, quite distinct from their natural function.

Functional nanostructures can incorporate individual biological molecules. For example, biosensors can use natural sugars or proteins as target recognition groups (30). Modified biological structures can be used to act in MEMS devices — for example, modified photosynthetic membranes can split water to hydrogen and oxygen (54). Functional multi-component structures can use molecules in unusual ways. The filament protein actin, found in muscle, can be attached to the enzyme ATP synthase, which is involved in the production of most of the cell's ATP, its "energy currency" (115), and act as a molecular motor.

Many specific functions performed by living systems employ nanometer-size structures in particularly intriguing ways that we would very much like to emulate:

- Living systems utilize **self-assembling** multiple individual parts in a precisely defined functional structure.

- Living systems are hierarchically organized into **complex structures**. For example, collagen, a fiber that rivals steel in strength, is built through successive aggregation of single amino acid strands into triple helices, triple helices into microfibrils, microfibrils into fibrils, and fibrils into fibers.
- Living systems use **template**-based elements, such as DNA, for **reproduction** and recovery (125).
- Organisms can **sense** their molecular surroundings, having developed exquisitely sensitive nanometer-size **sensors** on their outer surfaces. Using the principle of molecular recognition, only the specific desired target can bind to the surface-mounted "receptor" molecules. Upon binding, these receptors change shape in a manner that alerts other components of the system to the presence of the target (78).
- Living systems use nanometer-size structures to act as **highly selective pumps**. The electron transport chain, which is central to the trapping of the energy content of nutrients, pumps protons from one side of the mitochondrial membrane to the other, against the chemical gradient (114). Neurons pump sodium ions out and potassium ions into the cell to prepare it for the next impulse (139).
- Living systems use nanometer-size structures as **switches**. Within 200 msec of the binding of a repellant molecule to a receptor, a phosphoryl group is transferred to a protein and the rotation of the bacterial "tail" is switched from counterclockwise to clockwise. This turns the organism around and allows it to swim away from the repellant (92).
- Living systems use nanometer-size structures to perform **catalysis** with specificity, selectivity, and rate enhancements that are hardly achieved artificially. Enzymes can be selective enough to catalyze a reaction with only one particular molecule from a mix of many, ignoring even its mirror image. Enzymes can selectively catalyze only one of many chemically allowed reactions with that molecule, with rate enhancements up to 10^{16} fold (164).

B. New Manufacturing Paradigm

The concept of manufacturing at the "nano" or atomic scale dates to more than three decades ago. Many developments in biotechnology, chemistry, computational tool building, electrical engineering, and physics have moved the scientific and engineering community closer to operating smoothly on the nanoscale. Manufacturing of new nano-materials with pre-determined functionality is a sequence of macroscale processes combined with the microscale control and energy delivery (see Figure 127.3).

All individual steps in the suggested manufacturing sequence already exist at least in the lab-scale experiments. The aim of the next decade is the integration of individual steps and components into the working system.

Extensive molecular manufacturing applications, if they become cost-effective, will probably not occur until well into the future. However, some products benefiting from molecular manufacturing technology may be developed in the near term. As initial nanomachining, novel chemistry, and protein engineering (or other biotechnologies) are refined, initial products will likely focus on those that substitute for existing high-cost, lower-efficiency products. Likely candidates for these technologies include a wide variety of sensor applications; biomedical products including diagnostics and therapeutics; extremely capable computing and storage products; and unique, tailored, smart materials, including those for food processing and biosecurity applications. Areas that are important to the future of molecular nanotechnology-based advanced manufacturing, and in which successful discoveries could serve other applications, include the following:

- Macromolecular design and folding (32, 59, 94, 172);
- Self-assembly methods (79, 124, 174, 181);
- Catalysis (inorganic, enzyme, and other) (135, 160, 161);

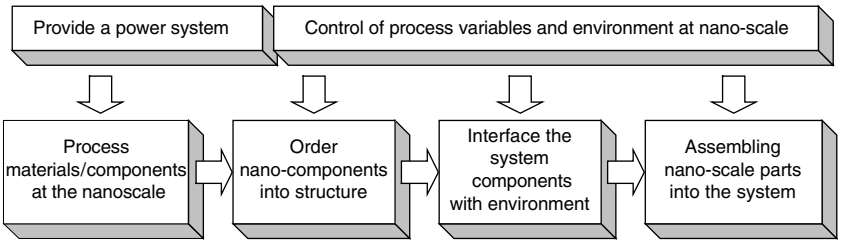

FIGURE 127.3 Manufacturing at nanoscale.

- Dendrimers, fullerenes, and other novel chemical structures development (48);
- Bioenergetics, nanobatteries, and ultrasound-driven chemistry (17, 31, 33, 38, 134);
- Semiconductor-organic/biological interfaces studying (36, 53, 62).

C. Synthesis of Individual Building Blocks

The first step of nanoscale manufacturing process is the fabrication of individual components (building blocks for the entire system) at nanoscale. These components can greatly differ in nature and required processing conditions, but all are suitable for the high-volume production.

1. Nanocrystals

In the last decade there have been significant advances in the preparation of nanocrystals (26, 104). Many common materials, such as metals, semiconductors, and magnets, can be prepared as nanocrystals using colloidal chemistry techniques, which lead to a wide range of applications in unexpected areas, such as in biological tagging (25, 29).

2. Nanotubes and Rods

The exciting discovery of the fullerenes was followed closely by the discovery of nanotubes of carbon (156). Carbon-based nanotubes have the potential to act as a hydrogen storage medium that could exhibit very high storage density per unit weight, which is critical for hydrogen-based transportation systems. A crucial issue is whether or not the hydrogen could be extracted efficiently from such a storage medium at relatively low temperatures. Nanotubes also show tremendous promise as building blocks for new materials.

3. Polymeric Electronic Materials: Dendrimers and Block Copolymers

Tremendous advances in the preparation of organic building blocks of considerable complexity have been made through the last decade (105, 152, 159).

D. Templated Growth and Assembly

High surface area materials with nanoscale dimensions, i.e., small particles and clusters with very high surface-to-volume ratio, can be attained by creating materials where the void surface area (pores) is high compared to the amount of bulk support material (119). Nano-porous inorganic oxides can be an example of such materials. Properties of these materials, e.g., chemical reactivity, magnetic moment, polarizability, and geometric structure exhibit the strong dependence on surface dimensions.

Nanoscale surfaces as well as nano-particles have considerable utility as controlled drug delivery systems and biosensitive molecules carriers (109). Increased surface area of a nano-structured material leads to the increasing of the surface chemical reaction rate and intensification of the electron transfer (i.e., biosensor output signal) through the solid-liquid interface. Furthermore, ordered nanoscale structure of a surface substrate stimulates ordering and self-assembly of deposited specific biological components at the molecular level. The use of nanoscale fabrication techniques for low dimensional devices is being investigated to complement the more traditional fabrication methods (40). These nano-synthesizing techniques take advantage of the self-patterning of natural systems, where the biointerface material is synthesized in the size and shape of the desired nano-structure. These methods include fabrication of nano-structure arrays using self-assembled epitaxial growth (14), chemical synthesis of colloidal nano-structures (2), synthesis of nano-structures in glass and polymer materials (155), and template based chemical synthesis of nano-structures (136). Preparation of mesoporous inorganic solids has been greatly advanced by Antonelli (4). The initial work showed that it is possible to use organic surfactant molecules to prepare complex patterns. These patterns can serve as the templates for the formation of an inorganic phase.

E. Driven Systems

A very promising area for processing of three-dimensional bulk nanoscale structures originates with the recent discovery that mesoscopic structures can be obtained by nonequilibrium processing, such as ion irradiation, implantation, and mechanical working (ball milling, etc.) (11, 88, 103). It is worth mentioning that similar processing schemes perform very important functions in biological systems.

Self-assembly is one of the tools required to build ordered nanostructures. The dynamics underlying the self-assembly process is now well understood (24, 117). A material system embedding enormous complexity dynamically transits through a variety of states, squeezing out free energy along the way, to arrive at a functional (and desirable) configuration. The spontaneous organization of a vesicle and the folding of a protein are notable examples of this phenomenon. Self-assembly, however, is not a completely enabling and sufficient tool. Biological systems make extensive use of both self-assembly and dissipative processes to make important structures or effect adaptive changes (166, 167).

F. Phase Transformations

Many processing schemes involve transformations between different phases of the material. Although thermodynamics ultimately determines the equilibrium phase for a given set of conditions, the answers as to whether and how this phase

is achieved from the metastable precursor phase depend on system kinetics. Since most phase transitions involving nanostructured materials occur under conditions far from equilibrium, the kinetic pathways available to these systems are numerous and not well understood. This problem is further complicated by the large contributions to the free energy of nanoscale materials from interfaces, which substantially shift phase boundaries. It will be important for making progress in the areas of synthesis and processing of nanomaterials to develop better understanding of nanochemistry and the broader general issues of nucleation and growth. One example of how phase transformations are used in the processing of nanostructured materials has already been noted, namely the formation of metallic nanoparticles in silicate glass for non-linear optical devices (98). The processing of bulk nanostructured materials from bulk metallic glass provides another example of using phase transformations in nanotechnology (65, 179). Both materials are now commercially available.

G. Directed Synthesis of Nanoparticles, Nanotubes, and Nanostructured Materials

Nanostructured materials also promise greatly improved structural properties in comparison with conventional metal alloys. For example, small-diameter bundles of single-walled carbon nanotubes have been predicted and observed (126, 141). They have the largest strength-to-weight ratio of any known material with an elastic modulus ~1 TPa, which is approximately 10^2 times that of steel but with only 1/6 its weight. Such materials offer almost unimaginable economic benefits and product opportunities, if only they can be cross-linked to overcome the low shear modulus (141).

H. Nanomechanics and Nano-to-Micro Assembly

The future of nanoscale devices depends upon the abilities of scientific community to physically manipulate the nano-sized parts and to build and integrate larger micro-to-mini scaled devices (42). However, relative significance of fundamental physical forces changes as parts are reduced in size. Figure 127.4 shows the variation of different forces with respect to parts scale. For parts with features of the order of a few millimeters and above, classical mechanical phenomena such as mass and friction dominate the manipulation processes. However, when part sizes are reduced below one millimeter threshold, surface effects such as adhesion due to surface condensation and the electrostatic potential between parts start to dominate in manipulation over the classical inertia effects present in large-scale moving structures.

V. NANO-BIOENGINEERING

The use of natural biological processes to create a desired compound or material from a defined feedstock, e.g., compost material from plant and animal wastes, is called *bioprocessing*. Nanobioprocessing focuses on and utilizes nanoscale technology to achieve the goal of bioprocessing with greater efficacy. The use of molecular probes or development of assays that allow rapid identification of microbes present in a feedstock are examples of the research at nanoscale that can increase the efficacy of bioprocessing. The product itself may be the bulk material or nanomaterial.

Nano-engineering of a biological system is focused on the assembly of nanomaterials to create or enable a specific biological function and/or the subsequent characterization of that function. This can be viewed as a separate

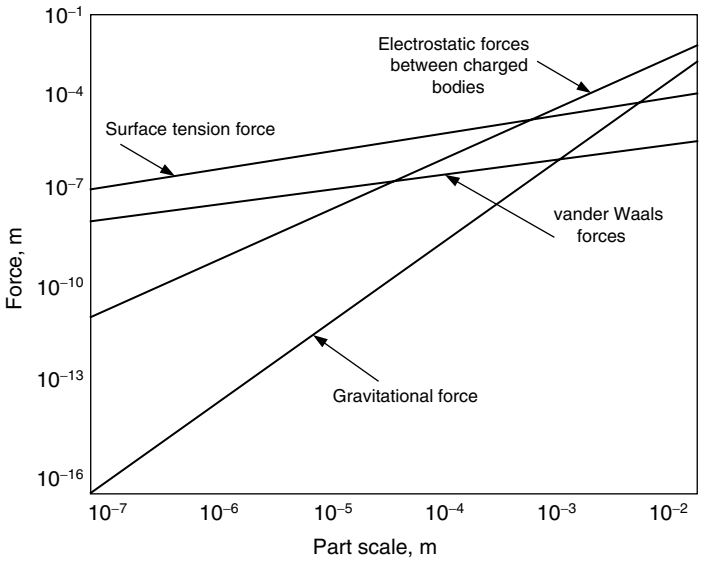

FIGURE 127.4 Forces variation with scale.

project from the study of nano-biomaterials themselves, which is defined by their isolation and characterization or their synthesis from basic building blocks (57, 151, 152).

The extension of nano-engineering to biology includes patterning of 2D templates to direct cell or tissue response for biocompatability or biosensor applications. Applications in medical science include implants, prosthesis, drug delivery, and diagnostics. Other examples include creating a biological input/output device using nano-fabrication techniques to enable communication with individual cells for information technology applications (53, 62, 110, 170). The field of computer science is struggling with the problem of how to integrate information science with biology (73). One approach has been through bioinformatics, where traditional computer science methodology and hardware is applied to manage the enormous amount of information now available from biotechnology (173). Another approach envisions the *integration* of the biology with computer science in creating new hardware and technology to enable direct communication with the biology. If successful, this will provide the platform for the treatment of biology as just another peripheral for sensing, data storage, and information security functions. Other applications of this hybrid system could include communication with individual cells to switch on and off the biomanufacturing of drugs *in vivo*, or the construction of biological–nonbiological hybrids for robotics studies and applications (63, 149, 153).

Nanopatterned surfaces are the environment and location on which most chemical and biological interactions occur (12, 143). A bioselective surface has either an enhanced or reduced ability to bind or hold specific organisms or molecules (128). Bioselective surfaces are important to the development of biosensors, detectors, and catalysts, in the separation or purification of mixtures of biomolecules, and in the processing and packaging of foods (37, 182).

The primary objective of nanoengineering is the engineering of the biological interface (66). The success of two-way communication between electrically active cells and microelectronic devices depends on the proper registration of cells with the microelectrode and their close association or "seal" to this microelectrode (80). The "seal resistance," R_{seal}, is measured between the electrode and the grounded recording media. Low values of R_{seal} are associated with poor electrode-to-cell adhesion resulting in an attenuated and distorted bioelectrical signal, a problem inherent in most extra-cellular recording systems. In contrast, R_{seal} values in the GOhm range, which are typically achieved using glass micropippettes during electrophysiology measurements, permit clearer resolution of bioelectric signals. In tissue this seal is accomplished by the interactions of proteins and other biological macromolecules with the glycocalyx, or outside surface of the cells. The first step in recreating this interface is nanoengineering of the non-biological surface with biologically compatible materials such as proteins, peptides, and biologically active functional groups (47, 83, 89). Surface modification allows a large variety of biomolecules to be attached to a microelectrode surface, which facilitates cell–microelectrode adhesion, increases R_{seal}, and allows for geometric placement of cells (131). For example, it is possible to control nutrients supplied to cells, so that they produce desirable surface groups that allow binding of those cells to specific nonbiological surfaces (175). The immediate benefit is that if a cell is associated with a single microelectrode, it becomes an individual sensor permitting multiple independent assays that then enable statistical analysis. Extracellular recordings of these individual sensor elements would allow long-term, multi-site measurements of electrically active cell bodies and processes for building information technology devices (144).

Modern chemistry and material sciences allow the systematic and parallel patterning of matter on the nanoscale (2). The controlled positioning of atoms within small molecules is of course routinely achieved by chemical synthesis of moles of identical molecules. Nanometer-size objects are much larger entities, comprised of thousands or even millions of atoms. There are many powerful new approaches to patterning on the nanoscale, including atom manipulations by scanning probe tips, and electron beam lithography (132, 165).

VI. CONTROL AND MEASUREMENT PARADIGM AT NANOSCALE

A. Nanoscale Instrumentation

Progress in nanotechnology requires the appropriate tools to observe, characterize, and control phenomena at the nanoscale. A whole new generation of analytical instrumentation and nanoscale devices, capable of providing information about physical, chemical, and mechanical phenomena, and material properties at nanoscale must be developed. Nanotechnology is already benefiting from novel instrumentation developed during the past two decades, for example scanning probe microscopes (SPM, see Figure 127.5), and the new generation of synchrotron x-ray sources capable of studying materials at the nanoscale. On the other hand, recent discoveries in nanoscale science and engineering provide the basis for the development of unprecedented new tools. Thus, both opportunities and challenges in developing instruments for synthesizing nanostructures, as well as for characterizing of existing nanostructures and measuring properties of nanomaterials, will exist during the next decade.

Scanning probe microscopy is a family of techniques, which provide images of the surface topography and, in some cases, surface properties on the atomic scale. The inventions of the scanning tunneling microscope (STM) (16) and the atomic force microscope (AFM) (15) have spawned the development of a variety of new scanning probe

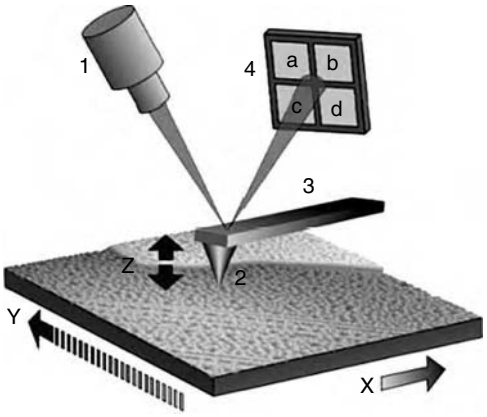

FIGURE 127.5 Schematic representation of Scanning Probe Microscope 1 — Laser source, 2 — tip, 3 — canteliever, 4 — photodetector array.

microscopes (SPMs)(168). Whereas the STM and AFM have found applications mainly in topographical imaging, the other SPMs added more functionality. Examples include the near-field scanning optical microscope (NSOM) (13), scanning thermal microscope (SThM) (99, 100), scanning capacitance microscope (SCM) (171), magnetic force and resonance microscopes (MFM) (72, 138), and the scanning electrochemical microscope (SECM) (7). Some current applications of SPM for nano-materials analysis include a sensor that can measure atomic-level forces that develop between two surfaces as they approach each other and come into contact also has been developed (74). The Interfacial Force Microscope (IFM) utilizes a feedback force sensor that eliminates the snap-to-contact event that is inherent in other scanning force microscope designs. The IFM allows measurement of the full range of adhesive interactions and can be used to image surfaces by controllably hovering out of range of contact.

Understanding of how an atom travels over a surface at different temperatures, and ultimately incorporates into the surface, is crucial to making smaller, faster, smarter nanodevices. A new instrument called "Atom Tracker" (154) can observe an individual atom in motion, and track atomic motions up to 1000 times faster than a conventional STM. Continuous monitoring of the motion of an individual atom as it binds to various sites on a surface allows this diffusing atom itself to become a probe of the surface structure and properties.

In order to understand processes used to produce nano-sized particles deposited on surfaces, the new aerosol instrumentation is needed. Significant progress has been made recently, with instruments now available for detecting particles as small as several nanometers in diameter (145, 150).

Nano-sensors have a high potential for deployment in areas and media that are not readily amenable to probing by traditional devices (177). An example is medical operations requiring minimally invasive surgery. A collection of specialized devices may be needed to provide all necessary functionalities. One can imagine an ensemble of micro- or nanorobots that cooperatively explore, assess, and operate on various locations in an organ. This poses formidable challenges in signal processing, control, and interconnectivity (178). Consequently, as non-destructive, real-time measurements of the physical properties of nanoparticles and nanostructured materials evolve, and as their use to monitor nanomaterials processing is developed, they will provide exceptional opportunities for fundamental and applied investigations and problem-solving at nanoscale (27, 62).

B. Nanosensors

Conventional sensors now can provide an abundance of information about the environmental conditions such as temperature and weather, data on air, land, and sea transportation, chemical contaminants, deceleration for release of airbags in automobiles, and countless other parameters. Biological organisms also have the ability to sense the environment. For example, humans sense the environment through sight, touch, taste, smell, and sound. In living organisms, various sensors operate over a range of scales from macro- (ear drum vibrations), to micro- (nerve cells impulses), to nanoscale (molecules binding to sensors in our noses).

The exciting possibility of combining biology and nanoscale technology into sensors holds the potential of increased sensitivity, and therefore a significantly reduced response time to potential problems (120, 121, 162, 176). It is possible to design a bio-analytical nanosensor that could detect a single virus long before it multiplies and the symptoms become evident in a plant or an animal (133, 163). The potential applications for bioanalytical nanosensors include detection of pathogens (85), contaminants (55), heavy metals, particulates or allergens, and environmental conditions (35).

Thundat *et al.* (157) has demonstrated that the interactions of antigen molecules with their corresponding antibodies, attached to surface of an AFM cantilever, can provide sufficient surface stress to bend the cantilever beam. Such a device is an example of hybridization and integration of nanostructures at several levels, because along with nanocomponents (antibodies bound to a cantilever surface) it has microcomponents (cantilever beams), which can be delivered in a chip (millimeter scale components), that integrates biology and biochemistry with engineering. Boxer (19) has recently developed the method of the deposition of lipid membranes into lithographically defined corrals. Early results suggest that this approach may allow *electrochemical addressing* of photo-defined membrane cells. Consequently, this is the first step towards integrating the functional nanotechnology demonstrated by living cells into robust machine architecture. The design

and assembling of specific structures at near-atomic scales requires precise controlling of the materials according to macro- and mesoscopic specifications, which are actually decided at the quantum level (180).

The development of chips/sensors for rapid detection of biological pathogens is a critical area with applications in the food handling/processing industry, in biological/chemical warfare, and in emerging biosecurity systems with early warning for exposure to air- and water-borne bacteria, viruses, and other antigens (9, 107). Microfabricated chips for DNA analysis (93, 97) and for the detection of polymerase chain reaction (91) have already been demonstrated. The μChemLab (50) has performed the research to incorporate similar structures into a fully autonomous analytical system that can be integrated into on-a-chip architectures. For example, organically functionalized mesoporous structures have been successfully integrated on a micromachined heating and flow stage to provide 1000-fold chemical preconcentration for on-a-chip analysis of chemical warfare agents.

C. Smart Systems Integration: Sensing, Localization, Reporting, and Control

The nanotechnologies can only reach their full potential through integration. The "Smart Systems Integration" is similar to designing and building the logic of a "nervous system" that allows the individual parts to work together (56). Integration of the nanotechnologies into a working food safety management system (whether remotely or automatically controlled) requires successful electronic communication between several components, including sensing systems, reporting systems, localization systems, and control systems (101, 122). The logic to control the subsystems (control algorithms) must be developed and eventually translated into a computer language (35).

VII. APPLICATIONS OF NANOTECHNOLOGY IN FOOD INDUSTRY

A. Nanodevices for Identity Preservation and Tracking

Application of nanotechnology in agriculture brings the opportunities that once were only possible in science fiction. Identity preservation (IP) is a system that provides customers with information about the practices and activities used to produce a particular crop, food, or other agricultural product. Regulatory agencies can take advantage of IP as a more efficient way of recording, verifying, and certifying agricultural practices. Through IP it is possible to provide stakeholders and consumers with access to information, records, and supplier protocols regarding the food product's farm of origin, environmental practices used in its production, food safety and quality, and animal welfare issues.

Each day multiple shipments of different agricultural products are moved all over the world. Currently, there are financial limitations of the number of inspectors that can be employed at critical control points for the safe production, shipment, and storage of foods and agricultural products (64). Quality assurance of agricultural products' safety and security can be significantly improved through the IP. Nanoscale IP holds the possibility of the continuous tracking and recording the history of manipulations, processing steps, and transformations which a particular agricultural product experiences. In the future, these nanoscale intelligent monitors can be linked to recording and tracking devices to improve identity preservation of foods and agricultural products (35).

Originally developed by the 3M Corporation, the MICROTAGGANT® brand identification particle is a microscopic, traceable, anti-counterfeit device that is highly versatile in its applications. The MICROTAGGANT is a distinct numeric code sequence represented in multiple colored layers format. The code becomes a unique "fingerprint" to which the meaning is assigned. Optional fluorescent, magnetic, and other qualities may be added that are detectable by scanners and sensors providing enhanced coding and identification capabilities. These particles can be easily detected in the field using UV/VIS light, 100X magnification glass, magnetic, or laser scanners. The color code sequence in every particle is identical for each specific color code lot (108).

B. Nanodevices for Smart Treatment/Delivery Systems

MEMS technology is based on techniques used in the semiconductor fabrication industry and has generated significant enthusiasm among physicians and surgeons in recent years. At their most basic levels, MEMS are devices with dimensions of micrometers to a few millimeters that combine electrical and mechanical components to acquire data or do work. Implantable and transdermal drug delivery microsystems allow patients both accurate and continuous dosing of medication and allow delivery of drugs directly to their intended sites of action (18, 23).

Today, the application of agricultural fertilizers, pesticides, antibiotics, probiotics, and nutrients is typically performed by spray or drench methods to soil or plants, or through feed or injection systems to animals. Delivery of pesticides or medicines is either provided as "preventive" treatment, or once the disease has multiplied and symptoms are evident in a plant or animal. Nanoscale devices are envisioned to have the capability to detect and treat an infection, nutrient deficiency, or other health problem long before the symptoms become evident at the macroscale. This type of treatment can be targeted to the specific area affected by the disease.

"Smart delivery systems" for agriculture can be defined as a combination of the following: time-controlled, spatially-targeted, self-regulated, remotely regulated, preprogrammed, or multifunctional release of treatment to avoid biological barriers for successful pathogens inactivation (90). Smart delivery systems also can have the capacity to monitor the effects of the delivery of pharmaceuticals, nutraceuticals, nutrients, food supplements, bioactive compounds, probiotics, chemicals, insecticides, fungicides, or vaccinations to people, animals, plants, insects, soils, and the environment (35). Smart treatment delivery systems are envisioned as bioactive systems: drugs, pesticides, nutrients, probiotics, nutraceuticals, and implantable cell bioreactors (34).

C. Nanoparticles Technology

There is currently considerable research interest in the use of microparticles as carriers for poorly bioavailable drugs and vaccines via mucosal (particularly oral) routes (39, 41, 76, 140). A variety of therapeutic moieties, including peptides and proteins, have shown enhanced oral uptake when entrapped within various types of microparticulate system constructs, and this approach has also been used successfully for the oral, nasal, and rectal delivery of a variety of vaccines (8, 48, 71, 123, 137). Numerous investigations have shown that both tissue and cell distribution profiles of anticancer drugs can be controlled by their entrapment in submicronic colloidal systems (nanoparticles) (22, 123, 137). The rationale behind this approach is to increase antitumor efficacy, while reducing systemic side effects.

Naturally occurring antioxidants in raw fruits and vegetables are thought to provide significant health benefits, such as reduced risk of heart attack, stroke, neurodegenerative diseases, and cancer. Processed foods, which are statistically more likely to be consumed by the high-risk individuals, as opposed to raw fruits and vegetables, typically lose some or all of the potency of their natural antioxidant content. Heat-sensitive nutrients like beta-carotene, Omega-3 fatty acids, and other anti-oxidants are significantly or totally degraded upon pasteurization and canning. In foods that do not naturally contain anti-oxidants, introduction of anti-oxidant compounds is difficult due to these compound's high susceptibility to heat, pH variations, and other conditions existing during food processing.

Now nanoscale engineered materials can protect antioxidants and other health-promoting food components from degradation during manufacturing and storage. Nanoparticles (46) and various types of nano-containers — silica-shell (61) and "nanocochleate delivery vehicles" — offer protection for a wide variety of nutrients that currently cannot be delivered in high-temperature, adverse pH, or other conditions. BDSI's Nanocochleates offer the following benefits for processed food nutrients: pressure and shear resistance; protection from oxidants (air, free radicals); protection from temperature extremes; protection from photodegradation (10).

D. Nanoemulsion Technology

The method of infection control with conventional disinfectants requires a tradeoff: to ensure microorganisms are killed, the toxic chemical must be present at levels that create health and contamination risks. Nanoemulsion formulation works very differently (112, 118, 174). Nanospheres of oil droplets $<1\,\mu m$ are suspended in water to create a nanoemulsion requiring only miniscule amounts of active antimicrobial ingredient (60, 113). The nanospheres carry surface charges that efficiently penetrate the microorganisms' membranes (44, 84, 127, 169). Nanoemulsions are effective against a variety of food pathogens including Gram-negative bacteria (58). The nanoemulsions can be rapidly produced in large quantities and remain stable for many months at room temperatures (6). Nano-emulsions are composed of ingredients, which are either food, e.g., vegetable oils, or are on the FDA GRAS list of food ingredients. They are proved to be effective for decontamination of food processing plants, and for reduction of surface contamination of meat and poultry products (28, 118).

E. Packaging

No longer is packaging expected just to safely contain a product — it may now capture the history of a package, interact with the consumer, have functions other than dispensing (e.g., heating/cooling), communicate with appliances, or allow itself to be tracked through the supply chain (1). Nanotechnology has rised a new packaging paradigm — Smart Packaging (5) — which includes active packaging (147), smart tagging/labeling (52), self-venting films, anticounterfeiting and tamper-proof materials/technologies, RFID devices (81, 82), self-opening packages,

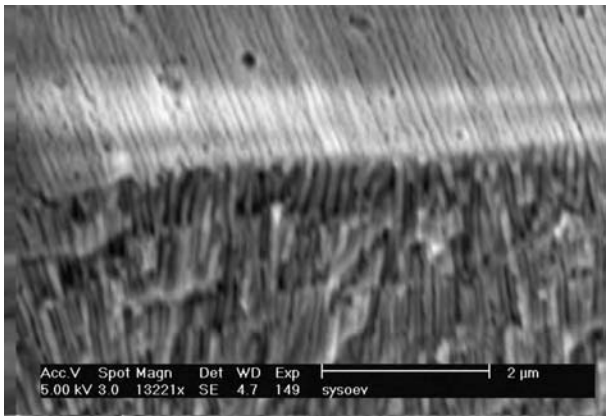

FIGURE 127.6 Nano-patterned aluminum barrier film — multifunctional substrate for sensor/packaging applications.

diagnostic and freshness indicators, responsive labels, time-temperature indicators, self heating/cooling packages, etc.

The addition of reinforcing agents is widely used in the production of packaging films (77, 102, 142). It is expected that the reducing of the added particles size to nanoscale could enhance the performance of these materials (95, 130). The new polymer nanocomposite materials, which can be produced by adding the nanoscale ceramic powders to commercial products, are aimed to substitute more expensive barrier plastic films in food industry (45, 84).

VIII. CONCLUSION

Many other examples can be given to illustrate the close link between fundamental studies of nanoscale phenomena and their technological applications. Although observed at nanoscale changes in material properties can dominantly affect the nanoscale structures, we still have remarkably little experience or intuition for the anticipated phenomena and their practical implications, except for the case of electronic systems. The physics, chemistry, and biology of phenomena occurring at nanoscale is effectively the new subject with its own set of physical principles, theoretical descriptions, and experimental techniques, which we are only in the process of discovering. Thus, there is an urgent need for broad investigations of the phenomena associated with nano-systems and structures, especially in materials and structural contexts where the implications are not at all well understood.

Implementation of nanoscience methods and nanoscale materials in the food industry can bring it to the next technological level. Fundamental changes in food manufacturing and technology due to scientific advances add new qualities into the established industrial practice:

- control of mass and heat transfer at nanoscale;
- improved nanomaterials;
- vastly increased manufacturing capacity due to the miniaturization and combination of processes;
- improved logistics due to the high performance computing and integration of "smart" nanodevices into products packaging and transportation;
- better access to resources and control of energy consumption by introducing micro- and nanoscale power sources and more efficient processes;
- total food quality control by managing food additives and health promoting food components interacting with the product matrix at nanoscale.

In short, nanotechnology has the potential to make as much difference as the discovery of agriculture, steel, germ theory, the assembly line, the colonization of America, electricity, the airplane, computers, and genetic engineering all put together — without further environmental damage! And this is expected to happen within the next few decades.

128 Biosensor Technology for Food Processing, Safety, and Packaging

Paul Takhistov
Rutgers University

CONTENTS

Biosensor technology is a powerful alternative to conventional analytical techniques, harnessing the specificity and sensitivity of biological systems in small, low cost devices. Despite the promising biosensors developed in research laboratories, there are not many reports of real applications in food safety and quality monitoring. A sensor is the device that can detect a property or group of properties in a food product and respond to it by a signal, often an electric

TABLE 128.1
Sensor Operation Modes

On-line	<5 min	Sensors/detectors operate directly in the process stream, giving a real-time signal related to the quality factor of concern.
At-line	<30 min	Sensors are used, in split-flow measurements, requiring reagent additions or sufficient time for the equilibration or chemical reaction to occur
Off-line	1 hr–24 hr	Sensors/assays are used in the laboratory with extensive periods of time required to performing the measurements

signal. This signal may provide direct information about the quality factor(s) measured, or may have known relation to the quality factor. Usually, sensors are classified according to their mode of use (see Table 128.1).

I. NEEDS OF FOOD QUALITY/SAFETY CONTROL

Food quality control is essential in the food industry; nowadays, an efficient quality assurance is becoming increasingly important. Consumers expect adequate quality of food product at a fair price, long shelf-life, and high product safety, while food inspectors require safe manufacturing practices, adequate product labeling, and compliance with the FDA regulations. Further, food producers are increasingly demanding the efficient control methods, particularly through on-line or at-line quality sensors to satisfy consumers' and regulatory requirements, and also to improve the feasibility of automated food processing, quality of sorting, and to reduce the production time (increase throughput) and the final product cost.

Extensive development of biosensors for food safety and quality control were stimulated by acquiring several new food safety and key quality concepts during the last decade: Hazard Analysis Critical Control Points (HACCP), Total Quality Management (TQM), ISO 9000 Certifications. The wave of terrorist acts and foodborne diseases outbreaks has raised the importance of the food traceability and authentication (77, 99). There are specific safety problems (pathogenic microorganisms, BSE, GMF, pollutants, etc.), which require intensive control, data logging, and data treatments and can be effectively controlled only with the new generations of biodetection systems (46). All these tasks require in-time and on-line sensors for new data analysis systems, warning systems, tight feedback loops for automated processing, etc.

Figure 128.1 explains needs for biosensors in food safety and quality management, showing the sources of biohazard contaminations in foods and their influence on technological, "shelf-life," and perception properties of food products. The major sources of undesirable contaminants and changes in foods can be combined in five groups by their localization and occurrence. Three of them are food

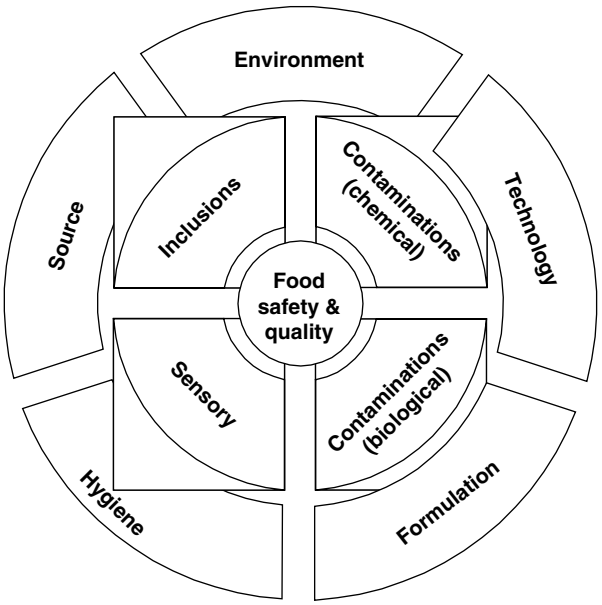

FIGURE 128.1 Needs for food safety and quality control: sources of pollution and contamination.

manufacturing-related: technology (processing and sequence of process operations), industrial hygiene (food safety management at the plant level, HACCP), and formulation (product development, interactions of food additives/ingredients with food matrix, bioavailability). The sources of food raw materials and their quality are the issue of biosafety/biosecurity in the agricultural processing including post-harvesting technologies and logistics. The fifth source of biohazards is the environment in the broadest sense, including pollution, climate changes, and anthropogenic environmental factors.

Below is the brief description of some possible sources of undesirable contaminations and/or changes in food products.

A. Food Processing

It is well known that many important nutrients are denaturalized, altered, or even destroyed by the faulty processing of foods. Food can also become contaminated during processing, handling, distribution, and consumption. Many undesirable or even harmful substances can enter the food as additives and toxic metabolites during its processing and preservation.

B. Food Contamination

Food can become contaminated during every step of food processing sequence, from cultivation to consumption. The contaminants may be:

Microbiological: viral, bacterial, parasitological, and fungal;

Chemical: pesticide residues, nitrates, nitrites, high-salinity, fluorides, arsenic compounds, lead, and other heavy metals. These pose serious and long-term health threats;

Harmful metabolites and biological toxins (e.g., methyl alcohol, estrogen-like substances, hormones, biotoxins including mycotoxins especially aflatoxins, allergens, and carcinogens).

C. Sources/Raw Materials

The major aspect in the area is the utilization of food sources, which were previously wasted or not used. This is mainly to enrich fodder, thus ensuring better recovery for human consumption indirectly.

D. Food Substitutes and Genetically Modified Foods (GMF)

There has been incredible progress in new biotechnology with commercialized products of insulin, human growth hormones, interferon, and recombinant vaccines using human cell culture or "novel" bacteria (90). Unfortunately, some people are allergic to some food ingredients. A reliable system of diagnosis and treatment of infant's milk intolerance exists in all countries. Allergies to natural foods are less common and less serious compared to those to food additives and untraditional or inedible food varieties.

E. Food Industry Hygiene

In addition to the need for development of appropriate policy related to health (135), agriculture, trade, manufacture, and licensing, the rational consumer protection regulatory systems are to be developed and enforced (30).

The next level of the diagram in Figure 128.1 represents the major types of changes in foods caused by the sources of undesirable contaminants. They can be instrumentally controlled, hence represent the primary targets for biosensors development and design. Indeed, the great challenge is to develop the real-time and on-line sensors and data systems suitable for surveying processes and products, controlling automated processes and the raw material stream, sensing the final products quality, typing the product labels with nutritional and health information, and much more.

II. SOURCES OF INFORMATION FOR BIOHAZARDS DETECTION

The detection of biohazards can be performed directly (see Figure 128.2) by measurements of the pollutants/pathogens concentration in a food product with specifically aimed biosensors. Another (indirect) approach to determining the presence/level of biohazard is through the measurements of changes in processing parameters (temperature, pressure, water activity, etc.) that lead to variations in microbial contamination levels. External information can alert the food safety management system on possible increase of bacterial contamination or risk of bioterrorists' attack and/or environmental pollution splash. This information, i.e., expectations of high contamination level, can be used to perform changes in screening and sampling procedures, and extend the range of pathogens to be detected.

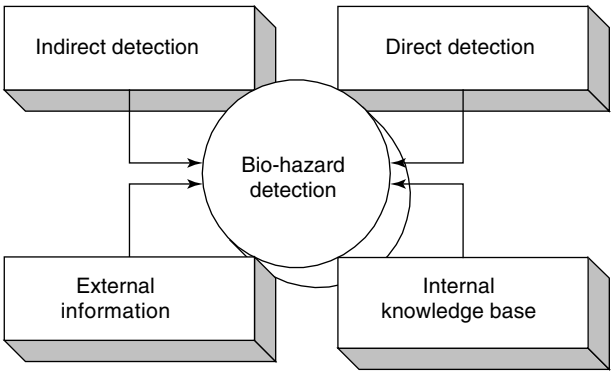

FIGURE 128.2 Sources of information for biohazards detection.

Internal knowledge base ("sensor-free detection") is the set of accumulated data/records giving the correlation between the properties of raw materials, process parameters, and biohazard level in manufactured products.

Today, the most important quality parameters and concepts in food production control are:

- *Sensory*: appearance, flavor, taste, texture, stability, etc.;
- *Nutritional,* including health implications, such as "high in fiber," "low cholesterol," "GMF free," etc.;
- *Composition and labeling*: additives lists, quality and ethical claims (e.g., ecological information), etc.;
- *Pollutants record*: environmental pollutants, veterinary drugs, agricultural chemicals, BSE-prions and mycotoxins;
- *Detection of foreign bodies*, such as stones, glass, or metal fragments;
- *Microbial safety*, in particular *Listeria, Salmonella, Campylobacter*, *E. coli*, and *Yersinia*;
- *Shelf-life*: microbial, sensory, chemical, sterility testing, F_0-values;
- *Production hygiene*: cleaning, decontamination;
- *HACCP*: traceability and authentication;
- *Process parameters control*: machine settings, temperature, pressure, flow, aseptic conditions, and many others;
- *Packaging*: integrity, pinholes, gas permeability, migration control.

III. BIOSENSORS: GENERAL FACTS

Biosensors usually are small analytical bio-electronic devices that combine a transducer with a sensing biological component (biologically active substance). The transducer, which is in intimate contact with the biologically sensitive material, can measure weight, electrical charge, potential, current, temperature, or optical activity of the substance. The biologically active species include enzymes, multi-enzyme systems, antibodies or antigens, receptors, populations of bacterial or eukaryotic cells, or whole slices of mammalian or plant tissue, to name a few. Substances such as sugars, amino acids, alcohols, lipids, nucleotides, etc. can be specifically identified and their concentration measured by these sensors.

A schematic functional representation of a biosensor and the detection principle is depicted in Figure 128.3. The biosensor consists of a biological sensing element integrated with a signal transducer; together they produce a reagent-free sensing system specific for the target analyte.

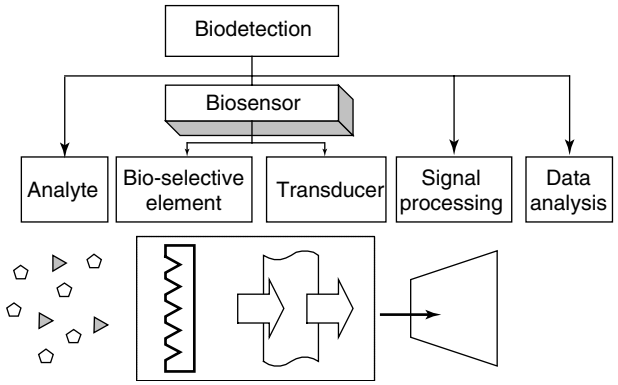

FIGURE 128.3 Schematics of biodetection and biosensor design.

The biological component of a biosensor used for the molecular detection is made of highly specialized macromolecules or complex systems with the appropriate selectivity and sensitivity. Biosensors can be classified according to the biocomponents used for the detection.

The biodetection principle can be schematically described as follows. A chemical, biological, or physical sensor produces a signal (e.g., voltage, absorbance rate, heat, or current) in response to a detectable event, such as binding between two molecules. In case of a biological or chemical sensor this event typically involves a receptor (e.g., macrocyclic ligand, enzyme, or antibody) binding to a specific target molecule in a sample. Physical sensors, on the contrary, measure inherent physical parameters of a sample, such as current or temperature, which can change due to reactions occurring in it. In any case, the signal is then transduced by passing it to a circuit where it is digitized. The obtained digital information can be stored in a memory, displayed on a monitor, or made accessible via digital communications port.

Since it is essential that the sensor's response be detected, it is necessary that an appropriate transduction mode for electrochemical signals, optical signals utilizing changes in the fluorescence or absorbance rate of a sample, or plasmon resonance be available. With most sensors, transduction is accomplished electrochemically or optically.

The transducer transforms the physicochemical variations occurring in the biosensing element as the result of a positive detection event into an electric signal, which is then amplified by an *ad hoc* designed electronic circuit, and used for the control of external devices. The transducers can be electrochemical (amperometric, potentiometric, conductometric/impedimetric), optical, piezoelectric, or calorimetric. Very often this classification is used to identify the type of biosensor (see Figure 128.4).

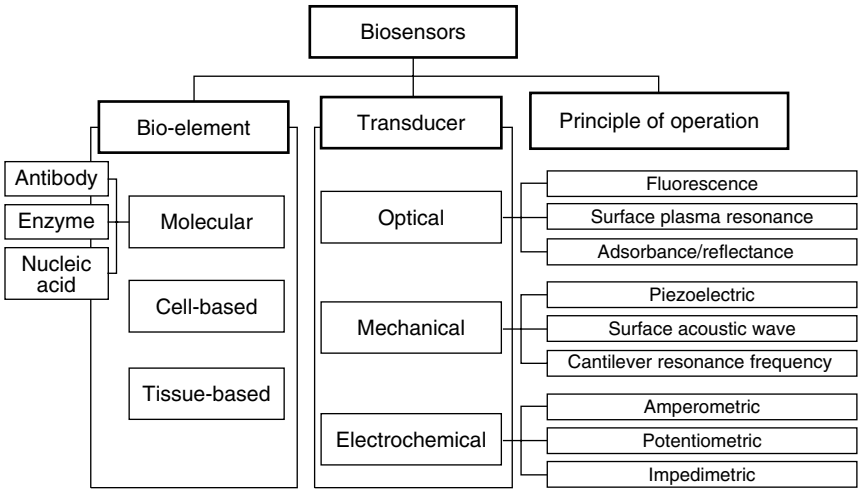

FIGURE 128.4 Biosensors classification.

The bio-specific elements of the biosensor and transducer can be coupled together in one of the four possible ways (80), schematically shown in Figure 128.5: membrane entrapment, physical adsorption, matrix entrapment/porous encapsulation, covalent bonding.

In the membrane entrapment scheme, a semi-permeable membrane separates the analyte and the bioelement, and the sensor is attached to the bioelement (collagen membranes, synthetic preactivated membranes (102), cellulose-acetate membranes). The physical adsorption scheme is depending on a combination of van der Waals forces, hydrophobic forces, hydrogen bonds, and ionic forces to attach the biomaterial to the sensor surface (52). The porous entrapment scheme is based on forming a porous encapsulation matrix around the biological material that helps in binding it to the sensor (nylon net (60), carbon paste (36) or graphite composites (3)). In the case of covalent bonding the sensor surface is treated as a reactive group to which the biological material can bind (108). One of the bioselective elements most frequently used in biosensors is an enzyme. These are large protein molecules that act as catalysts in chemical reactions, but remain themselves unchanged at the end of reaction.

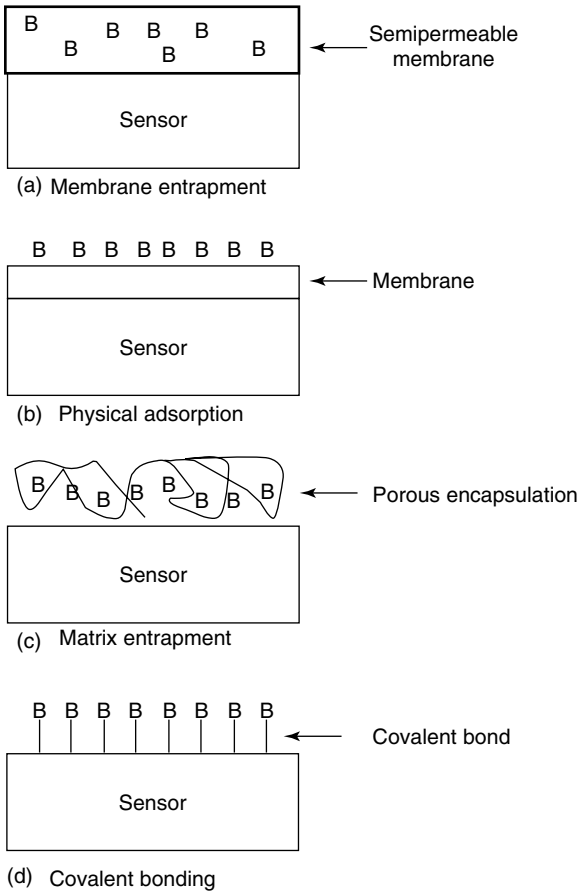

FIGURE 128.5 Coupling of biomaterial with the transducer on a substrate.

IV. TYPES OF BIOSENSORS

A. Mechanical (Resonant) Biosensors

In this type of biosensor an acoustic wave transducer is coupled with an antibody (biosensitive element). When the analyte molecules (antigens) attach to the membrane (cantilever, Figure 128.6), the membrane mass changes, resulting in a subsequent change in the resonant frequency of the transducer (57). This frequency change is detected and measured (80).

1. Sensors Based on Electromagnetic Waves

Electromagnetic sensors may be classified by the wavelength of the electromagnetic waves they use: visible (400–700 nm), ultraviolet (10–400 nm), infrared (700–30,000 nm: NIR (95), FTIR (78), MRI (68)) waves, microwaves (37) (1–10 cm), radiofrequency (59) (1–10 m), X-rays (2) (100 pm–1 nm). Each sensor class may be further sub-divided according to the molecular information that can be obtained through the interaction. For instance, infrared sensors may be subdivided into near-infrared (700–2500 nm), mid-infrared (2500–30000 nm), far-infrared (up to 1,000,000 nm), and thermography (1–15 μm) sensors, which all extract different information from the molecules (sample) interacting with the waves. We may also classify these sensors according to their precise type of interaction: absorbance, transmittance, or reflectance of light.

Sensors based on interactions with electromagnetic radiation waves have been on the market for many years, in particular for laboratory purposes. On-line examples of such sensors are also numerous: x-rays used for foreign body detection (94), visible light sensors for color recognition or machine vision inspections (22), near-infrared sensors for quality inspection and temperature measurements (81), or microwave sensors for the detection of water content (15).

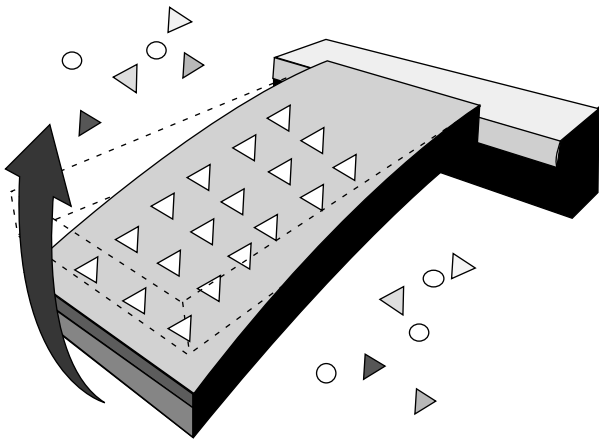

FIGURE 128.6 Cantilever-based systems can detect biomolecules.

B. Optical Detection Biosensors

Strictly speaking, optical biosensors belong to the larger class of electromagnetic detectors, but due to their importance and broad use they are usually considered as a separate group of biosensitive devices. The output signal measured in this type of biosensors is a light signal (119). These biosensors can be made based on optical diffraction or electrochemiluminescence (41).

1. Surface Plasmon Resonance

Surface plasmon resonance (SPR) is another optical phenomenon used in new sensors, often in those involving antibodies or enzymes. The optical range used is most often in the visible part of the spectrum, but may also be in the NIR range. Traditionally, SPR devices (see Fig. 128.7) detect minute changes in the refractive index of the sensing surface and its immediate vicinity. They may detect these changes by a diffraction grating, or with a prism on a glass slide, or through an optical waveguide carrying a thin metal layer (gold). The metal layer carries a sensitizing layer, e.g., immobilized antibodies or other molecules binding the analyte specifically; this layer is in contact with the sample. Inside the device, a collective excitement of electrons in the metal film occurs, and leads at a specific wavelength to a total absorption of light at a particular angle of incidence. This angle depends on the refractive indices on either side of the metal film. Specific molecules binding to the sensitizing layer change the refractive index, thus changing an angle of total absorption; this angle is measured and correlated to the concentration of the analyte.

The SPR detection technique has been used by Hellnaes (69) for on-line and at-line detection of veterinary drug residues (hormones and antibiotics) in dairies and slaughterhouses. Clenbuterol and ethinyl-estradiol in bovine urine, sulfamethazine (SMT) and sulfadiazine (SDZ) in porcine bile, and SMT, SDZ, and enrofloxacin in milk have been successfully detected by the technique. The developed biosensor operates in real time and can simultaneously detect up to 8 different veterinary drugs with a throughput of up to 600 samples per day. The project participants have established a new company to produce and further develop the sensor systems, and several new and elegant designs of SPR sensors are now under development by other groups. The SPR sensor principle has also been used by Patel (113). The sensor developed as a result of this research has been applied to the quantification of mycotoxins, *Listeria,* and markers for growth hormones (recombinant bovine somatotrophin, rBST).

Most current research is focused on the NIR/VIS sensors, SPR sensors (surface plasmon resonance), and NMR sensors (pulsed and low resolution); some work has also been done on fluorescence sensors, MIR and Raman sensors, Fourier transform NIR sensors, thermography based sensors, and sensors combining two or more sensor principles.

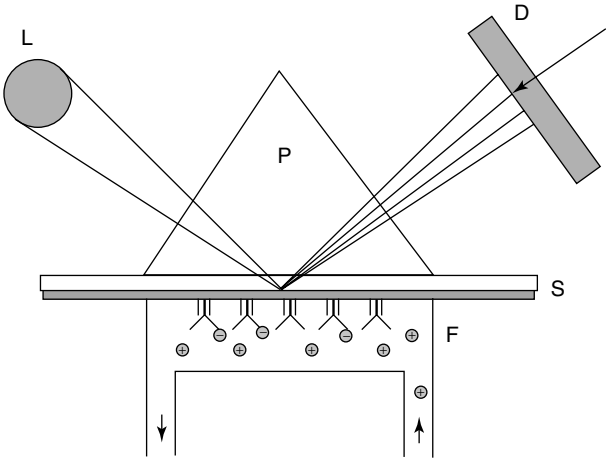

FIGURE 128.7 Surface plasmon resonance detection unit. L: light source, D: photodiode/photodiode array, P: prism, S: sensor surface, F: flow cell.

C. Electrochemical Biosensors

Electrochemical biosensors are mainly used for the detection of hybridized DNA, DNA-binding drugs, glucose concentration, etc. The underlying principle of these biosensors is that many chemical reactions produce or consume ions or electrons which in turn cause some changes in the electrical properties of the solution; these changes can be sensed out and measured (75). The electrochemical biosensor can be classified based on the measured electrical parameter as conductimetric, amperometric, or potentiometric (126).

D. Impedimetric/Conductometric Biosensors

Many biological processes involve changes in the concentrations of ionic species. Such changes can be utilized by biosensors, which detect changes in electrical conductivity. The measured parameter is the electrical conductance/resistance of the solution. When electrochemical reactions produce ions or electrons the overall conductivity/resistivity of the solution changes (47). This change is measured and calibrated to a proper scale. Conductance measurements have relatively low sensitivity. The electric field is generated using sinusoidal voltage, which helps in minimizing undesirable effects such as Faradaic process, double layer charging, and concentration polarization (17).

Impedimetric biosensors utilize changes in the electrical conductivity in the frequency domain (impedance) of a biological system for sensing and detection (4, 52, 71). Impedance spectroscopy provides a powerful tool for investigating a variety of bioelectric processes for both electrical and non-electrical applications. In impedance spectroscopy

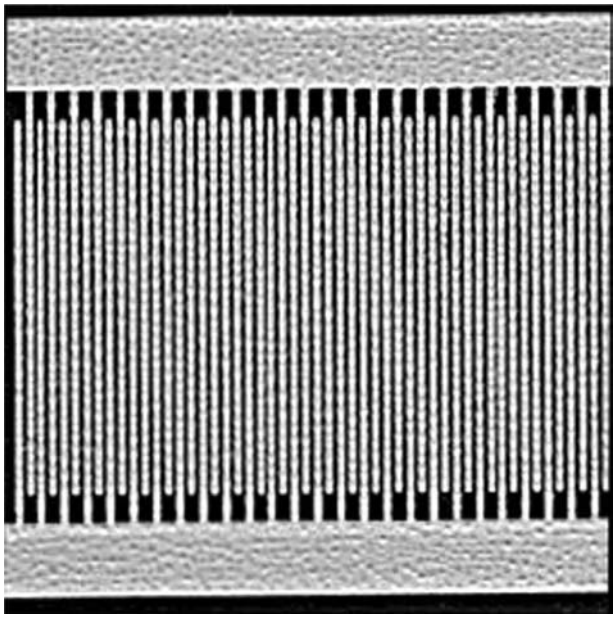

FIGURE 128.8 Conductometric biosensor — interdigitated electrode arrangement.

the current flowing through a sample cell containing a nanoscale patterned bio-interface and the voltage across this cell are measured as a function of frequency (5, 8, 20). Design of impedimetric sensors is very similar to conductivity-based sensors (see Fig. 128.8) (61, 75, 86, 107, 117, 122). Enzyme/antibody immobilization on electrode surface makes these sensors highly selective and sensitive (128).

E. Amperometric Biosensors

This highly sensitive biosensor can detect electroactive species present in biological test samples. Enzyme-catalysed redox reactions can form the basis of a major class of biosensors if the flux of redox electrons can be determined (104). Normally, a constant voltage is applied between two electrodes and the current, due to the electrode reaction, determined. The first and simplest biosensor was based on this principle. It was for the determination of glucose and made use of the Clark oxygen electrode (Figure 128.1). In case of amperometric biosensors, the measured parameter is an electric current. Some of the most recent applications of amperometric biosensors include: glucose sensor for meat freshness (106); glucose sensor for use in fermentation systems (124); rapid cell number monitor (19); monitor for herbicides in surface waters (24, 85); amperometric ELISA method based on the self enzyme amplification system (84); amperometric and novel fluorescent DNA probes (150).

F. Potentiometric Biosensors

In this type of sensor the measured parameter is an oxidation/reduction potential of an electrochemical

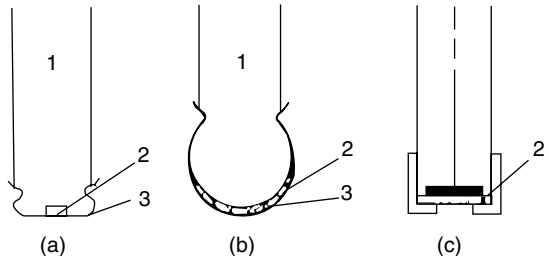

FIGURE 128.9 Amperometric enzyme electrodes. (a) "Clark's" electrode — dialysis membrane electrode with soluble enzyme, (b) entrapped enzyme, and (c) enzyme, membrane electrode. (1) Transducer, (2) enzyme, (3) dialysis membrane.

reaction (13). The simplest potentiometric technique is based on the concentration dependence of the potential, E, at reversible redox electrodes according to the Nernst equation (17):

$$E = E_0 + \frac{RT}{nF} \ln a_s$$

where E_0 — standard redox potential, R — gas constant, T — absolute temperature, F — Faraday constant, n — number of exchanged electrons of the substance S, and a_s — activity of the substance S. Changes in ionic concentrations are easily determined by use of ion-selective electrodes (13). This forms the basis of potentiometric biosensors (4). Many biocatalysed reactions involve charged species, each of which will absorb or release hydrogen ions according to their pK_a and the pH of the environment (88). This allows a relatively simple electronic transduction using the commonest ion-selective electrode (see Fig. 128.9), the pH electrode (121).

1. Field Effect Transistors (FET) and Ion-Selective Field Effect Transistors (ISFET)

Potentiometric biosensors can be miniaturized by the use of field effect transistors (FET). Ion-selective field effect transistors (ISFET) are low cost devices that are in mass production (148). A recent development from ion-selective electrodes is the production of ion-selective field effect transistors (ISFETs) and their biosensor use as enzyme-linked field effect transistors (ENFETs). Enzyme membranes are coated on the ion-selective gates of these electronic devices, the biosensor responding to the electrical potential change via the current output. Thus, these are potentiometric devices although they directly produce changes in the electric current. Figure 128.10 shows a diagrammatic cross-section through an npn hydrogen ion responsive ISFET with a biocatalytic membrane. The build-up of positive charge on this surface (the gate) repels the positive holes in the p-type silicon causing a depletion layer and allowing the current to flow. In (1) Langmuir-Blodgett films containing butyrylcholinestrase

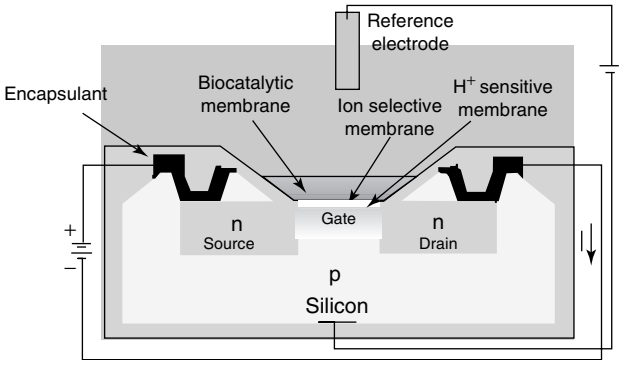

FIGURE 128.10 An ion sensitive FET-based potentiometric biosensor.

(BuChE) are fabricated to realize an ion-sensitive field-effect transistor (ISFET) for the detection of organophosphorus pesticides in water.

G. Cell-Based Biosensors

Cell-based biosensors have been implemented using microorganisms, particularly for environmental monitoring of pollutants (109). Biosensors incorporating mammalian cells have a distinct advantage of responding in a manner that can offer insight into the physiological effect of an analyte (33, 66). Several approaches for transduction of cellular signals (67) are described in the literature: measures of cell metabolism, impedance (129), intracellular potentials, and extracellular potentials (72). Among these approaches, networks of excitable cells cultured on microelectrode arrays (9, 33, 43, 103, 109) are uniquely poised to provide rapid, functional classification of an analyte and ultimately constitute a potentially effective cell-based biosensor technology. Keese and Giaever (82) have designed a biosensor that can be used to monitor cell morphology in tissue culture environment. The sensing principle used is known as electric cell-substrate impedance sensing (ECIS). In this process, a small gold electrode is immersed into tissue culture medium. After cells attach and spread over the electrodes, the electric impedance measured across the electrode chamber changes. These changes in impedance can be used for understanding cell behavior in the culture medium. The attachment and spreading of the cells are important factors for successful use of this biosensor. Unfortunately, some types of cells, e.g., cancerous cells, can grow and reproduce freely in a medium without being attached to any substrate/surface; that makes them impossible to detect with these sensors.

Proposed in (34) biosensor mimics biological sensory functions and can be used with most types of receptors, including antibodies and nucleotides. The technique is very flexible and even in its simplest form it is sensitive to pico-molar concentrations of proteins.

H. Lab-on-a-Chip Systems and DNA Detection Devices

Significant advances have been made in the development of micro-scale technologies for biomedical and drug discovery applications. The first generation of microfluidics-based analytical devices (Lab-on-a-Chip (141)) have been designed and are already functional. Microfluidic devices offer unique advantages in sample handling (45, 65, 142), reagent mixing (23, 79, 140), separation (54, 89, 98), and detection (27). They include, but are not limited to: devices for cell sampling (7), cell trapping and cell sorting devices (9, 12, 16, 44, 152), flow cytometers (49, 105, 142), devices for cell treatment: cell lysis, poration/gene transfection and cell fusion devices (145).

Biosensors used for DNA detection are used to identify small concentrations of DNA (of microorganisms such as viruses or bacteria) in a large sample. The detection relies on comparing sample DNA to a DNA of known microorganism (probe DNA) (28). Since the sample solution may contain only a small number of microorganism molecules, multiple copies of the sample DNA need to be created for proper analysis (31). This is achieved with an aid of the polymerase chain reaction (PCR). PCR starts by splitting the sample's double-helix DNA into two parts by heating it. If the reagents contain proper growth enzymes, each of these strands would grow the complementary missing part and form the double-helix structure again. This happens after the temperature is lowered. Thus, in one heating/cooling cycle the amount of sample DNA is doubled (10). In general, PCR is very power-consuming, so it was previously not possible to fabricate portable biodetectors able to perform PCR. But, using newly developed MEMS devices, such biodectors (also known as lab-on-a-chip systems) have been created. In these MEMS-based devices the amount of reagent used is scaled down (115).

I. DNA-Based Sensors/Assays

The general principle of DNA probe assay is similar to the immunoassay described in Figure 128.11. Indeed, even the applications of DNA probes and monoclonal antibody immunoassay frequently overlap, thus establishing a "competition" between the two possible approaches.

One of the most important applications for DNA probes is the testing for virus infections (96). For probes of infectious disease, it is assumed that all strains can still contain a common DNA sequence region, and thus be identified by a single probe. Recognized by the cell as a foreign body, viruses will induce an antigenic reaction causing antibody generation so they can also be detected in an immunoassay (73).

Another type of biosensor developed by the Naval Research Laboratory (10) uses magnetic field instead of optics or fluorescence. This sensor equipped with magnetic

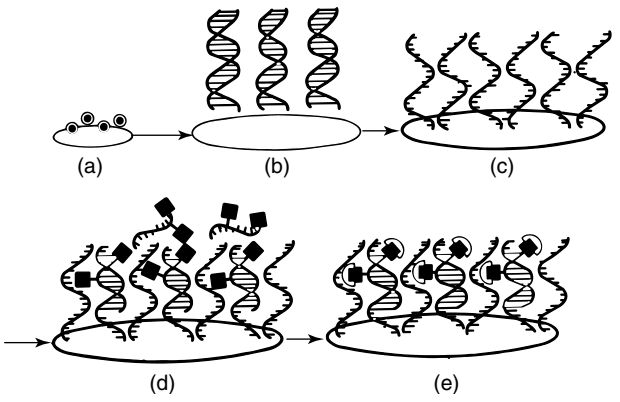

FIGURE 128.11 DNA probe assay. (a) Deposit sample organism on immobilization matrix; (b) release DNA; (c) immobilize DNA to matrix and separate strands; (d) add labeled DNA probes and hybridize; (e) read label.

sensors and microbeads (131) is able to detect the presence and concentration of bioagents. The magnetic sensor (group of sensors) is coated with single-stranded DNA probes specific for a given bioagent or sample DNA. Once a single strand of DNA probe and a single strand of sample DNA find each other, they form a double stranded (double-helix) structure, which in turn binds a single magnetic microbead. When a magnetic bead is present on a sensor surface, its resistance decreases which can be detected and measured.

V. APPLICATIONS OF BIOSENSORS IN FOOD SCIENCE AND MANUFACTURING

Detailed description of all existing biosensors for food applications requires a separate book and is definitely out of the borderlines of this chapter. Instead, this chapter aims to compare needs for biosensors in food safety/biosecurity management systems and existing biosensor technologies. The general classification of sensors, principles of their operation, and some practical examples given in this chapter accomplish this goal. To find more information about specific biosensors and applications readers should refer to other papers. Biosensors for food safety applications are reviewed in references (64, 75, 111, 114). Additionally, the author can recommend a good description of existing market for food safety applications (6). The general review of electrochemical biosensors for food pathogens detection can be found in references (91, 126, 134). Specific details are presented in the following articles about biodetection in poultry industry (93), and pathogen detection in muscle foods (42). The needs for fast, on-line, and accurate sensing, e.g., *in situ* analysis of pollutants in crops and soils, detection, and identification of infectious diseases in crops and livestock, on-line measurements of important food processing parameters (62), monitoring animal fertility, and screening therapeutic drugs in veterinary testing are well-described in another work (138).

A. Sensors for Pathogens Detection

The broad spectrum of foodborne infections keeps changing dramatically over time, as well-known pathogens have been controlled or eliminated, and new ones have emerged. The burden of foodborne diseases remains substantial: one in four Americans is estimated to have a significant foodborne illness each year. The majority of these illnesses is not caused by known pathogens, so more of them remain to be discovered. Among the known foodborne pathogens, the recently identified predominate, suggesting that as more and more is learned about pathogens, they would come under control. In addition to the emergence or recognition of new pathogens, other trends include global pandemics of some foodborne pathogens, the emergence of antimicrobial resistance, the identification of pathogens that are highly opportunistic, affecting only the most high-risk subpopulations, and the increasing identification of large and dispersed outbreaks. New pathogens can emerge because of changing ecology or technology that connects a potential pathogen with the food chain. They also can emerge by transferring the mobile virulence factors, often through bacteriophage (133).

Over the past decade many improvements have been seen in both conventional and modern methods of pathogenic bacteria detection in foods (75). Modification and automation of conventional methods in food microbiology involve sample preparation, plating techniques, counting, and identification test kits. ATP bioluminescence techniques are increasingly used for measuring the efficacy of surfaces and utensils cleaning. Cell counting methods, including flow cytometry and the direct epifluorescent filter technique, are suitable for rapid detection of contaminating microorganisms, especially in fluids. Automated systems based on impedance spectroscopy are able to screen high numbers of samples and make total bacterial counts within 1 day. Immunoassays in various formats make a rapid detection of many pathogens possible. Recently, there have been important developments in the nucleic acid–based assays and their application for the detection and subtyping of foodborne pathogens. The sensitivity of these methods has been significantly increased by employing the polymerase chain reaction and other amplification techniques. Alternative and rapid methods must meet several requirements concerning accuracy, validation, speed, automation, sample matrix, etc. Both conventional and rapid methods are used in the frame of biohazard analysis critical control point programs. Further improvements especially in immunoassays and genetic methods can be expected, including applications of biosensors and DNA chip technology (38).

In recent work of Bokken (18) a surface plasmon resonance biosensor was used to detect a *Salmonella* pathogen through antibodies reacting with *Salmonella* group A, B, D, and E (Kauffmann-White typing). In the assay designed, anti-*Salmonella* antibodies immobilized onto the biosensor surface were allowed to bind injected bacteria, followed by a pulse with soluble anti-*Salmonella* immunoglobulins to intensify the signal. No significant interference was found for mixtures of 30 non-*Salmonella* serovars at 109 CFU ml^{-1}. A total of 53 *Salmonella* serovars were successfully detected at 107 CFU ml^{-1}, except those from groups C, G, L, and P, as expected.

Another sensor technology recently developed uses a micro-electrophoretic system (mFFE) that separates and concentrates the analyte in question by a number of electrophoretic methods: preparative zone, interval zone, isotachophoresis, or isoelectric focusing. The mFFE system can be designed as a plain glass substrate 1.5 mm thick, and a cross-linked polydimethyl-siloxane (PDMS) top layer with micromachined sample channels. The central separation chamber ($12 \times 4 \times 0.15$ mm) is connected to 34 inlet channels for sample injection, and 36 outlet channels for sample collection. The detector unit can be based on several principles. In the case of *Listeria*, the detector unit may be a well-known ATP luminescence detector. For other analytes, the SPR detection system may be used with an immobilized bio-specific layer, e.g., antibodies (111).

A new ion-channel biosensor based on supported bilayer lipid membrane for direct and fast detection of *Campylobacter* species has been reported (76). The sensing element was composed of a stainless-steel working electrode, covered with an artificial bilayer lipid membrane (BLM). Antibodies to bacteria embedded into the BLM are used as channel-forming proteins. The biosensor has a strong signal amplification effect, which is defined as the total number of ions transported across the BLM. The biosensor has demonstrated a very good sensitivity and selectivity to *Campylobacter* species.

A novel assay system for the detection of *Escherichia coli* O157:H7 has been recently developed. The detection is based on the immunomagnetic separation of the target pathogen from a sample and absorbance measurements of p-nitrophenol at 400 nm from p-nitrophenyl phosphate hydrolysis by alkaline phosphatase (EC 3.1.3.1) on the "sandwich" structure complexes (antibodies coated onto micromagnetic beads — *E. coli* O157:H7-antibodies conjugated with the enzyme) formed on the microbead surface (92). The selectivity of the system has been examined, and no interference from other pathogens including *Salmonella typhimurium, Campylobacter jejuni,* and *Listeria monocytogenes* was observed. The sensor's working range is from 3.2×102 to 3.2×104 CFU/ml, with the relative standard deviation of 2.5–9.9%. The total detection time is less than 2 hours.

An improved antibody-coated sensor system based on quartz crystal microbalance analysis of *Salmonella spp*. has been developed, using thiolated antibody immobilization onto the gold electrode of the piezoelectric quartz crystal surface (110). The best results in sensitivity and stability were obtained with the thin layer of a thiol-cleavable, heterobifunctional cross-linker. The long bridge of this reagent can function as a spacer, facilitating antibody–*Salmonella* interaction on the gold electrode. The sensor's response was detected for the microbial suspension concentrations ranging from 10^6 to 1.8×10^8 cfu/ml.

A label-free immunosensor for the detection of pathogenic bacteria using screen-printed gold electrodes (SPGEs) and a potassium hexacyanoferrate (II) redox probe has been reported by Susmel (130). Gold electrodes were produced using screen-printing, and the gold surfaces were modified by a thiol-based self-assembled monolayer (SAM) to facilitate antibody immobilization. In the presence of analyte a change in the apparent diffusion coefficient of the redox probe was observed; it can be attributed to impedance of the diffusion of redox electrons to the electrode surface due to the formation of the antibody-bacteria immunocomplexes. No change in the diffusion co-efficient was observed when a non-specific antibody (mouse IgG) was immobilized and antigen added. The system has been demonstrated to work with *Listeria monocytogenes* and *Bacillus cereus*.

B. Sensors to Monitor Food Packaging and Shelf-Life

In recent work (147) a cell-based biosensor has been used to control meat freshness. Samples of fresh meat stored at 5°C were periodically removed from storage and washed with water for periods of up to 2 weeks. The water was then charged into a flow injection analysis (FIA) system combined with the microbial sensor using yeast (*Trichosporon cutaneum*) as a sensitive element. This sensor has been specifically developed in this work for monitoring the freshness of meat. Relationships between the sensor signals obtained by the FIA system, the amounts of polyamines and amino acids produced from the meat, and the number of bacteria that had been multiplying in the meat during the aging process were investigated. The sensor response has been found to correspond to the increase in amino acid levels and viable counts in the meat during the first stage of aging. This is due to the fact that amino acids produced initially by enzymes in the meat serve as a nutrition source for septic bacteria, and as a result, the amount of bacterial cells increases with an increasing level of amino acids.

1. Foreign Body Detection

The presence of foreign bodies in processed food is of major concern to the producers. Mechanical separation

techniques based on size and weight of different components have been used for many years to help find foreign bodies in powdered and flowing products. Optical inspection techniques were able to extend the range of detectable foreign objects in free-flowing materials with regard to their shape and color. Metal detectors enabled metallic particles inside the product to be found. With recent achievements in sensor technologies advanced foreign body detection systems are becoming available (55).

The working principle and design of an ultrasonic transducer system with auto-alignment mechanism was first described by Zhao (151). The proposed system has been used for detecting foreign bodies in beverage containers. Variations in reflection amplitude were analyzed as a function of the ultrasound beam incident angle to the beverage container surface. It has been concluded that a quadratic relationship exists between the strength of the reflected signal and the incident angle. Furthermore, a calculation for effective angular increment for searching the normal to a curved surface was introduced. Experiments conducted using the sensor prototype have demonstrated that foreign bodies are detectable in containers of various juices. This sensor design is also applicable to nondestructive inspection of canned food products for the presence of foreign bodies.

C. Biosensors for Food Quality/Additives Control

Existing food processing equipment frequently includes microprocessors that are activated by electronic or biological sensors. Recent advances in electronic vision and computer technology have opened the research horizons for greater accuracy in process control, product sorting, and operation. The development of new sensors and instruments in this area is focused on measuring/evaluating the product's internal and external quality and flavor (138).

The aim of food additives control and measurement is to develop, extend, and enhance the instrumental methods in order to improve consumer-perceived macroscopic quality factors. For quality assessment, grading, and sorting of food products, several types of electronic sensors that can provide rapid and non-destructive determination of product internal qualities have been investigated and described in the literature.

A near infrared sensing technique can rapidly determine the sugar content of intact peaches. This technology has been extended to a number of other commodities, including testing avocados for oil content, and kiwifruits for starch and sugar content. NMR method, for example, can be used for nondestructive detection and evaluation of internal product quality factors, such as existence of bruises, dry regions or worm damage, stage of maturity, oil content, sugar content, tissue breakdown, and the presence of voids, seeds, and pits (see Figure 128.12).

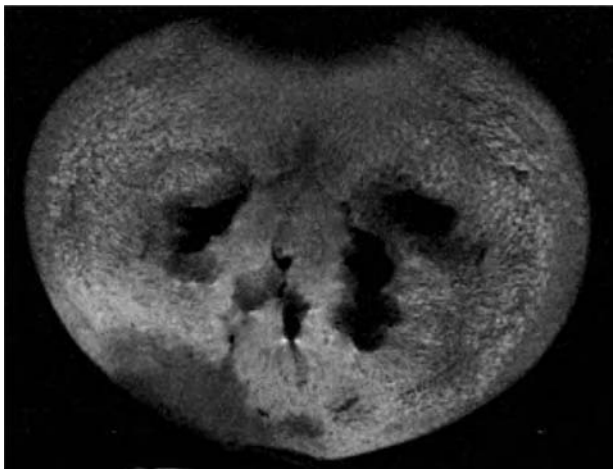

FIGURE 128.12 MRI image of blueberry.

Machine vision for postharvest product sorting and grading is being investigated for a number of commodities. Recent research has included development of a high-speed prune defect sorter, color and defect detector for fresh-market stone fruits, raisin grading, and flower grading machines. In this technology, electronic cameras are used for monitoring the product in various packing-line handling situations. Quality features are computed from digitized images, and the control system allows for product grading and sorting. The NIR/VIS region has been used in several different sensors. Thus, Crochon in his work (35) has presented the design of a glove-shaped apparatus equipped with various miniaturized sensors providing information on fruit quality parameters, i.e., sugar content, maturity, mechanical properties (firmness, stiffness), and internal color. The sugar content and internal color were measured by a miniaturized spectrometer (NIR/VIS) coupled with optical fibers. A sound sensor evaluated the mechanical properties, and the size was measured by a potentiometer placed at the hand aperture. These sensors were coupled to a microcomputer that delivered processed information about the fruit overall quality grade, based on previously established variety and quality classes. The weight of the glove prototype was 400 g, and the electronic devices were held in a rucksack weighing 1000 g. The glove may be used before harvest to control the growth and to estimate the harvest date, at harvest to select fruits with specific qualities, or after harvest to control and measure the quality of the crop.

In (11) chlorophyll fluorescence and reflectance in the NIR/VIS spectrum has been used for the mechanical quality factors assessment of green beans, broccoli, and carrots. Biosensors have been used for evaluating the effects of pasteurization on vegetable quality by measuring the remaining enzymatic activity. Use of mid-infrared (MIR) spectroscopy, as well as Raman scattering, for on-line quality assessment in bakeries, breweries, dairies, and fruit farms has been reported (56).

Another method working in the NIR/VIS range, called time-resolved diffuse reflectance spectroscopy (TDRS), has been used to measure the internal quality of fruits and vegetables (149). The group has developed statistical models for the analysis of relationships between the TDRS signals and the firmness, sugar, and acid content of kiwifruit, tomato, apple, peach, nectarine, and melon. They have also developed the classification models to sort apples, peaches, kiwifruits, and tomatoes into quality classes. Using a pulsed laser diode (70–200 pico-seconds/pulse), the single measurement time was about 100 milliseconds. The absorption coefficient was related to the tissue constituents, while the scattering coefficient was related to the firmness and fiber content. A real-time sensor in the NIR/VIS range can be also used to measure product quality traits, such as maturity, flavor, or internal diseases and defects in potatoes, apples, and peaches (26).

Among the optical sensor systems developed and demonstrated in industrial environments are machine or artificial vision sensors. The system for olives sorting, using a traditional vision camera and three CCD color sensors for the shape, size, and color evaluation, has been described (118). The new algorithm allowed the olives to be sorted into four classes with the speed of 132 olives/sec, and 6 images/sec.

The molecular imprinted polymers (MIP) technology is the new technology used for the development of biosensor substrates (97). The polymers are produced by imprinting the recognition sites of predetermined specificity into cross-linked synthetic polymers. The polymer is consequently able to selectively re-bind the imprinted molecule (100). These sensor materials are called "artificial antibodies" (123). The MIP technology has particular strengths for small molecular analytes up to about 400 Dalton; it may be used to bind and detect many chemicals polluting food products, e.g., pesticides and veterinary drugs in meat and dairy products.

This technology has been successfully employed to develop and optimize plug-in detection cartridge supporting the molecularly imprinted polymer assay (83) for detection of different β-lactam antibiotics in milk. The sensor consists of a micro-fabricated column accommodating an optical detection window. Molecular imprinted polymers in the form of beads were used as packing materials and recognition elements; analyte binding was detected by the fluorescence. The same MIP technology has been used in several other studies, the overall objective of which was to develop novel and robust MIP-based technology that can be used in sensors for real-time measurements of food product contaminants (112, 114, 136). The results of the study indicate that MIP can be used to prepare both selective and general recognition matrices for either individual analytes or groups of compounds, with very good detection reproducibility and stability (136). SPR based sensor shows similar results for dairy product quality applications (48). The MIP developed for clenbuterol has been successfully applied in preparing a novel sensor comprising MIP as the selective element and amperometric detector as the transducer (97). The responses from several sensors were determined to have a variability of 10%. The feasibility for an oxacillin MIP-based sensor was also demonstrated.

At-line immunological sensors using amperometric detection of the resulting antibody-antigen complexes were described (125). The target quality factor assessed in this project was the presence of toxic chlorophenolic fungicides and their chloroanisole breakdown products in potable water, wine, and fruit juices. The electrochemical immunosensor uses monoclonal antibody preparations. The investigations of the effects of liquid food matrices on electrochemical transduction processes indicated that horseradish peroxidase is a suitable label for interrogation of the analyte-antibody immune complex, using amperometry and in-house fabricated screen-printed electrodes. The detection of hormonal substances for growth promotion, also based on immunosensors has been recently reported by Guilbault (58). The sensor has to be used prior to slaughtering, and can detect and measure testosterone, methyltestosterone, 19-nortestosterone, stanozolol, and trenbolone levels in biological fluids (blood). Analysis time achieved was about 30 minutes, compared to 24–36 hours for tests used in laboratories today.

D. Biosensors for Sensory Evaluation of Food Products

"Electronic noses" (139, 146) and "electronic tongues" (32) are the common names of devices responding to the flavor/odor (volatiles) or taste (solubles) of a product using an array of simple and non-specific sensors, and the pattern recognition software system (50). Historically, the sensors used were advanced mass spectrometers or gas/liquid chromatographs, producing a unique fingerprint of the analyte. Nowadays, these sensors have been substituted by arrays of simple electric and/or frequency sensors, or sensors measuring changes in voltage or frequency as a response to the food contact.

Electronic noses and tongues are used in food production and quality control of different products, typically for laboratory tests or at-line control, but may be further developed for in-line operation in the future. Testing times are often in the range of a few minutes, and the largest drawback of these devices is the lack of sensor stability. Examples of claimed successful applications include (14):

- Discrimination between single volatile compounds;
- Tracking of aroma evolution of ice-stored fish or meat;
- Tracking of the evolution of cheese aroma during aging;

- Classification of wines;
- Determination of boar odor (androsterone) in pork fat;
- Classification of peaches and other fruits;
- Differentiation of spices by the area;
- General raw materials control;
- Testing of coffee, soft drinks, and whisky;
- Control of beer quality and faults.

Essentially, each odor or taste leaves a characteristic pattern or fingerprint on the sensor array, and an artificial neural network is trained to distinguish and recognize these patterns (see Figure 128.13). Pattern recognition is gained by building a library of flavors from known flavor mixtures given to the network. Thus, e-noses and tongues are the devices intended to simulate human sensory response to a specific flavor, sourness, sweetness, saltiness, bitterness, etc. (14, 132).

The potentiometric chemical sensors such as ion selective sensors are most often used in the electronic noses. Considerable interest exists in the development of cheap, portable electronic noses to detect, on-line or at-line, odor quality of many foods. For instance, olive oil producers would tremendously benefit from the possibility of detecting oil quality and shelf-life, and classifying the oils by their quality (e.g., Extra Virgin olive oil). This was the objective of a course project in which scientists from olive producing countries developed electronic noses especially for the olive production plants, and tested them with great success (25).

In (40) different tea samples were used to evaluate the applicability of electronic noses for sensory studies. A metal oxide sensor-based electronic nose has been used to analyze tea samples with different qualities, namely, drier month, drier month again over-fired, well fermented normal fired in oven, well fermented overfired in oven, and under fermented normal fired in oven.

Electronic tongues are also widely used to assess taste quality of various products. An electronic tongue based on voltammetry measurements, and a multichannel lipid membrane taste sensor based on potentiometry were compared using two aqueous solutions: detergent and tea (74). The electronic tongue consists of four electrodes made of different metals, a reference electrode and a counter electrode. The measurement principle is based on pulse voltammetry technique in which an electric current is measured during the amplitude change of the applied potential. The taste sensor consists of eight different lipid/polymer membranes. The voltage difference between the electrodes and an Ag/AgCl reference electrode is measured when the current is close to zero. The multichannel electrochemical (potntiometric) sensors have demonstrated better sensitivity, faster dynamic response, but lower reproducibility of the results.

In study performed by Legin (87) the electronic tongue based on a sensor array comprising 23 potentiometric cross-sensitive chemical detectors, and pattern recognition and multivariate calibration data processing tools, has been applied to the analysis of Italian red wines.

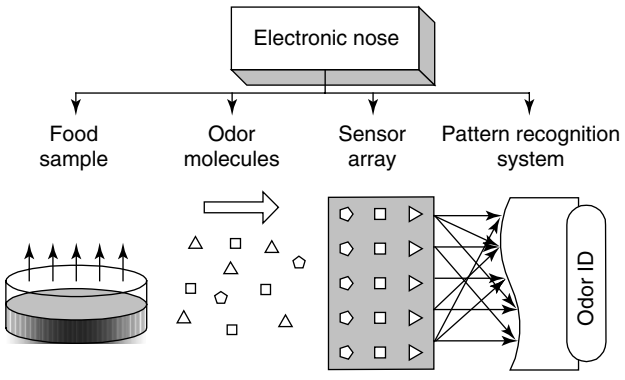

FIGURE 128.13 Principle of the electronic nose operation (42).

VI. ROLE OF BIOSENSORS IN THE FOOD SAFETY MANAGEMENT SYSTEM

A. Biosensors and Biosecurity

Food industry is one of the major potential targets for bioterrorism. The most damage can be attained through: (1) final product contamination using either chemical or biological agents with an intent to kill or cause illness among consumers; (2) disruption of food distribution systems; (3) damaging the food producing cycle by introducing devastating crop pathogens or exotic animal diseases such as foot-and-mouth disease, which could severely impact the food system.

Efforts to develop recognizing preparedness and response strategies for protecting the nation's food supply pose substantial challenges for a number of reasons, including the following (70, 127, 144):

- The food system encompasses many different industries;
- A great variety of biological and chemical agents could potentially contaminate the food supply, and the possible scenarios for deliberate contamination are essentially limitless;
- The public health system is complex, and responsibilities for foodborne diseases prevention and control may overlap, or much worse, fall in the "gray area" between authorities of different agencies.

To achieve an adequate food supply chain and agricultural security, improvement is needed in the activities on bioterrorism prevention, detection, and response. In

addition, appropriate areas for applied research must be identified:

- *Recognition of a foodborne bioterrorism attack.* This may be delayed because of background levels of foodborne diseases and the potential wide distribution of the contaminated product or ingredient.
- *Rapid diagnostic methods* for identifying food-contaminating agents. They are not yet consistently available, and coordinated laboratory systems for pathogens detection are not fully operational.
- *Rapid trace-back procedures* for potentially contaminated products.

B. Biosensors and HACCP

Timely detection of unsafe foods is the main issue that the food safety system should address, providing guidance for the design and integration of such system into the existing food safety management structures, i.e., HACCP. The preventive detection of the biohazard can be accomplished by direct measurements with the biosensors, or indirect detection by the process/environment monitoring and control. Such detection is based on the data from physical and chemical sensors, which are very reliable and allow scale-down, which means the possibility of easy integration into the existing information carriers. The HACCP system for food safety management is designed to identify health hazards, and to establish strategies to prevent, eliminate, or reduce their occurrence. An important purpose of corrective actions is to prevent potentially hazardous foods from reaching consumers. Where there is a deviation from the established critical limits, corrective actions are necessary. Therefore, corrective actions should include the following elements: (a) determine the disposition of non-compliant product; (b) determine and correct the cause of non-compliance; (c) record the corrective actions that have been taken.

Currently, the use of HACCP is voluntary, but it is widely used in the food processing industry as a successful component of comprehensive food safety program. HACCP is a food safety management system in which food safety is addressed through the analysis and control of biological, chemical, and physical hazards from raw material production, procurement and handling, to manufacturing, distribution, and consumption of the final product. The terms "HACCP" and "food safety" are used interchangeably in the food industry, implying that HACCP may be the only approach to achieving food safety. HACCP is designed for use in all segments of the food industry from growing, harvesting, processing, distributing, and merchandising, to preparing food for consumption (135).

However, there is a need for enhancement and integration of the existing HACCP system into the total quality management system, and food safety/biosecurity management on higher levels. The system currently includes the mechanisms to decrease the potential for contamination of or damage to the food supply from farm to table (i.e., prevention activities); systems to ensure early detection of deliberate food contamination at any point along the production pathway, including surveillance, rapid laboratory diagnostic, and communication systems; systems to ensure a rapid and thorough response if a bacterial contaminant is detected, including protection of workers and consumers (i.e., emergency response, control, trace-back, and mitigation activities).

The ultimate goal is the integration of sensors and sensor networks into the food safety management structure (see Figure 128.14). Such integration will allow one to perform on-line and "on-shelf" control of the internal and/or external food product quality and package environment.

The integrated sensor information system combines data from multiple sensors (from different packages and/or products) and the information about environmental and process conditions to achieve highly specific information that cannot be obtained by using a single, independent microbiological assay. The emergence of new information carriers and advanced processing methods will make the food safety management system increasingly dependable. A successful biohazard detection system should be able to: (a) identify potential hazards; (b) identify hazards that must be currently controlled; (c) conduct hazard analysis; (d) recommend control factors, critical limits, and procedures for hazard monitoring and verification; (e) recommend appropriate corrective actions if a deviation occurs.

Based on a comprehensive model for multisensor data processing, developed by the US Joint Directors of Laboratories (JDL) Data Fusion Group on DoD request (63), the integrated concept of multiple sensors data processing has been developed for the existing HACCP system of food safety monitoring and biohazard prevention (see Figure 128.14). This model is specifically adapted to the HACCP workflow and utilizes the principle of information

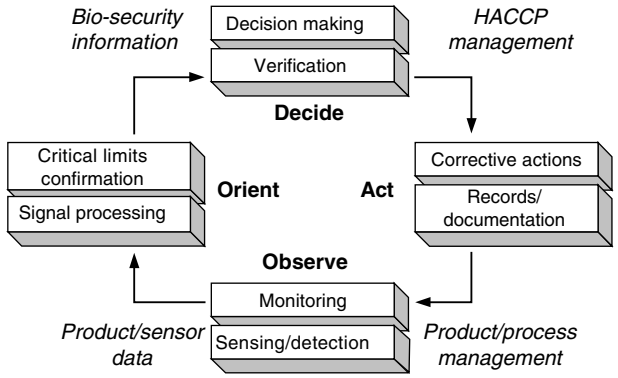

FIGURE 128.14 Schematic process model for integrated HACCP and biohazard detection system.

system cyclic interaction with the environment. The four major steps, including observation/ detection, hazard recognition, decision making, and corrective actions, strictly correspond to the seven HACCP principles. Integration of such a system does not require the redesigning of existing manufacturing and control processes.

The new integrated sensors are able to monitor HACCP control points with corresponding material packaging flow on a continuous basis, or with pre-determined monitoring frequency. Statistically designed data collection or sampling systems lend themselves to this purpose. Issues that need to be addressed when considering implementation of an integrated food safety monitoring system include: where the system would be established; how it would be funded; how the data would be generated, analyzed, summarized, and disseminated; and how "snap surveys" could be utilized as a part of the system.

Microbiological tests are rarely effective for food safety monitoring due to their time-consuming properties and problems with ensuring detection of contaminants. Physical and chemical measurements are preferred because they are rapid and usually more effective for the control of microbiological hazards. For example, the safety of pasteurized milk is based upon the measurements of heating time and temperature rather than on testing the processed milk for the absence of surviving pathogens.

In order to address the issues of connectivity between biosensor devices, the Connectivity Industry Consortium (CIC) has been formed to set up the standardized communication platform for all devices (29). The CIC has identified five requirements: bidirectionality, connection commonality, commercial software interoperability, security, and QC and regulatory compliance (120). Under these standards, new devices should seamlessly link into the existing data management system without additional expenses.

Traditionally, food quality monitoring units consist of a sensor for the particular analyte, an electronic unit to convert the response into a digital signal, and a cable to communicate with the base station. Advances in technology now enable sensors to be integrated with the base station through wireless communication that frees sensors from being physically attached to it. An interest in such freestanding monitoring units is growing rapidly, since they offer the potential for developing integrated networks of sensing devices that can detect, diagnose, and monitor various food safety problems. The merging of computing with wireless communication systems and sensors has led to an increased accessibility to the real-time information in digital form. Due to achievements in communications and connectivity, data from these sensors can even now be easily accessed via personal digital assistants, PCs, mobile phones, and networks. On the other hand, the communications network that has assembled over the past decade and continues to attract huge investments will fuel demands for more sources of health-related information and data.

New technologies do not come into existence easily. It is not just the matter of making conventional laboratory instruments smaller or putting a sensor into the human body. The new sensor devices and networks must satisfy food industry needs by delivering new benefits to users, offering new ways of monitoring food product properties/ contaminations, developing tests that are cheaper, or creating devices that have significant advantages over those already available.

It has been predicted that the trend in biodetection systems development lies in the autonomous sensing technology with the next-generation handheld, portable sensing devices, "smart" sensing, and in-line biodetection. The only limitation to the fast progress in this area is the fact that the sensors — especially chemical and biological ones — lag behind the electronics.

In the future, the evolution of integrated food safety management system may lead to the emerging of a food processing control "nervous system," which will comprise multitudes of sensors and sensing technologies. Such systems could provide the information "nodes" for food safety management and control applications.

VII. FUTURE OF BIOSENSING: DETECTION OF CELLULAR RESPONSE WITH NANOSENSORS

Cells are the smallest functional and integrating communicable units of living systems. Cultured cells transduce and transmit a variety of chemical and physical signals by producing specific substances and proteins throughout their life cycle within specific tissues and organs. Hence, cells and their responses might be usefully employed in screening tools to obtain important information for both pharmaceutical and chemical safety, and drug efficacy profiles *in vitro*. However, cellular signals are very weak and cannot be easily detected with conventional analytical methods. By using novel micro- and nanobiotechnology methods and integrated on-a-chip devices, higher sensitivity to cellular responses and better signal amplification have been achieved (12, 53, 101). Micro- and nanotechnology are now rapidly evolving to suggest new combinations of methods with improved technical performance (53), helping to resolve challenging bioanalytical problems including detection sensitivity, signal resolution, and specificity by interfacing these technologies in micro-scale format in order to confirm specific cellular signals (21, 33, 51, 116, 137, 143). Receiving cell signals in rapid time and small space, and importantly, integration of signals from different cell populations (communication and system modeling), will permit more valuable measuring of the dynamic aspects of cell responses to various chosen stimuli (39). This represents the near future for cell-based biosensing (67).

Concerns over biosafety and security have accelerated the implementation of biohazard control processes, including hazard identification, assessment of its impact on human health, and determination of when, where, and how it would have an impact. Continuous biosafety control is used for assessing the exposure to a hazard, and predicting the necessary dose response.

SDS	sodium dodecyl sulphate
spp.	species
ss	single stranded
Taq	*Thermus aquaticus*
T-DNA	transfer DNA
Ti	tumor inducing
UV	ultra violet
Vir	virulent

FOREWORD

The application of biotechnology in food industry is not entirely new. Traditional biotechnology has played a key role in the production of food for thousands of years. For many centuries, the process of fermentation has used microorganisms (yeasts and bacteria) to produce beer, yoghurt and cheese. Naturally occurring microorganisms occur in bread making, beer brewing and vegetable pickling and nowadays, traditional biotechnology techniques are still widely used in the production and preservation of foods.

The basis for modern biotechnology, also referred to as gene technology, is DNA. All organisms are composed of cells containing DNA. This DNA contains the genetic information of an organism. Each organism has its own genetic fingerprint made up of DNA, which determines the regulatory functions of its cells, and thus the characteristics that make it unique. Prior to genetic engineering, the exchange of DNA was possible only between individual organisms of the same species or closely related parent plants to produce offspring, having desirable traits such as disease resistance. The limitations of traditional or conventional biotechnology are time and precision; considerable time may be necessary to achieve the desired traits and the offspring may or may not exhibit the trait of interest, hence the lack of precision.

However, due to improvements in scientific techniques and the advent of genetic engineering in the 70s, scientists have been able to identify specific genes associated with desirable traits in one organism, and transfer those genes beyond the species boundary into another organism. For example, genes from bacteria, viruses or animals may be transferred into plants to produce genetically modified plants with desired characteristics. Through the use of modern biotechnology precision increased and the time to reach the desired trait or characteristic in a cell, animal or microorganism was reduced.

The impact of genetic engineering on the contemporary life has reached unseen heights. Biotechnology continues to be a growing choice among farmers worldwide as the global acreage of crops enhanced through biotechnology increased by 15 percent, or 22 million acres in 2003, according to a report released from the International Service for the Acquisition of Agri-biotech Applications (1).

For the seventh consecutive year, farmers worldwide adopted biotech crops at a double-digit pace, with 2002 global biotech acreage reaching 167 million acres. More than one-fifth of the global crop area of soybeans, corn, cotton and canola acres are now biotech. Nearly 6 million farmers in 18 countries chose to plant biotech crops in 2003, up from 5 million farmers in 13 countries in 2001.

The aim of this chapter is to provide enough information and some examples to give the reader a sound knowledge of the use of plant biotechnology for food purposes. It is not intended to provide an encyclopaedic coverage of the subject though. The text describes the most common technologies that enable the genetic manipulation of crop plants and some applications in food industry. Furthermore, attention is focussed on the detection of genetically modified organisms in food products.

I. HISTORICAL BACKGROUND

Since life began, genes have crossed the boundaries of related and unrelated species in nature. Biotechnology applications by humans date back to 1800 B.C., when people began using yeast to leaven bread and ferment wine. By the 1860s, people started breeding plants through deliberate cross pollination. They moved and selected genes to enhance the beneficial qualities of plants through cross-breeding without knowing the traits for which the genes coded. Most foods, including rice, oats, potatoes, corn, wheat and tomatoes, are the products of traditional cross-breeding. This time-tested practice continues to produce crops with desirable traits.

However, traditional cross-breeding has its limitations. It can only occur in the same or related plant species, so genetic resources available are limited. Moreover, when plants are cross-bred, all plant's genes are mixed, producing random combinations. Since traditional plant breeders ultimately want only a few genes or traits transferred, they typically spend 10 to 12 years backcrossing hybrids with the original plants to obtain the desired traits and to breed out the tens of thousands of unwanted genes. Clearly, this process is not speedy nor precise.

With the advent of recombinant DNA technology in the 1970s, the genetic manipulation of plants entered a new age. Traits previously unavailable through traditional breeding could be acquired through the advance of recombinant DNA technology, developed in 1973. The technique allowed for effective and efficient transfer of genetic material from one organism to another. Genetic engineering of plants began in 1983 when researchers reported that the Ti plasmid of *Agrobacterium tumefaciens*, a common soil bacterium, could be modified to allow transfer of foreign DNA into the plant genome (2, 3). The researchers introduced new genes into plants with the aid of the *Agrobacterium* and also introduced a marker gene for kanamycin resistance to select the transformed cells (2, 4, 5).

The production of genetically modified plants rapidly became an important tool for scientific investigation, and transformation methods for a wide variety of crops were subsequently developed (6–11). Many technological breakthroughs in the laboratory soon followed, including engineered resistance to plant viruses, insect resistance based on expression of *Bacillus thuringiensis* (*Bt*)

proteins, tolerance to various herbicides, control of fruit ripening and softening in tomatoes, engineered male sterility and restoration, modified carbohydrate composition and altered oil composition (12). Elite plant varieties from all of these discoveries at the laboratory bench have now been developed. They have been approved by regulatory agencies and are being prepared or grown for commercial applications.

In the 1990s, the first genetically engineered foods were made available to the public. In 1990, Pfizer Corporation's genetically engineered form of rennet used in making cheese was approved, but it received little public attention. Only four years later, in 1994, the Food and Drug Administration (FDA) gave approval for Calgene Corporation's Flavr Savr Tomato, the first genetically engineered whole food approved for the market (13).

II. TRANSFORMATION METHODS

A transgenic plant is a plant that has received a DNA segment or gene(s) from another organism. The foreign segment of DNA is incorporated into the plant's genome through natural systems present in plant cells. Numerous methods to introduce foreign DNA into plant cells have been developed. A transformation system should allow for (14):

- stable integration into the host genome without structural alteration of the foreign DNA,
- integration of a distinct number of copies of the transforming DNA,
- stability of the new phenotype over several generations,
- eventual tissue and development specific regulation of the introduced gene.

Among the array of genetically engineered plants which currently have been approved, the transformation of choice has been the use of modified plasmids of *Agrobacterium.* Other transformation methods are based on physical and chemical principles.

A. Agrobacterium tumefaciens

Plant transformation mediated by *Agrobacterium tumefaciens*, a soil plant pathogenic bacterium, has become the most used method for the introduction of foreign genes into plant cells and the subsequent regeneration of transgenic plants. Jozef Schell and Marc Van Montagu were the first to discover that the bacterium *A. tumefaciens* transfers a copy of parts of its genetic material into cells of wounded plants, causing the formation of crown gall tumors (3). The ability to cause crown galls thus depends on the ability of *Agrobacterium* spp. to transfer bacterial genes into the plant genome (15).

Virulent strains of *A. tumefaciens* and *A. rhizogenes* contain a large plasmid (more than 200 kb), respectively known as the Ti-plasmid (tumor inducing) (Figure 129.1) and the Ri plasmid (root inducing). These bacteria possess the exceptional ability to transfer T-DNA, a particular mobile DNA segment of the Ti or Ri plasmid, into the nucleus of infected cells where it is then stably integrated into the host genome and transcribed, causing the crown gall disease (Ti) and hairy roots (Ri) respectively (16, 17). The process of T-DNA transfer is mediated by the cooperative action of proteins encoded by genes determined in the Ti plasmid virulence region (*vir* genes) and in the bacterial chromosome.

The initial results of the T-DNA transfer process to plant cells demonstrate three important features for the practical use of this process in plant transformation. Firstly, the tumor formation is a result of the integration of T-DNA into the plant cells and the subsequent expression of the T-DNA genes. Secondly, the T-DNA genes are transcribed only in plant cells and do not play any role during the transfer process. Thirthly, every DNA sequence can be transferred to plant cells, no matter where it comes from. These well-established facts allowed the construction of

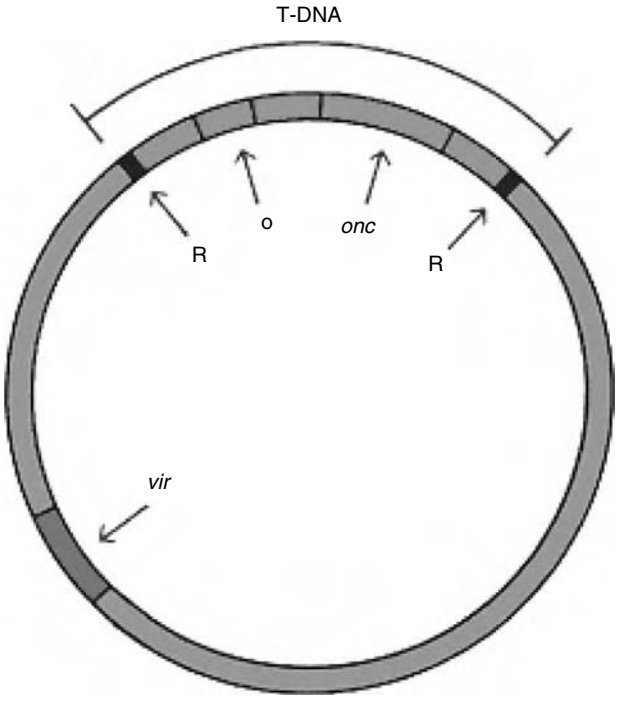

FIGURE 129.1 The Ti plasmid of *A. tumefaciens*. [R: repeat (border) sequence, O: coding for an opine-synthesizing enzyme, *onc*: coding for enzymes that are involved in the biosynthesis of plant hormones, *vir*: controls the transfer of the T-RNA to the host (plant) chromosome.]

the first vector and bacterial strain systems for plant transformation (18).

B. Biolistics

Particle (gun) bombardment, or biolistics, is the most important and most effective direct gene transfer method in regular use. In this method, rapidly propelled tungsten or gold microprojectiles coated with DNA are blasted into target plant material, where the DNA is released and can integrate into the genome (6, 19). The integration of the transgenic DNA though is infrequently. In order to generate transgenic plants, the plant material, the tissue culture regime and the transformation conditions have to be optimised quite carefully and in many cases tissue regeneration is necessary.

Shortly after its discovery, researchers demonstrated the effectiveness of the microprojectile mediated system by successfully transforming monocots, the first of which was Black Mexican Sweet corn (10, 20). This new ability to transform and regenerate monocot plants marked a significant advance in plant transformation.

C. Electroporation

The electroporation of cells can be used to deliver DNA into plant cells and protoplasts. The vectors used can be simple plasmids. The genes of interest require plant regulatory sequences, but no specific sequences are required for integration. Material is incubated in a buffer solution containing DNA and subjected to high voltage electrical pulses. The DNA then migrates through high voltage induced pores in the plasma membrane and integrates into the genome (21). Electroporation has been successfully used to transform all the major cereals, particularly rice, wheat and maize.

D. Microinjection

Simmonds and coworkers reported the use of microcapillaries for the introduction of plasmid DNA into the germ line precursor cells of apical meristems by microinjection (22). Despite a positive indication by PCR amplification of DNA isolated from injected apices, this approach has failed to yield any transgenic plants (23).

E. Polyethylene Glycol

This procedure revolves around the use of protoplasts and their totipotent ability to regenerate into mature plants. Protoplasts are plant cells whose cell walls have been removed leaving only a plasma membrane around the cells. Plant protoplasts can be transformed with naked DNA by treatment with polyethylene glycol (PEG) in the presence of divalent cations (usually calcium). The PEG and the divalent cations destabilise the plasma membrane of the plant protoplast and render it permeable to naked DNA. Once inside the protoplast the DNA enters the nucleus and integrates into the genome (24). PEG treated protoplasts for the most part have been abandoned as a genetic delivery system, because of the low effectiveness.

An advancement to PEG mediated transformation was the liposome mediated transformation technique. Foreign DNA is encapsulated in a spherical lipid bilayer termed a liposome (25). In the presence of PEG, the host protoplast will bind and envelop the liposome through endocytosis (26). After endocytosis, the DNA is free to recombine and integrate with the host genome. The liposomes are formed from neutral lipids similar to those which compose the plasma membrane and can be produced in a variety of sizes ranging from 30–50 nm with a volume of approximately 2 ml. The DNA is packaged *in vitro* and then combined with the target protoplasts. As with other transformation systems, a variety of vectors including viral vectors can be incorporated into this system.

F. Silicon Carbide Fibres

With this technique, plant material is introduced into a buffer containing DNA and silicon carbide fibres, which is then vortexed. The fibres penetrate the cell wall and plasma membrane, allowing the DNA to gain access to the inside of the cell (27). Although the procedure has been utilised with friable callus from maize (28), this type of friable callus is limited only to a few genotypes of maize and oats. Many cereals produce an embryogenic callus that is hard and compact and therefore not easily transformed with this technique. Recently though, some progress has been made in transforming such material, and procedures are being developed to allow transformation of cereals such as rice, wheat, barley and maize without the need to initiate cell suspensions (29).

III. TRANSGENES

Transgenes are not necessarily different from endogenous genes. However, transgenes are often chimeric, that is cobbled together from elements found naturally in different genes. The most important element is usually the protein coding region, which consists of one open reading frame.

A. The Promoter

Promoters mediate the initiation of transcription in a manner that is dependent on tissue type and sometimes other signals. Promoters of variable strength and tissue specificity are available. They can be constitutive (typical) or inducible by environmental or chemical stimuli (rare). The most widely used promoter is the promoter driving

expression of the 35S Cauliflower Mosaic Virus. CaMV 35S is a strong promoter that is active in essentially all dicot plant tissues. Promoters have also been constructed that are inducible by heat shock, copper ions, glucocorticoid hormones, alcohol, antibiotics and other stimuli. Native plant promoters are usually less than 1 kb in length. A plant promoter will often work in many different plant species, but yeast, human or bacterial promoters do not function in plants (15).

B. The Terminator

The terminator serves as a transcriptional stop signal to the polymerase. Various terminators are in widespread use, e.g., one derived from CaMV and one derived from the nopaline synthase (nos-3′) gene of *Agrobacterium*. The various terminators are basically equivalent (30).

C. Structural Genes

The structural genes are the DNA sequences which contain the information encoding the protein of interest. Distinction should be made between target genes and reporter genes (see marker genes).

Many genes have been used for the generation of the currently approved transgenic crops. Some of these genes, such as accd, accS and sam-k (tomatoes) and some genes coding viral coat proteins have only been used in one particular genetically engineered product. As a consequence, the identification of sequences of one of these genes in food would represent a product-specific detection method, provided the actual sample did not contain the natural sources of these sequences (e.g., from bacteriophages or plant viruses) (30).

More common is the endotoxin gene from *Bacillus thuringiensis* (insect resistance — corn, potato, tomato) or the *bar*/*pat* gene, originally isolated from *Streptomyces hygroscopius*, coding for the enzyme phosphinothricin acetyltransferase (herbicide tolerance — chicory, corn, soybean, oilseed rape, sugar beet, rice). Variants of the CP4 EPSPS gene from *Agrobacterium* (herbicide resistance — corn, soybean, cotton, oilseed rape, sugar beet, potato), the β-lactamase gene (tomato) and the polygalacturonase gene (tomato) have also been introduced. Furthermore, the gene encoding for barnase from the bacterium *Bacillus amyloliquefaciens* encodes a ribonuclease which catalyzes the hydrolysis of single stranded RNA molecules. The gene is expressed in the anther only and causes male sterility (chicory, corn, oilseed rape) (30, 31).

Other genetically modified (GM) foods currently available are:

- melon: reduced accumulation of S-adenosylmethionine (SAM), and consequently reduced ethylene synthesis, by introduction of the gene encoding S-adenosylmethionine hydrolase,
- papaya: papaya ringspot virus (PRSV) resistant papaya produced by inserting the coat protein (CP) encoding sequences from this plant potyvirus,
- wheat: selection for a mutagenised version of the enzyme acetohydroxyacid synthase (AHAS), also known as acetolactate synthase (ALS) or acetolactate pyruvate-lyase,
- squash: cucumber mosiac virus (CMV) and/or zucchini yellows mosaic (ZYMV) and watermelon mosaic virus (WMV) resistant squash produced by inserting the coat protein (CP) encoding sequences from each of these plant viruses into the host genome.

D. Marker Genes

One of the technical problems encountered in attempts at gene transfer is knowing whether a particular gene has actually been introduced into a new host cell and, if transferred, whether it is directing the synthesis of protein. To overcome this problem, reporter or marker genes have been developed, which can be transferred to the plant cell using *Agrobacterium*.

The choice of a selectable marker gene depends on the plant species and the specific genotype of the plant. In general, antibiotic resistance genes make good selectable markers for many dicotyledonous species, such as tobacco or *Arabidopsis thaliana*. In contrast, many monocot species are quite resistant to common antibiotics, and herbicide resistance genes are preferred in this case. Herbicides are also cheaper than antibiotics and they can be applied to soil grown plants.

Marker genes tend to be developed from bacterial genes coding for easily assayed enzymes (32–34). A typical marker gene is the neomycin phosphotransferase II gene (nptII), with kanamycin resistance, as used in the Flavr Savr™ tomato (30, 35, 36). An alternative system uses the gene for a naturally derived enzyme, phosphomannose isomerase (37, 38). This particular enzyme enables plant cells to use mannose as a source of energy. The cells that manage to grow in the presence of mannose have acquired the marker gene and have therefore also taken up the other genes of interest. This system, and similar ones based on other sugars, should allay the fear that GM poses a danger to human health. These should allow a refocusing of effort to tackle the overuse of antibiotics in intensive farming and their overprescription in medicine which pose a far greater threat to our health.

GUS, the *Escherichia coli* β-glucuronidase gene (39, 40), and the luciferase gene, which is obtained either from fireflies (*Photinus pyralis*) or the marine bacterium *Vibrio harveyi* have been very successful as reporter genes too (41).

In the near future, it can be expected that the selection of markers for antibiotic resistance will be avoided. There is no current list though of antibiotic resistance markers that

cannot be used in the genetic modification of plant crops. In Europe, Article 4(2) of Council Directive 2001/18/EC refers to the phasing out of genes expressing resistance to antibiotics which may have adverse effects on human health and the environment or are of use in medical or veterinary treatment. This phasing out must take place by 31 December 2004 in the case of GM crop plants for marketing and by 31 December 2008 in the case of the release of GM crop plants for research and development purposes. In accordance with this requirement the commission has established an expert working group to address the use of antibiotic resistance marker (ARM) genes that genetically modified organisms (GMOs) may contain and will aim to produce a list of ARMs which must be phased out.

IV. STRATEGIES FOR GENETIC MANIPULATION

Enzymes are the products of the majority of transgenes introduced into the currently approved genetically engineered agricultural crops. The expression of these enzymes has conferred novel traits to the respective plants. Proteins without an enzymatic activity, such as toxins, or antisense constructs have also been expressed.

A. Sense Strategy

In order to add a new trait to a crop, one or more genes or their complementary DNA (cDNA) should be added to the genome of the host plant. For this purpose, the gene or cDNA is cloned in a sense orientation in between promotor and terminator. This results in the expression of messenger RNA to a protein.

B. Transgene Silencing

Instability of transgene expression is still a problem encountered in many experiments involving transgenic plants and is often referred to as gene silencing. Gene silencing can involve a variety of methods and is still relatively poorly understood.

When the chromosomal locus harboring a transgene is analyzed carefully, one can find either a single T-DNA or multiple copies of the T-DNA. If multiple copies are present, they can be arranged as direct repeats (sense) or inverted repeats (antisense), or partial copies may be present next to complete copies. Transgene loci with multiple copies, especially inverted repeats, are often associated with gene silencing, meaning that the transgene(s) are poorly expressed.

Gene silencing is thought to represent a highly sequence specific plant genome surveillance mechanism. The plant is able to recognize certain nucleic acids as foreign and it has means to suppress the expression of such genes. Two mechanisms can be distinguished. Either the rate of transcription is reduced (transcriptional gene silencing) or the mRNA is destabilized (post-transcriptional gene silencing). Transcriptional gene silencing occurs when genes share homology in their promoter regions. It usually results in altered methylation patterns and altered chromatin conformation, which results in gene silencing by repressing transcription (42).

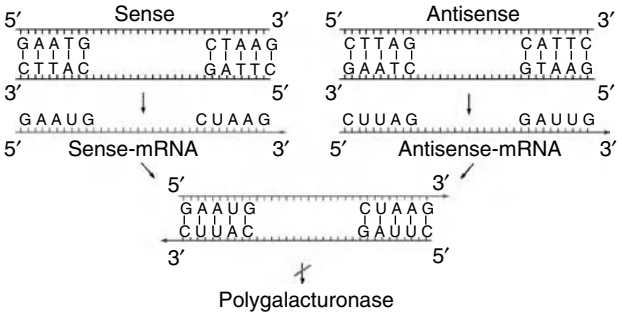

FIGURE 129.2 Construction of the antisense mRNA technology for the polygalacturonase vector.

Sometimes, even endogenous genes that are similar in sequence to the transgene are silenced along with the transgene (co-suppression). This is usually undesirable, although the effect has been exploited to some advantage as well. For example, the delayed fruit softening in the Flavr Savr™ tomato is controlled by co-suppressing the endogenous gene for ethylene production with a transgene of related sequence (43). This tomato contains a gene that is transcribed into a messenger RNA anti-sense to the mRNA from the polygalacturonase (PG) gene (Figure 129.2). The complementary *in vivo* base pairing of these two molecular species results in inhibition of the expression of the gene, with a dramatically decreased PG activity in the transgenic tomatoes. The enzyme PG degrades pectin, a major constituent of the cell wall of the fruit. Its inhibition increases the shelf-life of the tomatoes and prevents them from becoming soft (44).

Unfortunately, it is almost impossible to control whether single or multiple T-DNAs are integrated. One has to generate several independent transgenic lines and screen them for stable gene expression, or stable silencing, as the case may be. It is also possible to find T-DNAs at several unlinked sites in the genome (normally 1–4). Multiple sites are also associated with gene silencing. In this case, genetic backcrossing to wild-type plants should reduce the number of transgene loci and may overcome silencing.

V. APPLICATION OF GENETIC MANIPULATION IN THE FOOD INDUSTRY

A. Benefits of GM Foods

Most of the research in the application of gene technology on food crops has sought to improve product quality and

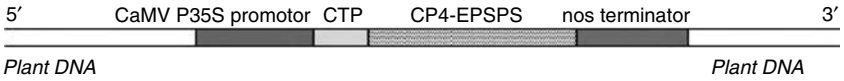

FIGURE 129.3 Constructs introduced in the glyphosate resistant Roundup Ready soybean.

agronomic traits and develop a better resistance to the environment.

Genetic engineering can be used to increase crop yield and reduce crop loss by making plants tolerant to pests, weeds, herbicides, viruses, insects, salinity, pH, temperature, frost and drought. Insect resistant corn (see frame 1), soybean, cotton, potato and apples, virus resistant cantaloupes, squash, papaya, cucumbers and herbicide tolerant corn, tomatoes, potatoes, canola and soybean (see frame 2) have all been produced (45–47). These crops with improved agricultural qualities are considered as the first generation of GMOs, introduced on the market from 1995.

Nowadays, more attention has been paid to the development of GMOs with a clear, direct and significant advantage for the consumer. This second generation of GMOs should gain consumer's interest, trust and acceptance. These foods may have one of the following benefits:

- improved shelf-life, e.g., the Flavr Savr tomato, and organoleptic quality of foods (48),
- improved nutritional quality and health benefits, e.g. oils with an improved fatty acid profile (49), higher lycopene levels in tomato and peppers (47, 50), golden rice with provitamine A (50–54), allergen free rice and peanuts, …,
- improved protein quality and/or quantity (cassava) or increased content in essential amino acids (55–59),
- increase in food carbohydrate content, e.g., potato with a high solids content, which makes it useful for making French fries (60, 61),
- edible vaccines and drugs, e.g., banana with proteins that may be used as vaccines against hepatitis, rabies, dysentery, cholera, diarrhoea or other gut infections prevalent in developing countries (62, 63).

Examples

Bt corn

Bt is a naturally occurring soilborne bacterium that is found worldwide. A unique feature of this bacterium is its production of crystal-like proteins that selectively kill specific groups of insects (Cry proteins). Plant molecular biologists created Bt corn by inserting selected exotic DNA into the corn plant's own DNA. Proteins have been found with insecticidal activity against the Colorado potato beetle (for example, Cry3A, Cry3C), corn earworm (Cry1Ac, Cry1Ab), tobacco budworm (Cry1Ab) and the European corn borer (Cry1Ab, Cry1Ac, Cry9C).

Glyphosate-tolerant soybean

Roundup Ready® soy (Monsanto), the first biotechnologically improved soybean to be marketed, became commercially available in 1996. Glyphosate, the active ingredient in Roundup herbicide, controls weeds by inhibition of the enzyme 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS). EPSPS is an enzyme in the shikimate pathway for aromatic amono acid biosynthesis in plants. Roundup Ready soybean event 40–3–2 was produced by particle acceleration transformation of active EPSPS isolated from *Agrobacterium* sp. strain CP4 (CP4 EPSPS) into the genome of the soybean cultivar A5403. The insertion of DNA (Figure 129.3) includes the Cauliflower Mosaic Virus (CaMV)-derived 35S promotor with duplicated enhancer, the petunia-derived chloroplast transit peptide (CTP) region, which is responsible for the correct processing of the protein in the cell, the EPSPS gene and the nopaline synthase (nos) sequence to terminate the transcription of the genetic construct.

B. Potential Risks of Genetically Modified Foods

The critics of genetic engineering of foods have concerns, not only for safety, allergenicity, toxicity, carcinogenicity and altered nutritional quality of foods, but also for the environment. The use of marker genes has been restricted to prevent the development of antibiotic resistance. Furthermore, genetic pollution, the creation of superweeds and superpests have to be considered.

1. Food Safety

The introduction of modified foods has led to a shift in the food safety assessment towards a greater need for whole food safety assessment. An important feature in determining the potential risks is whether or not the GMO is able to cause disease to humans, animals or plants.

In the United States, it is the responsibility of the Food and Drug Administration (FDA) to provide oversight for all foods, including those derived from GMOs. More than 15 years of laboratory research and field trials with rDNA-engineered plants indicate that the risks posed by these plants are not any greater than or different from the risks posed by plants produced by traditional breeding methods used for more than 100 years (64).

Various organisations and the biotechnology industry have been working together since 1990 to design a safety assessment strategy for genetically modified crops and

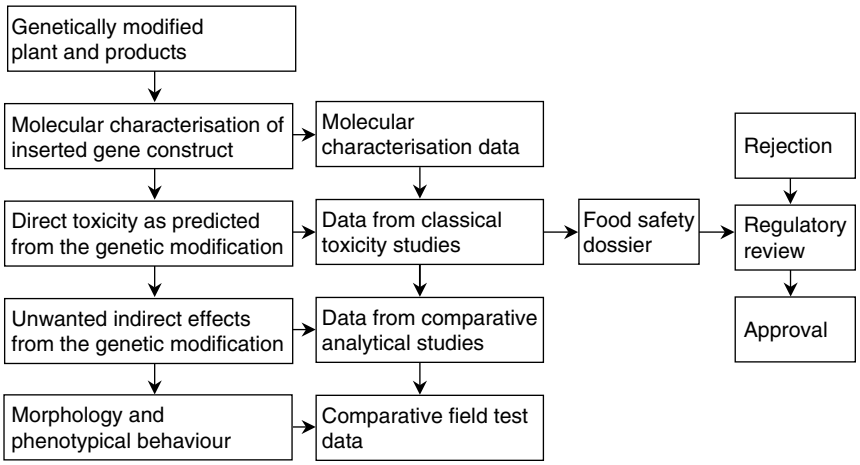

FIGURE 129.4 The current approach for the safety assessment of genetically engineered food (Pedersen *et al.* 2001).

their derived products. The EU legislation has elaborated different rules covering the safety of genetically modified foods: the Directive on the deliberate release into the environment (2001/18/EC) and the Regulation concerning novel foods (258/97/EC).

The food safety assessment of genetically engineered foods should determine whether the modified food is as safe as its traditional counterpart. As a starting point for the safety assessment the concept of 'substantial equivalence' was introduced as a means of establishing a benchmark of safe food. The potential risks associated with the use of a GMO are determined by the characteristics of the organism which receives the modification, the characteristics of the used genetic material and the circumstances under which the GMO is applied.

The food safety assessment of genetically engineered foods is considered to consist of the following parts: (1) a molecular characterization of the insert, (2) determination of any unwanted direct toxicological effects as can be predicted from the nature of the inserted sequences, (3) determination of any unwanted indirect toxicological consequences resulting from the modification and (4) a morphological and behavioral analysis of the plant under relevant field conditions.

The concept of substantial equivalence was applied for the first time in the safety assessment of the Flavr Savr™ tomato before it was placed on the USA market in 1994. In the following years, a lot of experience with the safety assessment of a large variety of genetically modified plants has been gathered. In the EU food ingredients derived from herbicide tolerant soybeans and from several insect and/or herbicide tolerant maize lines, and refined oils derived from several herbicide tolerant rape seed lines were registered and approved according to the legal requirements that have been put in place since 1990 and 1997 respectively.

2. Food Related Concerns

One of the major concerns regarding food safety is the potential allergenicity of genetically modified foods. Well known is the methionine rich protein (MRP) soy from Pioneer Hi-bred International. To increase the protein content of its animal feed, the company incorporated Brazil nut genes into soybeans. This gene modification caused allergic reactions to consumers who were allergic to Brazil nut, so this product was voluntarily recalled in 1996 (65). It is also believed that foreign genes might alter nutritional value of foods in unpredictable ways by decreasing levels of some nutrients while increasing levels of others. Moreover, genetic modification could inadvertently enhance natural plant toxins by switching on a gene that has both the desired effect and capacity to pump out a poison (66).

3. Environmental Concerns

Environmentalists are concerned that transgenic crops will present environmental risks when they are widely cultivated (62). Genetically modified crops with herbicide and insect resistance could cross-pollinate with wild species, creating superweeds (63, 67). These superweeds can become invasive plants with the potential to lower crop yields and disrupt natural ecosystems.

A critical and very controversial aspect of the antibiotic resistance issue is the utilization of antibiotic resistance genes as the selection marker in genetically modified organisms (GMOs). The main safety concern relates to the escape or transfer of the antibiotic resistance genes to sensitive bacterial strains when these GMOs are introduced into the environment. Moreover, the extended exposure to plant produced pesticides could result in the development of a resistance mechanism in the target organism (63).

Plants engineered to contain virus particles as part of a strategy to enhance resistance could facilitate the creation

of new viruses in the environment (53). Plants engineered to express potentially toxic substances such as drugs and pesticides will present risks to other organisms that are not intended as targets. One example includes pollen from transgenic corn, which has been suggested to kill the Monarch butterfly larvae. It has been shown that hybrid corn expresses a bacterial toxin in its pollen, which is then dispersed over 60 meters by wind. In this range, the corn pollen is deposited on other plants near cornfields where it can be ingested by non-target organisms including the Monarch butterfly. These butterflies have been found to eat less, have a slower growth rate and higher death rate (68). On the other hand, research has proven that the Monarch butterfly population has not been affected (69). Since *Bt*-176 corn is no longer available in US maize varieties, the risk to the Monarch butterfly populations from current *Bt* maize varieties is low (15).

4. Other Concerns

The debate involves not only scientific but also political, socio-economic, ethical, religious and philosophical issues (63, 70–73). Some critics of genetic modification argue that patenting which allows corporations to have monopoly control of genetically altered plants or animals violates the justice of life (74).

C. Genetically Modified Microorganisms

Council Regulation 258/97 defines a novel food as food which has not been used for human consumption to a significant degree within the European Community. Within this scope fall foods and food ingredients consisting of or isolated from microorganisms, fungi or algae.

Developments in modern biotechnology facilitate the production of bacterial strains with particular properties. The introduction of such microorganisms into food raises several issues that need to be addressed as part of the safety evaluation. These include: (1) the risk of infectivity and pathogenicity, (2) the potential for colonization and gene transfer within the gastrointestinal tract, and the consequences thereof, (3) their effects on microflora composition and function, including the production of deleterious metabolites and (4) their effects on gastrointestinal mucosa and function (75, 76).

There is huge potential for using biotechnology to develop foods with improved processing qualities. Biotechnology is also likely to be used to produce improved microorganisms, both to improve conventional fermentation processes and to develop new ones. These could include microorganisms for the production of foods (e.g., bread, wine, yoghurt and cheese), or for a wide range of fermentation products for use in food processing (e.g., enzymes, vitamins, amino acids and high-grade chemical additives such as citric acid, a flavouring and acidifying agent).

The major areas currently attracting attention are described in this section.

1. Lactic Acid Bacteria

The vast majority of bacteria used in the food and dairy industries belong to the group known as the lactic acid bacteria (LAB). In general, genetic manipulation of LAB is achieved either by the inactivation of a gene or by the expression/overexpression of a gene (77). Such manipulation may affect a biochemical pathway resulting in different end products or altered yields of end products. This in turn affects the taste, texture, yield or quality of the fermented food.

A commercially important area is the production of new strains of lactic acid bacteria which carry out a faster, more efficient fermentation. For example, using plasmid technology, new strains of *Lactobacillus* spp. have been produced to provide improved starter cultures for cheese production. The potential for the more rapid production and maturation of cheeses, and a whole range of other fermented products, is being exploited. Another important achievement is the introduction into lactic acid bacteria of genes resistant to destructive bacteriophages. Additionally, lactic acid bacteria are excellent producers of peptidases, which are already widely used in food technology. This characteristic is thought to have enormous potential, not least because these bacteria, being associated with the production of traditional foods, are largely recognised as being 'safe.' GM lactic acid bateria have also been used in meat and sausage fermentation (78, 79).

2. Enzymes

Enzymes are very important in food processing. Apart from enhancing nutritional value, they can be used to influence flavour, aroma, texture, appearance and speed of production.

Microorganisms are the most important sources of these enzymes. There is no reason why the ability to synthesise enzymes normally associated only with plants and animals should not be engineered into microorganisms for culture in fermenters. This was achieved some time ago for the enzyme chymosin (rennin), used in cheese manufacture.

Chymosin from transgenic yeast was the first enzyme from a genetically modified organism to gain regulatory approval for food use in 1988. Three such enzymes are now approved in most European countries and the USA derived from *Escherichia coli*, *Kluyveromyces lactis* and *Aspergillus niger*. These proteins behave in exactly the same way as calf chymosin, but their activity is more predictable and they have fewer impurities. Such enzymes have gained the support of vegetarian organisations and of some religious authorities. Chymosin obtained from recombinant organisms has been subjected to rigorous tests to ensure its purity (80).

3. Yeasts

Much attention is currently being paid to the possible use of yeasts as a vehicle in which to express transferred genes. Yeast is an important microorganism in the food industry and has applications in brewing, baking and in the production of fermented foods such as soya sauce.

In recent years, much research has been conducted into the genetic manipulation of *Saccharomyces cerevisiae* in order to enhance endogenous characteristics, such as ethanol tolerance and to obtain expression of foreign genes and the secretion of foreign proteins, some of which are useful to the food industry (81–83). The yeast *Saccharomyces cerevisiae* var. *diastaticus*, whilst not itself suitable for use in brewing, produces an amylase capable of hydrolysing starch residues which normally remain in the brew. The high calorie starch residues are thus converted into fermentable sugar. A gene coding for the enzyme is transferred, via a plasmid, to normal brewing strains of yeast. The transgenic yeast can be used to produce a high alcohol premium product or, alternatively, a greater volume of low calorie 'lite' beer. New yeast strains that are tailored to the barley and hops that are grown in different regions of the world are being developed for use in the brewing industry.

4. Fungal Factories for Enzyme Production

Fungi are of major economic importance as opportunistic pathogens and spoilage organisms but they also have a number of positive uses in food and non-food industries, e.g., the production of catalase, glucose oxidase, lipase and pectinesterase. These useful fungi may be modified genetically to improve their efficiency and enzyme-secreting capacity (84).

VI. DETECTION OF GMOs

A. Labelling of GMOs

There is a need for processors and traders to meet emerging mandatory GMO-labelling requirements in certain countries, in particular the EU, but also in Switzerland, Australia, New Zealand, Japan, etc. The tolerance levels for labelling may differ among countries or still have to be decided. EU legislation on labelling is summarised in the following section.

Since 18 April 2004 two new regulations (1829/2003 and 1830/2003) (86, 87) concerning traceability and labelling of GMOs entered into force in the EU. A harmonised community system is set up to trace GMOs, the labelling of GM feed is introduced, the current labelling rules on GM food are reinforced and a streamlined authorisation procedure for GMOs in food and feed and their deliberate release into the environment is established. Today, labelling of GM food or feed is mandatory, even when the specific DNA or protein of the GMO can no longer be identified in the final product. Adventitious and technically unavoidable presence of GMO are not subject to these labelling provisions as long as this presence is below a 0.9% threshold of the food ingredient individually considered. For the presence of GM material that is not approved in the EU but benefits from a favourable scientific risk assessment by the Scientific Committees or the European Food Safety Authority, a 0.5% threshold is established. These laws also extend the labelling requirements in order to cover food and food ingredients produced from GMOs under the level of detection, e.g., soya or maize oil produced from GM-soya or GM-maize and biscuits with maize oil produced from GM-maize.

It is obvious that the development and application of reliable and quantitative analytical detection methods are of utmost importance for the implementation of these labelling rules. In general, detection methods for GMOs are based on DNA or protein level. The first uses the polymerase chain reaction (PCR), the latter is based on immunoassays. Other detection strategies will be discussed briefly.

B. Detection Based on DNA

1. DNA Isolation

Provided that the laboratory sample is representative for the field sample, batch or lot of the product and that is has been adequately homogenised, even small aliquots of vegetal material are sufficient for DNA extraction, usually between 100 mg (87) and 350 mg (88).

For the extraction of DNA from plant tissues and food products, a vast range of methods is available. An overview has been given by Anklam *et al.* (31). Currently, three different approaches to DNA isolation from plant material and plant-derived products are favoured for GMO detection: the CTAB method, DNA binding silica columns (various commercially available kits) (89) and a combination of these two. In general, DNA extraction from plant material has to accomplish the following steps (31):

1. the breakage of cell walls is usually achieved by grinding the tissue in dry ice or liquid nitrogen,
2. the disruption of cell membranes is achieved by using a detergent (e.g., CTAB or SDS),
3. inactivation of endogenous nucleases is achieved by the addition of detergents and/or EDTA, which binds Mg^{2+}, an obligatory co-factor of many enzymes. Proteinase K may be added for inactivation and degradation of the proteins, particularly in protocols using DNA binding silica columns,
4. separation of inhibitory polysaccharides is possible due to the differential solubility of polysaccharides and DNA in the presence of cetyltrimethylammonium bromide (CTAB),

5. separation of hydrophobic cell constituents, e.g. lipids and polyphenols is attained by extraction with an organic solvent like chloroform,
6. finally, the separation from the detergent and concentration of DNA is carried out by alcohol/salt precipitation.

2. PCR — Principle

The polymerase chain reaction allows the millionfold amplification of a target DNA fragment in a highly sensitive and specific manner. DNA fragments with a length of 100 to 1000 base pairs are amplified with the aid of the polymerase enzyme and two primers. Primers are oligonucleotide sequences complementary to either one of the two strands from the double stranded DNA target.

The kinetics of the PCR are determined by the temperature profile used. Because of the high temperatures required for the denaturation of DNA, the use of a thermostable DNA polymerase is necessary. For this purpose, a polymerase isolated from the thermophylic bacterium *Thermus aquaticus* (*Taq*-polymerase) is used. The PCR protocol exists of a 20 to 50 cycle program, each consisting of the following steps (Figure 129.5):

- denaturation: the single stranded DNA molecules are obtained by heating the DNA solution to a temperature of 94–95°C, enough to break the hydrogen bonds between the strands,
- annealing: by decreasing the temperature to around 55°C, the primers bind to their complementary DNA sequence. Template DNA, primers and DNA polymerase are included in the reaction from the beginning of the PCR,
- extension: a polymerisation step is carried out at around 72°C under the action of the DNA polymerase.

The primer extension products synthesised in one cycle will serve as a template in the next. The repetitive series of cycles results in the exponential accumulation of a specific fragment whose termini are defined by the primers.

After the PCR, the length of the amplification products has to be checked using the electrophoresis technique, although other separation methods such as high performance liquid chromatography (HPLC) and capillary electrophoresis (CE) have been used (90, 91). For the separation of large DNA fragments agarose gels are used, while polyacrylamid gels are more suitable for the separation of small fragments. For GMO detection, gel electrophoresis is preferred. Under an electric field, the negatively charged DNA molecules will move through the gel at different rates depending on their size, resulting in a segregation of the different fragments of DNA. The DNA is stained with a fluorescent molecule that binds to DNA and is visualized under UV light.

3. PCR Strategies for GMO Screening and Identification

Any PCR based detection strategy depends on a detailed knowledge of the transgenic DNA sequences and the molecular structure of the GMOs in order to select for the appropriate oligonucleotide primers.

Before conducting a GMO specific or screening PCR assay, the presence of amplifiable DNA in food samples must be determined by using species specific primers. Several (GM) food ingredients have been analyzed using PCR: soy (92), wheat (93), canola, potatoes (94), rice, papaya (40), alfalfa (39), maize, sugarbeet and tomatoes (95).

Nowadays, routine GMO is focused on the detection of the Cauliflower Mosaic Virus (CaMV) 35S promotor (P-35S) and the *Agrobacterium tumefaciens* nos terminator (*nos3′*), which are present in many GMOs currently on the market. However, additional target sequences are needed in order to guarantee a complete identification procedure. Moreover, these target sequences may occur as natural contaminants in the sample (from plant viruses and bacteria). Therefore, specific sequences that are characteristic for the individual transgenic organism should be targeted,

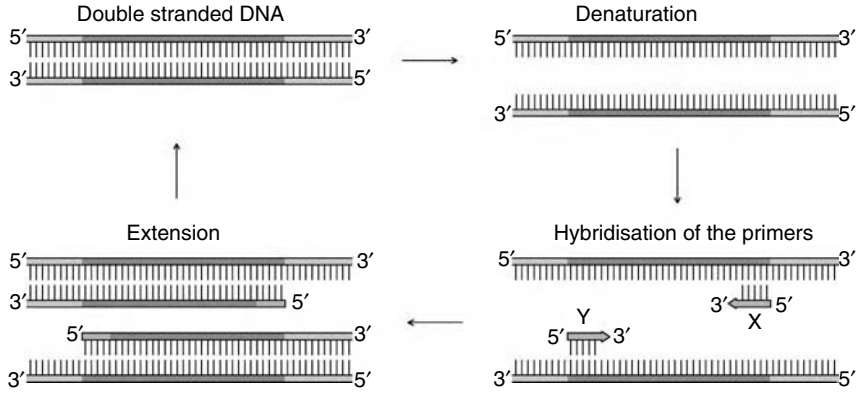

FIGURE 129.5 The polymerase chain reaction.

such as the cross border regions between the integration site and transformed genetic element of a specific GMO, or specific sequence alterations due to truncated gene insertions (i.e., cDNA, or altered codon usage) (96).

If there is any doubt about the fragment identity, the amplified fragment can be checked more precisely using specific endonucleases (restriction fragment analysis). These enzymes cut only the expected DNA sequence into two fragments of known size (97).

With Southern blotting, the sample DNA is isolated and fixed onto nitrocellulose or nylon membranes and probed with double stranded labelled nucleic acid probes specific for the GMO. Hybridisation can be detected radiographically, fluorometrically or chemiluminescently.

Recently, an alternative Southern blot technology has been attempted with near infrared (NIR) fluorescent dyes (emitting at ~700 and 800 nm) coupled to a carbodiimide-reactive group and attached directly to DNA in a 5 min reaction. The signals for both dyes are detected simultaneously by two detectors of an infrared imager (98, 99).

Another strategy for GMO identification recently discussed makes use of amplified fragment length polymorphism (AFLP), a DNA fingerprinting method, which has already been used successfully to discriminate between and identify plant varieties, including processed agricultural materials (100, 101).

Other methods to confirm PCR results are: hybridisation (96), direct sequencing of the PCR product (98, 102, 103), nested PCR (97, 104, 105), anchored PCR (106, 107) and mass spectrometric detection of PCR products (108).

4. Quantitative Detection Methods Based on DNA

Two kinds of PCR strategies are currently being used for the quantification of GMOs in food: end-point PCR (quantitative competitive PCR) and real-time PCR.

a. Quantitative competitive PCR (QC-PCR)

The principle of quantitative competitive PCR is the (co-) amplification of internal DNA standards together with target DNA. A small difference between target and control sequence (<40 bp) makes it possible to distinguish between the two reaction products. Each sample is amplified with increasing amounts of competitor, while keeping the sample volume/concentration constant. PCR products are separated by an appropriate method, such as agarose gel electrophoresis and subsequently quantified by photometric methods. At the equivalence point, the starting concentration of internal standard and target are equal (i.e., the regression coefficient is >0.99 and the slope of the regression line ≈1) (109). Although the presence of PCR inhibitors will be noticed immediately because the amplification of both internal standard and target DNA will be simultaneously affected, competition between the amplification of internal standard DNA and target DNA generally leads to loss of detection sensitivity. QC-PCR has been developed for Roundup Ready soybean, *Bt* and Maximizer maize, the P-35S promotor and nos3′ terminator (110–114).

b. Quantitative real-time PCR (RT-PCR)

The real-time PCR technique was originally developed in 1992 by Higuchi and co-workers, allowing to follow the amplification of the target DNA sequence during the whole reaction by indirect monitoring of the product formation (115). Real-time detection strategies rely on the continuous measurements of the increments in the fluorescence generated during the PCR. Therefore, several formats can be used: (1) the ds-DNA-binding dye SYBR Green I, (2) hybridisation probes or fluorescence resonance energy transfer (FRET) probes, (3) hydrolysis probes (TaqMan® technology) and (4) molecular beacons (116). The number of PCR cycles necessary to generate a signal statistically significant above the noise is taken as a quantitative measure and is called the cycle threshold (C_t). As long as the C_t value is measured at the stage of the PCR where the efficiency is still constant, the C_t value is inversely proportional to the log of the initial amount of target molecules.

More than 150 food products containing GM soy (e.g., baby food, diet products, soy drinks, desserts, tofu and tofu products, cereals, noodles, fats, oils and condiments) have been analysed by TaqMan®, proving this method to be sensitive (112, 117–120). Other research has been done on GM maize (121).

c. PCR-ELISA

PCR-ELISA uses the strategy of real-time PCR and can be quantitative when the PCR is stopped before a significant decrease in amplification efficiency occurs (i.e., before the plateau phase is reached). Then ELISA can be used to quantify the relatively low amounts of PCR products (122, 123).

C. Detection Based on RNA

The RNA based methods rely on the specific binding between the RNA molecule and a synthetic RNA or DNA molecule (primer). The primer must be complementary to the nucleotide sequence at the start of the RNA molecule. Usually binding between the RNA molecule and the primer is followed by conversion of the RNA to a DNA molecule through reverse transcription. Finally the DNA can be multiplied with PCR or translated into as many as 100 copies of the original RNA molecule and the procedure can be repeated by using each copy as a template using nucleic acid sequence-based amplification (NASBA). The specific primers needed for the procedure cannot be developed without prior knowledge of the composition of the RNA molecule to be detected (124).

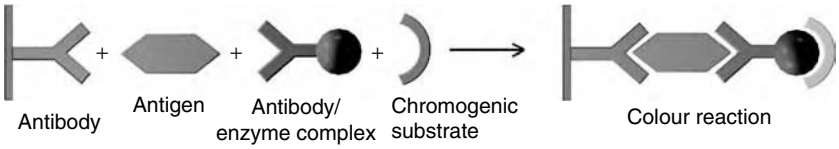

FIGURE 129.6 ELISA principle.

The first consideration when using reverse transcriptase PCR for mRNA analysis is RNA isolation. The RNA should be high quality and free from genomic DNA contamination. However, since most reverse transcriptase PCR methods amplify only a few hundred bases rather than the complete mRNA sequence, the sample RNA can be slightly degraded. The major problem for the use of reverse transcriptase PCR for GMO analysis though is the chemical instability of the RNA molecule and the ubiquitous presence of RNAses.

D. Detection Based on Protein

GMOs are characterised by an altered genome which may lead to the expression of new proteins. Therefore GM foods might be identified by testing for the presence of the introduced DNA or by detecting expressed novel proteins encoded by the genetic material.

Immunoassay technologies with antibodies are ideal for qualitative and quantitative detection of many types of proteins in complex matrices when the target analyte is known. Both monoclonal (highly specific) and polyclonal (often more sensitive) antibodies can be used depending on the amounts needed and the specificity of the detection system (e.g., antibodies to whole protein or specific peptide sequences), depending on the particular application, time allotted for testing and cost (125). On the basis of typical concentrations of transgenic material in plant tissue ($>10\,\mu g$ per tissue), the detection limits of protein immunoassays can predict the presence of modified proteins in the range of 1% GMOs (126).

Both Western blot and enzyme-linked immunosorbant assay (ELISA) techniques have been used for the analysis of protein products of transgenic crops.

1. Western Blot

The Western blot is a highly specific method that provides qualitative results for determining whether a sample contains the target protein below or above a predetermined threshold level (127), and is particularly useful for the analysis of insoluble protein (128). Although developed for the detection of modified soy (129, 130), this method is preferred for research purposes rather than for routine analysis.

2. ELISA

ELISA is the most common type of immunoassay. Antibodies, raised against proteins derived from GMOs, are coated on a microwell plate. For the detection of GMOs, several approaches can be used. In a sandwich ELISA setup (Figure 129.6), the protein extract is spread on the microwell and a specific antigen–antibody binding takes place. After removal of the excess of protein extract, a second enzyme labelled antibody is added, which binds the target antigen. Unbound enzyme labelled antibodies are removed and an enzyme specific substrate is added, which results in a colour reaction if all of the previous reactions have taken place. The intensity of the signal is a measure for the amount of GMO present in the tested sample.

TABLE 129.1
Main Characteristics of DNA and Protein Based GMO Tests (170)

Characteristics	DNA (PCR)	Protein (ELISA/Lateral Flow)
Test sensitivity	High	Medium
Contamination sensitivity	High	Low
Test complexity	High	Medium/low
Test speed	Medium	Medium/high
Universal markers	Yes	No
Test design flexibility	Yes	No
Markers availability	Yes	Low (antibodies)
Automation chance	Yes	Yes/no
Quantification chance	Yes/no	Yes/no
Complex matrices detection	High	Low

One of the major drawbacks of immunochemical assays is that their accuracy and precision can be adversely affected in a complex matrix, such as those found in many processed agricultural and food products. The possible causes for interference from the matrix have been attributed to nonspecific interaction with the antibody by proteins, surfactants (saponins) or phenolic compounds, antibody denaturing by fatty acids and the presence of endogenous phosphatases or enzyme inhibitors. Moreover, detection and measurement may be rendered difficult by low levels of expression of transgenic proteins, the degradation associated with thermal treatments or pH changes, a poor antibody affinity or the commercially available source of antibodies and standards (31, 128, 131).

In summary, the main characteristics and peculiar differences between the DNA based and protein based tehniques for GMO detection are listed in Table 129.1.

Nonetheless, several immunoassay-based methods have so far been developed, such as for the neomycin phosphotransferase II (*npt*II), the EPSPS enzyme (Roundup Ready soy), *Bt* insecticide Cry1Ab and PAT proteins

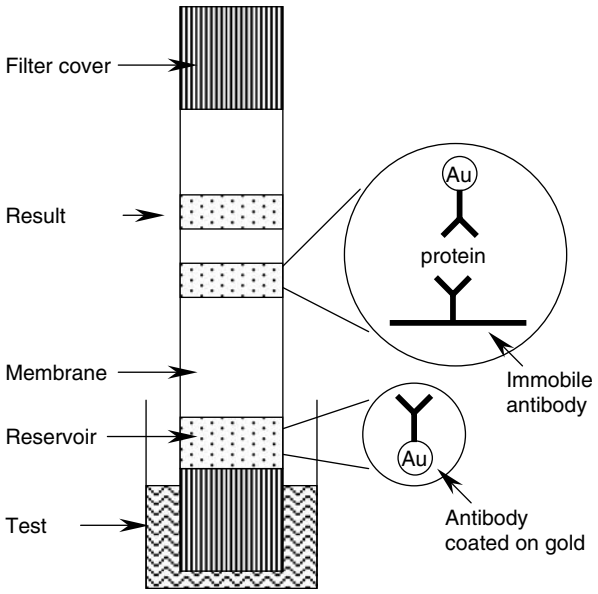

FIGURE 129.7 Schematic representation of the strip test.

(132, 133, 130, 134). Several commercial immunoassay methods are currently available for detection and quantitation of biotech crops expressing Cry1Ab, Cry1Ac, Cry3A, Cry2A, Cry9C, CP4 EPSPS and PAT proteins.

3. Lateral Flow Strip

A variation on ELISA uses strips instead of microtiter wells. A typical strip consists of a reservoir, a result window and a filter cover (Figure 129.7). The reservoir contains (gold) coated antibodies against the target protein. Once the strip has been put into the test solution and this solution reaches the reservoir, the labeled antibodies bind the target proteins. When this complex reaches the area of the second (immobilised) antibodies, a sandwich complex is formed and a colour reaction is observed on the strip, while antibodies are immobilised on the strip. As a positive control, a second band (control line) must be visualised. The lateral flow strip gives results in 5 to 10 min, is economical, consumer friendly and suitable as an initial screening method early in the food chain (125).

4. Other Immunoassays

In addition to microplate ELISA and lateral flow devices, other immunoassay formats are being developed, i.e., in combination with instrumental techniques. For example, in addition to the hyphenated methods, such as immunoassay–mass spectrometry, considerable advances in relative observation of antibody binding to target molecules using biosensors have been reported. Furthermore, immunoassays can be performed with magnetic particles as the solid support surface. The magnetic particles can be coated with the capture antibody and the reaction carried out in a test tube. The particles with bound reactants are separated from unbound reactants in solution by a magnet. Advantages of this format are superior kinetics because the particles are free to move in reaction solution and increased precision owing to uniformity of the particles (128).

E. Other Detection Methods

1. Chromatography

Where the compositon of GMO ingredients, e.g. fatty acids or triglycerides is (significantly) altered, conventional chemical methods based on chromatography can be applied for detection of differences in the chemical profile. This has been demonstrated with oils derived from GM canola for which high performance liquid chromatography (HPLC) coupled with atmospheric pressure chemical ionisation mass spectrometry (APCI-MS) has been applied to investigate the triglyceride patterns (135).

2. NIR Spectroscopy

Recently, NIR has been used in attempts to distinguish Roundup Ready soy from conventional soybean (136). In this study, spectral scans were taken from three spectrometers of whole grains. Results varied slightly, but were promising in alle cases. However, the capability of NIR to resolve small quantities of GMO varieties in non-GMO products is assumed to be low, as is true for the chromatographic methods.

3. Microarray

With the microarray or DNA chip technology microscopic arrays of single stranded DNA of the specific transgene of interest are spotted on a solid support (probe DNA). DNA isolated from the sample of interest (target DNA) is amplified using multiplex PCR. Addition of an exonuclease transforms the double stranded PCR products into single stranded DNA, which is able to hybridise with the spotted ss-DNA. After incubation, fluorescent signals are observed where a positive reaction occured. Analysis of the resulting pattern of spots with a significant degree of hybridisation, and therefore with a significant fluorescent signal, reveals the presence and, depending on the spotted sequence, the identity of GM varieties present in the sample (137).

The method allows fast and simultaneous analysis of several thousand nucleic acids within the very small area of the chip. Therefore, it is very cost saving while maintaining high precision and reproducibility.

4. Nucleic Acid Lateral Flow Immunoassay (Nalfia)

With the Nalfia technique, DNA is amplified through PCR, using primer pairs with different labels. After PCR,

several microliters of the PCR product is pipetted onto a filter (strip), containing an enzyme which interacts with one label of the amplified DNA (originating from one of the introduced labelled primers). The sample then migrates through a nitrocellulose membrane containing another protein, which is able to bind the second labelled primer. If the sample under investigation contains the target gene, the PCR products will contain both labelled primers, which will be sandwiched by the two enzymes from the strip and a colour signal is observed. For the screening of GMOs a prototype of this test has been developed for Roundup Ready soy (138).

VII. THE EFFECT OF FOOD PROCESSING ON THE DETECTION OF GMOs BY PCR

DNA is the preferred analyte for almost any kind of sample (raw materials, ingredients, processed foods) due to the fact that DNA is a rather stable molecule and the most common DNA based detection method, namely the polymerase chain reaction (PCR), is highly sensitive.

The efficiency of the PCR reactions depends on the quality, quantity and purity of the extracted DNA. These factors vary according to the material, the degree of processing of the sample and the DNA extraction method. The DNA quality is determined by its fragment length and its degree of damage due to processing. The quantity of the DNA is determined by the food products itself, the degree of processing and the extraction method applied. The purity of the DNA usually depends on the method of extraction. The detectability of the DNA fragment is also dependent on the PCR approach (nested PCR, real-time PCR, multiplex PCR) and the choice of the primers.

For routine PCR diagnostics in processed foods, amplicon length should be situated below 300 basepairs (30). Damage within the DNA fragments is believed to be caused by the exposure to heat, enzymatic degradation by nucleases, temperature, ionic strength, chemical agents and pH values (139–141). The mechanism of DNA destruction by heat is based on depurination or deamination. At temperatures above 100°C a significant strand scission and irreversible loss of secondary structure occurs (142, 143). The influence of pH may be limited due to cell wall structures protecting the DNA from cleavage. Detectability of DNA template after prolonged incubation at low pH suggests that after initial cell lysis and preliminary DNA destruction, the enzymes responsible for DNA degradation (endogenous nucleases) are destroyed quicker than DNA itself and its further breakdown is avoided (143). In food the rates of these DNA degradation reactions are strongly affected by matrix properties as well as the processing and storage conditions.

Basically no difference between the stability of DNA of a wild type and recombinant organism can be identified. Modifications resulting from methylation or association with DNA binding compounds (e.g., histones, polyamins) might cause minor effects on DNA stability, but these factors apply to any DNA. These conclusions are supported by studies of DNA stability in food such as dairy products, maize polenta, fermented sausages, tofu from soybeans or breads (144).

It is clear that the purity of DNA can be affected by various contaminants in food matrices. These contaminants may originate from the material under examination, e.g., polysaccharides, lipids polyphenols (97, 145, 146) or chemicals used during the DNA extraction procedure, such as CTAB (88, 147). Furthermore, nitrite salts used in sausages (78) and dairy products (148) have been shown to be potent inhibitors of the PCR. A long list of salts, carbohydrates and other compounds frequently used in buffer solutions also decrease the performance of PCR (149, 150). The choice and optimisation of DNA extraction procedures, which eliminate potential inhibitory components may thus be of crucial importance for the success of a given PCR method (151).

Different succesfull DNA extractions have already been published for several GM foodstuffs (30, 85, 88, 92, 97, 141, 146, 152–161).

Although the basic reactions contributing to DNA degradation are already known and many methods have been developed for the detection of DNA sequences of GMOs in foods according to the current legislations, only limited data are available about the release of DNA from cells, as well as its presence and stability during processing and storage of foods.

Bauer *et al*. (144) investigated the kinetics of degradation of plasmid DNA by the process parameters acidic pH and/or temperature using a tomato serum (pH 4.3 and temperature of 65°C). The highest degradation was found for the combined effect of acidic conditions and heating.

Thermal treatment of corn meal at 100°C and potatoes at 80°C contributed to degradation of DNA to fragments smaller than 585 bp and 792 bp respectively (162). A similarly effective thermal DNA degradation was also described for dry corn grains by Chiter *et al*. (163) and for corn gluten and flaked corn by Forbes *et al*. (164). Specific attention has been paid to the degradation of DNA during alkaline boiling (pH 11.0) of corn meal. Alkaline-cooked corn, called nixtamal of corn masa, is an instant product for the production of Mexican corn-based foods such as tortillas, corn chips, taco shells and tamalas. Kharazmi *et al.* (162) reported the failure of amplification of fragments greater than 585 bp while Hupfer *et al.* (140) still detected 1914 bp DNA fragments of corn after boiling at pH 9.0 for 60 min. In a real-time quantitative PCR approach, Quirasco *et al*. (165) were able to detect and

quantify up to 0.1% StarLink corn, in spite of progressive degradation of genomic DNA during processing.

In soybean flour, a rapid decrease in the maximal detectable length of plant DNA under acidic conditions (pH 4.75) was found, even at ambient temperature (144). This is in agreement with the results found by Hupfer *et al*. (140) which illustrated that DNA fragments of 1914 bp were no longer detectable after boiling of Bt-176 maize flour for 5 min at pH 2.0 to 3.0, whereas after boiling for 60 min at pH 8.5 to 9.5 the fragments remained detectable. It was shown for the production of feed that DNA was degraded during ensilaging of Bt-176 maize (pH 3.9–4.1) and fragments of 1,914 bp were no longer detectable after 106 days.

For production of soy milk and tofu, DNA degradation during heat treatment does not significantly contribute to the DNA degradation, the mechanical step of grinding of soaked soybeans is a more crucial DNA degrading step (162). A similar extent of degradation was also observed by Hupfer *et al*. (140) during chopping of whole corn plants. It can be assumed that during grinding or chopping DNA is released and becomes sensitive to the attack of nucleases. Such nucleolytic activities were shown to occur in food matrices, e.g., in bread dough (166) or sugar beet raw juice (167) and it was observed that their action depends on the processing temperature. Klein *et al*. (167) showed that DNA is completely removed during the production of sugar and the overall efficacy of DNA elimination was calculated to 10^{14}.

In addition, the degradation of the plant DNA during production of bread was monitored indicating that temperature and pH are the major effective factors (141, 166).

Still, for some refined and highly processed food products, the detection of DNA remains difficult, resulting in the impossibility to perform a GMO analysis. This category of products contains among others: starch, sugar cane, caramel, dextrose, sorbitol (155, 158), bread with soy sauce (158), refined soybean oil (159, 168), refined corn oil (158), tomato concentrate, tomato puree and tomato ketchup (158), cocoa drinks containing lecithin (97). For these food products, GMO analysis is impossible, or a higher sample volume should be required (160, 161, 169).
